We next proceed to describe the *Section*. A section is the projection or geometrical representation of a building supposed to be cut by a vertical plane, for the purpose of exhibiting the interior, and describing the height, breadth, thickness, and manner of construction of the walls, &c. By the section we are made acquainted with a variety of particulars, in regard to which a plan cannot be made to afford any information. It shows us the thickness of the walls and floors, the heights of the rooms, the forms and profiles of ceilings, whether flat, coved, or arched, also the exact forms of domes and skylights. It shows the heights of the doors, how they are panelled and decorated, the form of the chimney-pieces, &c., and, in some instances, furniture and fittings-up are advantageously introduced, with a view to judge of effect. For detailed and filled-up sections, it is usual to employ outline with the walls and floors shaded, the former as more solid, being made darker than the latter. When, on the other hand, the elevations of the rooms themselves are shadowed, the thickness of the intersected walls, &c., are left white, in order to prevent confusion, and exhibit the profiles better.

Indispensable and interesting, however, as they are, sections are a far more conventional mode of drawing than elevations, because they represent a building as it never can be seen, except where the front of a house has been taken down for the purpose of rebuilding it, while the floors and partition-walls are left standing; in which case any one may obtain a good idea of the nature of a section, but of one seen in perspective.

Besides general sections showing the whole of a building from top to bottom, there are frequently partial ones, showing only the rooms on one floor, or even a single room, when it is desired to show any particular apartment on a larger scale than could conveniently be done any other way. Sometimes recourse is had to a plan of the room with each of its sides drawn around it, as if laid flat on the ground, by which means the whole of the apartment is described. Horizontal sections also are given, to show more accurately than can be done on a plan, the soffits of entablatures, the ceiling and its ornaments, the window recesses, and door-cases, and the capitals of columns and projection.

Besides the usual plans, elevations, and sections, there should also be detailed drawings, answering, in some respect, to what are termed *working drawings;* these give a more correct idea of the minutiæ and finishing of the subject than can be obtained from the general design only.

In a complete design, however, it is desirable to have perspective views both of the exterior and principal parts of the interior. These enable a person to comprehend the character and effect of the design as a whole, which, without such drawings, can be judged of only piecemeal. The perspective drawing of the exterior ought to exhibit the edifice from one of the most frequented points of view, and ought also to be so contrived as to make it impressive from every point whence it can be seen, and particularly from those positions in which the greatest part of the design is comprehended at one view.

In very large works, a model will be useful for preventing many mistakes that might otherwise arise, as all the parts can be easily seen by inspection; but when drawings only are used, from the number that are necessary to the performance of the work, a long examination and consideration are requisite; and after all, some of the most essential parts of the construction may be, and frequently are, overlooked.

For other particulars respecting designs, we refer to the articles Apartment, Break, Building, House.

DESIGNING, the art of delineating or drawing the appearance of natural objects by lines on a plane.

DESK, a part of a pulpit; as the clerk's or precentor's *desk;* also a kind of rostrum where the clergyman reads the printed service of the English Church.

DESTINA, Latin, a pillar or other support of a building, in which sense the term is used by Vitruvius; but when employed by ecclesiastical writers, it is usually applied by them to the aisle of a church, or to a small cell.

DETACHED COLUMN, the same as Insulated Column, which see.

DETAIL, (from the French, *détailler*) the delineation of all the parts of an edifice, so as to be sufficiently intelligible for the execution of the work. The detail is otherwise denominated *the working drawings.*

The expression *detail* is also used in other ways, as, when a moulding is exhibited in profile by abutting on a plane, it is said to *detail* on the plane. Details in the fine arts are minute and particular parts of a picture, statue, or building, as distinguished from the general conception, or larger parts of a composition.

DETERIORATION, (from the Latin, *deterior*) the act whereby a thing is rendered worse. This was the fate of architecture in passing from the Greeks to the Romans, and more particularly in the decline of the Roman empire.

DETERMINATE, a word applied in mathematics to those problems which have one answer only, or at least a certain and finite number of answers.

DETERMINING LINE, in conic sections, the intersection of a plane parallel to the cutting plane with the plane of the base of the cone. In the sections of a cone which produce the hyperbola, the determining line falls within the base of the cone; in parabolic sections, it forms a tangent to the base. In the elliptic section, it falls without; and when the section is a circle, the determining line will, in one case, never meet the plane of the base, as in this instance the cutting plane is parallel to the plane of the base.

DIACONICON, (from *διακονεω*, *I serve, I minister*) a place adjoining to the ancient churches, where the sacred vestments, vessels, relics, and ornaments of the altar, were preserved. This apartment was otherwise called *sacristy*. It was also denominated *ασπ ςικον*, and in Latin, *salutatorium*; because it was here that the bishop received and saluted strangers. Sometimes it was called *μητατωνιον*, or *μιτατωριον*, *mensa*, on account of the tables kept there.

DIAGONAL, (from the Greek, *διαγώνιος*) in geometry, a line drawn through any figure, from the vertex of one angle to that of another.

Every rectilinear figure may be divided into as many triangles, wanting two, as the figure has sides.

Every diagonal divides a parallelogram into two equal parts.

A most excellent theorem in elementary geometry, first demonstrated by Mr. Lagny, in the *Mémoires de l'Academie Royale des Sciences, an.* 1706, is, that the sum of the squares of the two diagonals of every parallelogram is equal to the sum of the squares of the four sides; and it is evident that the 47th proposition of Euclid may be derived as a mere corollary from this theorem. The demonstration is as follows: Let A B C D be an oblique parallelogram, of which B D is the greater diagonal, and A C the lesser. From the vertex, A, of the obtuse angle D A B, drop the perpendiculars A E and B F to C D; then the triangles A D E, B C F, are equal and similar; for A D is equal to B C, and the angles A D E and B C F are equal to each other; also the angles A E D, and B F C, are equal to each other; consequently D E is equal to C F. Now, by proposition xii. lib. ii. of Euclid, in the obtuse-angled triangle B D C, the square of the side B D is equal to the sum of the squares B C, C D, together with double the rectangle C F by C D; and by the 13th proposition of the same book, in the triangle D A C, the square of A C is equal to the sum of the squares of A D and C D, abating double the rectangle of C D by D E equal to C F; for C F is equal to D E: now, since

$$BD^2 = BC^2 + CD^2 + 2(CF \times CD)$$
$$\text{and } AC^2 = AD^2 + AB^2 - 2(CF \times CD)$$

$$\text{Therefore } BD^2 + AC^2 = BC^2 + CD^2 + AD^2 + AB^2$$

Then, if the parallelogram be right-angled, the diagonals are equal, and consequently each equal to the squares of the two sides containing other right angles opposite that diagonal.

Hence, if one of the diagonals and a side be known, the other diagonal will likewise be known.

Another proposition, of a similar nature to the above, was discovered by Ptolemy, viz., that the rectangles of any two diagonals of a quadrilateral figure inscribed in a circle, is equal to the sum of the two rectangles contained by the opposite sides.

In taking the dimensions of a building, in order to make a plan, it is by far the most accurate and expeditious method, to take the diagonals. In carpentry and joinery, no polygonal frame whatever can be rendered stationary or immovable about the angles, without diagonal pieces, as the strength consists in dividing the work into triangles. In geometry, a polygon cannot be constructed by the linear dimensions of its sides only, without the diagonals, as the area of the figure may be variable under the same number of sides, *ad infinitum*, from a certain position of the sides, in which they will contain the greatest possible area to any less area whatever.

The impulse given to a body, at the same instant, by two forces, in different directions, causes that body to move in the diagonal of a parallelogram, of which, each of the forces acting separately, would cause the body to describe a side, in the same time as the body moved conjointly by the two forces.

DIAGONAL BUTTRESS, a buttress placed at the angle of a building, chiefly used in churches of mediæval date, and employed to resist the thrusts of the ribs of the last severy of the vaulting. It answers the same purpose as two distinct buttresses set square with the two walls at their intersection, but with less material. Diagonal buttresses do not seem to have been employed to any extent previous to the fourteenth century, but are common in buildings of the Decorated style. Previously, two buttresses at right angles were employed.

DIAGONAL MOULDING, the same as ZIG-ZAG or DANCETTE.

DIAGONAL PAVING. *See* PAVEMENT.

DIAGONAL RIB, a rib or groin passing diagonally across a bay of vaulting from one angle to the opposite.

DIAGONAL SCALE, a compound scale, by which a subdivision may be made of any part of the smallest unit upon a straight line, by means of equidistant parallels crossing others of the same kind.

DIAGRAM, (from *διαγραφω*, *I describe*) in geometry, a scheme for the explanation or demonstration of a figure.

DIAL, (from the Latin, *dies*, day) an instrument serving to measure time by the shadow of the sun. Or more particularly, the surface of a body so graduated that a certain line parallel to the earth's axis will show the hour of the day, when the sun shines upon the surface of such body.

DIAMETER, (from *δια*, *through*, and *μετρειν*, *to measure*) a straight line passing through the centre of a circle, and terminated at each end by the circumference; the diameter is therefore a chord passing through the centre of the circle, and is consequently greater than any other chord in the same circle.

The diameter of a circle divides the circumference into two equal parts.

For other particulars, see the article CIRCLE.

DIAMETER OF A COLUMN, the thickness of the lowest part of the shaft at the bottom. In a colonnade, or range of columns, the intercolumns should always be proportioned to the diameter of the column.

DIAMETER OF A CONIC SECTION. *See* CONIC SECTION.

DIAMETER, *Conjugate*. *See* CONIC SECTION.

DIAMETER OF DIMINUTION, the diameter at the top of the shaft.

DIAMETER OF A SPHERE. *See* SPHERE.

DIAMETER, *Transverse*, the longest axis of an ellipsis.

DIAMETERS, *Conjugate*, of a circle, two diameters at right angles.

DIAMOND, an instrument for cutting glass.

DIAMOND, the small instrument used by glaziers for cutting glass, and formed by the setting of a fractured piece of diamond in a wooden handle. There are now in use two descriptions of pencil diamonds, the old one, and the new or patent pencil. The defect of the former is the difficulty experienced in placing it on the glass in, at once, the proper angle, so as to make it cut and not scratch. The patent pencil overcomes this difficulty, the diamond being fixed by the peculiar mode of its setting at the correct angle at which it will cut the glass. The diamond in these pencils is about the size of an ordinary pin's head, and is set in a nipple of brass or copper. They are differently fitted up, according to the quality of the material which they are to work upon.

DIAMOND FRET, a species of moulding consisting of fillets intersecting each other, so as to form diamonds or rhombuses.

DIAMOND, *Glass*. *See* GLASS.

DIAMOND, *Pavement*. *See* PAVEMENT.

DIANA, *Temple of*. *See* TEMPLE.

DIAPER, a panel or recessed surface enriched with carving in low relief, and frequently gilded and coloured; or a plain surface enriched with polychrome. Also a kind of linen-cloth wrought with figures in weaving.

DIAPERING, the decoration employed in the relief of any plain surface by the interweaving of fret-work, or covering the field with ornamental patterns. In some cases, it consists in the application of colour only, but in others of embossed or carved work, delicately chiselled, and also enriched with gilding and colour. Diaper-work is usually composed of small square panels, containing flowers in low relief, as in the spandrels of the choir arches, and in other parts of Westminster Abbey. There is a beautiful specimen of later date on a monument in the choir of Canterbury cathedral; the design is composed of a flower of six leaves in low relief, within a sexagonal compartment, the sides of which are formed by the sides of six spherical triangles, and are foliated within, and coloured azure and gules. Another specimen is to be seen in the Lady Chapel, Ely, at the back of the canopies of the ornamental arcade which surrounds the walls; others at Waltham Cross, and in many buildings erected during the reigns of Henry III. and Edward I. Diaperings of a rich and tasteful design were also employed in ecclesiastical hangings, vestments, &c. Some very beautiful designs may be seen in *Pugin's Glossary*.

DIASTYLE, (from *δια*, and *ςυλος*, *a pillar*) in classical architecture, that distance between columns equal to three diameters of the column; or the word is applied to the edifice itself, in which columns are applied at this interval.

DIATHYRA, the vestibule in front of the doors of a Greek house, answering to the prothyra of the Romans.

DIATONI, quoins or corner-stones bonding two walls together.

DIDORON, (from the Greek) a kind of brick used by the Greeks, being one foot long and half a foot broad.

DIE, of a pedestal, that part contained between the base and the cornice. *See* DYE.

DIFFERENTIAL, a term used to denote an infinitely small quantity. The differential method is applied to the doctrine of infinitesimals; it consists in descending from whole quantities to their infinitely small differences, and comparing them. Hence it is called the differential calculus or analysis of infinitesimals.

DIGGING is performed by the solid yard of 27 cubic feet.

In soft ground, where only cutting with the spade is necessary, a man will throw up a cubic yard in an hour, or 10 cubic yards in a day. But if hacking be necessary, an additional man will be required; and very strong gravel will require two. The rates of a cubic yard depending thus upon each circumstance, they will be in the ratio of the arithmetical numbers 1, 2, 3. If, therefore, the wages of a labourer be 2s. 6d. per day, the price of a yard will be 3d. for cutting only; 6d. for cutting and hacking; and 9d. when two hackers are necessary.

In sandy ground, when wheeling is requisite, three men will be required to remove 30 cubic yards a day, to the distance of 20 yards, two filling and one wheeling; but to remove the same quantity in a day, to any greater distance, an additional man will be required for every twenty yards.

To find the price of removing any number of cubic yards to any given distance:

Divide the distance in yards by 20, which gives the number of wheelers; add the two cutters to the quotient, and you will have the whole number employed; multiply the sum by the daily wages of a labourer, and the produce will be the price of 30 cubic yards.—Then,

As 30 cubic yards is to the whole number, so is the price of 30 cubic yards to the cost of the whole.

Example.—What will it cost to remove 2,750 cubic yards, to the distance of 120 yards, a man's wages being three shillings per day?

2,0)12,0

6 number of wheelers.
2 fillers.

8 men employed.
3 shillings per day.

24 price of 30 cubic yards.

$$30 : 2750 : : 24 : \frac{2750 \times 24}{30} = £110.$$

See farther under EXCAVATION.

DIGLYPH, (from the Greek, *διγλυφος*), a tablet with two engravings or channels.

DIKE, or DYKE, (from the Saxon, *dic*, a bank or mound), a work of stone, timber, or earth, supported by fascines, raised to oppose the entrance or passage of waters of the sea, a river, lake, or the like. These dykes usually consist of elevations of earth, strengthened with hurdles or stakes, stones, and other matters.

DILAPIDATION, (from the Latin), the state of a building suffered to fall into a ruinous condition by neglect. The term is usually restricted, in its legal sense, to the pulling down or destroying the houses or buildings belonging to an ecclesiastical benefice, or suffering them by neglect to fall into ruin or decay. In the experience of every-day life, there are few families who have not had occasion to feel how much of annoyance, inconvenience, and loss may be hidden under the word *dilapidations*.

In the "Builder" of January, 1849, there appeared an excellent letter on this subject, and as it is evidently written by one well acquainted with it, we consider its insertion here will be both interesting and useful:—

"This subject," says the writer, "is one that has never received proper consideration from the hands of a large class who are interested and affected by it—'tenants.' Men who are daily imposing upon themselves heavy responsibilities, the extent, or the peculiar obligations, and the ultimate result of which they are totally unacquainted with.

"Few persons on taking a lease think of raising objections to covenants which are, they are informed, of the usual character; or, if prudent enough to pledge themselves to an agreement of but three years, they fearlessly, and without hesitation, affix their signatures to a clause promising to 'uphold, maintain, and sustain,' &c., or that which really may turn out an impossibility; for some houses, so to speak, have the elements of destruction and disease upon them from their infancy. Bad brickwork, causing by its humidity damp walls, rots everything; unseasoned timber, that shrinks and twists in all directions, throwing floors out of their level, and making settlements from top to bottom, through which the doors and windows have to be constantly eased and rehung; faulty and imperfect drainage, which becomes constantly choked; the roof acting like a sieve; and this list of ills that modern houses are heir to, is no exaggeration; yet many a man, and he, too, who may be esteemed in his own business a prudent man, is induced, from a want of consideration, readily to promise to do and perform all needful and necessary repairs, or at least to leave the house in tenantable repair. It is not a little amusing to observe the tenant's surprise at the end of his tenancy, on receiving a notice of dilapidations. What! he exclaims, and leave the house 100 per cent. better than when I took it? This, and the various sums of money paid to jobbing tradesmen, all the accounts of whom he can enumerate by heart, constitute the anchor of hope to the poor tenant, when informed, in spite of all the benefits the house has derived from him during his tenancy, that still such and such are dilapidations, and as such he is answerable for their being reinstated. In the present age, remarkable for the number of scantily-constructed houses, with so nice and clean, yet deceitful, an exterior, invitingly waiting for tenants on lease or agreement, it cannot fail to be useful to consider the nature of the obligation that exists between landlord and tenant upon the hire of house-property; for as mistakes will happen in the best regulated families, so do the friendship and good understanding that may have existed between landlord and tenant suddenly cease with the termination of the lease. Covenants to repair, when once entered into, are irrevocable; it is, therefore, most important that each party should clearly understand what constitutes repairs or dilapidations; and as to all defects, whether they arise from accident, neglect, or decay, and by which party they are to be made good.

"A landlord, on making a claim from his tenant for dilapidations, must show that they are such as were stipulated for in the lease, as the obligation on the part of the tenant to make good, varies, in nearly every case, according to the different covenants of the lease, by which the tenants are bound by more or less stringent clauses, involving greater or less responsibilities.

"Mr. Gibbons, in an excellent treatise on this subject, defines dilapidations as the act or default of a person having to use a tenement to the injury of another having a right to the same tenement, or a tenant's obligation may be considered as depending on the old maxim—'You must not injure another's property, but use it as your own.'

"It is an imperative act of justice to himself for the future tenant to make a stipulation that, previous to the commencement of his tenancy, the premises shall be surveyed; so that, if then there can be considered anything unsound or defective on the premises, it may be made good before the agreement is concluded, otherwise the tenant will find that he must make good all, whatever was the state of repair when he took possession of the premises.

"*Houses held on lease.*—In the case of premises being let on lease, as tenant should not be compelled to supply and make good defects that may arise from time and use, because, as the tenant bargained for use, and gives to the owner an equivalent rent, the landlord has a claim only for a restoration of the tenement as injured by the tenant, but has no right to make a claim for the wear to be made good; but then, as the tenant agrees to keep the house in tenantable repair, he is bound to supply all occasional and accidental defects which may expose the premises to premature decay. Accidents happening during his tenancy, if not inevitable, must be made good by the tenant, for it is fair to presume, that had he adopted proper precautions, the accident might have been prevented; therefore, there exists an obligation not to suffer dilapidations, and it is evident that the tenant is equally bound not to do any act that will cause an injury to the tenement.

"*Voluntary waste* means an alteration in the tenement, it being held in law that a lessee cannot change the nature of the thing demised; the act of alteration exceeds the right to use, and infringes on the condition that the landlord shall receive back the premises in the same state and condition as when the lease was granted. It is, therefore, essential that a tenant contemplating an alteration or improvement should receive proper permission and authority from the landlord."

"*Permissive waste* consists of a neglect on the part of a tenant to supply the repairs required by time and use, and also a neglect to make good occasional and accidental dilapidations. Houses and outbuildings are the principal subject of dilapidations, but the law extends to trees, land, changing the course of industry, &c., but the chief subject is buildings. These, though subject to decay in the progress of time, are capable of having the defective or decayed parts made good, and are therefore subject to both permissive and voluntary waste.

"A tenant hiring premises on lease is bound to perform tenantable repairs, which may be divided into three heads,—the ornamental, which includes the trades of painter and paper-hanger; the substantial, which includes the trades of bricklayer and carpenter; the third includes all works which tend to preserve the fabric from decay—as, stopping out wind and weather, which includes the trades of the joiner, plasterer, and glazier.

"Dilapidations caused by accident are very serious upon a tenant, as not only is the accident considered as a dilapidation, but injuries arising therefrom, of which the following is an illustration from Mr. Gibbons:—'If a building be covered with weather-boarding, and such boarding decay from age, so long as it form an entire and complete covering, it is no dilapidation; but if, owing to any neglect, any of the internal woodwork become injured, that is a dilapidation. If the main timbers decay, they are not chargeable as a dilapidation, so long as they are an efficient support; but if they give way, the tenant is bound not only to replace the timbers, but all damage done by their fall. Accident, shown to be inevitable, such as resulting from tempests, does not fall upon the tenant, as in the case of a house being prostrated, the tenant need not rebuild, but if the roof be blown off, the tenant must replace it. A tenant, generally speaking, is *not* answerable for dilapidations resulting from natural decay, or the result of time, or fair ordinary wear and tear, but *is* answerable for all extraordinary decay. For instance, as to decay, caused by the premises being exposed to the weather, as if the roof be suffered to go in bad repair, the tenant must make good the rafters and other timbers, if they are injured.' Lord Chief Justice Tindal defined a tenant's obligation to repair thus:—'Where an old building is let, and the tenant enters into a covenant to repair, it is not meant that the old building is to be restored in a renewed form at the expiration of his tenancy, or that the premises shall be of greater value than it was at the commencement. What the natural operation of time flowing on effects, and all that the elements bring about in diminishing the value, which, so far as it results from time and nature, constitute a loss, falls upon the landlord. But then the tenant must be careful that the tenement do not suffer more than time and nature would effect. He is bound to keep the premises in nearly the same state of repair as when demised.'

"*An annual tenant's* obligation has been thus laid down by Lord Kenyon:—'A tenant from year to year is bound to commit no waste, and to make from time to time fair and tenantable repairs, such as windows and doors that be injured during the tenancy.' Lord Tenterden decided that 'an annual tenant was bound to keep the premises wind and water tight.'

"It seems but justice, that under any mode of letting or hiring of house property, a tenant should be bound to use all ordinary precautions to preserve the building from decay; therefore there exists an obligation to keep the outside and the roof sound, perfect, and water-tight; and if the internal woodwork decay sooner than it otherwise would do for want of paint, &c., the tenant is bound to restore it. Glass, if cracked or broken, becomes dilapidation, it being an outside covering.

"*A tenant with no agreement as to duration of his tenancy*, cannot be bound to perform any repairs, the nature of his tenancy being so weak that he cannot be expected to do any repairs, as his landlord might immediately determine his tenancy, and reap the advantage to be derived from the outlay: besides, if the house require any repairs being done, the landlord can enter, and take any necessary steps for its preservation; but not so with premises let for a definite time.—then, the landlord having granted the use for a certain period, has not a right to enter upon the premises until the expiration of the tenancy. A tenant under this mode of letting. is however bound neither to commit nor permit waste. This kind of tenancy may be considered rather as a 'deposit than as a letting on hire,' and the tenant's obligation may be defined as 'to use the house with care.'"

The above extract gives a very clear and concise description of the responsibilities undertaken by tenants under varied forms of tenancy. It is well worthy the attentive perusal of the young professional man, and indeed the whole subject of dilapidations is an important one, requiring his careful study. It is one on which he is very frequently called upon to advise; and he will scarcely be competent to do so unless well acquainted with the just claims of the landlord, and the fair obligations of the tenant. To give in a list of repairs required to be done, is simple enough in acting for the landlord, but the surveyor should be well assured, from a practical acquaintance with what really are dilapidations, to what extent he is justified in calling on the tenant to do them.

DIMENSION (from the Latin) a principal distance measured in a straight line on the surface of a body, in some particular direction, or through some certain point, by the help of which the body may be constructed or measured as to its superficial or solid contents.

The dimensions of rectangular figures and solids are taken along, or parallel to the straight lines which bound their surfaces; and consequently rectangles have two dimensions, viz. length and breadth, and rectangular prisms three dimensions, viz. length, breadth, and thickness. The dimension of a parallelogram are the length of one side, and the distance from that side to the opposite side of the same, so that the two dimensions of a parallelogram are at right angles to each other. The dimensions of any plane figure are the lengths of the sides and diagonals. The dimensions of a circle are its radius, diameter, or circumference, or all. The dimensions of a regular polygon are the length of one of its sides, and their number. The dimensions of any prism are the dimensions of one of its ends or bases, and the perpendicular or distance between the said ends or bases. The dimensions of a pyramid are the dimensions of its base, and the distance or perpendicular form the apex to the plane of the base. The dimensions of a sphere are its diameter or circumference. The dimensions of a spheroid are the fixed and revolving axes. The dimensions of an irregular surface or body are in a great measure arbitrary. The dimensions of an irregular surface are thus taken: Fix upon some principal line passing through the middle of the body in the direction of its greatest extension, as nearly as can be judged; then divide the length of this line into equal parts; through the points of division, draw perpendiculars, terminated by the boundary; then the length of the first line and of the perpendiculars are the dimensions. The dimensions of a definite body may be limited as to number, and the body may be accurately ascertained, either with regard to its construction or solidity; but an indefinite body can never be ascertained for either, whatever may be the number of its dimensions: greater accuracy, however, will be obtained, the greater the number of dimensions taken. The dimensions of an irregular plane figure or solid, ought to be taken in equidistant lines or planes.

The subjects to which dimensions are applied belong to geometry, mensuration, and the construction of solids. The method of squaring dimensions will be found under the articles Cross Multiplication, Decimals, and Duodecimals.

In writing the dimensions of a body, consisting of many different parts, in order to avoid mistakes, an eye-draught, or sketch of the body, should be made, and two angles, each with its apex fixed in the opposite extremities of the extension, with a number placed between them to denote the length of the line: thus, ⟨ - - - - - 36 ft. - - - - - ⟩ denotes 36 feet between the point of one angle and that of the other: the opening of each angle is always turned towards the centre of the line. By this method no mistake can occur, even though ever so many other dimensions cross one another, unless they come so close as to confuse. Simple rectangles, or rectangular prisms, are most frequently written down without any eye-draught, and the dimensions entered in the book with a cross between each, or the word by; thus, for a rectangle, 3 . . 9′×4 . . 8′, or 3 . . 9′ by 4 . . 8′; that is, 3 feet 9 inches by 4 feet 8 inches; the mark thus′, signifying that the figures below are inches, and consequently that the first is the place of feet. A solid is thus denoted, 5 . . 3′ × 4 . . 8′ × 12 . . 6′, or 5 . . 3′ by 4 . . 8′ by 12 . . 6′; that is, the end, or base, is 5 feet 3 inches by 4 feet 8 inches, and 12 feet 6 inches from end to end; or the solid is 12 feet 6 inches long, 5 feet 3 inches broad, and 4 feet 8 inches thick.

In finding the contents of artificers' works in buildings, the dimensions are placed one under the other, according to their denominations, and the surface or solid is known by the number of its dimensions; in order therefore to distinguish any set of dimensions from the next, whether above or below, a horizontal line must be drawn between them. *See* the article Brickwork.

Dimension Book, a book in which the measurement of the builder's work is entered, specimens of which are given under the head Brickwork.

DIMINISHED BAR, of a sash, one that is thinner on the inner edge, or the edge next to the apartment, than where it recedes close to the glass, in order to give it a lighter appearance.

Diminished Column, one whose upper diameter is less than the lower; as is to be seen in all the regular orders of architecture.

Diminishing Rule, a board cut with a concave edge, so as to ascertain the swell of a column. and try its curvature. For the method of forming a diminishing rule, *see* Column.

Diminishing Scale, a scale of gradation, used in finding the different points for drawing the spiral curve of the Ionic volute, by describing the arc of a circle through every three succeeding points, the extreme point of the last arc being one of the next three; each point through which the curve passes being so regulated as to be in a line drawn to the centre of the volute, and the lines at equal angles with each other. *See* Spiral and Volute.

DIMINUTION OF COLUMNS, the continued contraction of the diameter from the base to the top of the shaft.

Some modern authors make the diminution to commence from one-third of the height of the column; but if ancient methods are to have a preference, we shall find few examples to authorize this practice. In all the Grecian antiquities of Athens, or Ionia, the diminution commences invariably from the bottom of the shaft, immediately above the apophyge: and, according to the engravings from Stewart's drawings, the diminution is continued in a straight line, excepting in the Temple of Corinth, where the swell is shown. The diminution is rarely less than one-eighth, or greater than one-sixth, of the inferior diameter.

In Gothic architecture, neither swell nor diminution is used; all the horizontal sections being similar and equal.

In ancient examples, even of the same order, the diminution is very variable.

Other particular remarks will be found under Column.

DINING-ROOM, an apartment in a house, appropriated to the eating of dinners. The dining-room and drawing-room ought to have some relation to each other in point of size, as the company move from one to the other. In the smallest houses, the dining-room ought to be the largest, and nearly square upon a plan. In houses of a middle size, they are very frequently of the same magnitude, which may be 18 feet in breadth, 24 feet in length, and 13½ feet in height, or 3-4ths of the breadth. In larger houses, the length may be extended to 40 feet; and in very considerable edifices even to 50 feet: in the latter case the length may be double the breadth.

Dining-rooms are sometimes fitted up with a recess at one end for receiving the side-board; but if the apartment be very large, a recess at each end is necessary: these recesses may be either square, or in the form of a niche. *See* House, *and* Room.

DINOCRATES, an eminent architect, patronized by Alexander the Great; whose history is thus related by Vitruvius:—"At the time that Alexander was conquering the world, Dinocrates, the architect, confiding in his knowledge and genius, and being desirous of obtaining the royal commendation, left Macedon, and repaired to the army. He carried with him letters from his relations and friends in his own country, to the nobles of the first rank, that he might thereby more easily gain access. Being favourably received, he requested to be immediately presented to Alexander; they gave him many promises, but made delays, pretending to wait till a proper opportunity should offer. Dinocrates, therefore, suspecting that he was derided, sought the remedy from himself. He was very large of stature, had an agreeable countenance, and a dignity in his form and deportment. Trusting to these gifts of nature, he clothed himself in the habit of a host, anointed his body with oil, crowned his head with boughs of poplar, put a lion's skin over his left shoulder, and holding one of the claws in his right hand, approached the tribunal where the king was administering justice. The novelty of the appearance attracting the notice of the people, occasioned Alexander also to see him, who, wondering at the sight, commanded way to be given, that he might approach. Alexander then demanded who he was. Dinocrates replied, 'I am a Macedonian architect, who come to thee with ideas and designs, worthy of the greatness of thy fame; I have formed a design to cut Mount Athos into the statue of a man, in whose left hand shall be a large city, and in his right a bason, which shall receive all the rivers of the mountain, and again discharge them to the sea.' Alexander, delighted with the idea, immediately inquired, if the country adjacent would produce sufficient food for the sustenance of the inhabitants. When he understood that provision must be conveyed thither by sea, he replied: 'Dinocrates, I discern the excellence of thy design, and am pleased with it; but I consider, that whoever should establish a colony in such a place, would hereafter be justly blamed; for, as a new-born infant cannot be nourished, or gradually reared to the different stages of life, without the milk of the nurse; so neither can a city be peopled, nor can it thrive, without fertile land and plenty of provision; however, as I approve the design, though I disapprove the place, I will have thee attend me, that elsewhere I may employ thee.' From that time, Dinocrates remained with the king, and attended him into Egypt. There Alexander, observing a spot which had a haven formed secure by nature, an excellent place for an emporium, the adjacent country through all Egypt being fruitful, and having the accommodation of the river Nile, ordered him to build the city now called, from his name, Alexandria. Thus, by the means of a graceful countenance and dignity of person, Dinocrates became eminent."

Dinocrates was also employed to superintend the rebuilding of the temple of Diana, at Ephesus, when burnt by Erostratus, which he did with more magnificence than before. The last design which history ascribes to him, was that of erecting a temple to Arsinoë, queen of Ptolemy Philadelphus, at Alexandria, with a dome above it, which was to enclose a magnet, in order to keep suspended in the air an iron statue of that queen. Ptolemy approved the design, and gave orders for its execution; but both the king and the architect died before the project could be accomplished.

DIOPHANTINE PROBLEMS, in mathematics, certain questions relating to square and cube numbers, and right-angled triangles, &c., the nature of which was determined by Diophantus.

DIOPHANTUS, a celebrated mathematician of Alexandria, reputed to have been the inventor of algebra. The exact date of his birth is unknown; some authors asserting that he lived before Christ, and others after, in the reigns of Nero and the Antonines. His reputation was very high among the ancients, since they ranked him with Pythagoras and Euclid in mathematical learning.

Diophantus left behind him thirteen books of arithmetical questions, of which, however, only six are extant.

DIORAMA, a mode of painting and scenic exhibition invented a few years ago by two French artists, Daguerre and Bouton. The peculiar, and almost magical effect of the diorama arises, in a great degree, from the contrivance employed in exhibiting the painting, which is viewed through a large opening or proscenium. Within this proscenium the picture is placed at such a distance, that the light is thrown upon it, at a proper angle from the roof, which is glazed with ground glass, and cannot be seen by the spectators. While the light is thus concentrated on the picture, the spectators are left in comparative darkness, by which the effect is materially increased; and the illusion is rendered still more complete, by the skilful manner in which the transitions of light are managed. The light may be diminished or increased at pleasure, and that either gradually or suddenly, so as to represent the change from ordinary daylight to sunshine, from sunshine to cloudy weather, or to the obscurity of twilight, and also the difference of atmospheric tone attending them. By means of different folds or shutters attached to the glazed ceiling, transitions are produced in regard to light and atmospheric effects of the most pleasing character. The diorama is indeed a most perfect scenic representation of nature; by varied and ingenious contrivances, it is capable of displaying the greatest difference in its pictures. It is peculiarly adapted for moonlight subjects, and for exhibiting such "*accidents*" in landscapes as sudden gleams of sunshine and their disappearance. For showing architecture, particularly interiors, it is unrivalled, as powerful relief may be obtained without that exaggeration in the shadows which is almost inevitable in every other mode of painting. Although as yet only employed for purposes of public exhibition, the diorama might undoubtedly be made use of for the embellishment of such parts of a building as corridors and the like, where light can only be obtained from one extremity.

The Diorama in the Regent's Park, was erected for the exhibition of pictures with the effects we have been describing; and as one of the most interesting and remarkable of the "sights in London," deserves a passing notice.

The pictures exhibited are each about 72 feet long, and 42 feet wide, and are capable of being shifted and exchanged for others when required. They are placed at distances from the spectator proportioned to the angle at which he would view the object in nature; and by the united talents of the artist and the machinist, the illusion is rendered so perfect, and so true to nature, that the beholder is almost led to doubt that they are really the effect of art. Thus, in architectural subjects, as the interior of the cathedral, the whole is at one moment subdued by gloom, as by the overshadowing of some passing cloud. The "long-drawn aisle" and deep recesses are obscured, all seems about to be buried in darkness, when, in an instant, as though the interruption had passed away, and the bright light of day was permitted to shine through the windows in its full lustre, the Gothic architecture is illumined in the most beautiful manner, the shadows projected with force and truth, and the secondary lights produced beneath the groinings of the roof in all the delicate gradations of natural reflections. Landscape scenes undergo similar changes, and admirable effects are produced in the transitions from shade and darkness, to the brightness of light and sunshine.

The elevation of the building was designed by Mr. Nash; it is of the Ionic order, the basement embellished with columns and pilasters, &c., the centre of which is the approach to the theatre. The building consists of a vestibule and two lateral houses, facing a circular part of the edifice, which may be regarded as the audience-room of the theatre, and is occupied by boxes, and an open area for spectators. The sides of this circular part are painted and adorned with festooned draperies, and the top is covered with a transparent painting, divided into many compartments, and charged with medallion likenesses of several eminent artists. Over this semi-transparent ceiling, or inner roof, rises a conical roof, nearly half of which is glazed. The circular part consists of a wall, two-thirds of a circle, with two small doorways, and two large openings to the compartments of the scenic theatre. Immediately within this wall, but detached from it, is another wall, rising from the floor to the inner ceiling, and which, with the floor, revolves on a pivot beneath. A large square opening, like the proscenium of a theatre, allows the audience to view the pictures.

The Diorama was opened to the public in October, 1823, and has ever since continued to be visited as one of the most popular exhibitions in the metropolis.

DIPTERON, or Dipteros, (from the Greek), or Diptere, (from the French), in ancient architecture, a temple surrounded with a double row of columns, forming a sort of porticos, called *wings*, or *aisles*. Vitruvius informs us, that dipteral temples were octostyle; but this he must mean only in general; for they may be also decastyle. Indeed, they could not have been less than octostyle, as no room would have been left for the cell. The same author also observes, that Hermoginus made a very great improvement in the construction of dipteral temples, by taking away the interior range of columns, which occasioned confusion in the perspective appearance.

DIRECT RADIAL, a right line from the eye, perpendicular to the picture.

DIRECTING LINE, the line in which an original plane would cut the directing plane.

Directing Plane, a plane passing through the point of sight, or the eye, parallel to the picture.

Directing Point, that in which any original line produced cuts the directing plane.

DIRECTOR of an original Line, the straight line passing through the directing point and the eye of the spectator.

Director of the Eye, the intersection of the plane with the directing plane, perpendicular to the original plane and that of the picture, and hence also perpendicular to the directing and vanishing planes; since each of the two latter is parallel to each of the two former. The director of the eye is also sometimes called *the eye director.*

DIRECTRIX, or Dirigent, in geometry, a term expressing the line of motion along which a describent line, or surface, is carried in the genesis of any plane or solid.

Thus, if the line A B move parallel to itself, and along the line A C, so that the point A always keeps upon the line A C, it will form a parallelogram, A B C D, of which the side A B is the describent, and A C the dirigent. So, also, if the surface A B C D be supposed to be carried along the line C E in a position always parallel to itself, in its first situation, the solid A D E H will be formed, when the surface A D is the describent, and the line C E is the dirigent.

DIRETTA, the same as Gola, or Sima-Recta, which see.

DISCHARGE, (from the French), a term applied to a brick wall, or post, when trimmed up to a piece of timber overcharged in its bearing; in which case the wall or post is a discharge to that bearing.

Discharging Arches, rough brick or stone arches, built over the wooden lintels of apertures. These are scheme arches, being the segments of very large circles. Discharging arches are employed in the inside of external walls or in partition walls. The length of the chord of a discharging arch should exceed that of the wooden lintels beneath, so that when the wood begins to decay, the lintels may be taken out, and the arch will be sufficient to sustain the superincumbent part of the wall, as well as that the arch may be sustained by the walls, and not have any dependence upon the lintels. To make the arches resist with greater force, the lintels should not have more wall-hold than what may be found sufficient to sustain the superincumbent part while building: indeed, if walls be well built, upon firm ground, wooden lintels may be dispensed with.

Discharging Struts, the same as *auxiliary rafter*, or *principal braces:* the term is used by Batty Langley.

DISH-OUT, to form coves by any kind by means of ribs, or to form wooden vaults for plastering upon.

Dishing-out, any kind of coved work formed by wooden ribs, for plastering upon. The term is of the same import as *cradling.*

DISPLUVINATED CAVÆDIUM. *See* Cavædium.

DISPOSITION, (from *dispono*, to place), in architecture, the just placing of the several parts of a building, according to their use; as, disposition of apartments, disposition of columns, as eustyle, diastyle, pichnostyle, &c.

DISTANCE of the Eye, in perspective:—If a straight line be drawn from the eye, perpendicular to the plane of the picture, the intercepted part of such line is termed *the distance of the eye.*

Distance, *Point of.* *See* Point of Distance.

Distance of a vanishing Line, the length of a perpendicular, falling from the eye perpendicular to the vanishing line.

Distance, *Inaccessible.* *See* Trigonometry.

DISTEMPER, (from the French, *détremper*, to temper or dilute,) in painting, the working up of colours with something besides mere water or oil. If colours be prepared with water, the painting is called *liming;* and if with oil, it is called *painting in oil*, or simply *painting.*

If the colours be mixed with size, whites of eggs, or any such proper glutinous or unctuous substance, and not with oil, they then say it is done *in distemper;* as those of the admirable cartoons, formerly at Hampton Court, and as all ancient pictures are said to have been before the year 1410.

In distemper, the white colour or base generally used is the finest whiting, which is prepared in large quantities by various manufacturers. The colours most commonly mixed with it for producing the various tints are as follows:—Straw colour may be made with white and masticot, or Dutch pink; fine grays, with white and refiner's verditer; an inferior gray may be compounded with blue black or bone black, and damp blue or indigo; pea-greens, with French green, Olympian green; and fawn colour, with burnt sienna or burnt umber and white, and so of any intermediate tint. All the colours used in distemper, should either be ground very fine, or washed over so as to ensure the most minute division of their particles. In general, the size made of common glue is used with a proper quantity of water to render the colour liquid, but where the work will afford it, parchment-size will be found greatly superior.

It will not require less than two coats of any of the foregoing colours, in order to cover the plaster, and bear out with an uniform appearance. When old plastering has become discoloured with stains, and it be desired to have it painted in distemper, it is advisable to give the old plaster, when properly cleaned off and prepared, one coat at least of white-lead ground in oil, and used with spirits of turpentine, which will generally cover all old stains, and, when quite dry, will take the water-colours very kindly.

The best methods of compounding the colours with the vehicles, is to mix the size in water, then to levigate the colours in part of it, and afterwards to put each kind into a proper pot, adding as much more of the melted size as will bring it to a due consistence, and mixing the whole well together in a pot with a brush or wooden spatula. Warm water may be afterwards added, if necessary, for grinding the colours, or for working. The pots must be covered with bladders, and tied. This method of painting is chiefly confined to scenes and grosser works, where the effect depends more upon the perspective and opposition of the colours, than upon their brightness.

DISTRIBUTION, the dividing and disposing of the several parts of a building according to some plan, or to the rules of architecture. The proper distribution or arrangement of the various apartments in a large building is of great importance, and may be either good or bad, as they may be best suited to answer their use. That arrangement only can deserve the former appellation, in which every apartment seems placed in its very best position, with regard to architectural symmetry, elegance of appearance, and domestic convenience.

DISTYLE, (Greek, δυω-στυλος), a portico of two columns. It applies rather to a portico with two columns in antis, than to the mere two-columned porch.

DITRIGLYPH, an interval admitting two triglyphs over the intercolumn; that is, if in two adjoining columns a triglyph be placed with its middle over each, the ditriglyph will contain three metopes, or spaces, two half triglyphs, and two whole triglyphs.

DIVAN, among the Orientals, a council-chamber, or the saloon or hall in which a council is held: it is applied generally to denote a state apartment, or room in which company is received.

DIVERGING LINES, such as are continually increasing in their distance from each other.

DIVIDERS. *See* Mathematical Instruments.

DIVISION, *Harmonical.* *See* Harmonical Division.

Division of an Order. *See* Order.

DOCK, an artificial receptacle for shipping, generally formed by excavation, and enclosed by gates, which open for the ingress and egress of vessels; the sides are usually constructed of masonry.

Dock, a place artificially formed on the side of a harbour or bank of a river, for the reception of ships. Docks are of two kinds, wet docks and dry-docks. A wet-dock is an excavation or basin, of considerable extent, which vessels can enter to discharge or take in their cargoes, and in which they are always afloat; of this kind are the immense docks of London, Liverpool, and other places of great commerce. A dry-dock is used for inspecting and repairing ships, and is so contrived, that the water can be admitted or excluded at pleasure, so that a vessel can be floated in when the tide is up, and the water may run out with the fall of the tide; or, the gates of the dock being closed to prevent the egress of the water, it is pumped out by steam-power. Dockyards belonging to the government usually consist of dry-docks for repairing ships, and of *slips* on which new vessels are built; besides which they comprise storehouses, in which various kinds of naval stores are kept, and workshops in which different processes subsidiary to ship-building, are carried on.

DODECAGON, (δωδεκα, *twelve* and γωνια, *angle*), a regular polygon or figure, with twelve equal sides and angles.

If the radius of a circle O A D F, be so divided into two parts, that the rectangle under the whole and the one part shall be equal to the square of the other part; then this last part will be equal to the side C D of a regular decagon A B C D E F, &c., inscribed in the circle; and that line whose square is equal to the two squares of the whole, and of the same part, will be equal to the side, A C, of a regular pentagon inscribed in the same circle. For, draw the radii O A, O C, O D, O F; also draw A D, cutting O C in G, and let A H be perpendicular to O G. The triangle O D G, having the angle $COD\ (= \frac{1}{2} DOF = OAD) = ODA$, is isosceles: the triangle A O G, having $AGO\ (= GDO + DOG = 2\,DOC) = AOC$, is likewise isosceles; as is also the triangle C D G; because, CGD being $= AGO$, and $CDG\ (CDA) = FAD$, the triangles A O G and C D G are equiangular; consequently, C D, A O; C G, G O, being corresponding sides, we have $CG \times AO\ (CG \times CO) = CD \times GO = GO^2$, because $GO = GD = DC$, the side of the decagon, &c. Moreover, because $AG = AO$, HG will be $= HO$; and GC being the difference of the segments H O and H C, we have $AC^2 - AO^2 = CO \times GC = OG^2$; and consequently AC^2 (*i. e.* the square of the side of the pentagon) $= AO^2 + OG^2$.

Let $CO = a$, $GO = x$, then will $CG = a - x$; and by this proposition, $\overline{a - x} \times a = x^2$ and $x^2 + a x = a^2$; and resolving this quadratic equation, we shall have $x^2 + a x + \frac{1}{4} a^2 = a^2 + \frac{1}{4} a^2 = \frac{5}{4} a^2$; whence $x + \frac{1}{2} a = \sqrt{\frac{5}{4} a^2}$, and $x = \sqrt{\frac{5}{4} a^2} - \frac{1}{2} a$. Let the radius a be $= 1$, and G O, or the side of a regular decagon inscribed in the circle, is $= \sqrt{\frac{5}{4}} - \frac{1}{2}$. Hence it appears that the sine of 18^0 (or half the side of a decagon inscribed in the circle) is $= \frac{1}{2} \sqrt{\frac{5}{4}} - \frac{1}{4} = \frac{1}{2} \sqrt{1.25} - \frac{1}{4} = \frac{1.11803398}{2}$, &c. $- \frac{1}{4} = .55901699$, &c. $- .25 = .30901699$, &c.

If the side of a dodecagon be 1, its area will be equal to three times the tangent of $75^0 = 3 \times 2 + \sqrt{3} = 11.1961524$ nearly; and, the areas of plane figures being as the squares of their sides, 11.1961524 multiplied by the square of the side of any dodecagon, will give its area. Hutton's *Mensuration*, p. 114.

To inscribe a dodecagon in a given circle.—Carry the radius six times round the circumference, which will divide it into six equal parts, or form a hexagon, (See HEXAGON); then bisect each of those parts, which will divide the whole into 12 parts, for the dodecagon.

DODECAHEDRON, (from δωδεκα, *twelve*, and ἑδρα, *seat*,) one of the regular bodies comprehended under twelve equal sides, each of which is a pentagon; or, a dodecahedron may be conceived to consist of twelve quinquangular pyramids, whose vertices, or tops, meet in the centre of a sphere conceived to circumscribe the solid; consequently they have their bases and altitudes equal.

To find the solidity of the dodecahedron.—Find that of one of the pyramids, and multiply it by the number of bases, viz., 12; the product is the solidity of the whole body. Or its solidity is found by multiplying the base into one-third of its distance from the centre, twelve times; and to find this distance, take the distance of two parallel faces; the half is the height.

The diameter of the sphere being given, the side of the dodecahedron is found by this theorem; the square of the diameter of the sphere is equal to the rectangle under the aggregate of the sides of a dodecahedron and hexahedron inscribed in the same, and triple the side of the dodecahedron.

Thus, if the diameter of the sphere be 1, the side of the dodecahedron, inscribed, will be $(\sqrt{\frac{5}{3}} - \sqrt{\frac{1}{3}}) \div 2$; consequently, that is to this as 2 to $(\sqrt{\frac{5}{3}} - \sqrt{\frac{1}{3}})$ and the square of that, to the square of this, as six : $3 - \sqrt{5}$. Therefore the diameter of the sphere is incommensurable to the side of an inscribed dodecahedron, both in itself and in its power.

If the side, or linear edge, of a dodecahedron be s, its surface will be

$$15 s^2 \sqrt{1 + \frac{2}{3} \sqrt{5}} = 20.6457788 s^2: \text{ and its solidity}$$

$$\frac{5 s \sqrt{47 + 21 \sqrt{5}}}{40} = 7.66311896 s^3.$$

If the radius of the sphere that circumscribes a dodecahedron be r, then is

$$\text{its side or linear edge} = \frac{\sqrt{15} - \sqrt{3}}{3} r,$$

$$\text{its superficies} = 10 r^2 \sqrt{2 - \frac{2}{3}\sqrt{5}}, \text{ and}$$

$$\text{its solidity} \quad \frac{20 r^3}{8} \quad \frac{\sqrt{u + \sqrt{5}}}{30}$$

The sides of a dodecahedron inscribed in a sphere is equal to the greater part of the side of a cube inscribed in the same sphere, and cut according to extreme and mean proportion. If a line be so cut, and the lesser segment be taken for the side of a dodecahedron, the greater segment will be the side of a cube inscribed in the same sphere. The side of the cube is equal to the right line which subtends the angle of a pentagon, of the dodecahedron inscribed in the same sphere.

DODECASTYLE, an edifice having twelve columns in front.

DOG-LEGGED STAIRS, such as are solid between the upper flights; or those which have no well-hole; and the rail and balusters of both the progressive and retrogressive flight, fall in the same vertical plane. The steps are fixed to strings, newels, and carriages; and the ends of the steps of the inferior kind terminate only on the side of the string, without any housing.

No. 1. The plan.—*a* the seat of the newel; *g* the seat of the upper newel.

The dotted lines represent the faces of the risers, and the continued lines the nosings of the steps.

No. 2. The elevation.—A B the lower newel, the part B C being turned; G H the upper newel; D E, F G, the lower and upper string-boards, framed into the newel; K L a joist framed into the trimmer I; *k l*, *n o*, *q r*, *&c.*, the faces of the risers; *m n*, *p q*, *s t*, the heads, or cover-boards; *m*, *p*, *s*, *&c.*, nosings of the steps; M O, F Q, the upper and lower ramps.

To describe the ramps.—Suppose the upper one to be drawn; produce the horizontal part, H M, of the rail to P: draw M N perpendicular to P H, and produce the straight part, B O, to N: make N O equal to N M: draw O P at right angles to B N: from P, as a centre, describe the arc M O: and describe another concentric circle to meet the under side of the rail, and the sloping part B O; and the ramp will be completed.

R S, the story-rod; this is a necessary article in fixing the steps; for if a common measuring rule be used for this purpose, the workman will be very liable to err either in excess or defect, and thus render the stairs extremely faulty; which cannot be the case if the story-rod be applied to every riser, and if the successive risers be regulated thereby. When steps are put up without the use of the story-rod, the smallest error is liable to multiply.

In the construction of dog-legged staircases, the first thing is to take the dimensions of the stair and the height of the story, and lay down a plan and section upon a floor to the full size, representing all the newels and steps; then the situation of the carriages, pitching-pieces, long bearers, and cross bearers, will be ascertained, as also of the string-boards.

The quantity of room allowed for the stairs, and the situation of the apertures and passages, will determine whether there are to be quarter-paces, half-paces, one-quarter winders, or two-quarter winders. In order to give all the variety possible, we shall suppose the flight to consist of two-quarter winders.

The strings, rails, and newels, being framed together, they must be fixed with temporary supports; the string-board will show the situation of the pitching-pieces, which must be put up next in order, wedging one end firmly into the wall, and fixing the other to the string-board; this being done, pitch up the rough strings, and thus finish the carriage part of the flyers. In dog-legged staircases, the steps and risers are seldom glued up, except in cases of returned nosings; suppose them, therefore, to be of separate pieces; proceed to

Fig 1. No 2

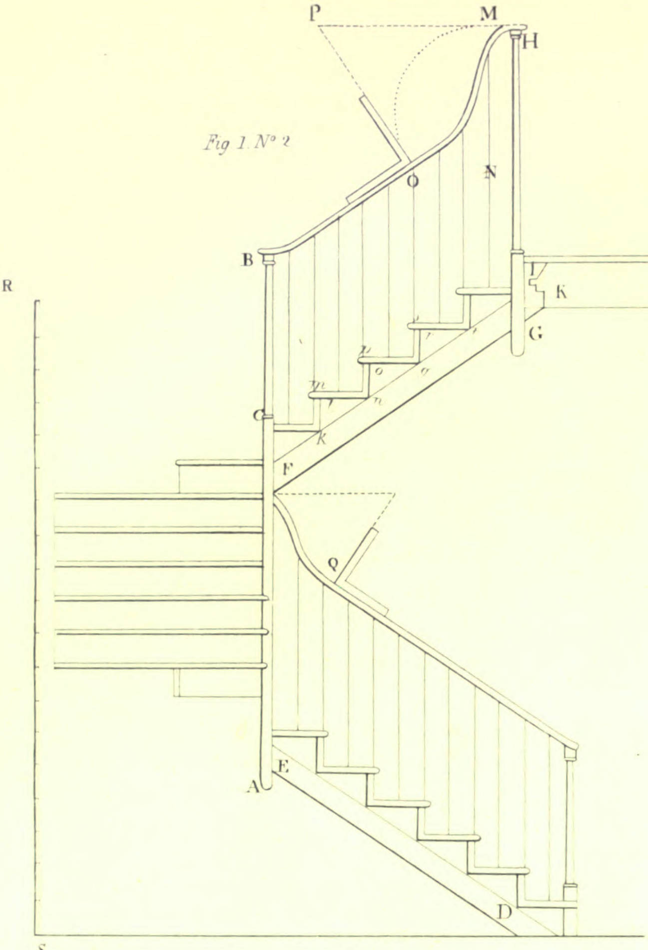

Fig 2.

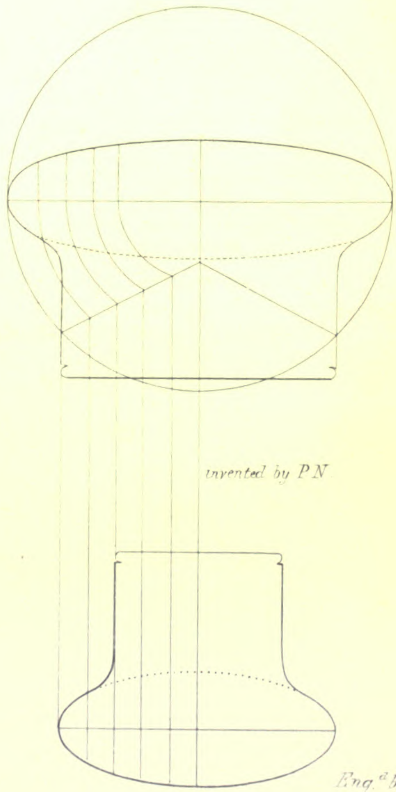

Fig 1. No 1.

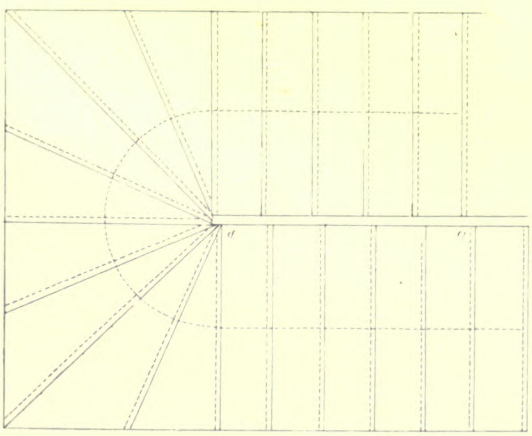

Drawn by P. Nicholson.

Engd by R Tho

put up the steps: place the first riser in its situation, having fitted it down close to the floor; the top being brought to a level at its proper height, and the face in its right position, fix it with flat headed nails, driving them obliquely through the bottom part of the riser into the floor, and then nailing the end to the string-board; proceed then to cover the riser with the first tread, observing to notch out the farther bottom angle opposite the rough strings, so as to make it fit closely down to a level on the top side, while the under side beds firmly upon the rough strings at the back edge, and to the riser towards the front edge: nail down the tread to the rough strings, driving the nails from the seat, or place on which the next riser stands, through that edge of the riser into the rough strings, and then nailing the end to the string-board; begin with the second riser, having brought it to a breadth, and fitted it close to the top of the tread, so that the back edge of the tread below it may entirely lap over the back of the riser, while the front side is in its regular vertical position: nail the head of the riser, from the under side, taking care that the nails do not go through its face, and thereby spoil the beauty of the work.

Proceed in this manner, with tread and riser alternately, until the last parallel riser. The face of this riser must stand the whole projection of the nosing back from the face of the newel. Then fix the top of the first bearer, for the first winding tread, on a level with the top of the last parallel riser, so that the farther edge of this bearer may stand about an inch forward from the back of the next succeeding riser, for the purpose of nailing the treads to the risers upwards, as was done in the treads and risers of the flyers; and having fitted the end of this bearer against the back of the riser, and nailed or screwed them fast together, fix a cross-bearer, by letting it half its thickness into the adjacent sides of the top of the riser, and into the top of the long bearer, so as not to cut through the horizontal breadth of the long bearer, nor through the thickness of the riser, as this would weaken the one, and spoil the look of the other. Then fix the riser to the newel, driving a nail obliquely from the top edge of the former into the latter: then proceed to put down the first winding tread, fitting it close to the newel, in the bird's-mouth form. Proceed in this manner with all the succeeding risers and treads, always fixing in the bearers, previously to laying each successive tread, until the steps round the winding part are entirely completed. Then proceed with the upper retrogressive range of flyers as with those below. Fit the brackets into the backs of the risers and treads, so that their edges may join each other on the sides of the rough strings, to which they are fixed by nails, and thus the work is completed. Some workmen do not mind the close fitting of the riser; but it certainly makes the firmest work.

In the best kind of dog-legged stairs, the nosings are returned; sometimes the risers are mitred to the brackets, and sometimes mitred with quaker-strings: in the latter case, a hollow is mitred round the internal angle of the under side of the tread, and the face of the riser. Sometimes the string is framed into the newel, and notched to receive the ends of the steps; the other end having a corresponding notch-board, and the whole flight is put up like a step-ladder. In order to get the lower part for the turning, set the thickness of the capping on the return string-board, and where that falls on the newel below, is the place of the lower limit for the turning.

To find the section of the cap of the newel for the turner.— Draw a circle to its intended diameter: draw a straight line from the centre to any point without the circumference, and set half the breadth of the rail on each side of that line; through the point draw a line parallel to the middle straight line, and the extreme lines will contain the breadth of the rail: draw any radius of the circle, and set half the breadth of the rail from the centre towards the circumference; through the point where this breadth falls, draw a concentric circle; from the point where this circle cuts the middle line of the rail, draw two lines to the points where the breadth of the rail intersects the outer circle, and these lines will show the mitre. *See* HAND-RAILING and STAIRCASING.

DOGS, otherwise termed *andirons* or *endirons*, *creepers*, &c. iron standards used in the olden times to support the logs of wood when consumed for fuel. The distinction between the andirons and creepers consists in the former being of a larger size than the latter; the use of the andirons was to support the logs, and of the creepers to keep the brands off the hearth. ENDIRONS.

DOG-TOOTH, an ornament very prevalent in edifices of the Early English style, in which it forms a very marked feature. It consists of a pyramidal flower of four leaves, so disposed as to have the space between the two adjacent leaves in the centre of the sides of the pyramid; a series of such ornaments is very frequently seen inserted in a hollow moulding.

DOME, a term applied to a covering of the whole or part of a building. The Germans call it *Dom*, and the Italians *Duomo*, and apply the word to the principal church of a city, although the building may not have any spherical or polygonal dome. From this and other circumstances we may infer the term to be derived from the Latin *Domus*, house.

A dome is an arched or vaulted roof, springing from a polygonal, circular, or elliptic plan; presenting a convex surface on the outside, or a concavity within, so as that every horizonal section may be of a similar figure, and have a common vertical axis. According to the plan from which they spring, domes are either circular, elliptical, or polygonal; of these, the circular may be spherical spheroidal, ellipsoidal, hyperboloidal, paraboloidal, &c. The word dome is applied to the external part of the spherical or polygonal roof, and cupola to the internal part. Cupola is derived from the Italian *cupo*, deep, whence also our word cup. But cupola and dome are often used synonymously, although perhaps incorrectly. Such as rise higher than the radius of the base, are denominated *surmounted domes;* those that are of a less height than the radius, are called *diminished* or *surbased;* and such as have circular bases, are termed *cupolas*.

The remains of ancient domes are generally spherical in their form, or built of stone or *tufo*. Ruins of numerous ones still exist in the neighbourhood of Rome and Naples. They were frequently used among the Romans, after the accession of Augustus, in whose reign, the use of the arch, and consequently of domes, first became common. The arch, indeed, is of Grecian origin, though in all the ancient edifices of that country, we do not meet with a single instance of a built dome: that which covers the monument of Lysicrates, being only a single stone, can only be looked upon as a lintel: and the invention of this species of vault seems justly attributed to the Romans, or Etrurians.

Of the ruins of domes in and near Rome, the principal are the Pantheon, and the temples of Bacchus, Vesta, Romulus, Hercules, Cybele, Neptune, and Venus, and also some of the chambers of the Thermæ. The most magnificent dome of antiquity is that of the Pantheon, at Rome, built in the reign of Augustus, and supposed to be a chamber of the great baths of Agrippa. It is still entire, and consists of a hemispherical concavity, enriched with coffers, and terminating upwards in an aperture, called *the eye*. The exterior rises from several degrees, in a sloping direction, nearly tangent to the several internal quoins, and presenting to the spectator the truncated segment of a sphere, considerably less than a hemisphere. The diameter of the dome internally is 142 feet 8½ inches; the circular opening at the top in the centre 28 feet 6 inches in diameter; the height from the top of the attic 70 feet 8 inches. The interior of the dome is ornamented with five rows of square compartments, and as these converge towards the top, each row is considerably larger than that immediately above it. Each of the large squares contains four smaller ones sunk one within the other. It is supposed that these were decorated with plates of silver. The base of the dome externally consists of a large plinth with six smaller plinths or steps above it; and in the curve of the dome a flight of steps is formed which leads to the opening at the top of the dome. From the drawings of Serlio, it appears that similar flights of steps were formed at intervals all round the dome, but these are now covered with lead. The dome is constructed of bricks and rubble. The thickness at the base is about 17 feet; at the top of the highest step, 5 feet 1½ inches; and at the top of the dome, 4 feet 7 inches. The circular wall which supports the dome is 20 feet thick, but is divided by several large openings, and has discharging arches of brick. The dome of the Pantheon is incombustible, and is perhaps the cheapest as well as the most durable and unconsumable roof which could have been erected over so large a building.

The dome of the temple of Bacchus is also internally hemispherical, though without coffers. Externally it is now covered with a common roof, which may have been the original form; such a roof is also to be seen over the dome of the temple of Jupiter, in the palace of Diocletian, at Spalatro.

The dome of one of the chambers of the Thermæ of Catania was 111 feet in diameter. In the Thermæ of Titus there are two domes, each 84 feet in diameter; and in the baths of Constantine there was one of 76 feet. There were three domes in the baths of Diocletian, of which two still remain; one is 73 feet 6 inches in diameter, and the other 62 feet 3 inches. Judging from those that remain, it would seem that in the Thermæ they were lighted from the top, in the same manner as in the dome of the Pantheon. In the neighbourhood of Puzzuoli there is a circular edifice which has a dome built of pumice-stone and volcanic tufa: its diameter is about 96 feet. The temple of Minerva Medica at Rome, was on the plan, a polygonal dome of ten sides, without any opening at the top. Domes were sometimes constructed on corbels by the ancients. In one of the octagonal rooms of the enclosure round the baths of Caracalla the corbels which supported the dome still remain, and at Catania there is a spherical dome covering a square vestibule.

The dome of Santa Sophia, at Constantinople, built in the reign of Justinian, ranks next to the Pantheon in point of antiquity, and is the most remarkable and the earliest constructed after those of the Romans. Anthemius of Tralles, and Isidorus of Miletus, were the architects. Anthemius had promised to raise a dome over this edifice, of such magnitude as to eclipse the magnificence of the Roman Pantheon. With this view, he erected four pillars at the angles of a square, at about the distance of 115 feet from each other, and nearly of the same altitude. The church was to be of the form of a cross, and vaulted with stone; he therefore threw arches over the pillars, and filled up the angular spaces between the archivaults, till he had gradually shaped them into a complete circle, at the level of the extradoses of the arches. On the ring thus formed, the dome was raised, being the first ever built on pendentives. The pressure of the eastern and western arches was resisted by four walls almost solid, forming transepts, and running longitudinally, two from the north, and two from the south sides of the pillars, to the distance of about 90 feet. The east and west arches were abutted upon by half-domes, resting on cylindrical walls, which, it was supposed, would have been sufficient to resist the pressure of the arches on the north and south; but in this the architect was mistaken; for the superstructure gave way towards the east, and, at the end of a few months, fell, taking with it the half-dome on that side. After the death of Anthemius, the superintendence of the building devolved on Isidorus, who strengthened the eastern pillars, by filling up certain voids left by his predecessor; but when the dome was turned upon them, the east end proved still too weak for the support of so great a load, and again gave way, before the work was completed. In order to counteract this thrust on the east, Isidorus now built strong pillared buttresses against the eastern wall of a square cloister that ran round the building; from which he threw flying buttresses over the void, and then raised the dome a third time, but with very little success; for though every precaution was taken to lessen its weight, by using pumice-stone and other light materials, and by reducing its thickness, the arches were so much fractured, that he was under the necessity of filling up the large arcades on the north and south sides, with arches of less dimensions, in three stories.

We have mentioned these circumstances, to show that the architects of the age to which this building is referred, were not so well acquainted with the principles of dome-vaulting, as those of more modern date: for the latter would probably have hooped or chained such a dome immediately over the arches and pendentives, so as to confine its pressure to a perpendicular thrust, or nearly so. Such was the case, in the far more ponderous dome of St. Peter's, at Rome, erected by Michael Angelo; and such, more recently, was the practice of our countryman, Sir Christopher Wren, in the cupola of St. Paul's, at London. The present dome, however, of Santa Sophia, was reconstructed by the nephew of Isidorus. It rests on the square formed at the intersection of the arms of the Greek cross; the diameter being about 111 feet, and the dome 40 feet high, and is supported by corbellings placed in the angles of the square. These corbels are surmounted by a kind of cornice on which rests a circular gallery. The lower part of the dome has a row of windows adorned with columns on the exterior, and the top is surmounted by a lantern on which is a cross. The dome of Anthemius and Isidorus, was not so high; and was partly destroyed by an earthquake a few years after its construction. In rebuilding it, the nephew of Isidorus used a very light white brick, made at Rhodes, and much lighter than the common brick.

The dome of St. Mark, at Venice, erected about the year 973, and that of the cathedral at Pisa, built early in the eleventh century, are both upon the same plan with the preceding. The church of Saint Mark, built in the tenth century, has five domes; the central dome being much larger than the others. Each dome is enclosed within four pieces of semi-cylindrical vaulting together forming a square; in the angles of this square are four corbels, which gather in the circular base of each dome. In 1523, Sansovinus, the architect, repaired the great dome, and placed a circle of iron round it to prevent its falling. A similar precaution was taken with one of the smaller domes by Andrew Tirali, in 1735, with the same successful result.

The dome of San Vitale at Ravenna, is of very curious construction. The plan of the lower part is that of a regular octagon, supported by eight piers at the angles of the dome. Between these angles are seven tall niches divided into two stories. The lower part of these niches is open, and adorned with columns. The remaining side of the dome is an arch of the same diameter and elevation as the niches; this arch forming an entrance. Above these the wall sustains a hemispherical dome, the plan being a circle within an octagon. Corbels are not employed at Santa Sophia, but the arches support the gathering over, which forms the circular base of the dome. In the base are eight windows, each window being divided in the centre by a column supporting two small arches. The dome itself is built with a double row of pipes, hollow at one end and pointed at the other, so that the point of one is received in the hollow of the preceding one, continuing thus in a spiral line until they finish at the top. Both the exterior and the interior of the dome are covered with mortar.

In 1298, the cathedral of Santa Maria del Fiore, was begun at Pisa, by the celebrated Arnolfo Lusii; but he died two years after, and no architect could be found who would undertake to execute the dome upon the vast plan that its projector had designed: it consequently remained unfinished for one hundred and twenty years; when, in a professional convocation, Philip Brunelleschi was permitted to attempt its completion. (*See* Brunelleschi.) Notwithstanding the opposition he met with, and the vapouring sarcasms with which he was treated by his contemporaries, who held his scheme to be impracticable, he carried on the building, and completed the cupola, in a manner worthy of his great reputation. This dome, which is octangular, and of great elevation, is formed of two vaults, with a vacancy between them; and is supported merely by the springing wall, without the aid of buttresses, though its dimensions exceed those of all the ancient Roman domes, with the sole exception of that of St. Peter's.

The church of St. Peter's, at Rome, is the largest temple ever built: it was begun by Bramante, in 1513, and carried on successively by Raphael, San Gallo, and Michael Angelo, the latter of whom designed the dome as it now appears. The following description, extracted from the "Encylopédie Méthodique," and the "Penny Cyclopædia," will enable the reader to form some idea of this superb work.

"The dome, which is double, is circular on the plan. The internal dome is constructed on double consoles, instead of corbellings. The double consoles are crowned with a small cornice, forming an impost for eight arches, from the upper part of which springs the dome; on the top is a lantern-light, which is not apparent externally. Up to this time domes had been constructed on walls and corbellings, but in St. Peter's at Rome a new plan was adopted. The dome of St. Peter's stands upon four piers, 61 feet 11 inches high, and 30 feet 10 inches thick, measured in a straight line with the arches. From the arches spring the corbellings, which are finished by an entablature. Upon this entablature is a plinth. The plinth is externally an octagon, and internally a circle. The external diameter of the octagon is 192 feet 9 inches, and the internal circle 134 feet 8½ inches; the thinnest part of the wall, between the octagon and the circle, is 29 feet 3 inches. On the plinth is a circular stylobate, 28 feet 6½ inches thick. This thickness is divided into three parts by a circular passage 5 feet 10 inches wide; the two walls on each side of this passage are, respectively, the internal wall 14 feet 7½ inches thick, and the external 8 feet. In the internal wall are other smaller passages, 2 feet 10 inches wide, forming flights of steps communicating with the four spiral staircases formed in the thickness of the wall of the drum of the dome. Above the circular stylobate, which is 12 feet 4½ inches high, is placed the drum of the dome, which is 10 feet 1½ inch thick, measured to the inside line of the pilasters, which decorate the interior of the dome. The pilasters themselves are 1.78 feet thick in addition. The construction is formed of rubble and fragments of brick. The interior is formed with bricks stuccoed. Externally the work is faced with thin slabs of travertine stone. The drum is pierced with 16 windows, 9 feet 3¾ inches wide, and 17 feet high. The walls are strengthened on the outside, between the windows, with 16 buttresses, constructed with solid masonry. These buttresses are 13 feet 3 inches wide, and 51 feet 6 inches in height from the base to the top of the entablature. Each buttress is decorated and strengthened with half-pilasters, and terminates with two coupled columns engaged, the diameter of which is 4 feet; the order is Corinthian. When the base of the dome had been built to the height of the entablature of the drum, Michael Angelo died; but some time before his death he had caused a model to be made, with ample details, to which he added drawings and instructions. After his death Pirro Ligorio and Vignola were appointed the architects. Giacomo della Porta, the pupil of Vignola, followed his master as architect to the cathedral; but although the designs of Michael Angelo were strictly followed, the dome itself was constructed under the pontificate of Sixtus V. Sixtus gave Giacomo della Porta as a colleague, Domenico Fontana, by whom the dome was constructed.

"On the constructions of Michael Angelo a circular attic was first formed, 19 feet 2¼ inches high, and 9 feet 7 inches thick. This attic is strengthened externally by 16 projections, 2 feet 11 inches deep, and 6 feet 4½ inches wide, placed over the buttresses of the dome; on the attic rises the double dome, the internal diameter of which at the base, is 138 feet 5 inches. The curve externally is an arc of a circle whose radius is 84 feet 1.62 inches. To the height of 27 feet 8 inches from the attic the dome is solid. At the base the thickness is 9 feet 7 inches; and as the external dome is raised higher than the internal dome, the thickness is increased as the curve ascends, so that where the dome is divided the thickness is 11 feet 4 inches. The circular space which divides the two domes is 3 feet 2¼ inches wide; the internal dome is 6 feet 4 inches thick; and the height from the attic to the opening of the lantern is 83 feet 10 inches. The diameter of the lantern is 24 feet 10 inches. The external dome is 2 feet 10½ inches thick, where it separates itself from the internal dome; and it is strengthened externally by 16 projecting bands of the same thickness. The dome is pierced with three rows of small windows, as the curves of the dome are not concentric, the space between them becomes wider as it rises; so that at the opening of the lantern the space is 10 feet wide. These domes are joined together by 16 walls or spurs, diminishing in thickness as they ascend to the lantern; at the base they are 8 feet thick, and at the summit 3 feet. The base of the lantern is arched, and pierced with small windows. Above the two domes is a circular platform, surrounded with an iron gallery. In the centre rises the lantern on a stylobate broken into 16 parts, forming projecting pedestals, above which are buttresses similar to the buttresses of the drum, decorated externally with coupled Ionic columns, 17½ inches in diameter. The space between the buttresses is filled with arched openings, which give light to the lantern. The external diameter of the lantern is 39 feet; the internal diameter 25 feet 6¾ inches; and the height from the platform to the top of the cross is 89 feet 7½ inches. The whole height, from the external plinth of the dome to the cross, is 263 feet. The total height internally, to the top of the dome of the lantern, is 387 feet.

"Sixtus V. covered the external dome with lead, and the bands with bronze gilt. During the construction of the dome it is believed that only two circles of iron were placed round the masonry, one of which was placed on the outside of the internal dome, at about 36 feet from its springing, and one foot above the division of the domes. The bands of iron of which this circle is composed are 3 inches wide by $1\frac{3}{4}$ inches thick. A similar circle is placed about the middle of the solid part of the dome at about 17 feet 6 inches above the springing of the internal dome. Near the top of the internal dome there are several holes, at the bottom of which upright iron bars appear. These bars are said to be the connecting rods which keep together other circles of iron placed at different heights within the masonry, which are finally terminated by a circle round the eye of the dome.

"The domes were constructed with such haste, that sufficient time was not allowed to the work to form solid beds as it was carried up, in consequence of which a great number of vertical settlements took place, and the circle of iron round the internal dome was fractured. To obviate the danger arising from these settlements, six circles of iron were placed round the external dome at different heights, and the broken circle of the internal dome was repaired. The first circle was placed above the cornice of the external stylobate, or continuous plinth, on which the buttresses stand; the second circle was placed above the cornice of the buttresses; the third, above the attic, at the springing of the external dome; the fourth, half way up the external dome; and the fifth under the base of the lantern. A sixth was shortly after placed at one foot below where the dome divides itself. The iron bands are flat, from 16 to 17 feet long, $3\frac{1}{2}$ inches wide, and $2\frac{2}{15}$ inches thick. At one end of the pieces of iron a hole is made; the other end is turned up, and passed through the eye of the next band. The whole of these bands are fixed with iron wedges, driven into the rubble with mallets. Sheets of lead are placed under the iron circles." (*Coupole, Encyclopédie Méthodique; 'Architecture.'*)

St. Paul's cathedral, London, the workmanship of the great Sir Christopher Wren, was begun in 1685, and finished in 1710. "The dome is placed over the intersection of the four naves. The ground plan is a regular octagon, each face of which is 44 feet $8\frac{3}{4}$ inches wide: four of these sides are formed by the four great arches of the naves; the other four sides are formed by false arches of the same size; in each of these arches there is a great niche, the base of which is pierced with two arches. By this means eight supports are obtained instead of four, and the corbellings do not project too much, as in other similar constructions. The corbellings gather in a circle, the diameter of which is 104 feet 4 inches, the octagon base being 107 feet. The corbellings are surmounted by a complete entablature, 8 feet three inches high, decorated with consoles. The drum is set back 3 feet $2\frac{1}{4}$ inches from the face of the frieze, and this intermediate space is occupied by two steps and a seat. The cornice is 98 feet $9\frac{3}{4}$ inches from the pavement. The height of the drum from the top of the seat is 62 feet $6\frac{1}{2}$ inches to the springing of the internal dome. The wall forming the drum is inclined internally 4 feet $11\frac{1}{2}$ inches, or about the 12th part of its height. This was designed by the architect to increase the resistance of the walls to the united pressure of the large internal vault, and the conical dome which carries the lantern.

"The interior of the drum is decorated with a continuous stylobate, on which is an order of Corinthian pilasters. The 32 spaces between the pilasters are filled with 24 windows and eight large niches. Externally the drum is decorated with an order of 32 Corinthian columns engaged, which are united to the wall of the drum by eight solid constructions in masonry. In each space between the constructions there are three intercolumniations, the columns being joined at their bases by wall pierced with arches. The external colonnade is surmounted by an entablature; behind this is a terrace, formed by the recessing back. The attic is 22 feet $4\frac{1}{2}$ inches high from the top of the balustrade to the under side of the cornice of the attic. Above the internal order of the drum rises the interior dome, the diameter of which at the springing is 102 feet $2\frac{3}{4}$ inches by 51 feet in height. The top of the dome has a circular opening 14 feet $10\frac{3}{4}$ inches in diameter.

"Above the attic are two steps, from which the external dome springs. The external dome is constructed of wood, covered with lead, and decorated with projecting ribs forming panels, curved at the ends. This dome terminates with a finishing which joins the base of the lantern: the circular gallery formed on the finishing is 274 feet 9 inches above the pavement of the nave. The lantern is supported on a conical tower, terminated by a spherical dome. This tower, which is joined to the internal dome at its base, disengages itself from it at the height of 8 feet 6 inches above the springing of the same. The perpendicular height of this tower is 86 feet 9 inches, and the walls are inclined 24 degrees from the perpendicular, the diameter of the base is 100 feet 1 inch measured externally, and 34 feet 1 inch at the springing of the spherical dome which finishes it. The wall of this tower is built of brick, and is 1 foot 7 inches thick, with circular rings of masonry, fastened with iron bands. The spherical dome at the top of the tower has an opening 8 feet in diameter at the summit. Between the attic and the wall of the tower are 32 walls or buttresses, which also serve to bear the ribs of the wooden external dome."—*Penny Cyclopædia.*

About the same time that Wren built the dome of St. Paul's, Hardouin Mansard, a French architect, constructed the dome of the Invalides at Paris. The plan of this dome is a square, in which is inscribed a Greek cross; in the angles of the square there are four chapels. The dome is raised in the centre of the Greek cross; the base supporting it is an octagonal figure, with four large and four small sides. The dome, which is double, rises from a springing which is common to both. The lower or internal dome constructed with masonry is spherical. The outer dome is of a spheroidal form, constructed of stone at the base, and of brick above. It is framed of wood and covered with lead, like St. Paul's, London, but the construction is much heavier. The total height to the top of the cross which surmounts the lantern is 330 feet.

The modern Pantheon at Paris, formerly the church of St. Geneviève, was built by J. G. Soufflot, who distinguished himself by his architectural works, in the reign of Louis XV. The dome, which is lofty, is sustained by four pillars, arched over the cross parts. The angular spaces are filled up with pendentives, terminating in a circular ring, on which a cylindrical wall is built, supporting the cupola. In the latter particular it is similar to St. Paul's.

Of wooden domes, that of the Halle du Blé, at Paris, is an excellent example; it being more than 200 feet in diameter, and only a foot in thickness.

A new material has been lately employed in the construction of the dome of the church of St. Isaac, at St. Petersburg, erected under the direction of the Chevalier de Montferrand. An account of the construction is given by Mr. Godwin as follows:—"The walls of the dome are carried up in solid construction of brick, with tiers of stone-bond, and are above 8 feet thick. On the level of the top of the cornice of the circular colonnade which girds the drum, there is a series of twenty-four cast-iron ribs, the feet of which rest on a cast-iron plate 7 feet wide, which runs quite round the circumference. At their head all the ribs are attached to a horizontal plate or curb, 6 feet 3 inches wide, which follows the periphery of the dome. At this height the rib is divided into 2, the one part about 12 feet 6 inches deep, following the sweep of the inner dome for a height of 20 feet, is at its summit bolted to a cast-iron perforated cylinder, 21 feet in diameter, and 7 feet high; this forms the centre aperture at the summit of the inner dome. The other part follows the line of an intermediate cone, with a catenary outline, and similar to the one in St. Paul's; it is also 21 feet long, and 2 feet 6 inches deep, and perforated to render it lighter. At this height the heads of the ribs are again secured to another horizontal plate or curb, which forms a complete circle, and is 3 feet wide; and this curb and the ribs are tied to the cylindrical opening of the inner dome, already mentioned, by radiating beams 2 feet 3 inches deep. The conical ribs have then another length of 21 feet, and their heads are again connected by another horizontal plate, from which spring the circular ribs, about 16 feet long, forming a dome to the intermediate cone, and their heads are also bolted to a cylinder, 8 feet 6 inches in diameter, and 18 inches high. But the upper portions of the ribs diverge at top, so as to form a base for the octagonal cupolino, which consists of a series of cast-iron story-posts, ribs, and bracketings, inclusive of the dome of the cupolino, with its ball and cross at the apex, which last are of brass-gilt. The filling in between the ribs consists of pots, the surfaces of which are subsequently rendered with plaster, and painted with sacred subjects. The external face of this outer dome is covered with bronze gilt in three thicknesses of leaves of ducat gold. The whole entablature and flat, and the balustrade over the peristyle of the drum of the cupola, likewise consist of cast and wrought iron framing, faced with plates of copper, to form the profiles and mouldings. The 24 pedestals of this balustrade carry winged angels of bronze, above 9 feet high, each of a single casting.

"The quantity of metal employed in the work is as follows:—

Ducat gold	247 lbs.
Copper	52½ tons
Brass	321½ "
Wrought-iron	524½ "
Cast-iron	1068 "
	1966½ tons 247 lbs.

"The roofing is wholly of iron, covered with copper. The raising of the monolithic shafts of the 24 columns of the exterior peristyle of the dome—each of which weighed nearly 66 tons—to the height of 150 feet, was an operation requiring considerable skill. The first column was raised on the 17th November, 1837, and in two months the 24 columns were completely fixed.

"The skeleton of the entablature of the peristyle of the dome is of cast and wrought iron, resting on the columns, and affixed to them by wrought-iron pins, which are let a considerable depth into the shafts, and the frame-work is also let into the cylindrical wall of the dome, securely affixed to three templates. The cornice, with its modillions and mouldings, rests on cast-iron corbels; the caissons and rosettes of the inner soffit also rest on cast-iron girders.

"The careful skill with which the architect has fulfilled his part, and the feeling for decorative art with which he has embellished the church of St. Isaac, render it one of the most striking edifices of the nineteenth century."

All the ancient Roman domes are on the convex side a much less portion of a sphere than a hemisphere; but those, from the completion of the church of Santa Sophia, to the finishing of St. Paul's cupola, are of the surmounted kind, approaching in a greater or less degree to the proportion of towers, or spires, which were so much admired and adopted in the middle ages. The sides of the section of St. Paul's dome are struck with centres in the base line, which, if continued, would meet in an angle in the axis of the dome. Since the revival of Grecian architecture, the contour of the old Roman dome has also been revived, especially in cases where other parts of the building are decorated with any of the orders. Exterior domes can never be correctly applied to buildings in the pointed style of architecture.

The following are the admeasurements of some of the principal domes in Europe, taken from Mr. Ware's "Tracts on Vaults and Bridges:"—

Domes of Antiquity.

	Feet in diameter taken externally.	Height from the ground line.
Dome of the Pantheon	142	143
" Minerva Medica, at Rome . . .	78	97
" Baths at Caracalla	112	116
" Baths at Diocletian	74	83
Temple of Mercury	68	
" Diana	98	78
" Apollo	120	
" Proserpine and Venus	87	77

Domes of comparatively Modern Times.

Santa Sophia, at Constantinople	115	201
Mosque of Achmet, "	92	120
San. Vitate, at Ravenna	55	91
San. Marco, at Venice	44	

From the time of Brunelleschi to the present period.

Santa Maria del Fiore, at Florence	139	310
The Chapel of the Medici	91	199
Baptistry, at Florence	86	110
Cathedral of St. Peter, at Rome	139	330
Chapel of the Madonna della Salute, at Venice	70	133
Chapel of the Superga, at Turin	64	128
" Invalides, at Paris	80	173
" Val de Grace, Paris	55	133
" Sorbonne, Paris	40	110
Pantheon, or St. Geneviève, Paris	67	190
Cathedral of St. Paul's, London	112	215

In the reigns of queen Elizabeth, and her successor king James I., square turrets, surmounted with domes resembling a bell in their outline, were much used.

Domes are sometimes made convex below, and concave above; the former being a much greater portion of the side than the latter: these may be denominated Moresque, Turkish, or Hindoo.

Mr. Bunce invented a dome that requires no centering; in this construction, all the abutting joints are continued in uninterrupted vertical planes; but the horizontal joints of every two stones break on the middle of the stones on either side; so that every alternate stone of a course projects upwards, and leaves a recess for the insertion of the stones of the next course. Upon this principle, the intervals, as the building approaches nearer the top, becomes more wedge-formed, and, the interior circumference being less than the exterior, the stones can be inserted only on the outside: consequently, if made so exact as just to fit into their places, they cannot fall inwardly. This mode of joining stones may be convenient, as requiring no centering; but unless the courses be nicely equilibrated, it is more liable to burst, than when a dome is constructed in the ordinary manner, since every row of stones, from the base to the top, forms an arch independent of the rest.

The equilibrium and pressure of domes is very different from that of common arching, though there are some properties common to both. Thus, in cylindrical and cylindroidal vaulting, of uniform thickness, if the tangent to the arch at the bottom be perpendicular to the horizon, the vault cannot stand; neither can it be built with a concave contour in whole, or in part; and to bring an arch to an equilibrium, whether its section be circular or elliptical, the intrados being given, both extremities of the arch must be loaded, *ad infinitum*, between the extrados of the curve which runs upwards, and the vertical assymptote rising from each foot. So, in thin domes, of equal thickness, if the curved surface rise perpendicularly from the base, it will burst at the bottom, whatever be the contour.

Yet, though dome-vaulting, in this particular, agrees with common arching, they differ materially in several other points. For, in order to equilibrate the figure of the former, after the convexity has been carried to its full extent of equilibrium around, and equidistant from the summit on the exterior side, the curvature may be changed into a concavity: here the interior circumference of the courses is less than the exterior, and therefore, whatever the pressure towards the axis, the course cannot fall inwardly, without squeezing the stones into a less compass. Hence a vault may be executed with a convex surface inwardly, and a concave surface outwardly, and be sufficiently firm.

The strongest form of a circular vault, required to bear a weight on its top, is that of a truncated cone, similar to the exterior dome of St. Paul's, London, of which it is impossible to conceive any force acting on the summit, that would be capable of disturbing its equilibrium: for the pressure being communicated in the sloping right line of the sides of the cone, perpendicular to the joints, the conic sides have no tendency to bend to one side more than to another; the gravity of the materials towards the axis, being counteracted by the abutting vertical joints.

In dome-vaulting, the case is very different: for here the contour being convex, there is a certain load, which, if laid on the top, must burst it outwardly, which weight becomes greater in proportion as the contour approximates towards the chords of the arches of the two sides, or to a conic vaulting on the same base, carried up to the same altitude, and ending in the same circular course. For example, suppose a horizontal line, tangent at the vertex, proceed from the key-stone downwards, course by course; it will be evident, that every successive coursing-joint may be made to slant as much, and consequently, that the pressure of the arch-stones of any course towards the axis will be so great, as to be more than adequate to the resistance of the weight of all the superincumbent parts. Hence it may be clearly deduced, that there is a certain degree of curvature to be given to the contour, which will just prevent the stones in any succeeding course from being forced outwardly.

The circular vault, thus balanced, is indeed an equilibrated dome; but, instead of the strongest, it is the weakest of all between its own contour and that of a cone upon the same base, rising to the same height, in a key-stone, or in an equal circular course. The equilibrated dome has therefore the boldest contour; but is the limit of an infinitude of inscribed circular vaults, all of them stronger than itself.

In other respects, circular vaulting differs from straight vaulting in being built with courses in circular rings; and in having the stones in each course of equal length, which pressing equally towards the axis, cannot slide inwardly. Circular vaults may therefore be open at the top; and the equilibrated dome, which, as we have just observed, is the weakest of all, may be made to bear a lantern of equal weight with the part that would otherwise have completed the whole. Domes of flatter contours will bear more, in proportion as they approach nearer to that of a cone: and circular vaults, that are either straight or concave on the sides, if chained at the bottom, may be loaded to any degree, without giving way, until the materials of which they are built be crushed to powder.

The foregoing description of the equilibrium and pressure of domes may be comprehended without any acquaintance with either algebra or fluxions, and will be of use to the ordinary workmen; for the satisfaction of more scientific readers, we subjoin Dr. Robison's theory.

Problem.—To determine the thickness of dome-vaulting when the curve is given, or the curve when the thickness is given.

Plate 1. *Figure* 1.—"Let B b A be the curve which produces the dome by revolving round the vertical axis A D. We shall here suppose the curve to be drawn through the middle of the arch-stones, and that the coursing or horizontal joints are everywhere perpendicular to the curve. We shall suppose (as is always the case) that the thickness K L, H I, &c. of the arch-stones is very small in comparison to the dimensions of the arch. If we consider any portion H A h of the dome, it is plain that it presses on the curve of which H L is an arch-stone, in a direction b C, perpendicular to the joint H I, or in the direction of the next superior element β b of the curve. As we proceed downwards, course after course, we see plainly that this direction must change, because the weight of each course is superadded to that of the portion above it to complete the pressure of the course below. Through B draw the vertical line B C G meeting β b, produced in C. We may take b c to express the pressure of all that is above it, propagated in this direction to the joint K L. We may also suppose the weight of the course H L united in b, and acting on the vertical. Let it be represented by b F. If we form the parallelogram b F G C, the diagonal b G will represent the direction and intensity of the whole pressure on the joint K L.

"We have seen, that if b G, the thrust compounded of the thrust b C exerted by all the courses above H I L K, and if the force b F, or the weight of that course be everywhere coincident with b B, the element of the curve, we shall have an equilibrated dome; if it fall within it, we have a dome which will bear a greater load, and if it fall without it, the dome will break at the joint. We must endeavour to get analytical expressions of these conditions. Therefore draw the ordinates b δ b'', B D B$''$, C d c''. Let the tangents at b and b'' meet the axis in M, and make M O, M P, each equal to b C, and complete the parallelogram M O N P, and draw O Q perpendicular to the axis, and produce b F, cutting the ordinates in E and e. It is plain that M N is to M O as the weight of the arch H A h to the thrust b C, which it exerts on the joint K L (this thrust being propagated through the course of H I L K,) and that M Q, or its equal b e, or δ d, may represent the weight of the half A H.

"Let A D be called x, and D B be called y. Then $b\,e = \dot{x}$, and e C $= \dot{y}$ (because b C is in the direction of the element β b). It is plain if we make $\dot{y}$ constant, B C is the second fluxion of x, or B C $= \dot{x}$, and b e and b E may be considered as equal, and taken indiscriminately for $\dot{x}$. We have also b C $= \sqrt{x_2 + y_2}$; let d be the depth or thickness of H I of the arch-stones. Then $d\sqrt{\dot{x}_2 = \dot{y}_2}$; will represent the trapezium H L; and since the circumference of every course increases in the proportion of the radius y, $d\,y\sqrt{\dot{x} + \dot{y}}$ will represent the whole course. If s be taken to represent the sum or aggregate of the quantities annexed to it, the formula will be analogous to the fluent of a fluxion, and $s\,d\,y\sqrt{\dot{x}^2 + \dot{y}^2}$ will represent the whole mass, and also the weight of the vaulting down to the joint H I. Therefore we have this proportion: $s\,d\,y\sqrt{\dot{x}^2+\dot{y}^2} : d\,y\sqrt{\dot{x}^2+\dot{y}^2} = b\,e : b\,\text{F} = b\,e : \text{C G} = \delta\,d : \text{C G} = x : \text{C G}$. Therefore C G $= \frac{d\,y\,x\sqrt{\dot{x}^2+\dot{y}^2}}{s\,d\,y\sqrt{\dot{x}^2+\dot{y}^2}}$

"If the curvature of the dome be precisely such as puts it in equilibrium, but without any mutual pressure in the vertical joints, this value of C G must be equal to C B, or to $\ddot{x}$, the point G coinciding with B. This condition will be expressed by the equation $\frac{d\,y\,\dot{x}\sqrt{\dot{x}^2+\dot{y}^2}}{s\,d\,y\sqrt{x^2+y^2}} = \ddot{x}$ or more conveniently by $\frac{d\,y\sqrt{\dot{x}^2+\dot{y}^2}}{s\,d\,y\sqrt{\dot{x}^2+\dot{y}^2}} = \frac{\ddot{x}}{\dot{x}}$. But this form gives only a tottering equilibrium, independent of the friction of the joints and cohesion of the cement. An equilibrium, accompanied by some firm stability produced by the mutual pressure of the vertical joints, may be expressed by the formula. $\frac{d\,y\sqrt{\dot{x}^2+\dot{y}^2}}{s\,d\,y\sqrt{\dot{x}^2+\dot{y}^2}} > \frac{\ddot{x}}{\dot{x}}$, or by $\frac{d\,y\sqrt{\dot{x}^2+\dot{y}^2}}{s\,d\,y\sqrt{\dot{x}^2+\dot{y}^2}} = \frac{\ddot{x}}{\dot{x}} + \frac{\dot{t}}{t}$, where t is some variable positive quantity which increases when x increases. This last equation will also express the equilibrated dome, if t be a constant quantity, because in this case: $\frac{\dot{t}}{t}$ is $= 0$

"Since a firm stability requires that $\frac{d\,y\,\dot{x}\sqrt{\dot{x}^2+\dot{y}^2}}{s\,d\,y\sqrt{\dot{x}^2+\dot{y}^2}}$ shall be greater than $\ddot{x}$, and C G must be greater than C B. Hence we learn that figures of too great curvatures, whose sides descend too rapidly, are improper. Also since stability requires that we have $\frac{d\,y\,\dot{x}\sqrt{\dot{x}^2+\dot{y}^2}}{\ddot{x}}$ greater than $s\,d\,y\sqrt{\dot{x}^2+\dot{y}^2}$, we learn that the upper part of the dome must not be made very heavy. This, by diminishing the proportion of b F to b C, diminishes the angle C b G, and may set the point G above B, which will infallibly spring the dome in that place. We see here also, that the algebraic analysis expresses that peculiarity of dome-vaulting, that the weight of the upper part may even be suppressed.

"The fluent of the equation $\frac{d\,y\sqrt{\dot{x}^2+\dot{y}^2}}{s\,d\,y\sqrt{\dot{x}^2+\dot{y}^2}} = \frac{\ddot{x}}{\dot{x}} + \frac{\dot{t}}{t}$ is most easily found. It is L $s\,d\,y\sqrt{\dot{x}^2+\dot{y}^2} = \text{L}\,\dot{x} + \dot{t}$, where L is the hyperbolic logarithm of the quantity annexed to it. If we consider $\dot{y}$ as constant and correct the fluent, so as to make it nothing at the vertex, it may be expressed thus:

L $s\,d\,y\sqrt{\dot{x}^2+\dot{y}^2}$ − L a = L $\dot{x}$ − L $\dot{y}$ + L t. This gives us L $\frac{s\,d\,y\sqrt{\dot{x}^2+\dot{y}^2}}{a}$ = L $\frac{\dot{x}}{\dot{y}}t$, and therefore $\frac{s\,d\,y\sqrt{\dot{x}^2+\dot{y}^2}}{a} = t\frac{\dot{x}}{\dot{y}}$

This last equation will easily give us the depth of the vaulting, or thickness, d, of the arch, when the curve is given. For its fluxion is $\frac{d\,y\sqrt{\dot{x}^2+\dot{y}^2}}{a} = \frac{t'\dot{x} + t\ddot{x}}{\dot{y}}$ and $d = \frac{a\,t'\dot{x} + a\,t'\ddot{x}}{y\,\dot{y}\sqrt{\dot{x}^2+\dot{y}^2}}$, which is all expressed in known quantities: for we may put in place of t any power or function of x or of y, and thus convert the expression into another, which will still be applicable to all sorts of curves.

"Instead of the second member $\frac{\ddot{x}}{\dot{x}} + \frac{t'}{t}$ we might employ $\frac{p\,\ddot{x}}{\dot{x}}$, where p is some number greater than unity. This will evidently give a dome having stability; because the original formula $\frac{d\,y\,\dot{x}\sqrt{\dot{x}^2+\dot{y}^2}}{s\,d\,y\sqrt{\dot{x}^2+\dot{y}^2}}$ will be greater than $\ddot{x}$. This will give $d = \frac{p\,a\,\dot{x}^{p-1}\ddot{x}}{y\,\dot{y}^p\sqrt{\dot{x}^2+\dot{y}^2}}$. Each of these forms has its advantages when applied to particular cases. Each of them also gives $d = \frac{a\,\ddot{x}}{y\,\dot{y}\sqrt{\dot{x}^2+\dot{y}^2}}$ when the curvature is such as in precise equilibrium: and lastly, if d be constant, that is, if the vaulting be of uniform thickness, we obtain the form of the curve, because then the relation of $\dot{x}$ to x and to y is given.

"The chief use of this analysis is to discover what curves are improper for domes, or what portions of given curves may be employed with safety.

"The chief difficulty in the case of this analysis arises from the necessity of expressing the weight of the incumbent part, or $s\,d\,y\sqrt{\dot{x}^2+\dot{y}^2}$. This requires the measurement of the conoidal surface, which in most cases can be had only by approximation, by means of infinite series. We cannot expect that the generality of practical builders are familiar with this branch of mathematics, and therefore will not engage in it here; but content ourselves with giving such instances as can be understood by such as have that moderate mathematical knowledge, which every man should possess, who takes the name of engineer.

"The surface of any circular portion of a sphere is very easily had, being equal to the circle inscribed with a radius equal to the arch. This radius is evidently equal to $\sqrt{x^2+y^2}$.

"In order to discover what portion of a hemisphere may be employed (for it is evident we cannot employ the whole) when the thickness of the vaulting is uniform, we may recur to the equation or formula $\frac{d\,y\,\dot{x}\sqrt{\dot{x}^2+\dot{y}^2}}{\ddot{x}} = s\,d\,y\sqrt{\dot{x}^2+\dot{y}^2}$. Let a be the radius of the hemisphere. We have $\dot{x} = \frac{a\,y\,\dot{y}}{\sqrt{a^2-y^2}}$ and $\ddot{x} = \frac{a\,\dot{y}^2}{\overline{a^2-y^2}|^{\frac{3}{2}}}$. Substituting these values in the formula, we obtain the equation $y^2\sqrt{a^2-y^2} = s\frac{a^2\,y\,\dot{y}}{\sqrt{a^2-y^2}}$. We easily obtain the fluent of the second member $= a^2 - a^2\sqrt{a^2-y^2}$, and $y = a\sqrt{-\frac{1}{2}+\sqrt{\frac{5}{4}}}$. Therefore, if the radius of the hemisphere be one-half, the breadth of the dome must not exceed $\sqrt{-\frac{1}{2}+\sqrt{\frac{5}{4}}}$, or 0.786, and the height will be 618. The arch from the vertex is about 51° 49′, much more of the hemisphere cannot stand even, though aided by the cement, and by the friction of the coursing joints. This last circumstance, by giving connection to the upper parts, causes the whole to press more vertically on the course below, and this diminishes the outward thrust; but at the same time diminishes the mutual abutment of the vertical joints, which is a great cause of firmness in the vaulting. A Gothic dome, of which the upper part is a portion of a sphere not exceeding 45° from the vertex, and the lower part is concave outwards, will be very strong, and not ungraceful.

"Persuaded that what has been said on this subject convinces the reader that a vaulting, perfectly equilibrated throughout is by no means the best form, provided that the base is secure from separating, we think it unnecessary to give the investigation of that form, which has considerable intricacy, and shall merely give its dimensions. The thickness is supposed uniform. The numbers in the first column of the table express the portion of the axis counted from the vertex, and those of the second are the length of the ordinates.

A D	D B	A D	D B	A D	D B
0.4	100	610.4	1080	2990	1560
3.4	200	744	1140	3442	1600
11.4	300	904	1200	3972	1640
26.6	400	1100	1260	4432	1670
52.4	500	1336	1320	4952	1700
91.4	600	1522	1360	5336	1720
146.8	700	1738	1400	5756	1740
223.4	800	1984	1440	6214	1760
326.6	900	2270	1480	6714	1780
465.4	1000	2602	1520	7260	1800

"The curve formed according to these dimensions will not appear very graceful, because there is an abrupt change in its curvature at a small distance from the vertex. If, however, the middle be occupied by a lantern of equal, or of smaller weight than the part whose place it supplies, the whole will be elegant and free from defect.

Figure 3 represents four different contours of domes, upon a square plan, No. 5; No. 1, shows a semicircle contour; No. 2, a pointed contour; No. 3, a Turkish, or Mahometan contour; No. 4, a bell-formed contour, as used in the reigns of Elizabeth and James I.

Figure 4 represents five different contours, upon an octagonal plan, No. 6; No. 1, the contour of a dome, the vertical section of which being a semi-ellipsis, with the lesser axis placed horizontal; No. 2, the contour of a semicircular section; No. 3, the contour of a dome, the vertical section of which is a semi-ellipsis, placed upon the greater axis; No. 4, the contour of a dome, the vertical section parallel to either side being the segment of a circle: No. 5, a pointed contour, formed similar to the dome of the cathedral church of Sta. Maria del Fiore, at Florence, which was both octangular upon the plan, and pointed in its vertical section.

Figure 5 represents five contours upon a circular plan, No. 6; No. 1, is formed by having its vertical section the segment of a circle, which was the general practice of the Romans, in the exterior form of their domes, as in the Pantheon at Rome; No. 2, a dome with a semicircular axal section, a form very frequently used in modern times; No. 3, an ellipsoidal dome, whose axis is the greater semi-axis of the ellipsis; No. 4, represents a dome with a parabolical contour, the vertical section being that of a curve, and the axis of the parabolical section being the same as that of the dome. This contour is more pointed than any part of an ellipsis; No. 5, represents a dome with an hyperbolical contour, the vertical section being an hyperbola; this is still more pointed than the parabolical dome.

Figure 6 shows four variations of contours: No. 1, pointed like the dome of St Paul's cathedral church, London, which is composed of two arcs of a circle; No. 2, a dome with a small concavity upwards, springing perpendicularly from its base; No. 3, another contour of a dome, with a small concavity at the top, but spreading outwards as it rises from the bottom, with a convexity in its vertical section; No. 4, a dome of the same nature as the last, but dissimilar in its form, the convex part being much quicker. Such forms as the last three may be denominated Moresque, Turkish, or Hindoo, as they are practised by the Moors, Turks, and Hindoos. This form was introduced into England in the reign of Henry VII., and in constant use in the time of Henry VIII. Its use was in the crowning of turrets, as in the octagonal buttresses of Henry the Seventh's chapel, and the towers of King's College chapel, Cambridge: the turrets at the entrance of Christ's College, Oxford, executed by Sir Christopher Wren, are surmounted with domes of this form. The bell-formed dome, *Figure* 3, No. 4, succeeded *Figure* 6, No. 2; examples of it may be seen at Audley-End, in Essex, built in the reign of James I., and in the Tower of London.

It is a property of all domes to have their horizontal sections similar to each other, and to the base of the dome.

What may be properly denominated a Roman dome, is one whose axal section is a semicircle, or the segment of a circle less than a semicircle. Among the ancients, domes were only used in covering whole buildings of a circular plan; but among moderns they are used in covering any apartment, or distinct portion of a building, which too frequently has a very insignificant appearance, and, for want of magnitude, destroys the general contour of the whole, producing a kind of mixed outline at the finish of the edifice; where in most points of view it is completely lost.

In modern architecture, the dome, when used, is generally raised upon a tower, or turret, and by this means the figure is shown more completely than if it were immediately raised from the walls; but care should be taken, that if the place over which it is to be erected be too small, it should not be adopted; and if admitted in an edifice, it should bear a good proportion to the whole mass: when a dome is properly managed, nothing adds more grace or dignity to the termination of an edifice than the domic contour.

Plate III. *Figure* 1.—*Given the plan of a square dome, and one of the axal ribs, at right angles to one of the sides; to find the curve of the angle rib, and the covering.*

The axis of a square dome is the vertical line in which the diagonal planes would intersect each other.

Let A B C D be a plan of the dome; A C and B D the intersections of the diagonal planes; E F the base of the rib; E K the height of the given rib; and the curve line K I H G F, the section of the upper surface, which comes in contact with the boarding. Produce E F to *k*; divide the curve line K F into any number of equal parts, the more the truer will be the operation; let the parts be F G, G H, H I, I K, which extend upon the straight line F *k*; the first from F to *g*, the second from *g* to *h*, the third from *h* to *i*, and the fourth from *i* to *k*; from the points G, H, I, in the curve of the given rib, draw G G′ N, H H′ O, I I′ P, parallel to A D, cutting the base of the rib E F at the points G′, H′, I′, and the half diagonal D E at the points N, O, P; also, through the points *g*, *h*, *i*, draw *n g n*, *o h o*, *p i p*, parallel to A D. Take the intercepted parts G N, H O, I P, between E F and E D, apply them successively to the lines parallel to A D, on each side of F *k*, from *g* to *n*, and from *g* to *n*, from *h* to *o*, and from *h* to *o*, from *i* to *p*, and from *i* to *p*, and through the points A, *n*, *o*, *p*, *k*, on each side of F *k*, draw a curve; then the space, A *k* D, comprehended between the two curve lines and the side A D of the plan, is the form of the whole covering for each side of the dome.

To find the hip-line of the angle rib whose base is E D.

From the points, N, O, P, E, draw N Q, O R, P S, and E T, perpendicular to E D: make N Q, O R, P S, E T, successively equal to G′ G, H′ H, I′ I, E K: and through the points D, Q, R, S, T, draw a curve, which will be the hip-line.

Figure 2.—A dome likewise upon a square plane, but the given axal rib at right angles to the side, is the segment of a circle less than a semi-circle.

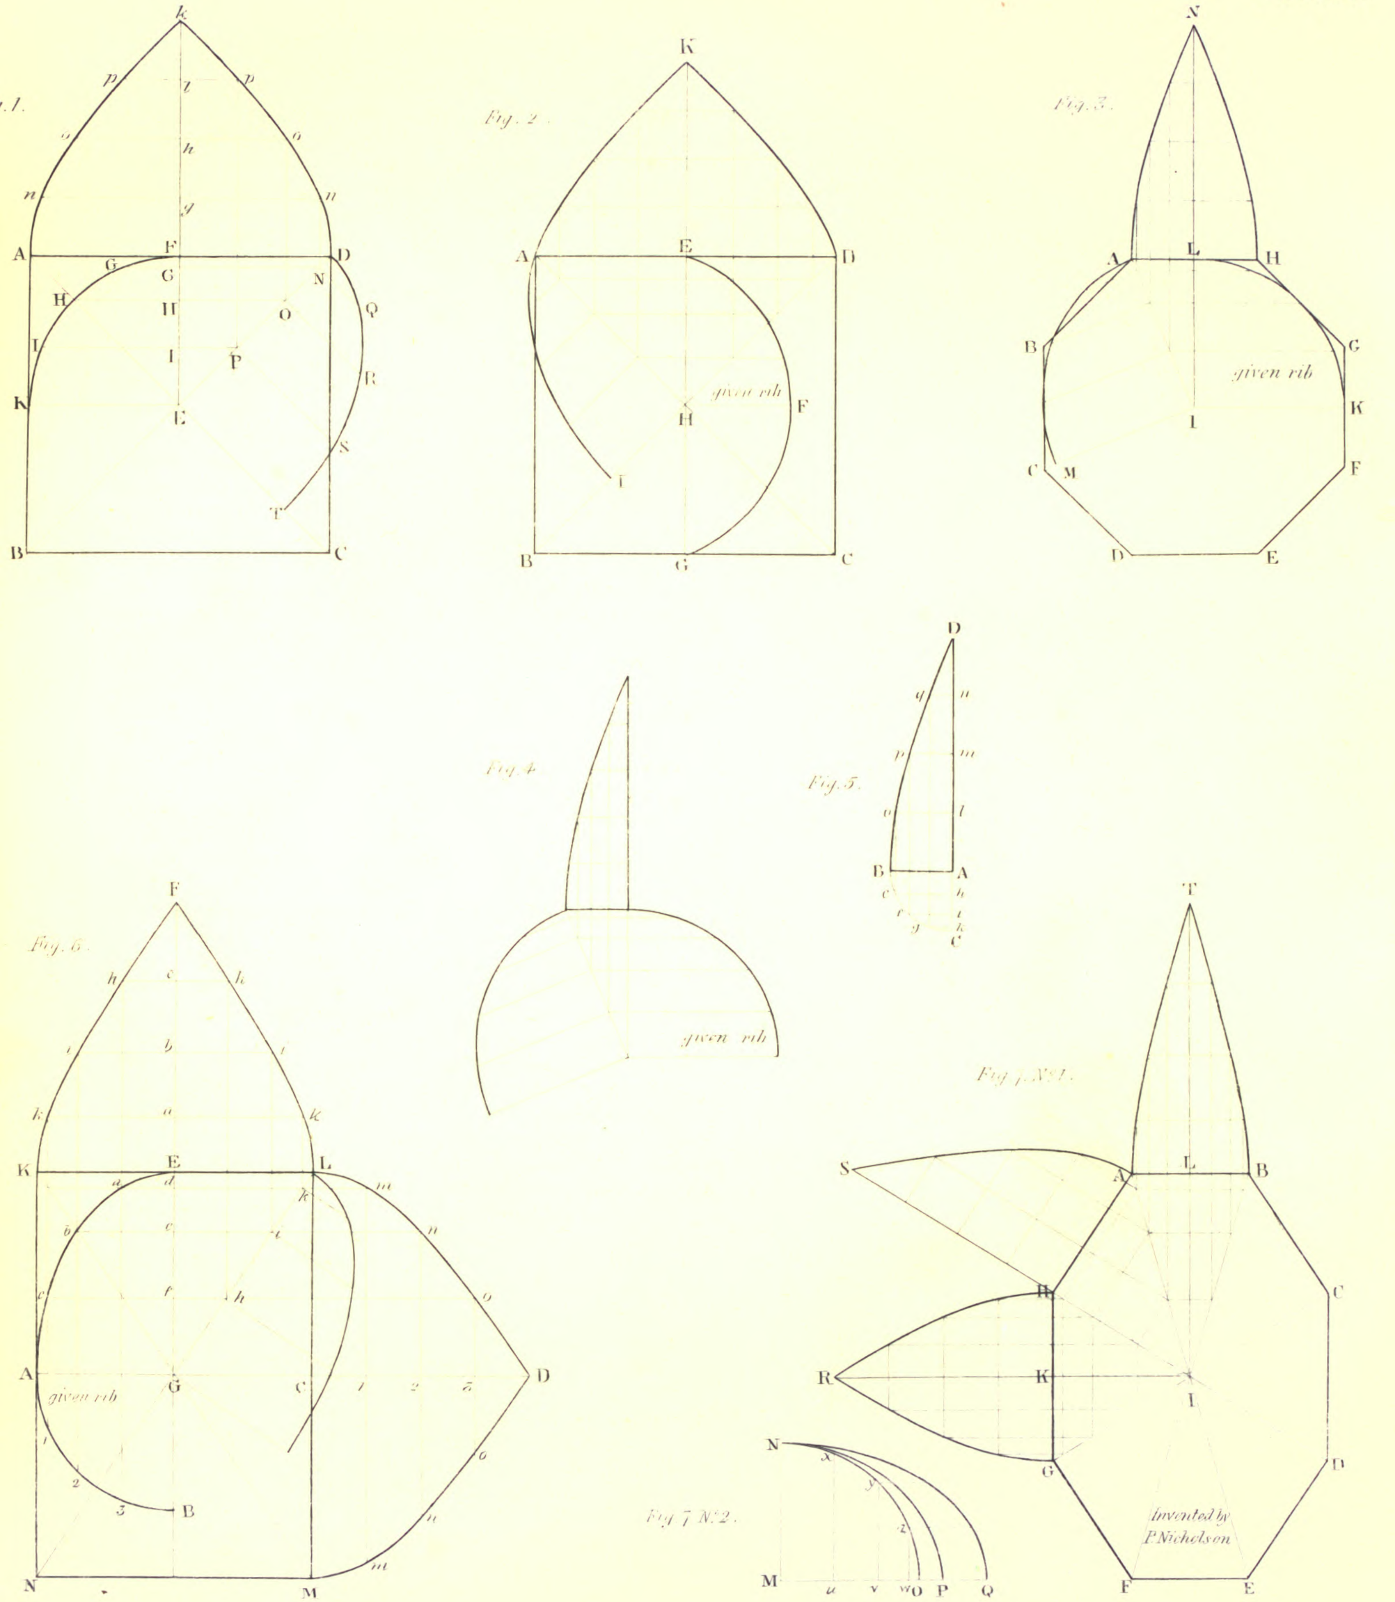
PLATE III.



son.

R. Thew

Figure 3.—Plan of a polygonal dome, showing the covering extended, and the angle-rib. The method of finding the covering and angle-rib for *Figures* 2 and 3, is the same as in *Figure* 1, and may be described in the same words.

Instead of laying out the covering and angle-rib, as in *Figure* 3, of the octagonal dome, they may be laid down as in *Figure* 4, without laying down the whole plan; and if only the covering be wanted, it may be found without any part of the plan, as in *Figure* 5. Thus, let A D represent the middle of the boarding for one of the sides, and let A B, at right angles thereto, be half the breadth of the side A H, *Figure* 3; let A B, *Figure* 5, represent half the base of the rib; on A B describe a quadrant or similar figure to the given rib, I L K, *Figure* 5: make A D equal to the circumference, L K, of the given rib. The rule for this purpose will be found under those for measuring segments of circles; see the article SEGMENT; or if the arc be that of a quadrant, the quadrantal arc may be found, as in the article CIRCLE, and then taking a fourth part of the whole circle, or the half of a semi-circle. We shall here give examples both for a complete quadrant, and for a rib which is the half of a segment less than a semi-circle:

Figure 3.—Suppose the base, I L, to be 20 feet, then

$$\frac{3\frac{1}{7} \times 20}{2} = 31 \text{ feet } 5 \text{ inches.}$$

Again, suppose the base to be 12 feet, as before, but the height to be only 5 feet, then the whole chord will be 24 feet, and the versed sine 5 feet.

RULE.—Multiply the sum of six times the square of the half chord, and five times the square of the versed sine, by the chord; and divide the product by the sum of six times the square of the half chord and the square of the versed sine; and the quotient is the length of the arc, nearly.

Here the half chord is 12 feet: therefore,

$$\frac{(6 \times 12^2 + 5 \times 5^2) \times 24}{6 \times 12^2 + 5^2} = 26.69, \text{ the answer.}$$

Or thus, at full length:

then $6 \times 12^2 + 5^2 = 864 + 25 = 889$.

12	5
12	5
$144 = 12^2$	$25 = 5^2$
6	5
$864 = 6 \times 12^2$	$125 = 5 \times 5^2$
125	

$989 = 6 \times 12^2 + 5 \times 5^2$

24 whole chord, or base of two ribs.

NOTE.—The above rule is the invention of the author.

Figure 5.—Then making A D equal to the length of the arc, divide the curve B C into any number of equal parts, and draw the lines *e h*, *f i*, *g k*, parallel to B A, cutting A C at *h*, *i*, *k*; divide the straight line A D into as many equal parts as the curve B C is divided into, at the points *l*, *m*, *n*, and draw *l o*, *m p*, and *n q*, parallel also to A B; making *l o*, *m p*, *n q*, respectively equal to *h e*, *i f*, and *k g*, and through the points B, *o*, *p*, *q*, D, draw a curve; then the space comprehended between this curve and the straight lines A D and A B, will be half the covering of one of the sides.

Figure 6.—*Given* K L M N, *the plan of an oblong dome, and the rib* A B; *to find the hip and the rib parallel to the longitudinal side, also the covering upon the longitudinal and transverse sides.*

Divide the curve A B into any number of equal parts, at the points of division 1, 2, 3, and draw lines 1 *k*, 2 *i*, 3 *h*, parallel to N K, the longitudinal side cutting the seat of the hip K G: from the points of intersection in K G draw lines parallel to K L, the breadth of the dome, to the points *m*, *n*, *o*; draw G E parallel to N K, and produce it to F; also produce A C to D; take the parts of the given rib A B, and extend them on C D, from C to 1, from 1 to 2, from 2 to 3, and from 3 to D: make 1 *m*, 2 *n*, 3 *o*, on each side of C D, respectively equal to the parallel distances from A K, comprehended between the lines A G, and K G; from the points *d*, *e*, *f*, cut by the lines parallel to K L, make *d a*, *e b*, and *f c*, respectively equal to the several heights of the given rib A B, and trace a curve through the points E, *a*, *b*, *c* A: upon the straight line E F, extend the parts E *a*, *a b*, *b c*, *c* A, of the arc E A, from E to *a*, from *a* to *b*, from *b* to *c*, and from *c* to F; through the points *a*, *b*, *c*, in E F, draw *k k*, *i i*, *h h*, parallel to K L; make the parts *a k*, *b i*, *c h*, respectively equal to the parallels of E K, comprehended between E G and K G; then K F L, is the form of the boarding for each end, and L D M, that of the sides.

The angle-rib is found the same as in the square dome.

Figure 7, No. 1.—*To find the covering of an oblong polygonal dome.*

Given the plan A B C D E F G H I, and the axal section through its breadth, a semi-circle. Take any straight line, N Q, No. 2; in No. 1, draw lines from the middle point I, perpendicular to the sides G H, H A, A B, of the polygon, and let these perpendiculars be I K, I H, and I L: on the straight line M Q, No. 2, make M O equal to I K, M P equal to I H, and N Q equal to I L, No. 1. In No. 2, draw M N perpendicular to M O; from the centre M, with the radius M O, describe the quadrant O N: divide the arc O N into any number of equal parts, say four, *w z*, *z y*, *y x*, *x* N, at the points *z*, *y*, *x*; from the points *x*, *y*, *z*, No 2, draw lines *x u*, *y v*, *z w*, cutting M O at *u*, *v*, *w*; transfer the distances M *u*, *u v*, *v w*, *w* O, to the straight line I K, No. 1. Through the points of division, draw lines parallel to H G, to cut the diagonals G I, and H I; from the points of section in H I, draw lines parallel to H A, to cut the next diagonal A I: from the points of section in A I, draw lines parallel to A B, cutting B I: take the parts O *z*, *z y*, *y x*, *x* N, No. 2, and extend them to K R, No. 1, and draw lines through the points of section, parallel to H G; make the two parts of the lines so drawn on each side of K R, respectively equal to the lines drawn parallel to H G, terminated by K I, and H I. With the greater semi-axis M P, and lesser semi-axis M N, describe the quadrant of an ellipsis N P M: through the points *z*, *y*, *x*, draw lines parallel to M P, to cut the elliptic curve: extend the elliptic curve so cut, upon the straight line H S, and through the points of section, draw lines parallel to H A; transfer each of the lines contained between H I and A I, respectively, to each of the parallels on the other side of H A; or draw lines through the several points of section in the diagonal A I, parallel to I S, to cut the lines perpendicular to H S, and the points of intersection will form the direction of the line for the edge of the covering H S A. In like manner, by describing the quadrant of the ellipsis M Q N, and by drawing lines through the points z, y, x, to cut the curve N Q, by proceeding as before, we shall obtain the covering A B T. The three coverings G R H, H S A, A T B, cover more than one-quarter of the whole, by the half coverings G R K, and L T B, of the side and end. The covering of each side so found answers to the opposite side, by turning the back for the front. Each covering, except that upon the side, and that upon the end, will cover four different sides: the covering upon the sides and ends only answer in two opposite places.

The angle-ribs of this dome are found as usual. If the circumference of each quadrant or rib perpendicular to the side, were ascertained by calculation, then the boarding could easily be laid out without the use of a plan, upon the same principle as in *Figure* 5, as is obvious from what has already been said.

To construct the ribs of a spherical dome, with eight axal ribs, and one purlin in the middle.

Plate II. *Figure* 1, No. 1.—Let A B C D E F G H, be the semi-plan, which is supposed to be divided into four equal parts, and let A H be the diameter, terminating the semi-plan; divide the semi-circumference into four equal parts, from the extremity A, to the other extremity H, of the diameter A H; and the points of division will mark the middle of the back, or convex sides of the ribs. This being the case, let B C *c b*, D E *e d*, F G *g f*, be the plans of the intermediate ribs, B C, D E, and F G, having the points of division in the middle; the lines B *b*, C *c*, D *d*, E *e*, F *f*, G *g*, being the places of the vertical sides, and parallel to the lines drawn from the middle of B C, D E, F G, to the centre. Draw V X, No. 2, parallel to A H, No. 1: from the side A *a*, B C *c b*, D E *e d*, &c., draw lines cutting V X, perpendicular to A H; then taking V X for the under side of the kirb or wall-plate, draw its proper thickness. In the elevation, No. 2, of the dome, the front ribs are quadrants, forming a semi-circle with the upper side of the wall-plate, which is of course the diameter; the curves of the sides of each of the other ribs are the quadrants of an ellipsis of the same height with the front rib, and their projected places, from the plan upon the kirb V X, gives the lesser semi-axis. To form the purlins, place the section of one of them in its situation, and, circumscribing its angles, draw the square *m n o p*, draw *m q*, and *n r*, parallel to V X, and the lines from the several angles of the purlins, also parallel to V X; then, where they cut the opposite rib V X form the section of the purlin, and then the circumscribing square *q r s t*. First form a ring, whose greater diameter is *m q*, or *n r*, and whose inner, or less diameter, is *p t*, or *o s*, and whose thickness is *m n*, or *p o*; the ring being thus formed, gauge lines from each of the sides, as is shown by the section; then cut off the angles made by the horizontal and perpendicular surfaces, between each two lines, on each two adjoining sides, and the purlin will be formed. The ribs of this dome are not complete quadrants, as they abut upon the upper kirb W Y at the top.

The method of covering this dome is, to suppose the surface polygonal; the principle is the same as is shown in *Plate* III.

Figure 2.—The ribs of an elliptic dome are formed in the same manner as in *Figure* 1, and the covering as in the preceding Plate; the covering of one quarter being found, answers for the whole, as has been observed. It may be noticed, once for all, as a general rule to cover any dome, divide a quadrant of the plan into as many equal parts as there are to be boards in each quarter, then draw lines from the points of section, to the centre of the plan, and draw chords by joining each two adjacent points, so that there will be as many triangles formed as there are boards: from the centre of the plan, draw a perpendicular to each of the chords, meeting each chord; make the length of each perpendicular the base of a rib, and take the common height of the dome as the height of each rib, and place it at the extremity, at right angles to each base; and describe the quadrant of a circle or ellipsis, according as the base and height may be equal, or unequal. To find the covering for any side, divide the curve of the upper side of the rib, so found, into any number of equal parts, and draw lines perpendicular to the base to intersect therewith, and the whole will be completed, as shown in *Plate* III.

No. 6, shows the covering over I O N; No. 7, over I N M; No. 4, the middle rib; No. 5, the rib between the side and end ribs.

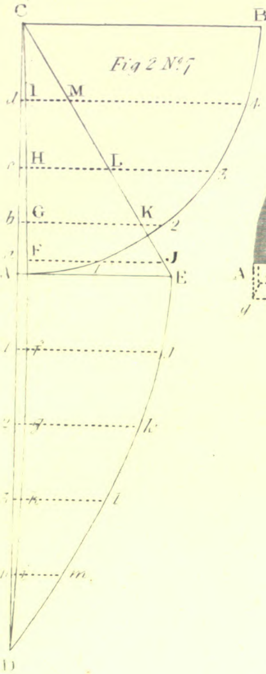
To find the solidity of a square dome, the axal sections through the middle of the sides being semi-circles.

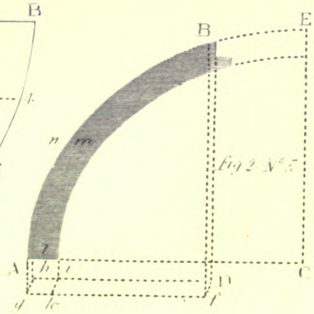
Let the radius of the circle be represented by r; suppose then, in the vertical section, that we draw any line parallel to the base, for the section of the generating plane, which is equal to the side of the generating square. Suppose the axis to be drawn upon the section, and the part of the axis from the summit to the generating line, to be denoted by x and y, to denote the half generating line, we shall then have, by the property of the circle, $y = (2\,r\,x - x^2)\,\frac{1}{2}$, and consequently $2\,y = 2\,(2\,r\,x - x^2)\,\frac{1}{2}$ the whole length of the side of the generating square.

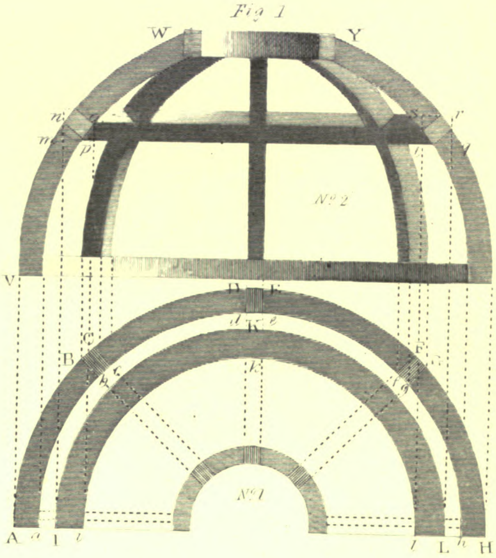
Therefore, $4\,y^2 = 4\,(2\,r\,x - x^2)$

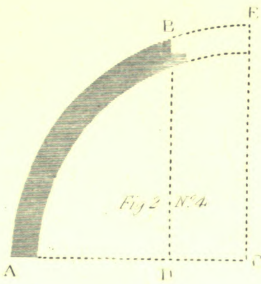
and $4\,y^2\,\dot{x} = 4\,\dot{x}\,(2\,r\,\dot{x} - x^2)$ the fluxion of the solid. The fluent of $4\,y^2\,\dot{x} = 4\,r\,x^2 - \frac{4\,x^3}{3}$ for the solidity of the segment of the dome. Now, therefore, if the solidity of the whole dome be required, it is only supposing x to become equal to r; we then find $4\,r\,x^2 - \frac{4\,x^3}{3} = 4\,r^3 - \frac{4\,r^3}{3} = \frac{8\,r^3}{3}$. Suppose $d =$ the diameter, equal to $2\,r$, and $a = r$, the altitude, then will $\frac{8\,r^3}{3} = \frac{2\,d^2 a}{3}$, that is, the solidity of the dome is equal to two-thirds of the circumscribing rectangular prism. If in the above dome all the horizontal sections had been circles instead of squares, the dome would have been spherical; let us suppose that $p = .7854$, the area of a circle, the diameter of which is unity, then in the case of the segment of the sphere we have $p\left(4\,r\,x^2 - \frac{4\,x^3}{3}\right)$ for the solidity of the dome when less than a hemisphere; or, putting $2\,r = d$, and a equal to the altitude of the segment, then $\left(4\,r\,x^2 - \frac{4\,x^3}{3}\right) = p\left(2\,d\,a^2 - \frac{4\,x^3}{3}\right)$ and the hemispheric solidity is $p\,\frac{2\,d^2\,a}{3}$. The same form of expression may be shown for all polygonal domes whatever: it is only using a proper multiplier for p, when the radius of its circumscribing circle is unity.

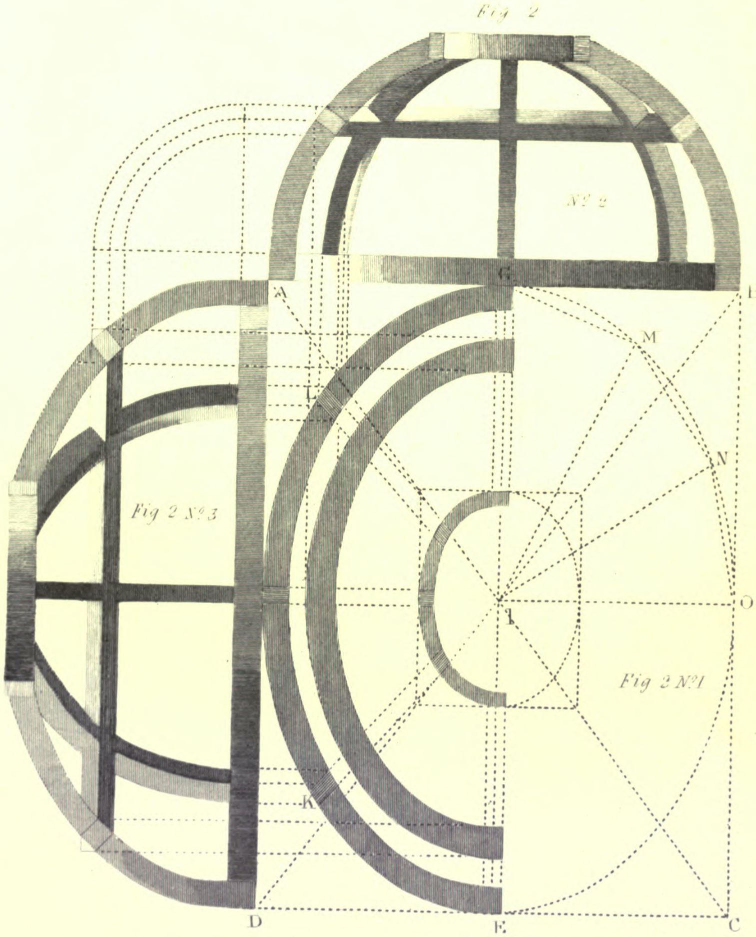
Suppose it were required to find the solidity of a trun-

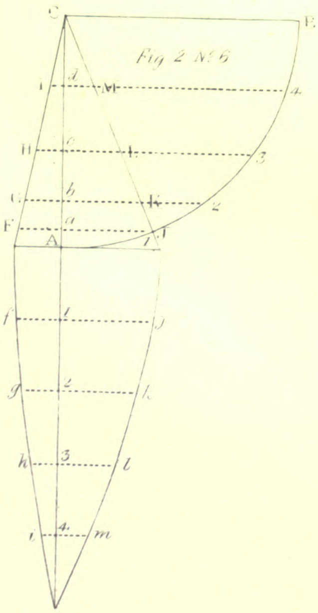












Invented & drawn by P. Nicholson

Engd by R. T

cated hemispheric dome, let $x =$ the altitude of the dome, as before, then, by the nature of the circle, we have
$y^2 = r^2 - x^2$ equal to one quarter of the generating square.
$4\,y^2 = 4\,r^2 - 4\,x^2$ for the generating square.
$4\,y^2\,x = 4\,r^2\,x - 4\,x^2\,x$ the fluxion of the solid.

The fluent of $4\,y^2\,x = 4\,r^2 x - \frac{4\,x^3}{3}$: now let $d =$ the diameter equal $2\,r$, and a equal the altitude of the dome, then $4\,r^2\,x - \frac{4\,x^3}{3} = d^2\,a\,\frac{4\,a^3}{3}$ equal to the solidity of the square truncated dome, and $p\left(d^2\,a - \frac{4\,a^3}{3}\right)$ equal the solidity of the circular dome. Let us suppose the same expression to be applied to a hemispheric dome,

then $p\left(d^2\,a - \frac{4\,a^3}{3}\right) = p\left(d^2\,r = \frac{4\,r^3}{3}\right)$

$= p\left(d^2\,r - \frac{d^2\,r}{3}\right) = p\,\frac{2\,d^2\,r}{3} = p\,\frac{2\,d^2\,a}{3}$, the same formula as above.

Practical application of the preceding rules.

To find the solidity of a dome less than a hemisphere, upon a square plan, when its axal sections, parallel to the sides, are circles.

From twice the diameter of the vertical section multiplied into the square of the altitude, subtract the third part of four times the cube of the altitude, and the remainder is the solidity of the square segmental dome.

Example.—Suppose the altitude of the dome to be 4 feet, and the diameter of the vertical section 20 feet, the solidity of the dome is required.

20	4
2	4
40 twice the diameter of the vertical section.	16 square of the altitude.
16	4
640	4
$85\frac{1}{3}$	16
$554\frac{2}{3}$ solidity required of the square dome.	4
	64
	4
	3)256
	$85\frac{1}{3}$

Suppose now a circular dome of the same dimensions: Then

.7854
$554\frac{2}{3}$
31416
39270
39270
435.1116
2618
2618
435.6352 feet, the solidity required.

To find the solidity of a truncated square dome, the axal section being that part of a semi-circle left by cutting off a segment parallel to the diameter.

From the square of the side of the base, multiplied into the altitude of the dome, subtract the third part of four times the cube of the altitude, and the remainder is the solidity required.

Example.—Suppose the side of the base 20 feet, and the altitude 6 feet, what is the solidity?

20	6
20	6
400	36
6	6
2400	216
288	4
2112 solidity of the dome required.	3)864
	288

But if the horizontal sections had been circles instead of squares, we should then have the solidity of the circular dome as follows:

2112
.7854
8448
10560
16896
14784
1658.7648 the solidity of the dome when the horizontal sections are circular.

It may here be remarked, that the segment and truncated domes make together a complete square dome, each side of the base being 20 feet, and the altitude 10 feet.

Now the solidity of the segment dome is $554\frac{2}{3}$ feet.
and that of the truncated dome . . . 2112
Therefore the whole square dome whose vertical section is a semi-circle, is . . $2666\frac{2}{3}$

Now, the rule for measuring a square dome with semi-circular vertical sections parallel to the sides of the base, is to take two-thirds of the area of the base, multiplied into the height:

20
20
400 area of the base
10
3)4000
$1333\frac{1}{3}$
$1333\frac{1}{3}$
$2666\frac{2}{3}$ the solidity, as before.

But as it may be objected by many, that, when a square or circular dome, whose vertical section is the segment of a circle, is required to find its solidity, it is difficult to find the diameter of the vertical section, and that it would be more eligible to find the solidity from the side or diameter of its base, and the altitude of the section: in order to save the trouble of finding the diameter, we shall here show the investigation of another rule, independent of any foreign or adventitious dimension.

Let s equal the side of the square base,

then $\frac{s}{2}$ is equal to half the side of the base;

and if d be the diameter of the section, and a its altitude, then, by the property of the circle,

$$\frac{s^2}{4} = a\,(d - a) = d\,a - a^2$$

$$\text{therefore, } d\,a = \frac{s^2}{4} + a^2$$

$$\text{consequently, } d = \frac{s^2}{4a} + a$$

$$\text{and } 2\,d = \frac{s^2}{2a} + 2\,a$$

Therefore, by substituting $\frac{s^2}{2a} + 2\,a$ for $2\,d$ in the formula $2\,d\,a^2 - \frac{4a^3}{3}$, we obtain $\frac{as^2}{2} + \frac{2a^3}{3}$ for the solidity of the segmental dome, independent of the diameter of the section.

This rule may be expressed thus:

To half the area of the square base, multiplied into the altitude, add two-thirds of the cube of the altitude, and the sum will be the solidity of the dome.

Let us take the same example as at first, and we shall find the side of the square of the base to be 16 feet: therefore,

16	4
16	4
96	16
16	4
256 square of the base.	64 cube of the altitude.
4 altitude.	2
2)1024	3)128
512	$42\frac{2}{3}$
$42\frac{2}{3}$	
$554\frac{2}{3}$ cubic feet, as before, in the segmental dome.	

The solidity of any dome whatever may be found by the following general rule:

To the areas of the two ends, add four times the area in the middle; then, one-sixth of the sum multiplied by the altitude, gives the solid contents. This rule applies to all domes whose vertical section is contained between any two opposite arcs of the same circle, and two parallel lines, and will even apply to those domes which are the segment of a sphere. In the seccond example, the side of the square of the base being 20, and of the top 16, the middle area will be found to be 364.

20	16	364
20	16	4
400 area of base.	96	1456
	16	256
		400
	256 area of top.	
		2112 solidity.

Because multiplying and dividing by 6, gives the same number.

To find the solidity of a hollow square truncated dome, the shell being of equal thickness, supposing each edge of the base equal to the diameter of the circle of which the section is a part.

We found before, supposing $d =$ the side of the square base, and a equal the altitude, that the solidity of the solid dome was expressed by $d^2\,a - \frac{4a^3}{3}$, then to find the solidity of the shell, it is only finding the solidity of two solid domes, of the same altitude, but of different dimensions at the base, and deducting the greater from the less.

Now let D be the side of the base to the external surface, and d the side of the base corresponding to the internal surface; then the solidity of the solid comprehended within the external surface, and the two parallel planes forming the end, is $\quad D^2\,a - \frac{4a^3}{3}$:

In like manner, the solidity of the solid which would fill the cavity, is $\quad d^2\,a - \frac{4a^3}{3}$;

then, by subtracting the latter of these expressions from the former, we obtain $\quad D^2\,a - d^2\,a = a\,(D^2 - d^2)$

for the solidity of the shell.

This rule may be thus expressed in words:

Multiply the difference of the areas of the bases by the altitude of the dome, and the product will give the solidity of the shell.

Example.—Suppose the side of the base, between the external convex surface, to be 20 feet, and the side of the base of the internal cavity, or bason, to be 18 feet, the solidity of the shell is required.

18	20
18	20
144	400 area of the base contained between the convex surface.
18	324 area of the base contained between the concave surface.
324	76 difference of the areas of the bases.
	6
	456 solidity of the shell, as required.

To find the convex surface of a dome.

Let the diameter B G $= d$

B A $= x$

and C A $= y$

B C $= z$

we have, by similar triangles,

A O C and C E D, C A : C O : : C E : C D

that is, $y : \frac{d}{2} : : \dot{x} : \dot{z} = \frac{d\dot{x}}{2y}$:

but since the fluxion of the surface whose sections are circular is denoted by $2\,p\,y\,\dot{z}$, where p is equal to 3.1416;

therefore, we have $2\,p\,y\,\dot{z} = p\,d\,\dot{x}$

and the fluent of $2\,p\,y\,z = p\,d\,x$: therefore, the superficies of the segment of a hemispheric dome is equal to the convex surface of a cylinder of the same altitude, and of a diameter equal to the diameter of a great circle of the sphere; now, when the segment becomes a hemisphere, then $p\,d\,x = \frac{pd^2}{2}$, but since $p = 4 \times .7854$, we shall have $\frac{pd^2}{2} = 2 \times .7854d^2$; that is, the convex area of the hemispheric dome is double the area of its base; and since the area of any segmental dome is the same as that of a cylinder of the same altitude, and of a diameter equal to that of its great circle; it follows also, that the convex surface of any truncated dome is equal to the surface of a cylinder of the same altitude, and of a diameter equal to the great circle of the sphere.

To find the convex surface of the segment of a dome, independent of the diameter of the great circle.

Let D = the diameter of the great circle,
a = the altitude of the dome,
d = the diameter of the base of the dome;

then, by the property of the circle, $\text{D}\,a - a^2 = \frac{d^2}{4}$,

therefore $\text{D} = a + \frac{d^2}{4a}$,

But $p\,\text{D}\,a$ is equal to the convex surface; therefore

$p\,\text{D}\,a = p\,a^2 + \frac{pd^2}{4} =$ the area of the convex surface $= p\left(a^2 + \frac{d^2}{4}\right)$. Therefore,

To find the area of the segment of a dome:

Multiply the sum of the square of the altitude and the fourth part of the square of the diameter of the base, by 3.1416, and the product will be the superficies of the dome.

Example.—What is the superficies of the segment of a dome, the diameter of the base being 17.25 feet, and the height 4.5 feet?

```
       17.25                       4.5

```

To show that the superficies of any portion of a sphere, contained between any two parallel planes, is equal to the product of a circumference of a great circle into the distance of the parallel planes; that is, equal to the surface of a cylinder, the base of which is equal to the great circle of the sphere, and the altitude equal to the distance of the parallel planes:

Let A equal the altitude of the segment of the sphere, including both the altitude of the segment wanting, and the distance of the parallel planes; also, let a equal the altitude of the segment wanting; and let c be the circumference of the great circle.

Then, whether the segment include the part contained between the parallel planes, or be the segment cut off, the area of the curved surface will still be expressed by the product under the circumference of the great circle and the height of the segment; therefore, $c\,\text{A}$ is equal to the superficies of the segment, including that of the solid contained between the two parallel planes; also, $c\,a$ is the superficies of the segment cut off; but the difference between the areas of the curved surfaces of these two segments is equal to the curved surface of the solid contained between the two parallel planes; therefore, $c\,\text{A} - c\,a = c(\text{A} - a)$ is the surface of the sphere contained between the parallel planes.

It would, however, be very desirable to have another substitute in terms of the upper and lower diameter of the solid, in place of the diameter of a great circle; for this purpose, we shall here give the following rules:

Given any two parallel chords in a circle, and their distance, to find the distance of the greater chord from the centre.

To the square of the distance between the chords add the square of half the lesser chord. The difference between this sum and the square of half the greater chord, divided by twice the distance of the chords, gives the distance from the greater chord to the centre.

Example.—Suppose the greater chord, C D, is 48 feet, and the lesser, A B, 30 feet, and their distance, E O, 13 feet; what is the distance, E F, from the centre to the greater chord, C D?

```
 13     30 = 15                48 = 24
 13     --   15                --   24
 --      2   --                 2   --

             169 square of distance. 394
             ---
             394               26) 182 (7 dist. required.
                                   182
```

Given the chord of a circle, and its distance from the centre, to find the radius of the circle.

To the square of the half chord, add the square of the distance from the centre, and the square root of the sum will be the radius required.

Example.—Given the chord C D, 48 feet, and its distance E F from the centre, 7 feet, the radius of the circle is required.

```
   48 = 24          7 × 7 = 49
   --   24
    2   --
        96
       48
       ---
       576
        49
       ---
       625 (25 the radius required.
       4
       ---
   45) 225
       225
```

Suppose, then, that we would wish to obtain the area o. the curved surface of a dome, contained between two parallel planes, the greater of which is 30 feet diameter, and the lesser 20 feet diameter, and the distance between them being 5 feet.

```
 10 × 10 = 100        15 × 15 = 225
  5 ×  5 =  25                  125
          ---                   ---
          125           1,0) 10,0 the difference.
                              10. feet,
```

the distance of the greater chord from the centre.

$(15)^2 = 225$
$(10)^2 = 100$

$325\ (\ 18.02$ the radius of the circle.
1

$28\ )\ 225$
224

$3602\ )\ ..\ 10000$
7204

$.2796$

Say then, that the diameter is 36 feet, omitting the very small fractional part .02.

Then $36 \times 3.1416 = 113.976$ the circumference of a great circle.

Therefore $113.976 \times 5 = 569.880$ feet, the superficial content of the dome.

Figure 2.—In order to show the truth of the above rule, for finding the above diameter of a circle, from the two chords, and the distance between them being given;

Let $y =$ F I, the height of the lesser segment;
$h =$ F B, the distance between the chords;
$x =$ B D, the distance from the nearest chord A G, to the centre I;
$C =$ A B, half the greater chord A G;
$c =$ E F, half the lesser chord;

Then, by the property of the circle, we have

$$\text{F I} \times \text{F K} = \overline{\text{E F}}^2 = c^2$$

and $\text{B I} \times \text{B K} = \overline{\text{B A}}^2 = C^2$
But $\text{F I} = y$
and $\text{F K} = y + 2x + 2h$
also $\text{B I} = y + h$
and $\text{B K} = y + h + 2x.$

Therefore $y \times (y + 2x + 2h) = c^2$ first equation;
$(y + h) \times (y + h + 2x) = C^2$ the second equation;
$y^2 + 2xy + 2hy = c^2$, the first actually multiplied;
$y^2 + hy + 2xy + hy + h^2 + 2hx = C^2$, the second multiplied.

Then by putting n in the place of $x + h$ in each of these equations,
the first becomes $y^2 + 2ny = c^2$
and the second $y^2 + 2ny + 2hx = C^2 - h^2$

$y^2 + 2ny + n^2 = c^2 + n^2$ by completing the square of the first. Therefore
first value of $y = (c^2 + n^2)\frac{1}{2} - n$

$y^2 + 2ny = C^2 - h^2 - 2hx$ second transposed;
therefore $y^2 + 2ny + n^2 = C^2 - h^2 - 2hx + n^2$
$y + n = (C^2 - h^2 - 2hx + n^2)\frac{1}{2}$; the second
value of $y = (C^2 - h^2 - 2hx + n^2)\frac{1}{2} - n.$

Then by making the first and second value of y equal to each other, and by taking away the negative quantity $-n$, which is common to both sides, and squaring the equation, we obtain

$$c^2 + n^2 = C^2 - h^2 - 2hx + n^2$$
or $c^2 = C^2 - h^2 - 2hx$
or $2hx = C^2 - c^2 - h^2$

and consequently $x = \dfrac{C^2 - c^2 - h^2}{2h} = \dfrac{C^2 - (h^2 + c^2)}{2h}$
which expression agrees with the rule.

The second rule for finding the radius of the circle, is only to find the hypothenuse of a right-angled triangle: the two sides containing the right angle being given, the square of the hypothenuse is equal to the sum of the squares of the two sides by the 47th Proposition of Euclid.

DOMESTIC ARCHITECTURE, that department of the art which relates especially to the design and erection of edifices adapted to private purposes as distinguished from those erected for public uses, more particularly of such as are employed as private dwellings. Although holding an inferior position in the scale when compared with other branches of the art, domestic architecture is of sufficient importance at the present day to merit the greatest attention of the professional man. Amongst the ancients this department held a very low position, all the energies of the architect being employed on the public buildings and temples. Such a term would scarcely have been understood amongst the Greeks and Egyptians, and but little amongst the earlier Romans, their private dwellings scarcely deserving the name of buildings. As luxury increased at Rome, the houses of private individuals increased in size and magnificence, as well as in accommodation, and the country-residences of the higher classes seem to have been buildings of some importance; Pliny's villa contained thirty-seven apartments on the ground-floor. Specimens of Roman houses exist at Herculaneum and Pompeii, as well as some few elsewhere. There is a villa at Bignor in Sussex, which contains 74 rooms, and covers an area 630 feet in length, by 335 feet in breadth.

Of English Domestic architecture, we need say little in this place; the term can scarcely be applied to any habitable buildings erected previous to the reign of Henry VII., and the buildings of this date will be dilated upon when treating of the style known, after the name of the reigning family, as the Tudor style. Up to the period in which this style prevailed, all the larger residences in England were fortified more or less. For an account of the earlier of these edifices we refer to CASTLES. *See* also HOUSE, TUDOR or ELIZABETHAN ARCHITECTURE, VILLA, ROMAN ARCHITECTURE, &c.

DOMICIL, or DOMICILE, (*domicilium*, a mansion), in general, the place of residence of an individual or family; in a more restricted sense, where a person resides only for a time.

DONJON, or DONGEON, the principal tower of a castle usually raised on a natural or artificial mound, in the innermost court or ballium. Its lower part was used as a prison, and it was frequently called the donjon-keep. Hence the modern term dungeon.

DOOKS, pieces of wood, about nine inches in length, inserted in stone or brick walls; the term is used in Scotland, and is of the same import with the London term, *plugs*, or *wood bricks*.

DOOR, (from the Saxon *dor*), the gate of a house, or the passage into an edifice, apartment, &c.

The construction of doors naturally divides itself into two branches, viz., the formation and proportion of the aperture, or opening, which, in outer walls, belong to the mason or bricklayer; and framing of the gate or leaf, by which the entrance is to be secured, together with its appurtenances, which appertains to the joiner's department.

The proportion of the aperture must always be according to the size and intention of the building, and should be attended to above every other consideration: in general the dimensions may be in the ratio of one to two, for large doors, and from three to seven in those of less size.

Entrances are of two kinds; doors and gates. The former are used only for the passage of persons on foot; the latter admit horsemen and carriages. Doors are used for churches, public edifices, dwelling-houses, and apartments: gates serve as inlets to cities, fortresses, parks, gardens, &c. Apertures of gates, being always wide, are usually arched; while the figure of doors is generally a parallelogram.

According to Vitruvius, the hypothyron, or aperture for doors, should be as follows:—"The height from the pavement to the ceiling of the temple being divided into three parts and a half, two of the whole parts were allowed for the height of the door. These two parts were subdivided into twelve smaller parts, of which five and a half were allowed as the width of the door at the base; and the upper part was contracted according to the following rules: if not more than 16 feet high, the contraction was one-third of the width of the jamb on the face; if the height was more than 16 and not more than 25 feet, a fourth part of the width of the jamb only was employed; and from beyond 25 feet, and not exceeding 30 feet, one-eighth only."—*Vitruvius*, book iv.

Public buildings, palaces, and noblemen's mansions, where a great concourse of company may be expected, should have doors of much greater dimensions than those of buildings of inferior rank; from six to twelve feet may be taken for the width of the outer entrance, and from four to six feet for those in the interior; in private houses, the latter, if they have but one leaf, should never be more than three feet and a half in breadth, nor less than that of the windows. In all cases their height should be proportioned to that of the story in which they are placed, except where they are used for laying two apartments into one; in which case they will be of a height less than double the width.

Vitruvius, as we have before observed, has prescribed rules for Attic, Ionic, and Doric doors, all of which have their apertures wider at the bottom than at the top; examples of this shape may be seen in the ruins of the temple of Minerva Polias at Athens, the temple of Vesta at Tivoli, and in other Greek and Roman remains. These doors possess the advantage of shutting themselves, to which they probably owe their invention; and they may be conveniently adopted in modern houses, as they rise in opening, and will clear a carpet, though when shut, they go close down upon the floor.

The principal entrance to a building of any magnitude should be in the centre, as productive of the greater symmetry of appearance, and as communicating more readily with the various apartments of the interior. In the principal rooms, the door should be two feet, at least, from the return of the wall, to admit of furniture being placed close up in the corner.

The lintels of exterior doors should always range with those of the windows. Apertures placed in blank arcades, are usually placed at the same height as the springing of the arch: when they have dressings, the head of the architrave, or cornice, is generally on the level of the impost.

The decorations of a door-way commonly consist either of an architrave surrounding it, with or without a cornice, or with a complete entablature: consoles are sometimes introduced, flanking the architrave jambs, and supporting the ends of the cornice. When the architrave jambs are flanked with pilasters, whether of the orders, or of some emblematical form, the projections of their bases and capitals are always less than that of the surrounding architrave, and the architrave over the capitals is similar to that over the door itself. Doors are sometimes decorated with one of the five orders, and in very considerable buildings, the entrance is adorned with a portico, so as to resemble an ancient Grecian temple.

In embellishing the piers of gates, or outer doors, it should be remembered, as a general rule, that as the pier is itself only an inferior building, it should never be richer than the front of the house. As for instance, where the front of the latter is ornamented with Doric columns, the Ionic should not be found in the piers; and it would be better to omit columns altogether, than use the Tuscan order for piers in any case. If the Ionic or Corinthian orders be used in the front of the house, the Doric or Ionic may be with propriety introduced in the piers. Niches are almost always introduced into piers, for which reason the columns do better on pedestals, because the continued moulding from their cap forms an agreeable ornament under the niche.

The wooden closures by which the apertures are opened or closed, come within the province of the joiner: these are properly the doors, and are either framed, battened, or ledged, as described in the following articles. In ordinary, and even in good houses, frequently, the doors are of deal; in noblemen's mansions, they are often of mahogany, solid or veneered, and sometimes of wainscot, especially when the building is in the antique style. Apartments reserved for the reception of money, plate, jewels, &c. are usually secured with iron doors; and in the descriptions of ancient temples, we read of doors of ivory, brass, silver, and gold.

Door, *Baize*, the inner door of an apartment, covered with baize for securing the room from the influx of the cold air.

Doors, *Batten*, though formerly much in use, are now confined to buildings in the pointed style of architecture. They consist of boards glued together, to the size of the aperture, with styles, rails, and munnions, made of battens, nailed upon them, so as to give the appearance of a framed door. This may be done, either on one or both sides; and the door is accordingly denominated single or double battened. The vertical joints should be hid by the munnions of the framing; and the latter, instead of being glued, should be bolted through to a framing behind, which will make them very strong. The large gates and doors of ancient British edifices are thus constructed. The practice of imitating the framing of Grecian and Roman doors, is not, however, to be recommended in modern times, especially if no bolts be used: for the stuff, however well seasoned, will be subject to the influence of the atmosphere, and shrink or swell, as the air is dry or damp. It is scarcely necessary to remark, that this evil will be enhanced in proportion as the wood is less seasoned.

Doors, *Framed*, which are either single, folding, double, or double margin, are employed in all descriptions of buildings, and consist of styles, rails, panels, and, in most cases, of munnions also. The framing includes all the parts but the panels, and is held together with mortices and tenons. The styles are the vertical parts of the framing at the sides. The rails are the horizontal pieces, tenoned into the styles. Munnions are parts of the framing, tenoned into the rails. The panels fill up the holes left in putting the framing together, and are let into grooves cut in the internal edges of the styles, rails, and munnions. Doors are generally framed in rectangular compartments; though other forms, as circles, ellipses, lozenges, &c. may be adopted, according to the fancy of the proprietor, or the taste of the builder. Framed doors are either square or moulded; the former are used only in common houses. Mouldings are of various forms, some confined within the framing, and others projecting beyond it. The mouldings and form of the panels of the door, generally regulate those of the window-shutters.

Folding doors, or *doors of communication*, are made in two breadths, and have a pair of styles to each leaf.

The Building Act (7 and 8 Vict. cap. 84) requires that openings through party walls be secured by wrought-iron doors.

"Such openings must not be made wider than six feet, nor higher than eight feet, unless in each case, and upon special evidence of necessity for convenience or otherwise, the official referees shall previously authorize larger openings.

"And the floor, and the jambs, and the head of every such opening, must be composed of brick or stone, or iron work throughout the whole thickness of the wall.

"And every such opening must have a strong wrought-iron door on each side of the party wall, fitted and hung to such opening without wood-work of any kind; and such doors must not be less than one-fourth of an inch thick in the panels thereof.

"And each of such doors must be distant from the other not less than the full thickness of the party wall."

Double doors are contrived to close against each other, in opposite directions, the one opening outwards, the other going inwards, in order to keep the apartment warm: the inner door being generally covered with baize.

Double margin doors, are single doors, with a broad piece running vertically down the middle, called the *staff-style*, imitating the two internal styles of folding doors when shut.

Whatever kind of door be adopted, it should, for the sake of uniformity, be used in all the apartments of the same story.

Farther particulars may be seen under ARCHITRAVE, and JOINERY.

The term *door* is sometimes applied to the gates of locks or sluices.

DOORWAY, the entrance or aperture in which the door is hung. Doorways are usually rectangular in shape, but sometimes arched. In the early styles previous to the introduction of the arch, all apertures consisted by necessity of an horizontal lintel supported by two vertical jambs, although not unfrequently the jambs inclined converging upwards. Doorways were enriched in a variety of ways, often by a platband running round the jambs and lintel, and sometimes by an entablature above the lintel. An elaborate work upon the subject has been published by Professor Donaldson.

Soon after the introduction of the arch, that form was applied to doorways, the form of the arch, whether semicircular, pointed, or otherwise, being determined by the date and style of the building. Of the first form, the Romanesque style affords us some very beautiful specimens; witness that of the Temple Church, London, which is a very fine example, and consists of a compound arch, that is to say, a series of concentric and receding arches, each arch with its pier being profusely adorned with pillars and enriched mouldings of all kinds. These doorways seem to have been admired in all ages, for frequently, when all the rest of a church has been pulled down to make room for one of a more elaborate or more fashionable style of architecture, the old Romanesque doorway has been preserved, and worked up in the new structure. For exquisite examples of doorways in the pointed styles, we have only to refer to the magnificent western entrances of the Continental cathedrals, and the smaller and less elaborate, though not less beautiful, examples in our own country.

DOORWAY-PLANE, a term sometimes applied to the space between the doorway properly so called, and the larger door archway within which it is placed. This space is frequently ornamented with sculpture, &c.

DORIC ORDER, the most ancient Grecian order of architecture, was first used in building the temple of Juno at Argos, at the period when Dorus, father of the Dorians, reigned in the Peloponnesus; though, according to Vitruvius, its symmetry and proportions were not fixed till Ion, the nephew of Dorus, and chief of the Ionians, led an Athenian colony into that part of Asia Minor which was afterwards distinguished by his name, and there built a temple, after the fashion of those in the Dorian states, the columns of which were six diameters in height, taking the proportion from the ratio that a man's foot bears to the height of his body.

The Doric is distinguished, in general appearance, from the succeeding orders, by its bold and massy proportions, as well as by its comparative want of ornamentation; all its parts are bold and prominent, its details few and imposing.

Its origin is stated by Vitruvius to have been derived from the primitive buildings of the Greeks, which were made of timber; but others derive the style from the stone structures of Egypt, and others from those of Persia and the East. It would be the more natural method to discuss this subject ere proceeding farther, but as the discussion could not be readily understood without some previous acquaintance with the details and general character of the order, it may be as well to turn our attention to these matters first of all.

This order then consists, like the others, of column and entablature, but differs from them in this, that the first mentioned division comprises only two members, the shaft and capital; the base, which is indispensable in the other orders, being omitted in this, at least in the earlier and purer examples, as practised by the Greeks. The reason of this omission has been accounted for in various ways by different writers; Vitruvius will have it, that the base was first introduced in the Ionic order to represent the sandal or covering of a woman's foot, and that in the Doric, which resembled in some way or other a strong muscular and barefooted man, this member was not appropriate. Some are of opinion that the omission was occasioned by the close proximity of the columns in this order, which would not admit of any excrescence at the base. It is true the intercolumniation is very contracted, and the addition of any base, especially of a square one with its angular corners, would render the passage between the columns extremely narrow and inconvenient; indeed, even without a base, the space was inconveniently small, and was felt to be so, as we gather from the fact that the intercolumniation of the portico opposite the entrance-door was increased in width, evidently to afford readier access to the interior; notwithstanding, we can scarcely bring ourselves to conclude that this was the reason of the absence of a base. We rather incline to believe that a base had as yet never been thought of, the idea had not yet suggested itself; in Egyptian temples, from which we believe the Doric order to have emanated, the columns were usually devoid of bases, and it is but reasonable to presume that in their earlier essays, the Greeks aimed at nothing more than a copy, and did not think either of addition or improvement.

The Doric shaft then rises immediately from the platform on which the building stands, but this platform was usually raised on a series of three or more steps or gradations, the risers of which are proportioned not to the capacity of the human step, but to the magnitude of the building. The shaft, when compared with those of the other orders, is of stunted and massy proportions, its height being only 5 or 6 times greater than its lower diameter; the upper diameter, however, is of much smaller dimensions, the column converging rapidly towards the capital, a circumstance which gives an appearance of great stability. Towards the top of the column, a narrow channel is carved out round the shaft, so as to form an annulus in recession, and this marks the division between the shaft and capital, although a portion above this is in form nothing more than a continuation of the shaft. The shaft was almost universally fluted, very few exceptions to the contrary existing; the number of the flutes is either 16 or 20, and their profile is that of a segment of a circle less than a semi-circle, being much broader and flatter or shallower than those of the succeeding orders. These flutes meet each other in a sharp arris, without the intervention of fillets, which are universal in the later orders; a slight fillet, however, is to be found in examples at Eleusis, Sermium, Rhamnus and Thoricus, but so narrow as to be insignificant. Much pains have been taken by various authors to account for the introduction and use of those flutes, but in our opinion without success; one supposes that they are imitations of the crevices in the stems of the trees out of which the timber-huts, the primitive models of the stone structures, were constructed; another, that the idea was occasioned by the rain-streak running down the shafts of the columns; and a third, that flutings were hollowed out for the purpose of resting spars in the crevices. Such hypotheses are doubtless very ingenious, although not to all minds equally convincing; for our own part, we do not see the absolute necessity there is to account for the reason and origin of every small member or ornamental detail. We require no further reason for the use of flutes, beyond the effect produced by them as a means of decoration, and as such we think their origin very easily accounted for. In the majority of Egyptian examples, from which—to prejudge the question—we suppose those of Greece to have been derived, the columns were reeded, or ornamented with projecting staves instead of recessed flutes; nor are the two methods of decoration so dissimilar and unconnected, for we have only to remove the staves to produce the flutes: and besides these methods we find another, in which the columns are what is called canted, that is to say, have their horizontal sections rectilineal polygons, the faces of the polygon or sides of the column being flat, instead of convex or concave. Thus we have three kinds of polygonal columns, the first of which seems to possess the primitive form, and the others to be merely enriched variations of the same. At Amada in Nubia, there is a very curious illustration of the progress made in the improvement and enrichment of columns, where in the same building we find one column a mere pier or simple parallelopiped, and another and adjoining one both rounded off at the corners and fluted; this last bears a remarkable resemblance to the Grecian Doric, on which account we shall have to refer to the subject again ere the close of this article. Specimens of Doric canted columns are to be found in the portico of Philip, king of Macedon, and in the temple of Cora; the flutes, however, are the most prevalent, as they are the most beautiful means of enrichment; the pleasing effect produced by them is attributable mainly to the diversity of light and shade so created, but this is not their only advantage; they likewise give a variety and lightness of appearance to the column, which would otherwise appear heavy, and at the same time, by the diminution of the breadth of the channels as viewed by the eye, add to the apparent circularity of the column. We have no specimens of reeded columns in this order. The flutes diminish in width as they reach the top of the shaft, to correspond with the diminution of the shaft; they are carried above the necking of the capital, and usually terminate immediately below the annulets, butting upon a plane surface perpendicular to the axis of the columns, or parallel to the horizon, as in the Propylæa at Athens. In other cases, as in the temples of Theseus and of Minerva at Athens, as well as in the Portico of Philip, in the island of Delos, the upper ends of the flutes terminate upon the superficies of a cone, immediately under the annulets, in a tangent to the bottom of the curve of the echinus of the capital. The same kind of termination takes place in the temple of Apollo, at Cora, in Italy; but in this example, the conic termination of the flutes is not immediately under the abacus, but at a small distance down the shaft, leaving a small portion quite a plain cylinder, and thus forming the hypotrachelium or neck of the capital. Palladio and other Italian authors have terminated the flutes of the shafts of their design of Doric columns in the segments of spheres tanged by the surfaces of the fluting. In some few instances the shaft is fluted only at the upper and lower extremities, the other part being left plain, although probably with the intention of being ornamented in a similar manner at some future time. Examples of this are to be found at Eleusis and Thoricus in Attica, at Egesta and Selinus in Sicily, at the temple of Apollo at Delos and at Rhamnus, which last forms a peculiar instance, the columns of the pronaos being fluted the whole length of the shaft in front; with eleven channels, having at the back nine plain surfaces. We have above stated the number of channels to be 16 or 20, but the latter is by far the more usual; examples of which practice are, the Parthenon, Theseum and Propylæa at Athens, with others at Corinth, Delos, Eleusis, Rhamnus, Thoricus, Bassæ, Agrigentum, and in the temple of Ceres, at Pæstum. There are but few examples with only 16 channels, of which number are those at Sunium, and the upper range of the interior columns in the temple of Neptune at Pæstum, in which last mentioned building there are specimens of columns with as many as 24 flutes. The channels were not always circular, but sometimes semi-ellipses, and at others eccentric curves. Doric antæ were never fluted.

The first object which attracts notice in passing the eye up the column, and which breaks the outline of the fluting, is what is termed the hypotrachelium, or under-necking of the capital. This consists of one or more channels cut in recession round the upper part of the shaft; in some instances, as at the temple of Minerva at Sunium, in the Agora at Athens, and in most of the examples at Agrigentum; this division is so fine as almost to escape notice, and in others is very prominent, the channels varying both in size and number. In the Parthenon, and in the Propylæa at Eleusis, and at Rhamnus, there is a single rectangular groove; at the Propylæa at Athens, a groove chamfered on the upper edge, and at the Theseum, a groove chamfered on both edges, so as to form an acute angle at the meeting of the chamfers. At Corinth there are three channels similar to those in the Propylæa at Athens, having a fillet between each two, as also at the temple of Apollo at Bassæ, but in this example the channels are of a curvilinear section. At Pæstum there are three fine channels, which, at their junction with the arrises of the flutes, are cut into the shape of diamonds, the projecting edge of the arris being chamfered off. The hypotrachelium of three channels is considered a mark of antiquity, for although they are not of necessity found in all ancient examples, yet they are never inserted in those of later date. Some writers consider those channels as the commencement of the capital, while others are inclined to think them but a continuation of the shaft. In the other orders the corresponding member is certainly the division between the two parts, all above being giving to the capital, and all below to the shaft; the difficulty in this case arising from the fact of the continuation of the flutes above this point, the space between the hypotrachelium and annulets being precisely similar to the lower portion of the shaft, yet at the same time it is difficult to assign any other reason for the introduction of the grooves, except they serve to mark the division between the two members of the column. Without the intervention of such a mark as this the capital would have appeared stunted and heavy, but, as it is, the shadow produced by the sinking, marks to the eye a distinct division, and, in appearance at least, increases, at the same time, the length and comparative lightness of the capital.

Above the hypotrachelium, the shaft, with its fluting, is continued for a short distance, and meets the annulets of the capital in a curve or *apothesis;* this portion forming, according to our notion, the necking of the capital. The annulets come next, and form the lower portion of what may be termed the capital-proper, about which there exists no difference of opinion. The following particulars of the number and form of annulets in different examples are furnished by a contributor to "The Builder," to whose valuable writings, on this subject, we shall have occasion to advert more than once in this article:—

"The annulets, in Grecian Doric columns, vary as well in their profile as in their number. Some examples may be interesting, to show the exhaustless genius of the Greeks, even in details the most minute, and that although the general principles of art in the Doric order are the same, yet that they could produce great variety in their details. In the Parthenon, that best and purest of all examples, we find, under the echinus of the capitals in the porticos, five rings, placed on a slope, continued, as it were, from the lower link of the echinus, and in the columns of the pronaos of the same edifice, there are but three rings. In the temple of Theseus, the profile of the annulets is somewhat similar to that of the Parthenon; the rings are four in number, and the under side of the lower arris of each ring is slightly undercut. In the example from the portico at Athens, presumed to belong to the Agora, or market-place, we see how widely the artist departed from the graceful and flowing outline of earlier patterns; this, of the age of Augustus, is one of the latest known examples of Grecian-Doric, yet in many points it cannot be safely recommended for modern imitation. In the temple of Apollo Epicurius, at Bassæ, a building of the pure age of Greek art, the annulets are four in number, resembling in their contour those in the Parthenon, excepting that the second and third rings recede a little from a line drawn from the first to the fourth. At Rhamnus, where are two temples, at Sunium, and in the Dodecastyle portico of Ceres at Eleusis the rings are three in number, profiled like the best examples at Athens; at Egesta and Selinus, they are three in number; at the temple of Jupiter Olympus, at Agrigentum, of Apollo in the isle of Delos, and in the portico of Philip at the same place, at Corinth (where the annulets have a great projection, and are very deeply undercut), in the Hypæthral temple at Pæstum, in the temple of Diana, in the Propylæa at Eleusis, in the Propylæa at Athens (an excellent example) and at Thoricus, the rings are four in number. At the latter place the annulets are remarkable, and probably singular in their way. In the capital from the Pseudodipteral temple at Pæstum, in which many peculiarities are observable; the immense size and projection of the abacus seem to crush the echinus, which has beneath it two rings, under which the flutings curl in the form of leaves. At Selinus, Mr. Woods noticed some remarkable features in the capitals:—'The shape of these capitals is very peculiar; I have seen nothing like them in Greece, except a fragment on a very small scale which I noticed at Corfu. The common Grecian-Doric capitals in the best examples form a sort of ogee, and we find this curve at the third temple, but in the great temple, and in two of the three smaller ones, a deep hollow interrupts the flow of the lines.' These capitals were each cut out of a block of stone thirteen feet square."

The next member of the capital is the echinus, which is similar to an ovolo, or quarter-round moulding, and which, spreading out from above the annulets, serves to support the overhanging abacus. In the best examples it is usually very flat in profile, being little more than a frustum of an inverted cone, having its base rounded off at its edge, and quirked, as it were, where it meets the abacus. Its use seems to have originated from an imitation of the cushion-capitals of the Egyptians, the lower portion only being reserved in Grecian buildings. The diameter of the top of the echinus is equal to, or somewhat greater than, the lower diameter of the column. We refer again to the writer above alluded to.

"In those buildings which belong to the best age of Grecian art—the days of Pericles, and his chief architects, Callicrates and Ictinus—as seen at Athens, Bassæ, Sunium, Thoricus, Eleusis, Rhamnus, and elsewhere, we shall find that the echinus has its lower part either very slightly curved or else perfectly straight; whilst, in buildings of later date, and of equivocal taste, we find that the moulding nearly resembles an elongated or ovate quarter-round, as in the Agora at Athens, and in a building at Cadachio. Professor Donaldson has drawn notice to the general principle which "directed the Greeks in composition of their Doric capitals. From the necking to the abacus, the outline is that of a cyma-reversa, having a projection that varied according to the era, or style of art peculiar to the country; the existing Attic examples being but slightly projecting, while the immense abacus of the orders now remaining at Corinth, Pæstum, and in Sicily, gives a bolder profile to the capital." Some idea may be formed of the vast proportions of the temple of Jupiter, at Agrigentum, when we find that the echinus of each column is formed of two stones, each weighing $21\frac{1}{2}$ tons, held together by plugs or dowels by the centre stone of the abacus, which is in three pieces. In the capitals of the antæ of Greek examples the echinus is generally undercut, so as to form that remarkable moulding called the hawk's-beak, or bird's-beak moulding. The proportionate depth of the abacus and echinus to each other, is not always the same; but, as a general rule, it may be held, that the former member should have the greatest depth. In the Parthenon, the relation, in this respect, is as 11 to 9; at Sunium and at Bassæ, as 7 to 6; at Thoricus, as 6 to 5; at Eleusis, as 12 to 9. In the best examples with which we are acquainted—as, for instance, in the Parthenon and Theseum—the echinus has nearly the same projection as the abacus (it is actually the same in the temple of Apollo Epicurius, at Bassæ); and we shall find, that the sharper is its outline—that is, the more it is remote from the quarter-round—the more it is held in estimation; and that, as it approaches the ovolo in form, so it may be traced to belong to a declining period, or one nearer to the time of the Roman use of the Doric order. If we grant for a moment, that timber construction afforded the first hints for architectural composition, and that the origin of the abacus may be traced to the intervention of a cube of wood between the column and its entablature; where will the advocates of this system find the prototype of the echinus? To the Greeks we must look for adoption of this beautiful moulding, which connects, in such a happy manner, the square abacus with the circular shaft; and truly may it be said to be their own invention, even if we are compelled to admit, that some slight hint for it is to be found among the heavy capitals of Egypt. Professor Hosking has well observed: "Greek architecture is distinguished for nothing more than for the grace and beauty of its mouldings; and it may be remarked of them generally, that they are eccentric, and not regular curves. They must be drawn, for they cannot be described, or struck; so that, though they may be called circular, or elliptical, it is seldom that they are really so; not but that they may be; but if they are, it is considerably the result of chance, not of design. Hence, all attempts to give rules for striking mouldings are worse than useless, for they are injurious; the hand alone, directed by good taste, can adapt them to their purpose, and give them the spirit and feeling which render them effective and pleasing."

The abacus at the top of the capital is of the simplest description, being merely a square slab of stone, of considerable thickness, harmonizing well with the massy appearance of the entire column. It projects considerably beyond the upper part of the shaft, and sometimes even beyond the lower diameter, and always advances in front of the general surface of the epistylium. Where the abacus overhangs beyond the foot of the column, it is considered as an indication of the antiquity of the building; examples of which occur at Corinth, Pæstum, Egesta, and elsewhere. This completes the description of the column.

It may be well to mention in passing, that Doric antæ differ from columns, in maintaining the same width from top to bottom, which equals the average diameter of the column. They have a simple moulding and groove at their base; the capital likewise is very simple, and the abacus and other mouldings are much narrower than in the capital of the column. Antæ are never fluted.

The Doric entablature consists as usual of three members, architrave, frieze, and cornice, the first or lowermost of which, otherwise termed the *epistylium*, is simply a plain fascia surmounted by a broad fillet termed the *tænia*, which forms the separation between it and the frieze, and to which another fillet, with small cylindrical guttæ depending from it, is attached in separate portions beneath each triglyph of the frieze. The epistylium recedes from the face of the abacus, projecting beyond the upper diameter of the shaft, but falling short of the extremity of the lower diameter, so as only partially to overhang the column. A line dropped vertically from the face of the architrave would cut the abacus, pass without the upper portion of the shaft, but fall within it ere it reached the base. The average height of this member, inclusive of the tænia, is equal to the upper diameter of the column.

Above the architrave is the frieze, which forms the most characteristic feature in the whole entablature, although of no greater dimensions than the epistylium. The height of the two members is nearly equal, with but slight variations in any example, the frieze being seldom, if ever, the deeper, more frequently the shallower of the two. The peculiar ornamentation of this portion of the entablature gives it its specific character; being divided into a series of projecting and recessed panels. The distinguishing feature is the *triglyph*, which is a slightly projecting tablet, somewhat wider than the semi-diameter of the base of the column, and channelled vertically with three grooves, or γλυφες, whence the name triglyph. These channels are so disposed, that there shall be a space in the centre of the projecting slab, with a channel on each side of it, and beyond these again, on either side, another equal space, with a half-groove outside, on the edge of the slab, which indeed is nothing more than a chamfered edge. The two channels, and the two halves on the extremities together make up the three grooves, or *glyphs*.

Beneath each triglyph, and attached to a fillet, are a series of guttæ or drops, immediately under the tænia of the architrave. This decoration we have alluded to in describing the epistylium, but although it is attached to that member, it belongs, strictly speaking, to the triglyph, of which it is a continuation; its position, however, in this place, serves a very useful purpose, for it both gives a variety to the otherwise monotonous surface of the architrave, and, at the same time, presents to the eye a sort of connection between this portion of the entablature and the frieze above it. The guttæ are six in number, of a conical form, and are said to represent drops of rain that have trickled down the channels of the triglyph, and settled beneath the tænia; others again suppose them to represent the heads of nails, or screws, used in the wooden structure. The channels of the triglyph are of a triangular section, and are not continued the entire height of the block, although at the bottom they butt against the tænia. Each triglyph is surmounted by a capital, or slightly-projecting band, which, in the Greek examples is of very slight projection, and is not returned at the sides, except in the case of triglyphs at the angles of the building. The position of these ornaments is such, that there shall be one over the centre of each column, and one midway between every pair of columns; but there is an exception to this disposition at the angles of buildings, where the triglyph is not placed over the centre of the column, but is brought up quite to the edge or outer angle of the frieze, so that a line dropped perpendicularly from the outer edge of the corner triglyph, would touch the base of the column. This disposition gives occasion for an alteration of the intercolumniation between the two end columns, these being brought closer together by the space of half a triglyph; an advantage is obtained by this means, inasmuch as an appearance of greater strength is given to the extremities of the colonnade.

The spaces between the triglyphs are called *metopes*, and are usually filled up with sculptures in bas-relief, from which circumstance the frieze was called by the Greeks *zoophorus*, because it contained representations of living figures, men or animals. These metopes are usually of a square form, their breadth being equal to the height of the frieze, but there is a slight variation in different examples. In the Doric portico at Athens, the breadth of the metope is 3′,, 3″ and 3′,, 3″.6, while the height is 3′,, 0″. 7, including the band or capital over it; or without the band, 2′,, 9″ . 05; in the temple of Minerva at Athens, the height of the metope, without the band, is 3′,, 11″ . 15, and its breadth 4′,, 3″ . 35: in the Propylæa, the breadth is 3′,, 8″ .25, and the height 3′,, 9″ . 85, including the band and the bend over it; and in the Theseum, the breadth is 2′,, 6″ .475, and the height 2′,, 5″, without the band. Each metope is surmounted with a band, or capital, similar to that of the triglyph, though not of equal width or projection.

The entablature belonging to the monument of Thrasyllus is an exception to the general rule, the frieze being without the characteristic addition of triglyphs, their place being filled up with wreaths; the guttæ, however, are retained, but instead of being disposed at intervals, they are continued uninterruptedly beneath the fillet.

The Doric cornice consists of few but bold parts, the most characteristic of which are the mutules. These are a series of shallow plates attached to the soffit of the corona, sloping forward, so that the bottom of the mutule in front is considerably lower than at the back, and having their soffits studded with cylindrical or conical guttæ; these guttæ were eighteen in number, and placed in three rows of six each. A mutule was placed over each triglyph, and an intermediate one over each mutule; their width being equal to that of the triglyphs. Under the mutules was generally a plain band, but sometimes an ogee is found in this place. The corona is a boldly-projecting flat moulding, of somewhat greater depth than the abacus of the capital, and is generally finished off above with a small ovolo and fillet supporting the cymatium, which consists of two similar mouldings, but of more imposing dimensions. In raking cornices the mutules are omitted, but a new moulding, termed the *epitithedas*, is added as a finish, which is either an ovolo or cymatium.

When used, the epitithedas was continued a little way at the angles, and terminated against a carved block. The pediment in this order is of a low pitch, and always about the same height, whatever the span may be; upon an average the height equals that of the entablature, more or less, but is scarcely ever so great as to make the tympanum higher than the entablature.

Having completed this general description of the order, it may be as well to say a few words about the proportions observed in the different parts.

The height of the column varies from four times the lower diameter, as in the earliest existing example at Corinth, to $6\frac{1}{2}$ times, as at the portico of Philip, but in the purest examples the height is about $5\frac{1}{2}$ times the lower diameter, the upper diameter being $\frac{1}{6}$ less than the lower. The entablature varies from $1\frac{3}{4}$ to 2 diameters in height, of which $\frac{2}{5}$ go to the epistylium, $\frac{2}{5}$ to the frieze, and the remainder to the cornice.

To afford more detailed information, we give the following proportions from the temple at Sunium, and the accompanying table, as prepared by Mr. Brown.

"The proportions of the temple at Sunium are thus ordered: make the column 6 diameters high, and the entablature $\frac{3}{10}$ of the column, or divide the whole height into 13 parts, of which give 10 to the column, and 3 to the entablature. The upper diameter of the column is $\frac{3}{4}$ of the lower. The capital $\frac{1}{2}$ a diameter, which, being divided into 5 parts, 2 are to be given to the abacus, 2 to the ovolo and annulets, and 1 to the necking. The length of the abacus $1\frac{1}{8}$ diameter. The entablature is to be divided into 8 parts, giving 3 to the architrave, 3 to the frieze, and 2 to the cornice. In dividing the cornice, take $\frac{3}{7}$ for the cymatium, fillet, and moulding, $\frac{3}{7}$ for the corona alone, and leave $\frac{1}{7}$ for that part of the fascia which appears below a horizontal line drawn from the lower front edge of the corona. The whole projection of the cornice is 1 diameter, reckoning from the centre of the column. The capital of the triglyph to be $\frac{1}{9}$ of the whole height of the frieze. The capital or fillet of the architrave to be $\frac{1}{2}$ of the height of the architrave. The architrave to overhang the upper part of the shaft by $\frac{1}{2}$ the difference between that and the lower diameter. In distributing the triglyphs, take $1\frac{1}{4}$ diameter, or 75 minutes for the width of the triglyph and metope, and of this give $\frac{3}{8}$ to the former, and $\frac{5}{8}$ to the latter, or nearly 28 and 47 minutes. Thus a monotriglyph intercolumniation will be 75+75—60=90 minutes, or $1\frac{1}{2}$ diameter."

A Table of the Proportions of some of the Grecian Doric Orders, according to the Module of Sixty Parts, formed at the bottom of the Shaft of the Column.

	Lower Diameter.	Upper Diameter.	Height of Column.		Architrave.	Frieze.	Cornice.	Intercolumniation.		Pedestal.
	Minutes.	Minutes.	Diam.	Min.	Min.	Min.	Min.	Diam.	Min.	Rise.

Inner Peristyle of Temple of Neptune	60	43	1	$13\frac{1}{8}$	39	—	—	1	$22\frac{3}{4}$	—
Upper Columns to ditto	60	$44\frac{1}{8}$	3	50	68	—	—	2	49	—
Temple of Egesta (plain shaft)	60	$44\frac{3}{4}$	—		$49\frac{3}{4}$	$52\frac{3}{8}$	$40\frac{3}{4}$	1	11	—

In comparing the above with the table on the next page, in which the dates are given, it will be readily observable with what regularity the proportionate height of the columns increased from the earliest example at Corinth to the latest, the Agora at Athens: the last, however, forming somewhat of an exception to the rule, the height being less in this case than in the two previous examples, viz; those of the temple of Jupiter Nemæus, and of the Portico of Philip of Macedon. The diminution of the shaft will be seen to average about 15 minutes, the upper diameter ranging from $49\frac{1}{2}$ in the portico of Philip, a late example, to $35\frac{1}{2}$ in the temple at Selinus, one of the earlier buildings; thus affording additional proof of the comparative lightness of the later structures. We have to call attention likewise to the general equality in height between the architrave and frieze, noticing at the same time one or two exceptions in which there is a considerable variation, especially in that at Agrigentum; the height of the architrave of the upper colonnade in the temple of Neptune is remarkable, as is also that of the frieze and cornice at Egesta.

The following useful, though somewhat different table, is the compilation of the writer to whom we have previously alluded.

This table exhibits at one view the proportions of the columns in some of the principal buildings in Greece and its colonies, concluding with the scale which the Roman and Italian schools assigned to the Doric.

Date of Erection.	Name of Building.	Name of Architect.	Height of Column. ft. in.	Diameter. ft. in.	Number of Diameters high.	Number of Columns in Portico.	Number of Columns on the side.
About 800 B. C.	Temple at Corinth		23 8	3 10	$4\frac{2}{35}$	6	—
600 or 700 B. C.	Great Hypæthral Temple at Pæstum		28 10	7 0	$1\frac{1}{21}$	6	14
500 B. C.	Temple at Selinus		32 6	7 6	$4\frac{1}{3}$	6	12
	Octostyle at Selinus		48 7	10 7	$4\frac{3}{5}$	8	16
	Temple of Minerva at Syracuse	Probably Archias of Corinth.	28 8	6 6	$4\frac{16}{39}$	—	—
About 450 B. C.	Temple of Hercules at Agrigentum		33 0	7 0	$4\frac{5}{7}$	6	14
	Temple of Concord at ditto		22 2	4 8	$4\frac{3}{4}$	6	—
500 B. C.	Temple of Jupiter Panhellenius at Egina	Libon.	17 1	3 2	$5\frac{9}{10}$	6	—
About 461 B. C.	Temple of Theseus		18 7	3 3	$5\frac{28}{39}$	6	13
448 B. C.	Parthenon	Ictinus.	34 0	6 2	$5\frac{14}{37}$	8	17
About 430 B. C.	Temple of Apollo at Bassæ	Ictinus.	19 6	3 7	$5\frac{19}{43}$	6	15
	Temple of Minerva at Sunium	Ictinus.	19 7	3 4	$5\frac{7}{8}$	6	—
Age of Pericles.	Temple of Ceres at Eleusis	Corabus.	—	6 6	Supposed $5\frac{1}{2}$	12	—
Age of Pericles.	Temple of Diana Propylæa at Eleusis		14 10	2 7	$5\frac{3}{4}$	2 in antis.	—
	Temple at Rhamnus	Alcamenes, a pupil of Phidias.	13 4	2 4	$5\frac{1}{2}$	6	12
	Temple of Apollo, Delos		18 8	2 11	$6\frac{2}{5}$	—	—
About 338 B. C.	Portico of Philip of Macedon, Delos		18 8	2 10	$6\frac{2}{5}$	—	—
	Temple of Jupiter Nemæus		33 8	5 2	$6\frac{16}{31}$	6	—
100 B. C.	Agora, at Athens		26 2	4 4	$6\frac{1}{25}$	4	—
Time of Augustus.	Theatre of Marcellus, at Rome		21 0	3 0	7	—	—
About 80 A. D.	Coliseum		27 3	2 10	$9\frac{21}{34}$	—	—
About 300 A. D.	Baths of Diocletian		—	—	8	—	—

The intercolumniation of this order differs from that of all the others, inasmuch as the intercolumns are determined not by the diameters of the column, but by the arrangement of the triglyphs; and the different methods, instead of being distinguished as *pycnostyle*, *eustyle*, *aræostyle*, *&c.*, are comprehended under the terms *monotriglyph*, *ditriglyph*, *&c.*, according to the number of triglyphs over each intercolumn; the former term designating the arrangement in which there is but one triglyph between the columns, the latter that in which there are two within the same limiis. This method of disposing the columns naturally arises from the employment of the triglyph, for this ornament forms so conspicuous an object in the elevation, that it was necessary to make its position conform with the other principal members of the order, of which the column is the most important, so that the colonnade and entablature might present to the eye a similar arrangement. Had the triglyphs been placed in the frieze without reference to the position of the columns, the eye, after passing up the length of the column, would have been confused upon reaching the frieze, and probably would have stopped short at that member, there being nothing to carry it upward to the cornice. Did we adopt the Vitruvian theory, the position of the triglyph would readily be accounted for in another way, for it stands to reason, that the feet of the rafters would be placed immediately over their support.

It being necessary then that the triglyph should stand over the centre of each column, and the proportion of the metope or space between the triglyph being determined, we only require the height of the frieze, and the intercolumniation is fixed. The width of the metope being about equal to the height of the frieze, and the triglyphs somewhat less, it is evident, that to place a column under every triglyph, would be impracticable, without increasing the height of the frieze quite beyond proportion; there would be scarcely room for the feet of the columns, much less for any space between. It became necessary therefore to place another triglyph in the centre of each intercolumn, with two metopes instead of one: this arrangement answered very well, and is the most frequent in Doric temples, and indeed is seldom departed from in any buildings. By inserting another triglyph, you are compelled to add another metope, and this makes the intercolumn half as wide again, which is almost too wide to suit the requirements of taste, as well as the proportions and construction of Doric buildings. There are very few instances of this arrangement, and these only in the centre intercolumn opposite the entrances, where greater space was required; this is especially noticeable in the Propylæa, where a large space was required for the admission of chariots. It may be supposed, that the monotriglyphic method would cause the columns to appear too closely set, and this certainly would be the case in some instances, where the columns are less than a diameter and half apart, were it not that the shafts converge so rapidly towards the upper diameter as to leave a space under the soffit of the architrave, even in such instances equal to more than twice the upper diameter.

The peculiar position of the extreme triglyph has already been noticed in speaking of that member, as also the effect produced by it in lessening the extreme intercolumn by the space of half a triglyph; but there still remains to notice another peculiarity, which was first published by Mr. Donaldson; we allude to the inward inclination of the outer columns.

"The axis of the columns of the Parthenon," says he, "both on the flanks and on the fronts, as well as those of the temple at Egina, and of Concord at Agrigentum, have a considerable inclination inwards (a circumstance I am not aware to have been before noticed) though not to such a degree as required by Vitruvius, and not confined, as he directs, to the columns of the peristyles only." Vitruvius thus directed:—"The bases being thus completed, we are to raise the columns on them. Those of the pronaos and posticum are to be kept with axes perpendicular: the angular ones excepted, which, as well as those on the flanks right and left, are to be so placed, that their interior faces towards the cella be perpendicular. The exterior faces will diminish upwards, as above mentioned. Thus the diminution will give a pleasing effect to the temple."

Mr. Bartholomew alludes to the same circumstance thus:—"The ancients, knowing how much more secure were their fabrics when made to settle together and consolidate by their own gravity, set the lateral columns of their temples with their axes falling towards the cells, so that the inner faces of the shafts of the columns should be perpendicular, and the outer faces of them receding the whole quantity of columnar diminution, in order to afford to the building a more solid, pyramidal, and graceful appearance; and by this shrewd device they rendered the avenues between the side-walls and the colonnades of their temples no wider next the soffits of the architraves than down upon the pavement; and it is not improbable, that the preservation of this symmetry led to the omission of the inner columns of the ancient Pseudodipteral temples; whereas the moderns, in general, not attending to his dynamic and optical nicety in architecture, so set their columns, that when we walk down a modern collonnade, we cannot divest ourselves of the idea that the axes of all the columns are falling outwards: and, indeed, accurate admeasurement would often find this to be no illusion, since the work, not erected so as to fall together, will, in general, with the slightest inevitable settlement, expand at its upper part." It is worthy of remark, that, in many instances, the angular columns are made somewhat thicker than the others, so as to give them an appearance of much greater strength.

Having arrived thus far, we cannot do better than give descriptions of some of the more noted edifices belonging to this order, amongst which are the Parthenon, Theseum, the ancient temple at Corinth, the Propylæa at Athens, and the Poseidonium at Pæstum. The following accounts are selected from Mr. Godwin's lectures on Architectural Antiquities."

"The Parthenon, or the temple dedicated to the virgin-goddess Minerva (the Greek word *παρθένος*, signifying a virgin), was designed by Ictinus and Callicrates, about the year 438 B.C., whilst Phidias wrought the marble figures into life by his magic touch. This temple, erected upon the site of the old Hecatompedon destroyed by the Persians, is justly looked upon as the finest example of the Grecian Doric, and has excited for 22 centuries the admiration and delight of all who have seen it. With the words of the noble author before quoted, all will probably agree. 'In the majestic simplicity of its general design, the grandeur of its proportions and the exquisite taste and skill displayed in the execution of its ornamental parts, it is undoubtedly the most perfect, as well as deservedly the most celebrated, production of Grecian art.' (Lord Aberdeen's Inquiry, p. 142.)

"When Sir George Wheeler and Dr. Spon visited this edifice, A. D. 1676, the temple was entire. In the year 1687 Athens was besieged by the Venetians, when a shell falling on the structure, the Parthenon was reduced to the state in which it was seen by Stuart and Revett. This celebrated temple had at each end a portico of 8 columns in front, and on the sides were 30 more, making 46 to the colonnade which surrounded the cell of the building. The breadth of the front of the building is 101 feet, the length 227 feet on the upper step, and the height 65 feet. The columns are 6 feet 1 inch in diameter, those at the angles are 2 inches more, and the distance from column to column is 7 feet 11 inches. The sculptures of the Parthenon extended to a range of 1,100 feet, consisting of upwards of 600 figures. Behind the great porticos, there are two of smaller dimensions, which are called the pronaos and posticus; these inner porticos have in each 6 columns. The portion of the building enclosed by the columns was divided by a cross wall into two parts, whereof the larger, called the cella or naos (ship) answered to our nave; the smaller part, in which was the public treasury, was called the opisthodomus. In this part, according to Wheeler, were six columns, but no vestige remains of them. The cell, where was placed the famous statue of Minerva by Phidias, was open to the sky in the centre (whence such a temple was called hypæthral from the Greek *ὑπὸ*, under, and *αἰθὴρ*, *æther*, air), having a colonnade round it, supporting a gallery above, in which was a second row of columns. These have all likewise disappeared, but the circles were traced by Stuart on the pavement whereon the lower range of columns had stood. The sculptures in the pediment of the eastern front represented the introduction of Minerva among the assembled gods, giving us an admirable idea of the mythology of the ancients, each of the deities being distinguished by his or her peculiar symbols. The metopes or spaces between the triglyphs, recorded the battles between the Centaurs and the Lapitha, a fruitful subject of illustration among poets as well as sculptors, and a favourite theme with the Greeks, from their famous heroes Hercules and Theseus bearing a prominent part in the contest; fifteen of these metopes are in the British Museum. The western pediment contained a representation of the contest between Minerva and Neptune (in the opinions of Colonel Leake and Mr. Cockerell, this contest was in the eastern pediment); but the most celebrated sculpture is that which represents the Panathenaic procession: this composition is 3 feet 4 inches high, and was continued in the frieze quite round on the outside wall of the cell of the temple. The figures of these groups, which occupy a length of 520 feet, are generally allowed to be of finer execution than those in the metopes.

"'With respect to the beauty of the basso-relievos,' says the great Flaxman, 'they are as perfect nature as it is possible to put into the compass of the marble in which they are executed, and that of the most elegant kind.' Another sculptor, Rossi, calls them 'jewels.'

"The Panathenaic procession, which, with fifteen of the metopes, formerly likewise belonging to the Parthenon, now adorns the British Museum, under the name of the Elgin Marbles, consists, as before observed, of many hundred figures. Among them are several equestrian figures, which are designed in the most admirable manner, and are remarkable for the varied attitudes of the horses, and for the ease and grace of the riders. Other figures in the procession are charioteers in their cars, one of whom is supposed to be the victor in a chariot-race, as a man is about to crown him. Then follow men carrying trays; then the sacrificers and the oxen, each Athenian colony sending an ox to this great festival. Females are also present; some carrying dishes or pateras, others bearing pitchers of water. Two of the young females had situations of great importance, their office being to carry the sacred baskets. Several gods and goddesses are likewise introduced: they are seated to denote their dignity. These figures are all in high relief, so that they are visible at some distance; and although it is impossible now to decide how much was the actual work of Phidias himself, it is highly probable that they, as well as the other sculptured decorations of the temple, were all designed by the great master. (It is known, he practised the art of painting previously to that of sculpture.) It has been ascertained, that they are as carefully finished behind as before, and in places which could not be visible when once they had reached their destination; hence, it is justly inferred, that all these sculptures had to undergo the ordeal of a searching criticism of the public eye, before they left the artist's studio.

"In addition to the embellishments already described, which adorned the temple, Phidias made the celebrated statue of Minerva which stood in the cell, or open part of the building. This figure, formed of ivory and gold, was thirty-seven feet high. Pausanias says that it stood erect; the goddess was represented with her garments reaching to her feet, helmeted, and with a Medusa's head on her breast; in one hand she held a spear, and on the other stood a Victory of about four cubits high. Monsieur Quartreinere de Quincy, who bestowed great pains in investigating the subject of ancient sculpture, has calculated, that the value of the gold employed on this famous statue was equal to £130,000 sterling.

"A fac-simile of the Parthenon, as far as the architecture is concerned, has been erected at Edinburgh, on the Calton-hill, in a situation resembling the Athenian Acropolis. Mr. Bankes proposed it as the model for the Fitzwilliam Museum, at Cambridge. The proportions of its Doric order are imitated in the portico of Covent Garden Theatre.

"The Temple of Theseus which is generally reckoned to belong to the age of Pericles, and earlier in date than the Parthenon, is one of the noblest monuments of Athenian magnificence, and, in the the time of Stuart, was one of the most perfect. 'The sanctuary of Theseus was raised by the Athenians after the Medes were at Marathon, when Cimon, the son of Miltiades, expelled the people of Scyros, a retribution for the death of Theseus, and carried his bones to Athens.' (Pausanias.)

"Plutarch places this event at a date which is generally considered equivalent to the year 467 B.C. The Parthenon is, by some writers, believed to have been commenced about 448 B. C. (the year in which Cimon died), and to have occupied sixteen years in erection. In the opinion of Lord Aberdeen, 'The temple of Theseus may be considered as nearly coeval with the buildings of the Acropolis, or perhaps of an origin somewhat earlier.' (Inquiry, p. 143.) The Theseum is built of Pentelic marble, and is raised upon two steps, being peculiar in this respect. The portico at each end consists of six columns in front; at each side are eleven columns, not counting the angle-columns of the portico; so that the building is surrounded by thirty-four columns. Behind the porticos are others, consisting of only two columns between antæ; there are three deep recesses, which lead to the cell. There is here no division in the internal part, where it is presumed that the remains of Theseus were buried. This temple is 104 feet long, 45 feet wide, both dimensions being taken on the upper step, and 25 feet 2 inches high; the diameter of the columns is 3 feet 3 inches. The sculptures in the metopes were representations of the exploits of Theseus, and of the labours of Hercules, who appears to have been honoured in this temple, as well as Theseus, his kinsman and friend. The frieze of the wall behind the eastern portico was adorned with a representation of a battle and victory, in which six of the divinities are present; three of whom are Jupiter, Juno, and Minerva. Among the combatants is one of superior stature and dignity, hurling at his assailants a stone of prodigious size; he is supposed to be Theseus, in the act of overthrowing the Persians at Marathon. The battle between the Centaurs and Lapithae was sculptured on the wall behind the western portico. The sculptures (of which are casts in the British Museum) are, according to Pausanias, supposed to be the work of the famous Michon.

"It has been discovered of late years, that the Parthenon, and nearly all the buildings at Athens, had colours applied to their different enrichments; but it does not appear that the advocates of Greek polychromy have clearly made out that this practice belongs to the pure age of Pericles and Phidias. It is much more likely to have been introduced long after their time.

"The temple of Corinth is probably the most ancient specimen of the Doric order in existence. It is built of a rough porous stone, and is supposed to have had porticos of six columns, five of which remain in the western front, and six are seen on one flank; its arrangement, perhaps, was similar to that of the temple of Theseus; the columns are 5 feet 10 inches in diameter, and their shafts, 21 feet in height, are composed each of a single stone. There is no sculpture upon the temple, as all above the architrave has long since disappeared. Since Stuart's time, five of the columns which appear in the flank, in his work, have been blown into fragments by gunpowder, to assist in building the house of a governor of Corinth. Lord Aberdeen observes, 'It has been said, that this temple was dedicated to Venus; but, in fact, no information is to be obtained respecting its origin. Whatever may have been its destination, no one can doubt, from the appearance of the ruins alone, that they formed part of a structure of the most remote antiquity.

"One of the noblest efforts of the genius of Ictinus is to be seen in the temple of Apollo Epicurius, in Arcadia. It offers many architectural peculiarities, and exhibits a greater variety of details than are usually met with in the Grecian temples.

"Pausanias, speaking of this building, which is at Bassæ, near Phigalia, states, that 'the temple of Apollo Epicurius (the deliverer), which, together with the roof, is of stone, surpasses all the temples which are in Peloponnesus (with the exception of that in Tegea) in the beauty of the stone, and harmony of the proportions.'

"The entrance to the temple was facing the north, contrary to the usual practice. The temple was 47 feet broad, 125 feet long, and ascended by three steps. There were six columns in each front, and fifteen on each flank, all 3 feet 7 inches in diameter, and 19 feet 6 inches high. In the interior of the cell were *attached* columns, of the Ionic order, of a very ancient character, (together with a single insulated column of the Corinthian order,) over which, on the four sides of the cell, ranged the sculptured frieze. The columns and walls are constructed of the hard and beautiful limestone of the country, but the sculpture and roof are of marble. It would not appear, from Mr. Donaldson's description, that any decorations existed in the pediments, or metopes. 'The arrangement of the engaged columns of the cella is very peculiar. A similar disposition has never hitherto been found, though, perhaps, in the temple of Apollo Didymæus, at Branchidæ, near Miletus, the projecting pilasters conveyed the same effect, less distinctly expressed. The spaces between the Ionic columns seem to afford admirable situations for statues, as they would be secured by the columns on each side, and by the soffits above, from the occasional inclemencies of even that mild atmosphere.'

"The Propylæa, a Doric structure, forms the only entrance to the Acropolis of Athens. Pausanias says, 'There is only one entrance to the Acropolis, it being in every remaining part of its circuit a precipice, fortified with strong walls. The entrance was fronted by a magnificent building, called the Propylæa, covered with roofs of white marble, which surpassed, for beauty, all that he had before seen. This was begun during the ministration of Pericles, B.C. 437, and was finished in five years (Mnesicles being the architect), at an expense equivalent to £464,000. The front of the Propylæa consisted of six columns, and at the back of the building was a small portico; between the two was the wall, in which were five gates. The centre reached from the platform to the height of the entablature; it was 13 feet wide, and was used on solemn occasions for the chariots. The road-way was between two rows of Ionic columns; a gate of 6 feet wide, and of less height than the centre, occupied each side, and beyond them were two smaller doorways, which were used for ordinary passage. On the right of the Propylæa was a building called the temple of Victory-without-wings. On the left, was an edifice adorned with paintings, the work of Polygnotus; the subjects chiefly from Homer; and it is supposed, that herein stood a group of the Graces, draped, the performance of the celebrated Socrates, who pursued his father's profession of a sculptor, until he devoted the energies of his wonderful mind to the study of philosophy.

"Similar in plan to the building at Athens, is the Propylæa at Eleusis, and, in design, little inferior to its Athenian prototype. It was erected, together with the Temple of Ceres, to which it served as a vestibule, and the connected Temple of Diana-Propylæa, by Pericles, for the solemnization of the Mysteries of Ceres, the most sacred among the religious rites of Greece.

"The Propylæa bears a striking resemblance to that at Athens, having at each end a portico of six columns, five gates, and two rows of Ionic columns within. To make the central opening large enough to admit chariots, the usual arrangement is departed from, by the addition of a triglyph in the frieze over the space between the central columns. The pavement, the steps, and every part of the superstructure, were of fine Pentelic marble; the roof, also, was covered with marble slabs, worked into the shape of tiles; the joints of these tiles were covered with others, which follow the slope of the roof, to prevent the admission of water. This ingenious contrivance was the invention of Byzes, of Naxos; and it was so highly appreciated by the Greeks, that they honoured the inventor with a statue. The termination of the joint-tiles was formed by an upright tile, on which was painted the lotus. Byzes lived 580 years before the Christian era.

"After passing through the Propylæa at Eleusis, the votaries had to enter another building, forming a second vestibule to the grand mystic temple. The order in this building was the Ionic. Beyond this vestibule was the Temple of Ceres, which was protected by the sacred inclosure, or wall. In front was a portico of twelve columns, which have the peculiarity of not being fluted from top to bottom, as Doric columns usually are, but their shafts plain throughout their whole height, with the exception of a part at their top and at the bottom of each, about 7 inches high, which is fluted. Within the temple, according to a passage in Plutarch, it is imagined there were two ranges of columns, with others over them. The architect of this building was Xenocles.

"In front of the Eleusinian Propylæa was the temple of Diana Propylæa, presenting an arrangement in its porticos differing from any examples we have hitherto noticed; instead of columns at its angles, antæ, which are often improperly called pilasters, terminate its fronts: the distinction between the Greek antæ and Roman pilasters is very great. The former were never diminished (or so slightly as not to appear so to the eye), and were not fluted, their capitals consisted of straight lines; whereas the Roman pilasters were diminished like their columns, frequently fluted, and their capitals generally resembled those of the accompanying columns. The temple of which we are speaking, was small, with a front measuring only 20 feet 10 inches on its upper step; its length 39 feet 9 inches, and its height to the top of the cornice 20 feet 6 inches; the building was of Pentelic marble, but with roof-tiles of baked clay.

"At Olympia, in the Peloponnesus, once existed a magnificent hexastyle temple of Jupiter, of which the dimensions are presumed to have been 230 feet by 95 feet. Mr. Dodwell measured a column, of which the diameter was 7 feet 3 inches. Within this building was enshrined the master-piece of Phidias, his statue of Jupiter, of gold and ivory, 50 cubits high.

"At Rhamnus in Attica, on the sea-coast, is a fine Doric temple of Nemesis, which stands in a noble situation, elevated 300 feet above the sea. Pausanias says that it was built by Alcemenes, the pupil of Phidias. This temple, and a smaller one adjoining it, dedicated to Themis, were inclosed by a wall of white marble, remains of which are yet to be traced. The temple of Nemesis had at each end porticos of 6 columns, and flanks containing 12 each; the external columns, like those to the temple of Ceres, were only fluted at top and bottom. It is ascertained that the mouldings of the cornices were painted red, a practice adopted by the Greeks in other temples. The details in this building are very fine. Close to it is the small building which bears the name of Themis, but which is supposed to be the original temple of Nemesis, injured by the Persians; and the Greeks not caring to repair a structure desecrated by their enemies, chose rather to erect another. The smaller building is in fact of an earlier style, being one of the class called *in antis*, a mode of building well known to be of great antiquity. It is very similar to the small temple of Diana at Eleusis.

"At Sunium, which is a promontory forming a southernmost point of Attica, are the remains of two Doric buildings; one is a Propylæa, the porticos of which have two columns placed between antæ. The other building is a temple dedicated to Minerva-Sunias. The portico consisted of 6 columns, and 10 have been ascertained on the flanks; but the building is so much in ruins, that the exact number cannot be clearly made out. The structures are of marble, highly finished, and belong to the best ages of Grecian architecture. 'The striking remains of the temple of Minerva on the promontory of Sunium are, in all probability, to be attributed to the same authors.'

"At Thoricus, about eight miles to the north of Cape Sunium, are the remains of a singular Doric building, which was found half-buried in the sand, which being cleared, a portico was discovered, having 14 columns on each front, and 7 in each return; and as no remains of walls were discovered within the area, it is conjectured that the building was not a temple, but an open portico, perhaps an agora; these columns are only fluted at their upper and lower extremities.

"Leaving Attica, we shall now pass into Sicily, where we find the remains of one of the most astonishing specimens of Doric architecture, surpassing in magnitude all that we have hither to noticed. This is the celebrated temple of Jupiter Olympius at Agrigentum, now called Girgenti, and which Virgil styled, from a neighbouring river, Agragas. It was the wealthiest and most powerful city of Sicily, and according to Diogenes Laertius, contained within its territory 800,000 persons. 'The temples of Agrigentum, numerous and costly as they are, appear to have arisen during little more than a single century. The prosperity and independence of the city commenced with Theron, about 450 years before Christ; after the battle of Himera (fought on the same day as that of Salamis), his thoughts were entirely turned to its decorations, and the Carthaginian prisoners were made to assist by their labour in the erection of trophies to perpetuate the glory of their conquerors. The Agrigentines continued in this employment until a second and more successful invasion of the Carthaginians found them occupied in completing the temple of Jupiter Olympius, the greatest in the island, and one of the most stupendous monuments of ancient times.'

"The temple of Jupiter was, in its proportions, truly colossal, and it ranked among ancient Greek temples as second only to that of Diana at Ephesus, (which was 425 feet long, and 220 feet in breadth); it was 369 feet in length, its breadth 182 feet, and its height 120 feet, in which dimensions Mr. Cockerell is of opinion that it exceeded the building at Ephesus. Unlike other Doric structures, in this temple the columns are not detached from the walls, thus they present only the appearance of half-columns; these, however, are 13 feet in diameter, so that if the columns had been disengaged, their circumference would have been more than 40 feet, a dimension exceeding the largest columns in Egyptian architecture. (The Roman-Doric column, erected by Sir Christopher Wren, called the Monument, is only 15 feet in diameter, though of a proportion much loftier). The echinus of the capitals is formed of two large stones, each weighing 21½ tons; the triglyphs are in single stones, each weighing 12¼ tons; few of the stones employed in the entablature weigh less than 8 tons; and a man could stand in one of the flutings of the columns. As compared with a modern building, we may observe, that the width of the cell is two feet more than the nave of St. Paul's, and the height exceeds it by 18 feet. The front portico, in which were 7 columns, had the battle between the Gods and the Titans represented in the pediment; and in that of the other portico was sculptured a representation of the siege of Troy, in which each hero was distinguished by the peculiarity of his dress and arms. (Diodorus). In the interior was a double row of pilasters ranging like the pillars of a cathedral; the attic story above the pilasters was supported by the figures of the rebellious and defeated giants, most appropriately placed there to contribute to the glory of Olympian Jove, whose power they dared to oppose. The proportions of the Titans are as vast as the other parts of the structure: being 25 feet in height; with heads alone 3 feet 10 inches, and chests 3 feet across.

"The other temples of Agrigentum were very numerous; in the year 1790, by Sir Richard Colt Hoare, 11 could be traced in different stages of dilapidation. The next in size to that of Jupiter was one dedicated to Hercules, which was 154 feet long, and 55 feet broad, having 6 Doric fluted columns in each front, and 14 on each flank; the columns were 7 feet in diameter at bottom, and only 4 feet 10 inches below the capitals, showing a very great diminution.

"At Selinus, or Selinuntium, (so called from the great quantity of parsley, σελινον), on the southern coast of Sicily, were six magnificent Doric temples, probably the largest ever erected in this style, and which appear to have been overthrown by an earthquake. One of these is believed to have been 331 feet long, and 161 feet broad, with columns 60 feet high; a stone, which is supposed to have formed part of an architrave, is 40 feet long, 7 feet deep, and 3 feet thick, and some of the columns were found to be 12 feet in diameter, and others 10 feet 10 inches, and 48 feet high. Near these ruins were the remains of a hexastyle-peripteral temple, computed to have been 186 feet long, and 76 feet broad on its upper step, and to have had 36 columns in all, 6 feet 8 inches in diameter. Another temple, not far from these, was 232 feet by 83 feet on its upper step, with fluted columns, 6 in each front, and 16 on the flanks. The other three temples are supposed to have been unfinished when they were thrown down. One of these had porticos of 7 columns in front with 17 on each flank; another had 6 columns in the porticos, and 16 on each flank. In the quarry near Campo Bello, whence it is presumed the materials were derived, are yet some shafts of columns, 10 feet in diameter, and one of 12 feet, still joined to their natural bed of stone. Mr. Wood measured one block of an architrave, 26 feet 2 inches long, 4 feet 9 inches wide, and 6 feet 10 inches high. The city was, 409 B. C., nearly destroyed by the Carthaginians.

"At Segeste, the ancient Ægesta, is a famous Grecian-Doric temple, almost entire, standing in a splendid situation on the brow of a precipice. There are 6 columns in each front, and 14 at each side, making 36 in all; these are about 30 feet high; the length of the building is 190 feet, its width 78 feet; the stones composing the architrave are of great size, and one extends over two columns: the date of it erection, as well as the nature of its dedication, are unknown. The columns, which are fluted, are 6 feet 7 inches in diameter at the base, and 4 feet 11 inches below the capital.

"In a notice of Grecian-Doric architecture, we must not omit to speak of some ancient temples in Italy, namely, at Pæstum, the ancient Posidonium, so denominated from its tutelary God, Neptune, who, by the Greeks, was called Ποσειδων. From its unhealthiness, the place had, in very early times, fallen into decay, and Augustus visited the temples as venerable antiquities in his day; but they were completely forgotten, until in 1755 discovered by an artist of Naples. Among the ruins, which are very extensive, are three buildings of imposing character, two of them are temples. The temple of Neptune, raised on 3 steps, was 194 feet long, and 78 feet broad, having 6 fluted columns in each front, and 14 (including the angular ones) at each side. The entablature and capitals were equal to half the height of the columns, of which the shafts only were 27 feet, the lower diameters 6 feet 10 inches, the upper diameter 4 feet 8 inches, and with 24 flutings; the intercolumns are 7 feet 7 inches wide. The cell is 90 feet by 43 feet, having 14 columns in 2 rows, with shafts 16 feet 11 inches high, 4 feet 9 inches in diameter, and with 20 flutings. These columns support a deep architrave, on which rises another set of columns, about 11 feet high. The largest stone in this building is 13 feet 8 inches by 4 feet 8 inches by 2 feet 3 inches. Professor Wilkins, in this temple, detects a close resemblance to the temple of Solomon, (Prolusiones). The temple of Ceres is in a lighter style than the former building. It is 108 feet long, and 48 feet broad, with the same number of columns, as in the temple of Neptune; the diameter of the columns is at bottom 4 feet 3 inches; at top, 3 feet 3 inches; and their shafts have 20 flutings. The third building is called a Basilica, because there is no appearance of a cell, or altar. It is 170 feet long, and 80 broad; and it is raised on three steps, having nine columns in each front (the only example of such arrangement), and eighteen on each side, with the lower diameter 4 feet 6 inches, and 20 flutings. Both fronts have a vestibule, and the interior was divided by columns. The date of these structures is unknown. One of the most ancient Doric temples in Greece is in the island of Egina; this was a hexastyle temple, dedicated to Jupiter Panhellenius. "It is said by Pausanias to have been built by Eacus, considerably before the Trojan war, a story wholly incredible, but which serves to prove that it had outlived all tradition of its real origin. It is still nearly entire." There were twelve columns on each flank, making thirty-six in all, of a porous stone, covered with a thin stucco, and the architrave and cornice were painted in colours. Fifteen statues, formerly belonging to this temple, are now at Munich: they are supposed to represent the Greeks and Trojans contending for the body of Patroclus; they have been restored by Thorwaldsen. Illustrations of the Temple of Jupiter have been published by Mr. C. R. Cockerell, and have proved a valuable addition to our knowledge of Doric architecture.

Modern examples of this order are to be seen in Covent Garden Theatre; the Corn Market, Mark Lane, where the details of the monument of Thrasyllus are copied; in the new galleries and entrance of the British Museum, where polychrome is introduced; and at the entrance-gateway to the Terminus of the North Western Railway.

The origin of the Doric order has ever been a disputed point amongst writers upon the subject, some following one theory, and some another. Vitruvius, whose opinion is valuable, as coming from the oldest writer upon architectural matters, will have it, that the earliest stone temples of Greece were but imitations of the wooden structures previously employed, and that the members of the Doric order, both structural and ornamental, owe their origin to similar parts in the less permanent building. This primitive mode of building is supposed to have been similar, in some respects, to the log-houses erected by colonists of the present day, consisting of trunks of trees fixed vertically in the ground, at short distances from each other, and forming the support to the several members of the roof. From the various portions of this timber construction, are supposed to have been derived those of the later stone edifice. The following opinion as to some of the corresponding parts of the two kinds of structures, is given by Vitruvius:

"In the upper part of all edifices, timbers, called by various names, are disposed, which, as in names so in uses, differ. The trabes are those laid over the columns, parastatæ and antæ, in the contiguations and floors. If the span of the roof is great, under the culmen, in the top of the fastigium, are disposed columens (from whence columns derive their name), transtræ, and capreols; but if the span is small, columens and canthers, projecting to the extremities of the eaves. Above the canthers are the templats, and over them, but under the tiles, are the assers, projecting so far as to shelter the walls. Thus each, according to its use, has its proper place and order. This disposition of the work, the artificers, when they erected sacred edifices, imitated in sculptures of stone and marble; and this invention the ancient workmen thought proper to pursue. Thus, whenever they constructed any building, they laid the joists from the interior walls to the extreme parts, then built up the interjoist, and, to give the work a pleasing appearance, adorned the top with a cornice and fastigium; then, as much of the joists as projected beyond the wall they sawed off, which, appearing unhandsome, they made tablets, like triglyphs now in use, fixed them against the sawed ends of the joists, and painted them in wax, that the sectures of the joists might not offend the sight. Thus, the triglyphs, interjoists, and opæ, in Doric work, had their origin from the disposition of the timbers of the roof.

"Afterward, in other works, some made the canthers, that were perpendicularly over the triglyphs, to project outward, and carved their projecture; hence, as the triglyphs arose from the disposition of the joists, so the mutules under the corona were derived from the projecture of the canthers; wherefore, in stone or marble structures, the mutules are represented declining, in imitation of the canthers; and, also, on account of the droppings from the eaves, it is proper they should have such declination.

"From this imitation, therefore, arose the use of triglyphs and mutules in Doric work; for it cannot be, as some erroneously assert, that the triglyphs represent windows; because triglyphs are disposed in the angles, and over the quarters of the columns, in which places windows are not permitted; for, if windows were there left, the union of the angles of buildings would be dissolved; also, if the triglyphs are supposed to be situated in the place of the windows, by the same reason, the dentils in Ionic work may be thought to occupy the places of windows; for the intervals between the dentils, as well as between the triglyphs, are called *metopæ;* the Greeks calling the bed of the joists and assers, *opas* (as we call it *cava, columbaria*); so, because the interjoist is between two opæ, it is by them called *met-opæ.* As the triglyphs and mutules in the Doric order are founded upon those principles, so the dentils, in the Ionic, derive their proper origin from the workmanship; and as the mutules represent the projectures of the canthers, the dentils in the Ionoic order are in imitation of the projecture of the assers."

This theory is a very plausible one, so far as it goes; and were we unable to account for such matters in a different way, it might be passed over as correct, but for one objection, and that alone at once throws discredit upon the whole account. The difficulty may be put in this way: if the prototype of the stone structure were constructed of timber, how comes it, that the proportions of the former are of so heavy and massive a character? and how is it, that the columns are so thickly set? Timber construction would have led to very different results; slenderness and lightness are the characteristics of buildings of such material, and so, necessarily, of its antitype. The reverse, however, is the case; and not only so, but we find, that the older the edifice, (and therefore the more similar to its prototype) the heavier, also, its proportions; whereas, if Vitruvius's theory be correct, the contrary should be observable. But, besides this, we can account for all the details alluded to by Vitruvius in a very different, and, to our mind, far more satisfactory manner, as we shall attempt to explain presently.

As regards the date of the introduction of this style of building into Greece, nothing can be stated with certainty; neither can it be satisfactorily ascertained in what locality it first appeared: great differences of opinion exist on both subjects. Vitruvius, as usual, decides the matter without any apparent difficulty. He says:

"The most ancient and first invented of the three kinds of columns is the Doric; for, when Dorus, the son of Hellenus, and the nymph Opticos, reigned over all Achaia and Peloponnesus, the temple of Juno, in the ancient city of Argos, was erected, and this order happened to be used in the fane. The same order was also used in the other cities of Achaia before the laws of its symmetry were established.

"Afterward, when the Athenians, according to the responses of Apollo and Delphos and the common consent of all Greece, transplanted, at one time, thirteen colonies into Asia, apportioning to every colony a leader, they gave the chief command to Ion, the son of Xuthus and Creusa, whom also the Delphian Apollo acknowledged for his son. These colonies he conducted to Asia, seized on the territory of Caria, and there founded many large cities, as Ephesus, Miletus, Mynuta, (which last was formerly overflowed with water, and its rites and privileges, by Ion, transferred to the Milesians), Priene, Samos, Teos, Colophon, Chios, Erythræ, Phocis, Clazomenæ, Lebedus, and Melite. This latter, on account of the arrogance of the citizens, was destroyed in the war declared against it, by the unanimous determination of the other cities, and, in its place, by the favour of king Attalus and Arsinoe, the city of Smyrna was received amongst the Ionians. When those cities extirpated the Carians and Leleges, they, from their leader, Ion, called that territory Ionia.

"There they began to erect fanes, and constitute temples to the immortal gods. First, they erected the temple of Apollo Panionias, in the manner they had seen it in Achaia; which manner they called Doric, because they had seen it first used in the Dorian cities. In this temple they were desirous of using columns, but were ignorant of their symmetry, and of the proportions necessary to enable them to sustain the weight, and give them a handsome appearance: they measured the human foot, and finding the foot of a man to be the fifth part of his height, they gave that proportion to their columns, making the thickness of the shaft at the base equal to the sixth part of the height, including the capital. Thus the Doric column, having the proportion, firmness, and beauty of the human body, first began to be used in buildings."

The former part of this statement may or may not be correct, but if its credit stands upon an equal footing with that of the latter part, we shall not be justified in placing much confidence in it; for ere we can give credence to his opinion respecting the proportions of the order, we must suppose the men of that age to have been of a very different description to those of the present day.

If Vitruvius be correct in his supposition regarding the introduction of the order, we must suppose several temples to have been erected in this style before Homer's time, but, if so, it would appear strange that one, generally so minute in his descriptions of persons and places, should not have given us some description of them. It is true, that he alludes to three or four temples,—to those of Minerva at Athens and Troy, and of Apollo and Neptune at Delphi and Ægæa, respectively,—still he has not given any description of them, and leaves us entirely to conjecture: according to the account of Pausanias, the temple at Delphi was nothing better than a hut covered with laurel and branches. But if we discard the account given by Vitruvius, we shall not be much nearer the goal, having no data to work upon. If we allow the name of the order to give us some clue as to its origin, we are still in the same predicament, for many provinces bore the name of Doris; and at best, as Lord Aberdeen remarks, a name is often the least satisfactory mode of accounting for the birth of the thing which bears it. Many are of opinion that the order was first employed in the cities of Corinth, Sicyon, and Argos, shortly after the return of the Heraclidæ, but others suppose it to have originated amongst the colonists of Asia Minor, and there certainly does appear some reason for supposing that the temples here were far in advance of those in Greece-proper.

In whatever part of Greece the Doric order was first employed, there seems very good reason to believe that it had its origin in Egypt, or rather perhaps that the temples of that country suggested the idea; nor is there any *prima facie* grounds for rejecting this supposition, for we know, in the first place, that Greece was, at least, to some extent, colonized from Egypt; Cecrops was from that country, and Cadmus from one not far distant; and besides this, we know that in after times the Greeks were in the habit of trading with Egypt, and were held in so great esteem by Amasis, that he gave them the city of Naucratis, and afforded them every encouragement and convenience. Another internal evidence of the connection of the two people is afforded in the identity of their mythology.

But let us consider the architectural features observable in the buildings of the two countries. In general appearance they agree; they are both of massive proportions, and both consist of similar parts, columns, entablature, and such like. Nor are they less similar in detail; in Egyptian temples we have an entablature consisting of three members, architrave, frieze, and cornice, the first of which, like the Doric, is comparatively plain, and the last simple, but bold. The similarity of the frieze in both styles is remarkable, extending even to triglyphs and mutules, and in both styles are those features equally essential. The similarity of the columns may not be at first so apparent, although we can point out many Egyptian columns without bases, with square plain abaci, and may suggest the probability of the Grecian echinus being copied from the lower portion of the bulging or cushion-capitals of Egypt: the annulets round the necking of the capital are likewise of very frequent occurrence in that country. As regards the rest of the column, it is true, speaking generally, that Egyptian specimens are not fluted, neither do they diminish, like the Greek, from the lower to the upper diameter; instead of concave flutes, however, we have convex rods, or probably reeds; and if the latter, we have only to divide them vertically down the centre, and we have the Doric flutes. But even if this last idea be too fanciful, the difference between a cabled and fluted column is not so great, the ornamentation is decidedly of a similar character; end even if this be disallowed, there are specimens of fluted columns in Egypt, and specimens which altogether bear a very marked resemblance to the Grecian-Doric. These columns were first noticed by Mr. Barry, who considers them of greater antiquity than any Grecian specimens. The first is a portico of two fluted columns in antis, about 5½ diameters in height, and surmounted by a plain abacus; the flutes are 20 in number, and of shallow contour; the columns are without bases. The next example is from Kalaptchic on the Nile, the abacus of which is square, and 11 inches thick; the shaft, which has a trifling diminution, is 7 feet 8 inches high, and 3 feet 2 inches diameter. The circumference is in 24 divisions, whereof 4, which are at right angles with each other, are flat faces, covered with hieroglyphics, and the other intervening ones are sunk into flat elliptical flutes a quarter of an inch deep. Another specimen is to be seen at Amada in Nubia, consisting of two columns, one of which is a simple parallelopiped, and the other, at the corner of the building, is both cylindrical and fluted, leaving, however, a square abacus similar to that of the parallelopiped, which, in this case, is the only capital; the base is also of a square plan. Of these two columns, the former is evidently the earlier design, the latter, previously of the same shape, whether for convenience or otherwise, has been rounded off at the corners and somewhat ornamented.

Were it allowable to select portions from these examples and place them together at discretion, there would be no great difficulty in forming a very perfect specimen of Grecian-Doric, but even without such a metamorphosis, we suggest, there can be no difficulty in perceiving a great and indubitable similarity between the structures of Egypt and the earlier ones of Greece, the likeness being more striking in some examples than in others, yet not being entirely absent in any. We may conclude, therefore, we presume, that there is a very strong probability of the Doric order having been derived from the architecture of Egypt.

This order, as practised by the Romans and Italians, differs in some essential particulars from that above described, and in process of time its original character seems to have been all but entirely lost, the identity being evidenced only by the remains of some few details. The few points in which the resemblance between the Greek and Roman orders is preserved, are—the employment of triglyphs and metopes in the frieze, and of mutules in the corona, the fluting with arrises instead of fillets, when indeed flutes were introduced, and the general form of the capital consisting of echinus and abacus. The distinctions are much more numerous, amongst which may be mentioned the elongation of the shaft and the not unfrequent absence of flutes; the addition of a base, variations in the form of the capital and of the several members of the entablature, the amplification of mouldings and such like; so that were two examples, one of each kind, placed before a person unacquainted with the subject, he would have greater difficulty in tracing their resemblance, than in pointing out their incongruities.

The height of the column is increased from six to eight diameters, and in some cases, as recommended by Vitruvius for porticos, to eight and a half. It is either fluted or left plain, and sometimes is partially fluted, the channels extending about two-thirds of the shaft, the remaining portion below, from the base upwards, being left blank.

The addition of the base follows very naturally the elongation of the shaft, for were it still to be omitted, the lower portion of the column would look too small, and would give to the edifice an appearance of weakness; the columns would seem unsteady; whereas in the Greek examples, the massive proportions and the rapid spreading of the shaft from the capital downwards, gives the effect of strength and stability. The base generally used is that termed the attic, and consists of a plinth, a torus, a hollow moulding or scotia with a fillet above and below it, upon the uppermost of which is another torus and fillet, out of which the shaft rises with an apophyge; a simpler base, however, is sometimes made use of, comprising only a torus and two shallow fillets above it, and occasionally merely a plinth and simple fillet.

In the capital, the sunk annulets of the Greek examples are converted into projecting fillets in the Roman; the shaft is separated from the cap by an astragal which gives much greater distinctness to the necking, which again is sometimes relieved with rosets and buds, or other ornament. Above the neck are three flat annular fillets, and these above the ovolo surmounted by the abacus. The ovolo, however, is not of so much importance as in the Greek order, nor of the same severe contour; the abacus likewise is much shallower, and has the addition of mouldings on its top. The height of the capital is equal to $\frac{1}{2}$ a diameter, or 1 module, but this is not always the case, for in the Theatre of Marcellus at Rome, it is 33 minutes, and in the Coliseum as much as 38.

The architrave is often similar in appearance to the Greek, but is of less height, being equal to only two-thirds of the frieze, or half a diameter; in a few instances, the architrave is composed of two fascias. The new frieze is also very similar to the old one, with some slight exceptions, the mutules being frequently filled with ox-skulls and patteras, and sometimes left plain; the capitals of the triglyphs are of greater projection than before, and are returned at the ends. The triglyphs besides are in Roman examples, invariably placed over the centre of the columns, so that the ends of the frieze are finished with half-metopes, and not with triglyphs as in the Grecian order. In the Coliseum, the triglyphs are entirely omitted.

The cornice differs considerably from the Grecian, having its soffit flat and the mutules square, with a similar interval between them. In Grecian examples, the guttæ generally appear in front below the mutules; but in the Roman, they do not so, and are sometimes even omitted; sometimes the mutules entirely disappear, as in the Theatre of Marcellus, where dentils with an ogee bed-mould are substituted in their place, and the Basilica at Vicenza, designed by Paladdio, has merely a bold ogee and ovolo in their place. The intervals between the mutules are frequently enriched with panels and sculpture. The mutules and band are surmounted by a small ogee moulding, and under them is an ogee or ovolo forming a bed-moulding. The mutules support the cornice-proper, consisting of the corona, an ogee and fillet, and a cavetto finished at the top with a fillet.

With Vitruvius's account of the order, we conclude this article; it runs as follows:—

"Some architects," says he, "have maintained that temples should not be built of the Doric order, because it occasions an imperfection and an inconvenience in the symmetry; for this reason it was rejected by Tarchesius, Pytheus, and also by Hermogenes: the latter, after he had prepared marble materials for a Doric temple, altered them, and from the same materials, raised an Ionic temple to Bacchus. However, it was not because the appearance was unhandsome, or the manner or form ignoble; but because it impeded the distribution, and the arrangement of the triglyphs and lacunars was unsuitable to the design; for it is necessary that the triglyphs should be disposed over the middle quarters of the columns; the metopes which are between the triglyphs, be made as long as high; and the triglyphs over the angle columns be placed at the extremities, and not over the middle quarters. So that the metopes which adjoin the angular triglyphs, are not square, but more oblong by half the breadth of a triglyph. Those who would make all the metopes equal, contract the extreme intercolumn half the breadth of a triglyph; but this, whether it is done by lengthening the metope, or by contracting the intercolumn, is a defect. On this account, the ancients avoided the use of the Doric order in sacred edifices. Following, however, our method, we shall give the explanation of this order, as we have received it from the masters; so that those who attend to these precepts will here find described the rules by which they may erect a temple in the Doric manner, without fault or imperfection.

"The front of the Doric temple, where the columns are erected, is, if tetrastyle, divided into 28 parts; if hexastyle, into 44. Of these parts one will be a module, called in Greek, embates, by which the distribution of the whole work is regulated. The thickness of the column is two modules; the height, including the capitals, 14. The thickness of the capital one module, the breadth two and the sixth part of a module. The thickness of the capital is divided into three parts, of which one is for the abacus with its cymatium, another for the echinus with its annulets; and the third for the hypotrachelion. The columns are diminished in the same manner as described for Ionic columns in the third book.

"The height of the epistylium with the tenia and guttæ is one module. The tenia is the seventh part of a module.

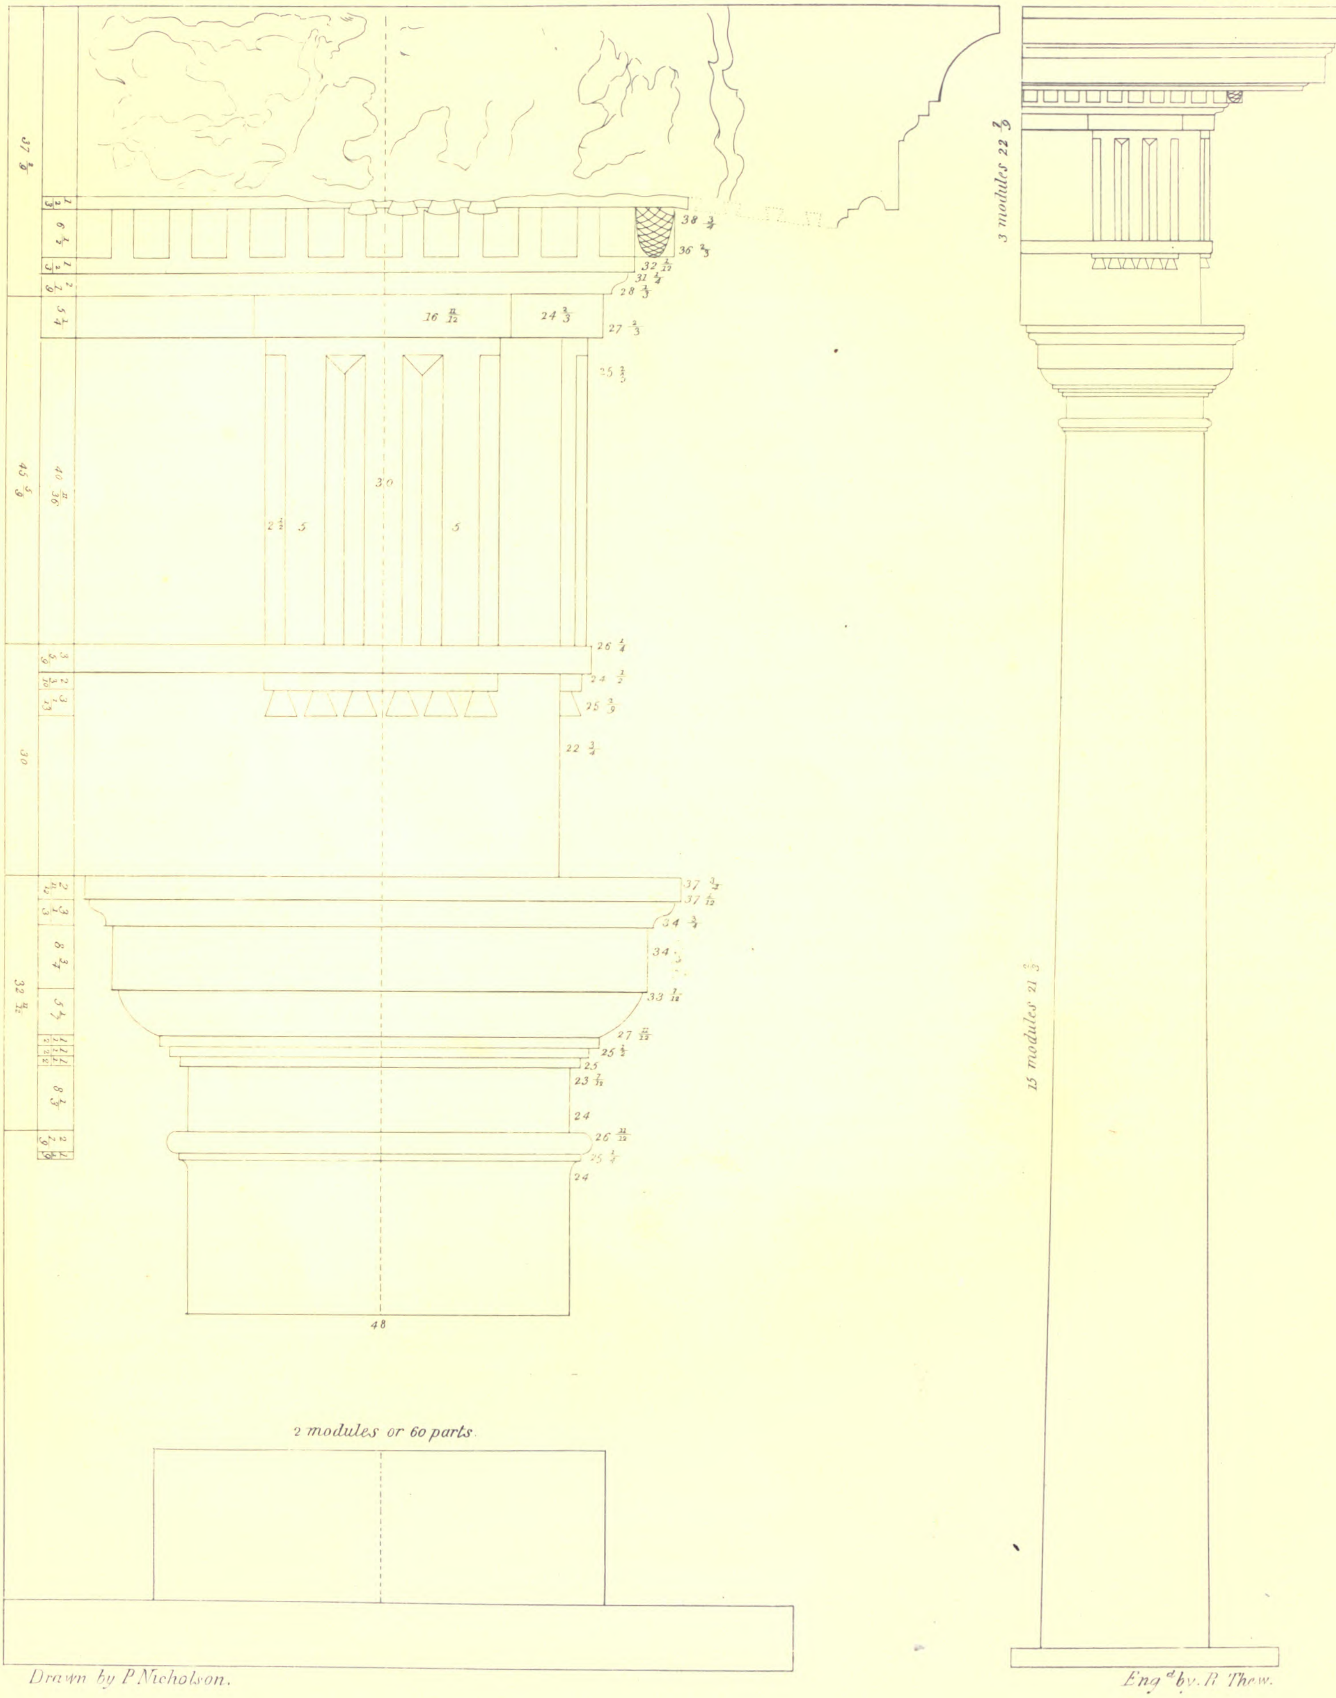
FROM THE THEATRE OF MARCELLUS AT ROME.

PLATE IV.



Drawn by P. Nicholson.

Eng.d by R. Thew.

The length of the guttæ, under the tenia, coincides with the perpendicular of the triglyphs. Their height, with the regula, is the sixth part of a module. The breadth of the bottom of the epistylium answers to the hypotrachelion at the top of the columns.

"Upon the epistylium, the triglyphs, having the metopes between them, are placed; being one module and a half high, and one module broad in front; they are so distributed, that those which happen over the angle, as well as over the intermediate columns, may be perpendicular to the middle quarters thereof; two are left in the intercolumns; and in the middle intercolumn of the pronaos and of the posticus, three; for, by this enlargement of the middle interval, the approach to the image of the god is rendered more commodious and free from impediment.

"The breadth of the triglyph is divided into six parts; of which, five are placed in the middle, two and a half being on either side. The middle one makes the regula, or femur, which the Greeks call meros. On either side this, are the channels, sunk as if imprinted with the elbow of a square. To the right and left of these, another femur is formed, and at the extremities, semi-channels are slanted.

"The triglyphs being thus disposed, the metopes, which are between the triglyphs, are as high as long. At the extreme angles, semi-metopes are impressed, half a module broad. Thus, the metopes, intercolumns, and lacunars, being regularly distributed, all defects will be avoided. The capital of the triglyph is made the sixth part of a module.

"Over the capital of the triglyphs, is placed the corona, projecting the half and the sixth part of a module, having a Doric cymatium below, and another above. The thickness of the corona, with the cymatiums, is half a module. In the under part of the corona, perpendicular to the triglyphs, and to the middle of the metopes, the directions of the viæ, and the distribution of the guttæ, are to be so contrived, that there may be six guttæ in length, and three in breadth. The remaining spaces (the metopes being broader than the triglyphs) are left plain, or have the sculptures of thunderbolts. Near the edge of the same corona a line is enchased, which is called scotia. The tympan, sima, corona, and the rest, are executed in the same manner as has been described for the Ionic order.

"The foregoing is the method for composing diastyle works; but if the structure is to be made sistyle and monotriglyph, the front of the temple, if tetrastyle, is divided into twenty-three parts; if hexastyle, into thirty-five. Of these, one part will be a module, by which the work is to be regulated, as before written. Then, over every epistylium, two metopes and triglyphs are disposed. In the angles, this species is larger than the former by as much as the space of the bisected hemitriglyph. So that there happens in the middle epistylium, under the fastigium, the space of three triglyphs and three metopes, for the enlargement of the middle intercolumn renders the entrance of the temple more spacious, and gives an appearance of dignity towards the statue of the god.

"Upon the capital of the triglyphs the corona is to be placed, having, as before said, a Doric cymatium at bottom, and another at top. The thickness of the corona, with its cymatiums, is half a module. The under part of the corona, perpendicular to the triglyphs and to the middle of the metopes, is to be divided, for the direction of the viæ, and the distribution of the guttæ; all the rest are the same as has been mentioned in the diastyle species.

"The columns are to be wrought in twenty striæ, which, if made flat, form twenty angles; but if they are hollowed, they are to be thus performed: A square is described whose sides are equal to the interval of a striæ; in the centre of the square, the central point of the compasses is placed, and a circular line drawn touching the angles of the square; and that portion of the curve which is between the lines of the circle and the square, forms the hollow of the striæ. Thus, the Doric column will have its proper kind of striature. With regard to the swelling which it has in the middle, it is the same as has been described for Ionic columns."

To exemplify this order, and illustrate the true Grecian Doric, we have chosen that beautiful specimen from the magnificent portico of the Parthenon, at Athens, exhibited in *Plate* I.: the proportions are numbered in minutes, in the usual way. The outline exhibits the profile of the flank, and the finished order shows the profile on the front of the portico, adjoining that represented by the outline.

Plate II.—Outline of the modern Doric.

Plate III.—A finished plate of the same, from Sir Wm. Chambers, who took his example from Vignola.

Plate IV.—Roman Doric, from the theatre of Marcellus, at Rome; showing both the outline and finished plate.

DORMAN, a cross beam.

DORMAN-TREE, a joist, or sleeper.

DORMANT, or DORMER, a window made upon the sloping plane, or side of a roof, with a glass frame perpendicular to the horizon.

Dormer windows occur frequently in domestic edifices of the Gothic style, in which they form a very picturesque feature. Their frequency is especially remarkable in the old halls, &c., of France and Flanders.

DORMANT-TREE, see SUMMER.

DORMITORY, a sleeping room.

DORON, the Grecian palm, whence their bricks were called *tetradoron*, and *pentadoron*.

DOS D'ANE (French), an obtuse ridge, formed by the intersection of two inclined planes. The term is synonymous with our word, coped.

DOSEL, or DOSER, a rich hanging of tapestry or other stuff, or screen of ornamental woodwork employed to decorate the back of an altar, throne, &c.

DOUBLE VAULT, two vaults of brick or stone, carried up separately, and including between them a hollow or cavity, such as that of St. Peter's, at Rome.

DOUBLE BUILDING, one in which the walls are carried up double; sometimes cellars are carried up with double walls, and double vaults, so as to include a cavity of air in order to keep the wine cool.

DOUBLE COLUMN. *See* COLUMN.

DOUBLE CURVATURE, the curvature of a curve, of which no part can be brought into a plane, such as the cylindro-cylindric curve, &c.

DOUBLE DOORS, those where two doors are made in the same aperture, in order to keep the apartment warm. *See* DOOR.

DOUBLE FLOOR, one constructed of binding and bridging-joists. *See* FLOOR.

DOUBLE-HUNG SASHES, are those where the window consists of two sashes, each of which is moveable by means of weights.

DOUBLE MARGIN DOOR, that which represents two doors in the same breadth, but is, in fact, only one door. *See* DOOR.

DOUBLE TORUS. *See* MOULDING.

DOUBLE WINDING STAIRS. *See* STAIRS.

DOUBLING, the same as eaves-boards; the term is used in Scotland.

DOUCINE, or DOUCHINE, (from the French), the *sima-recta*.

DOVE-COT, a small building or box in which domestic pigeons breed.

DOVE-TAIL, in joinery, a piece of wood formed like the tail of a dove.

DOVE-TAILING, the method of fastening one piece of wood to another, by projecting pins, cut in the form of dove-tails in one piece, and let into hollows of the same form in the other. Dove-tailing is either exposed or concealed; concealed dove-tailing is of two kinds, lapped and mitred.

DOVE-TAIL MASONRY. *See* MASONRY.

DOVE-TAIL MOULDING. A moulding used in Norman buildings, so called from the shape of the running ornament employed in its decoration, which consists of a fillet, tracing in its progress the form of a dove-tail, the alternate dove-tails being inverted, and having one side common to both.

DOVE-TAIL NOTCH, a *common* dove-tail notch is that where the bottom is in the form of a trapezoid.

An *undercut* dove-tail notch is that where the bottom is a parallelogram of greater breadth than the width of the parallelogram cut out of the surface; the excess in breadth being alike on both sides.

DOVE-TAIL SAW, a saw used for dove-tailing. Its plate is about 9 inches long, and has about 15 teeth in every inch; a rigid iron or brass back is added, to give stiffness to the plate.

DOWEL, the pin or tenon used in joining together two pieces of any substance. This pin or dowel is of wood or iron, and is thus used. Holes corresponding to each other are made in the boards to be joined; one-half of the pin is inserted into the hole in the one piece, and the other piece is then thrust home on it.

DOWELLING, or DOWELING, the fastening together two boards by the method above described.

DRAG, a term applied to anything bearing down, or rubbing upon another; thus, a door is said to drag, when its hinges are so loosened, that the lower edge rubs upon the floor: and the term is also applied in masonry to a thin plate of steel indented on the edge, used for finishing the dressing of soft stone which has no grit.

DRAGON-PIECE, a beam bisecting the wall plate, for receiving the heel or foot of the hip-rafters. It is most commonly a very short piece of timber, fixed at right angles into another piece, called the *angle-tie*, or *diagonal-tie*, which is again supported by each adjoining wall-plate being cocked down thereon.

DRAGON-BEAMS, according to Neve, are said to be "two strong braces or struts, that stand under a bressummer, meeting in an angle under the shoulder of a king-piece." —Neve's *Builder's Dictionary.* The writers of the present work have never heard the term applied to story-posts and bressummers, nor have they been able to learn any such application of it; the word *beam* is improper for any piece of timber, that stands slanting as a brace or strut. Neve's *Builder's Dictionary* was an original work; and it is probable that the author, who subscribes himself "Philomath," (a lover of learning) instead of architect, carpenter, joiner, mason, &c., might have been misinformed by the workmen, among whom he made his inquiries. The *Builder's Dictionary*, in two volumes, was copied from Neve, as was the *Dictionary* of the first volume of the *Builder's Magazine;* and we may farther add, most of the Cyclopædias and Encyclopædias have applied the term in the same way as Neve, and have used the same words in describing it. But with regard to the application of the term *dragon-piece*, as it is defined above, we can refer the reader to the oldest books that are published; see page 230, in the *Rules for framing roofs*, at the end of Godfrey Richards' *Palladio*, where that author says, "3. Dragon-beams for the hip to stand on," and immediately following, he says, "4. Beam or summer, wherein the dragon-beams are framed;" referring at the same time to *Figure* c, or Plate c; see also our review of carpentry, at the end of Godfrey Richards' *Palladio.* The sense in which Godfrey Richards uses the term, is the same as that now in use. It is true, that Moxon explains dragon-beam in the same way as Neve, but he refers to no figure. The second edition of Godfrey Richards' *Palladio* is dated 1676, and the first edition must be much more early. The first edition of Neve's *Builder's Dictionary* is dated 1703; we have also the corroboration of Batty Langley, see *Plate* II. of the *Addenda*, consisting of fourteen plates of roofs, at the end of his designs, where he says, "*a e*, *b e*, *c e*, *d e*, dragon-pieces to receive the feet of the hip-rafters" so that Godfrey Richards and Batty Langley apply the same meaning to the term. We have been thus particular, because a proper explanation of the word, as it is used, has not been given, and to show that it is an injury to a work, to describe a term which has no existence, or, if it has, must be confined to some remote corner.

DRAIN, a subterraneous passage for water. If a building is obliged to be erected in a damp soil, it will be proper to drain the ground before the foundation is laid. In large buildings, there must be one principal drain, and several smaller ones, depending on the extent of the ground; and observe, that those with circular bottoms are better than those which have straight ones, as the water will run much deeper in the former, than in the latter, and will consequently clear away the sediment much easier. The large drain ought to be of sufficient height to admit a person to clean it with ease. Circular, barrel, or cylindric drains, are much stronger than common drains, in which the sides are formed by vertical walls. *See* DRAINAGE and SEWERAGE.

DRAINAGE. As we shall have occasion to treat this important subject at some length, and as, in so doing, it is desirable to consider the question both in its more comprehensive and general sense, as well as in its details, we shall refer the reader to the article SEWERAGE. Under that head, we shall enter fully into the various methods of house drainage, as suggested by the improved knowledge of modern times, and describe the extensive works which have been constructed for this purpose in the metropolis. See CLOACA, SEWER, SEWAGE.

DRAUGHT, in architecture, the representation of a building on paper, explanatory of the various parts of the exterior and interior, by means of plans, elevations, and sections, drawn to a scale, by which all the parts are represented in the same proportion as the parts of the edifice intended to be executed. All the horizontal parts are explained by plans; the faces of the vertical parts are represented by elevations and sections; particularly, when the plane of delineation is parallel to the faces to be represented. The vertical dimensions of buildings upon circular and polygonal plans are understood from the elevations and sections. In complex buildings, besides the general plans, elevations, and sections, a set of drawings should be made to show the detail of the small parts.

In addition to the drawings which are used in conducting the work, a perspective representation of the exterior should be furnished by the architect, in order to show the general appearance and effect of the intended edifice to the employer, and perhaps, in some instances, two or more perspective representations will be necessary, in order to bring more parts into view, which should be drawn to such points as those in which the building will be most generally seen.

When several stories of a building differ in their construction, each story requires a separate plan. The sections are generally parallel to the sides of the edifice, taken through the most complex or principal part. Most buildings require at least two sections, some many more. When the sides of a building are dissimilar, as many elevations will be necessary as the edifice has sides.

The number, the form, and disposition of rooms are shown by the plans. The architect who gives the design of a building, ought to be well acquainted with the constructive parts of carpentry, masonry, and bricklaying, before he commits his ideas to paper, or otherwise he may be liable to public censure. See Design.

Draught, in mechanics, the force or power necessary to move any machine, as a horse-mill, waggon, cart, plough, &c.

Draught, in carpentry and joinery; when a tenon is intended to be pinned to the cheeks or sides of a mortise, and when the hole through the tenon is put nearer to the shoulder than the holes through the cheeks of the mortise from the abutment, which receives the shoulder of the tenon, or which comes in contact with the shoulder of the tenon, the pin is said to draw, or have a draught.

Draught, in masonry, a part of the surface of the stone hewn to the breadth of the chisel on the margin of the stone, either according to a curve or straight line, as the surface of the stone is to be reduced to a plane or curved surface. When the draughts are formed round different sides of the stone, the intermediate part is wrought to the surface, by applying a straight-edge or templet. In large stones, particularly when the substance is required to be much reduced, sometimes several intermediate parallel draughts, dividing the stone equidistantly in its length, are made, and thus the intermediate parts may be hewn down nearly by the eye, without the application of the straight-edge or templet.

DRAUGHT COMPASSES, those provided with several moveable points, to draw fine lines in architecture. See the words Compass and Mathematical Instruments.

DRAW-BORE, when a mortise and tenon is intended to be pinned, by piercing the hole through the tenon, nearer to the shoulder than the holes through the cheeks from the abutment, in which the shoulder is to come in contact, the mortise and tenon is said to be draw-bored: see the following word.

DRAW-BORE PINS, pieces of steel, made in the form of the frustum of a cone, but rather taper, and inserted in handles, with the greatest diameter next to the handle, for driving through the draw-bores of a mortise and tenon, in order to bring the shoulder of the rail close home to the abutment on the edge of the style; when this is effected, the draw-bore pins, if more than one be used, are to be taken out one at a time, and the holes immediately filled up with wooden pegs.

DRAW-BRIDGE, in general, a bridge constructed of several boards nailed or bolted to a frame. This being fastened at one end, by means of strong hinges, to a beam laid horizontally, and parallel to the frame, and being acted upon at its other extremity by levers, or by chains, worked either by wheels or by hand; the platform thus constructed may be raised to a perpendicular direction. Drawbridges are usually placed over narrow ditches, in fortresses, at the ends of great bridges, and especially over the excavations close to the gates, so that they may be raised or let down at pleasure.

When drawbridges are made close on the outside of the gates, the masonry ought to be sunk so as to admit of the whole depth of the frame to lie within it; else the oblique fire from the besiegers' batteries would act on the edge of the frame, and soon render it unserviceable. In canal navigation, and in wet docks, swing bridges, that turn horizontally upon one end as an axis, have almost wholly superseded drawbridges. See Iron Bridge.

DRAWING, in its strict meaning, may be defined as the art of representing objects, on any convenient surface, by lines describing their form and contour. This is independent of colour, and even of shadow; because, notwithstanding form may be expressed by outline alone, shadow, while giving surface and substance, must be dependent upon form, and, in many cases, requires to be accurately defined according to the rules of perspective.

Before proceeding to describe the process of ordinary architectural drawing, we shall venture to insert some caustic, though just observations of Mr. Bartholomew, on this necessary study.

"There is no small boasting, in the present day, of architectural drawing. An architect cannot draw too well; but when he obtains much practice, he will find, that, besides designing the form and the details of his works, he has little time for drawing; in general, he has as little time for making the clean and fair copies of his drawings as the sculptor has for the stone-cutting department of his art; while, if he cannot design, and is unacquainted with the other many branches of knowledge which he should possess, he should cease to call himself an architect.

"In making drawing his sole study, (but with the interruptions which business will naturally bring,) the pupil becomes only a bad artist, and no architect at all. The pernicious folly of imagining, that he who can make an architectural drawing must of necessity be able to make an architectural building, has wrought largely towards the ruin of real architecture, and has tended more than any thing else to fill our metropolis, and other places, with white-washed and even stone ruins, which the weak have mistaken for architecture, and has led to that general disregard to structural propriety, which is the besetting sin of modern works.

"Now, the time spent in learning to draw badly; a work without truth, without philosophy, without art, without structural excellence, without geometrical ground-work, without adaptation to its purpose, without real beauty, either abstract or obvious; this time, so misemployed, might have been successfully employed by him (were architectural education such as it should be) in, by the age of twenty-five or thirty years at the utmost, learning thoroughly all the known arts of trussing, of roofing, of vaulting, of doming, of framing arches, pyramids, and all other parts of architecture in structural perfection. This safe ground-work, with the necessary growth of mind, expansion of power, freedom of ability, would lead the professing architect to soar aloft, over all the chained spirits who fancy a few water-colours alone can raise them above San Micheli and Palladio—above Wren and Chambers. They know they cannot surpass Raffaello and Buonarotti in drawing; yet they do not consider that they might with ease surpass them both in architectural design and construction: thus they choose that competition in which they cannot succeed, and neglect the one in which they might gain an easy victory. They might be the first of architects, but they choose rather to be the last of artists: instead of gazing with an astonished ignorance upon ancient buildings, they might as much surpass them as the science of the moderns surpasses that of the ancients."—'Bartholomew's Specifications for Practical Architecture.' However severe these strictures may appear, there is great truth in them, and they deserve the serious attention of the student.

Drawing is the basis of architecture, engraving, and painting; and may be divided into outlines and shadowing. The outline, or contour, represents the boundaries of an object, as they appear to terminate against the back ground; the outline, as its name implies, takes in all the parts of the body. The interior parts are marked by lines, if such be distinct on the body, and the different inclinations of the surface are defined by depth of colour, in proportion to the inclination.

In fanciful objects, whatever the figure may be, the general form should be first sketched out slightly, that what is found to be amiss may be more easily removed, and corrections more easily made. Estimate as nearly as you can the principal points of the original, and fix dots at proportional distances, disposed at equal apparent angles on your paper; then draw your lines carefully to them, beginning at the upper part, and working either from the right to the left, or in the contrary direction, according to their tendency downwards. Put in the divisions first, and when these are nearly right, mark in the smaller parts; then, having got your work altogether, examine it scrupulously, rubbing it gently with a piece of bread, in order to render the lines more obscure: revise and correct the whole as often as it may be found necessary. Compare all the parts of the copy with the original, in every direction, first horizontally and then vertically, from a given point, which may be supposed to be the centre of the picture.

Beginners should make their drawings of the same size as the original, in order to exercise the eye in measuring with exactness; after some practice, however, it will be better to vary the size from the original, in order to acquire the habit of estimating distances, that, when combined, will form parts, similar to the whole, as also to the whole mass or general contour.

After the outlines are finished, the learner may proceed to the shadows; the first lesson should be simple, only indicating the principal projections. The simplest method of forming these is, by repeated lines nearly parallel to the outline, and as he advances with more shades, these lines should be crossed by other equidistant lines. This manner of sketching constitutes that peculiar manner of drawing called *hatching*, a mode very well calculated to give freedom of hand in any style of drawing. The chief things to be attended to are, that the lines conform as much as possible to the original, bearing all their inflections in the same ratio; the intersections should not be too violent, nor the lines so strong as to have the appearance of net-work.

In architectural drawing, the shadows are made out by washing or tinting the paper with Indian ink, sepia, or bister, laid on with a camel-hair pencil: this may be done in two different ways; the one is by laying down the shades as nearly in their places as possible, with tints sufficiently dark, and softening off the edges with a clean pencil and water, and when dry, the process may be repeated again, as often as may be found necessary; the other is by working with very light tints at first, in blotches placed near each other, then blending these by a faint wash over the whole, and when nearly dry, strengthening them by filling up the interstices with other blotches: thus, by repeated blotches, the surface will acquire the degree of tint required in the various parts. This mode is called *stippling*, and in the hand of an artist is perhaps the best, at least for finished drawings. In the shadows of anything projecting from a surface, we shall, for the sake of example, suppose a pole projecting from the surface of a wall, at a considerable distance from it; the outline of the shadow next to the foot of the pole will be very dark and definite, but in proceeding towards the extremity, the edge becomes more penumbral, and at last, in a very extended shadow, is hardly definite. All shadows are darker nearer to the body than those which are more remote; attached columns and pilasters will throw a stronger shadow than insulated columns upon the wall behind, and the projections of the shadows of insulated columns will be darker, and more defined upon their edges, than those which are placed at a greater distance from the wall, and, again, the middle part of the shadows will be darker than the edges.

The shadow of a plane figure falling upon a plane parallel to it, will form a figure similar and equal to that which throws it, as the shadow of all lines on a plane, parallel to these lines, will also be parallel to the same lines which project them. Besides what has been already hinted above, there is another method, which is excellent for mouldings, particularly when small, viz., to use very little ink in the pencil; let us, for example, suppose we were to shade a moulding: take the camel-hair pencil with so little ink that it cannot run, or that it will dry the instant it is put on the paper, and run it the whole length of the moulding, upon that part which requires to be the darkest; then repeat the process in the same manner, by making the tint broader, or to spread farther over; repeat in this manner, by making the last tint spread over each edge of the preceding, keeping the edges of every tint as straight and parallel as possible, until the moulding has acquired its full variety of tints, so as to represent all the various inclinations of the original surface. If any part appear too light, it is only necessary to go over that part again, touching only the part that is too light. Or, the learner may begin the reverse way, by making the broad tints first, and proceed to make narrower and narrower tints each time.

In shadowing a cylinder of considerable width, begin at the line of demarcation of light and shade, where a plane from the luminary would touch the curved surface in a straight line of contact, and having gone the whole length of this line with a tint, soften the edges with water. Proceed in the same manner the second time with a broader tint, covering the edges of the former, and washing off the edges as before, thus continually spreading each repeated tint, until you come to the line of light, viz., where a plane extended from the luminary to the axis of the cylinder, included in the plane, would cut the surface of the cylinder. Then from the opposite edge of the representation of the cylinder, lay a light tint close to the line, as narrow as it can be put on, and soften the edge of it next to the line of light; lay a broader tint next time, and soften the edge in like manner, next to the line of light; proceed in this manner, until you come again in contact with the line of light; observing, that the depth of colour in receding from the line of light in the parts which represent equal distances, should be the same, or of an equal degree. In washing towards the line of light, the washes must be lighter and lighter, as too much colour will destroy the delicacy necessary to be preserved in the light part. If, after all, any part should appear to be too light, the defect may be made up by tinting that part only, with very little ink in the pencil. For other information, concerning the manner of preparing the tints, we shall refer to the article SHADOWING.

DRAWING-KNIFE, an edged tool, made sharp at the end, for cutting a deep incision into the wood, along a straight-edge, the edge of a square or templet, in order to enter the saw without ragging the wood. A chisel or firmer is sometimes used instead of the drawing-knife. In joinery, the drawing-knife is useful in rebating across the grain, cutting the shoulders of tenons, grooving across the fibres.

DRAWING-ROOM, a principal apartment of a great mansion, or nobleman's house, to which it is usual for company to withdraw after dinner, and in which formal visits are received. *See* DINING-ROOM. In small houses, the drawing-room may communicate with the dining-room, but in large houses, it will be no detriment, and might even be preferred by many, if the library, or an ante-room should intervene. The term is frequently written *withdrawing-room. See* ROOM.

DRAWING-SLATE, a soft stone of fine grain, used as a marking or drawing material. It is sometimes called *black chalk.*

DRAWINGS, *Working, See* WORKING DRAWINGS.

DRAWN THROUGH OR ALONG THE AXIS, OR THROUGH OR ALONG A STRAIGHT LINE, is when a plane meets a straight line, so that all parts or points in the line are also in the plane.

DREDGING. The operation of removing mud, silt, and other depositions from the bottom of harbours, canals, rivers, docks, &c., by means of a DREDGING MACHINE.

DRESS, in masonry, to prepare stones for building.

DRESSED, the preparation that a stone requires before it is ready to be used in building, &c. Stones are dressed sometimes by the hammer only, thence termed hammer-dressed; sometimes by the mallet and chisel, the face afterwards being rubbed smooth. In Scotland the term is only understood of hammer-dressing.

DRESSER, a kind of bench or table, with drawers, set in the kitchen, used for culinary purposes: it is generally reckoned as a fixture of the building, or a part thereof.

DRESSING-ROOM, a room adjoining a sleeping-room, used for dressing in, as its name implies. A dressing-room ought to have two doors, one to communicate with the sleeping-room, and another to communicate with the passage, for the valet, or servant.

DRESSINGS, all kinds of mouldings projecting beyond the naked of walls or ceilings, are called by the general name of *dressing.* In joinery, the architraves of apertures, or other appendages, as also the projecting moulding used as a finish, is called *a dressing,* and frequently *facing.*

DRIFT, the horizontal push or force, which an arch exerts from the gravitation of the stones, which are kept from descending by the inclination of the beds of the arch, and the resistance of the pier. The terms *shoot and thrust,* are also employed to express the same idea.

DRIP, the edge of a roof; the eaves; the corona of the cornice. *See* LARMIER, CORONA.

DRIPPING EAVES, when the slope of a roof is continued downwards, so as to project over the roof of a building, the part thus projecting over is called *dripping eaves,* in contradistinction to those roofs that have blocking courses, which run above the slope of the roof, and which have gutters behind for carrying off the water. Dripping eaves are prohibited, in the city of London, by the Building act.

DRIPS, steps made in flat roofs, to walk upon. This way of building is much used in Italy, where the roof is not quite flat, but a little raised in the middle, otherwise the steps would have no rise.

DRIPSTONE, the projecting moulding or cornice over windows, doorways, &c., is called a dripstone. Its use is to throw off the rain, and in some of the old buildings in the country, it has been made of an ornamental character. The dripstone is of various forms, and when a head is not used as a termination or support, a simple moulding is adopted. It is also called label, weather-moulding, and water-table.

The term *dripstone,* however, is more particularly applied to the boss at the termination of the moulding from which the rain drips, after being conducted down the moulding; the latter is distinguished by the appellation of *weather-moulding.*

DRIVER, *Pile. See* PILE DRIVER.

DROPS, in architecture, small pendent cylinders, or the frustums of cones attached to a vertical surface, the axis of the cylinders or cones having also a vertical position, and their upper ends attached to a horizontal surface.

Drops are used in the cornice of the Doric order under the mutules, and in the architrave under the triglyphs. Each mutule has three rows from front to rear, with six drops in each row, disposed at equal distances, in lines parallel to the front. The drops upon the architrave are also six feet under each trigylph, disposed also equidistantly. Drops in the form of frustums of cones, are only peculiar to Roman architecture, and to some of the temples of Pæstum; there are some Grecian-Dorics, however, wherein the drops in their vertical section have the upper part nearly parallel, and terminate below with a concavity, the part above being a tangent to the curve. In the Roman-Doric, the surface of the metopes is the same with that of the architrave, and the vertical surface of the trigylph projects at the same distance as the drops, which are hung from the tenia. In the Grecian Doric, the faces of the triglyphs are generally disposed in the same vertical surface with the face of the epistylium, and consequently, the regula and drops pending therefrom project. The Doric portico at Athens, the portico of Philip king of Macedon, and the temple of Apollo in the island of Delos, are instances wherein the surface of the epistyle is within the surface of the triglyph; but it is to be observed, in the two latter examples, that there is a drop in each angle common to every return face. All examples of the Doric order, except the portico of the Agora, or Doric portico, at Athens, have the sides of each extreme drop under the regula in the same vertical line as each edge of the triglyph above, and the whole six drops are contained within the perpendiculars, by producing the edges of the triglyphs.

In all the drops of the Doric architraves to be met with, the horizontal sections are circles, increasing towards the bottom of the drops, or of a cylindrical form, except in the instance of the temple of Apollo at Cora, in Italy, where the soffits of the drops in the architraves are inclined. It is singular, that in this example, the drops pending from the corona are continued equidistantly without interruption in three rows, two behind the front row; and that those pending from the corona are perfectly cylindrical, with level soffits, while those pending from the regula are conical, and have inclined soffits, which form an obtuse angle with the face of the epistyle. In the choragic monument of Thrasyllus, the tenia of the epistylium has a continued row of drops, but this example cannot be accounted a Doric order, having no other peculiarity to the Doric composition.

The drops pending from the soffits of the mutules, have their soffits in a plane parallel to the soffits of the mutules, and consequently, inclining; while those of the epistyle have their soffits in a horizontal plane.

The height of the drops in the cornice of the Doric portico at Athens, is little more than one quarter of their diameter, while those of the epistyle have their height more than half their diameter.

In the peripteral temple at Pæstum, the corona has no pending mutules, nor any drops. In the theatre of Marcellus at Rome, there are no mutules, the interstices between the drops are formed by excavating upwards into the soffit of the corona, and are covered on the front with a moulding, which has its soffit in the same inclined plane with the soffits of the drops, so that the drops show no geometrical elevation. In the enneastyle, or nine-column temple at Pæstum, the cornice is destroyed, and the architrave seems to have been originally without either mutules or drops.

The term *guttæ* is also applicable to what we have called *drops*.

DROVED ASHLAR, a term used in Scotland for chiseled, or random-tooled ashlar. It is the most inferior kind of hewn work used in building. It is true, that what is there called broached work, is sometimes done without being droved, but in good broached work, the face of the stone should be previously droved, and then broached. See the article MASONRY.

DROVED AND BROACHED, a term used in Scotland, in a more specific manner than that of broached work; see the preceding word.

DROVED AND STRIPED, work that is first droved and then striped: the stripes are shallow grooves done with a half or three-quarter inch chisel, about an eighth of an inch deep, leaving the droved interstices prominent. These kinds of hewn work are not used in England, or at least very seldom; the work is either regularly tooled, or rubbed smooth.

DRUIDICAL TEMPLE, stone pillars, arranged in the circumference of the circle, surmounted with an architrave or entablature, such as Stonehenge. *See* CELTIC ARCHITECTURE.

DRUM, a cylinder, generally formed of cast-iron, but sometimes of wood, and used on the inclined planes of railways, for receiving the rope which is wound round the surface of its periphery, by which movement the waggons are conveyed along the line. Drums are used when the plane is worked by a single rope.

DRUM, of the Corinthian and Composite capitals, the solid part, in the form of a vase, to which foliage, stalks, and caulicoli are attached. The drum is otherwise called *vase*.

DRUM. *See* DOME.

DRY-ROT, a highly destructive vegetable disease, affecting the timber in the foundations, and other parts of buildings, in particular soils and situations. It affects the wood, or ligneous parts, in such a manner, as to leave it connected by nothing but the small hard fibrous portions, which give it a curious tremulous appearance, but all of which, when touched by the hand in the more advanced stages of the disease, readily moulder into a brownish snuff-like dust. It is attended with a peculiar earthy smell, similar to that which issues from wood fresh dug up after having lain some time in the ground in contact with decaying animal matter, and is materially different from that natural sort of decay which takes place in wood from the presence of wetness.

On the causes of this decay numerous volumes have been written, and equally numerous have been the nostrums for its prevention or "cure." There can be little doubt that, in very many cases, dry-rot has been engendered by the extreme wetness of the timber, caused by its long immersion in the water, in docks, canals, &c. In our hastily-constructed buildings, the timber, after having been thus swelled by soaking too much beyond its former and its ultimate bulk, is frequently framed together while in this wet state, and it cannot be surprising that the dry-rot soon appears as a natural consequence of such unwise proceedings.

It has been said, that moist and warm situations, where the circulation of the air is impeded, is the generating cause of this disease; that the effluvia from timber so diseased, will carry their effects to the circumjacent timber; and that any sort of wood, dry as well as damp, so exposed, will be soon destroyed. Timber once infected cannot be restored, and the only remedy lies in cutting away the diseased parts, to prevent the extension of the evil to the remainder; and to effect even the latter, a free circulation of air must be admitted, and the parts be washed over with a strong solution of iron, copper, or zinc. Patents have been granted for various applications of the latter, as preventives of the dry-rot, the distinguishing features of the processes therein employed consisting in first preparing the timber by a good steaming, or drying out of the sap, and afterwards injecting, soaking, or boiling the timber in a solution of copperas, or other metallic salt. The following observations on this important subject were some time since addressed to the editor of the "Engineers and Mechanics' Encyclopædia," by Mr. John Gregory, who is an experienced and observant shipwright; and as they appear to mark out clearly the true cause of, and to suggest a very simple remedy for, the evil, it is right to give them a place in this work. Mr. Gregory says, "Instead of squaring a piece of timber according to the usual method, by leaving the heart of the tree in the centre, my plan is to saw it right down the middle, through the heart, into two equal parts, immediately after the tree is felled; and my reasons for this I will now endeavour to explain, to the best of my ability. It is, I believe, a well-known fact, that a tree does not, literally speaking, *die* on receiving the final stroke of the axe, but that it continues for a long period afterwards to vegetate, though less vigorously. At length, however, the sap ceases to circulate, the pores become closed, and the juices of the tree thus shut up undergo decomposition, and lay the foundation of dry-rot. It is well known, that a man, who dies in a full habit of body, soon decays; the same effect takes place in a tree full of sap, unless we adopt the same method with respect to it as the Egyptians practised with the human body, viz., that of depriving it of all moisture, which process would give to our timber a durability almost everlasting. My mind has been long impressed with this idea, which has been confirmed by my having recently noticed, that several of the timbers, in a very ancient public building, which had been sawn originally in the manner I have proposed, were *perfectly sound*, although they had withstood the dilapidating hand of time for seven hundred years; while other timbers in the same building, which had not been so cut, but apparently squared out with the heart in the centre, were perfectly rotten. That the dry-rot is certainly caused by the juices being enclosed in the heart of the timber, I have had frequent opportunities of observing during my long practical experience in the repairing of ships. In the frame of a ship in which such large quantities of timber are employed, I have uniformly noticed: First, that the decay commences in the run fore and aft, which is owing to the timbers being fitted so close together at the heels or lower ends. The evil being thus enclosed in the hearts of the timbers, and the air having no access to the exterior of them to carry off the moisture by evaporation, internal decay is the necessary consequence. I have sometimes witnessed these parts of the frame of a ship in such a rotten state, as to have been justly compared by the workmen to a heap of manure. Secondly, those timbers in the midships that have been bored off with the outside planks, are not so affected, which I attribute to the circumstance of the holes admitting a current of air through them, the destructive juices being thereby carried off. Thirdly, it frequently happens, that the floor-timbers of an old ship are found, on breaking up, to be nearly as sound as they were when first put in. Their preservation seems to be owing to the effect of the salt water, which constantly laves over them, causing them to become, in a manner, pickled; or it may be, that the salt entering into the composition of the wood, the destructive effects of its natural juices are thereby prevented. Fourthly, the planks in the bottom, nearest to the timbers, take the infection first; and where the tree-nails are not close, the disease rapidly extends endways of the grain. Fifthly, those parts of the deck-planks that lie *upon* the beams are those which are first infected with the rot, the cause of which is evident, as those parts that are *between* the beams are generally quite sound. Sixthly, in the beams of ships the decay usually commences in the internal parts, which is decidedly owing, in my opinion, to the erroneous method of preparing the timber, as before-mentioned; but when timber, so prepared, is used, I would recommend, as the best preventive of the rot, that a few holes be bored through the beam fore and aft, and, what would still add to the benefit, to bore another hole lengthways of the grain, to meet those which are bored crossways. But the best preventive, I am confident, would be the adoption of my mode of preparing the timber, viz., to saw it lengthways right through the heart, by which not only greater durability would be obtained, but great economy in the consumption of the timber."

Though, as we have before observed, volumes have been written on the subject of dry-rot, the causes of it are still, perhaps, as little understood as ever; and, as was stated by Mr. Bramley, of Leeds, in a paper read to the Society for the Encouragement of Arts, &c., "to bring the matter to the test by experiments, would require the observations of a long period, and in selected situations." "Wood used for the general purposes of man," he observes, "is cut down at different periods; and although it may be felled at the proper season, or when most free from sap or moisture, it is not always to be effected. Nay, even admitting it to have been cut down in the most favourable situation, it still abounds with such an extra proportion of moisture, as to require a regular exposure to the air prior to its being applied to use, if we wish to guard against that shrinking which always takes place where this precaution has not been taken. And although the fir-kind contains less of this watery portion, yet it assuredly possesses a considerable share; and it is in this species, he apprehends, that the evil, called *the dry-rot*, most generally occurs; as, from the facility of working the same, it is most generally applied to buildings. But, supposing it to be fir, or any other species, wood felled when abounding with any extra proportion of sap, and applied to use without the proper seasoning or exposure to a free current of air, until such extra moisture has had time to exhale, is most liable to the disease in question; and the cure, or principal prevention against it, would be the precaution of felling all wood only at the proper season, or when the sap is not in circulation. The next mode of prevention would be to use such wood only as has been for a considerable period exposed to the influence of a free current of air, or, where convenience will admit, to that of air heated to a moderate degree; such air extracting, with greater facility, the enclosed moisture, and in a more certain ratio than the irregularity of our atmosphere will allow under other circumstances."

This is not the place for examining into the comparative merits of the different processes which have been introduced for seasoning timber. The most noted of these are Kyan's, Burnett's, Payne's, and Bethell's, all of which have been described by their advocates as perfect preventives of dry-rot; it is sufficient to say, that they have all been found successful, and have also all failed. The best preventive of dry-rot, in our opinion, is to have the timber thoroughly dry before it is converted, and to let plenty of air get to it when the building is completed.

DUBBING, in bricklaying, is replacing and making good any decayed brickwork, when the wall is to be repointed.

DUN, or BURGH, the name of an ancient species of buildings, of a circular form, common in the Orkney and Shetland Islands, the Hebrides, and northern parts of Scotland. The latter term points out the founders, who at the same time bestowed on them their natal name of *borg*, "a defence or castle," a Suco-Gothic word; and the Highlanders universally apply to these places the Celtic name *dun*, signifying a hill defended by a tower, which plainly points out their use. They are confined to the countries once subject to the crown of Norway. With few exceptions, they are built within sight of the sea, and one or more within sight of the other; so that on a signal by fire, by flag, or by trumpet, they could give notice of approaching danger, and yield a mutual succour. In the Shetland and Orkney islands, they are most frequently called *wart* or *ward hills*, which shows that they were garrisoned. They had their wardmadher, or watchman, a sort of sentinel, who stood on the top, and challenged all who came in sight. The gackman was an officer of the same kind, who not only was on the watch against surprise, but was to give notice if he saw any ships in distress. He was allowed a large horn of generous liquor, which he had always by him, to keep up his spirits. Along the Orkney and Shetland shores, they almost form a chain; and by that means not only kept the natives in subjection, but were situated commodiously for covering the landing of their countrymen, who were perpetually roving on piratical expeditions. These towers were even made use of as state prisons; for we learn from Torfæus, that after Sueno had surprised Paul, count of Caithness, he carried him into Sutherland, and confined him there in a Norwegian tower. Out of our own kingdom, no buildings similar to these are to be found, except in Scandinavia. On the mountain Swalberg in Norway is one; the Stir-biskop, at Upsal in Sweden, is another; and Umseborg, in the same kingdom, is a third.

In these buildings, there is no appearance of an arch; the wall, which consists of the best flat stones the workmen could find, is well laid, is in thickness about 14 feet, and in some instances not more than 12 feet high; the structure of a dun is upon a circular plan, about 20 or 30 feet in diameter. The door of entrance is very low, and was shut up occasionally with a broad flat stone. In some instances, where the stones were not flat or well bedded, the wall is found propped up with heaps of stones, like buttresses, on the outside; so as to give the whole more the appearance of a mount, than of a building, as is particularly the case with one at Lothbeg, in the parish of Lothis. The most entire dun is that at Glenby, not far from Inverness, and described by Mr. Pennant, in his voyage to the Hebrides; from whose very curious and original account, the following particulars are extracted:—

"It is placed about two miles from the mouth of the valley. The more entire side is about thirty feet six inches in height, and was, some years ago, about ten feet higher. The whole structure appears to have been, on the outside, of a conical form; but on the inside, the surrounding wall is quite perpendicular; so that it must have been much thicker at the bottom than at the top. It enclosed a small circular area of thirty-three feet and a half in diameter; and was constructed merely of flat stones neatly placed one upon another, without any cement or mortar. At ten feet from the ground it was found to be seven feet four inches thick; and within this thickness were two surrounding galleries; one quite in the lower part of the tower, about six feet two inches high, and two feet five inches wide at the bottom; but made narrower at the top; and flagged and covered with great flat stones. And the other gallery was placed directly over this, having these flag-stones for its floor, and being only five feet six inches high, and only twenty inches wide at the bottom; but covered at top, in like manner, with other great flat stones.

"This upper gallery, in which a man could barely make his way, went quite round the tower, without any division or partition; but the lower gallery, underneath this, is parted off into separate spaces, by great flag-stones placed upright; which several spaces, or little cells, were in general accessible only by means of holes in the floor or gallery above; so that nothing can be more obvious, than that these cells were intended for the keeping and preserving of stores; whilst the upper gallery cannot but remind us somewhat of the little gallery within the wall of the round tower at Brunless.

"Besides these galleries, there were, on the inside of the circular wall, open to the circular enclosed apartment, four perpendicular rows of small cavities, or, as they have been described by others, four stages or nests of small square open holes, dividing the interior circular wall into four parts, and turning up from the lower part of the tower to the top; each little hole, or nest, in the row, divided from that beneath only by a sort of shelf, or flag-stone, and forming a little cupboard.

"The appearance of this sort of little cupboards, as well as that of the sections of galleries, is similar to those in this tower, as they are seen in the wall of another dun, in the same neighbourhood. And these square cavities seem obviously to have been intended to hold the drinking horns, and other utensils for banqueting in these rude dens."

DUODECIMALS, a term applied to an arithmetical method of ascertaining the number of square feet and square inches in a rectangular space, whose sides are given in feet and inches.

In this series of denominations (beginning with feet) every unit in the preceding denomination makes twelve in that which succeeds it: that is, every foot contains 12 inches, or firsts; every first, 12 seconds; and so on. There will be as many denominations in the product as in both factors taken together.

Feet are either marked with or without an *f;* inches are called *firsts* by the mark thus (′) being placed above; *seconds* by the mark thus (″) being placed above; *thirds* thus (‴), and so on. In multiplying any two single denominations together, the value of the product will be known by adding the indices of the two factors. Thus, suppose $7''$ to be multiplied by $11'''$, then the product is 77^{v}, or 77 fifths, because adding the index ″ of the seven to the index ‴ of the eleven, produces v or fifths.

To multiply duodecimals together.—Write the multiplier under the multiplicand, so that the place of feet may stand under the last place of the multiplicand; begin with the right-hand denomination of the multiplier, and multiply it by every denomination of the multiplicand, throwing the twelves out of every product, and carrying as many units to the next; place the remainders, if any, under the multiplier, so that like parts in the product may be under like parts of the multiplicand; proceed with every successive figure of the multiplier, towards the left, in the same manner, always placing the first figure of the product under the multiplier; then the sum of the products will be the total.

Example 1.

Multiply 6..9′ by 3..6′

$\overset{ft}{6}..9'$
$\quad 3..6'$
3..4..6 = 6..9 × 6
20..3 = 6..9 × 3
Answer 23..7..6

Example 2.

Multiply 6..5′..4″ by 3..6′

$\overset{ft}{6}..5'..4''$
$\quad 3..6$
3..2..8..0 = $\overset{ft}{6}..5'..4''$ × 6
19..4..0 = 6..5..4 × 3
Answer 22..6..8..0

In the first example, there is only one place of duodecimals in each factor; there are, therefore, two places in the product. In the second example, there are two places of duodecimals in the multiplicand, and one in the multiplier, which make together three; there are, therefore, three denominations in the product.

Example 3.

What is the product of $\overset{ft}{4}..3'..2''..8'''..9^{iv}..5^{v}..3^{vi}$ by $3'..0''..5'''..0^{iv}..0^{v}..6^{vi}..2^{vii}$

$\overset{ft}{4}..3'..2''..8'''..9^{iv}..5^{v}..3^{vi}$
0.. 3..0..5..0..0.. 6..2
8..6..5..5..6..10..6
2..1.. 7..4..4..8..7.. 6
1..9..4..1..7.. 11..2..3
1..0..9..8..2..4..3.. 9
1..0..11..5..6..8..2.. 0.. 1..1..2..2..4..6

In this example, because there are no feet in the multiplier, the place is supplied by the cipher. The multiplicand has six places of duodecimals, and the multiplier seven; there are, therefore, thirteen places of duodecimals in the product. The first place of figures is feet, and the succeeding are the duodecimal places; the product is one foot, no inches, eleven seconds, five thirds, &c. But, independently of the consideration of there being as many places of duodecimals in the product as in the multiplier and multiplicand, the method of placing the denominations of the factors gives the correct places of the product, since like parts of the product stand under like parts of the multiplicand; it also shows the affinity, not only between duodecimals, but between decimals and every series of denominations, of which the same number in any place makes one of the next towards the left hand. The consideration is also useful, in discovering readily what kind of product arises by multiplying any two single denominations together.

When the number of feet runs very high in each factor, it will be much better to reduce all the denominations in both into the lowest, then multiply the factors, so reduced, and divide by 12 as often as there are duodecimal places in the product.

Example 4.

Multiply $\overset{ft}{6}..5'..4''$ by $\overset{ft}{3}..6'$ as in Example 1.

6 5..4″	3..6′
12	12
77	42
12	
928	
42	
1856	
3712	
12)38976	
12)3248	
12)270..8	
22..6..8 the same as before.	

Example 5.

Multiply $3^{ft}..6'..4''..6'''..5^{iv}..$by $0^{ft}..0'..5''..3'''$

$5''..3'''$ $3^{ft}..6'..4''..6'''..5^{iv}$

5..3	3..6..4..6..5	
12	12	
63	42	
	12	Proofs by duodecimals.
	508	$3^{ft}..6'..4''..6'''..5^{iv}$

the product, the same as by duodecimals.

In this example, because there are seven places of duodecimals in the two factors, viz., four in the multiplicand, and three in the multiplier, the product 4613427 is divided seven times successively by 12.

There is another method of duodecimals, almost equally convenient. The rule is as follows: First.—Under the multiplicand, place the corresponding denominations of the multiplier.

Then multiply each denomination, from right to left, of the multiplicand, by each term of the multiplier successively from the left to the right, placing the first denomination of each row, or product, one place nearer to the right, and carrying one from every twelve in the product of any denomination, to that which succeeds it towards the left, up to the place of feet; then the sum of all the like products will be the total.

Example 6.

Multiply $10^{ft}..4'..5''$ by $7^{ft}..8'..6''$

$10^{ft}..$ $4'..$ $5''$ Multiplicand.

There is the same number of figures in each operation, but in the last the products are inverted. The first method, which is here used to prove the second, is similar to the common method of multiplication of integers, the first place of figures of every product being placed under the second denomination towards the left.

When feet and inches only are concerned, the reader is referred to the articles CROSS MULTIPLICATION, and PRACTICE.

DWANGS, a term used in Scotland, for the short pieces of timber employed in strutting a floor.

DWARF WALLS, low walls of less height than the story of a building. Sometimes the joists of a ground-floor rest upon dwarf walls; and the enclosures of courts are frequently formed by them with a railing of iron on their top: indeed, any low wall used as a fence, may be termed a dwarf wall.

DWELLING-HOUSE. *See* BUILDING and HOUSE.

DYE, the plain part of a pedestal, contained between the base and cornice, in the form of a square prism, approaching frequently to a cube or dye, whence the name originates.

The dye of a pedestal is generally placed in the same vertical plane with the vertical sides of the plinths of columns; there is, however, an instance in the dye of the pedestals of the columns of the Stoa, or Portico, at Athens, where the dye recedes within the vertical sides of the plinths of the bases. The practice of using pedestals under columns, is bad at the best; but in this instance their employment is still more ridiculous, being contrary to the rules of true taste and philosophy.

DYE, is also used for a cube of stone, placed under the feet of a statue and beneath its pedestal, to raise, and show it to more advantage.

DYE. *See* DADO.

DYNAMOMETER, (*measurer of power*), a term which has been applied to an instrument for measuring force or power. The Dynamometer has been used by engineers for ascertaining the tractive power required in drawing carriages upon roads or vessels, upon canals, and also for measuring the relative force of men and other animals. These effects are usually manifested by the compression or distension of a strong spring, or by a steel-yard upon the principle of a bent lever balance; but in both these constructions the instrument is subject to great vibration, owing to the inequalities in the resistance and in the moving force, which render the indications very uncertain. A very ingenious application of the Dynamometer was made by Sir John Macneill, to the Road indicator, in experiments on the comparative condition of different descriptions of roads.

DYPTERON. *See* Dipteron.

E.

EARS. *See* Crosettes and Ancones.

EAGLE, in architecture, a figure of that bird anciently used as an attribute of Jupiter, in the capitals and friezes of the columns of temples consecrated to that deity.

Also a lettern, or reading-desk, used in churches, from whence the lessons are read. It is so called from its form, which is that of an eagle with outspread wings, on which the book is laid, sometimes represented as trampling under foot a serpent. The material is generally brass, and the image is supported on a stem of similar material, pierced and otherwise enriched. *See* Lettern.

EARTH-TABLE, the course of masonry or other work level with the ground.

EARTHEN FLOORS. *See* Floors.

EATING-ROOM. *See* Dining-Room.

EAVES, (from the Saxon,) the margin or edge of the roof of a house, which overhangs the walls, in order to throw off the water from the face of the masonry or brickwork.

Eaves Lath, or Eaves Board, an arris fillet, or thick feather-edged board, placed at the eaves of a roof, for raising the bottom of the first course of slates above the sloping plane of the side of the roof, so as that the next course may be properly bedded: that is, when the lower ends rest firmly upon those which form the eaves-course. It is sometimes also called *eaves catch.*

EBONY, a species of hard, heavy, and durable wood, which admits of a fine polish or gloss. The most usual colour is black, red, or green; but the best i sa jet black, free from veins and rind, very heavy, astringent, and of an acrid pungent taste. Ebony is wrought into toys, and is much used for mosaic and inlaid work.

ECATÆA, statues erected to the goddess Hecate, for whom the Athenians had a great veneration, believing her to be the overseer and protectress of their families.

ECBATANA, the capital of ancient Media, and the residence of the Median and Persian kings. It was situated in a plain, about twelve stadia from mount Orontes. Diodorus says it was 250 stadia in circuit. The walls were seven in number, built upon a circular plan, rising gradually above each other, by the height of each wall conforming in a great measure to the situation of the ground. In the book of *Judith*, we read that they were 60 cubits in height, and 50 in breadth; that the towers over the gates were 100 cubits in height, and the breadth of the foundation 60 cubits, and that the walls were built of hewn and polished stones, each stone being 6 cubits in length and 3 in breadth. The royal palace and treasury were within the inmost of the seven walls. Diodorus says, the timber of the palace was cedar or cypress; and various parts of it were cased with gold or silver. There are no monuments remaining of this superb palace, where the monarchs of Asia generally passed their summer; and it is rather to be lamented that a disagreement should exist among modern travellers, about the site on which this stately metropolis stood.

The site of Ecbatana has been a matter of dispute; but the dispute has arisen solely because those who have discussed the question, either did not know the evidence on which the question must be decided, or did not understand it. The route of commerce between the low country in the ancient Seleucia, and the modern Bagdad and the high table-land of Iran, is determined by the physical character of the country, and has continued the same from the earliest recorded history of those countries, to the present day. The places marked in the "Itinerary" of Isidore, as lying between Seleucia and Ecbatana, are the places indicated by modern travellers as lying on the route between Bagdad and Hamadan.

ECCENTRICITY, the distance between the foci of an ellipsis; it is otherwise called *ellipticity.*

ECCLESIASTICAL ARCHITECTURE. Under this title it is our intention to inquire into the nature of the places of worship employed by the early Christians, to consider the origin and progress of buildings devoted to this purpose, with a cursory glance at their history, and to describe generally their form, distribution, and structural arrangement.

Information on such subjects is to be sought for amongst the patristic writings, the early ecclesiastical historians, more especially Eusebius, and the early Christian writers generally. Collateral evidence corroborative of the testimony afforded from such sources, is to be found amongst cotemporary heathen authors in their occasional and incidental reference to such subjects. Evidence on this matter from all sources has been carefully collated, and much valuable information gained by the patient and learned research of Bingham, who has included it in his most elaborate work, the *Origines Ecclesiasticæ;* to which we shall have occasion frequently to refer in the following pages.

Of the forms of churches for the first three centuries, during the time of persecution, we know but little; and it is probable that during the very earliest period, when the Christian church was in a normal state, so to speak, whilst she numbered but few advocates, and they poor and of little influence, when "not many wise, not many noble were called;" it is probable, we repeat, that Christians had no fixed form or arrangement of parts in their places of public worship, but that a dwelling-house of some member or even a portion of such house, was set apart for the purpose. It is nearly certain that no structures were built for the especial purpose, during the first division of this period; for not only would they have attracted attention and suspicion, but would have been destroyed together with the worshippers: the earliest Christians were compelled to secrecy and obscurity, at least they did not bring themselves offensively or ostentatiously forwards into notice, although not shrinking from an open avowal of their faith when called upon for it; for be it remembered, they were to be "wise as serpents, and harmless as doves."

In the Sacred Writings, more especially in the "Acts of the Apostles," and in the epistles to the various churches, we not unfrequently meet with the word *church*, or *εκκλησια*, which must in some cases undoubtedly apply to the edifice or room in which it was customary for the Christians to assemble; we know besides that it was a practice with the early Christians of the apostolic times to assemble together in some appointed place for the purpose of worship and devotion. It is evident from the accounts of the evangelists, that the eleven continued together after their Master's crucifixion, whether engaged in prayer and fasting, we cannot say; but they were certainly in one place when the women came and told them of the resurrection. In the evening of the same day, likewise, it is mentioned that they were assembled together in one place, and with closed doors, for fear of the Jews; and eight days afterwards, they were again together with closed doors. These would seem somewhat to invalidate the supposition of their being collected together for prayer, or at least public prayer, for it is mentioned that after the return of the apostles from Bethany, "they were continually in the Temple praising and blessing God." Again on the day of Pentecost, they were all together in one house, and, as it is noticed, with one accord, which expression would seem to express the existence of some object, reason, or purpose of their being together, and what more likely than for common prayer? yet they still attended the public services of the Temple, for it is related that after this, "Peter and John went up together into the Temple at the hour of prayer, being the ninth hour." After the incident which occurs at this time in the Temple, and when Peter and John were released from custody, they returned to their companions, who were assembled together —probably in the same place as before—and after relating the circumstances, it is told us that they prayed and "spake the word of God with boldness." Some time subsequent to these events, it is related of Paul and Barnabas, while at Antioch, that for a whole year they assembled themselves with the church, and taught much people. This was in all probability in a stated place set apart for the purpose. Still stronger is the probability with regard to the house of Mary, where Peter fled after his escape from prison, and where many Christians were gathered together praying; one might suppose that a room in her house had been given by Mary for the purpose of public worship. Lydia probably made a similar gift. But, not to multiply instances, we would particularly allude to a circumstance which occurred while Paul was staying at Troas; for it is related that "upon the first day of the week, when the disciples came together to break bread,"—in other words, to celebrate the eucharist,—"Paul preached unto them, ready to depart on the morrow, and continued his speech until midnight. And there were many lights in the upper chamber, where they were gathered together. Now there sat in a window, a certain young man named Eutychus, being fallen into a deep sleep; and as Paul was long preaching, he sunk down with sleep, and fell down from the third loft, and was taken up dead;" upon which Paul goes down to him, and restores him to life. This is probably the most minute description of the place, time, and mode of worship recorded in the Sacred Writings. It will not escape remark that the room in this instance is said to have been an upper room, and there is reason to believe that it was a practice amongst Christians, to use the upper room, or Hyperōon, for this purpose; it will be remembered that it was an upper room in which the Saviour celebrated the passover and instituted the eucharist, and it may possibly have been for some reason of this kind, rather than from the situation and nature of the place, that the upper room was adopted.

It has been maintained that the early Christians had no places set apart for public worship; but as Bingham combats this argument, it may be as well to let him speak for himself. His remarks are for the most part a summary of the inquiries of the learned Mede, who has treated this particular subject at considerable length:—

"A very singular paradox has been advanced by some learned man," says Bingham, "that for the three first centuries after Christ, (i. e.) before Constantine ascended the throne of the Roman empire, A.D. 306, when he established Christianity, and soon after abolished paganism, the Christians, owing to the cruel persecutions to which they were exposed by the pagans in these centuries, first under the tyrant Nero, A.D. 64; and next under the Roman emperor Domitian, A.D. 94, had no such places of worship as churches. This statement is grounded upon some mistaken passages of Origen, Minutius Felix, and Arnobius, who say that the Christians had no temples, which they take as a denial of their having any churches; which opinion, though advanced with some show of learning by Vedelius, Suicerus, and others, is altogether without foundation, contradicted by the authors which they allege, and by themselves in the arguments they produce. Dr. Mede has given us an elaborate disquisition on the subject, in confutation of this opinion, wherein he has collected the authorities of the ancients, which, for the three first ages, prove the existence of Christian churches.

"We shall briefly, for the sake of those who have not that learned author, give the substance of his proofs, and add some others of our own observation. In the first place, he shows that the ancient authors, St. Austin, St. Basil, St. Jerom, and St. Chrysostom, and those under the name of Sedulius, Œcumenius, Theophylact, in their comments on that passage of St. Paul, (1 Cor. xi. 22,) 'Have ye not houses to eat and drink in? or, despise ye the church of God?' all took the word church there, not for the assembly, but for an assembly-room, or place expressly set apart for sacred devotional purposes. Now the apostles, at stated seasons, were in the habit of meeting together for prayer, and supplication for the prosperity of Christianity, upon mount Zion, at Jerusalem, the Hyperōon, or upper room, so often mentioned in the Acts of the Apostles, (Acts i. 13,) and where they were gathered together when the Holy Ghost came upon them, (Acts ii.) and where our blessed Lord also celebrated his Last Supper, and where he appeared to his disciples on two successive sabbaths after his resurrection, to their great amazement, and at a time when the doors were close shut and barred, for fear of the Jews, (John xx. 19.) Here the seven deacons were elected and ordained, (Acts vi. 3,) and here the first council of the churches was held at Jerusalem, (Acts xv.) This place becoming holy and sacred by these meetings, was afterwards inclosed within a goodly edifice, called the church of mount Zion; and in the time of Cyril, bishop of Jerusalem, it was called the high church of the apostles.

"This was the *οἱκος*, or same house of assembly at Jerusalem, that is mentioned, (Acts ii. 46,) where the apostles met for the breaking of bread, when they had all things in common. Some think the word *κατ οἱκω* is not to be translated from house to house, as in our version, but in the house or room where the Christian assembly was used to meet together. The next argument is drawn from what Eusebius observes of the *θεραπευται* in Egypt, whether Essenes, or Christians, they had their *σεμνεια*, or places appropriated for divine worship, from the days of St. Mark, and that such places are to be understood in all such passages of St. Paul, as "Salute ye the churches" in such and such an house; that is, the congregation which meet in the houses of such pious Christians, who had generally some part of their dwelling, or upper rooms, or housetop, (see Acts x. 9,) remote from noise, set apart for the church to assemble in, or, like that of Lydia's, (Acts xvi. 15.) At Macedonia was such an appropriated room, (see Acts xx.,) where St. Paul, on the first day of the week, preached to an immense multitude, and continued his discourse till midnight, when a young man, named Eutychus, sitting in the window where the lattice was open, being overcome by sleep, fell from the upper story, and was taken up dead, but whom St. Paul again restored to life. That there were devotional places, or oratories, set apart expressly for Christian worship in the first century, I think we have sufficient evidence; whether we call these places churches or not. The following century is, however, more clear, where they are called sometimes by the name of Cœnaculum; at others, by that which we have before mentioned, as Hyperoon. Thus we find Lucian, a pagan, or whoever was the author of the dialogue called Philopatris, about the time of Trajan, one of the pagan emperors, bringing in one Cretias, telling how the Christians carried him into a Hyperōon, the place of their assembly, with a design of making him a proselyte to their religion. He argues further, from the tradition of the church, derived from the ancient author of the Recognitians, under the name of Clemens Romanus, which says, that Theophilus, to whom St. Luke is supposed to have inscribed his Gospel at Antioch, where the name of Christians was first given to the followers of Christ, did convert his house into a church; and the like is reported of the house of Pudens, a Roman senator and martyr, in the Acta Pudentis, that it was turned into a church after his martyrdom. He concludes this first century with the testimony of Clemens Romanus, in his genuine epistle to the Corinthians, who says, that God has ordained well-appropriate places, where at appointed times and seasons he would be solemnly served, so that all things might be done religiously and orderly.

"In the second century, while the persecutions were still rife against the Christians, more cruel acts were passed under Trajan, A. D. 107, and Marcus Aurelius, A. D. 166, against them, by which it became necessary for them to act with firmness, and in compact. Thus Ignatius, in his epistle to the Magnesians, exhorts them to meet together in one place, which he calls *τὸ ναὸν Θεȣ*, the temple of God, and, in his epistle to the Philadelphians, he informs us, that at this time there was one altar in every church, and one apostolic bishop, or head, appointed with his presbytery and deacons. The present Greek copies, indeed, read it a little different from Dr. Mede, leaving out the word church, but the mentioning one altar is sufficient to intimate they had then a stated place for their ecclesiastical or Christian assembly. Tertullian, who lived in the following century, has clearly intimated that the Christians, at this time, had churches, when, complaining against those who followed the trade of idol-making, (for the Gentiles excused themselves, that they did not worship them,)—he says, 'the zeal of faith cannot declaim all the day long upon this point, bewailing that any Christians should come into the house of God from the shop of the enemy, and lift up their hands to God the Father, which were the mothers or makers of idols.' In another place he calls the church *Domus Columbæ*, the house of the dove, meaning either Christ, or his dove-like religion. And again, he expressly distinguishes between the baptistry and the church, which in those days were places separate from each other. In this age, Pius, bishop of Rome, wrote two short epistles to Justus, bishop of Vienne in Gaul; in the first of which is mentioned one Euprepia, a pious matron, who is said to have consigned the title of her house over to the church, in which was to be celebrated Divine offices of worship. And in the other epistle is named one Pastor, a presbyter, who is commended for erecting a titulus, that is, a small Christian church; Clemens Alexandrinus, towards the end of this century, also uses the name Ecclesia, for the place of the assembly, as well as the congregation; for, speaking of the church, he says, 'I call not now the place alone by this name, but the congregation of the elect people, the church;' and so, in his famous homily, *Quis dives Salvetur*, he brings in the Asian bishop, to whom St. John committed the young man to be trained up in the Christian discipline, complaining that the youth was become a villain and a robber, and, instead of following the church, had now betaken himself to the mountains, with a company like himself. By this it is plain, that, in his time, the word Ecclesia was taken for a church, or sacred place, as well as for the Christian assembly themselves, and that such a building as a church must have been known and understood. We have also the Scripture accounts of the seven Apocalyptic churches, in Asia Minor, to whom St. John the Divine, wrote from the isle of Patmos, where he was banished by the emperor Domitian, A. D. 96. These churches were Ephesus, Smyrna, Pergamos, Thyatira, Sardis, Philadelphia, and Laodicea, (Revelation ii. and iii.); some of whose ruins, as travellers inform us, now remain.

"In the third century, the testimonies are both more numerous and certain respecting the churches of the Apostolic Christians, though a succession of Roman emperors had passed edicts against them of a more severe and cruel nature, with the exception of that of Nero's. The persecuting emperors of this century were Septimius Severus, A.D. 203; Maximinus Thrax, A. D. 236; Decius, A. D. 250; Gallus, A. D. 253; Valerianus, A. D. 258; and lastly, Diocletian, A. D. 302.

"We have a testimony, in this age, of the existence of Christian churches, from a heathen author. Lampridius, in the life of Alexander Severus, reports, 'that there happening a dispute between the Christians and victuallers about a certain noted public place, each party challenging it as their own, the emperor's rescript determined it thus, in favour of the Christians: that it was better that God should be worshipped there after any manner, than that it should be given up to the victuallers.' About the middle of this period lived the famous Gregory of Neocæsarea, surnamed Thaumaturgus, who himself built several churches in Neocæsarea, and the adjacent parts of Pontus, as Gregory Nyssen reports in his life. St. Cyprian, about the same time, speaks of the place where the church assembled, under the name of Dominicum, the Lord's house; and, in another, opposes the church and the capitol—the altar of the Lord's house, and the altars of images and idol-gods, to one another; for, speaking against some that had lapsed, and, without due contrition, were for intruding themselves into the church again— 'If this were once permitted,' says he, 'what then remains but that the church should give way to the capitol, and the priests withdraw and take away the altar of the Lord with them, and let the images and idol-gods, with their altars, succeed, and take possession of the sanctuary, where the venerable bench of our clergy sit?' About this time, also, Dionysius, bishop of Alexandria, speaks of the churches as appropriate to the service of God.

"It appears further, from the rescript of Gallienus the emperor, recorded by Eusebius, where he restores the Christians their churches, under the name *τοποι θρησηδισμοι*, worshipping places; and from what has been noted before, out of the letter of Aurelian, which chides the senate for demurring about opening Sibylline books, as if they had been consulting, not in the capitol, but in a Christian church. As also that other rescript of his, in Eusebius, that the request of the council of Antioch ordered Paulus Samosatensis to be turned out of the house of the church. But the testimony of Eusebius goes further beyond all others; for, speaking of the peaceable times which the Christians enjoyed from the persecutions of Valerian to that of Diocletian, he observes, 'that the number of Christians so grew and multiplied in that *fifty years*, that their ancient churches were not large enough to receive them, and therefore they erected, from the foundations, more ample and spacious ones in every city.'

"The only objection against all this, made with any show of probability, is drawn from some of the ancient apologists—Origen, Minutius Felix, Arnobius, and Lactantius, who seem to say, 'that the Christians, in their time, had no temples or altars, nor ought to have any;' but, as Dr. Mede shows at large, this is only spoken against such temples, as the heathens pleaded for in the notion of encloistering the Deity by an idol, otherwise the very authors from whom the objection is drawn, must largely contradict themselves; for Arnobius owns they had their conventicula, houses of assembly, which he complains were barbarously destroyed in the last persecutions. And Lactantius says the same, giving them also the name of the temples of God, which Diocletian ordered to be demolished, at Bithynia. And Origen himself speaks of adorning the Christian churches and altars, in one of his Homilies upon Joshua. Lactantius, in another of his Institutions, speaks of one of the Christian conventicula in a town of Phrygia, which the heathen had burnt, with the whole assembly in it. And in his book *de Mortibus Persecutorum*, he gives a more particular account of the destruction of the churches throughout the heathen world; for he not only mentions the demolishing the stately churches of Nicomedia, in the kingdom of Bithynia, but intimates, that the same fate attended the churches over all the world; however it was, both Eusebius and Lactantius agreed in this one point, that there were churches before the last persecution.

"As a further proof of the existence of Christian churches in the middle of this century, we have a remarkable story told by Eusebius concerning the martyr Marinus, A.D. 259, in the time of Gallienus Marinus, who, being a candidate for a Roman office at Cæsarea, was informed against as a Christian, by an antagonist, who pleaded that he ought not to have the office, upon that score. The judge, upon examination finding it to be so, gives him three hours to consider whether he would quit his religion or his life. During this space, Theotecnus, bishop of Cæsarea, meets with him, and, taking him by the hand carries him to the church, and sets him by the holy table, then offers him a Bible and a sword, and bids him take his choice. He readily, without demur, lays his hand upon the Bible, whereupon the bishop thus bespake him: 'And here,' says he, 'adhere to God, and in his strength enjoy what thou hast chosen, and go in peace:' with this he immediately returned from the church to the judge, makes his confession, receives his sentence, and dies a martyr.

"Optatus takes notice of forty churches in Rome before the last persecution, which, being taken from the Christians, were afterwards restored to them by order of Maxentius, as St. Austin has more than once informed us. We have also read of some Christian churches in Africa, that were demolished in this persecution; as at Zama and Furni, noticed in the Gesta Purgationis of Cecilian and Felix. Others were taken away; and, in the mean time, till they were restored again, both councils and church-assemblies were held in private houses, as Optatus observes of the council of Cita. And St. Austin after him says, 'It was not to be wondered at, that a few bishops should hold a council in a private house, in the heat of persecution, when the martyrs made no scruple, in the like case, to be baptized in prison, and Christians meet in prison to celebrate the sacrament with the martyrs, as well as in secluded places.' But not to multiply instances of this nature, the very tenor of the imperial edicts, which raised the last persecution, is undeniable evidence, that the Christians, in all parts of the world, had their public churches, to which they resorted so long as they had opportunities to frequent them; for Eusebius says, 'the edicts of the emperors of Rome were sent to all the Roman provinces, even to Britain, commanding the churches of the Christians to be levelled with the ground, and the Bibles to be given up and burnt.' This was the last persecution, when Diocletian boasted that he had annihilated Christianity, and proclaimed the extirpation by exulting inscriptions—*Nomine Christianorum deleto qui templa evertebant;* and, *Superstitione Christi ubique deleta.* But the flame was not extinguished; it was again to break forth, for the mouth of the Lord had spoken it. Diocletian had now become hateful; soon after which he abdicated the throne, and Constantine the Great assumes the imperial sway of the Roman empire."

To these remarks we would add some further ones of Mede, and likewise give, at length, some passages referring to this subject, drawn from the writings of the early fathers who were living during the period we are speaking of.

Basil, speaking of the passage before alluded to, of *Have ye not houses to eat and to drink in?* &c., says, that we ought not to dishonour sacred places or things by the mixture of things of common use; and in answer to the question as to whether the Eucharist may be celebrated in a common house says, that as the word doth not allow that any common vessel or utensil shall be brought into places that are sacred, so likewise doth it forbid that the holy mysteries should be celebrated in a common house; for neither would the Old Testament permit any such thing to be done, nor our Lord, who said, "There is here one greater than the temple;" nor the apostle, saying, "Have ye not houses to eat and to drink in," &c. Whence we may learn, that we ought not to take our common supper in the church, nor should we dishonour the Lord's supper by eating it in a private house. But if one be necessitated to communicate in private, let them choose out the most clean and decent room for such a purpose, and withal see that he do it in the fittest and most seasonable time. St. Chrysostom says, on the same subject, "Behold a further change, that not the poor only, but also the church itself is injured. For, as hereby thou makest the Lord's supper a private supper, so thou dealest no better with the place, in that thou usest the church as a private and ordinary house." So again, Theodoret, "If ye come together to feast it, do this in your own houses, for to do thus in the church is a manifest contempt, a plain dishonour done to the church. For how can it but seem a thing wholly indecorous and absurd for you to fare deliciously in the temple of God, where the Lord himself is present, who hath prepared for us a common table, when at the same time those Christians that are poor are hungry, and out of countenance by reason of their poverty?" The author of the commentaries upon the epistles, alluding to the same text, says, "Ye despise the church of God, making it a place for common feasts and banquetings," and in the same track follow Theophylact and Œcumenius.

With regard to the nature of the earliest churches, and more especially to the Hyperōon, Mede says, "For the first it is not to be imagined they were such goodly and stately structures as the church had after the empire became Christian, and we now, by God's blessing, enjoy; but such as the state and condition of the times would permit, at the first some capable and convenient room within the walls or dwelling of some pious disciple, dedicated by the religious bounty of the owner to the use of the church, and that usually an Ἀνώγεον, or Ὑπερωον, an upper room, such as the Latins call *Cœnaculum*, being, according to their manner of building, as the most large and capacious of any other, so likewise the most retired and freest from disturbance, and next to heaven, as having no other room above it. For such uppermost places we find they were wont then to make choice of, even for private devotions, as may be gathered from what we read of St. Peter, (Acts x. 9,) that he went up to the housetop to pray; for so δῶμα signifies *ex usu Hellenistarum*, and is accordingly here rendered by the vulgar Latin, *in superiora*.

"Such an Hyperöon as we speak of, was that remembered by the name of *Cœnaculum Sion*, where, after our Saviour was ascended, the apostles and disciples assembled together daily in prayer and supplication, and where, being thus assembled, the Holy Ghost came down upon them in cloven tongues of fire at the feast of Pentecost. Concerning which there hath been a tradition in the church, that this was the same room wherein our blessed Saviour, the night before his passion, celebrated the Passover with his disciples, and instituted the mystical Supper of his Body and Blood for the sacred rite of the gospel; the same place where, on the day of his resurrection, he came and stood in the midst of his disciples, the doors being shut, and, having showed them his hands and his feet, said '*Peace be unto you*,' &c; the place where, eight days, or the Sunday after, he appeared in the same manner again unto them, being together, to satisfy the incredulity of Thomas, who the first time was not with the rest; the place where James the brother of our Lord was created by the apostles, bishop of Jerusalem; the place where the seven deacons were elected and ordained; the place where the apostles and elders of the church at Jerusalem held that council, and pattern of all councils, for decision of that question—whether the Gentiles which believed were to be circumcised or not; and for certain, the place of this *Cœnaculum* was afterwards enclosed with a goodly church, known by the name of the church of Sion, upon the top of which it stood; insomuch that St. Jerome, in his *Epitaphio Paulæ*, made bold to apply that of the Psalm to it,'Her foundations are upon the holy hills; the Lord loveth the gates of Sion more than all the dwellings of Jacob.' How soon this erection was made, I know not; but I believe it was much more ancient than those other churches erected in other places of that city by Constantine and his mother, because neither Eusebius, Socrates, Theodoret, nor Sozomen, make any mention of the foundation thereof, as they do of the rest. It is called by S. Cyril, who was bishop of the place, *the upper church of the apostles*; and says he, 'The Holy Ghost descended upon the apostles in the likeness of fiery tongues, here in Jerusalem, *in the upper church of the apostles*.'

"If this tradition be true, it should seem by it that this *Cœnaculum*, from the time our blessed Saviour first hallowed it by the celebration of his mystical Supper, was thenceforth devoted to be a place of prayer and holy assemblies. This is the more easy to be believed, if the house were the possession of some disciple at least, if not kindred also to our Saviour according to the flesh, which both reason persuades, and tradition likewise confirmeth it to have been.

"And if this were so, why may not I think that this *Cœnaculum Sion*, or upper room of Sion, was that οἶκος whereof we read, concerning the first Christian society at Jerusalem, that 'they continued daily in the Temple, and, breaking bread (κατ' οἶκον) in the house, ate their meat with gladness and singleness of heart?' the meaning being, that when they had performed their devotions daily in the temple at the accustomed times of prayer there, they used to resort immediately to the *Cœnaculum*, and there having celebrated the mystical banquet of the Holy Eucharist, afterwards took their ordinary and necessary repast with gladness and singleness of heart. For so κατ' οἶκον may be rendered; for ἐν οἴκῳ, and not *domatim* or *per domos*, *house by house*, as we translate it, and so both the Syriac and Arabic render it, and the New Testament elsewhere uses it."

It would seem from this last passage, that Mede sees no difficulty in reconciling the attendance of the apostles on the public service of the Jewish Temple, with the supposition that they likewise celebrated a common worship in their own chapels or consecrated places; and if we look into the matter, this double service will not appear extraordinary, for as yet they adhered to their Master's practice of worshipping at the Temple, while at the same time there were many peculiar and distinctive services in their new religion, which they could not perform in the Temple. For instance, the celebration of the Holy Eucharist was an essential no less than a peculiar rite, which they would not have been allowed, even supposing them willing, to have celebrated in the Temple; they were necessitated therefore to fulfil this command in their own places of worship. This seems to have formed a continuation and completion of the Temple service.

"Such as these, I suppose," continues Mede, "were the places at first set apart for holy meetings, much like to our private chapels now in great men's houses, though not for so general a use.

"In process of time, as the multitude of believers increased, some wealthy and devout Christian gave his whole house or mansion, either while he lived, if he could spare it, or bequeathed it at his death, unto the saints, to be set apart and accommodated for sacred assemblies and religious uses.

"At length, as the multitude of believers still more increased, and the Church grew more able, they built them structures of purpose, partly in the cemeteries of martyrs, partly in other public places; even as the Jews—whose religion was no more the empire's than theirs—had, nevertheless, their synagogues in all cities and places where they lived among the Gentiles."

The following quotations from writers of the period will give some insight into the general use and nature of distinct places of worship in their days. In the second century, Ignatius speaking to the Magnesians, says, in the passage alluded to above, "All of you meet together for prayer in one place, let there be one common prayer, one mind, one hope in love, in the immaculate faith in Jesus Christ, than which nothing is better. All of you as one man run together to the temple of God, as to one altar, to one Jesus Christ, the High Priest of the unbegotten God."

In the third century Hippolytus, describing the state of the world at the coming of antichrist, says, "the temples of God shall be as common and ordinary houses; churches shall be utterly demolished everywhere; the Scriptures shall be despised:" thus showing the esteem in which churches were then held.

Gregory of Neocæsarea, surnamed Thaumaturgus, who lived in the middle of the third century, describing the five degrees or admission of penitents according to the discipline of his time, says, 1st. *Weeping* (the first degree of penance) was without the porch of the oratory, where the mournful sinners stood, and begged of all the faithful as they went in to pray for them. 2d. *Hearing* (the second degree) was within the Porch, in the place called *Narthex*, the place where these penitent sinners (being now under the *ferula* or censure of the church) might stand near to the catechumens, and hear the Scripture read and expounded, but were to go out before them. 3d. *Prostration or lying along on the Church-pavement*. These *prostrate* ones were admitted some what further into the church, and went out with the catechumens. 4th. *Standing or staying with the People or*

Congregation. These *Consistentes* did not go out with the *Catechumens*, but after they and the other penitents had left, remained, and joined in prayer with the faithful. 5th. *Participation of the Sacraments.*" This is a somewhat remarkable passage, to which we shall have occasion again to refer.

In the rescript of Galienus the churches of the Christians are mentioned as Τοποι θρησκευσιμοι or Places of Worship. Gregory Nyssen, speaking of the success of Gregory of Neocæsarea, relates, "How that, becoming all things to all men, he had in a short time gained a great number of converts through the assistance of the Divine Spirit, and that hereupon he had a strong desire to set upon the building of a temple or place for sacred assemblies; wherein he was the more encouraged by the general forwardness he observed among the converts to contribute both their moneys and their best assistance to so good a work. This is that temple which is to be seen even at this day." Eusebius, speaking of the long peace which the Church enjoyed before the persecution of Diocletian, says, "How shall any one be able to express those infinite multitudes of Christians assembling in every city, those famous meetings of theirs in their oratories or churches? and therefore they, not being content with those smaller churches which before they had, (those their ancient edifices not being large enough to receive so great a number,) took care to erect from the very foundation fairer and more spacious ones in every city."

Soon after this dreadful persecution Constantine succeeded to the government, and having been fully convinced of the truth of the Christian faith, with hearty and unremitting zeal set about its establishment, nor to any thing did he give more constant attention than to the erection and adornment of churches. Before, however, entering upon a description and examination of these edifices, it may be as well to say a few words respecting a subject which has not been agreed upon amongst the learned; it is this, whether the early Christians made use of heathen temples for the performance of their public services. Bingham enters into the subject at some length, from whom we quote the following:—

"At first, when the reformation from heathenism was in its infancy, no idol-temples were made use of as churches, but were either permitted to the heathen for some time, or else shut up or demolished. Till the twenty-fifth year of Constantine, A.D. 333, the temples were in a great measure tolerated, but in that year he published his laws commanding temples, altars, and images to be destroyed, which laws are sometimes referred to in the Theodosian code. And pursuant to these laws, a great many temples were defaced in all parts of the world, and their revenues confiscated, as appears not only from the Christian writers, St. Jerome and Eusebius, and others, but also from the complaints of the heathen writers, Eunapius, Libanius, and Julian. In some of the following reigns also the same method was taken to shut up or to deface the temples, as is evident from the account which Ruffin gives of the general destruction of them in Egypt by the order of Valentinian. But in the next reign, in the time of Theodosius, another method was taken with some of them. For as Gothofred observes, out of the Chronicon Alexandrinum:—'Theodosius turned the famous temple of Heliopolis, called Balanium, into a Christian church, (εποιησεαντο εκκλησιαν χριστιανων.) And about the same time Socrates tells us, 'That when Valens had banished the two Macarii, the heads of the Egyptian monks, into a pagan island, they converted all the inhabitants, and turned their temple into the form of a church.' The like was done by the famous temple of the Dea Celestis at Carthage, by Aurelius, the bishop, in the time of Honorius, A.D. 399, which the author of the book, *de prædictionibus*, under the name of Prosper, tells, with this remarkable circumstance, 'that it had been dedicated before by one Aurelius, a heathen high-priest, with this inscription, *Aurelius pontifex dedicavit*, which our author says was left in the frontispiece, to be read by all the people, because, by God's providence, it was fulfilled again in Aurelius the bishop, for whom it served as well as the former Aurelius, when he had once dedicated it to the use and service of the Christian religion, and set his chair in the place of the goddess. Not long after this, Honorius published two laws in the Western empire, forbidding the destruction of any more temples in cities, because they might serve for ornament, or public use, being once purged of all unlawful furniture—idols and altars, which he ordered to be destroyed wherever they were found.

"These laws, as Gothofred rightly observes, seem to have been published at the instance of the African fathers, who, as appears from one of the canons of the African code, petitioned the emperor, that such temples as were in the country only, and private places not serving for any ornament, might be destroyed. Arcadius published such another law for the Eastern empire, which relates only to the destruction of temples in country-places, and not in cities, where now there was no such danger of superstition, since they might be converted to a better use. And upon this ground the author, under the name of Prosper, commends Honorius for his piety and devotion, because he gave all the temples, with their adjacent places, to the church, only requiring the idols to be destroyed. 'Tis true, indeed, after this we find a law of Theodosius Junior commanding all temples to be destroyed; but, as Gothofred seems rightly to interpret it, "the word *destroying*, in that law, is to be understood only of despoiling them of their superstition, because it follows in the same law, that they were to be expiated by placing the sign of the cross upon them, which was a token of their being turned into churches. And his observation may be confirmed further from what Evagrius reports of Theodosius—that he turned the Tycæum, or Temple of Fortune at Antioch, into a church called by the name of Ignatius. The like was done by a great temple at Tanis in Egypt, as Valesius has observed out of the Itinerary of Antonius the martyr.

"Cluver also, in his description of Italy, takes notice of a place in the Jerusalem Itinerary, called Sacraria, betwixt Fulginum and Spoletum, near the head of the river Clitumnus, which he thinks was no other than the temple of Jupiter Clitumnus, though another learned antiquary makes it somewhat doubtful as to the present church now standing there. However, we have seen instances enough of this practice, and Bede tells us, that 'Gregory the Great gave Austin the monk instructions of the same nature about the temples here among the Saxons in Britain,—that if they were well built they should not be destroyed, but only be converted from the worship of devils to the service of the true God.' And so he observes it was done at Rome, where, not long after, Boniface the Fourth turned the heathen temple, called the Pantheon, into the church of All Saints, in the time of the emperor Phocas. Sometimes the temples were pulled down, and the materials were given to the church, out of which new edifices were erected for the service of religion, as Sozomen and Ruffin particularly observe of the temples of Bacchus and Serapis at Alexandria. I have already shown out of Antonius, that the Roman halls or basilicæ were likewise turned into churches. The like is reported of some Jewish synagogues by the author of the Chronicon Alexandrinum, who takes notice particularly of a synagogue of the Samaritans, in a place called Gargarida, which Zeno the emperor converted into a large Christian church.

"And though it is not agreed by learned men whether the temples said to be built by Hadrian were intended for the worship of himself, or the worship of Christ; for Casaubon and Pagi think he designed them for himself, whilst Huetius defends Lampridius, his relation, who says, "He designed them for the honour of Christ;" yet it is certain, that after they had been used to other purposes, they were at last, some of them, turned into Christian churches: for Epiphanius says, 'There was a great temple at Tiberias, called the Hadrianum, which the Jews made use of for a bath; but Josephus Comes, the converted Jew, in the time of Constantine, turned it into a church.' And the like was done by another of them by Athanasius at Alexandria, having before been the hall or place of Licinius, as the same Epiphanius informs us. So that now, partly by the munificence of the emperors, and partly by their orders for converting heathen temples into churches, and partly by the great zeal and liberality of private Christians in times of peace, churches became another thing from what they were in former ages, that is, more noble and stately edifices, more rich and beautiful."

Thus far Bingham, who seems to conclude from the above quotations of the early writers, that to convert heathen temples into Christian churches was not an uncommon practice: a writer, however, in the Quarterly Review, in a critique on the publications of Knight and Bunsen, on Ecclesiastical Antiquities, arrives at a very different conclusion; and as he has evidently given more than ordinary attention to the subject, it may not be amiss to refer to his remarks, in this place:—

"The antipathy," says he, "borne by the early Christians to the fine arts, debased by the pollutions of heathen idolatry, can neither be denied nor concealed; and the same causes which prevented the cultivation of the arts, ensured the degradation and subversion of their proudest and most splendid monuments. Excluding for the present the consideration of other agencies, the first paragraph in the rise of Christian architecture, must narrate the fall of the structures devoted to the superstition, which it was the end of the gospel to obliterate and destroy.

"The heathen temples were doomed to inevitable ruin. Laws had been promulgated by Theodosius for their preservation; conducive to the decoration of the city, they might be perhaps rendered useful for the purposes of civil society. Some may have been thus respited, though not rescued, until the decayed remains crumbled to the ground; they were never respected or honoured by public opinion, and could rarely be adapted to the objects pointed out by the imperial law, without such alterations as in most cases amounted to destruction. Others were accidentally preserved in desolate or secluded situations, in the forest or the marsh, or the mountain-glen, or on the shore, whence the inhabitants have been extirpated, or chased away. Such are the columns of Pæstum: the heavens are yet as bright as when the garlands hung down from the ruined architrave; the sea as azure as when the waves were ploughed by the painted prows; the crushed herbs beneath your feet, still send up their rich perfume. To the senses, the works of art are still as noble, the works of nature as sweet and gay; but the whole scene mourns under the curse inflicted upon scoffing, lascivious, corrupted Hellas. Language, people, race—their very name has disappeared. The wasting pestilence still hovers, and will ever hover, marking the vengeance which has fallen on the deserted shore.

"Few temples were ever adapted for the purposes of Christian worship; fewest of all in the capital of the Christian world. 'Of the Christian hierarchy,' says Gibbon, 'the bishops of Rome were commonly the most prudent and the least fanatic; nor can any positive charge be opposed to the meritorious act of saving and converting the majestic structure of the Pantheon.' In casting the account of the merits and demerits of the Christian hierarchy, such a pontiff as Gregory the Great would have been ill inclined to accept the encomium. In the *gergo* of Gibbon, 'fanaticism' is piety, and 'prudence' unbelief. The 'meritorious act,' thankful as we may be for the result, was a single item, by no means influencing the general balance of praise or dispraise; it was the solitary performance of Boniface IV.; it was an act from which no consequences resulted. With the exception of the Pantheon, we fail to detect any real example in Rome, of a temple which can be said to owe its *preservation*, in the *proper sense* of the term, to the Christian clergy. They had no thought of the kind—they took no pleasure in such antiquities. They sought no credit for such care. Antiquaries, with eager zeal, have collected about ten examples in which this preservation is asserted. Even in the cases which are least dubious, no further merit can be claimed for the hierarchy than the accidental preservation of a portico, a cella, or a wall, an encumbrance which it was troublesome to remove—a fragment which saved some expense, built up, concealed, marred, or deformed by the new erection to which it was unwillingly conjoined.

"It could not be otherwise. In the early Christians, any participation in our modern worship of heathen art, would have been false and unnatural. All the opinions, all the habits, all the feelings, all the conscience, of the early Christians strove against the preservation of the memorials of heathenism. Neither beauty nor convenience, if they had possessed the latter requisite, would, save in some few special cases, like that of the Pantheon, plead for the preservation of the relics of classical antiquity. They considered the idols as accursed. No object which had in anywise been connected with the worship of idols, or could be supposed to have been employed in their service, was to be used without exorcism. Thus, in the ritual of the church of Durham, there is a form of prayer for hallowing the vase found in the Roman encampment, which could not be employed for any Christian use until subjected to such purification. Nor was this belief confined to the rude Northumbrian peasant, or to a barbarous age. Let us place ourselves before the portal of St. Peter's, fresh from the workmen's hands. Four months have been employed in removing the huge obelisk of Sesostris from the ruins of Nero's Circus to the front of the great Basilica. Eight hundred workmen, toiling at creaking winch and groaning capstan, heave up the mass; whilst the breathless crowd watch the slow rising of the gigantic beam. It stops; when the one cry, '*aqua alle funi*,' which subjects the individual who suggests the happy expedient, to the pain of death, enables the maestro to complete his task; amidst the thunder of the cannon, the 'guglia' stands firm and erect upon its basement. But is the work complete? No: the trophy of the victory of Christianity over heathenism cannot yet be received as such, until all connection with its former slavery to the fiend has been destroyed. In solemn procession, the supreme pontiff exorcises the magnificent work, so long dedicated to the foul superstition of Misraim, and devotes it to the honour of the Cross, performing the rites which were deemed to expel the evil spirit. Those who may not share in the belief which dictated these ceremonies, must, nevertheless, respect the sentiments contained in the simple majestic language, commemorating the consecration of the spoils of heathenism to the service of the Cross. 'Ecce Crux Domini—Christus vincit—Christus regnat—Christus imperat—Christus ab omni malo plebem suam defendat—Vicit Leo de tribu Juda.'

"Thus did Pope Sixtus record his triumph. Yet there was a greater triumph felt by the zeal which taught the early Christians to glory in casting down the altars and the high places devoted to sin; deeming—we will not presume to judge whether rightly or wrongly—that such a testimony to the truth was imperatively enjoined upon them. By their deeds they contemned the temporizing policy of the emperors. They sought the actual and visible victory of literally erecting the temple of the Lord upon the ruins of the habitation of the demon. The statues were broken, to be buried in the foundations; hence few sculptures have ever been found at Rome, which did not, like the Venus of the Medici, show by their defacement and fractures, the aversion of which they had been the objects. Amongst the great congregation of the faithful, the distaste, the horrors excited by paganism —its structures, monuments, glories, charms—were unconquerable and paramount. Idols might have been removed, and the building consecrated by the rites, which, according to the primitive belief, would drive away the demon; yet no lustration could entirely heal the leprosy of the walls. The language of the Virgin Martyr was echoed in every heart:—

> 'Your gods, your temples, brothel-houses rather;
> Or wicked actions of the worst of men,
> Pursued and practised. Your religious rites!
> Oh! call them rather juggling mysteries,
> The baits and nets of hell. . . . . .
> Your Venus whom you worship, was a harlot—
> Flora, the foundress of the public stews,
> And has for that her sacrifice.
> Your Jupiter, a loose adulterer,
> Incestuous with his sister. Read but those
> That have canonized them. You will find them worse
> Than in chaste language I can speak them to you.'

"Whatever had been touched by paganism, seemed, and can we say unjustly? to be reeking with impurity."

On this subject we incline towards the opinions of the reviewer, notwithstanding the evidence adduced by Bingham; at the same time we do not mean to deny the occasional application of pagan temples to Christian uses under peculiar circumstances, as in the case of Austin and the Saxons at a later date, yet we do think the instances of such application were comparatively few, and formed the exception rather than the rule. For not only were the feelings of the early Christians enlisted against every thing connected with the worship of the heathen deities,—or devils, as St. Paul calls them,—but the form also of pagan temples was totally unsuitable for churches. Temples were little more than cells for the reception of the idol and priests, the people stood outside. The services of the Christian church required a very different arrangement; here you required accommodation for worshippers within the walls, as the very name *εκκλησια*, *assembly*, implies; there is here a communion or organized congregation. Christians came together not merely to behold as it were a spectacle, but to pray together, and to hear the Gospel read to them. "The Christian temple," says Professor Willis, "was a heathen temple turned inside out;" in the heathen temples the colonnade was outside, in the Christian church it was necessary to transpose it to the inside, to obtain greater internal space, as we see was the case in their later structures. Taking all this into consideration, we think there is some reason to decide that the examples of the adaptation of temples to the purpose of Christian worship, formed but exceptions. The very term *temple* was never used by the earlier writers, when speaking of the *church;* the terms were distinctive of the religion to which they belonged, the former when used, implying always heathen temples. The term employed in contra-distinction to this is *εκκλησια*, which, from being the name of the assembly, soon came to be applied to the place in which they met; this word is very common. Another appellation is *κυριακον*, *Dominicum, or Domus Dei*, which is met with in Eusebius and two or three councils; *Domus Columbæ* used by Tertullian, is a similar term. Other terms found in Eusebius, Socrates, Sozomen, and others, are *προσευκτηρια* and *οικοι ευτηριοι*; but one very frequent in the writers of the fourth and fifth centuries, though scarcely seen before, is Basilicæ. The word *temple* was seldom or never used in this sense during the first three centuries.

The earliest descriptions of early churches, now extant, are to be found in the writings of Eusebius, who gives somewhat lengthened accounts of the Holy Sepulchre at Jerusalem, and of the church of Paulinus at Tyre, which we proceed to notice. The descriptions are not very lucid; they show us how richly churches were adorned, and throw some little light upon their structure and arrangement, although the account is in many places confused; still it gives us some idea of the buildings, and, by comparison of this with other accounts, and with the remains of what are supposed to be earlier churches, we are enabled to decide pretty nearly their original form and distribution. He commences with a description of the Holy Sepulchre.

The Empress Helena, after a long search, succeeds in discovering the place of the Holy Sepulchre; which had been covered over by the pagans, and polluted by their rites, the place having been dedicated by them to Venus, a statue of which goddess was erected over the Sepulchre. Constantine having destroyed all the remains of heathenism, and having had the place purified from such abominations, proceeds to consider the erection of a suitable church upon the spot, and sends directions to Macarius, bishop of Jerusalem, upon the subject, a portion of which, as given by Eusebius, we transfer to these pages.

"Moreover, I would persuade you to that which is clear and evident, namely, that we ought to take especial care that this place, which we have purified and cleansed from superstitious idols, and which God and good men, from primitive times accounted sacred and holy, and which was afterwards so esteemed for the attestation and confirmation it gave to our belief in Christ's passion, should be honoured by erecting a church thereat. It is meet therefore that your wisdom should so dispose of this work, and prudently provide all things necessary thereto, that the beauty of the temple may excel all other churches, and the several parts of it may exceed the chief churches in other cities. Know therefore that we commit the care of erecting, building, and curiously adorning the walls thereof, to our friend Dracilianus and the president of your province. For out of our gracious bounty we have commanded them that they should have recourse to your wisdom to know what artificers and workmen shall be necessary to the building thereof, and accordingly shall straightway provide them, and send them thither. And when you have cast and contrived what marble pillars, or other marble works, will be necessary, either to adorn it, or make it more durable, look that you certify us by your letters, that when we understand what shall be necessary, we may provide accordingly. For this, which is the most special place of all the world, ought to be adorned with all kinds of work of cost and curiosity.

"I would have you certify me whether the roof of the sanctuary should be arched, or built in some other form; but if it be built archwise, it may be conveniently gilded. It remains therefore that your holiness should speedily signify unto those whom we have appointed to be overseers of the work, both what artificers and labourers will be necessary and what charge it will require; and also to certify us not only concerning the pillars and other marble work, but also concerning the wood-work of the roof, if you think fit that it should be built in that form."

Then follows a glowing description of the building when completed, from which we extract the following:—

"First of all, then, he adorned the sacred cave itself, as the chief part of the whole work, and the hallowed monument of which the angel radiant with light had once declared to all that regeneration which was first manifested in the Saviour's person. This monument, therefore, first of all, as the chief part of the whole, the emperor's zealous magnificence beautified with rare columns, and properly enriched with the most splendid decorations of every kind. The next object of his attention was a space of ground of great extent, and open to the pure air of heaven. This he adorned with a pavement of finely-polished stone, and enclosed it on three sides with porticos of great length. For at the side opposite the sepulchre, which was the eastern side, the church itself was erected, a noble work rising to a vast height, and of great extent both in length and breadth. The interior of this structure was floored with marble slabs of various colours, whilst the external surface of the walls, which shone with polished stones exactly fitted together, exhibited a degree of splendour in no respect inferior to that of marble. With regard to the roof, it was covered on the outside with lead, as a protection against the rains of winter. But the inner part of the roof, which was finished with sculptured fretwork, extended in a series of connected compartments, like a vast sea, over the whole church; and being overlaid throughout with the purest gold, caused the entire building to glitter as it were with rays of light.

"Besides this, were two porticos on each side, with upper and lower ranges of pillars corresponding in length with the church itself, and these also had their roofs ornamented with gold. Of these porticos, those which were exterior to the church were supported by columns of immense size, while those within these rested on piers of stone beautifully adorned on the surface. Three gates placed exactly east were intended to receive those who entered the church.

"Opposite these gates, the crowning part of all was the hemisphere, which rose to the very summit of the church. This was encircled by twelve columns, (according to the number of the apostles of our Saviour,) having their capitals embellished with silver bowls of great size, which the emperor himself presented as a splendid offering to his God.

"In the next place he enclosed the atrium, which occupied the space leading to the entrances in front of the church. This comprehended first the court, then the porticos on each side, and lastly the gates of the court. After these, in the midst of the open market-place, the entrance-gates of the whole work which were of exquisite workmanship, afforded to passers-by, on the outside, a view of the interior, which could not fail to inspire astonishment.

"This temple, then, the emperor erected as a conspicuous monument of the Saviour's resurrection, and embellished it throughout on an imperial scale of magnificence. He further enriched it with numberless offerings of inexpressible beauty, consisting of gold, silver, and precious stones in various forms; the skilful and elaborate arrangement of which, in regard to their magnitude, number, and variety, we have not leisure at present to describe particularly."

The following is our author's description of the church of Paulinus at Tyre, in his letter to that bishop:—

"Thus then, embracing a much wider space, he strengthened the outer enclosure with a wall to compass the edifice, that it might be a most secure bulwark to the whole work. Then raising a large and lofty vestibule, he extended it towards the rays of the rising sun; and, on entering the gates, he has not permitted you to enter immediately, with impure and unwashed feet, within the sanctuary, but leaving an extensive space between the temple and the vestibule, he has decorated and enclosed it with four surrounding porticos, presenting a quadrangular space, with pillars rising on every side. Between these he carried round the frame-latticed railing, rising to a proportionate and suitable height; leaving, however, the middle space open, so that the heavens can be seen, and present the splendid sky irradiated by the beams of the sun. Here, too, he has placed the symbols of the sacred purification, by providing fountains built opposite the temple, which, by the abundant effusion of its waters, affords the means of cleansing, to those that proceed to the inner parts of the sanctuary. And this is the first place that receives those that enter, and which, at the same time, presents to those that need the first introduction, both a splendid and convenient station.

"After passing this, he has made open entrances to the temple, with many other inner vestibules, by placing again three gates on one side towards the rising sun. Of these he constructed the middle one, far exceeding those on each side in height and breadth, embellishing it, at the same time, with exceedingly splendid brazen plates bound with iron, and decorated with sculpture, superadding them, as guards and attendants to a queen. In the same way, after disposing the number of the vestibules, also with the porticos on each side of the whole temple, he constructed above these different openings to the building, for the purpose of admitting more light, and these lights or windows he also decorated with various kinds of ornamental sculpture.

"But the royal temple itself he has furnished with more splendid and rich materials, applying a generous liberality in his expenses. And here it appears to me to be superfluous to describe the dimensions, the length and breadth of the edifice, the splendid elegance, the grandeur that surpasses description, and the dazzling aspect of the works; for when he had thus completed the temple, he adorned it with lofty thrones in honour of those who preside, and also with seats decently arranged in order throughout the whole, and at last he placed the holy altar in the middle. And that this again might be inaccessible to the multitude, he enclosed it with frame-lattice work, accurately wrought with ingenious sculpture, presenting a beautiful appearance to the beholders. And not even the pavement was neglected by him, for this too he splendidly adorned with marble, and then proceeded to the rest and to the parts outside the temple. He provided spacious exhedræ and oëci on each side, united and attached to the church, and communicating with the entrance to the middle of the temple."

Of the above structures, the former is still in existence; not indeed the identical building, but, as there seems reason to believe, a building similar in general form and arrangement. The text of Eusebius is difficult and obscure, and conveys but an indefinite idea of the edifice. Strange to say, we have a plan and description, which may be relied upon as genuine, in our own isles.

At Iona flourished abbot Adamnan, so distinguished by his participation in the great paschal controversy, A. D. 705; and he supplies the architectural antiquary with the knowledge so much desired. We owe the information to a singular contingency. After a long pilgrimage and continued residence in the Holy Land, a Gaulish bishop, named Arculphus, driven to the Hebrides, became the guest of the Culdee monastery. Here he related his perils, describing the holy places he had visited; and the "*Sebellus de Locis Sanctis*" contains his narrative.

Rarely has any work been transmitted with more peculiarity and authenticity. Adamnan wrote upon his tablets, from the actual dictation of the stranger; the notes so taken became the book we now possess. The Holy Sepulchre, as might be anticipated, was the main object of Adamnan's curiosity; and in addition to the verbal description, Arculphus drew a plan of the buildings upon the tables with his own hand. This plan Adamnan copied in his manuscript; he speaks of his drawing with extreme humility, calling it a vile figuration; but, as will be seen by comparing it with the plan of San Stefano Rotondo, it affords valuable information. The church was wholly of stone, of "wonderful rotundity," supported by twelve columns; having, as it would seem, three aisles; it was entered by four doors; and the sepulchre itself was illuminated by twelve lamps, burning day and night in honour of the twelve apostles. Since Adamnan speaks of three walls, we must suppose that the interior circle marks the columns, and the lines were probably staircases, leading to an upper church or gallery. When Aculphus saw the Holy Sepulchre, it had been somewhat damaged by the Persians, and it was subsequently ruined by the Arabs; yet, as the existing church still retains the original shape, we do not doubt but that it was rebuilt upon the original foundations.

Other churches were built by Constantine, at Jerusalem, Antioch, Nicomedia, Mambre, Heliopolis, Rome, and Constantinople, but few remain to the present day, few, at least, that have not been materially altered. Perhaps the most perfect specimen remaining is the church of S. Constantia; the burial-place of the daughter of Constantine; it is circular in plan, and divided by concentric rows of pillars, from which spring arches to support the roof. The model from which it was constructed was evidently identical with that of the Holy Sepulchre, even were it not that structure itself. It is the opinion of some, that the form of circular churches was derived from that of heathen temples of the same kind, such as those of Vesta, or Minerva Medica; this, however, does not seem to be the case, for although they are both circular in plan, they are of entirely different construction and arrangement. The temple has its columns on the exterior, supporting an entablature, while the church has its detached columns arranged in concentric circles within, connected by arches springing from the capitals, forming one or more aisles; the arrangement, it will be acknowledged, is totally dissimilar, and the mere outline cannot have much weight in the consideration.

But some have gone still further, and claimed the very structures themselves for heathen temples: the building mentioned above is supposed by such to be an ancient temple of Bacchus; but as Mr. Knight, in his beautiful work on this subject, says, "This opinion is principally founded on the mosaics with which the ceiling of the aisles is adorned, and which represents vine-leaves and grapes. But the vine is a Christian emblem, and is so frequently introduced in the decoration of Christian places of worship, that little weight can be attached to this circumstance. The architecture of this building is in conformity with the style of the time of Constantine, and not in conformity with that of a much earlier date." The fact is, the circular is the most natural form for sepulchral chapels, where the chief object is a tomb, placed in the centre. Other similar chapels are still in existence, of which, probably, the most remarkable, is that of S. Stephen. Baptisteries were likewise frequently of the same form, as is that of S. John Lateran, but more frequently octagonal, and sometimes octagonal within and circular without. All such buildings seem to have been simply baptisteries or sepulchral chapels; the form is totally unfitted for the requirements of the Christian liturgy, nor do they seem to have been employed for such purpose, with the exception, perhaps, of the church of the Holy Sepulchre, and this was not purely circular, but had parts of different plan attached to it, something like to the Temple Church, London. The form is very suitable for a baptistery. *See* Round Churches.

The more usual plan of Christian churches is that of a parallelogram, which form is said to have been derived from the heathen courts of justice; but ere entering upon the consideration of this matter, it will be well to give some description of the parts and arrangement of the early Christian churches, as collected from the descriptions of Eusebius above given, and from the writings of other authors who allude to the subject.

From such authorities, it would seem that churches of this period consisted not merely of a building for public service, but also of *exhedræ* or out-buildings, employed for the secular as well as religious concerns of the church; such as schools, libraries, houses of residence for the clergy, &c.; the whole being surrounded and enclosed by an outer wall. This arrangement is very similar to that of our existing cathedrals. That all within this outer wall was considered as belonging to the church, and consecrated ground, is evident from the fact of its being acknowledged as a sanctuary in after times. The position of the church within this enclosure, was generally east and west, having the altar toward the east; but this custom was not always observed, as we meet with many exceptions. That such a custom did prevail in spite of such exceptions, we have the authority of several writers. Socrates, noticing an example of the contrary practice, says, that the church at Antioch stood in a different position to other churches, for that the altar did not look towards the east, but to the west; and a similar observation is made by Paulinus Nolanus, respecting one of his own churches, and he gives the reason for his departure from the usual custom, namely, that the structure was made to look towards another, in memory of the Saint in whose name the latter was dedicated. The Apostolical Constitutions direct that churches should be built toward the east, but Walafridas Strabo says, "The ancients were not nicely curious which way their churches stood, but yet the most usual custom was for Christians to pray toward the east, and therefore the greater proportion of churches were built with respect to that custom."

Allowing this custom to have prevailed then, we shall have our first or outer entrance in the west wall of the enclosure, and this is called by Eusebius the προπυλον μεγα and προτη εισοδη. Through this vestibule, admittance was obtained into a large quadrangle or open area, surrounded by cloisters, which is called by Eusebius, *αιθριον* and *αυλη*, and by the Latins, *atrium;* the cloisters being distinguished in the former case by the name of *στοαι*, and consisting of a covered way, the roof supported by pillars or an open arcade. The object of this court seems to have been to receive the penitents of the first order, or mourners, who were not permitted to enter the main body of the church; in after times it was used for a place of burial, but then only for persons of distinction; kings thinking it a great honour to be buried within the gates. This place was sometimes named *impluvium*. In the centre of the open area was a fountain or large basin of water, in which it was customary for the Christians to wash their hands and face, and perhaps their feet, ere they entered the church, such practice being a symbol of the purity of heart which should attend them there. Tertullian speaks of the absurdity of going to prayer with washed hands and a polluted soul. A similar custom still prevails in the Romish church, borrowed doubtless from primitive practice, although differing in the intention and object for which it is observed. The fountain is called indifferently, φιαλη φρεαρ, *nymphæum*, *cantharus*, and *leontarium*, the latter term supposed to have been applied from the spouts being sometimes in the form of lions' heads. Socrates, speaking of the skirmish between the Catholics and the Macedonian heretics, says, "Such a slaughter was made, that the court (*αυλη*) was filled with blood, insomuch that the fountain (*φρεαρ*) was overflowed therewith, and ran through the adjoining cloisters (*στοαι*) even into the street." Examples of the atrium in its primitive shape are yet preserved in the churches of San Clemente, San Lorenzo, San Paolo, San Georgio in Velabro, Sta Maria in Trastevere; remodelled in San Giovanni Laterano, and Sta Maria Maggiore, and rebuilt in modern shape in St. Peter's. At San Ambrogio, Milan, the atrium is fully as large as the nave.

Entrance was obtained from the atrium into the *pronaos* or *narthex*, through three gates, of which the central one was frequently the largest and most important. The narthex formed the first division in the body of the church, and was used as the station for the catechumens, and such of the penitents as came under the title *ακουομενοι*, or hearers, so called from the circumstance of their being allowed to listen to the lessons and sermon, to which privilege also Jews, heathens, heretics, and schismatics were admitted, in this part of the church. Here also, somewhat in advance, stood the *substrati*, or third class of penitents, so called from the custom of prostrating themselves before the bishop, after sermon was ended, to receive his benediction. There were frequently more narthecces than one in a church, that of Sta Sophia is said to have had no less than four.

We have now arrived at the *ναος*, or nave, the principal division of the church, in which the body of the faithful, those who were under no censure, and in full communion with the church were congregated. This part was separated from the narthex by rails of wood, and was entered by gates which are distinguished by writers as *πυλαι καλαι*, or *βασιλικαι*, the beautiful or royal gates, so named perhaps from the circumstance of kings laying aside their crowns at this place, ere they proceeded further into the church. Leo Grammaticus notices it as a flagrant want of reverence in the emperor Michael, that "when he came to the royal gates, he did not lay aside his crown, as kings were used to do."

It was a practice with the early Christians to separate the sexes in public service, one portion of the church being allotted to the males, and another to the females. The author of the Apostolical Constitution speaks of this separation as usual in his time, for he says, "Let the doorkeepers stand at the gate of the men, and the deaconesses at the gate of the women;" and S. Cyril says, "Let men be with men, and women with women, in the church." Socrates also remarks of Helena, that "she always submitted to the laws of the church in this respect, praying with the women in the women's place." In some cases, the women were placed on the north side of the church, but probably this was not an universal practice; in the Greek church the galleries were reserved for the women. Besides this, there was a further subdivision, distinct positions being allotted to virgins, widows, and matrons. In the Apostolical Constitutions, the virgins, widows, and aged women were placed in the highest rank, and the matrons behind them. In this manner were the communicants disposed in the nave, but besides them the fourth or last order of penitents were admitted into this part of the church; they were called *Consistentes*, and were allowed to remain during the celebration of the Eucharist, although not to participate.

At the farther end of the nave, was the choir, which was divided from it by a low wall or wooden partition; here were located the singers, and here also the gospel and epistles were read from the *ambo*, or pulpit. This was an elevated desk, ascended by several steps, which S. Cyprian calls *pulpitum* and *tribunal ecclesiæ*, and which was elsewhere called *βημα γνωστων*. Bona cites Prudentius to prove that the bishops and priests made their sermons from this pulpit, but this seems to be a mistake, for the bishops anciently addressed the congregation from the steps of the altar, as is evident from Valesius. S. Chrysostom, it appears, did preach from the ambo, but only in order that he might be the more audible to the people; such was not the usual custom. A very perfect example of the form and arrangement of the choir still remains in the church of San Clemente.

We now arrive at the last division, which answered to the holy of holies of the Jewish temple, being appropriated to the priests and the celebration of the most sacred offices of the church. Eusebius calls this place *αγιασμα*; and it is elsewhere named *αγιον*, or the sanctuary. The Latins call it *sacrarium*. The term *θυσιαστηριον*, which is more particularly applied to the altar, is sometimes used to denote the whole sanctuary, as is evident from the decrees of the council of Laodicea, which forbid lay persons entering the *θυσιαστηριον*. A more common appellation is that of *βημα*, which is so employed from the circumstance of this part of the church being elevated above the nave by a series of steps. A further separation was effected by means of rails, or lattice-work, named *cancelli*; whence our term *chancel*. In his description of the church of Paulinus, Eusebius states the office of these cancelli to be the rendering the sanctuary inaccessible to the multitude; and the council of Trullo directs, "that no layman whatsoever be permitted to enter the place of the altar, excepting only the emperor, when he makes his oblation to the Creator, according to ancient custom." A similar order of the council of Laodicea has been given above. From this practice, the sanctuary obtained the epithet *αδυτα*, *αναβατα*, *inapproachable*. This part of the church was usually of a semicircular plan, around the circumference of which, in close proximity to the wall, were ranged the seats for the bishop and clergy. The throne of the bishop was in the centre, immediately behind the altar, and raised to a greater elevation than those of the presbyters, which were ranged on either side of him. Gregory Nazianzen speaks of himself, as bishop setting upon a high throne, with the presbyters, on lower benches, on either side.

The altar was situate in the centre of the chancel, in front of the bishop's throne, so as to allow of a passage all round it; it was named indifferently *ara*, *altare*, *θυσιαστηριον* and *βωμος*; the latter, however, qualified by the addition of *αναιμακτον*. The most ancient altars were of wood, as we learn from several passages in the Fathers: amongst others, S. Austin, speaking o an outrage by the Donatists against a Catholic bishop, says, "They beat him cruelly with clubs, and such like weapons, and at last with the broken pieces of the wood of the altar." Optatus, again, speaking of the Donatists, says, "They brake the altars in such pieces as would afford them plenty of wood to make new; but where there was a scarcity of wood, they contented themselves with scraping them, by way of pretended expiation." When stone altars began to be employed, is very uncertain; all that can be determined upon this point is, that the material was in use for such purpose in the time of Gregory Nyssen, but how long before we cannot tell. Gregory, speaking of the sacred character of the church and its furniture, says, "This altar whereat we stand is by nature only common stone, nothing different from other stones, whereof our walls are made and our pavements formed; but after it is consecrated and dedicated to the service of God it becomes a holy table, an immaculate altar which may not promiscuously be touched by all, but only by the priests in the time of divine service." In the next century, a decree was passed at the council of Epone, that no altars should be consecrated, but such as were of stone. The Pontificals speak of silver altars dedicated by Constantine. The early wooden altars were similar in shape to tables, but when stone was employed for this purpose they assumed a somewhat different appearance, consisting either of slabs supported by a central pier, or of a structure built up similar to a sarcophagus, or tomb.

The altar was covered by a canopy, supported by pillars, frequently twelve in number, in allusion to the number of the apostles, and having their capitals adorned with silver bowls. The canopy which was spherical, was surmounted with a cross and the space between the pillars hung with veils, which served to conceal the altar. These are, perhaps, the veils alluded to by Chrysostom, where, speaking of the consecration of the elements, he says, "When you see the veils withdrawn, then think you see heaven opened, and the angels descending from above." Curtains, however, were used in other parts of the church, before the doors, and at the entrance to the sanctuary, which were sometimes richly adorned with gold, as was that given by Chosroes to the church at Antioch. Epiphanius relates his tearing to pieces a veil suspended before the doors of the church, because it had a picture on it; and Athanasius, speaking of the enormities of the Arians, says, "They took the bishop's throne, and the seats of the presbyters, and the table which was of wood, and the veils of the church, and whatever else they could, and carried them out and burned them." Sometimes a silver dove was suspended over the altar. The canopy was turned *ciborium*, or *πυργος*. In later times, crosses were set upon the altar, but the time of their introduction is not known: Sozomen and Evagrius are among the first who allude to the practice. The altar was covered with a linen cloth, as is evidenced by Optatus, who, in allusion to the extravagant pretensions of the Donatists in purifying everything that had been touched by the Catholics, says "that if anything was polluted, it must be the covering, and not the tables;" and adds, that they pretended to wash these palls. Sometimes such coverings were of richer stuff, for Palladius has reference to some Roman ladies, who bequeathed their silks to make coverings for the altar. The sacred vessels were of various materials. We learn from Irenæus, Epiphanius, and Jerome, that chalices were made of glass in their time; but there can be no doubt that silver and gold were frequently employed for this purpose; for it is related of Laurentius, who was martyred in the time of Valerian, that he would not deliver up the plate in which they were used to celebrate the sacred mysteries; and in an inventory delivered up at the same period, by Paul, bishop of Cirta, we find mention made of two gold cups, six silver cups, and various other vessels of the same materials.

In many churches, besides the altar, was a side-table, in a recess, on one side of the *bema*, where the offerings of bread and wine were received, and which is called by various names, *παρατραπεζα*, *prothesis*, *paratorium*, *oblationarium*, and *corban*. In the recess on the opposite side of the bema, was the *Scenophylacium*, which was a sort of vestry in which the priests robed, and where the deacons brought the vestments and vessels from the Diaconicum, previous to service. It was likewise called the *Diaconicum Bematis*, to distinguish it from the larger building of the same name and uses outside the church.

Under the general term *exhedræ*, are comprehended all the buildings that were contained within the outermost enclosure, but without the walls of the church, properly so called: these were many in number consisting of schools, residences for the priests, &c.; but we shall here only take notice of the more important.

The *Baptistery*, during the first five centuries, formed a separate building outside the church, as we gather from Eusebius, Paulinus of Nola, and Gregory of Tours. It was a large and capacious edifice, containing several apartments, some perhaps for the catechumens, and was not unfrequently octagonal in plan. It was necessary that these buildings should be somewhat extensive, for the sacrament of baptism was but seldom celebrated, the two seasons set apart for the purpose being Easter and Pentecost; so that a large number of persons were congregated together at the same time; and there is reason to suppose that there was but one baptistery to each city, however numerous the churches may have been. In the centre of this building was the font, which was large enough for immersion.

The *Secretarium*, or *Diaconicum*, was a building in which all the property belonging to the church, such as vestments, vessels, offerings, &c., were deposited when not in use, and whence they were carried into the church when required. It was called diaconicum from the fact of the deacons having charge of all matters contained therein.

Another outbuilding was the *Library*, as we learn from Eusebius, who tells us that he was greatly indebted to that founded by Alexander, bishop of Jerusalem, in procuring materials for the compilation of his history; and Julius Africanus is said to have founded another at Cæsarea. The largest library was probably that belonging to the church of Sta Sophia, Constantinople, which is said to have contained one hundred thousand books, and was burned down by the firing of the city in a proper tumult. That *Schools* were attached to the church, we may know from what Socrates says of Julian, "that, in his youth, he frequented the church, where, in those days, the schools were kept."

Amongst the exhedræ are likewise reckoned the *mitatorium*, *gazophylacium* and *pastophoria* but of these we know little or nothing.

As regards the decoration of the interior of the church, we may gather, that the walls were sometimes coated with marble, and most frequently adorned with inscriptions of passages of Scripture, or other religious writings appropriately disposed. Thus S. Ambrose speaks of the text, "There is a difference between a wife and a virgin," &c., being written on the walls near the virgins' seats; Paulinus mentions several passages applied to the same purpose, as do also Sidonius and Apollinaris. The roofs were enriched with mosaic, or what is called lacunary or panel-work, and in this case gilding and colour were employed; in the church of Sta Sophia is an instance of the former practice, and in that of Constantine at Jerusalem, an example of the latter, where the roof was panelled, and covered with gold. S. Jerome likewise speaks of lacunary golden roofs, walls adorned with marble, pillars with capitals of shining gold, gates inlaid with ivory and silver, and altars set with precious stones and gold. Such was the arrangement and decoration of an early Christian church.

We have already considered the question relative to the conversion of heathen temples to the purposes of Christian worship; but there is yet another building in use amongst the pagans, which lays claim to the same honour, and with some greater show of probability, it is the *basilica*. The Roman basilica was the hall of public justice, the court in which, during the early history of that nation, the kings sat to hear and decide the causes of their subjects; it was, in fact, at that period a royal palace situate in the Forum, whence the name. The word, however, is Greek, and was first applied to the portico in the Athenian Ceramicus immediately beneath the Pnyx; the custom, as well as the building, was borrowed by the Romans. Such edifices varied in form in different instances, but not to any very great extent, the same disposition seems to have been universally observed and was as follows:—

The plan was an oblong, terminated at one, or sometimes both ends, with a semi-circle; the semi-circle was occasionally omitted, and sometimes there were two or three of different dimensions. Internally the breadth was divided into three—rarely into five—by two or four rows of columns running down the length of the church; at the extreme end was the semi-circular apse, in the midst of which was the seat of the prætor, whence he administered justice; this was the tribunal. On either side of the prætor, but lower down, were the benches for his assessors, the centumviri, and other officers, and all these were separated from the other part of the building by an enclosure of lattice-work, to which was given the name of *cancelli*. Outside of this screen was a place allotted to the notaries and advocates, the remainder of the building being occupied by the people.

We have here a three-aisled structure, the divisions being formed by two central rows of columns and two outer walls, the columns frequently supporting a gallery in the outer divisions. The central portion was generally lighted from windows or openings in a wall raised above the columns, thus forming a sort of clere-story. This roof was invariably of wood, and did not always cover the whole building. For a further description *see* BASILICA.

Some writers suppose that several such buildings were delivered by Constantine into the hands of the Christians, and were employed by them as churches, or places of public worship. Some go so far as to assert, that they were the prototype of the succeeding churches, not only in form but in the division and disposition of the parts. The writer we have had occasion to quote in a previous part of this article speaks thus:—

"Had the basilica, such as we have described it, been planned for the express reception of a Christian congregation, it scarcely could have received a more convenient or appropriate form—none more happily combining magnificence with utility—none more consonant to the ideas which then prevailed. The general shape of the church as prescribed by the Apostolical Constitutions, was to be an oblong like unto a ship, that is, to the vessel of the ark. Does not the outline of the ground-plot of the basilica entirely meet the suggestion? and the terms *nave*, *nef* or *vaisseau*, applied to the main portion of the edifice, show how enduringly the idea prevailed in subsequent ages. The apse in which the prætor administered justice, surrounded by the centumviri and other judges offered a dignified tribunal for the bishop and his clergy; the dark chambers below suggested the subterraneous chapel, in which might be deposited the remains of saint or martyr. The enclosures, the *cancelli* for the notaries and advocates, might receive the singers of the choir. The lengthened aisles would furnish space for the congregation of the faithful: the galleries seclude the women; and the porch fronting some of the basilicas, or the uncovered portion which, if separated from the rest by a wall, would constitute a court, was prepared for those who had been separated from the rest of the congregation by their sins, or were not yet allowed to participate in the sacraments. Hence we find from one of those incidental notices which often are more instructive than the set narrative of history, that the basilica had been given up, bodily, for the purpose of Christian worship. A poet, but also a rhetor, addressing an emperor, tells him that these structures, heretofore wont to be filled up with men of business, were now thronged with votaries praying for his safety; '*Basilica olim negotiis plena, nunc votis pro tua salute susceptis.*' This occupation of the Roman basilicæ was, nevertheless, only transitory. They did not become the abiding-places of the faith. Why was this privilege denied them? In situation they were most convenient, placed in the centre of business and population; their plan and form so convenient as to invite the purposes of worship. Unpolluted by the idol or sacrifice, they were free from the recollections rendering the heathen temple odious. With the smallest proportionate expense or labour, the basilicæ of the Forum might have been rendered the most stately and dignified of sanctuaries. Yet they fell! Only one example can be found of a secular basilica actually converted into a Christian church—and that example, memorable as it is, does not exist in Rome. As if for the purpose of constantly demonstrating to mankind the visible triumph of the spiritual kingdom, every stage in the early development of the empire of Christianity seemed destined to efface the honours of heathen sovereignty. The Christian basilica, though entirely modelled upon the heathen basilica, and constructed with the spoils of the basilica, was therefore fated to be its ruin and destruction.

"A single cause suffices—a cause of which we now can scarcely appreciate the potency. Veneration for the graves of the martyrs, as an almost irresistible motive, attracted the Christian basilica away equally from the precinct of the secular basilica as from the site of the heathen temple. By determining the locality assigned to the Christian edifice, this feeling necessarily determined the neglect, ruin, and destruction of the proud monuments of senators and Cæsars. The demolition of earlier structures, for the purpose of furnishing materials, had already been long practised. Thus the interior of the Coliseum displays the friezes and fragments, mixed up in confusion, amidst the masonry of the beautiful yet appalling circuit of its walls. These, perhaps, may have resulted from the removal of other buildings previously existing on the site; but under Constantine similar demolitions proceeded, as it should seem, equally from the desire of sparing expense, and the increasing inability to execute works of art. The splendid Forum of Trajan, which had excited Constantine's admiration, fell at his command, and furnished by its spoils the decorations of the arch of the first Christian emperor. Abandoned for more hallowed ground, the civil basilicas were destroyed, and the columns which supported them transported to the new sites, where they arose in lengthened perspective and barbaric splendour. By their very aspect, such of the Christian churches as retain their original features, show the haste and unskilfulness with which they are reared; one capital cut through and deprived of the lower range of the acanthus, to fit it into the required space; another projecting over the shaft; a third shrinking within; a fourth, the leaves blocked, and prepared for the touch—never to be given—of the chisel that was to have imparted Corinthian elegance;—the columns themselves of unequal circumference or unequal height, deprived of their due proportions, or rudely stilted to attain the necessary elevation. The richest materials are mixed with others of inferior quality; pavonazzo and verd antique, the products of the quarries of Syene or of Paros, and the homely Travestine, are intermingled without choice or discrimination."

This writer is of opinion that the heathen basilicas were not actually converted into Christian temples; there are many, however, who hold the contrary, amongst whom is Mr. Hope, who cites, as examples of such adaptation, the Sessorian basilica, and that in the palace of the Lateran, which he says were given to the church by Constantine. The strongest argument on this side, is, we think, the triumphant declaration of Ausonius, that the ancient halls of justice were filled with Christian worshippers; the above-mentioned reviewer alludes to this passage in the following words : —

"We have already seen that no one of the Christian basilicæ at Rome, resulted from any adaptation of the civil structures of heathenism to religious purposes. The columns fell, to rise in new localities. Rome furnishes no example of a basilica preserved by its application to Christian worship. No confirmation is given in the ancient capital to the orator's assertions, exulting, in the presence of Gratian, at the crowds which filled the ancient halls of justice, then, as he boasts, resounding with hymn and praise; yet we can point out one city in which his assertions are not a rhetorical phrase, but a truth. Do we seek for the verification of the words of the poet-rhetor, 'Basilica, olim negotus plena, nunc votis pro tua salute susceptis?' Here we find that which at Rome we search for in vain. Here alone can we behold the one example of a basilica consecrated as a Christian church, in which you enter, and see the Corinthian capitals just displaying their graceful foliage, mutilated and yet distinct—through the rude wall which encircles them—whilst the shaft of another, displaced and broken, lies in gigantic bulk before the portal of the edifice. This indeed is the very city in which the poet-rhetor was speaking—for he is Ausonius—and the city is Treves. The ancient capital of the Roman empire beyond the Alps, furnished the model for the structures, which, far more than those of Rome herself, assisted in the development of Christian architecture."

We cannot think this a satisfactory method of getting over the difficulty; Ausonius seems to speak of such facts as well and universally known; he is describing the general effect of Christianity, and glorying in its success; his are sweeping assertions, not applicable to merely individual instances, but to general custom. Besides, if the Christians at Treves converted basilicas into churches, why should they not do the same elsewhere? and especially in the metropolis, where there was a larger proportion of such buildings, and greater need of churches.

While saying this, we do not mean to deny that there was a strong repugnance amongst the early Christians to everything that had been connected with paganism, and that the application of the basilica was rather a matter of necessity than of choice. When Constantine legalized Christianity, the Christians numbered somewhat considerably, and no doubt increased rapidly upon that event; many who previously favoured that religion, but were fearful of the consequences of an avowal, now openly professing it. Churches were needed more than ever, and they had not skill wherewith to erect them; what could be done? where were churches to be found, while new ones were building? were there any existing buildings that could be adapted to such a purpose? The pagan temples were not fitted for such uses, even had there been no repugnance to their origin; but the basilicas would answer the purpose well, as far as their construction was concerned, nor were there equal objections to them on the score of their previous employment. What more likely than that they should be used at least for a time, until new structures could be erected?

The counter-argument arising from the absence of any examples of such adaptation of the civil basilica, may be accounted for without much difficulty: they were destroyed, to afford materials for new structures in other sites. The principal cause of their destruction or removal, is to be sought in the veneration of the Christians for the graves of the martyrs. On this subject, Mr. Knight says :—

"From the custom which had originated in the catacombs —from the habit which the primitive Christians had acquired of visiting the graves of the martyrs; it became a matter of necessity to associate the church with the tomb, and to provide a place of worship below ground, as well as above. This, in several instances, was accomplished at Rome by placing the church immediately above a part of the catacombs, as at San Lorenzo and Santa Agnese; or, as at St. Peter's, by placing the altar immediately above the spot to which the mortal remains of the apostles had been removed.

"The practice of associating the churches with the graves of martyrs, was the cause of their being frequently placed in situations which had little reference to public convenience; namely, without the walls of the cities to which they belonged; for, as executions usually took place without the walls, and as the martyrs were often buried, or supposed to have been buried, where they were put to death, the wish of that age could not be accomplished without frequently placing the churches in remote and insulated situations. Thus it was that Constantine placed the church of St. Peter adjacent to the circus of Nero, though the city of Rome was, at that time, at some distance from the Vatican Hill. Theodosius, for similar reasons, placed the church of St. Paul at an equal distance from the city on the opposite side. At that time, a liability, which afterwards exposed insulated churches and their frequenters to much peril, did not exist. At that time, the interior of the empire was still inviolate, and those who built the churches never imagined that the day might come, when their descendants could not go out of the walls without being liable to attacks, and when the churches themselves would be exposed to insult and injury. Little did Constantine imagine, that men of a newer religion than his own would ever reach and deface the cathedral which he had planted within sight of the metropolis of the world."

The existence of such a feeling amongst the early Christians, coupled with the circumstance of the tombs of martyrs being usually without the walls, and the prevalent custom of employing the materials of old buildings for the construction of new, will account, as we think, satisfactorily for the want of more tangible evidence of the conversion of the heathen basilica to Christian uses.

While we contend thus far, we do not wish to ally ourselves with those who maintain, that the arrangement of churches was derived from that of the civil basilica: there is no doubt a similarity of distribution and a certain analogy between the purposes which each division in either building served; still, there are strong grounds for believing that such disposition in the churches arose from the natural requirements of the religion, rather than from any extraneous influence. The description of the several orders of penitents, and of their positions in the church, as above given, is sufficient proof of such being the case, for that was written during times of persecution, before Constantine had ascended the throne; the division into parts, therefore, was determined long ere any basilicas were given up for Christian worship. It is not improbable, however, that the form of later churches was derived from that of the basilica; for it must needs be, that either some existing form was copied, or an entirely new idea originated. That the latter was the case is very improbable, from the nature of things, almost all novelties having emanated, in some degree or other, from things previously existing: but, besides this, such an occurrence was more especially improbable at the period alluded to, when art was falling to decay, and its influence was not strong enough even to retain previous acquirements, much less to originate new. The main features in the churches erected immediately after the establishment of Christianity, with the exception of Constantine's circular buildings, were those of the civil basilica: there were some few alterations and additions, it is true, to adapt the form to the requirements of the church; but these were at first not very considerable, although extended farther in after times. Of these were the atrium and out-buildings; and, in later times, transepts. With regard to the latter, it has been argued by some, that they are to be found in the civil structures; at least, in the internal arrangement; but this we think almost too nice a similarity. There was, indeed, a cross-passage at the end of the nave, so to speak, but we can scarcely set it down as the prototype of the transept. The cross-form originated in Christian symbolism; nor does it appear even in churches of the earliest date. The Apostolical Constitutions allude to churches as being in the form of a ship, and such seems to have been the actual shape of the first buildings. The cross-plan was a gradual development. At first, we find the cross a prominent feature in the internal decoration, as at St. Clement's, where the paving of the nave is arranged in that form; and afterwards forming an essential office in the construction, as in the Byzantine churches, and the later basilicas. We are of opinion, then, that, at the onset, civil basilicas were employed for Christian worship, though rather as a matter of necessity than choice; that the division and disposition of parts observable in the early churches was not derived from the basilica; but that their form and construction was so derived; and that hence was developed the form of churches in after ages.

As regards the styles of architecture employed, the earliest constructions can scarcely be said to belong to any style; they were composed of the ruins of heathen structures, promiscuously heaped together; columns from one building, entablature from another; or even one column from one building, and the next from a second; and not unfrequently the shaft or base of one column with the capital of another: columns of different heights and proportions were huddled into the same row, and the difference of level made up either by stilting or cutting short. The Byzantine churches, with their square plans and spherical roofs, are the first buildings which can be said to possess any style, and these were chiefly confined to Asia Minor, having little influence in Italy until the sixth century. (See, Byzantine Architecture.) Shortly after this, the Lombards established themselves in Italy; and although they brought with them no architecture of their own, they gave a somewhat novel character to the buildings erected by them, the difference being principallly in detail. This style prevailed in the north of Italy up to the end of the twelfth century, at the commencement of which some marked alterations were introduced. (See, Lombardic Architecture.) To this succeeded that most perfect form of Ecclesiastical Architecture, pre-eminently termed the Christian style, which has prevailed, with some interruptions, ever since; we need scarcely add, we allude to the Gothic, or pointed, which for its solemn grandeur, as well as for its perfect construction, is, of all, the most appropriate for a Christian temple.

We have now arrived at the conclusion of this interesting subject, and for any further information must refer to such articles as Church, Cathedral, Gothic, and Saxon Architecture, &c.

ECHINUS (from εχινος, a word denoting the prickly cover of a chesnut) a convex moulding in the form of a conic section, generally carved into ornaments representing truncated spheroids, or eggs, with the upper ends cut off, the upper part of the axis projecting, and the lower part receding. Each truncated spheroid is surrounded with a border, of an elliptic figure, in close contact, showing something more than a semi-ellipsis, the shorter axis being horizontal.

The projecting edge of the border is in the surface of the moulding, previously wrought, as is also the curvature of the upper part of the spheroid. Every two adjacent borders contain a space equal to the thickness of the border at the top, and gradually receding towards the bottom. In each recess, or space, is an anchor, or tongue; the front edge of which comes in contact with the surface of the original moulding, and is in a vertical line cutting the surface of the moulding at right angles.

In Grecian architecture, the front of each border, and also the front of each tongue, or anchor, is wrought to an angle, the section of which inclines equally to the surface. The bottom of the spaces on each side of the tongue, on the under side, is nearly in the same surface as the recess on the sides of the eggs.

In Roman architecture, the general contour is the segment or quarter of a circle, and the fronts of the surrounding borders are not brought to an angle, but remain as part of the moulding, either plain or with a hollow sunk between the edges, leaving a fillet next to each edge.

Its situation in an order, is in the entablature or capital, but never in the base.

In the original Doric order, the ovolo, which crowns the cornice, and that of the capital, are never carved. In the Ionic and Corinthian entablatures, it may either be carved or not, but in the antiques it is generally carved. The ovolo in the capitals of these orders, is, however, always carved into the ornaments we are describing. The French call this moulding, *quart de rond;* the English, *quarter-round*, or *boulting;* the Italians, *ovolo;* the Latins, *ovum*, from its being usually carved with the figures of eggs; and the French, for the same reason, sometimes call it *œuf.*

ECHO, (from the Greek, ηχος, *sound*, of the verb, ηχεω, *I sound*.) the reverberation of sound, occasioned by the particular construction of a vault or wall, the section of which is most commonly of an elliptical or parabolical figure. The method of making artificial echoes, is taught by the Jesuit Blancani, in his *Echometria*, at the end of his book *On the Sphere*.

We are informed by Vitruvius, that in various parts of Greece and Italy, there were brazen vessels, ingeniously arranged under the seats of the theatres, to render the sound of the actors' voices more clear, and make a kind of echo; by which means the prodigious multitude of persons present at their spectacles were enabled to hear with ease and pleasure.

The distribution of sound in public edifices, so that the echoes may be most advantageously brought to strengthen the original sound, is a subject practically deserving much attention. In Sir J. Herschel's Treatise on Sound, the reader will find some sensible observations on the errors of architects in this respect. The inattention of the latter to the effect of the reverberation of sound, was curiously exemplified in the cathedral of Girgenti, where the confessional was placed in a focus conjugate to another and unenclosed part of the church; by which unlucky error the echo was instrumental in informing a husband of the infidelity of his spouse. In many of our public buildings, though professedly erected for purposes where the proper distribution of sound is of paramount importance, it is no uncommon occurrence, that one part of the audience possesses a monopoly, while the remainder witness the ceremony or performance in dumb show.

Sounds are reflected by certain configurations of bodies, like the reflection of light from polished surfaces; so that if a person situated before one of these bodies utter a word, he will in a short time after hear the echo, or repetition of the sound. The vibratory motion of the air, which constitutes sound, is reflected by hard bodies, and, in certain cases, even by fluids. Thus the sides of a hill, houses, rocks, banks of earth, the large trunks of trees, the surface of water, especially at the bottom of a well, and sometimes even the clouds, have been found capable of reflecting sounds. The configuration of the surface of these bodies, is much more concerned in the production of the echo than their substance. A smooth surface reflects sounds much better than a rough one. A convex surface is a very bad reflector of sound; a flat one reflects very well; but a small degree of concavity, particularly when the sounding body is in or near the focus of concavity, renders the surface a much better reflector, and the echo is heard considerably louder.

Thus, in an elliptical apartment, if the sounding body be placed in one focus, the sound will be heard much louder by a person situated in the other focus of the ellipsis, that in any other part of the room. In this case, the effect is so powerful, that even when the middle part of the room is wanting, the sound expressed in one focus will be heard by a person situated in the other, but hardly at all by those who stand in the intermediate space.

Without attempting to explain the manner in which the vibrating air impinges upon, and is sent back by, the reflecting body, which would lead us too far into the science of acoustics, we shall briefly notice the following ascertained facts.

If a person standing before a high wall, a bank, a rock, &c., at a certain distance, and uttering a word with a pretty strong voice, or producing by a hammer, stone, &c., any short, sharp sound, hear a repetition of that word or sound, he will find that the time elapsed between his uttering the word, or striking with the hammer, and hearing of the echo, is equal to the time that a sound is known to employ in going through an extension of twice the distance between him and the reflecting wall, rock, &c.; for the vibratory motion of the air must proceed from the sounding person to the wall, &c., and back again from the latter to the former. Now, sound is known to travel at the rate of about 1,125 feet in a second of time; therefore, if the person who expresses the word, or any sound whatever, stand at the distance of 1,125 feet from the echoing wall, &c., two seconds of time must elapse between his uttering the sound and his hearing the echo. If the distance be equal to 4,500 feet, then eight seconds of time must elapse between the uttering of the sound, and the arrival of the echo; and so on. But the same original sound and the echo may be heard by persons at different distances, both from the original sounding-place, and from the reflecting body. The effect, however, will not be exactly uniform, for those who are nearer to the reflecting body, will hear the echo sooner than persons more remote. A situation may be easily found, from which they will hear both the original sound and the echo at the same instant, and as both sounds coalesce, they will only appear as one loud sound, without the echo.

But though several persons, in different situations, may hear the echo of the same sound, yet the echo will be heard better in one particular direction than in any other; now if two straight lines be drawn from the middle of a reflecting surface, one to the place from which the original sound proceeds, and the other to the above-mentioned best direction, those two lines will be found to make equal angles with the surface. Hence it appears, that in the reflection of sound, the angle of incidence is equal to the angle of reflection. Therefore, if a person wishes to hear the echo of his own voice in the best possible manner, he must stand in a direction perpendicular to the reflecting surface. And this shows, that though sound proceeds from an original sounding body, or from a reflecting surface, in every direction; yet a greater quantity of it proceeds in some particular direction than in any other, which is probably owing to the original impulse being given to the air more forcibly in one direction than in another, or from want of perfect freedom in the aërial fluid.

Several phenomena may be easily explained upon the above-mentioned property of sound: for instance, several reflecting surfaces are frequently so situated with respect to distance and direction, that a sound proceeding from a certain point is reflected by one surface first, then by a second, soon after by a third, and so on, but by all in one direction; in which case a multiplied tautological echo is produced; that is to say, the same word is heard repeated several times successively in the same tone and accent; the expression of one Ho! will appear like a peal of laughter; a musical instrument, properly played, will produce an agreeable repetition of as many instruments of the same sort, imitating each other.

According to the various distances of the speaker, a reflecting object will return the echo of several, or of a few syllables, for all the syllables must be uttered before the echo of the first syllable reaches the ear; otherwise it will make a confusion. The farther the reflecting object is, the greater number of syllables will the echo repeat; but the sound will be enfeebled nearly in the same proportion, till at last the syllables cannot be heard distinctly. When the reflecting object is too near, the repetition of the sound arrives at the ear whilst the perception of the original sound still continues, in which case, an indistinct sounding noise is heard. This effect may especially be observed in empty rooms, passages, &c., because, in such places, several reflections from the wall to the hearer, as also from one wall to the other, and then to the hearer, clash with each other, and increase the indistinctness.

From what has been said, it will be easily conceived, that with respect to echoes, a vast variety of effects may be produced, by varying the form, the distance, and the number of reflecting surfaces; and hence we hear of various surprising echoes being met with at different places.

In Woodstock Park, near Oxford, there is a famous echo, which repeats seventeen syllables in the daytime, and twenty at night, when the air is somewhat more dense. On the north side of Shipley Church, in Sussex, there is another remarkable echo, which, in favourable circumstances, repeats twenty-one syllables. At Rosneath, near Glasgow, in Scotland, is an echo, that repeats three times, completely and distinctly, a tune played with a trumpet.

Whispering-places, are those where a whisper, or other small noise, is conveyed from one part to another, at a great distance. They depend upon this principle, that the voice, being applied to one end of an arch, easily passes by a repetition of reflections to the other.

Hence sound is conveyed from one side of a whispering-gallery to the opposite one, without being perceived by those who stand in the middle. The form of a whispering-gallery is that of a sphere, or the segment of a sphere. The principle of whispering being that of continued reflection. If a person whisper softly against a wall, the rays which proceed from his mouth issue in all directions against the wall; we shall only take the rays which emanate from the whisperer's mouth (which we shall suppose to be a point) in a horizontal plane, then it is evident, that they will proceed to the right and to the left, and each particle of sound, as we may call it, for want of a more specific name, will cut off equal segments of the circle which forms the section of the wall; or, in other words, will pass along equal chords; and there will be an infinite number of such reflections; each particle describing chords different from those described by another, and an indefinite number of these will divide the semi-circumference into parts all equal to each other, in the same system of chords; therefore, all the describing particles of sound passing along the equal chords, will meet upon the other extremity of the diameter opposite the whisperer, and thus form a loud whispering noise. It is evident, that polished surfaces are the most favourable for this purpose. Accordingly, all the contrivance requisite in whispering-places is, that near the person who whispers, there may be a smooth arched wall, either cylindric or cylindroidic; though a body with circular sections will do, but not so well.

The most considerable whispering place in England, is the whispering gallery in the dome of St. Paul's Cathedral, London, where the ticking of a watch may be heard from side to side, and a very easy whisper be sent all round the dome. The famous whispering-gallery in Gloucester Cathedral, is no other than a gallery above the east end of the choir, leading from one side thereof to the other. It consists of five angles, and six sides, the middlemost of which is a naked window; yet two whisperers hear each other at the distance of twenty-five yards.

ECHOMETRY, the art of constructing vaults to produce echoes.

ECPHORA, or Ecphoran (from ἐκ, *out*, and φερω, *I bear*,) the projecture, or distance between the extremity of a member, or moulding, and the naked of the column, or other part it projects from.

Some authors, however, account the ecphora, or projecture, from the axis of the column, and define it to be a right line intercepted between the axis and the outermost surface of a member, or moulding. The word is used by Vitruvius, in Chapter III., book iii., in the explanation of columns and their ornaments. See Projecture.

ECTYPE (from the Greek): *αρχετυπον*, denotes the original, or model; *εντυπον*, the copy or image, moulded or struck *in creux;* and *εκτυπον*, the image *in relievo*, or embossed.

EDDYSTONE LIGHTHOUSE, a celebrated building erected upon a cluster of very dangerous rocks, situated in the English Channel, in latitude 50° 3′ N., and longitude 40° 21′ W. These rocks are about fourteen miles from Plymouth Sound, and, lying nearly in the track of vessels going up or down channel, have been the cause of many shipwrecks. To guard against these disasters, it was deemed necessary to erect a lighthouse; but to effect this in a complete and permanent manner, so as to resist storms and afford light, was a task of extreme difficulty.

The Eddystone rocks are so peculiarly exposed to the swell of the ocean from the south and west, that the heavy seas break upon them with uncontrolled fury. Sometimes, after a storm, when the sea is apparently quite smooth, and its surface unruffled by the slightest breeze, the ground-swell, or under-current, meets the slope of the rocks, and the sea beats tremendously upon them, and even rises above the light-house, overtopping it for the moment, as with a canopy of frothy wave. Notwithstanding this awful swell, Mr. Henry Winstanley undertook, in the year 1696, to build a light-house on the principal rock, for the rest are under water; and in 1700 he completed it. So confident was this ingenious mechanic of the stability of his edifice, that he declared his wish to be in it during the most tremendous storm that could arise. This wish he unfortunately obtained, for he perished in it, during the dreadful storm which destroyed it, November 27, 1703. Another light-house, of a different construction, was erected of wood, on this rock, by Mr. John Rudyerd, in 1709; which being consumed by fire in 1755, a third, of stone, was begun by the justly celebrated Mr. John Smeaton, April 2, 1757, and finished August 24, 1759, which has hitherto withstood the attacks of the most violent storms. The following account of this building, taken from Mr. Smeaton's "Narrative," must be read with interest, as a noble instance of the triumph of skill, science, and perseverance over obstacles of the most formidable character:—

Mr. Smeaton begins his account with a general description of the Eddystone rocks, the course of the tides, their situation, component matter, and the proper season for visiting them. He then takes an ample view of Mr. Winstanley's edifice, to whom he ascribes great praise for having undertaken and achieved what had been generally deemed impracticable; and after deploring that gentleman's disaster, goes on to describe the second lighthouse, built by Mr. Rudyerd, as a most complete edifice of the kind, being of timber, in the course of which he details the best methods of fixing iron chains, and securing timber-work to rocks, which we shall give in his own words.

"As nothing would stand upon the sloping surface of the rock without artificial means to stay it, Mr. Rudyerd judiciously concluded, that if the rock were reduced to level bearings, the heavy bodies to be placed upon it, would then have no tendency to slide; and this would be the case, even though but imperfectly executed; for the sliding tendency being taken away from those parts that were reduced to a level, the whole would be much more securely retained by the iron bolts or branches, than if, for the retention of the whole, they had depended entirely upon the iron-work; as manifestly appears to have been the case with the building of Mr. Winstanley. According to Mr. Rudyerd's print, the inclined surface of the rock was intended to have been reduced to a set of regular steps, which would have been attended with the same good effect, as if the whole could have been reduced to one level; but in reality, from the hardness of the rock, the shortness and uncertainty of the intervals in which this part of the work must have been performed; and the great tendency of the laminæ whereof the rock is composed to rise in spawls, according to the inclined surface, when worked upon by tools, urged with sufficient force to make an impression; this part of the work, that is, the stepping of the rock, had been but imperfectly performed, though in a degree that sufficed.

"The holes made to receive the iron branches, appear to have been drilled into the rock by jumpers, making holes of about $2\frac{1}{4}$ inches diameter; the extremities of the two holes forming the breadth for the branch, at the surface of the rock, were about $7\frac{1}{2}$ inches; and these holes were directed so that at their bottoms they should be separated somewhat better than an inch more, that is, so as to be full $8\frac{1}{2}$ inches. In the intermediate space, a third hole was bored between the two former; and then if the three holes were broken into one, by square-faced pummels, this would make the holes sufficiently smooth and regular. By this means he obtained holes of a dove-tail shape, being $2\frac{1}{4}$ inches wide, $7\frac{1}{2}$ broad at top, $8\frac{1}{2}$ at bottom, and 15 and 16 inches deep; and as these could not be made all alike, every branch was forged to fit its respective hole. The main pieces of each branch, were about $4\frac{1}{2}$ inches broad at the surface of the rock, and $6\frac{1}{2}$ at the bottom; and this being first put down into the hole, the space left for a key would be 3 inches at top, and 2 inches at bottom, which would admit it to be driven in so as to render the whole firm, and the main branch fixed like a dove-tail or lewis.

"The holes being each finished, and fitted with their respective branches, and cleared of water, a considerable quantity of melted tallow was poured into each hole: the branch and key being then heated to about a blue heat, and put down into the tallow, and the key firmly driven, all the space unfilled by the iron, would become full of tallow, and the overplus made to run over: when this was done, all remaining hot, a quantity of coarse pewter, being made red-hot in a ladle, and run into the chinks, as being the heaviest body, would drive out the superfluous melted tallow: and so effectually had this operation succeeded, that in those branches which were cut out in 1756, and had remained fast, the whole cavity had continued so thoroughly full, that not only the pewter, but even, in general, the tallow, remained apparently fresh: and when the pewter was melted from the irons, the scale appeared upon the iron, as if it had come from the smith's forge, without the least rust upon it.

"All the iron branches, which are shown, as I found them, in Plate I, having been fixed in the manner above-mentioned, they next proceeded to lay a course of squared oak balks, lengthwise upon the lowest step, and of a size to reach up to the level of the step above. Then a set of short balks were laid crosswise of the former, and upon the next step compoundedly, so as to make good up to the surface of the third step. The third stratum was therefore again laid lengthwise, and the fourth crosswise, &c., till a basement of solid wood was raised, two complete courses higher than the highest part of the rock; the whole being fitted together, and to the rock, as close as possible, and the balks, in all their intersections with each other, trenailed together. They were also fitted to the iron branches where they happened to fall in; for the branches do not seem to have been placed with any complete regularity or order, but rather where the strength and firmness of the rock pointed out the properest places for fixing them; they were, however, to appearance disposed so as to form a double circle, one about a foot within the circumference of the basement, and the other about three feet within the former; besides which, there were two large branches fixed near the centre, for taking hold of the two sides of a large upright piece of timber, which was called *the mast;* by which two branches it was strongly fixed down; and being set perpendicular, it served as a centre for guiding all the rest of the succeeding work.

"The branches were perforated, in their respective upper parts, some with three, and some with four holes; so that, in every pair (collectively called *a branch*) there would be at a medium seven holes; and as there were at least thirty-six original branches, there would be 252 holes, which were about seven-eighths of an inch in diameter; and, consequently, were capable of receiving as many large-bearded spikes, or jag-bolts, which being driven through the branches into the solid timber, would undoubtedly hold the whole mass firmly down; and the great multiplicity of trenails in the intersections, would confine all the strata closely and compactly together.

"I cannot omit here to remark, that though the instrument we now call *the lewis*, is of an old date, yet, so far as appears, this particular application of that idea, which Mr. Rudyerd employed in fixing his iron branches firmly to the rock, was made use of for the first time in this work: for though Mr. Winstanley mentions his having made twelve holes, and fixed twelve great irons in the rock, in his first year's work, yet he gives no intimation of any particular mode of fixing them, but the common way with lead; and the stump of one of the great irons of Mr. Winstanley's, that was cut out in the course of the work of the summer of 1756, was fixed in that manner; but we remarked, that the low end of this bar or stanchion, was a little club-ended, and that the hole was somewhat under-cut; so that, when the lead was poured in, the whole together would make a sort of dovetail engraftment: however, when these irons, by great agitations, became loose, and the lead yielded in a certain degree, they would be liable to be drawn out; as the orifice by which they entered must have been large enough to receive the iron club. Mr. Rudyerd's method, therefore, of keying and securing, must be considered as a material accession to the practical part of engineery; as it furnishes a secure method of fixing ring-bolts and eye-bolts, stanchions, &c., not only into rocks of any known hardness; but into piers, moles, &c., that have already been constructed, for the safe mooring of ships; or fixing additional works, whether of stone or wood.

"In this way, by building *stratum super stratum*, of solid squared oak timber, which was of the best quality, Mr. Rudyerd was enabled to make a solid basement of what height he thought proper: but in addition to the above methods, he judiciously laid hold of the great principle of engineery, that weight is the most naturally and effectually resisted by weight. He considered, that all his joints being pervious to water, and that though a great part of the ground-joint of the whole mass was in contact with the rock, yet many parts of it could not be accurately so; and therefore, that whatever parts of the ground-joint were not in perfect contact, so as to exclude the water therefrom, though the separation was only by the thickness of a piece of post-paper, yet if capable of receiving water in a fluid state, the action of a wave upon it edgewise, would, upon the principles of hydrostatics, produce an equal effect towards lifting it upwards, as if it acted immediately upon so much area of the bottom as was not in close contact.

"The more effectually therefore to counteract every tendency of the seas to move the building in any direction, he determined to interpose strata of Cornish moor-stone between those of wood; and accordingly having raised his foundation solid, two courses above the top of the rock, he then put on five courses, of one foot thick each, of the moor-stone. These courses were as well jointed as the workmen of the country could do it, to introduce as much weight as possible into the space to contain them: they were, however, laid without any cement; but it appears that iron cramps were used, to retain the stones of each course together, and also upright ones to confine down the outside stones.

"When five feet of moor-stone were laid on, which, according to the dimensions, would weigh 120 tons; he then interposed a couple of courses of solid timber, as before; the use of which was plainly for the more effectual and ready fastening of the outside uprights to the solid, by means of jag-bolts, or screw-bolts; and that these bolts might the more effectually hold in the wood, in every part of the circle (which could not be the case with timbers lying parallel to each other, because in two points of the circle, opposite to each other, the timbers would present their ends towards the bolt) he encompassed those two courses with circular, or what are technically called *compass timbers*, properly scarfed together, and breaking joint one course upon the other. We must not, however, suppose, that these courses were composed wholly of circular timbers to the centre, but that the circles of compass timbers on the outside, were filled up with parallel pieces within; and that the compass timbers were, in the most favourable points, jag-bolted to the interior parallel pieces.

"The two uppermost courses, after clearing the rock, and before the five moor-stone courses came on, were furnished with compass timbers, as well as some others below.

"The two courses of wood above the moor-stone courses terminated the entire solid of the basement; for a well-hole was begun to be left upon these courses for stairs in the centre, of 6 feet 9 inches in the square; and hereupon was fixed the entry door, or rather, one course lower, making a step up, just within the door; in consequence of this, the entire solid terminated about 9 feet above the higher side of the base, and 19 feet above the lower side thereof.

"In Mr. Winstanley's house, the entry was from the rock into an internal staircase, formed in the casing upon the south-east side; he therefore needed only a few external steps. But Mr. Rudyerd's entry door, being full eight feet above the highest part of the rock, would consequently need a ladder. This he made of iron, of great strength; and being open, whenever the seas broke upon this side of the house, they readily found their passage through, without making any violent agitation upon it.

"The two compass courses terminating the entire solid, having been established, as already mentioned, he again proceeded with five moor-stone courses; nearly the same as the former; allowing for the necessary difference resulting from there now being a central well-hole for the stairs, and a passage from the entry door, as described, to the well-hole: this passage was 2 feet 11 inches wide, and, as it appears, took up the whole height of the five courses. The weight of these five courses, according to the dimensions, amounted to 86 tons.

"He then again proceeded with two compass courses, covering the door-head and passage, so as now to leave no other vacuity than the well-hole; and upon these he laid four moor-stone courses, the weight of which amounted to sixty-seven tons. He then proceeded with two compass courses, and after that, with beds of timber, cross and cross, and compass courses interposing; and, last of all, with one compass course, upon which he laid a floor over all, of oak plank three inches thick, which made the floor of the store-room.

"The height of this floor above the bottom of the well, was near 18 feet; above the foot of the mast, 33 feet; above the rock on the higher side, 27 feet; and above the foot of the building on the lower side, 37 feet. In all this height, no cavity of any kind was intended for any purpose of depositing stores, &c. From the rock to the bottom of the well, all was solid, as we have shown; but as the building increased in height, and consequently was more out of the heavy stroke of the sea, a less degree of strength and solidity would be equivalent to the former, and therefore admit of the convenience of a staircase within the building, with a passage into it: which last, being made upon the east side, would be withdrawn from the heavy shock of the seas from the south-west quarter, and the rock being there highest, the ascent by the iron stair upon the outside, would be the least; the whole therefore, to the height of the store-room floor, as above-mentioned, having been made with all possible solidity, was denominated *the solid.*

"The height of Mr. Rudyerd's store-room floor was fixed as high as the floor of Mr. Winstanley's state-room, which was over his store-room; and as many were doubtless still living who had seen and examined Mr. Winstanley's light-house, during the four years that it stood in a finished state; and as in that time there would be an opportunity of knowing, from experience, to what height the unbroken water of the waves mounted in bad weather, we may very well suppose that Mr. Rudyerd regulated the height of his solid from that information.

"We have already seen, that the two compass courses of wood, which capped the first bed of moor-stone, and terminated the entire solid, were forcibly screwed down by ten large iron bars, or bolts, to the beds of timber below the moor-stone, and these by the trenails and branches to the rock. We must suppose this precaution to have been taken to prevent any derangement from the heavy strokes of the sea in storms and hard gales, which were liable to happen in the very finest part of the season, before there was any proper opportunity of connecting the upper part of the work with the lower, by means of the upright timbers that were to form the outside case; because, till the work was brought to that height, there could be no proper means of beginning to fix them; and as we do not find any traces or mention of binding the upper courses with the lower, after the staircase was set forward, we must suppose that the outside casing had been then begun from the rock, and carried on progressively, so as to become a bond of the upright kind; for, all such timbers as were high enough having been screwed fast to the compass courses, would be thereby secured to the lower courses; otherwise, from what I have myself experienced of the situation, I should have expected, that whenever the two courses of compass timber were put upon the second bed of moor-stone, if a hard gale should have come on at south-west, it would not only have lifted up and carried away the timber beds, but possibly would have deranged the moor-stone courses, notwithstanding the upright cramps to the outside stones.

"The solid being in this manner completed, the upper part of the building, comprehending four rooms, one above another, was chiefly formed by the outside upright timbers; having one kirb or circle of compass timber at each floor, to which the upright timbers were screwed and connected, and upon which the floor timbers were rested. The uprights were also jag-bolted and trenailed to one another, and, in this manner, the work was carried on to the height of 34 feet above the store-room floor, and there terminated by a planking of three inches thick, which composed the roof of the main column, as well as served for the floor of the lantern, and of the balcony round it.

"Thus the main column of this building consisted of one simple figure, being an elegant frustum of a cone, unbroken by any projecting ornament, or anything whereon the violence of the storms could lay hold; being, exclusive of its sloping foundation, 22 feet 8 inches upon its largest circular base, 61 feet high above that circular base, and 14 feet 3 inches in diameter at the top; so that the circular base was somewhat greater than one-third of the total height, and the diameter at top was somewhat less than two-thirds of the base at the greatest circle.

"The junction of the upright timbers upon each other was by means of *scarfs*, as they are technically called in ship-building and carpentry; that is, the joining of timbers end to end by over-lapping. The timbers were of different lengths, from 10 to 20 feet, and so suited, that no two joinings or scarfs of the uprights might fall together. The number of uprights composing the circle was the same from top to bottom; and their number being seventy-one, the breadth at the bottom would be 1 foot nearly; their thickness there was 9 inches; and, as they diminished in breadth towards the top, they also diminished in thickness. The whole of the outside seams were well caulked with oakum, in the same manner as in ships; and the whole payed over with pitch; consequently, upon a near view, the seams running straight from top to bottom in some measure resembled the flutings of columns; which, in so simple a figure, could not fail to catch the attention of the beholder, and prove an agreeable engagement of the eye.

"The whole of the building was, indeed, a piece of shipwrightry: for it is plain, from the preceding account, that the interposed beds of moor-stone had nothing to do with the frame of the building, it being entire and complete exclusive thereof: the beds of moor-stone could therefore only be considered in the nature of ballast, and amounted, from what has been before stated, in the whole, to the weight of above two hundred and seventy tons.

"All the windows, shutters, and doors, were composed of double plank, cross and cross, and clinked together; which falling into a rebate when shut, their outside formed a part of the general surface, like the port-holes in a ship's side; without making any unevenness or projection in the surface. There were, however, two projecting parts terminating this frustrum; one at the top, and the other at the joining with the rock; the utility of which seems to render them indispensable. They had each a projection of about 9 inches. The top projection, which is in the nature of a cornice, consisted of a simple bevel, and the use of it was very great; for in times of storms and hard gales of wind, when, according to the accounts of Mr. Winstanley's building, the broken sea rises to a far greater height than the whole structure, it would be likely to break the windows of the lantern, unless there was something to throw it off, as their use does not admit of any defence by shutters. Therefore Mr. Rudyerd applied this simple cornice, judging it sufficient to have the effect of throwing off the sea in times of storms; and yet not so much projection as that the sea, at the height of 71 feet above the foot of the building, could have power enough to derange it.

"The bottom projection, which has been called *the kant*, and which fills up the angle formed between the uprights and the sloping surface of the rock, so as to guard the foot of the uprights from that violence of action which the waves naturally exert when driven into a corner, was certainly a very useful application; but I am inclined to think it was not there upon the first completion.

"Upon the flat room of the main column, as a platform, Mr. Rudyerd fixed his lantern, which was an octagon of 10 feet 6 inches diameter externally. The mean height of the window-frames of the lantern above the balcony floor, was nearly 9 feet; so that the elevation of the centre of the light above the highest side of the base was 70 feet; that is, lower than the centre of Mr. Winstanley's second lantern by 7 feet; but higher than that of his first by 24 feet. The width of Mr. Rudyerd's lantern was, however, nearly the same as that of Mr. Winstanley's second; but, instead of the towering ornaments of iron work, and a vane that rose above the top of the cupola no less than 21 feet, Mr. Rudyerd judiciously contented himself with finishing his building with a round ball, of 2 feet 3 inches diameter, which terminated at 3 feet above the top of his cupola. The whole height of Mr. Rudyerd's lantern, including the ball, was no more than 21 feet above his balcony floor; whereas that of Mr. Winstanley's including the iron ornaments, was above 40.

"The whole height, then, of Mr. Rudyerd's light-house, from the lowest side to the top of the ball, was 92 feet, upon a base of 23 feet 4 inches, taken at a medium between the highest and lowest part of the rock that it covered.

"I have endeavoured to describe this building with all possible minuteness, because it affords a great and very useful lesson to future engineers. We are sure that a building such as Mr. Winstanley's was not capable of resisting the utmost fury of the sea, because, in four years after its completion, it was totally demolished thereby: but Mr. Rudyerd's building having sustained the repeated attacks of that element, in all its fury, for upwards of forty-six years after its completion; and then being destroyed, not by water, but by fire; we must conclude, it was of a construction capable of withstanding the greatest violence of the sea in that situation. And by withstanding it there, this light-house proves the practicability of a similar erection in any like exposure in the known world.

"I have seen a paper in the hands of one of the present proprietors, upon which were put down the quantities of materials said to have been expended in the construction of this building: viz., 500 tons of stone, 1,200 tons of timber, 80 tons of iron, and 35 tons of lead; and of trenails, screws, and rack-bolts, 2,500 each."

Mr. Smeaton then proceeds to detail the means by which the erection of the new lighthouse fell into his hands, his several interviews with the proprietors, and various other preliminary occurrences, among which the following remarks on the difference in structure of stone and wood, and on the bond of the stones to the rock and to each other, are particularly worthy of notice.

"In reflecting upon the late structure, it appeared most evidently, that had it not been for the moor-stone courses, inlaid into the frame of the building, and acting therein like the ballast of a ship, it had long ago been overset, notwithstanding all the branches and iron-work contrived to retain it: and that, in reality, the violent agitation, rocking, or vibration, which the late building was described to be subject to, must have been owing to the narrowness of the base on which it rested; and which, the quantity of vibration it had been constantly subject to, had rendered, in regard to its seat, in some degree rounding, like the rockers of a cradle. It seemed therefore a primary point of improvement, to procure, if possible, an enlargement of the base, which, from the models before me, appeared to be practicable. It also seemed equally desirable, not to increase the size of the present building in its waist; by which I mean that part of the building between the top of the rock and the top of the solid. If therefore I still kept strictly to the conical form, a necessary consequence would be, that the diameter of every part being proportionably increased by an enlargement of the base, the action of the sea upon the building would be greater in the same proportion; but as the strength increases in proportion to the increased weight of the materials, the total absolute strength to resist that action of the sea, would be greater by a proportional enlargement of every part, but would require a greater quantity of materials; on the other hand, if we could enlarge the base, and at the same time rather diminish than increase the size of the waist and upper works; as great a strength and stiffness would arise from a larger base, accompanied with a less resistance to the acting power, though consisting of a less quantity of materials, as if a similar conical figure had been preserved.

"On this occasion, the natural figure of the waist or bole of a large spreading oak, presented itself to my imagination. Let us for a moment consider this tree: suppose at 12 or 15 feet above its base, it branches out in every direction, and forms a large bushy top, as we often observe. This top, when full of leaves, is subject to a very great impulse from the agitation of violent winds; yet, partly by its elasticity, and partly by the natural strength arising from its figure, it resists them all, even for ages, till the gradual decay of the material diminishes the coherence of the parts, and they suffer piecemeal by the violence; but it is very rare that we hear of such a tree being torn up by the roots. Let us now consider its particular figure.—Connected with its roots, which lie hid below ground, it rises from the surface thereof with a large swelling base, which at the height of one diameter is generally reduced by an elegant curve, concave to the eye, to a diameter less by at least one-third, and sometimes to half of its original base. From thence its taper diminishing more slowly, its sides, by degrees, come into a perpendicular, and for some height form a cylinder. After that, a preparation of more circumference becomes necessary, for the strong insertion and establishment of the principal boughs, which produces a swelling of its diameter. Now, we can hardly doubt but that every section of the tree is nearly of an equal strength in proportion to what it has to resist: and were we to lop off its principal boughs, and expose it in that state to a rapid current of water, we should find it as much capable of resisting the action of the heavier fluid, when divested of the greatest part of its clothing, as it was that of the lighter, when all its spreading ornaments were exposed to the fury of the wind: and hence we may derive an idea of what the proper shape of a column of the greatest stability ought to be, to resist the action of external violence, when the quantity of matter is given whereof it is to be composed.

"In *Plate* V. *Figure* 1, is a sketch, representing the idea which I formed of this subject. It is farther observable, in the insertions of the boughs of trees into the bole, or of the branches into the boughs, (which is generally at an oblique angle) that those insertions are made by a swelling curve, of the same nature as that wherewith the tree rises out of the ground; and that the greatest rake or sweep of this curve is that which fills up the obtuse angle; while the acute angle is filled up with a much quicker curve, or sweep of a less radius: and *Figure* 2, of the same Plate, represents my conception of this matter. In this view of the subject, I immediately rough-turned a piece of wood, with a small degree of tapering above; and leaving matter enough below, I fitted it to the oblique surface of a block of wood, somewhat resembling the sloping surface of the Eddystone rock; and soon found, that by reconciling curves, I could adopt every part of the base upon the rock to the regularly turned tapering body, and so as to make a figure not ungraceful; and at the same time carrying the idea of great firmness aud solidity.

"The next thing was to consider how the blocks of stone could be bonded to the rock, and to one another, in so firm a manner, as that, not only the whole together, but every individual piece, when connected with what preceded, should be proof against the greatest violence of the sea.

"Cramping, as generally performed, amounts to no more than a bond upon the upper surface of a course of stone, without having any direct power to hold a stone down, in case of its being lifted upward by an action greater than its own weight; as might be expected frequently to happen at the Eddystone, whenever the mortar of the ground-bed it was set upon was washed out of the joint, when attacked by the sea before it had time to harden; and though upright cramps, to confine the stones down to the course below, might in some degree answer this end, yet, as this must be done to each individual stone, the quantity of iron, and the great trouble and loss of time that would necessarily attend this method, would in reality render it impracticable; for it appeared, that Mr. Winstanley had found the fixing twelve great irons, and Mr. Rudyerd thirty-five, attended with such a consumption of time (which arose, in a great measure, from the difficulty of getting and keeping the holes dry, so as to admit of the pouring in of melted lead) that any method which required still much more, in putting the work together upon the rock, would inevitably, and to a very great degree, procrastinate the completion of the building. It therefore seemed of the utmost consequence to avoid this, even by any quantity of time and moderate expense, that might be necessary for its performance on shore; provided it prevented hinderance of business upon the rock; because of time upon the rock, there was likely to be a great scarcity, but on the shore a very sufficient plenty. This made me turn my thoughts to what could be done in the way of dovetailing. In speaking however, of this as a term of art, I must observe, that it had been principally applied to works of carpentry; its application in the masonry way had been but very slight and sparing; for in regard to the small pieces of stone that had been let in with a double dovetail, across the joint of larger pieces, and generally to save iron, it was a kind of work even more objectionable than cramping; for though it would not require melted lead, yet being only a superficial bond, and consisting of far more brittle materials than iron, it was not likely to answer our end at all. Somewhat more to my purpose, I had occasionally observed, in many places in the streets of London, that, in fixing the kirbs of the walking-paths, the long pieces, or stretchers, were retained between two headers, or bond pieces; whose heads being cut dovetail-wise, adapted themselves to, and confined in, the strechers; which expedient, though chiefly intended to save iron and lead, nevertheless appeared to me capable of more firmness than any superficial fastening could be; as the tye was as good at the bottom as at the top, which was the very thing I wanted; and therefore if the tail of the header was made to have an adequate bond with the interior parts, the work would in itself be perfect. What I mean will be rendered obvious by the inspection of *Figure* 3, in *Plate* V. Something of this kind I also remembered to have seen in Belidor's description of the stone floor of the great sluice at Cherbourg, where the tails of the upright headers are cut into dovetails, for their insertion into the mass of rough masonry below. From these beginnings I was readily led to think, that if the blocks themselves were, both inside and out, all formed into large dovetails, they might be managed so as mutually to lock one another together; being primarily engrafted into the rock: and in the round and entire courses, above the top of the rock, they might all proceed from, and be locked to, one large centre stone. After some trials in the rough, I produced a complete design, of which *Figure* 5, *Plate* V., is the exact copy; the dotted lines representing the course next above or below, which in the original was drawn from the same centre, on the other side of the paper; so that looking on each side separately, each course was seen distinctly; or, looking through the paper, the relation of the two courses, showing how they mutually broke joint upon one another, was clearly pointed out: and this method of representation was pursued throughout; but not being practicable in copper-plate work, I am under the necessity of introducing the method by dotted lines, though attended with some degree of confusion of the main design.

"It is obvious, that in this method of dovetailing, while the slope of the rock was making good; by cutting the steps (formed by Mr. Rudyerd) also into dovetails, it might be said, that the foundation-stones of every course were engrafted into, or rather rooted in, the rock; which would not only keep all the stones in one course together, but prevent the courses themselves (as one stone) from moving or sliding upon each other. But after losing hold of the rock, by getting above it; then, though every stone in the same course would be bonded in the strongest manner with every other, and might be considered as consisting of a single stone, which would weigh a considerable number of tons, and would be farther retained to the floor below by the cement, so that, when completed, the sea would have no action upon it but edgeways; yet, as a force, if sufficiently great, might move it, notwithstanding its weight, and the small hold of the sea upon it, and break the cement before time had given it that hardness which it might be expected to acquire afterwards; I had formed more expedients than one for fixing the courses to one another, so as absolutely to prevent their shifting; but I shall not trouble my reader with a recital of those expedients at present, as they will more properly come in along with the reasons of my choice, in the detail of the actual proceedings."

Mr. Smeaton made his first voyage to the Eddystone on the 2d of April, 1756, but was prevented from landing by the weather; but on the 5th of the same month he was more successful, and staid upon the rock about two hours and a half, during which time he observed, "such traces of the situations of the irons fixed by Mr. Winstanley, as that it would not be difficult to make out his plan, and the position of the edifice; from whence it appeared very probable that Mr. Winstanley's building was overset all together; and that it had torn up a portion of the rock itself with it, as far as the irons had been fastened in it." He also "perceived that Mr. Rudyerd's iron branches, as then called, were much smaller and shorter than he had described them to be at the bottom of his print; that many of them were loose, and some broken and bent: and that, in regard to the steps, described to be cut upon the rock, there were only five of them, of which the traces were remaining: so that there was but one flat or tread of a step above the centre of the house; and the upper part of the surface of the rock above that, was a sloping plain, as it had been at first. Three steps, of the five now remaining, seemed to have been but faintly cut, and the uppermost but one was so imperfect, that he supposed a large spawl or splinter had come from it; and this appeared the more probable, as the uppermost step was so shaken, that another large spawl might have been easily raised from it, by a slight action of a wedge. Above the uppermost step the rock seemed to be of a softer nature, was cracked in many places, and probably had received some damage from the fire. None of the steps appeared to have been cut with much regularity, either as to level or square; but to have all the marks of hurry upon them. In the centre of the house a slight footing was cut for the mast, suitable to a square of 18 inches, with large iron branches, answerable to two of its sides, and a small hole bored in the centre, of about 1¼ inch diameter, being 6 inches deep. By consulting Plate I., many of the above matters will be made apparent to the eye.

"I then," says Mr. Smeaton, "proceeded to try the degree in which the rock was workable, and found that from a flat surface, indifferently taken, I could, with a pick, sink a hollow at the rate of five cubic inches per minute; and could cut or drill a hole with a jumper of 1¼ inch diameter, at the rate of one inch deep in five minutes. I also tried a method of forcing two holes into one, by a square flat-faced bruiser, or pummel; so that, if there should be occasion, I might be able to make a continued groove; or let in an iron branch, in the manner of Mr. Rudyerd, and I had the satisfaction to find that the whole succeeded to my wishes."

In the choice of materials, Mr. Smeaton was determined in favour of moor-stone or granite, for the outside work, and Portland stone for the inside. The latter was not eligible for the outer surface, on account of its liability to be destroyed by a marine insect; and the moor-stone was too hard and expensive in the working to admit of its being used throughout the building.

By the 15th of May, Mr. Smeaton had made ten voyages of observation to the Eddystone, and then returned to London, where having settled with the proprietors, he received his commission to proceed on the work. He then went back to Plymouth, and, on the 3d of August, landed with the first company of workmen on the rock, where he began to fix the centre and lines of the work. After describing the difficulties under which he laboured from the uncertainty of the weather, and the necessity in which the workmen were placed, of returning to shore every tide, till a vessel fit for their reception could be properly moored off the rock, Mr. S. observes upon his preference of the use of picks and wedges for operating upon the rock, that "it might seem, at first sight, that a greater dispatch would have been by the use of gunpowder, in blasting the rock, in the same manner as is usual in mines, and in procuring limestone from the marble rocks in the neighbourhood of Plymouth: but though this is a very ready method of working hard and close rocks, in proportion to the dispatch that could be made by picks and wedges; yet, as a rock always yields to gunpowder in the weakest part, and it is not always easy to know which part is weakest; it might often have happened, if that method had been pursued, that, instead of forming a dovetail recess, such as was required, the very points of confinement would have been lost. Besides, the great and sudden concussion of gunpowder might possibly loosen some parts that it was more suitable to the general scheme should remain fast. For these reasons, I had previously determined to make no use of gunpowder for this purpose.

"On the 7th of September," says Mr. Smeaton, "I sent to Portland the draughts for the six foundation courses, that were to be employed in bringing the rock to a level; which, with the draughts for eight that I had before dispatched, completed the order for the whole quantity of Portland stone to be used in the solid up to the entry door; being all that we could expect to set in place the next season. The rock was not indeed yet ready for completing the exact moulds for those stones that were to fit into the dovetails made in it; but, by ordering the stones large enough, and being scappelled something near their proper form, it would prevent loss of time in waiting to get the true figure from the rock, as well as unnecessary waste.

"Nothing happened to prevent the companies from working every tide from the 27th of August, till the 14th of September, in which time they had worked one hundred and seventy-seven hours upon the rock. In this interval, having procured a carpenter to be applied to that purpose, I began to make the moulds for the exact cutting of the stones to their intended shapes. This was done by laying down, in chalk-lines upon the floor of a chamber, the proposed size and figure of each stone, being a portion of the plan at large of the intended course; and the carpenter having prepared a quantity of battens, or slips of deal board, about three inches broad, and one inch thick, shot straight upon the edges by a plane; those battens being cut to lengths, and their edges adapted to the lines upon the floor, and properly fitted together, became the exact representatives of the pieces of stone whose figure was to be marked from them, when their beds were wrought to the intended parallel distance.

"It is obvious that there was no necessity for making moulds for a whole course after the work became regular; as was the seventh course, after the six foundation courses brought the rock to a level; it was sufficient to make one mould to each circle of stones, beginning with the centre stone; but as the six foundation courses were adapted to the particular irregularities of the rock, and consequently could not be strictly regular, it was necessary that a separate mould should be made for every separate stone composing that part of the work.

"During this interval, I visited the rock, and on arriving there the 8th of September, was informed by Mr. Jessop, that the preceding evening, there being a very strong tide, and no wind, a West-Indiaman, homeward bound, and a man-of-war's tender, were in great danger of driving upon the north-east rock; but that he timely perceiving their danger, though they themselves were not aware of it, ordered out the seamen and hands, who towed them off.

"On this visit, I staid two days; for as the working company had begun to take down the upper part of the rock, it was necessary to concert, and put in practice, the proper means of doing that, without damage to what was destined to remain. I have already mentioned my resolution of not using gunpowder; yet it was necessary, for the sake of dispatch, to employ some means more expeditious than the slow way of crumbling off the matter by the blunt points of picks. It has been already noticed, that the laminæ composing the rock were parallel to the inclined surface; and it was very probable that the chasm into which Mr. Winstanley's chain had been so fast jambed, that it never could be disengaged, extended farther into the rock than the visible disunion of the parts: this made me resolve to try a method sometimes used in this country, for the division of hard stones, called *the key and feather*, in order to cross-cut this upper stratum of the rock. The construction and operation of the key and feather is as follows:—A right line is marked upon the surface of the rock or stone to be cut, in the direction in which it is intended to be divided. Holes are then drilled by a jumper, at the distance of six or eight inches, and about one inch and a quarter in diameter, to the depth of about eight or nine inches; the distances, however, of the holes, and their diameters, as well as their depth, are to be greater or less, according to the strength of the stone, in the estimation of the artist directing the work. The above dimensions were what we used on this occasion. The key is a long tapering wedge, of somewhat less breadth than the diameter of the holes, and so as to go easily into them; the length being three or four inches more than the depth of the holes. The feathers are pieces of iron, also of a wedge-like shape; the side to be applied to the key being flat, but the other side a segment of a circle, answerable to that of the holes; so that the two flat sides of two feathers being applied to the two flat sides of the key, and the thick end of the feathers to the thin end of the key, they all together compose a cylindric, or rather oval kind of body; which in this position of parts is too big to go into the holes by at least one-eighth of an inch; that is, in the direction of a diameter passing through the three parts; but, in the other direction, is no broader than to go with ease into the holes. A key and a pair of feathers is made use of in each hole; and the feathers being first dropped in, with the thick ends downward, the keys are then entered between them; the flat sides of all the keys and the feathers being set parallel to that line in which the holes are disposed; the keys are then driven by a sledge-hammer, proceeding from one to another, and being forced gradually, as in splitting of moor-stone, the strongest stones are unable to resist their joint effort; and the stone is split according to the direction of the original line, as effectually, and much more regularly and certainly, than could be done with gunpowder, and without any concussion of the parts. Had our rock been entirely solid, this way of working might not have been applicable, on account of the crack's going too deep; but here, when it arrived at the joint where the chain was lodged, the split part became entirely disengaged from the rest; and in this way we were enabled to bring off the quantity of several cubic feet at a time: and thus the chain was released, after a confinement of above fifty years. The impossibility of disengaging it before now appeared very evident; for the pressure had been so great by the rock's closing upon it, as before suggested, that the links in their intersections were pressed into each other, as completely as if they had been made of lead; though the bolt-iron composing thec hain had been at least five-eighths of an inch in diameter.

"On Thursday, the 16th, I again went off to the rock, and found the work in the following situation. The lowest new step (the most difficult to work upon, because the lowest) with its dovetails quite completed. The second step rough-bedded, and all its dovetails scappelled out. The third step (being the lowest in Mr. Rudyerd's work) smooth-bedded, and all the dovetails roughed out. The fourth in the like state. The fifth rough-bedded, and dovetails scappelled out: and the sixth smooth-bedded, and all the dovetails roughed out. Lastly, the top of the rock, the greatest part of the bulk whereof had been previously taken down by the key-and-feather method, as low as it could be done with propriety, was now to be reduced to a level with the upper surface of the sixth step; the top of that step being necessarily to form a part of the bed for the seventh, or first regular course; so that what now remained, was to bring the top of the rock to a regular floor by picks: and from what now appeared, (as all the upper parts, that had been damaged by the fire, were cut off,) the new building was likely to rest upon a basis even more solid than the former had done.

"On Thursday, the 30th, I traced the outlines upon the upper part of the rock for the border of the seventh course, all within which was to be sunk to the level of the top of the sixth, and all without to be left standing, as a border for defence of the ground-joint of the work with the rock; and measuring the height of the top step above the bed of the first, I found it to be eight feet four inches: which would now be the difference of level between the west or lowest side of the new building, and the east or highest."

The setting in of the equinoctial winds prevented much farther progress in the work for this season; but on the 7th of November, the weather being somewhat moderate, Mr. Smeaton went off in the Eddystone boat, with battens, and the carpenter, to mould off the dovetails from the rock, when he found "four or five of the dovetails in the upper step wanting some amendment, that would employ as many men at each, for about four or five hours. The greatest part of the top of the rock was now brought to a regular floor, but some part of the north-east side wanted bringing down to a level." And here the operations for the year ended; for, on the 15th of the month, the workmen left the rock, having been able to make only thirty-eight hours and a half since the 2nd of October.

Mr. Smeaton occupies the interval between this period and the next working season with describing the regulations of his mason's yard, the size of the stones, &c., among which the following remarks may be useful to the reader.

"From the beginning I always laid it down as a fundamental maxim, that on account of the precariousness of weather to suit our purposes, (and without its being favourable, I think it has already sufficiently appeared, that nothing is to be done upon the Eddystone,) if we could save one hour's work upon the rock, by that of a week in our work-yard, this would always prove a valuable purchase; and that therefore everything ought to be done by way of preparation, which could tend to the putting our work together with expedition and certainty, in the ultimate fixing of it in its proper place; and for this purpose, it was necessary to make use of as large and heavy pieces of stone as, in such a situation as the Eddystone, were likely to be capable of being managed without running too great a risk.

"The common run of modern buildings, even of the largest size, are composed of pieces in general not exceeding five or six hundred-weight, except where columns, architraves, cornices, and other parts are to be formed, that indispensably require large single pieces; because stones of this size and bulk are capable of being handled without the use of tackles, or purchases, unless where they are to be raised perpendicularly: yet it appeared to me, that this choice of general magnitude resulted only from the workmen's not having commonly attained all that expertness in the management of the mechanic powers that they might have; in consequence of which, they avoid, wherever they can, the necessity of employing them. This arises not from the real nature of the thing, when properly understood; for a stone of a ton weight is, when hoisted by a proper tackle, and power of labourers, as soon and as easily set in its place, as one of a quarter of that weight; and, in reality, needs much less hewing than is necessary for the preparation of four stones to fill up the same space; nor need this reasoning stop at stones of a ton weight, but it might proceed even to as large sizes as are said to be found in the ruins of Balbec, if there were not inconveniences of other kinds to set on the opposite side of the question, as well as the want of quarries in this kingdom to produce stones of that magnitude.

"The size of the stones that could be used in the Eddystone lighthouse seemed limited by the practicability of landing them upon the rock: for as nothing but small vessels, that were easily manageable, could possibly deliver their cargoes alongside of the rock, with any reasonable prospect of safety; so no small vessels could deliver very large stones, because the sudden rising and falling of the vessels in the gut amounted frequently to the difference of three or four feet, even in moderate weather, when it was very practicable for a vessel to lie there; so that in case, after a stone was raised from the floor of the vessel, her gunnel should take a swing, so as to hitch under the stone, one of such a magnitude as we are now supposing, on the vessel's rising, must infallibly sink her; and hence it appeared, that much of the safety in delivering the cargoes would depend upon having the single pieces not to exceed such weight as could be expeditiously hoisted, and got out of the way of the vessel, by a moderate number of hands, and by such sort of tackles as could be removed from the rock to the store-vessel each tide: and on a full view of the whole matter, it appeared to me very practicable to land such pieces of stone upon the rock, as in general did not much exceed a ton-weight; though occasionally particular pieces might amount to two tons.

"The general size of our building stones being thus determined upon at a ton-weight, those would have been far too heavy to be expeditiously transferred and managed, even in the work-yard, unless our machinery rendered that easy, which would otherwise be difficult, without too great an expense of labour: and as the moving and transferring the pieces of stone in the work-yard would be greatly increased in quantity, by the very mode of attaining a certainty in putting the work together upon the rock; this consideration made it still the more necessary to be able to load upon a carriage, and move the different pieces from one part of the yard to the other, with as much facility (comparatively speaking) as if they had been so many bricks: for, that we might arrive at perfect certainty in putting the work ultimately together in its place upon the rock, it did not appear to be enough, that the stones should all be hewn as exactly as possible to moulds that fitted each other; but it was farther necessary, that the stones in every course should be tried together in their real situation in respect to each other, and so exactly marked, that every stone, after the course was taken asunder, could be replaced in the identical position in which it lay upon the platform, within the fortieth part of an inch. Nor was this alone sufficient; for every course must not only be tried singly together upon the platform, and marked, but it must have the course next above it put upon it, and marked in the same manner, that every two contiguous courses might fit each other on the outside, and prevent an irregularity in the outline: and this indeed, in effect, amounted to the platforming of every course twice: so that, in this way of working, every stone must be no less than six times upon the carriage:—1st. When brought into the yard from the ship, to carry it to the place of deposition, till wanted to be worked.—2ndly. When taken up and carried to the shed to be worked.—3rdly. After being wrought, to be returned to its place of deposition.—4thly. When taken up to be carried to the platform.—5thly. When finished on the platform, to be returned to its place of deposition.—6thly. When taken up to be carried to the jetty, to be loaded on board a vessel to go to sea.

"It might, at first sight, appear superfluous to try the courses together upon each other, as the under and upper sides of all the courses were planes: and, in case the work could have been put together upon the rock in the same way that common masonry generally is done, it would have been so: that is, if we could have begun our courses by setting the outside pieces first, then it would have been very practicable to have regulated the inside pieces thereto; but as our hope of expedition depended upon certainty in every part of our progress, this required us to be in a condition to resist a storm at every step: the outside stones therefore, unconnected with the inner ones, would have scarce any fastening besides their own weight, and would be subject to the most immediate and greatest shock of the sea; and, after completing the outward circle, the inner space would be liable to become a receptacle for water: the necessity therefore of fixing the centre stone first, as least exposed to the stroke of the sea, and of having sure means of attaching all the rest to it, and to one another, rendered it indispensable that the whole of the two courses should be tried together; that if any defect appeared at the outside, by an accumulation of errors from the centre, it might be rectified upon the platform.

"The moor-stone, though very hard with respect to its component parts, yet being of a friable nature, is extremely difficult to work to an arris (or sharp corner,) or even to be preserved, when so wrought by great labour and patience: that is, with sharp tools, and small blows; it therefore soon appeared to me, that we should make very rough and coarse work of it, if the finishing of the pieces were left to the workmen of the country where produced: for, though carefully wrought there in their place, yet in loading and unloading from their carriages, and again putting on board, and unloading from the vessels, the arrises would be very subject to damage. Therefore, to have as much done in the country as possible, and to save weight in carriage (leaving the finishing part to be done at home) rough moulds were sent for each size and species of stone, which were to be worked by them to a given parallel thickness, and with length and breadth enough, when so bedded, (as it is called) to be cut round all the sides to the true figure of the finishing mould: but they were to reduce them as near the size as they could safely do it by the hammer; and, that they might not leave an unnecessary waste, they were to be paid no more for either stone or carriage, than what the mould measured upon the thickness given; and if they were wanting of substance sufficient to make the figure complete, it should be at our option to reject them when they came home."

Our author next proceeds to detail his experiments on cements; but as they constitute no part of the building process, the reader is referred to the articles CEMENT and MORTAR, where the subject is duly considered.

On the 5th of June, 1757, the operations on the rock were recommenced, and by the 10th all the preliminary matters were settled; so that "on Saturday, the 11th of June, the first course of stone was put on board the Eddystone boat, (*see Plate* III. *Figure* 1.) with all the necessary stores, tools, and utensils. We landed at eight on Sunday morning, the 12th of June, and before noon had got the first stone into its place, being that upon which the date of the year 1757 is inscribed, in deep characters; and the tide coming upon us, we secured it with chains to the old stanchions, and then quitted the rock till the evening tide, when it was fitted, bedded in mortar, trenailed down, and completely fixed; and all the outward joints coated over with plaster-of-paris, to prevent the immediate wash of the sea upon the mortar. This stone, according to its dimensions, weighed two tons and a quarter. The weather serving at intervals, it was in the evening of Monday, the 13th, that the first course, consisting of four stones, was finished; and which, as they all presented some part of their faces to the sea, were all of moor-stone.

"The next day, Tuesday the 14th, the second course (*see Plate* III. *Figure* 2,) arrived; and some of it was immediately landed, proceeded with, and in part set the same tide: the loose pieces being chained together by strong chains, made on purpose for this use, and those ultimately to the stancheons, or to lewises in the holes of the work Course I. that had already been fixed. The sea was uncommonly smooth when we got upon the rock, this evening's tide, but while we were proceeding with our work, within the space of an hour and a half, the wind sprung up at north-east, and blew so fresh, that the Weston, lying to deliver the remainder of her cargo, had some difficulty in getting out of the gut; and, had it not been for the transport buoy, to which she had a fastening by a rope, it would probably have proved impracticable to have got her out again. And we soon saw it was necessary to get everything in the best posture time and circumstances would admit, in order to quit the rock with safety to ourselves, and security to what we must necessarily leave behind us.

"The pieces that were fixed and trenailed down, were supposed to be proof against whatever might happen; but the loose pieces, and those that were simply lowered down into their dovetail recesses, were considered as needing some additional security, to prevent their being carried away by the violence of the sea. Of the thirteen pieces of which Course II. consisted, five only were landed: No. 1 was completely set; No. 2 and 3 were lowered into their places, and secured by chains; and No. 4 and 5, which lay at the top of the rock, were chained together, and also to the slide-ladder, which was very strongly lashed down to the eye-bolts, purposely fixed on the rock for that intent.

"In the evening (of June 15,) we made a short tide upon the rock, and had the satisfaction to find that no material damage had happened to anything; we therefore proceeded with our work, and completely fixed No. 2 of Course II. On the morning of Friday the 17th we again landed for a short time; and, nothwithstanding we did not meet with anything amiss on our return to the rock on Wednesday evening, after the hard gale of wind, yet this morning we found a part of the rock in the border of our work, that secured a corner of No. 3, was gone: we therefore, to secure that stone to its neighbour, applied an iron cramp, of which we had some in readiness in case of accident. We were prevented landing in the evening, by a fresh wind and rain at north-west, but landed again on Saturday morning's tide, the 18th. However, we had not been long there before a great swell arose from the south-west; and though there had been no wind apparently to occasion it, yet it came upon us so fast, that we were obliged to quit the rock before we could get our work into so satisfactory a posture of defence as I wished. It was, however, as follows: No. 1, 2, 3, 4, and 5, were completely fixed as intended; No. 6 and 7, were fitted, and lowered upon their mortar-beds; No. 8, was simply got into its place, with a weight of lead of five hundred weight upon it; which, in all such trials as had hitherto been made thereof, had lain quietly. Not having time to get the stone, No. 9, into its place, we chained it upon the top of the rock to the slide-ladder, as we had done before on Tuesday. In this condition we left the rock, having staid till we were all wet from head to foot.

"The storm continued till Tuesday morning: about noon of that day," says Mr. Smeaton, "the wind and sea having become still more moderate, I judged it practicable to row ahead against it, so as to get to the westward of the rock, and reconnoitre our damages: accordingly, taking four oars in the light yawl, it being then near low water, I observed, when the sea fell away from the rocks, (every sea then breaking bodily over it,) that No. 9, and the slide-ladder to which it was chained, were both gone; that the two pieces of moor-stone, No. 5 and 6, which had only been let down upon their mortar-beds, without farther fastening, were also gone; that No. 3 had broke its cramp, and was gone; and that the five hundred weight of lead, that had been laid upon the most projecting part of the piece, No. 8, had, by the force of the sea acting edgewise upon it, been driven to the eastward, till it was stopped by the rise of the third step, against which it seemed abutted; so that having thereby quitted the piece, No. 8, upon which it was laid, that was gone also: we therefore, as it appeared, had lost five pieces of stone; the loss of which was, in the first instance, alleviated by finding that the first course appeared so thoroughly united with the rock, that its surface began to look black, with dark-coloured moss fixing upon it, and giving it the same hue as the rock itself: also, that our shears and windlass were all standing, without the least derangement.

"I did not wait for the subsiding of the winds and seas, so as to enable us to land, and look out whether or no we could recover any of the lost pieces; I immediately made for Plymouth in the light yawl, and landed at Mill Bay, at five o'clock on Tuesday evening, the 21st; and, having collected the moulds of the stones we had lost, and chosen proper spare blocks, I set a couple of men to work upon each piece of stone, day and night, till finished. This disaster, though it furnished a few reflections, yet they were not of the unpleasant kind; for, as every part of the stonework that was completed according to its original intention, appeared to have remained fixed, it demonstrated the practicability of the method chosen; and at the same time shewed the preference of wedging to cramping, as the cramp had failed: and also the utility of trenails, as a security till the mortar was become hard.

"At four o'clock on Monday morning the 27th, the weather serving, I went out with Richardson and company, in the Eddystone boat; we got to the buss at ten, and found the Weston at the transport buoy, but could not land till the afternoon's tide, being a complete week since we had been last upon the rock. We first replaced the ladder, and afterwards proceeded, without more than usual interruptions, till the 30th in the evening, when we closed and completed the Course No. II., and began upon Course III. The execution of these two courses had taken us up from the 12th to the 30th inclusive, and though they consisted of no more than seventeen pieces of stone in the whole, yet I found myself no ways disheartened; for, in establishing these two courses, I considered the most difficult and arduous part of the work to be already accomplished, as these two courses brought us up to the same level where my predecessor Mr. Rudyerd had begun.

"Friday, July the 1st, we were able to land. I observed, that during the last tide, the swell had washed some of the pointing out of the exterior joints, and also some of the grouting out of the upright joints; but as a heavy sea seemed likely to come on with the tide of flood, I judged it to be to no purpose to repair the cement while a violent swell continued; I therefore employed the company in cutting off the iron stancheons belonging to the former building, as they now began to be in our way, and as the hold we got of them ceased to be of use, in proportion as we got more fastening from the lewis holes of our own work.

"The weather having become more favourable, on Sunday morning, the 3d of July, I went on board, accompanied by Mr. Jessop and his party, to whom, as they had never had the opportunity of setting a stone, it behoved me to attend. We, however, not only met with a repulse this day, but could not make any farther attempt to go out till Tuesday, the 5th; and then the wind, though gentle, being contrary, had not the company on board the buss come with their two yawls and towed us thither, in all probability the day would have been spent in fruitless attempts. Our difficulty was considerably increased by the coming on of so thick a fog, that, all our efforts united, we had much ado to regain the buss. Richardson told me they had had such bad weather, that the slide-ladder had again broke its lashings and driven away; that they had, however, got all the irons cut off close to the rock; but that the last tide, though there was only a breeze at south-west, the swell was so great, and came on so suddenly, as to put them in great danger of being washed off from the top of the rock, before they could quit it.

"At two o'clock this day we landed, and Jessop's company set six pieces of stone, and effectually repaired the cement; and next day a proportionable dispatch was made, though the weather was not very mild.

"On Monday, the 11th, I again went out; Course III. consisting of twenty-five pieces, was closed on the following day, and Course IV. begun.

"Thursday, the 14th of July, the company pursued the work of Course IV.; and now, both companies being fully instructed in the method of setting the basement courses, I returned to Plymouth; from whence I proposed to visit each company as often as should seem expedient, but always once in each company's turn, if wind and weather should permit.

"Contrary winds, ground-swells, and heavy seas for several days, interrupted the regularity of our proceedings; however, taking such opportunities as we could, the Course IV., consisting of twenty-three pieces of stone, was closed in the morning's tide of the 31st of July, (*see Plate* III.); and in the evening's tide five pieces of Course V. were set. Our work went on regularly for some days together; and, visiting the work upon the 5th of August, I found the Course V. containing twenty-six pieces, closed in, (*see Plate* III.); but that by some inadvertency in proceeding with the interior part, the masons had been obliged to set two of the outside pieces so as to be farther out than they should have been by an inch each. However, as I found the work was sound and firm, I thought it better to cut off the superfluous stone from the outside, than to disturb the work by the violence that must have been used in unsetting the pieces; I therefore determined to let them stand as they were, till the cement was become so hard as to support the edges of the stone while the faces were working afresh; and which, from the mortar of our first and second course, we found was likely to be the case before the close of the season. One of the dovetails had also given way in driving a trenail, owing to a flaw in the stone; for the remedying whereof we applied a cramp.

"The 8th of August, at noon, the weather being exceeding fine, with a low neap tide, I took the opportunity of drawing a meridian line upon the platform of Course VI. the sea never going over the work during the whole tide, which was the first time it had not washed over all, since we began to build: we therefore took this favourable opportunity of carefully making good all our pointings and groutings, wherever the water had washed during the bad weather that had succeeded the last departure of the Eddystone boat; and which was the case with it, in places where it had not had time to set before a rough tide came on; but I observed, with much satisfaction, that whatever, not only of the original work, but of the repaired pointing, had once stood a rough tide without giving way, the same place never after failed. I also observed, that as in mending the pointings we had in some places made trial of Dutch tarras as well as puzzolana, interchangeably, the puzzolana, for hard service, was evidently superior to the tarras: and some particular joints had proved so difficult, that I was obliged to try other expedients; the best of which was to chop oakum very small, and beat it up along with the mortar. This was our last resource, and it never failed us.

"Upon the 11th, I again went out in the vessel that contained the remaining pieces of Course VI.: those I saw fixed; and that course, consisting of thirty-two pieces, closed in the same evening. (*See Plate* VI.) This completing our six basement courses, brought our work upon the same level to which we had, the preceding season, reduced the top of the rock; and upon this, as a common base, the rest of the structure was to be raised by regular entire courses. The time this part of the work (consisting of one hundred and twenty-three pieces of stone) had taken up, was from the 12th of June to the 11th of August inclusive, being a space of sixty-one days. We now considered our greatest difficulties to be successfully surmounted, as every succeeding course had given us more and more time, as well as more and more room; and this will appear from our proceedings; for it has already been noticed, that the two first courses, consisting of nineteen pieces of stone only, had cost us seventeen days.

"Having now got the work to this desirable situation, I apprehend it will be agreeable to my reader to be more particularly acquainted with the method in which the stones were set and fixed. I have intimated, that when each separate piece, of which a course was to consist, was separately wrought, they were all to be brought to their exact places with respect to each other, upon the platform in the work-yard, and so marked, that, after being numbered and taken to pieces, they could again be restored to the same relative position. This was done upon the complete circular courses by drawing lines from the centre to the circumference, passing through the middle of each set of stones; and likewise concentric circles through the middle of each tier or circle of stones, so as to indicate to the eye their relative position to each other: but to render the marks not easily delible, where those lines crossed the joints, a nick was cut and sunk into the surface of the two adjacent stones; for doing which, a piece of thin plate-iron was employed, with sand, upon the principle that stones are sawn; so that not only the sight, but feeling, could be employed in bringing them together again exactly; for the same or a similar plate being applied to the nick, the least irregularity of its position would be discoverable. In a similar manner the stones of the base courses were marked by lines drawn parallel to the length of the steps, and others perpendicular to the same, the crossings being sawn in, as before described. There was, however, a nicety in this part of the work, that required particular attention, and that was in forming a provision for setting the four radical stones, that occupy the four radical dovetails into which each step was formed, as may be observed in the several figures of *Plate* III. Those stones were formed, from the work of the rock's being actually moulded off, and from the manner, already described, of bringing those moulds to agree after they were brought home from the rock, those stones were laid upon the platform thereby, and then marked with lines upon their own substance, in the manner just mentioned: and as the distances of each of those stones were then ascertained by gauge-rods of white fir-wood, while upon the platform; it must be expected, as each step was reduced to a level plain, as the platform was, that when laid upon the rock in their due positions and distances, by the gauge-rods, they would nearly fit the dovetails that had been cut in the rock to receive them; and where there was the least want of fitness, as might possibly happen with bodies of so rigid a nature, either the stone or the rock was cut, till each stone would come into its exact relative position, and then all the rest would follow one another by their marks, in the same manner as they had done upon the platform.

"It is necessary to be noticed, that the waist of each piece of stone had two grooves cut, from the top to the bottom of the course, of an inch in depth, and three inches in width: applicable to those grooves were prepared a number of oak wedges, somewhat less than three inches in breadth, than one inch thick at the head, nearly three-eighths thick at the point, and six inches long. The disposition of these grooves is shown in the courses of *Plate* III. where the little black parallelogram figures, placed along the lines describing the joints of the courses, represent the tops of the grooves, and their place on the right hand or left of the joint line show in which stone the groove is cut. It is also to be noted, that where the flank side of a stone was not more in length than a foot, or fourteen inches, one groove was generally deemed sufficient; but those of eighteen inches or upwards had, generally, in themselves or the adjoining stone, a couple of grooves.

"The mortar was prepared for use by being beat in a very strong wooden bucket, made for the purpose; each mortar-beater had his own bucket, which he placed upon any level part of the work, and with a kind of rammer, or wooden pestle, first beat the lime alone, about a quarter of a peck at a time, to which, when formed into a complete, but rather thin paste, with sea-water, he then gradually added the other ingredient, keeping it constantly in a degree of toughness by continuance of beating. When a stone had been fitted and ready for setting, he whose mortar had been longest in beating came first, and the rest in order: the mason took the mortar out of the bucket; and, if any was spared, he still kept on beating; if the whole was exhausted, he began upon a fresh batch. The stones were first tried, and heaved into and out of their recesses, by a light movable triangle, which being furnished with a light double tackle, the greatest number of all the pieces could be purchased by the simple application of the hand; and this made our stones to be readily manageable by such machinery as could commodiously be moved and carried backward and forward in the yawls every tide. To the first stone, and some few others, we took the great tackle, that we might hoist and lower them with certainty and ease; but there were not in the whole above a dozen stones that required it.

"The stone to be set being hung in the tackle, and its bed of mortar spread, was then lowered into its place, and beat down with a heavy wooden maul, and levelled with a spirit level: and the stone being brought accurately to its marks, it was then considered as set in its place. The business now was to retain it exactly in that position, notwithstanding the utmost violence of the sea might come upon it before the mortar was hard enough to resist it. The carpenter now dropped into each groove two of the wedges already described, one upon its head, and the other with its point downward, so that the two wedges in each groove would then lie heads and points. With a bar of iron of about two inches and a half broad, three-quarters of an inch thick, and two feet and a half long, the ends being square, he could easily (as with a rammer) drive down one wedge upon the other, very gently at first, so that the opposite pairs of wedges being equally tightened, they would equally resist each other, and the stone would therefore keep its place; and in this manner those wedges might be driven even more tight than there was occasion for; as the wood being dry, it would by swelling become tighter; and it was possible that by too much driving, and the swelling of the wedges, the stones might be broken; and farther, that a moderate fastening might be effectual, a couple of wedges were also, in like manner, pitched at the top of each groove, the dormant wedge, or that with the point upward, being held in the hand, while the drift wedge, or that with its point downward, was driven with a hammer; the whole of what remained above the upper surface of the stone was then cut off with a saw or chisel; and generally a couple of thin wedges were driven very moderately at the butt-end of the stone; whose tendency being to force it out of its dovetail, they would, by moderate driving, only tend to preserve the whole mass steady together; in opposition to the violent agitation that might arise from the sea.

"After a stone was thus fixed, we never, in fact, had an instance of its having been stirred by any action of the sea whatever; but, considering the unmeasured violence thereof, the farther security by trenails will not seem altogether unnecessary, when we reflect, that after a stone was thus fixed in its place by wedges, a great sea coming upon it, (often in less than half an hour) was capable of washing out all the mortar from the bed underneath it, notwithstanding every defence we could give it by plaster or otherwise; and that when the bed of mortar was destroyed, the sea acting edgewise upon the joint, would exert the same power to lift it up, that the same sea would exert to overset it, in case its broad base was turned upright to oppose it; and as the wedges only fixed and secured the several pieces of which each course consisted, to each other, and had no tendency to keep the whole course from lifting together, in case the whole should lose its mortar bed; it seemed therefore highly necessary to have some means of preventing the lifting the whole of a course together, till the solidity and continuity of the mortar should totally take away that tendency. Adverting now to what was said, that a couple of holes, to receive oak trenails of one inch and three quarters in diameter, were bored in the work-yard through the external or projecting end of every piece of stone: we must now suppose these stones set in their places, and fixed by wedges; then one of the tinners, with a jumper, began to continue the hole into the stone of the course below, and bored it to about eight or nine inches deep: but this hole was bored of a less size, by one-eighth of an inch in diameter, than the hole through the stone above; in consequence, the trenails, having been previously dressed with a plane till they would drive somewhat freely through the upper hole, would drive stiffly into the under one, and generally would become so fast as to drive no farther before their leading end got down to the bottom; and if so, they were sufficiently fast: but as they sometimes happened to drive more freely than at others, the following method was used to render them fast, for a certainty, when they got to the bottom. The leading end of every trenail was split with a saw, for about a couple of inches, and into this split was introduced a wedge, about one-eighth of an inch less in breadth than the diameter of the trenail; it was a full quarter of an inch in thickness at the head, and sharpened to an edge; when therefore the head of the wedge touched the bottom of the hole, the trenail being forcibly driven thereupon, would enter upon it, till the whole substance was jambed so fast, that the trenail would drive no farther; and as the wood would afterwards swell in the hole, and fill the little irregularities of boring by the jumper, it became so fast, that, as it seems, they could sooner be pulled in two than the trenails be drawn out again. The trenail (originally made somewhat too long) being then cut off even with the top of the stone, its upper end was wedged cross and cross. There being generally two trenails to each piece of stone, no assignable power, less than what would by main stress pull these trenails in two, could lift one of these stones from their beds when so fixed, exclusive of their natural weight, as all agitation was prevented by the lateral wedges. The stone being thus fixed, a proper quantity of the beat mortar was liquefied, and the joints having been carefully pointed up to the upper surface, the grout so prepared was run in with iron ladles, and was brought to such a consistency as to occupy every void space; and though a considerable part of this was water, yet that being absorbed by the dry stones, and the more consistent parts settled to the bottom, the vacuity being at the top, this was repeatedly refilled till all remained solid: the top was then pointed, and, when necessary, defended by a coat of plaster.

"The several courses, represented in *Plate* III. are shown as they would appear, when completed with the whole of their wedges and trenails: and besides these, there being also generally two lewis holes upon the upper surface of each stone, those served as temporary fixtures for the work of the succeeding course.

"It was the same evening's tide, of the 11th of August, that the basement was completed and the centre stone of Course VII. was landed. Of the preceding courses, each was begun by the stones that engrafted in the dovetail recesses cut in the rock; these stones, therefore, being immovable by any assignable force acting horizontally, rendered those so likewise that depended upon them; but having now brought the whole upon a level, we could not have this advantage any longer; it therefore became necessary to attain a similar advantage by artificial means. For this purpose, the upper surface of Course VI., (*Plate* III. *Figure* 6,) had a hole of one foot square cut through the stone that occupied the centre; and also eight depressions, of one foot square, sunk into that course six inches deep, which were disposed at regular distances round the centre: these cavities were for the reception of eight cubes of marble, in masonry called joggles. As a preparation for setting the centre stone of Course VII., a parallelopiped (which, for shortness sake, I will call the plug) of strong hard marble from the rocks near Plymouth, of one foot square and twenty-two inches in length, was set with mortar in the central cavity, and therein firmly fixed with thin wedges. Course VI. being thirteen inches in height, this marble plug, which reached through, would rise nine inches above it; upon this, the centre stone (see *Plate* IV. *Course* VII.) having a hole through its centre of a foot square, was introduced upon the prominence of the plug, and, being bedded in mortar, was in like manner wedged (with wedges on each side of the plug) and every remaining cavity filled with grout. By this means, no force of the sea, acting horizontally upon the centre stone, less than what was capable of cutting the marble plug in two, was able to move it from its place: and to prevent the stone more effectually from being lifted, in case its bed of mortar happened to be destroyed, it was fixed down in the manner above described, by four trenails; which being placed near to the corners of the large square of that stone, they not only effectually prevented the stone from lifting, but aided the centre plug in preventing the stone from moving angularly, or twisting, which it might otherwise have done, notwithstanding its weight, which was two tons nearly.

"After setting the first centre stone of Course VII. we immediately proceeded to set the four stones that surround it, and which were united thereto, by four dovetails, projecting from the four sides of the centre stone. These stones being fixed in their dovetails by a pair of wedges on each side at bottom and top, as has already been mentioned, and held down by a couple of trenails to each surrounding stone, and still farther steadied by joint wedges at the head of the dovetails, and also in the mitre, or diagonal joints between each surrounding piece; the whole formed a circular kind of stone of ten feet diameter, and above seven tons weight: and which being held down by a centre plug and twelve trenails, became in effect one single stone; whose circumference was sufficient to admit of eight dovetail recesses to be formed therein, so as to be capable of retaining in their places a circle of eight pieces of stone, of about twelve hundred weight each, in the same manner, and upon the same principle, that the radical pieces of stono were engrafted into the dovetail recesses of the rock; and which being in like manner wedged and trenailed, we proceeded with circular tiers of stone, in the manner shown in *Plate* IV. *Figure* 1. It is, however, to be remarked, that the mode of applying the wedges and trenails being sufficiently explained in the several figures of *Plate* III. and also in *Plate* IV. *Figure* 1, to avoid a repetition of small work, the several succeeding figures simply show the general shapes and disposition of the different pieces composing a course, and other incidental larger matters wholly omitting the particular application of the wedges and trenails; yet it is to be observed, that they were everywhere equally applied, till we got to the top of the solid.

"My much esteemed master and friend, Mr. Weston, who came from London to be witness of our proceedings, arrived at Plymouth during this interval. I went off with him early on Wednesday morning, the 17th, attended by Mr. Jessop and his company, and landed upon the rock at ten: Richardson and company were then about to begin to set the fifth tier, or circle of stone, which was to contain the eight cubes before described. These cubes were so disposed upon the surface of Course VI. that the cavities cut on the under side of Course VII. to take the upper half of each cube, should constantly fall in the broad part of the stones of the fifth circle; which will appear plain by considering the dotted lines relative to Course VII. upon the surface of Course VI. (see *Plate* III. *Figure* 6.) There could consequently be no application of wedges in the upper course, to the fastening of the circle of stones, (No. 5,) upon their respective cubes: when therefore the stone respectively came upon them, we put as much mortar upon the top of the cube as would in part make good the joint between it and its cavity, but not enough quite to fill it; because, if too full, there was no ready way for the superfluous mortar to escape; but a hole, of the size of those for the trenails, being previously bored through each of these pieces, answerable to the middle of each cube; when the stone was set, wedged and trenailed, then it was very practicable, by dressing a trenail so as to become a ram-rod, to drive as much mortar down the hole as would completely fill every vacancy between the stone and its cube: insomuch that we soon perceived, that if this was attempted before the stone was completely trenailed down, it would very easily raise the stone from its bed, as might indeed be expected from the principle of hydrostatics: but, being done after such completion, it brought the whole to the most solid bearing that could be wished; and, when the cement was hardened, answered the end quite as effectually as if they had been wedged.

"It may here be very properly said, that since those cubes could be of little use in keeping the work firmly together, before the mortar was hardened; and after that had taken place, they could be of no use; because the number of one hundred and eight trenails, of which one of these courses consisted when complete, being supposed sufficient to keep it from lifting and moving out of its place; as the mortar hardened, and every additional course was an addition of its own weight upon the former, if those cubes could have been dispensed with in the first instance, they might have been so ever after. This reasoning I can very well admit to be true; yet, when we have to do with, and to endeavour to control, those powers of nature that are subject to no calculation, I trust it will be deemed prudent not to omit, in such a case, anything that can without difficulty be applied, and that would be likely to add to the security. It may farther be remarked, that as this building was intended to be a mass of stone, held together by the natural and artificial union of its parts, it would have been out of character, that, when completed, it should be beholden to certain parts of wood for its consolidation.

"I have mentioned, that I originally conceived more than one way of preventing the courses from shifting place upon one another. My first conceptions were to form a rise (or a depression) of three inches, bounded by a circle somewhat about the diameter of that in which the joggles are placed; which step, or depression, would have formed a socket, whereby the courses would have been mutually engrafted, not much different from what nature has pointed out in the basaltine columns of the Giant's Causeway; but, considering how much unnecessary trouble and intricacy would be hereby introduced, by one part of the bed of the same stone being liable to be three inches higher than the other, I judged that the end would be very sufficiently answered by the much more plain, easy, and simple method of joggles; especially as, for this purpose, the firmest and toughest kind of stone might be chosen, and the number multiplied at pleasure. One plug in the middle, of a foot square, and eight joggles of a foot cube each, of the hardest marble, disposed in the manner described, seemed to me, along with the additional strength and security arising from the trenails, as also from the infinite number of little indentures upon the surface of the courses, as well as the lewis holes, each being filled with an exuberance of mortar, which, when hard, would in effect become a steady pin; from the cohesion of the mortar as a solid, promising to be no less than that of the stone, together with the incumbent weight of every part of the building above; every joint, thus separately considered, seemed, in point of firmness, so satisfactory to my mind, that if the whole of this proved too little, it was out of my power to conceive what would be enough.

"In the morning and evening's tide of the 17th, we set the whole of the fifth tier, and consequently the whole of the eight cubes were then inlaid. The morning of the 18th we again landed, and in this morning and evening's tide, though rough, we had got set five pieces of Circle VI. and had landed the remaining three; as also one of the largest pieces of moor-stone for the east side (see *Plate* IV. *Figure* 1.) This evening's tide we worked with links, and it began to blow so fresh that we had much ado to keep them in, being obliged to make a fire of them upon the surface of the work. We were under the necessity, at last, to quit the rock with some precipitation, and were very glad to get into our yawls; things being left in the following posture: Two of the pieces, Tier 6, were simply dropped into their places, on the north-west side, while the third piece, being about a ton, and the piece of moor-stone near upon two tons, were chained together, and to the work of Course VII. that was already set; these two loose pieces being upon the top of that course, near the east side; the triangles we lashed down upon the floor of the work, as we had practised several times before. The sea became so rough in the night, that the Weston, at the transport buoy, was obliged to slip and make for a harbour. The bad weather continued to increase till the 28th, when there was a violent storm at south-west.

"The 29th, I perceived with my telescope, from the Hoa, the buss to ride safe, but could not see the shears, or indeed anything else upon the rock distinctly, except the breakers. The day following being more clear, and the sea somewhat subsided, I immediately went on board the Eddystone boat to reconnoitre. The wind being north-west, I passed the rock several times under sail, but there was no possibility of landing. I observed, that not only all the work which had been completely set was entire, but that the two stones mentioned to have been simply lowered into their places, also remained therein, and that the five hundred weight still rested upon the stone whereon it was left. The west face of the building had got so complete a coat of sea-weed, that it was only distinguishable from the rock by its form; but the shears and triangles were entirely gone; the two pieces of stone, that had been chained together and to the work, were also gone; the windlass frame broken and much damaged, and the roll gone; the fender piles and the transport buoy, however, remained in their places.

"It was the 3rd of September before the company could make a landing to do anything upon the rock; so that, since the 18th ult., there had been an interval of fifteen days, in which we had been totally interrupted by bad weather, in the very prime part of the season. However, everything having been expedited on shore, to get refitted for work, this day I went out therewith, and began to set up our new shears, windlass, &c., and with the shears got up the piece of Portland, of Circle 6, which was set, as also the others that had been left loose in their dovetails; but the tide of flood coming on, had deepened the water too much before we could try to get up the other.

"September the 5th, the seventh circle was finished and the eighth begun; and this day the wind being variable, from north-east to north-west, and very moderate, was very remarkable, as being the first time of the people having worked till they were obliged to quit the rock for refreshment: and now everything being reinstated, it was some time before we met with anything but the ordinary interruptions.

"The fineness of the season continued to favour the expediting of our works, insomuch that Course VIII., which was begun upon the 8th, was executed in five days, being entirely completed on the 13th, at the same hour. Everything went regularly on till the 20th; so that, in return for our continued interruption from the stormy weather for fifteen days, our works had an uninterrupted progression for eighteen days, when Course IX. was advanced to the fifth circle."

A series of land-swells from the south-west prevented further proceedings till the 30th September, when Course IX. was completed, "and the masons proceeded to rectify the face of the work, where it was in any degree wanting thereof, that there might be no need hereafter to disturb any part of the coat of weed, which was likely to fix upon it during the winter." This ended the operations for the year 1757.

On the 12th of May, 1758, Mr. Smeaton examined the work, and found it perfectly entire, except a small spawl, which had been washed from the rock itself; the whole did not seem to have suffered a diminution of so much as a grain of sand since the time he left it on the 1st of October of the preceding year: on the contrary, the cement, and even the grouted part, appeared to be as perfectly hard as the Portland stone itself; the whole having become one solid mass, entirely covered with the same coat of sea-weed as the rock, the top of the work excepted. This was washed so clean and white, that the lines upon it appeared more distinct than when they were in the work-yard; the cube-holes and lewis-holes, however, from their being constantly filled with water, were grown over with green weed, like the outside. The fender piles were indeed all gone, but this was a trifling disaster, as they could soon be renewed.

The tenth course was set on the 5th of July, the eleventh on the 18th, the twelfth on the 24th, the thirteenth on the 5th of August, and on the 8th of that month the fourteenth, which completed *the fundamental solid.*

From the top of this course begins that part of the building, also called the *solid,* which includes the passage from the entry door to the well-hole of the stairs as described *Plate* IV. *Figures* 2, 3, 4, from which a more adequate idea can be obtained than any words could convey.

Mr. Smeaton then proceeds to describe his method of regulating the superstructure: As "for the sake of the well-hole, we must necessarily lose our centre-stone, the four stones, which in the former courses were united to it by dovetails, were, as now prepared, to be united to each other by hook-scarf-joints, so as to compose, in effect, one stone: and as, in consequence, we had also lost our centre cubes, it became expedient, that the work might have a uniform texture and strength, that those four stones, making a complete circle for the staircase, should be provided with cubes, to prevent their being shifted by any shock applied horizontally, (see *Figure* 4,) as well as with the trenails to hinder them from lifting. By this means the principle of consolidation would be effectually preserved: but as the top of the fourteenth, or entry-door course, was twelve feet above the top of the rock, that is, twenty feet four inches above the base of the first course, the stroke of the sea must here become less violent, and therefore a less degree of resistance would be equally sufficient. And as the large cubes would too much cut the work, which was here of considerably less area; and as several cubes would be requisite for the well-hole stones, I had determined, above the entry-door course, to increase the number of cubes from eight to sixteen, and to diminish their size from twelve to six inches; but still to be of solid gray marble, and two of them to be introduced into each of the four well-hole stones.

"Upon the 9th of August, I marked out the entry and staircase; and having unloaded the Eddystone boat, which was loaded with the first pieces of Course XV., we immediately proceeded with it; and from this time were blessed with such an uninterrupted continuance of fine weather, that upon the 20th of August, Course XVIII. was completed, which reunites the building into a complete circle, by covering the passage to the staircase: the external face of the stone of that course, which makes the cover or head of the entry-door having the figures 1758, denoting the year in which this part of the work was accomplished, cut in deep characters upon it.

"On the 24th of August, the fine weather, and in consequence the works, were interrupted, Course XX. being then in hand; and it was not till the 24th of September, that, with every possible exertion, Course XXIV. was finished, which completed the solid, and composed the floor of the store-room.

"The 25th and 26th of September, Course XXV., being the first course of the superstructure, was successfully completed in its place; but, as the mode of construction now became entirely different from the former, it is necessary to give an account thereof, as also of the reasons for the change. The building was carried up solid, as high as there was any reason to suppose it exposed to the heavy stroke of the sea; that is, to thirty-five feet four inches above its base, and twenty-seven feet above the top of the rock, or common spring-tide high-water mark. At this height, as it was reduced to sixteen feet eight inches in diameter, it became necessary to make the best use of this space, and make all the room and convenience therein that was possible, consistent with the still necessary strength. The rooms being made of twelve feet four inches diameter, this would leave twenty-six inches for the thickness of the walls. These being made with single blocks in the thickness so that sixteen pieces might compose the circle, would, from its figure, compose a stout wall; yet moor-stone, as has been observed, being a tender kind of stone, in respect to the union of its component parts, any method of dovetailing the blocks together, at this thickness, appeared to me impracticable to any good purpose. What seemed to be the most effectual method of bonding the work together, was that of cramping with iron, which would confine each single piece to its neighbouring piece in the same circle: and if to this be added, that every piece should, at each end of it, lay hold of an inlaid piece, or joggle in the same nature as the cubes, then not only all the pieces in the same course would be united to each other by the cramps, but steadied from moving upon the under course by the joggles, and of consequence would be fastened at thirty-two points: for in each course there being sixteen joggle-stones, as each end of each principal piece, at its base, took hold of half a joggle, there would be thirty-two points of confinement in the circle above; that is, the joggles being made to occupy the middle of the upper bed of each block, in that situation they would cross the joints of the course above. These joggles, as well as the rest, were of sawn marble, and made eight inches long, four inches broad, and three inches thick: each end of each block, therefore, would occupy four inches in length, four in breadth, and one inch and a half in the height of each joggle; and this I judged quite sufficient to keep every course in its place, at the height that this kind of work was begun, and so as to constitute a piece of solid masonry. There was, however, another matter, that it seemed quite material also to attend to; and that was, to render the habitable rooms contained within those shells of walls, perfectly dry and comfortable in all weathers; and this seemed to merit very particular attention; for the seas that are said to rise up against, and in a manner to bury the house, in time of storm, would make effectual trial of every joint.

"The level joints being pressed together by the incumbent weight of the building, would keep firm and sound that cohesion of parts produced by the mortar; so that once being made water-tight, there was no doubt that they would so remain: but with respect to the upright joints, the least degree of shrinking, either of the stone or of the mortar between, tended to open the joint, so that it might always remain leaky, in a greater or a less degree; for we know of no degree of separation of parts, however minute, short of absolute contact, which will stop or prevent the percolation of water. For this purpose I conceived that if flat stones were introduced into each upright joint, so as to be lodged partly in one stone, and partly in its neighbour, (much upon the same idea that Dutch laths were formerly introduced into the joints of chamber floors, to hinder the passage of wet,) the water might be prevented from making its way through the upright joints of the walls.

"The manner in which it was executed was as follows: (see *Plate* IV. *Figure* 6.) At each end of each stone, answerable to the middle between the inside of the wall and the outside, was sunk a groove, two inches and a half wide and three deep, running from the top to the bottom: when, therefore, two contiguous pieces of stone were put together in their places, the two grooves being applied to each other, they would form a rhomb of six inches in length and two inches and a half in breadth, which in this state would be an unoccupied cavity from the top to the bottom of each course; the rest of the joint, where the surfaces of the two stones applied to each other, was made good with mortar in the ordinary way, and brought together by the gentle blows of a beetle. For the groove mentioned, a solid rhomb was prepared, of about two inches thick by five inches broad, and in length a little less than the depth of the cavity, which generally was eighteen or twenty inches; and for the sake of the firmness of those slender pieces of stone, I made choice of the flat paving-stones from Purbeck, which is a laminated marble of great strength and solidity. The joint-stones (which was the name we gave those rhombs) thus prepared, would readily go down the cavities; but, to fix them solid, a quantity of well-tempered mortar was prepared, made more soft than ordinary, by the addition of a little water; a competent quantity being put down to the bottom of the hole, the joint-stone was put down upon it, and, by the simple pressure of the hand, was forced down to the bottom, causing the semifluid mortar to rise up to the top, and completely fill the cavity; and, when forced down in the way described, having in this state a small quantity of superfluous moisture about it, a few very gentle blows, or raps, were given upon the top of it by the handle of a mason's trowel, which producing a small degree of agitation, while the dry stones were absorbing the moisture, contributed (like the beating of mortar) to bring all the parts into their most friendly state of contact, and, in consequence, to their firmest state of union; and this happened in the course of a few minutes, so that no farther agitation could be of any service.

"As the cramps, that were to bind the contiguous pieces together, must cross the joints upon their upper surface, they were of course to be applied after the joint-stones were settled in their places. Precaution was therefore necessary not to apply too much exertion in forcing down the joint-stones: for, however gentle the operation may appear, according as it has been described, yet it was found advisable not to put in the joint stones till an additional piece had been got down upon its joggles, and plain-jointed at each side of the two pieces, whose joint-stone was to be put in; for, by this means, they were the united efforts of all the joggles, and adhesion of the beds of two stones on each side of that where the effort was applied. Without any attention to this, the lateral force arising from merely pressing down a joint-stone was capable of breaking the adhesion of the joint where it was applied.

"The cramping was applied the last thing. The top or flat bars of the cramps were about thirteen inches long, two inches broad, and five-eighths of an inch thick, and were turned down at each end about three inches in length; forming a cylinder of one and one-eighth of an inch in diameter. Jumper-holes were previously bored when upon the platform, and the cramps fitted to their places; the surface of the stone under each cramp being sunk three-fourths of an inch, so that the two stones together would completely receive, or rather bury, the cramps: the joint-stones, as said above, being made so much shorter than the height of the course, as not to interrupt the bedding of the cramp. The places for the cramps being properly fitted and cleared, (as we now were not liable to be driven off the work in a moment, as had formerly been the case,) we took the opportunity, whenever time allowed it, of fixing the cramps of a whole course together. There was no danger of the cramps not fitting; as, besides that all the cramps were forged to fit a guage-bar having a couple of holes at the assigned distance, they were also fitted and marked to their particular places at Mill Bay, while upon the platform. Every cramp being now ultimately tried to its place, it was then put into a kettle of lead, made red hot; and the cramp continued there till it was also reddish. About a spoonful of oil was poured into the two cramp-holes, and the cramp being put into its place, the ebullition of the oil caused by the heat of the iron quickly gave a complete oily surface, not only to the whole cramp, but to the whole unoccupied cavity in the stone; then the hot lead being poured upon it, the unctuous matter caused the metal to run into and occupy the most minute cavity unfilled, and completely to cover each cramp; and they became by this means defended from the salts of the sea, even had they remained uncovered, upon Mr. Rudyerd's principle. Mr. Rudyerd had used coarse pewter. The lead we used was slag lead, which is harder and stiffer than fine lead: and, as we used no cramps, as an essential part of the building, till above the store-room floor, I judged pewter, merely for the sake of stiffness, there to be unnecessary. By cramping, in general, a whole course together, the contraction of the iron in cooling would greatly add to the tightness wherewith every stone was bound to its fellow. Thus according to this mode of fixing, (besides the union of the parts by the mortar itself,) to resist all violence and derangement whilst it was doing, and before the induration of the mortar, every course was retained in its place by sixteen joggles, and each single stone by two half-joggles at its lower bed; they were farther steadied to each other by the joint-stones, and lastly by the cramps, which completely prevented a separation; and this method proved so effectual, that we were not only free from all derangement of the stones when in their places, but I did not find a leaky joint, except one, in the whole building. By a due consideration of *Plate* IV., with the particular references to it, the whole of this process will become perfectly intelligible.

"On Saturday, the 30th of September, Course XXVIII. was completely set; and, being the first course upon which was rested the vaulted floor, which made the ceiling of the store-room and floor of the upper store-room; and, as here again occurred a difference in the mode of fixture, in this, as in all like cases, I attended the performance of the work: and that was the leading-in of the first circular chain, that was lodged in a groove cut round the middle of the upper surface of this course, which this day was satisfactorily performed; and the next day, Sunday, October the 1st, Course XXIX. was set, and its circular chain leaded-in also; which operation, with the reason thereof, it will be proper here to describe: The ordinary way of fixing the several courses by joggles and joint-stones, and also the bonding them together by cramps, has already been described; but those courses, upon which the floors rested and depended, seemed to demand every possible security. It will be seen, in the general section, *Plate* II. that each floor designedly rested upon two courses: it will also appear, by inspection, that the circumference of the floors was not made to rest upon the sloping abutments of an arch, in lines tending toward the centre of the sphere, of which the under side of the floor was a portion, but it rested upon a triple ledge going circularly round the two supporting courses. In consequence of this, had each floor been composed of a single stone, this lying upon the horizontal bearings furnished by these ledges, would, while it remained entire, have no lateral pressure or tendency to thrust out the sides of the encompassing walls: and that in effect, the several pieces, of which the floors were really composed, might have the same property as whole stones, the centre-stone was made large enough to admit of an opening, from floor to floor, or man-hole, to be made through it; and being furnished with dovetails on its four sides like those of the entire solid, it became the means by which all the stones in each floor were connected together; and consequently, the whole would lie upon the ledges like a single stone, without any tendency to spread the walls. But if, by the accident of a heavy body falling, or otherwise, any of those stones should be broken, though this might not destroy its use as a floor, or its properties as an arch; yet the parts would then exert their lateral pressure against the walls: and therefore, as a security against this, it became necessary that the circle of the enclosing walls should be bound together, and the building, as it were, hooped.

"This would be in a great measure brought about by the cramps tying the neighbouring stones together, as already described, for the ordinary courses; but yet this was no absolute security, because the outside stones might break and separate, between cramp and cramp: and I suppose, it was for reasons of this kind, that Sir Christopher Wren, in the construction of the cupola of St. Paul's, did not choose to depend upon cramping the stones together, of the course that served as a common base to the inside dome, and the cone for supporting the lantern; but chose to surround the whole with continued chains of iron. Upon this principle, an endless chain was provided for each of the two floor courses; see *Plate* IV. *Figure* 7. The bars composing the links being one inch and a quarter square, that the most iron might be included in a given space, the corners only were a little canted off; and the double parts being brought near together, the whole was comprehended in a groove, of somewhat less than four inches wide, and as much in depth; into which the chains being introduced and brought to a stretch, the rest of the cavity was filled with lead, of which each took about eleven hundred weight, in the following method. The chains were oiled all over before they came from the shore; and the circumference of the groove was divided into four parts by stops, or dams of clay, to prevent the lead from flowing farther than one quarter at a time. A couple of iron kettles were provided, capable of melting commodiously, when full, six hundred weight of lead each; and that quantity was brought in each to a full red; that is, somewhat hotter than we used for the cramps, as the iron of the chain, as well as the stone, were cold. The whole quantity of lead being brought to a heat that we judged proper, and the quarter-groove being supplied with oil sufficient to besmear the whole surface, two persons, with each a ladle, as briskly as they could, poured the melted metal into the same quarter of the groove; and, as soon as it was full, and the lead began to set, one of the clay dams was removed, and the melted hot metal was poured upon the end of the former mass, till it was perceived to re-melt and unite with the fresh metal. This done, the dam at the other end of the first-run mass was taken down, to prevent its cooling more than was necessary, and the third quarter was treated like the former; the end of the mass rendered solid by cooling, being re-melted by the fresh hot metal: lastly, both the remaining dams being taken down, and the metal at each end having a considerable heat, it was found practicable to dissolve both the ends of the former masses: first applying both ladles to that which had had the greater time to cool, and afterwards to the less: by this means the whole was brought to a solid consistence, and the chain entirely buried in the lead. It is, however, to be remarked, that to preserve proper impressions in the lead, for the joggles of the course above, those impressions were made by confining down bricks in proper places, which, when removed, the proper marble joggles were set with mortar in their places.

"Monday, October 2, we proceeded to set up the centre, composed of sixteen ribs, (see *Plate* VIII. *Figure* 3.) for putting the floor together upon; but the weather continued broken till Saturday, the 7th, on which day the Eddystone boat came out, having on board the roof, or platform, for covering the building, and protecting it from the entrance of the downfall spray; together with the doors, iron work, and timber for fitting up the same for habitation. This afternoon we landed, and went on with the setting of the outward circle of floor-stones, made the holes in the wall for fixing the hinges of the entry and store-room doors. In particular, I caused the middle stone to be laid upon the centre, by way of weight, to keep it steady. Three of the four stones that were to connect with the centre-stone were laid upon the top of the wall, on the north-east side: and the fourth I caused to be hoisted and suspended upon the triangle, in the posture that is shown *Plate* VI. at stage second. So that the triangle, which was all of it completely within the area of the top of the building, would be kept down by the weight of this stone, which was between seven and eight hundred weight. The other three that lay upon the wall, I caused to be carefully drawn within the circumference thereof, so that there might not be the least projecting part for the water to strike against in flying upwards; which I judged quite necessary, though the walls were then upwards of forty-three feet above the foundation-stone, and near thirty-five feet above the top of the rock."

The weather now set in so bad, that no farther operations of consequence took place that season. On the 10th of October, Mr. Smeaton was mortified with a copy of a resolution of the Trinity-Board, declining his proposal of exhibiting a light that winter upon the foundation of the building.

"During my stay in London, in the early part of the year 1759, I received regular accounts of the proceedings at Mill Bay, which were carried on with all the dispatch I could wish; but the weather having continued unfavourable to visiting the works at the Eddystone during the winter, I got no report thereon till I received Mr. Jessop's letter, dated the 27th of March, wherein he informed me that on the 21st of that month, being the first opportunity he could catch after the violent storm which had happened on the 9th preceding, they found not only the solid, but the hollow work perfectly sound and firm; all the mortar having become quite hard; and, in short, every part of the work in the situation in which it was left by the workmen in October: the only derangement was, that the sea had carried away the south fender pile from the rock; and also, from the top of the wall, one of the three stones that I had taken care to draw within the verge of the circumference of the wall, as mentioned. They had found the fourteen pieces of stone set in the circumference of the floor, stuck quite firm to the wall, though two of the pieces requisite to complete the circle were left unset; and that, finding the centre itself quite tight and firm underneath them, they had lowered down the stone suspended on the triangle upon it, and removed from tho wall the other two remaining stones to lie upon the centre; and lastly, that they took down the triangle, and stowed it away in the well-hole for the stairs: but, on farther search, nothing of the buoy that was left upon the mooring chains was to be seen.

"Thursday, the 5th of July, I landed on the rock with the men; they proceeded to set up the shears and windlass, while I inspected the work; and found everything perfectly sound and firm, without the least perceivable alteration since we left it; except that the cement used the first year, now in appearance approached the hardness of the moor-stone; and that used the last year, of the full hardness of Portland. We now proceeded to set the floor. The two remaining pieces of the outmost circle, which were left uncompleted last year, were soon set; and we proceeded to haul up the stones for the next circle (No 4.) from the store-room.

The work now proceeded so rapidly, that the second and third stories were completed in thirteen days. On the 8th of August, Course XLV. or the Cove Course, was completed with its two chains; and the next day, the elliptical centre for the balcony floor was set; and by the 16th, the interior area of the balcony floor was completed, the centre was struck, and the outer circle of stones which finished the cap of the main column, being parts of the corona, or cornice, was begun upon. *See Plate* II. and *Plate* IV. *Figure* 9.

"Friday, August the 17th, the last pieces of the corona were set, and therewith the main column was completed. I now examined the perpendicularity of the whole building, by letting fall a plumb line from the centre of the man-hole in the balcony floor to the centre of the bottom of the well-hole, being forty-nine feet and a half; and found it to fall a small matter to the eastward of the centre of the well-hole; as near as I could determine it, not more than one-eighth of an inch. I then measured the perpendicular heights of the several parts of the building, and found them as follows:

	Ft.	In.
"The six foundation courses to the top of the rock	8	$4\frac{3}{4}$
"The eight courses to the entry door	12	$0\frac{1}{2}$
"The ten courses of the well-hole to the store-room floor	15	$2\frac{1}{4}$
"The height of the four rooms to the balcony floor	34	$4\frac{1}{2}$
"Height of the main column, containing forty-six courses	70	0

"We proceeded this day to set up and lead-in the balcony rails, and completed them; and having brought out a temporary cover for the man-hole of the balcony floor, I this day applied it to use, as follows: a short tub, of about a foot high, was made without a bottom, and the smaller end of it being sized as near as possible to the man-holes of the floors, it was driven into that of the balcony; and, by the time it was driven about four inches, the compliancy of the wood to the stone rendered it quite tight; then the rest of its height, forming a border, and standing about eight inches above the floor, would prevent water from dripping into the rooms through the upper man-hole, or hatchway; and having also provided another tub, about nine inches deep, having a strong bottom in it, and so much more in diameter than the other, that it would, when inverted, cover it; this being applied as a cover, would in the greatest stress of weather defend the building from the entry of water at the top."

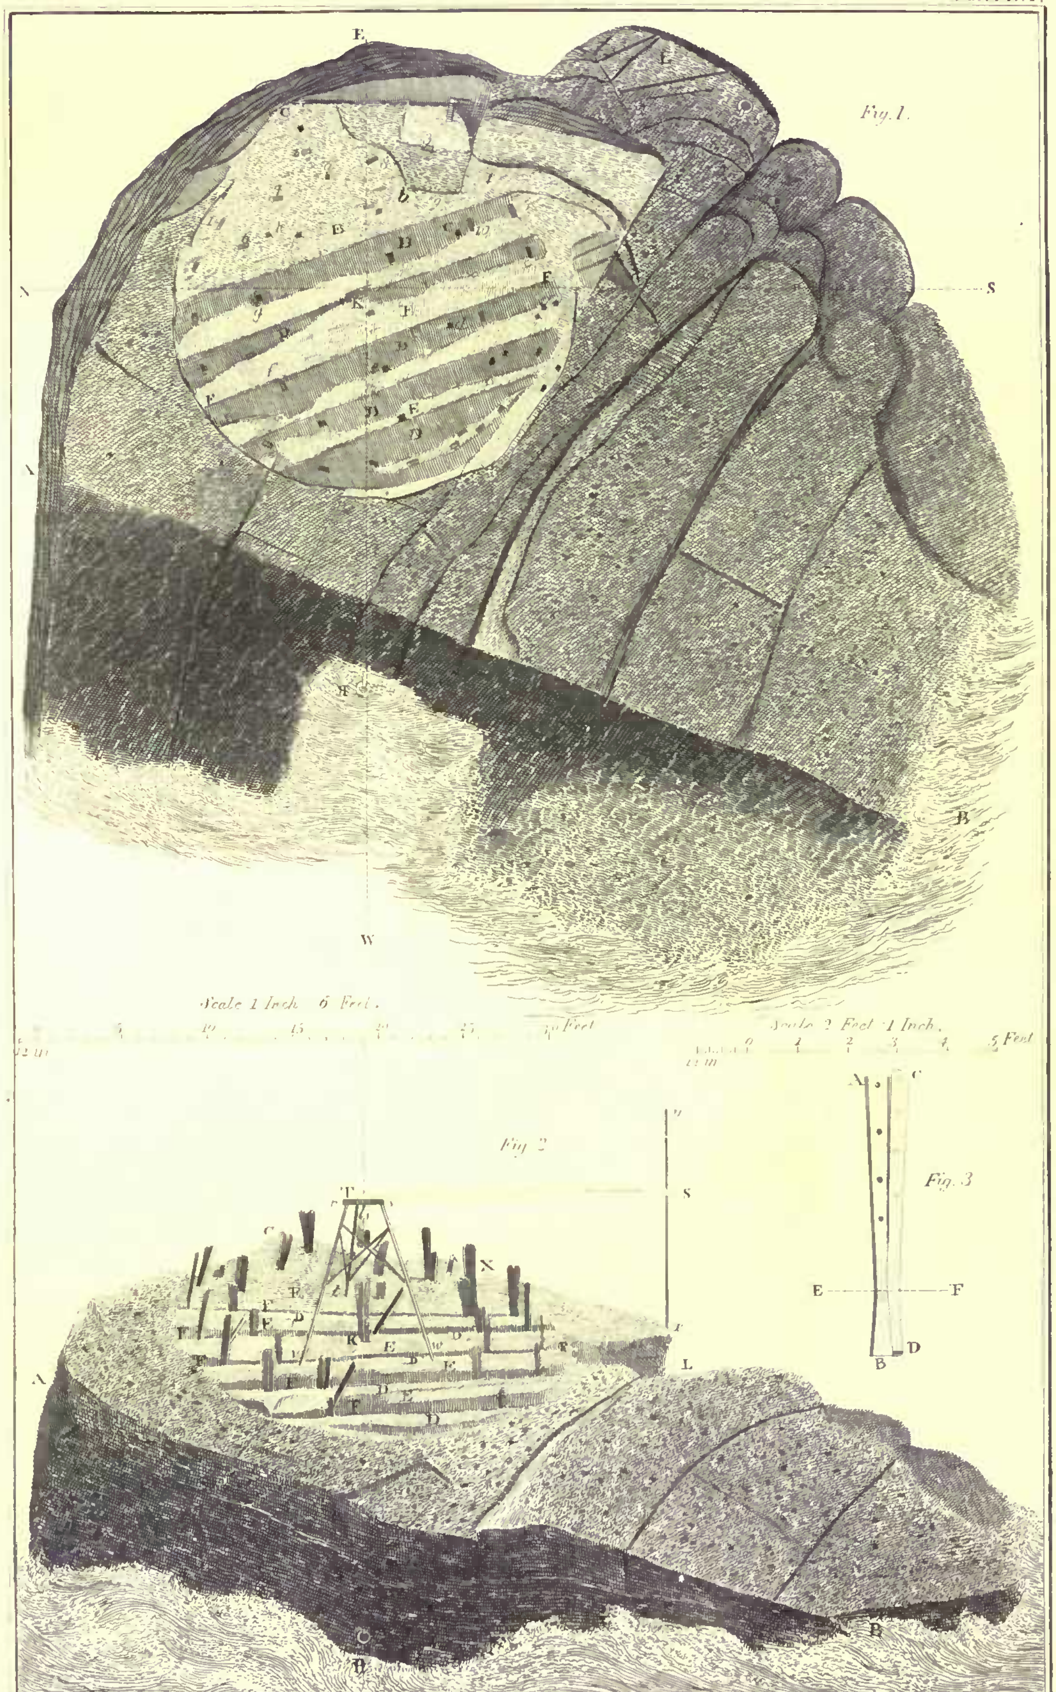
On the 18th of the same month, the first course of the lantern was begun; on the 24th, the last stone, being that which makes the door-head of the lantern, was set; and on Sunday evening, the 26th, the whole of the masonry was completed.

Stress of weather prevented the landing of the frame-work till Saturday, the 15th of September; on which day, "between three and four in the morning, the Weston was got into the gut, and delivered of her cargo, consisting of the pillars, sashes, and frame-work of the lantern. I gave my principal attention to the establishing the frame of the lantern upon a bed of lead, and the screwing of it carefully together; seeing that every joint was filled, and screw covered with white-lead and oil, ground up thick for paint; and every crevice so full that the bringing the screws home made the white-lead matter to ooze from every juncture; thereby to exclude all wet and moisture, and so as to prevent the iron-work from rusting.

"Sunday, September the 16th, was remarkably fine; so that by the evening the whole frame of the lantern was screwed together, and its groundsill was rested upon a bed of lead; which was done in the following manner: The whole frame being screwed together, was raised from its bearing upon the stone about three eighths of an inch, by a competent number of iron wedges; and adjusted by them to an exact perpendicular. Both the stone and the iron were taken care to be oiled before they were applied to each other; and one of the eight sides, having its wedges withdrawn, was run with hot lead; and making a place for it to overflow, as much could be used as would competently heat both the iron and stone, to bring them to a close bearing with the lead; then on the lead's cooling, as the frame became supported on one side by the lead, the wedges of a second side were withdrawn, and treated in the same manner, and so successively till the whole rested upon a solid basement of lead. It was not supposed that the succeeding mass could be sufficiently heated to re-melt the ends of the parts already leaded, as in the case of the chains: but being heated so as to bring them to a close contact, this I judged sufficient, as the lead so applied had no other intent but to bear weight, and give the frame of the lantern one solid uniform bearing.

"Monday, the 17th. This morning was also exceedingly fine; and the Weston being in sight, which was appointed to bring out the cupola, we began to set up our shears and tackle for hoisting it. This perhaps may be accounted one of the most difficult and hazardous operations of the whole undertaking; not so much on account of its weight, being only about eleven hundred, as on account of the great height to which it was to be hoisted, clear of the building; and so as, if possible, to avoid such blows as might bruise it. It was also required to be hoisted to a considerable height above the balcony floor; which, though the largest base we had for the shears to stand upon, was yet but fourteen feet within the rails; and therefore narrow, in proportion to their height. The manner in which this was managed, will, in a great measure, appear by the representation thereof, in *Plate* VI. (see the uppermost stage); but is more minutely explained in the technical detail of that Plate. As the legs of the shears that had been used upon the rock would have been in the way of the cupola they were now removed, as being done with there, and were used as a part of this machinery. About noon the whole of our tackle was in readiness; and in the afternoon the Weston was brought into the gut; and in less than half an hour her troublesome cargo was placed upon the top of the lantern, without the least damage.

"Tuesday, September the 18th, in the morning, the wind was at south-east, with intervals of thick fog; however,



Drawn by M. A. Nicholson.

Eng[d] by R. Thew

between those I had the satisfaction, with my telescope, to perceive the Eddystone boat, on board of which I expected the ball to be. The wind and tide were both unfavourable to the vessel's getting soon near us; therefore being desirous to get the ball screwed on, before the shears and tackle were taken down, one of the yawls was dispatched to bring it away. This being done, and the ball fixed, the shears and tackle were taken down. By this time the joiners had set up and completed the three cabin bedsteads, (for their plan and position between the windows, see *Plate* IV. *Figure* 8.)

"On Friday, the 21st, all the copper sash-frames were got completely fixed in, and ready for receiving the glass.

"On Sunday Morning, the 23d, the yawl landed two glaziers and a coppersmith, with their utensils and materials; the former began to glaze the lantern, and the latter to fit and put up the funnels. This day, with my assistant, the mason, I began to fix twenty-four iron cramps; that is three to each rib of the roof, and which were obliged to be fixed after the roof was together; and being fixed inside, and surrounding the ribs, served to key home the plates of the cupola to the ribs. For this purpose small wood wedges were used, as being more supple, elastic, and compliant, than wedges of metal, and therefore more suitable to this particular purpose. This day also the Eddystone boat brought out and landed a plumber, with his utensils and materials. The most considerable work for the plumber was the covering the whole balcony floor with thick plates of lead; and which extended from the top of the plinth, or first course of the basement of the lantern, quite down to the drip of the corona. They were fitted on separately, in sixteen pieces, and soldered together, in place, with strong ribbed joints; and, to prevent the sea from laying hold of them at the drip, and beating them up, they were turned under about one inch and a half; and being near half an inch thick, I judged them sufficiently stubborn to prevent being unripped.

"Thursday the 27th, the lead-work upon the balcony and corona being now entirely finished, and the cupola completely keyed home to the ribs; the straps and bolts were applied at each angle of the lantern, for screwing it down to the floor of the balcony.

"Friday, September the 30th, the joiners finished their work, which consisted of the following articles. Three cabin beds, to hold one man each, with three drawers and two lockers in each, to hold his separate property, which were fixed in the upper room, or chamber. (See plan thereof, *Plate* IV., *Figure* 8.) In the kitchen, besides the fire-place and sink, were two settles with lockers, a dresser with drawers, two cupboards, and one platter case. (*Figure* 7, of the same *Plate*, shows how these were disposed.) In the lantern a seat was fixed, to encompass it all round, the doorway excepted, serving equally to sit upon, or stand to snuff the candles; and to enable a person to look through the lowest tier of glass panes at distant objects, without having occasion to go on the outside of the lantern into the balcony. Besides the above, the joiners had fixed the ten window-frames, with their sashes; all which were bedded in putty, and falling into rebates cut for them in the original formation of the stone, they could be at any time removed, and replaced at pleasure, as they were fastened in only with wooden pins, driven into holes bored in the stone."

On Michaelmas-day, the glazing of the lantern was completed; on the 1st of October, the copper funnel was finished and tried by lighting a fire in the stove.

"The tackle was also fixed for raising and lowering the chandeliers; and those being hung, there was now nothing to hinder our making trial by lighting the candles, while it was daylight, to see that everything, regarding the light, operated in a proper manner. Accordingly, this afternoon, we put up twenty-four candles into their proper places, and continued them burning for three hours; during which time we had a very effectual trial; for it had blown a hard gale of wind at south-east all day, which still continued; and, keeping a fire at the same time in the kitchen, they both operated together without the least interference; not any degree of smoke appearing in the lantern, or any of the rooms: and, by opening the vent-holes at the bottom of the lantern, it could be kept as cool as we pleased; whereas, in the late lighthouse, this used to be complained of, as being so hot, especially in summer, as to give much trouble by the running of the candles.

"Wednesday, October the 3d, we began to fix the conductor for lightning. As the copper funnel reached through the ball, and from thence came down to the kitchen floor, above forty feet, (see *Plate* II.) I considered this as containing so much metal, that, if struck with lightning, it would thus far be sufficient conveyance; then joining the kitchen grate to the leaden sink, by a metal conveyance, the sink pipe of lead would convey it to the outside. From the sink pipe downwards, which being on the north-east side, was consequently the least subject to the stroke of the sea, we continued the electrical communication by means of a strap of lead, about one inch and a half broad and three-eighths thick, fixed on the outside by being nailed to oaken plugs, driven into two jumper-holes in the solid of each course; the prominent angles of the strap being chamfered off, it was bedded and brought to a smooth surface with putty. At the foot of the leaden strap, an eye-bolt of iron was driven into the rock; and to this was fixed an iron chain, long enough to reach at all times into the water; its lower end being left loose to play therein, and give way to the stroke of the waves: by this means an electrical communication was made from the top of the ball to the sea."

Everything being now completed, notice was sent to the Trinity House, and, on Tuesday evening, the 16th of October, 1759, the lights were first exhibited, amidst the fury of a violent storm.

This excellent building exhibited no other light than what was produced by twenty-four candles, which was not always sufficient, till 1809, when Mr. Robinson, surveyor of lighthouses to the corporation of the Trinity House, superseded these candles by the same number of Argand lamps, each accurately fixed in the focus of a large parabolic reflector of richly plated copper, arranged on circular frames; and consequently giving light in every direction. The improved brightness of the light, by this exchange, exceeded the most sanguine expectation of all in the neighbourhood of Plymouth.

TECHNICAL REFERENCES TO THE PLATES.

"*Plate* I.—*A plan and perspective elevation of the Eddystone Rock, as seen from the west; showing also the theodolite.*

"The representation is as I found the rock; *Figure* 1 being the plan, and *Figure* 2 the upright view. The same letters refer to the same parts in both; the cross lines upon the plan answer to the cardinal points, east, west, north, and south, according to the true meridian.

"L is the landing-place, and C the summit of the rock; the general declivity being towards the south-west; the grain of the laminated moor-stone that composes it being nearly parallel thereto. It has, however, considerable irregularities; for upon the line A B the rock makes a sudden drop of four and a half or five feet; and, by overhanging to the westward, when there is a ground-swell at south-west, the sudden check causes the sea to fly in an astonishing manner, even in moderate weather.

"The surface of the rock is shown, as supposed to have been for ages past; except where it is visibly altered by man's hand, chiefly within the circular area of the late building. The flat treads of the steps cut by Rudyerd are marked D; the upright faces of the steps F; and E denotes the spawled parts, parallel to the grain of the rock.

"*a b c d e f g h* show the remains of the cavities of eight of the twelve great irons fixed by Winstanley; of which the stump of one only, viz., that at *e*, remained for my inspection; it was run in with lead, and had continued fast, till in planting a dovetail there it was cut out, and found club-ended. Which of the other holes, that are left unmarked, made up the remaining four, I could not make out; as doubtless several of them appertained to the additional work that he fixed in the fourth year.

"*Figure* 3. A pair of Rudyerd's iron branches, to a scale three times larger than that of the plan; wherein A B is the main branch, or dovetail part; C D the key, driven hard in, but without touching the bottom; their depth in the rock is denoted by supposing the line E F its surface. The holes in the branches served to fasten the timbers, by large bearded spike-bolts. Of those branches I traced thirty-six original pairs, of different sizes; and two more modern: their places are shown in the upright, *Figure* 2, by inspection; and likewise in the plan, *Figure* 1, at 1, 2, 3, 4, 5, and 6, 7, 8, 9, 10, &c. forming a double circle; also two pair of them at K, to fix the mast, on two sides, to the centre. The irons that remained in the rock, are distinguished in the plan by being hatched with slant lines, the empty holes or cavities by being black. Those that remained whole, whether fast or loose, are distinguished in *Figure* 2, by their shapes.

"X. The place of the cave on the east side.

"R. A strong ring-bolt, put into the rock on the recommencement of the building in 1757, for fastening the western guy-chain of the shears.

"*Figure* 2, *r s t v w*. The three-legged stool, steadied with cross-braces. Upon the middle of the upper round plank *r s* was screwed down the theodolite T, to whose index was screwed the long horizontal rule T S, divided into feet, inches, and parts, upon one edge, tending to the centre. Upon any marked point of the rock to be ascertained, suppose *x*, the rod *x y* was set upright by a spirit-level, and was preserved in an upright position by two small slips of deal, applied as shores or struts, in two different directions. The divided edge of the rule being brought against the upright rod, was shoved up by a short staff, held in the hand tight against the rod, till a spirit-level laid upon the top of the rule showed it to be level. In this position the index would show the degree and minute of the circle; the upright rod would mark the distance from the centre upon the rule; and the rule would mark upon the rod, how much the intersection was above its bottom at *x*.

"*Plate* II. No 1.—*South elevation of the stone lighthouse completed upon the Eddystone in* 1759.

"A. The landing-place.

"B. The cave in the east side of the rock.

"C. The steps cut to mount the rock to the entry-door.

"D. An iron rod, serving as a rail to hold by, in passing to the foot of the ladder, occasionally put out from the entry-door at E.

"No. 2.—*Section of the Eddystone lighthouse upon the east and west line, as relative to* No. 1, *supposing it the low-water of a spring-tide.*

"In the section of the rock, A B shows the upright face or drop, marked with the same letters as No. 1, and the line B C shows the general direction of the grain and slope of the rock to the south-westward.

"The dotted line *a b* shows the level of the base of the first stone. The black line *c d* is the base of the stone in the first course that is intersected by the east and west line; and *e f* 1 is the level of the top of the first course, and bed of the second; 2, 3, 4, 5, and 6, mark relatively the tops of the six courses that bring the artificial part of the foundation upon a level with the reduced top of the natural rock; *e* 6 *f*, being the first entire course, marked VII. as being the seventh above the ground-joint.

"*f*. The foot of the temporary ladder; and there is shown the manner in which the ground-joint of the stone-work was sunk into the rock, all round, at least three inches.

"*h*. The first marble plug, or central joggle, that went through the sixth course, and reached half-way through the seventh; and so in succession to the top of Course XIV.

"*i k*. The place of the marble cubic joggles inlaid between each two courses, which were in an octagon disposition round the centre.

"*l*. Smaller cubes between the fifth and sixth course.

"Course XIV. terminates the entire solid; as upon it is pitched the entry and well-hole for the stairs. The temporary ladder, *f g*, to the entry-door D, is only put out when wanted; and then is lashed by eye-bolts to the stone; at other times, having a joint in the middle, it folds, and is laid along in the entry.

"Above the top of the entire solid, the centre stone being omitted to give space for the well, the cubic joggles were of double the number, and half the size. Course XXIV. terminated that part of the building called *the solid:* and here the habitable of the building began, whereof E is the lower store-room.

"F. The store-room door.

"G. The upper store-room.

"H. The kitchen.

"I. The fire-place, from which the smoke ascends through the floors and lantern, through a copper funnel, and through the ball.

"K. The bed-room.

"L. The stone-basement of the lantern.

"M. The lantern door into the balcony.

"N. The cupola.

"The ascent from room to room is by the perforations through the middle or key-stone of every floor; and the detached figures show the means, by inclined step-ladders, removable at pleasure.

"*Plate* III.—*Plans of the rock after being cut, and prepared to receive the stone-building. Showing the six foundation courses.*

"*Figure* 1. Plan of the rock, as prepared for the stone-work, somewhat extended, to show how it applies to *Plate* I. The line A B shows also here the place where the surface drops, as specified, *Plate* II. No. 2.

"In this figure, Course I. appears in its place, as fixed with its trenails and wedges. The part darker shaded, and marked D D, was not reduced to a dovetail on account of fissures, but was sunk two inches lower than the rest of Course II. The stones laid therein would therefore be encompassed by a border, and held fast in every direction. The letters E. W. N. S. in all the figures, denote the cardinal points; the same letters, in every figure, denoting the same parts.

"The part of the rock marked C, rises above the rest by an ascent, or step, of fifteen to eighteen inches, according to the line D F G E; which, lying somewhat without the general contour of the building, and affording a firm abutment, the advantage was taken; and the work of the first and second course carried against it, as shown at G.

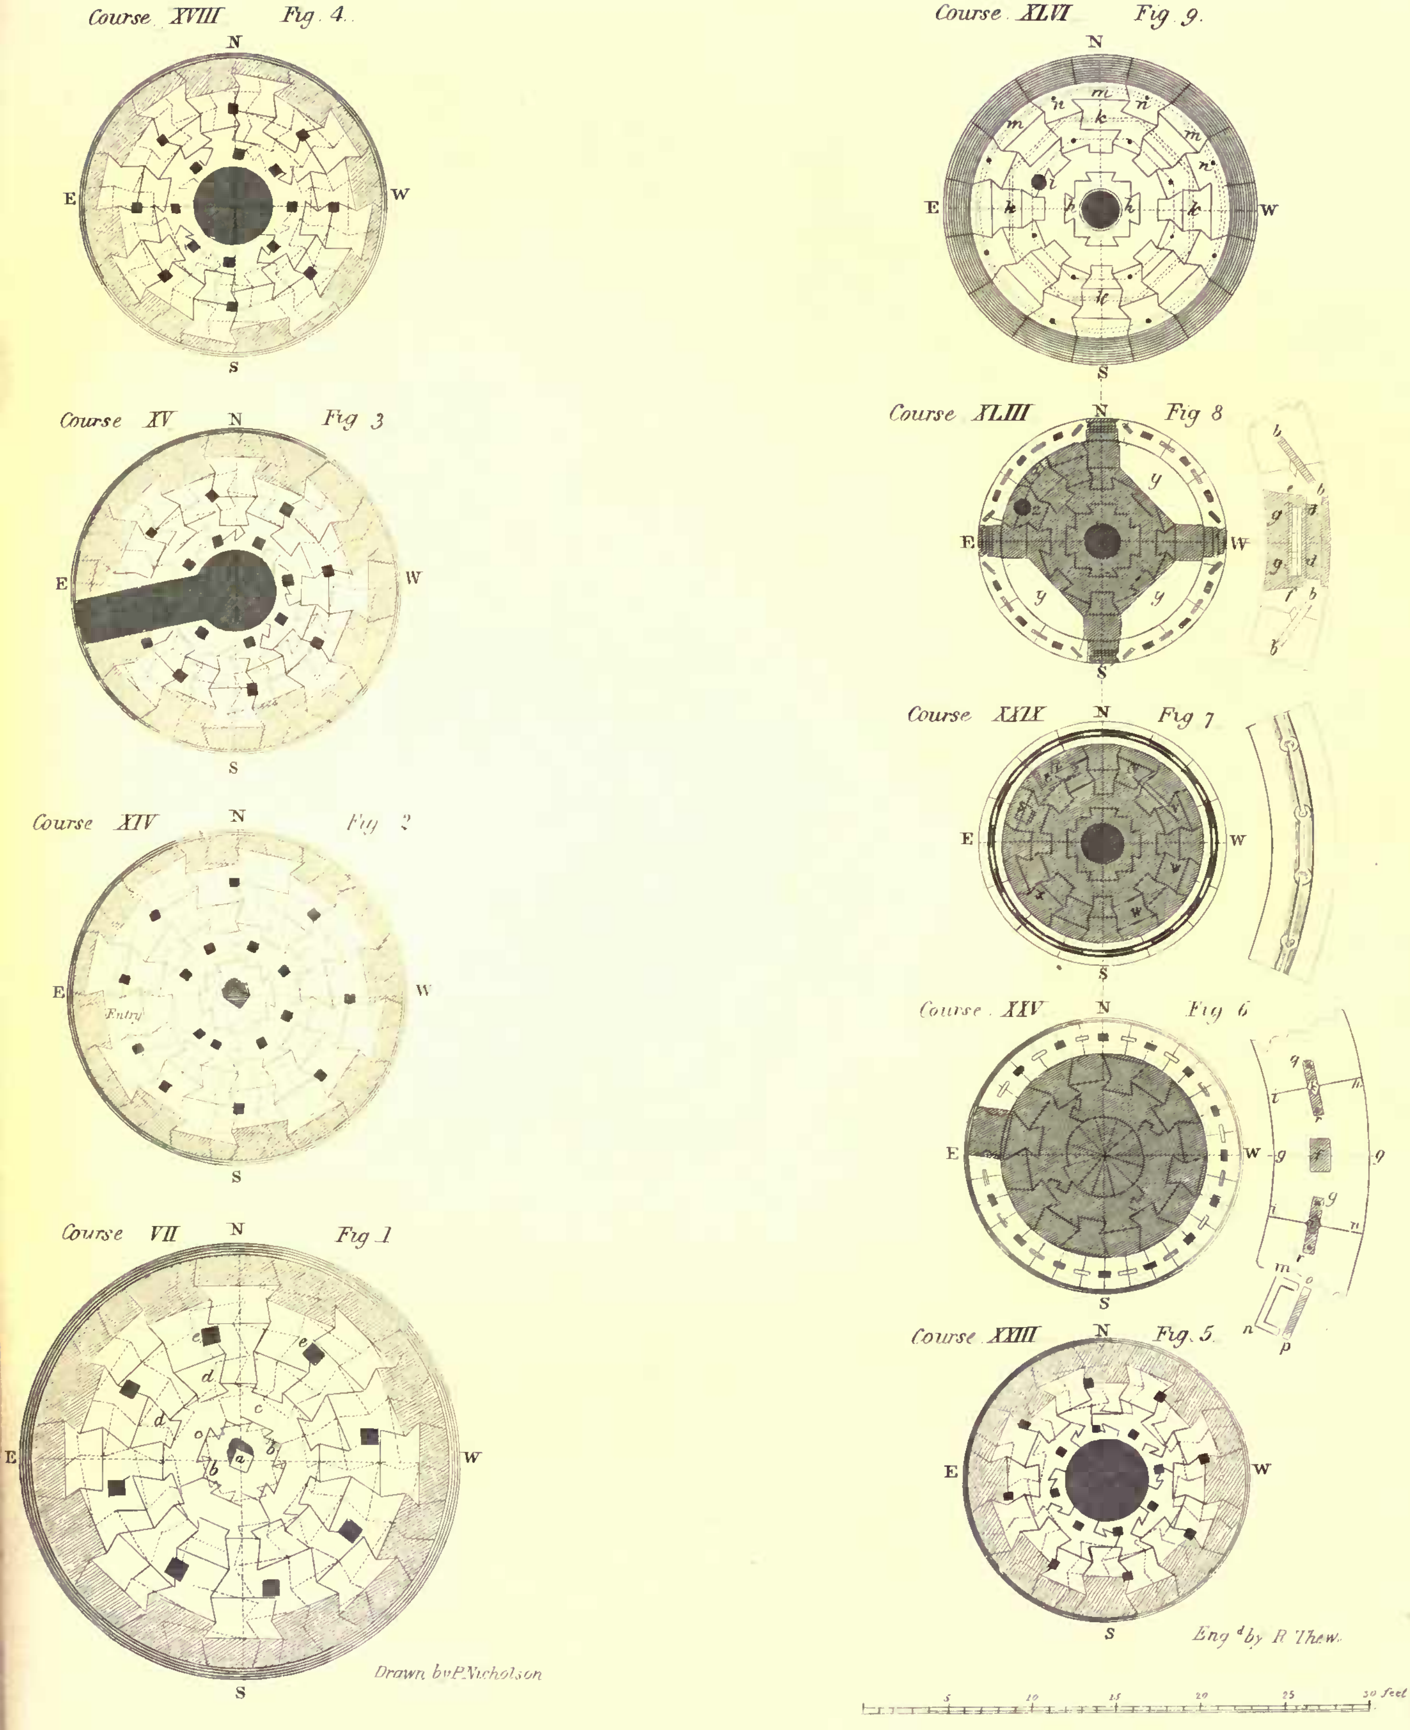
LIGHTHOUSE.

PLATE IV.



"1, 2, 3, 4, 5, and 6. The level platforms, or steps, for the different courses, whose upper sides are even with these numbers in *Plate* II. No. 2 being upon the level of Rudyerd's lowest step.

"x. A piece of stone engrafted into the rock, serving as a bridge to cross a chasm, opened by cutting down the top of the rock to that level, into the cave. Of this stone is formed a part of the border that encircles the work.

Figure 2 shows how the buttress, o, was terminated in the second course. It also shows the places of the trenails and wedges; which in all these figures are shown in the same manner. The dotted lines everywhere refer to the course that is to come on; and shows how it will break joint upon the course supposed laid.

"*Figure* 3 shows how the space H I K, in *Figure* 2, is filled up in *Figure* 3, being confined in by the rise of the step L at H I, and the cramps *a b;* the ground proving here irregularly shattered by cutting the steps for the former lighthouse.

"*Figure* 4 shows the structure of Course IV., where, in this, as all the others, the stones lighter-coloured denote the Portland, the darker the moor-stone.

"*Figure* 5. The position of three joggle-holes, Y, between this course and the next above.

"*Figure* 6 shows Course VI. complete, which brings the whole work to a level with the reduced rock: it shows the joggle-holes for the eight cubes; and the central plug-joggle, fixed in place at o, ready for the reception of the centre stone of Course VII.

"*Plate* IV.—*Plans of all the different courses from the top of the rock to the top of the balcony-floor inclusive.*

"*Figure* 1. The proper plan of Course VII. relative to the section, *Plate* II. No. 2. As being the first entire course, the trenails and wedges are shown; but afterwards omitted in the draughts, to prevent crowding the figures. The black lines and dotted lines show the joints of the alternate courses. The centre-stones, and the four stones surrounding, were alternately of the same size to the top of Course XIV.

"*a.* The centre plug, first set.

"*b b.* The square part of the centre stone; from each of whose four sides a dovetail projects, and thereon are fixed the four stones *c c*, by joint-wedges and trenails, as per figure; which five stones united make one stone, sufficiently large to receive eight smaller dovetail stones *d d;* and whose projecting parts form dovetails to receive another circle, or order of stones, fixed like the former. The cubic joggles are shown at *e e*.

"*Figure* 2. The plan of Course XIV. ending the fundamental solid, and on which the entry and well-hole are begun. It also shows the diminution from Course VII. Upon this figure is shown the distribution of the smaller cubic joggles, which take place upon the entire solid. The entry here appears to have a small inclination with the E. and W. line, which was not noticed in the section, *Plate* II. No. 2, to avoid ambiguities.

"*Figure* 3. The plan of Course XV. being the first of the entry-door and well-courses.

"*Figure* 4. The plan of Course XVIII. showing the work of the entry closed in, and the solid re-united. Also the manner of hook-jointing the four stones round the centre to each other; which, in the courses below the entry-door, were united by dovetails to the centre-stone. Joint wedges were applied in the hook, as per figure. Thus the arrangement, in circles from the centre, was again complete. In the entry-courses, as every piece had at least one cubic joggle and two trenails, the work was secure against all ordinary attacks of the sea: the weakness being on the east side; but when capped and bonded together by this 18th Course, the whole was again considered as one entire stone, out of which the cavity had been cut.

"*Figure* 5 shows Course XXIII. ready for putting on the cap-course of the solid.

"*Figure* 6. The cap-course, making the store-room floor, in its finished state; the first course of the habitable part of the building, viz. Course XXV. being upon it; and showing the store-room door, with its joggles, joint-stones, and cramps.

"The detached figure, relative to it, shows a part of the top of the wall of Course XXV. to a triple scale; wherein *h h i i* denote one of the pieces of stone, whereof sixteen complete the circle: *f* shows one of the joggles used in this part of the building; being slices of marble the size of a common brick, let half its thickness into the middle of the stone; so that the next course above, breaking joint upon the middle of this, according to the dotted line *g g*, half the joggle's length will take one of the upper stones, whose joint comes upon it, and the other half joggle the other: by which means every stone is fixed to its place, as it were, by two steady pins, one at each extreme. The black lines, *h i*, showing the joint at each end of this stone: the small lozenge figures, *k* and *l*, show the shape of grooves, cut from the top to the bottom of each end of each stone, and which, when two are joined together, form that figure: *k* denotes the lozenge empty, or unfilled, and *l* the lozenge filled with a joint stone.

"*m n.* The shape of one of the cramps, in upright; and *o p* as seen upon the flat. The holes in the stones at *q r* are bored, to receive the round shanks of the cramp, and the rectangular cavities *q r* are sunk, to bury the flat of the cramp *o p*.

"*Figure* 7. The plan of the kitchen floor, and the upper bed of Course XXIX. that encircles it: showing one of the endless chains; of which, as appears in the section, *Plate* II. No. 2, there are two to each floor. The detached figure shows an enlargement of the chain and groove that contains it.

"In the principal figure, the dotted lines at *s* show the place of the fire-grate.

"*t t.* The sink.

"*v v.* The dresser.

"*w w.* The settle.

"*x.* A place for a claw table, leaving a vacancy to the window between each.

"*Figure* 8. The plan of the bedchamber, taken upon the top of Course XLIII. which gives the horizontal sections of the windows.

"*y y y.* The places of the three cabin beds for the light-keepers.

"*z.* The hole in the floor for the copper funnel from the kitchen.

"*a.* The place of the clock.

"In the detached figure, *b b* shows how the cramps are disposed in the reduced jambs of the windows.

"*c.* The plan of the rebate, to receive the shutters, or ports of the windows, whereof the uprights are seen in *Plate* II.

"*d.* The sill of the clear opening; against the solid of which the window frame *e f* and sashes are lodged; the whole of which go in together, and are held in by wooden pins, two above and two below, as shown at *g g*: the holes being bored in the solid stone. If those pins are cut off, the whole can be drawn out and renewed, without injury to the stone-work. The joint of the wood frame with the stone-work is secured against wet by white-lead and oil.

"*Figure* 9. The plan of the cap of the main column, being in *Plate* II. No. 2, the 46th Course, and composes the balcony floor.

"*h h.* The man-hole in the centre, correspondent to the other floors.

"*i.* The funnel hole accordant with *z* in the last figure.

"The dotted lines *k k* trace out the octagon base of the lantern.

"The place of the under rail of the balcony is shown by the dotted lines *m m m*; and *n n n* denote sections of the studs upon which those rails are supported, correspondent to the uprights of *Plate* II.

"*Plate* V.—*Original ideas, hints, and sketches, from whence the general form of the present building was taken.*

"*Figure* 1. The bole of a spreading oak; its side-branches being lopped off, rising out of the ground with a sweep; its taper diminishing till the sides become perpendicular; and on the insertion of the great boughs, again swells and overhangs.

"*Figure* 2. The manner in which the smaller boughs and branches are obliquely inserted into the greater, with the reconciling curves that form the union.

"*Figure* 3. A specimen of paving to be found in the walking paths of London streets; being a mode of dovetailing in stone.

"*Figure* 4. A sample of stone dovetailing in the upright, taken from Belidor's *Archit. Hydraul.*

"*Figure* 5. A copy of the first complete design made out for the solid courses of the Eddystone. The only material alteration afterwards was to diminish the size and weight of the outward circle of stones.

"*Plate* VI.—*A view of the rock on the east side; and of the work advanced to Course* XV. *the first of the entry-courses; showing the manner of landing and hoisting the stones, &c. in every after-stage of the building.*

"*Figure* 1. The boat Weston in the gut, delivering her cargo.

"P. Q. The two fender piles, to prevent her rubbing against the rock.

"X. The cave, here seen in front.

"D. The gulley, through which a momentary cascade makes its way; and which was proposed to be stopped.

"E F G. The shears; from the head of which are suspended the main tackle-blocks A B, whose tackle-fall, after going to the snatch-block E, passes to the windlass, or jack-roll, whose frame being of iron, is fastened to the rock as per figure.

"The enlarged detached figure *a* shows the frame and roll frontwise, as seen from the snatch-block.

"*b.* The side-view thereof, the roll being seen endwise.

"*c.* The manner of coupling the back-stay to the upright stancheons; and *d* shows, by a figure still more enlarged, the upper end of the stancheons for receiving the gudgeons of the roll.

While the stone is hoisting, the man represented at I is heaving-in the tackle-fall of the runner and tackle H K: for, till the stones are cleared of the boat, the shears lay out considerably, and the out-hawler guy-rope, L M, is slack. This crosses the gut, and is fixed by a ring-bolt to one of the rocks of the south reef. By such time, therefore, as the stone is hoisted by the main tackle to the height of the entry-door, the shears are got into the perpendicular; and then by easing the out-hawler guy-tackle, L N, the stone comes into the entry door.

"The runner and tackle H K is hooked to the guy-chain, O, which crosses the work, and passes down to the ring on the west side of the rock; marked R in *Plate* I.

"In the detached *Figure* 2, the anchor-like piece of iron, by which the main tackle-blocks are hung, is shown to an enlarged scale at *e f g h*. This anchor being suspended upon a round bolt at *e*, that passes through the tops of the two shear legs, swings freely between them, and always putting itself in a perpendicular position, and producing fair bearings upon them, without any unnatural strain or twist, enables them to support the greatest weight possible.

"In like manner the two arms of the anchor *g h*, having the two guy-tackles hooked to them, the action of those tackles is upon the suspending bolt, and the feet of the shears turning freely upon eye-bolts fixed in the rock, they are at liberty to conform themselves to the position wanted; so that the stress upon the legs is always endwise.

"After the building was raised to the height shown *Figure* 1, the work was hoisted through the well-hole, till it arrived at the top of the solid, by means of the triangle and twelve-fold blocks wherewith the work was set; and are shown as standing upon the wall at the first vaulted floor by the letters *i k l m*, being the fourth stage: but after that was completed (the man-hole being too small, and the height too great, without losing time) a jack-roll was established, as shown at the third stage in the lower store-room at Q: and a pair of movable shears, the figure whereof is shown at the fifth stage, as upon the wall, at the kitchen-floor; which, instead of guy-ropes, had a back leg, longer than the rest, whose bottom or foot cut with a notch, stepped upon the internal angle of the opposite wall; and was long enough to suffer them to lean over sufficiently for the stone at P to clear the wall. The shears themselves were prevented from falling over by a luff-tackle, shown upon the back leg, whose lower block hooked upon a lewis, in that stone the back leg stepped upon; by which it was brought tight and steady. When the stone was to be landed, this tackle being a little slacked, till the notch could be disengaged, and then set upon, the back leg would, by going over the wall, suffer the shears to come to the perpendicular, or beyond it.

"The stones, now become in general less weighty, a common tackle was employed at the shear-head, which would go down to the entry door, and there met the stones hoisted by the great shears: the tackle-fall of the movable shears, being taken to the jack-roll Q, the stones were got to the top of the building, in the same time they were raised from the boat to the entry-door.

"The detached figure R is the plan of the movable shears; where the check, or safety rope, *n*, is shown at the foot of the back leg.

"In this manner all the heavy materials were got up; the movable shears rising with the work, till the cupola was to be set upon the lantern.

"The sixth stage shows the apparatus used for this purpose. The great shears being now done with, were taken down and put through the windows of the uppermost room, and there, being well steadied, served as booms. The detached figure S being the plan of this stage, shows their particular disposition; wherein *o p* show the places or feet of the legs of the shears used for this particular purpose; also marked with the same letters in the relative upright. In this, the rope *q r* shows a side-stay to the leg *o r*; and *s t* is the stay of the leg *p t*, each fastened to *q s*, the extremes of the booms.

"From each end of the cross-tree at the head of the shear-poles proceeded the ropes *w x*, *y x*, which, joining in one guy-rope at *x*, proceeds over a pulley in the end of the temporary timber at *z*: from thence, with the intermediation of a tackle, 1, 2, it proceeds to, and fixes at the extreme end of the boom 3; and as the weight to be hoisted will principally lay upon this guy, the stay, or shroud rope, 3, 4, is

LIGHTHOUSE.

passed from thence through the window of the room below, and is there fixed.

"It is now plain, that by the tackle 1, 2, the shears can be let go over as far as necessary, and brought back into the perpendicular; but to counteract this main guy, and keep all steady, the rope 5, 6, 7, with a small tackle upon it, performs the office of an out-hawler guy, fixing to the same ring in the rocks, as that of the main shears had before done. This apparatus enabled the cupola to be hoisted and set on whole without a bruise.

"*Plate* VII.—*Plan and description of the work-yard at Mill-Bay, with its furniture and utensils.*

"*Figure* 1. The general plan of Mill-Bay, wherein the dotted line *a b c* shows the line of low-water spring tides.

"*d e.* The channel dug from low water to convey vessels to the head of the jetty *f g*.

"*h i k l.* The area of the work-yard.

"Since the removal of this work, has been built L the long room.

"A C. The marine barracks.

"D D. New streets of Stonehouse.

"*Figure* 2. Plan of the work-yard and jetty. A B C D, the line terminating the head of the channel. Now any vessel lying against the two large piles B C, on which a pair of shears being erected, can be unloaded of her cargo of stone, and delivered upon a wheel-carriage; that passing along the jetty to the turn-rail E, the carriage is there turned round till it becomes fair with the rail-road E F; and passing along it, enters the work-yard, whose boundary is marked by G O G O.

"At T is another turn-rail, which enables the carriage to go on with its burden; either in the straight line, or to turn there and go along the rail-road in the middle of the yard, and arriving at any destined point, suppose H, it is there met by a roll-carriage; for which, planks being temporarily laid, as at I, the burden (being transferred on small rollers) will be easily moved thereon to the extremity of the yard sideways; and thus stones can be deposited, as at K K (shown edgewise upward) upon any point of the area of the yard, and returned by the same means.

"The area bounded by the line O G, and the dotted line L L, is the Portland workshed.

"M denotes one of the bankers; to which, from the wheel-carriage (supposed on the rail-road opposite) strong joists being laid, as shown by the dotted lines, the pieces of stone are brought on small rolls; the bankers having notches sunk therein, to receive the ends of the joists.

"In like manner, the area N O was the shed for the moorstone workers.

"The square area P Q denotes the extent of a roof, supported by four posts, covering the platform; whereof *a b* represents the platings of rough stone walls; *c d* one of its principal floor timbers, 6 by 12; these being covered with three-inch planks, and brought to a true level, made a stout floor, upon which the courses were brought together.

"R. The cabin for the foreman of the yard.

"S. A small store-room for tools and iron-work.

"G W. The store-shed for Watchet lime and puzzolana.

"V X. The shed for bucking or beating the larger parts of the puzzolana upon W Y, the bank with three cast-iron beds upon it.

"*Figure* 3. Supposed a detached figure, being the ground-plan of the turn-rail at T (*Figure* 2) to an enlarged scale, wherein A B is a dormant circle of wood well supported; of which C marks the centre-pin fixed in the transverse beam D D: E E being connected studs.

"F F. Portions of the rails, whereon the wheels move, which are kept in place by the fillets *f f*, nailed on each side.

"G G. The sleepers for supporting the rails at about a yard's distance middle and middle; as is also shown near E, in *Figure* 2.

"*Figure* 4. The plan of the movable turn-rail, and *Figure* 5 the relative upright; shewing also the section of the dormant circle. The three last figures having a mutual reference, the same parts are marked with the same letters: and furthermore, in *Figure* 4 and 5.

"H I. The rail part of the turn-rail, correspondent to those parts marked F F, *Figure* 3, in width and height. The rail parts, H I, are strongly framed upon the cross beam K K, and connected by the pieces L L. The whole being poised, with its burden, upon the pin C, but without absolutely touching the dormant circle A B while turning; for bearing only upon the flat shoulder of the pin, it turns easily; but, when it is bringing on, or wheeling off, the equilibrium upon the pin being destroyed, the ends, H, I, are then supported upon the dormant circle, and the wheels will move steady.

"*Figure* 7 shows the plan, and *Figure* 8 the upright view of the wheel-carriage, to the same scale as that of *Figures* 3, 4, and 5. Also *Figure* 9, and *Figure* 10, give the upright views of the roll-carriage in two directions, to the same scale; which show distinctly the manner of supporting the axis of the rolls on iron frames; and how the iron frames are kept upright by four pair of cross bars.

"*Figure* 11. The upright of the capstan-roll, axis, and middle part of the bar to the same scale. At 1, 2, is shown the capstan in full, to the scale of the yard; and 3, 4, and 5, mark the direction of the rope, which, from a snatch-block at 5, ascends to the upper block of the main tackle, suspended from the top of the shears, as per *Figure* 6, wherein the in-hauler guy-tackle is marked 7, being a runner and tackle; and the out-hauler, marked 8, are simple blocks. The guy-rope, 7, 6, was attached to a ring-bolt, passing through a large rough stone, rammed into the ground; its place being shown at 6, (*Figure* 2,) the out-hauler guy 8, 9, being secured in the same manner.

"The marble rocks, marked 10, go round the point of the bay.

"*Figure* 12. The elevation of the upper part of the jetty-head in front, with the shears upon it, to an enlarged scale; more particularly to show the smaller parts.

"A, B. The front pair of piles, to which the cross-beam C D is bolted, and, in like manner, to each pair of piles.

"E, E. The ends of the longitudinal half balks.

"F F. The cross joists.

"G, G. The ends of the flat rails that the wheels of the carriage run upon.

"H H. A single cross timber, serving as a stop to the carriage at the end.

"I. The snatch-block.

"*N. B.* The scantlings are marked, because this jetty or scaffold, erected as slight as possible for a temporary purpose, sustained the whole tonnage of the Eddystone matter, in and out, without derangement.

"The detached *Figure* 13, gives a part of the top of one of the shear legs, showing how they were plated on each side to support the bolt of the anchor from bending, and thereby from splitting the poles.

"*Figure* 14. The enlarged figure of the runner and tackle (marked 7, in *Figure* 6.)

"K. The runner-block of one large single pulley.

"L M. The tackle-blocks, of three pulleys each, making a purchase of twelve, equivalent to the great blocks.

"*Figure* 15. An upright diagonal view of the main-tackle blocks; having six pulleys each upon two pins; the larger tier being ten, and the lesser eight inches diameter. This figure distinctly shows the method of salvagee strapping; being double, that the pins being readily knocked out, they could be frequently greased without trouble.

"*N. B.* The shears, blocks, and tackles, used at Mill Bay, were nearly the same as at the rock; and one pair of main tackle blocks at each place, with the same pulleys, went through the whole service; but the pins were renewed each season, and sometimes oftener, being of wood, on account of the salt-water; but were frequently greased. The main tackle-fall at each place was no larger a rope than of three inches circumference; being a white rope, remarkably soft laid, hauser-fashion; and which is of material consequence.

"*Plate* VIII.—*Descriptions of supplemental matters, having reference to the Eddystone building.*

"*Figure* 1. An upright front view of the great tackle, or purchase-blocks of twenty sheaves, or pulleys.

"*Figure* 2. A side view of the same blocks, referring to *Figure* 1. The advantage of this construction is, that the tackle-fall, or running-rope, may be reeved through the twenty sheaves, without a cross or interference; so that the standing part, or beginning, may be in the middle of the upper block: and the ending, hauling part, or fall, upon the middle pulley of the same block. The weight therefore being suspended by twenty ropes instead of six, as in common triple-blocks, the tackle-fall, as relative to a given weight, may be lesser or of fewer yarns in the same proportion; which renders the whole much more flexible and pliant, and which, together with the advantage derived from the mode of reeving, occasions their rising and falling nearly upon a parallel. Beginning in the middle, the greater sheaves are reeved as far as can be on them; from thence going to the first of the smaller sheaves, and reeving the whole of them throughout, you then go to the first of the greater sheaves, before left unreeved, ending upon the middle sheave of the upper block; and thus arises a diminution of the friction from the more equal distribution thereof.

"*Figure* 3. An upright section of the store-room, to an enlarged scale; in it is shown the centre whereon the upper store-room floor was turned; and in like manner the rest.

"*Figure* 4. The plan relative thereto, the letters being common to both.

"*a b, c d.* Two of the sixteen ribs, formed to the circle of the vaults of the floors. These ribs are connected at their ends by two wooden rings, *e f, g h i k;* the former supported by four posts, three of which are shown in their places, and the latter by eight; of which only one is shown on the right hand, and one on the left, to avoid confusion. The rings are each made to take asunder, that after striking the centre they might be got out of the room.

"At *l l, m m,* two of the ribs are supposed taken out, to show their bearings upon the rings; they were open centres, that it might be seen underneath when the joints were fair.

"*Figure* 7, of *Plate* IV., shows how the sixteen radii of stones would apply to the sixteen ribs. In this plan, *Figure* 4, A shows the well-hole, and B B the cross timbers for supporting the four middle posts, whose places are marked out by dotted little squares.

"*Figure* 5. An elevation, and *Figure* 6, the relative plan of a dial stone, taken professedly from the general figure of the Eddystone lighthouse; being the design of the late James, Duke of Queensberry, and by him erected at Amesbury, Wilts, with a dial upon it, by Mr. Ramsden. The drawing, of which this is a copy, was given me by the Duke; and is placed here as an instance, that the Eddystone column may be applied to some uses of architecture.

"*Figure* 7. One of the silver medals given to the seamen as a token of the service.

"*Figure* 8. The tool wherewith the stones were got up from the bottom of the gut.

"A. One of the stones with two trenail holes.

"Suppose this stone lying flat in the bottom of the gut, the side A uppermost. The tool has a pole or staff, *b b*, about twelve feet long, sufficient to reach the bottom. This single prong, *c*, is forged to a very single taper, such as to be thrust eight or nine inches into a trenail hole, (all of them being bored to a gauge) it can be driven by the pole, till fast; observing that the arm *e* corresponds to the centre of gravity of the stone. The water is generally so clear as to see to the bottom; and, in case of any ruffle by the wind, can be in a great measure freed from agitation, by looking through a speaking trumpet, whose mouth is put down eight or ten inches into the water. The rope *d e f* being then set upon by the main tackle, instead of its drawing out, the length of the arm *g* causes the prong to jamb the faster in the hole; and the staff being quitted by the hand, with a cord to hinder its flying off too far, the whole assumes the position of the figure; and, when brought above water, is lowered into a yawl.

"*Figure* 9. A section of one of the mortar buckets, and in it the beater.

"*Figure* 10. One of the internal faces of the lantern's glass frames, and therein the cross bars of iron, as they were actually fixed. Besides the flat at each end of each bar, distinguished by a darker shade, and through which the screws passed; each end was also cranked about an inch, so as to set the transverse part of the bars clear of the copper sash-frame; and they were cleared of each other at their intersection, by one of them being made straight, the other curved in that part. All the panes being taller than the candles, the chandelier rings are so hung, that when the candles are at rest, dispensing their light, that of one chandelier passes through the range of panes A, and that of the other through the range B; and when the candles are snuffed, one of the rings of lights being seen through the range C, the other mounts to D, and *vice versa.*

"*Figure* 11. The chain of triangles from the Eddystone to the flag-staff of the garrison of Plymouth, for ascertaining their distance trigonometrically.

"*Figure* 12. An enlargement of the work within the headlands of the Sound.

"The whole country about Plymouth Sound being very uneven, I could not readily obtain a base better, than by very carefully measuring the two lines B G, B W, taking the intercepted angle W B G; whence the right line W G was obtained, making a base of 1871 feet, and which I cannot suppose to err more than half a foot. Again, the nearest place from whence the two beacons, W, G, could be commodiously seen for the purpose, was the point S; and all the three angles of the triangle W S G, being likewise carefully taken, I conclude the angle W S G $= 10° 23'$, taken true to a minute; that is, to $\frac{1}{623}$d part of the whole angle. The line S W could therefore be determined within $\frac{1}{623}$d part; which being considered as a new base of larger extent, may be esteemed true within $\frac{1}{600}$th part of the whole. From this, and the angles taken as marked upon the scheme, the lines W P, W M, and W E, were successively determined; and finally F E, the distance of the flag-staff from the Eddystone, came out very near, but somewhat less, than fourteen miles. But the interior harbour of Plymouth, called Sutton Pool, being about three furlongs farther from the Eddystone, than the flag-staff, the whole distance may be esteemed fourteen miles and a quarter from Plymouth harbour."

M. A. Nicholson del.

Thus was completed the Eddystone Lighthouse, which must ever be considered a masterpiece of its kind. The merit of utility is not its only characteristic; but in beauty, as well as in strength and originality, it deserves the highest amdiration. And when we remember the extraordinary difficulties by which a work like this must have been surrounded, we must own, that had its contractor left no other memento of his genius, the Eddystone alone would be sufficient to immortalize the name of Smeaton.

EDGE, the intersection of the two planes or surfaces of a solid, which is consequently either straight or curved according to the direction of the surfaces. *See* ARRIS.

EDGE is also that side of a rectangular prismatic body, which contains the length and thickness, but in this sense of the term, the body to which it applies is generally understood to be very thin; thus we say, "the edge of a door," the "edge of a board," meaning the narrow side.

EDGE OF A TOOL, the meeting of the surfaces when ground to a very acute angle.

EDGE-TOOLS, all those which chip or shave in the operation of working.

EDGING, in carpentry, the reducing of the edge of ribs or rafters, whether externally or internally, so as to range in a plane, or in any curved surface required; backing is a particular case of edging, and only applies to the outer edges of ribs or rafters, but edging, or ranging, is a general term, and applies indifferently, either to the backing or internal surface. *See the terms* BACKING and RANGING.

EDIFICE, (from the Latin, *ædificium*,) a building constructed either for use or ornament. The word is not usually applied to a mean or inferior building, but to temples, churches, or elegant mansions, and to other great structures. *See* BUILDING, HOUSE, TEMPLE, &c.

EDILE, (Latin, *ædilis*, from *ædes*, a building,) an officer in ancient Rome, whose business was to superintend buildings of all kinds, more especially those of a public character, as temples, aqueducts, bridges, &c.

EFFIGY, a representation or likeness of anything, the term being particularly applied to sculptured representations of human figures. Such effigies were very common on tombs erected from the fourteenth to the sixteenth centuries, and were of various materials, stone, marble, alabaster, and even of the precious metals.

EGGS, ornaments in the form of oblong spheroids having their greater axis inclined, projecting at the top and receding at the bottom, but each axis in a plane perpendicular to the surface of the ovolo. In straight mouldings, all the axes will be in the same plane; but in annular mouldings or those generated round an axis, all the axes of the spheroids will be in the surface of a cone, whose vertex will be downwards, and will terminate in the apex. The eggs are most generally truncated, or have their upper part cut off by a plane parallel to the horizon. *See* ECHINUS.

EGYPTIAN ARCHITECTURE. The character of the Egyptians, as developed in early history, would naturally lead us to suppose, that an inquiry into their style and manner of building would form a subject for interesting study, not only to the antiquary, but also to all such as take any interest in general history; and such doubtless is the case. The history of the place attaches an unusual interest to everything connected with it. Of the early history of Egypt, like that of the other primæval nations we know but little for certain, all narrative dating back beyond a certain period, having an air of mystery about it, which it is not easy to penetrate, and this fact is more especially true, as regards the origin of nations. If we believe the records of the Egyptian priests, as handed down to us by Herodotus, Manetho, Eratosthenes, and others, we shall have to carry back the date of its origin far beyond the period generally assigned as the commencement of history. Manetho gives us a series of dynasties upon dynasties, which, if successive, reach beyond the bounds of time; to obviate which difficulty, it has been suggested, that they were not all successive, but several contemporaneous, reigning over different parts of the country; but, indeed, the whole matter would seem to be fabulous, for in the same place is related the gigantic stature of several kings, their wonderful exploits, and other circumstances characteristic of mystical and confused tradition. The first king alluded to by historians is Menes or Men, who is supposed to have lived above 2,000 years B.C., about the time of the foundation of Assyria by Nimrod, and of the reign of the Chinese emperor Yao, with whom the historical period of China begins. It is doubtful which of these nations came first into existence; we are inclined to give the preference to the Assyrians, but whichever takes the lead, there was probably but little difference between them in point of time. It is certain that Egypt stood out pre-eminent in civilization, and that, too, at a very early period; its success in the cultivation of the arts, and in the pursuit of science, was greater than that of any contemporaneous people, as is evident from their remains to be seen at the present day. At the close of Manetho's sixteenth dynasty, the irruption of the Hyksos, or shepherds, is supposed to have taken place; his seventeenth dynasty consisting of shepherd-kings, from which period it is alleged that the erection of the existing edifices must commence, all the previously existing buildings having been destroyed by the shepherds. As a proof of this, is adduced the circumstance, that at Carnac, and other of the oldest monuments of Thebes, sculptures and painted stones, of good workmanship, are to be found, used as mere materials in the body of the walls.

Besides the ancient authors already mentioned, we have Strabo and Diodorus Siculus, who have given some account of Egypt and its buildings, and to these we shall have to refer occasionally as we proceed.

In turning to modern writers on this subject, we shall find but few who enter fully into the subject previous to the commencement of the present century, little or nothing having been known of Egyptian buildings unless it were of the Pyramids, until the French expedition, at the close of the last century; no satisfactory delineations of the temples, or their details, had been taken, but only such sketches as were calculated to convey some general idea of their characteristic massiveness. To Denon, and the contributors to the great French work on this subject, we are principally indebted for our present information. Pococke and Norden have treated somewhat largely on their researches in this country, but their remarks are too general and too loose to be of much service. Denon had advantages unattainable by any of his predecessors; independent of his own high qualifications, his efforts were seconded by the able assistance of men of talent, sent out for the purpose, themselves well fitted for the task. Besides these, we may mention Belzoni and Champollion; and, amongst our own countrymen, Savary and Wilkinson.

According to Manetho's account, the temples to which the remains described by Denon belong, were erected by the first dynasties of the Pharaohs, or about 2,200 before Christ: these first structures, however, were destroyed by the invading shepherds, as before noticed. These usurpers were, in turn, driven out by the Pharaohs, who were restored to their throne about 2,000 years B.C., and thereupon set about rebuilding the temples, the remains of which are seen at this day.

The character of Egyptian architecture is that of massy grandeur and severe simplicity, as exhibited in the simple, well-defined outline, and in the colossal dimensions of their temples, and the immense blocks of material employed in their construction. The great object of the builders seems to have been, that the strength and durability portrayed in the prodigious magnitude of their structures should serve to typify their own greatness. They did not consider, when they were erecting their temples, that they were building them for an age, but for eternity; nor, comparatively speaking, were they deceived in the estimate of their works; for now, after the lapse of three or four thousands of years, we have some portions which are likely to last as many more centuries, unless wantonly destroyed by the hand of man. Had, indeed, the buildings only to contend with the ravages of time, we should have many a structure perfect, where it is now a heap of ruins; had it not been for the reckless destruction of these wonderful monuments by Cambyses, it is questionable whether they would not all have been entire at the present day, and certainly in a better state of preservation than many modern buildings which have not numbered as many ten years as the former have centuries. Even now, the carving, and, in some instances, paintings, to be seen in the ruins, are as fresh and bright as if only just executed.

The immense size of the stones employed, and the mechanical art necessary for transporting them from the quarry, and afterwards raising them to the required elevation in the temples, when building, cause these sacred structures to appear like works of superhuman labour. In every degree, they exhibited a solemn majesty of style, and imposing grandeur; while austere simplicity, combined with order, uniformity, and regularity, pervade the whole design.

This, with the solidity and massiveness of the parts, and the prodigious dimensions of the stones, imparted an air of the most impressive and awful sublimity on the mind of the beholder.

Belzoni, who visited Egypt, observes, in his enthusiastic manner, when entering this magnificent temple—"I was lost in a mass of colossal objects, every one of which was more than sufficient of itself to attract my attention; I seemed alone in the midst of all that is most sacred in the world; a forest of enormous columns, adorned all round with beautiful figures, and various ornaments, from top to bottom; the graceful shape of the lotus, which forms the bell-shaped capitals, and which is so well-proportioned to the columns; the friezes, also adorned in every part with symbolical figures in low relief, representing battles, processions, triumphs, priests, and sacrifices; all relating to the ancient history of the country. The walls of the sanctuary, usually formed of red porphyry granite; the high portal, seen at a distance from the openings of this vast labyrinth of sacred edifices on each side of me, had such an effect upon my soul as to separate me in imagination from the rest of mortals, exalt me on high above all, and cause me to forget entirely the trifles and follies of life!" "It further appears," he says, on entering the city of Thebes, "like entering a city of giants, who, after a long conflict, were all destroyed, leaving ruins of their various temples as the only proof of their former existence." Champollion exclaims of Carnac, "These porticos must be the work of men one hundred feet in height;" and Denon adds, "Such structures appear like dreams, or the works of giants!"

Of the impression made upon the mind of Denon by these stupendous structures we have sufficient evidence in his work on the subject; the few following passages have been selected from a multitude of a similar kind.

Of the portico of Hermopolis, he says, "This was the first monument which gave me an idea of the ancient Egyptian architecnure, the first stones that I had seen which had preserved their original distinction without being altered or deformed, and had remained there for four thousand years; here I fancied I saw engraven on every stone the words Posterity—Eternity. It gave an idea of the immense range and high perfection to which the arts had arrived in this country. If a peasant should be drawn out from his mud-cottage, and placed before such an edifice as this, would he not believe that there must exist a wide difference between himself and the beings who were able to construct it, and, without any idea of architecture, would he not say, 'This is the work of a god; a man could not dare to do it, or inhabit it.'"

This is his first impression, nor is his admiration less apparent at the close of his researches; novelty may excite wonder and interest, but merit alone can maintain them. At a later period, the description of Tentyra calls forth the following remarks:—

"Nothing is more simple and better put together than the few lines which compose this architecture. The Egyptians borrowing nothing from the styles of other nations, have here added no foreign ornament, no superfluity of materials: order and simplicity are the principles which they have followed and they have carried them to sublimity. At this point they have stopped, and have attached so much importance to preserving the unity of design, that though they have loaded the walls of these edifices with bas-reliefs, inscriptions, historical and scientific representations, none of these rich additions intersects a single line of the general plan, all of which are religiously preserved unbroken; the sumptuous decorations which appear to the eye when close to the building, all vanish at a short distance, and leave full to view the grand elements of architectural composition which are dictated by sound reason. It never rains in this climate, all that is wanted therefore is a covering of plat-bands to give shade, but beyond this neither roof nor pendiment are added; the plain-slope is the principle of solidity; they have therefore adopted this form for every main supporter, doubtless with the idea that stability is the first impression that architecture should give, and is an essential constituent of this art. With these people the idea of the immortality of the Deity is presented by the eternity of his temple; these ornaments, which are always rational, always consistent, always significant, demonstrate a steadiness of principle, a taste founded upon truth and a deep train of reasoning; and if we even had not a full conviction of the eminent height to which they had attained in the abstract sciences, their architecture alone, in the state in which we now find it, would give the observer of the present day a high opinion of the antiquity of this nation, of its cultivation, and the impressive gravity of its character."

Of Carnac he at last exclaims—"One is fatigued to describe, and to read, and to think, of such a conception; after having seen it, one can hardly credit the reality of the existence of so many structures collected in one spot, of their size, of the determined resolution (*constance obstinée*) which exacted their erection, and of the incalculable expense of such magnificence."

Of the æsthetic character of Egyptian architecture, our author observes:—"These monuments, (Tentyra,) which imprinted on the mind the respect due to a sanctuary of the divinity, were the open volumes in which science was unfolded, morality dictated, and the useful arts promulgated; everything spoke, every object was animated with the same mind. The opening of the doors, the angles the most private recess, still presented a lesson, a precept of admirable harmony; and the lightest ornament on the gravest feature of the architecture, revealed under living images the abstract truths of astronomy."

"Painting added a further charm to sculpture and architecture, and produced at the same time an agreeable richness, which did not injure either the general simplicity or the gravity of the whole. To all appearance, painting in Egypt was then only an auxiliary ornament, and not a particular art; the sculpture was emblematical, and, if I may so call it, architectural.

"Architecture was therefore the great art, or that which was dictated by utility, and we may from this circumstance alone infer the priority, or at least the superior excellence, of the Egyptian over the Indian art, since the former, borrowing nothing from the latter, has become the basis of all that is the subject of admiration in modern art, and what we have considered as exclusively belonging to architecture, the three Greek orders, the Doric, Ionic, and Corinthian. We should therefore be cautious of entertaining the false idea which is so prevalent, that the Egyptian architecture is the infancy of this art, since it is, in fact, the complete type."

Such is the universal and oft-repeated admiration of modern travellers: had such expressions been used by an ancient author, and the buildings now demolished, we should have been apt to treat the matter as purely fabulous, but now they are undoubted realities, and stand as evidence of the truth of history. Such structures could doubtless have been erected solely under a despotic government, and probably, for the most part, by captives or slaves, and not by free Egyptians, as we read of the Israelites in the time of Moses being tasked in this manner; the manual labour employed on such structures must have been enormous. It is a matter of the greatest wonder how such immense masses of material were transported from the quarries, and fixed so accurately in their respective places; even in the present day, with all the advantages of machinery and steam-power which we possess, the erection of such structures as those of Egypt would be considered no light undertaking. Notwithstanding the vast magnitude of these erections, they were remarkable not only for their size, but no less for their enrichment; ornamentation of various kinds was lavishly distributed over the whole surface. It is true, the buildings appear to greatest advantage when exhibited as a whole, yet each minute portion will bear, nay, require, minute examination; a close inspection reveals the most elaborate enrichment, while a distant view exhibits the noble outline and the grander features of architectural composition.

No two styles would at first sight appear more dissimilar, more antagonistic, than the Egyptian and Gothic, the one ponderous and massive, the other light and elegant; the one flat, of low proportions, and presenting a great extent of unbroken horizontal lines, the other slender, lofty, and aspiring. What contrarieties do they present! and yet we shall find that they have many characteristics in common, not indeed in their architectural features, but in the æsthetic principles followed out in their construction and decoration. The temples of the Egyptians were but the embodiment of their religion; their massive proportions typified the greatness, as the continuity of the outline and repetition of parts illustrated the eternity and immutability of their deity. Their objects of worship inspired feelings of profound awe, so likewise did their temples. Nor were their decorations merely the result of caprice, but of studied design; every detail was subservient to some great end, and suggested by some urgent reason; they all have a symbolical meaning, illustrative of the Divine attributes, and consist, in short, of a series of religious dogmas and precepts, embodied as it were in forms. They were, as is said of the pictorial and carved enrichment of Gothic edifices, the books of the unlearned, each object speaking more intelligibly and more impressively to the eye and mind of the beholder, than would whole volumes of written precepts.

"The materialism of Egyptian worship," says a writer on this subject, "rendered all these details essential; it fixed the imagination on physical nature, and obliged the ecclesiastics to seek those forms best calculated to express the dogmas of their religion. And in contemplating their architecture, it is impossible not to be struck with the manifest influence religion has had in its creation." In allusion to another similarity as regards the circumstances connected with the erection of Egyptian and Gothic edifices, he says, "The priests, who were the great depositories of all knowledge, were the exclusive designers of their religious edifices; they alone directed the taste of the architect and the sculptor; and they employed architectural grandeur, with all its accessories, to influence the minds of those people whose actions they wished to govern; nor can I imagine anything better suited to inspire religious awe, and a profound reverence for the divinity, as well as his earthly agents amongst an idolatrous people, than this style of architecture." In passing, we may remark upon another affinity between the two styles, which approaches more nearly to an architectural characteristic, and that is, the practice of copying nature, all the decorative details of Egyptian, as of Gothic architecture, being the most beautiful imitations of the natural productions of their country—the lotus, palm, reed, papyrus, &c.

Having thus given a description of the general character of this style of architecture, it will be as well to proceed at once to the consideration of the buildings more in detail, as regards plan, distribution, and arrangement of parts, method of construction, and such like; in doing which we shall take as an illustration the temple at Edfou, or Apollinopolis Magna, one of the largest in Egypt.

The size of this temple is much more comprehensive, and its arrangement much more complicated than that of Grecian structures, for whereas the latter consisted of a single cell surrounded by a wall with external columns, the former was composed of several courts, one within and beyond the other, and having columns for the most part within the walls. The entrance to the whole building was through a door placed between, and somewhat in advance of two enormous pyramidal towers, termed propylæa, which rose considerably above the general mass of the building, and were covered on the sides with sculptured figures of colossal size. The plan of each pyramid in this case measures 104 feet in length and 37 feet in width at the base, the dimensions diminishing gradually to the summit, where they are 84 feet by 20 feet, the heihgt being about 150 feet. Each mole is finished by a projecting cornice, and is surrounded on all sides by a bold torus moulding. They may be considered as solid structures, for although they contain chambers with their approaches, still these bear so small a proportion to the entire mass, that they amount to no more than small voids or cavities. The colossal entrance between the pyramids is crowned with a cornice, and finished at the angles with a torus-moulding similar to the propylæa, and was probably furnished with folding doors, as the notches for hinges are still visible. This door-way gave admission into a peristyle court having twelve columns on either side, and four on either side of the entrance at a little distance from the propylæa. The pillars at the sides are placed at some distance from a wall, which commences at the moles and surrounds the entire temple, and the space between this wall and the columns is roofed over, so as to form a covered-way or piazza, which leads on either side to the doors of the staircases in the propylæa, and is continued in a similar manner in front of them, on the entrance-side of the area. The colonnade throughout is picnostyle, which seems to have been the usual disposition, the intercolumn being seldom greater than a diameter and a half, except in the centre of a portico, where a doorway intervened, which practice is identical with that of the Greeks, as evinced in the Doric order. The height of the colonnade from the base of the columns to the top of the projecting cornice, with which they were surmounted, is about 38 feet. This court is not level, but has a considerable ascent towards the farthest side, which is effected by a series of low and very wide steps, extending the whole width of the quadrangle, and commencing at its entrance. The width of each step is that of a column and intercolumn, and the total rise is 56 feet. This alteration of level seems to have been introduced for the purpose of giving elevation to the grand portico which forms the farther side of the court, and consists of eighteen columns, in three rows of six each, placed one behind the other, and flanked on either side by a wall so as to resemble a Greek hexastyle in antis, with the exception that here there are three parallel rows one behind the other, while in Grecian temples there are never more than two. The portico, however, bears a greater resemblance to the propylæa of the Greeks, than to their temples, both being open in front, and enclosed on their other sides, having several rows of columns one behind the other. The columns in this portico, or pronaos, are loftier than those in the court below. and are surmounted like them with a projecting cornice. The spaces between the front row of columns are filled up to about half their height with a screen or dado, which gives the upper part of the intercolumn the appearance of a window. The middle intercolumn is treated in a somewhat different manner, the wall or screen being carried up somewhat higher, and advanced a little in front of the general line; the sides likewise being flanked with short columns, and the entrance to the pronaos being cut through the screen. In the wall at the further end of this first hall, is an entrance into a second of smaller dimensions, a space being taken off each side for passages. This hall is hypostyle, covered with a flat roof composed of thick slabs of stone, resting on large stone beams, which are supported again by twelve columns disposed in three rows of four each, closely set, so as to leave only narrow passages between them. From this hall we come into a chamber, having its greatest length in the width of the building, as also has the portico, and having entrances to the passages at the side of this chamber, and the hypostyle hall, from which access is obtained by means of steps to the top of the *sekos*. Beyond this is another similar chamber of smaller dimensions, having a cell on either side, supposed to have been for the priests. Entrance is obtained from this chamber into the sanctuary, which is a small covered chamber having its greatest length parallel with that of the main building; its size is about 33 feet by 17, and in it was placed the image of the deity. Round the two sides and further end of the sanctuary, is a passage, to which access is obtained from the second chamber, and round this again a larger area of similar shape, into which the smaller one led, and which gave access to the top of the sanctuary. In most instances, in front of the whole building, and a short distance in advance of the propylæa, were erected two obelisks of great height, and covered with hieroglyphics, and in front of them a long avenue, or *dromos*, as it is called, formed by two rows of sphinxes, placed at short intervals from each other, the space between the two rows forming a way or road to the temple. Strabo, the historian, who saw this temple we have been describing, alludes to this avenue—"Before the pillars or propylæa," says he, "is a paved road or avenue about 100 feet in breadth, or sometimes less, and in length from the entrance from 300 to 400 feet, or even more. This is called the dromos; through the whole length of which, and on each side of it, sphinxes are regularly placed at the distance of 30 feet from each other, which forms a double row on each side. Between the sphinxes you advance towards the temple, until you come to a large propylæum or triumphal entrance, through which you pass; and as you advance, you come to another propylæum, which you pass through; then to a third; and still keep passing on until you come to the entrance into the temple."

The above description, although of a particular example, will answer with but little alteration for any other temple, all such buildings being built on a similar plan, with but slight variations in particular instances. They all consist of a *sekos*, or sanctuary, of small dimensions, situate near one extremity of the building, surrounded on all sides with chambers, passages, and courts, and approached through a series of covered halls and colonnaded atria, the whole of the buildings being inclosed within an outer wall, and having a grand entrance flanked by two pyramidal moles. No matter to what date a building may belong, or what position it may occupy, the general form is the same, the only difference being in the size, and in the number of adjoining courts and buildings. In some cases, we have two or more propylæa, and courts preceding the temple, and sometimes avenues of columns crossing the courts in a line from the entrance. The temple at Luxor has as many as three courts, the first with a double peristyle, the second with a double range of columns extending throughout its length, and the third flanked by colonnades, each consisting of a double row of columns. To give some idea of the magnitude of this work, we may add, that in the second court, the columns were 56 feet high, and 11½ feet in diameter.

We now pass on to consider the elevation of such buildings more in detail. The contour of the elevation was pyramidal throughout; not only did the obelisks and propylæa present this appearance, but even the walls, spreading out at the base, and converging towards the apex, and as these formed the external face of the building, they gave the whole a pyramidal appearance, which doubtless adds considerably to the expression of strength, which is a marked characteristic of the style. The columns are the only parts of the building in which this form is not observable, their profile being for the most part vertical. This is just the reverse of Grecian architecture; for there the walls are vertical, and the columns sloping or conical, the general effect, however, is the same—pyramidal; for whereas in the Grecian buildings, the sloping columns are placed on the exterior, in those of Egypt the walls are external, surrounding the upright columns, so that the profile of the building, taken as a whole, is the same, although the arrangement is reversed.

An Egyptian order—if we may so apply the term—consists, like the Greek, of column and entablature, which parts we proceed to consider separately. Existing remains offer us examples of columns in great variety, differing in shape, proportions, and decoration, a few specimens only of which we can pretend to notice. The diversity observable in them is so great, that it would be futile to attempt a detailed classification; for examples which present similarities of form or decoration, differ in proportions, while those agreeing in the latter vary in many other particulars. As in other styles, the column consists of three members, base, shaft, and capital: the first, however, can scarcely be termed a distinct member, being in some cases scarcely recognizable, and in none forming a very prominent feature. It is usually a plain circular slab of stone or plinth, sometimes projecting from and at others flush with the face of the shaft, or of the same projection as the widest or bulging portion of the shaft, and

projecting forwards somewhat at their junction, where the shaft curves inwards.

The shafts present many variations, both in contour and decoration; their most usual form is that of a cylinder, or more nearly approaching the cylindrical than any other figure, there being frequently a slight difference between the upper and lower diameters. Sometimes the shaft contracted suddenly immediately above the base, the contour of this portion being curvilinear, and forming a tangent with the upper surface of the base, resembling in shape the calyx of a flower, the similarity to which is made the more remarkable by the leaves carved upon its surface. This last form can scarcely be recommended for its beauty; for in spite of the assertions of its admirers, it certainly does present an appearance of weakness. It is said that in such cases the judgment comes to the assistance of the senses, and corrects the eye, and that what is well known to be strong, cannot fairly be said to appear weak, and this is doubtless true to a certain extent; nevertheless, speaking abstractedly and artistically, this form is decidedly objectionable. In some instances, the columns slope downwards in a slight degree, similar to those of Greece. The cylindrical shafts are usually reeded, giving the surface the appearance of a number of staves or reeds placed round a common centre, or of a bundle of reeds, whence this kind of column has obtained the name of the *bundle pillar*. This resemblance is borne out by the fact, that such shafts are usually cinctured at intervals by bands consisting of three or more rings, which gives one the idea of a bundle of reeds bound round with reeds or rushes to preserve them in their position. These bands are sometimes of greater width, and have a plain surface, or one of the intervals between two bands is left blank, which again is often filled up with hieroglyphics or other ornaments. Specimens of reeded shafts of the different descriptions mentioned, are to be found at Beni-hassan, Hermontis, and Latopolis, and indeed in almost every locality; they are more prevalent than any other form. At other times, the reeds entirely disappear, the plain shaft being divided vertically into a number of compartments as before, by means of annulets or bands of reeds, and these compartments filled in with hieroglyphics; many elaborate examples of this kind are to be seen at Dendera.

Although cylindrical shafts are by far the most general, yet we occasionally meet with examples of a polygonal form, and sometimes with plain rectangular piers; a remarkable instance of the former exists at a temple at Eilethyas, on the right bank of the Nile, a few miles south of Esneh, where, in the interior of a large vestibule, the whole of the roof, as Mr. Barry informs us, is supported on polygonal columns of sixteen sides. Examples of the rectangular piers are described by the same writer as existing at Beni-hassan.

Instances of the employment of Caryatid figures in the place of columns are not unfrequent, they are placed in front of square piers, and do not bear the whole weight of the superincumbent mass, whic his mainly supported by the piers. Examples of this kind are to be found at Ramesseion, Thebes, and Ibsambal, on the banks of the Nile, between Egypt and Ethiopia. The pronaos of the last-named temple, according to Belzoni, is 57 feet long and 52 wide, supported by two rows of square pillars, each having a figure of Sesostris attached to it about 30 feet high, finely executed, and in good preservation. The pillars are five and a half feet square, and the sides are covered with hieroglyphics.

Of capitals, Egyptian architecture affords a vast variety, widely differing in form and character. One prevailing form is the bulging or bulbous capital, which projects from the shaft in a flat curve, but, instead of continuing to expand as it proceeds upwards, it recedes back, gradually diminishing in thickness, until at its junction with the abacus its diameter equals that of the shaft; the contour is similar to that which would be produced by a slightly yielding body pressed down by a superincumbent weight. Sometimes this capital exhibits a plain surface, only relieved by hieroglyphics arranged in horizontal rings, as at Kournon; at others, it is divided into eight or more compartments, or shafts, running vertically from top to bottom, and covered with hieroglyphics, or reeded, in which latter case another subdivision of shafts frequently takes place about half way up the capital, or the shafts are interrupted by one or more horizontal bands, either plain or covered with hieroglyphics, as at Latopolis. The simplest capital of this kind is where the reeds of the shaft are carried up without any interruption, with the exception of a band at the top of the shaft, underneath the bulge of the capital.

Another form of capital, which was frequently adopted, is the bell-shaped, resembling, in contour, an inverted bell, and covered with leaves, flowers, &c., or they may be said to resemble the bell and petals of a flower, the upper rim turning over, and bending downwards. This rim was sometimes perfectly circular, but at others divided into a number of convex curves, forming so many distinct petals. The lotus, papyrus, and palm seem to have been the favourite plants for introduction into this kind of capital, and so beautifully were they carved, as frequently to exhibit the most delicate and minute parts, such as the petals, pistyles, reeds, &c. Examples are to be found in almost every building; among others we may mention those of Hermontis, Latopolis, and Apollinopolis Magna, where there are some exquisite specimens; indeed, all the capitals of this form are exceedingly delicate and beautiful, of elegant form, and chaste enrichment. An example of somewhat similar character is given selected from the temple of Esneh, but in this case the contour is different, being convex instead of concave; the treatment, however, is similar, and the design good. Another capital is frequently introduced in the greater temples, which may be termed a double capital, the lowermost of which consists of four Isis' faces, disposed so as to form a square larger than the shaft, the folds of the head-dress on each side hanging down, and projecting beyond it at the corners. Above each face is a projecting abacus, with a concave face, and standing upon these, a square temple, which forms the second capital. Instances are likewise to be found of triple capitals, which consist of the last-mentioned double form placed above one of the bell-shaped kind. Another instance of a double capital is given, taken from the temple of Typhon, which consists of a rectangular block placed upon a bell-shaped capital, against each of the four sides of which sits an image of the god. Heads of animals are sometimes carved in the place of capitals, amongst which are those of the bull, which form is worthy of notice as approximating to the capitals found at Persepolis. Rarely we find columns without capitals, or with a simple rectangular block, which is little better than an abacus. The Egyptian abacus varies from the Grecian in being nothing more than a plain square plinth, of considerably smaller dimensions than the capital, and therefore receding from, not projecting over, as in classical architecture; indeed it scarcely forms a member of the capital at all, for, on account of its great depth behind the capital, it is scarcely visible, unless it be of extraordinary height; its purpose seems to be, to form a marked division between the column and entablature, and obviate that heaviness of appearance which would otherwise be occasioned. The bulging capitals form an exception to this rule, for in them the abacus projects, and overhangs the capital, the object of which is apparent from the peculiar shape of the capital; in this case it is usually ornamented with hieroglyphics or otherwise.

We have here referred to some few of the specimens of capitals which remain, and but a few, for there is a great variety, several of which may frequently be found in the same building: and even in the same hall, or other part of a building, may be seen capitals of different design though of the same general appearance, which circumstance is similar to that observable in Gothic buildings. The proportions vary in like manner; they seem to have had no settled rule as to design or proportion, which were purely matters of individual taste. The arrangement was generally picnostyle, especially in the covered halls, where they had to support large masses of stone, which were used for roofing.

The design for the entablature, on the contrary, seems to have been unalterable, for with the exception of some little diversity in the ornamentation, they are universally of the same form and character, and this is the case, however much buildings may differ as regards their columns. It comprises two parts only, the epistylium and the cornice, the former of which was flush with the walls underneath at each end of the colonnade, answering to the Greek antæ, with which likewise they are enclosed within a bold torus-moulding, and present a similar appearance to the architrave of a door being returned at the sides. The torus-moulding is a marked feature in Egyptian buildings, running up every angle of the building, and then returning on both sides underneath the cornice. The architrave is frequently plain, sometimes covered with hieroglyphics, but most frequently has a winged globe over the entrance in the centre, which is supposed to have been symbolical of the deity.

The cornice is a very prominent feature in this style, and is introduced as a crowning or finish in every situation, with or without the architrave: it is seen at the entrance of the temple, over the doorway and propylæa; within, over the colonnade and portico; and on the exterior, crowning the whole length of wall. It consists of but little more than a deep cove, but produces a great and beneficial effect by the bold shadow which it casts. The surface is divided into panels by an ornament similar to the Doric triglyph, or a band of three or more reeds placed side by side, with generally a narrow interval between each two; when, however, the band is composed of a greater number of reeds, they are placed close together. The metopes or panels are filled up with some kind of ornamentation. This formed the termination of the building, for the roof being flat, there was no such thing as the pediment, the finishing line was horizontal.

Let us return for a few moments to the column, the simplest form of which appears in an example at Beni-hassam, as figured by Mr. Barry, and in reference to which he says:

"The prototype would appear to have consisted of four large reeds of the Nile, placed upon an angular block, and tied together by cords near the top, forming thereby the capital. Small sticks are introduced between the reeds at the place of ligature, to render the figure of a more circular form, and afford the means of more firmly tying the whole together. The top is crowned by a square abacus, and the reeds being thereby confined, the effect of any incumbent weight upon them would be to produce the form."

A column similar to the above, but in a more forward state of development, is to be seen at the British Museum; it consists of double the number of reeds, placed together in the same manner, with similar base and abacus. But besides the difference as to number, there is in this example another variation in the method of joining shaft and base, the reeds in this case being turned under so as to meet the base in a curve, a form frequently adapted in more elaborate specimens.

The next change seems to have been the introduction of horizontal bands, which became requisite, as the reeds increased in number, to hold them firmly together; in some cases we find several bands, of one, two, or more reeds. The next step was to leave one or more of the spaces between the bands plain, and the next to cover it with hieroglyphics, till at last we find all the divisions of this description, at the Tentyris. The progress of the capital would seem to have been of a like nature; at first we find them composed of the same materials as the shaft, with only a band to mark the separation, and a flat square abacus at the top. The capital is, however, of a somewhat different contour, bulging out towards the lower end or ligature. In the second example we have adduced, the same form is preserved, but the capital and abacus, as well as the shaft, are covered with hieroglyphics. The next alteration would be similar to what took place in the case of the shaft: the capitals were divided horizontally into bands, as at Latopolis, and these again ornamented with hieroglyphics as at Kournou.

The bell-and-vase-shaped capitals are of an entirely different description, and cannot be said to have been a development of the above; they must have arisen from an entirely new adaptation of natural forms; while the above consists of mere reeds, the new form was an imitation of foliage and flowers belonging to that climate—the palm, the lotus, and the papyrus. The outline as well as the decoration of this kind of capital, deserves the highest praise for its taste, combining as it does the admirable properties of severity and grace, and will bear comparison with the best examples of classic design, not excepting the Corinthian, to which it bears a very remarkable resemblance, so much so as to give us reason to believe that the Romans were indebted to Egypt for the origin of their most admired order. Some specimens bear a slight resemblance to the Ionic; we may allude to that at Latopolis, but this is not so obvious, although we certainly have the upper part of the Ionic capital with its volutes repeated as a minor decoration.

The square capitals, again, with a representation of the head of Isis or other deity on its four sides, form a third class, which seems to have had its origin in symbolism, or at any rate in the mysteries of religion; a supposition which is in some measure confirmed by the usual accompaniment of a temple.

There are some columns to be seen in Egypt of a very different description to any we have noticed, and to which Mr. Barry has called attention in a note appended to Mr. Gwilt's edition of Chambers; they bear a marked resemblance to the Grecian Doric, and are considered of earlier date than any existing specimen of that order. One illustration represents a portico of two fluted columns in antis, the flutes of which are shallow, and twenty in number, and the capital consists of an abacus only; the height of the column is about $5\frac{1}{2}$ diameters. Another striking example is found at Kalaptchie, on the borders of the Nile, in which, says Mr. Barry, "The abacus is square, and 11 inches thick; the shaft, which has a trifling diminution, is 7 feet 8 inches high, and 3 feet 2 inches diameter. The circumference is in 24 divisions, whereof 4, which are at right angles to each other, are flat faces covered with hieroglyphics, and the other intervening ones are sunk into flat elliptical flutes $\frac{1}{4}$-inch deep."

Another example is to be seen at Amada in Nubia, but here we have two different kinds adjoining each other, which throw some light upon the origin and purport of such columns. In this case the columns are but square piers with a slight projection at top and bottom, for abacus and base, not very different from those already described, as placed behind the Caryatid figures at Ipsambal; the pier at

the angle, however, presents a somewhat different appearance, for while the abacus and base remain as before, the shaft is both circular and fluted, the rounding of the angles seeming to have been effected as a matter of convenience, and the fluting as of ornament. We have already alluded to the not unfrequent occurrence of polygonal shafts, and we cannot help thinking that these, as well as the fluted examples just now described, find a common origin in the square pier of which they are all improvements. We are inclined to coincide with Mr. Barry in the following remarks:—"The general resemblance of the fluted columns to those of the Grecian Doric order, is manifest, and, in addition to many other remarkable indications in the Egyptian temple, clearly points to Egypt as the source of both Greek and Roman architecture." *See* Doric Order, Column.

Having now laid before the reader a general description of the elementary parts and details of Egyptian architecture, as well as of the usual form and distribution of their temples, it is our intention to give some more particular account of the more noted erections, and, in following out this scheme, we cannot do better than give the accounts of the various authorities in their own words.

The principal remains are to be found in Upper Egypt, in the cities lying on both sides of the Nile, but the spot in which they are most numerous and imposing, is in the neighbourhood of Thebes. The following is a list of the larger temples:—

Temple of Jupiter, at Karnac; of Jupiter Ammon; of Apollo, at Apollinopolis Magna; of Osiris, at Tentyra; of Venus; of Thebais, at Knubis. Temples at Luxor, Dendera, Edfou, Esneh, or Latopolis, Hermopolis, Ombos, Syene, Queron, Ipsambul; Caryatic temple, at Rhamesseion, and various temples in the islands of Philæ and Elephantina. In addition to which, we have the tombs and pyramids, the labyrinth, and various monuments, obelisks, and other isolated works.

We have already stated, that the grandest monuments are to be found at Thebes, and, of such, those of Karnac and Luxor take the pre-eminence; they form two separate erections, but are connected together by a long avenue of sphinxes, as hereafter mentioned. We select these two as subjects for the first description, the authorities being Denon and Wilkinson.

For a general description of the temple at Karnac, we shall refer to the French traveller, M. Denon, who, writing at the latter end of the last century (1798-9), says:—

"It is the sumptuousness alone of the Egyptians which is to be seen at Karnac, where not only quarries, but mountains, are piled together, and hewn out into massive proportions, the traits of which are as feebly executed, as the parts are clumsily connected; and these masses are loaded with uncouth bas-reliefs and tasteless hieroglyphics, by which the art of sculpture is disgraced. The only objects there which are sublime, both with regard to their dimensions and the skill which their workmanship displays, are the obelisks, and a few of the ornaments of the outer gates, the style of which is admirably chaste. If in the other parts of this edifice the Egyptians appear to us to be giants, in these latter productions they are geniuses. I am accordingly persuaded that these sublime embellishments were posteriorly added to the colossal monuments of Karnac. It must, however, be granted, that the plan of the temple is noble and grand. . . To the known descriptions of this great edifice of Karnac should be added, that it was but a temple, and could be nothing else. All that exists at present, in a somewhat entire state, relates to a very small sanctuary, and had been disposed in this way to inspire a due degree of veneration, and to become a kind of tabernacle. On beholding the vast extent of these ruins, the imagination is wearied with the idea of describing them. Of the 100 columns of the portico alone of this temple, the smallest are 7½ feet in diameter, and the largest 12. The space occupied by its circumvallation contains lakes and mountains. In short, to be enabled to form a competent idea of so much magnificence, it is necessary that the reader should fancy what is before him to be a dream, as he who views the objects themselves rubs his eyes to know whether he is awake. With respect to the present state of this edifice, it is, however, necessary, at the same time, to observe, that a great part of the effect is lost by its very degraded state. The sphinxes have been wantonly mutilated, with a few exceptions, which barbarism, wearied with destroying, has spared, and, on examining which, it is easy to distinguish, that some of them had a woman's head, others that of a lion, a ram, a bull, &c."

For the following more particular description of this temple, we are indebted to Sir I. G. Wilkinson.

"The principal entrance of the grand temple lies on the north-west side, or that facing the river. From a raised platform commences the avenue of Criosphinxes, leading to the front propyla, before which stood two granite statues of a Pharaoh. One of these towers retains a great part of its original height, but has lost its summit and cornice. In the upper part, their solid walls have been perforated through their whole breadth, for the purpose of fastening the timbers that secured the flag-staffs usually placed in front of these propyla; but no sculptures have ever been added to either face, nor was the surface yet levelled to receive them. Passing through the pylon of these towers, you arrived at a large open court, 275 feet by 329, with a covered corridor on either side, and a double line of columns down the centre. Other propyla terminate this area with a small vestibule before the pylon, and form the front of the grand hall, 170 feet by 329, supported by a central avenue of 12 massive columns, 66 feet high (without the pedestal and abacus), and 12 in diameter; besides 122 of smaller, or rather less gigantic dimensions, 41 feet 9 inches in height, and 27 feet 6 inches in circumference, distributed in seven lines on either side of the former. Other propyla close the inner extremity of this hall, beyond which are two obelisks, one still standing on its original site, the other having been thrown down and broken by human violence. A small propylon succeeds to this court, of which it forms the inner side; the next contains two obelisks of larger dimensions, being 92 feet high and 8 square, surrounded by a peristyle, if I may be allowed the expression, of Osiride figures. Passing between two dilapidated propyla, you enter another smaller area, ornamented in a similar manner, and succeeded by a vestibule, in front of the granite gateway of the pyramidal towers, which form the façade of the court of the sanctuary. This last is also of red granite, divided into two apartments, and surrounded by numerous chambers of small dimensions, varying from 29 feet by 16, to 16 feet by 8. A few polygonal columns, of the early date of Osirtesen I., the contemporary of Joseph, appear behind these in the midst of fallen architraves of the same era, and two pedestals of red granite crossing the line of direction in the centre of the open space to the south-east, are the only objects worthy of notice, until you reach the column or edifice of the third Thothmes. The exterior wall of this building is entirely destroyed, except on the north-east side; to it succeeds a circuit of thirty-two pillars, and within this square are twenty columns, disposed in two lines, parallel to the outer walls, and to the back and front row of pillars. Independent of the irregular position of the latter with regard to the columns of the centre, an unusual caprice has changed the established order of the architectural details, and capitals and cornices are reversed, without adding to the beauty or increasing the strength of the building. A series of smaller halls and chambers terminates the extremity of the temple, one of which is remarkable as containing the names of the early predecessors of Thothmes III., their founder. In the western lateral adytum are the vestiges of a colossal hawk seated on a raised pedestal; the sculptures within and without containing the name of Alexander, by whose order this was repaired and sculptured.

"The total dimensions of this part of the temple behind the inner propyla of the grand hall, are 600 feet, by about half that in breadth, making the total length, from the front propyla to the extremity of the wall of circuit, inclusive, 1,180 feet. The additions made at different periods, by which the distant portions of this extensive mass of buildings were united, will be more readily understood from an examination of the survey itself than from any description, however detailed, I could offer to the reader; and from this it will appear that Diodorous is fully justified in the following statement: that 'the circuit of the most ancient of the four temples at Thebes measured thirteen stadia,' or about one mile and two-thirds English; the thickness of the walls, 'of 25 feet,' owing to the great variety in their dimensions, is too vague to be noticed; but the altitude of the building, to which he allows only 45 cubits, falls far short of the real height of the grand hall, which, from the pavement to the summit of the roof, inclusive, is not less than 80 feet."

The next description of Luxor is from the same writer:—

"Luqsor, which occupies part of the site of ancient Diospolis, still holds the rank of a market-town, the residence of a Kàshef, and head-quarters of a troop of Turkish cavalry. Its name signifies the Palaces, and some might perhaps feel inclined to trace in that of El Qasryn, or El Uqsorayn, (the dual of the word Qasr,) by which it is sometimes designated, the existence of the two distinct parts of this building, erected by Amunoph III. and Remeses II. The former monarch, who, at the time of its foundation, appears to have reigned conjointly with his brother, built the original sanctuary and circumjacent chambers, with the addition of the large colonnade and pylon before it, to which Remeses II. afterwards added the great court, the pyramidal towers, or propyla, and the obelisks and statues.

"These, though last in the order of antiquity, necessarily form the present commencement of the temple, which, like many others belonging to different epochs, is not 'two separate edifices,' but one and the same building. A dromōs, connecting it with Karnak, extended in front of the two beautiful obelisks of red granite, whose four sides are covered with a profusion of hieroglyphics, no less admirable for the style of their execution, than for the depth to which they are engraved, which in many instances exceeds two inches.

"Two sitting statues of the same Remeses are placed behind these, one on either side of the pylon; but, like the obelisks, are much buried in the earth and sand accumulated around them. Near the north-west extremity of the propyla, another similar colossus rears its head amidst the houses of the village, which also conceal a great portion of the interesting battle-scenes on the front of these towers. At the doorway itself is the name of Sabaco, and on the abacus of the columns beyond, that of Ptolemy Philopater, both added at a later epoch.

"The area, whose dimensions are about 190 feet by 170, is surrounded by a peristyle, consisting of two rows of columns, now almost concealed by the hovels and mosk of the village. The line of direction no longer continues the same behind this court, the Remessean front having been turned to the eastward, in order to facilitate its connection with the great temple of Karnak, rather than to avoid the vicinity of the river, as might at first be supposed.

"Passing through the pylon of Amunoph you arrive at the great colonnade, where the names of this Pharaoh and his brother are sculptured. The latter, however, has been effaced, probably by order of the surviving monarch, as is generally the case wherever it is met with, and those of the immediate successor of Amunoph III. and of Osirei are introduced in its stead.

"The length of the colonnade to the next court is about 170 feet, but its original breadth is still uncertain, nor can it be ascertained without considerable excavation. To this succeeds an area of 155 feet by 167 surrounded by a peristyle of 12 columns in length and the same in breadth, terminating in a covered portico of 32 columns 57 feet by 111.

"Behind this is a space occupying the whole breadth of the building, divided into chambers of different dimensions, the centre one leading to a hall supported by 4 columns, immediately before the entrance to the isolated sanctuary.

"On the east of this hall is a chamber containing some curious sculpture, representing the accouchement of queen Maut-m-shoi, the mother of Amunoph and his brother; the two children nursed by the deity of the Nile, and presented to Amun, the presiding divinity of Thebes; and several other subjects relating to their education and subsequent history.

"The sanctuary, which had been destroyed by the Persians, was rebuilt by Alexander (the son of Alexander, Ptolemy being governor of Egypt,) and bears his name in the following dedicatory formula:

"'This additional work made he, the king of men, lord of the regions, Alexander, for his father Amunre, president of Tape (Thebes;) he erected to him the sanctuary, a grand mansion, with repairs of sand-stone, hewn, good, and hard stone, instead of his —— majesty, the king of men, Amunoph.' Behind the sanctuary are two other sets of apartments, the larger ones supported by columns, and ornamented with rich sculpture, much of which appears to have been gilded.

"Behind the temple is a stone quay, of the late era of the Ptolemies or Cæsars, since blocks bearing the sculpture of the former have been used in its construction. Opposite the corner of the temple, it takes a more easterly direction, and points out the original course of the river, which continued across the plain now lying between it and the ruins of Karnak, and which may be traced by the descent of the surface of that ground it gradually deserted. The southern extremity of this quay is of brick, and indicates in like manner the former direction of the stream, which now, having formed a recess behind it, threatens to sweep away the whole of its solid masonry, and to undermine the foundations of the temple itself.

The road to Karnak lies through fields of *halfeh* indicating the site of ancient ruins, and here and there, on approaching that magnificent building, the direction of the avenue, and the fragments of its sphinxes, are traced in the bed of a small canal, or watercourse, which the Nile, during the inundation, appropriates to its rising stream. To this succeeds another dromos of Criosphinxes, and a majestic pylon of Ptolemy Euergetes, with his queen and *sister* Berenice, who in one instance present an offering to their predecessors and parents, Philadelphus and Arsinöe. In one of the compartments within the doorway, the king is represented in a Greek costume, of which there are some other instances in Ptolemaic ruins. Another avenue of sphinxes extends to the propyla of the isolated temple behind this gateway, which was founded by Remeses IV., and continued by Remeses VIII., and a late Pharaoh, who added the hypæthral area and the propyla. His name, and the exact era at which he flourished, are not precisely ascertained; but if, as is very probable, we are authorized to read Bocchoris, this part will date in the time of the twenty-fourth dynasty, or about 810 B.C. Other names appear in different parts of the building, among which are those of Amyrteus and Alexander on the inner and outer gateways of the area."

Having made this digression in favour of Karnac and Luxor, we will now continue our descriptions, taking our examples in geographical order, commencing at the northern extremity of Upper Egypt, and travelling southwards. The first remains of which we have any notice are those of Hermopolis Magna, but they are little better than mounds of ruins, the portico described by Denon having been demolished. This portico was of great merit, and consisted of twelve columns in two rows of six each, surmounted with cornice and entablature. The next place we arrive at is Dendera, the ancient Tentyris, which contains ruins of several temples. The following account is given by Wilkinson.

"The name of Tentyris, or Tentyra, (in Coptic Tentoré, or Nikentore.) seems to have originated in that of the goddess Athor or Aphrodite, who was particularly worshipped there; and that the principal temple was dedicated to that goddess, we learn from the hieroglyphics, as well as from a Greek inscription of the time of Tiberius, in whose reign its magnificent portico was added to the original building. Egyptian sculpture had long been on the decline before the erection of this temple; and the Egyptian antiquary looks with little satisfaction on the graceless style of the figures, and the crowded profusion of ill-adjusted hieroglyphics, that cover the walls of Ptolemaic and Roman monuments; but architecture still retained the grandeur of an earlier period; and though the capitals of the columns were frequently overcharged with ornament, the general effect of the porticos erected under the Ptolemies and Cæsars, is grand and imposing, and frequently not destitute of elegance and taste. The same remarks apply to the temple of Dendera; and from its superior state of preservation, it deserves a distinguished rank among the most interesting monuments of Egypt. For though its columns, considered singly, may be said to have a heavy, and perhaps a grotesque, appearance, the portico is doubtless a noble specimen of architecture; nor is the succeeding hall devoid of beauty and symmetry of proportion. On the ceiling of the *pronaos*, or portico, is the Zodiac, which has led to much learned controversy, and which has at length, through the assistance of the Greek inscription, and the hieroglyphical names of the Cæsars that cover its exterior and interior walls, been confined to the more modest and probable antiquity of eighteen hundred years.

"The details of the cornice offer a very satisfactory specimen of the use of triglyphic ornament, which is common in many of the oldest Pharaohnic temples, though arranged in a somewhat different manner, and without so remarkable a metope as in the present instance.

"On the frieze, or rather architrave, is a procession to Athor, and among the figures that compose it are two playing the harp, and another with the tambourine. The inscription is on the projecting summit of the cornice, and commences with the name of the emperor Tiberius. Those of Aulus Avillius Flaccus, the military governor or prefect, and Aulus Fulmius Crispus, commander of the forces, though purposely erased, are still traced when the sun strikes obliquely on the surface of the stone; but the date of the emperor's reign is unfortunately lost.

"The small planisphere which was in one of the lateral chambers on the right-hand side of the temple, and behind the pronaos, has been removed to France, and from its position it probably dated a few years before the Zodiac. Numerous are the names of Cæsars in this temple. In the portico may be distinguished those of Tiberius, Caligula, Claudius, and Nero, and on the former front of the temple, now the back of the pronaos, are those of Augustus and Caligula. This was in fact the original extent of the building, and it was previous to the addition of the portico that it was seen by Strabo.

"The oldest names are of Ptolemy Cæsarion, or Neocæsar, and Cleopatra, who are represented on the back wall of the exterior; and it is probable that the whole *naos* was the work of the Ptolemies, though the sculptures remained unfinished till the reign of Tiberius, who, having erected the portico, added many of the hieroglyphics on the exterior walls.

"The portico is supported by twenty-four columns, and is open at the front, above the screens that unite its six columns; and in each of the side-walls is a small doorway.

"To this succeeds a hall of six columns, with three rooms on either side; then a central chamber, communicating on one side with two small rooms, and on the other with a staircase. This is followed by another similar chamber (with two rooms on the west, and one on the east side) immediately before the isolated sanctuary, which has a passage leading round it, and communicating with three rooms on either side. The total length of this temple is 93 paces (or about 220 feet,) by 41, or, across the portico, 50.

"In front of the temple was the dromos, extending for the distance of 110 paces to an isolated pylon, bearing the names of Domitian and Trajan. The attributes of Athor throughout this building very much resemble those of Isis; and she is in like manner represented nursing the young child Harpocrates, who is said, in the hieroglyphics, to be the 'son of Athor.'

"'Behind the temple of Venus,' says Strabo, 'is the chapel of Isis:' and this observation agrees remarkably well with the size and position of the small temple of that goddess; as it consists merely of one central and two lateral adyta, and a transverse chamber or corridor in front, and stands immediately behind the south-west angle of that of Athor. To it belonged the pylon that lies 170 paces to the eastward, and which, as we learn from a Greek inscription on either face of its cornice, was dedicated to Isis, in the thirty-first year of Cæsar (Augustus); Publius Octavius being military governor or prefect, and Marcus Claudius Posthumus, commander of the forces. In the hieroglyphics, besides the name of Augustus, are those of Claudius and Nero.

"Ninety paces to the north of the great temple of Athor is another building, consisting of two outer passage-chambers, with two small rooms on either side of the outermost one, and a central and two lateral adyta, the whole surrounded, except the front, by a peristyle of twenty-two columns. The capitals, ornamented or disfigured by the representation of a Typhonian monster, have led to the supposition that this temple was dedicated to the evil genius; but as the whole of its sculptures refer to the birth of Harpocrates, it is evident that it appertains to the great temple of Athor, who is here styled his mother; and it may be said rather to be dedicated to Harpocrates than to Typhon, who is only introduced in a subordinate character, as relating to the young deity. The names are of Trajan, Adrian, and Antoninus Pius.

"Around these buildings extends a spacious enclosure of crude brick, about 240 paces square, having two entrances, one at the pylon of Isis, the other at that before the great temple.

"About 230 paces in front of the pylon of Athor is an isolated hypæthral building consisting of fourteen columns, united by intercolumnar screens, with a doorway at either end; and a short distance to the south is the appearance of an ancient reservoir. A little to the north-east of it are other remains of masonry; but the rest of the extensive mounds of Tentyris present merely the ruins of crude brick houses, many of which are of Arab date.

"Five hundred paces east of the pylon of Isis is another crude brick enclosure, with an entrance of stone similar to the other pylons, bearing the name of Antoninus Pius. Over the face of the gateway is a singular representation of the sun, with its sacred emblem the hawk, supported by Isis and Nephthys. This enclosure is about 155 paces by 265, and at the south-east corner is a well of stagnant water.

"The town stood between this and the enclosure of the temples, and extended on either side, as well as within the circuit of the latter; but on the north-west side appear to be the vestiges of tombs.

"Between the town and the edge of the sandy plain to the south, is a low channel, which may once have been a canal; and it is not improbable that it was to this that the Tentyrites owed their insular situation mentioned by Pliny."

We next arrive at Kous, the site of the ancient Apollinopolis Parva, but the only distinguishable remains of the temple there consist of a large gate; proceeding therefore southward, we arrive at Thebes, the temples of which we have already described. On the opposite side of the river, however, we have several buildings worthy of note, of which the first is that of Qórneh or Kurnu, of which Wilkinson speaks thus:—

"To commence with the ruins nearest the river:—the first object worthy of notice is the small temple and palace at old Qórneh, dedicated to Amun, the Theban Jupiter, by Osirei, and completed by his son Remeses II., the supposed Sesostris of the Greeks. Its plan, though it evinces the usual symmetrophobia of Egyptian monuments, presents a marked deviation from the ordinary distribution of the parts which compose it. The entrance leads through a pyloné, or pylon, bearing, in addition to the name of the founder, that of Remeses III., beyond which is a dromos of 128 feet, whose mutilated sphinxes are scarcely traceable amidst the mounds and ruins of Arab hovels. A second pylon terminates this, and commences a second dromos of nearly similar length, extending to the colonnade or corridor in front of the temple, whose columns of one of the oldest Egyptian orders are crowned by an abacus, which appears to unite the stalks of waterplants that compose the shaft and capital.

"Of the intercolumniations of these ten columns, three only agree in breadth, and a similar discrepancy is observed in the doorways which form the three entrances to the building. The temple itself presents a central hall about fifty-seven feet in length, supported by six columns, having on either side three small chambers, one of which leads to a lateral hall, and the opposite one to a passage and open court on the east side. Upon the upper end of the hall open five other chambers, the centre one of which leads to a large room supported by four square pillars, beyond which was the sanctuary itself; but the dilapidated state of the north end of this temple affords but little to enable us to form an accurate restoration of the innermost chambers. The lateral hall on the west, which belonged to the palace of the king, is supported by two columns, and leads to three other rooms, behind which are the vestiges of other apartments; and on the east side, besides a large hypæthral court, were several similar chambers extending also to the northern extremity of its precincts."

The next building that attracts our notice is the Memnonium, and tomb of Osmandyas, of which ancient authors have given us such wonderful accounts; we give that of Diodorus Siculus:—

"Ten stadia from the tombs of the kings of Thebes," says this historian, "one admires that of Osimondué. The entrance to it is formed by a vestibule built with various-coloured stones. It is 200 feet long and 68 in elevation. On coming thence one enters under a square peristyle, each side of which is 400 feet long. Animals formed of blocks of granite 24 feet high, serve as columns to it, and support the ceiling, which is composed of squares of marble of 27 feet every way. Stars of gold, upon an azure ground, shine there the whole length of it. Beyond this peristyle opens another entry, followed by a vestibule built like the former, but more loaded with all sorts of sculpture. Before it are three statues formed of single stones, and hewn by Memnon Syenite. The principal one, which represents the king, is seated. It is the largest in Egypt; one of his feet, accurately measured, exceeds seven cubits. The two others, borne on his knees, one on the right, the other on the left, are those of his mother and his daughter. The whole work is less remarkable for its enormous size, than for the beauty of the execution and the choice of the granite, which in so extensive a surface has neither spot nor blemish. The colossus has this inscription:—'*I am Osimondué, the King of Kings; if any one wishes to know how great I am, and where I repose, let him destroy some of these works.*' Besides this, we see another statue of his mother, cut out of a single block of granite, and 30 feet high. Three queens are sculptured on the head, to show that she was daughter, wife, and mother, of a king.

"At the end of this portico, one enters into a peristyle more beautiful than the former. On a stone is engraved the history of the war of Osimondué against the revolted inhabitants of Bactria. The façade of the front wall shows this prince attacking ramparts, at the foot of which runs a river. He combats advanced troops, having by his side a terrible lion, which defends him with ardour. The wall on the right presents captives in chains, their hands and private parts cut off, in order to stigmatize their cowardice. On the wall to the left, different symbolical figures, very well sculptured, recall the triumphs and the sacrifices of Osimondué on his return from this war. In the middle of the peristyle, at the place where it is exposed, an altar was prepared, composed of a single stone of marvellous size, and of exquisite workmanship. In short, against the bottom wall, two colossuses, each of them of one block of marble, and 40 feet high, are seated on their pedestals. One comes out of this admirable peristyle by three gates; one of them between two statues, the two others are on the sides; they lead to an edifice 200 feet long, the roof of which is supported by 8 columns. It resembles a magnificent theatre; several figures in wood represent a senate employed in distributing justice. On one of the walls one observes 30 senators, and in the midst of them the president of justice, having at his feet a collection of books, and the figure of Truth with her eyes shut, suspended at his neck. One passed thence into a square surrounded by palaces of different forms, where were seen carved on the table all sorts of dishes which could flatter the taste. In one of them, Osimondué, clad in a magnificent dress, was offering to the gods the gold and silver he drew yearly from the mines of Egypt. Below was written the value of this revenue, which amounted to 32 millions of silver minas. Another palace contained the sacred library, at the entrance of which, one read these words: *Remedies for the Soul.* A third contained all the divinities of Egypt, with the king, who offered to each of them the suitable presents; calling Osiris, and the princes his predecessors, to witness that he had exercised piety towards the gods and justice towards men. By the side of the library, in one of the most beautiful buildings of the place, were to be seen twenty tables surrounded by their beds, on which reposed the statues of Jupiter, Juno, and Osimondué. His body is thought to be deposited in this place. Several adjoining buildings preserved the representations of all the sacred animals of Egypt. From these apartments one mounted to the king's tomb, on the top of which was placed a crown of gold, a cubit wide, and 365 round. Each cubit answered to one day of the year, and the rising and setting of the stars for that day was engraven on each of them, with such astrological observations as the superstition of the Egyptians attached to them. It is said that Cambyses carried off this circle when he ravaged Egypt. Such, according to historians, was the tomb of Osimondué, which surpassed all others, both by its extent, and by the labour of the able artists employed on it."

Upon this passage Savary remarks, "I dare not take upon me to warrant all these facts, advanced by Diodorus Siculus on the authority of preceding writers; for in his time the principal part of these buildings no longer existed. I admit even that all these wonderful descriptions would pass for pure chimeras in any other country; but in this fruitful land, which seems to have been first honoured with the creative genius of the arts, they acquire a degree of probability. Let us examine what remains to us of these monuments, and our eyes will compel us to believe in prodigy. Their ruins are in heaps, near to *Medinet Abou*, in the space of half a league's circumference. The temple, the peristyles, the vestibules, present to the eye nothing but piles of ruins, amongst which rise up some pyramidal gates, whose solidity has preserved them from destruction; but the numerous colossuses described by Diodorus, are still subsisting, though mutilated. That which is nearest to these ruins, composed of yellow marble, is buried two-thirds of its height in the earth. There is another in the same line, of black and white marble, the back of which is covered with hieroglyphics for 30 feet in length. In the space betwen them, trunks of columns and broken statues cover the ground, and mark the continuation of the vestibules. Farther on we distinguish two other colossal statues, totally disfigured. A hundred toises from them, the traveller is struck with astonishment at the sight of two colossuses, which, like rocks, are seated by the side of each other. Their pedestals are nearly equal, and formed of blocks of granite 30 feet long, and 18 feet wide. The smallest of these colossuses is also of a single block of marble; the other, which is the largest in Egypt, is formed of five courses of granite, and broken in the middle; it appears to have been the statue of Osimondué, for one sees two figures cut in *relievo*, the length of his legs, and which are about one-third of his height. These are the mother and the daughter of this prince. The other colossus, which is of one stone, and which corresponds with the dimensions of Diodorus Siculus, represented also the mother of the king. To give you an idea of the gigantic stature of the great colossus, it is enough to tell you, that his foot alone is near 11 feet long, which answers exactly to the seven cubits of Diodorus. This statue, the half of which remains upon its base, and is what Strabo calls the statue of Memnon, uttered a sound at the rising of the sun. It possessed formerly great renown. Several writers have spoken of it with enthusiasm, regarding it as one of the seven wonders of the world. A multitude of Greek and Latin inscriptions, that are still legible, on the base and the legs of the colossus, testify that princes, generals, governors, and men of every condition, have heard this miraculous sound."

The following account of a portion of the above, which is given somewhat more in detail, is from Wilkinson.

"Following the edge of the cultivated land, and about 180 yards to the west of this building, are two mutilated statues of Remeses II., of black granite, with a few substructions to the north of them; and 770 yards farther to the west, lies, in the cultivated soil, a sandstone block of Remeses III., presenting in high relief the figure of that king, between Osiris and Pthah; 1,400 feet beyond this, in the same direction, is a crude brick enclosure, with large towers, which once contained within it a sandstone temple, dating probably from the reign of the third Thothmes, whose name is stamped on the bricks, and who appears to have been the contemporary of Moses.

"Other fragments and remains of crude brick walls proclaim the existence of other ruins in its vicinity; and about 1,000 feet farther to the south-west, is the palace and temple of Remeses II., erroneously called the Memnonium: a building which, for symmetry of architecture and elegance of sculpture, can vie with any other monument of Egyptian art. No traces are visible of the dromos, that probably existed before the pyramidal towers which form the façade of the first hypæthral area, a court whose breadth of 180 feet, exceeding the length by nearly 13 yards, is reduced to a more just proportion, by the introduction of a double avenue of columns on either side, extending from the towers to the north wall. In this area, on the right of a flight of steps leading to the next court, was the stupendous Syenite statue of the king seated on a throne, in the usual attitude of these Egyptian figures, the hands resting on his knees, indicative of that tranquillity which he had returned to enjoy in Egypt, after the fatigues of victory. But the fury of an invader has levelled this monument of Egyptian grandeur, whose colossal fragments lie scattered around the pedestal, and its shivered throne evinces the force used for its demolition.

"If it is a matter of surprise how the Egyptians could transport and erect a mass of such dimensions, the means employed for its ruin are scarcely less wonderful; nor should we hesitate to account for the shattered appearance of the lower part by attributing it to the explosive force of powder, had that composition been know at the period of its destruction. The throne and legs are completely destroyed, and reduced to comparatively small fragments, while the upper part, broken at the waist, is merely thrown back upon the ground, and lies in that position which was the consequence of its fall; nor are there any marks of the wedge, or other instrument, which should have been employed for reducing those fragments to the state in which they now appear. The fissures seen across the head, and in the pedestal, are the work of a later period, when some of these blocks were cut for millstones by the Arabs, but its previous overthrow will probably be coeval with the Persian invasion. To say that this is the largest statue in Egypt, will convey no idea of the gigantic size or enormous weight of a mass, which, from an approximate calculation, exceeded, when entire, nearly three times the solid content of the great obelisk of Karnak, and weighed about 887 tons, 5 hundredweight and a half.

"No building in Thebes corresponds with the description given of the tomb of Osymandyas by Hecatæus. Diodorus, who quotes his work, gives the dimensions of the first or outer court, two plethra, or 181 feet 8 inches English, agreeing very nearly with the breadth, but not the length of that now before us; but the succeeding court, of four plethra, neither agrees with this, nor can agree with that of any other Egyptian edifice; since the plan of an Egyptian building invariably requires a diminution, by no increase of dimensions, from the entrance to the inner chambers; and while the body of the temple, behind the portico, retained one uniform breadth, the areas in front, and frequently the portico itself, exceeded the inner portion of it by their projecting sides. The peristyle and 'columns in the form of living beings,' roofed colonnade, sitting statues, and triple entrance to a chamber supported by columns, agree well with the approach to the great hall of this temple. The largest statue in Egypt can scarcely be looked for but in the building before us, yet the sculptures to which he alludes, remind us rather of those of Medeenet Hábo; nor is it impossible that either Hecatæus or Diodorus have united or confounded the details of these two edifices.

"The second area is about 140 feet by 170, having on the south and north sides a row of Osiride pillars, connected with each other by two lateral corridors of circular columns. Three flights of steps lead to the northern corridor behind the Osiride pillars, the centre one having on each side a black granite statue of Remeses II., the base of whose throne is cut to fit the talus of the ascent. Behind these columns, and on either side of the central door, is a limestone pedestal, which, to judge from the space left in the sculptures, must have once supported the sitting figure of a lion, or perhaps a statue of the king. Three entrances thence open into the grand hall, each strengthened and beautified by a sculptured doorway of black granite, and between the two first columns of the central avenue, two pedestals supported (one on either side) two other statues of the king. Twelve massive columns form a double line along the centre of this hall, and eighteen of smaller dimensions, to the right and left, complete the total of the forty-eight which supported its solid roof, studded with stars on an azure ground. To the hall, which measures 100 feet by 133, succeeded three central and six lateral chambers, indicating, by a small flight of steps, the gradual ascent of the rock on which this edifice is constructed. Of nine, two only of the central apartments now remain, each supported by four columns, and each measured about 30 feet by 55; but the vestiges of their walls, and appearance of the rock, which has been levelled to form an area around the exterior of the building, point out their original extent. The sculptures, much more interesting than the architectural details, have suffered still more from the hand of the destroyer; and of the many curious battle-scenes which adorned its walls, four only now remain."

Still southward is the village of Medeenet Haboo, which contains the ruins of two temples, of which we have not space to give a particular account. The smaller one consists of an open area 125 feet by 80, the north side being formed of a row of eight columns, through which access is obtained to a transverse area, having two pyramidal towers at its extremity, and between them an entrance into an hypæthral court with similar towers. These lead into a court 60 feet long, with a colonnade on either side, and at its extremity an entrance into the sanctuary, which is surrounded by colonnades and chambers. The larger edifice is approached through a dromos 265 feet in length, at the end of which are two propylæa leading into a large hypæthral court. At the further side of this court an entrance through pylons is given into a very fine peristyle court 123 feet by 133 feet, at the extremity of which is the portico. The large court contains specimens of Caryatid columns.

We now arrive at a different class of buildings—the tombs or catacombs, which consist of subterranean apartments and passages excavated out of the rock, and extending over a vast tract of land in the neighbourhood of Thebes, near Kurnu. The two following descriptions are from the writer previously quoted; the first relates to one of the tombs of the kings, which was first opened by Belzoni:—

"The tomb, which of all others stands pre-eminently conspicuous, as well for the beauty of its sculpture as the state of its preservation, is undoubtedly that discovered and opened by Belzoni. But the plan is far from being well regulated, and the deviation from one line of direction greatly injures its general effect; nor does the rapid descent by a staircase of twenty-four feet in perpendicular depth, on a horizontal length of twenty-nine, convey so appropriate an idea of the entrance to the abode of death, as the gradual talus of other of these sepulchres. To this staircase succeeds a passage of eighteen feet and a half by nine, including the imposts; and, passing another door, a second staircase descends in horizontal length twenty-five feet; beyond which two doorways, and a passage of twenty-nine feet, bring you to an oblong chamber twelve feet by fourteen, where a pit, filled up by Belzoni, once appeared to form the utmost limit of the tomb. Part of its inner wall was composed of blocks of hewn stone, closely cemented together, and covered with a smooth coat of stucco, like the other walls of this excavated catacomb, on which was painted a continuation of those subjects that still adorn its remaining sides.

"Independent of the main object of this well, so admirably calculated to mislead, or at last check, the search of the curious and the spoiler, another advantage was thereby gained in the preservation of the interior part of the tomb, which was effectually guaranteed from the destructive inroad of the rain-water, whose torrent its depth completely intercepted; a fact which a storm, some years ago, by the havoc caused in the inner cambers, sadly demonstrated.

"The hollow sound of the wall above-mentioned, and a small aperture, betrayed the secret of its hidden chambers, and a palm-tree, supplying the place of the more classic ram, forced, on the well-known principle of that engine, the intermediate barrier, whose breach displayed the splendour of the succeeding hall, at once astonishing and delighting its discoverer, whose labours were so gratefully repaid.

"Its four pillars, supporting a roof twenty-six feet square, are decorated, like the whole of the walls, with highly-finished and well-preserved sculptures, which, from their vivid colours, appear but the work of yesterday; and near the centre of the inner wall, a few steps lead to a second hall of similar dimensions, supported by two pillars, but left in an unfinished state, the sculptors not having yet commenced the outline of the figures the draughtsmen had but just completed. It is here that the first deviations from the general line of direction occur, which are still more remarkable in the staircase that descends at its southern corner.

"To this last succeed two passages, and a chamber seventeen feet by fourteen, communicating by a door, *nearly* in the centre of its inner wall, with the grand hall, which is twenty-seven feet square, and supported by six pillars. On either side is a small chamber opposite the angle of the first pillars, and the upper end terminates in a vaulted saloon, nineteen feet by thirty, in whose centre stood an alabaster sarcophagus, the kenotaph of the deceased monarch, upon the immediate summit of an inclined plane, which, with a staircase on either side, descends into the heart of the argillaceous rock for a distance of a hundred and fifty feet. This, like the entrance of the tomb and the first hall, was closed and concealed by a wall of masonry, which, coming even with the base of the sarcophagus, completely masked the staircase it covered and levelled with the floor.

"A small chamber and two niches are perforated in the north-west wall; at the upper end a step leads to an unfinished chamber, 17 feet by 43, supported by a row of four pillars; and on the south-west are other niches and a room about 25 feet square, ornamented with two pillars and a broad bench (hewn, like the rest of the tomb, in the rock) around three of its sides, four feet high, with four shallow recesses on each face, and surmounted by an elegant Egyptian cornice. It is difficult to account for the purport of it, unless its level summit served as a repository for the mummies of the inferior persons of the king's household; but it is more probable that these were also deposited in pits.

"The total horizontal length of this catacomb is 320 feet, without the inclined descent below the sarcophagus, and its perpendicular depth 90, or, including that part, about 180 feet, to the spot where it is closed by the fallen rock."

The second description is of tombs of more recent date, executed during the twenty-sixth dynasty, in the seventh century before our era; they are of great extent, and unusual uniformity.

"The smallest, which are those behind the palace of Remeses, commence with an outer court decorated by a peristyle of pillars, and to this succeeds an arched entrance to the tomb itself, which consists of a long hall, supported by a double row of four pillars, and another of smaller dimensions beyond it, with four pillars in the centre. The largest of them, and indeed of *all* the sepulchres of Thebes, are those in the Assaseef, one of which far exceeds in extent any one of the tombs of the kings. Its outer court, or area, is 103 feet by 76, with a flight of steps descending to its centre from the entrance, which lies between two massive crude brick walls, once supporting an arched gateway. The inner door, cut like the rest of the tomb in the limestone rock, leads to a second court, 53 feet by 67, with a peristyle of pillars on either side, behind which are two closed corridors; that on the west containing a pit and one small square room, the opposite one having a similar chamber, which leads to a narrow passage, once closed in two places by masonry, and evidently used for a sepulchral purpose.

"Continuing through the second area you arrive at a porch, whose arched summit, hollowed out of the rock, has the light form of a small segment of a circle, and from the surface of the inner wall are relieved the cornice and mouldings of an elegant doorway.

"This opens on the first hall, 53 feet by 37, once supported by a double line of four pillars, dividing the nave (if I may so call it) from the aisles, with half-pillars, as usual, attached to the end-walls. Another ornamented doorway leads to the second hall, 32 feet square, with two pillars in each row, disposed as in the former. Passing through another door, you arrive at a small chamber, 21 feet by 12, at whose end-wall is a niche, formed of a series of jambs, receding successively to its centre. Here terminates the first line of direction. A square room lies on the left (entering), and on the right another succession of passages, or narrow apartments, leads to two flights of steps, immediately *before* which is another *door* on the right. *Beyond* these is another passage, and a room containing a pit 45 feet deep, which opens at about one-third of its depth on a lateral chamber.

"A third line of direction, at right angles with the former, turns to the right, and terminates in a room, at whose upper end is a squared pedestal.

"Returning through this range of passages, and re-ascending the two staircases, the *door* above alluded to presents itself on the left hand. You shortly arrive at a pit (opening on another set of rooms, beneath the level of the upper ground-plan), and after passing it, a large square, surrounded by long passages, arrests the attention of the curious visitor. At each angle is the figure of one of the eight following goddesses:—Neith, Sate, Isis, Nephthys, Netpe, Justice, Selk, and Athor, who, standing with outspread arms, preside over and protect the sacred inclosure, to which they front, and are attached.

"A gentleman, an author, whose reading is far more respectable than his judgment, has not failed to discover something extraordinary in the position of these figures, referring, as he supposes, to the crucifix, adopted by the Christians.

"Eleven niches, in six of which are small figures of different deities, occur at intervals on the side-walls, and the summit is crowned by a frieze of hieroglyphics. Three chambers lie behind this square, and the passage which goes round it *descends* on that side, and rejoins, by an *ascending* talus on the next, the level of the front. A short distance further terminates this part of the tomb, but the above-mentioned pit communicates with a subterranean passage opening on a vaulted chamber, from whose upper extremity another pit leads, *downwards*, to a second, and ultimately through the ceiling of the last, *upwards*, to a third apartment, coming immediately below the centre of the square above noticed. This has one central niche, and seven on either side, the whole loaded with hieroglyphical sculptures, which cover the walls in every part of this extensive tomb.

"But to give an idea of its length, and, consequently, of the profusion of its ornamental details, I shall briefly state the total extent of each series of the passages both in the upper and under part of the excavation. From the entrance of the outer area to the first deviation from the original right line, is 320 feet. The total of the next range of passages to the chamber of the great pit, is 177 feet. The third passage, at right angles to this last, is 60 feet; that passing over the second pit, is 125; and adding to these three of the sides of the isolated square, the total is 862 feet, independent of the lateral chambers.

"The area of the actual excavation is 22,217 square feet, and with the chambers of the pits 23,809, though, from the nature of its plan, the ground it occupies is nearly one acre and a quarter, an immoderate space for the sepulchre of one individual, even allowing that the members of his family shared a portion of its extent."

At Hermontis, a short distance south of Thebes, are the ruins of a small temple, consisting of a colonnaded court with portico and sanctuary, and some distance beyond this, more extensive remains at Esneh, or Latopolis, but the only portion uncovered is a portico of considerable pretensions. Passing by several monuments more or less remarkable, we arrive at Edfou, or Apollinopolis Magna, the temple of which has already been described; and beyond this, at Ombos, where are ruins of two temples, one of which is remarkable for having a double entrance, and two sanctuaries side by side. In our way to the islands of Philöe and Elephantina, we would stop for a moment at Syene to notice the quarries of granite from which a great portion of the stone for building was supplied, previous to the working of the quarries near Philöe. The islands of Philöe and Elephantina are rich in remains, but more especially the former, which we accordingly select for illustration. Denon says:—

"As soon as I could set foot in the island (Philöe) I began first by going over all the inner part, to take a general survey of the various monuments, and to form a kind of topographical chart, containing the island, the course of the river, and the adjacent characteristic scenery. I found a convincing proof that this group of monuments had been constructed at different periods, by several nations, and had belonged to different forms of religious worship; and the union of these various edifices, each of them in itself regular, and crowded together in this narrow spot, formed an irregular group of most picturesque and magnificent objects. I could here distinguish eight sanctuaries or separate temples, of different dimensions, built at various times, and the limits of each had been respected in the construction of the succeeding ones, which had impaired the regularity of the whole. A part of the additions to the original buildings had been made with a view of connecting the old to the new, avoiding, with great dexterity, false angles and general irregularities. This kind of confusion of the architectural lines, which appear like errors in the plan, produce in the elevation a picturesque effect, which geometrical rectitude cannot give; it multiplies objects, forms elegant groups, and offers to the eye more richness than cold symmetry can ever command. I was here able to convince myself of the truth of a remark which I had before made at Thebes and Tentyra, which is, that the mode of building with the ancient Egyptians was, first, to erect large masses, on which they afterwards bestowed the labour of ages in the particulars of the decoration, beginning their work with shaping the architectural lines, proceeding next to the sculpture of the hieroglyphics, and concluding with the stucco and the painting. All these distinct periods of work are very obvious here, where nothing is finished but what belongs to the highest antiquity; where, as a part of the subordinate buildings which served to connect the various monuments, had been left in many particulars without finish, without sculpture, and even incomplete in the building. The great and magnificent oblong monument exhibits these different periods of workmanship; it would be difficult to assign any use to this edifice, if the presence of certain monuments representing offerings, had not pointed it out to be a temple. It has, however, the form neither of a portico, nor of a temple; the columns which compose its outer circumference, and which are engaged in the wall only half their height, support nothing but an entablature, and a cornice without roof or platform; it only opened by two opposite doors, without lintels, which made a straight passage through, in a longitudinal direction. As it was doubtless built in the later period of the Egyptian power, it shows the perfection of art in the highest purity; the capitals are admirable in beauty and execution; the volutes and the foliage are gracefully waved, like the finest Greek architecture, and are symmetrically diversified like those of Apollinopolis, that is to say, differing from the contiguous capitals, and similar to the corresponding ones, and all are exactly kept within the same parallel."

This group of buildings is 800 feet long and 420 feet broad, and it is almost entirely covered with the most stately monuments of different ages. The front is a rampart wall, to serve as a protection against the rising waters of the Nile. The entrance to the temple was approached by a magnificent double range of columns around a court 250 feet long, behind which were rooms for the priests. The pyramidal môles are each 47 feet long, 27 feet thick, and 75 feet high; two rows of gigantic hieroglyphics adorn them, representing five of their grand divinities; there are likewise other figures of priests, &c.; on each side of the door (which is 26 feet high) is an obelisk 18 feet high, and a sphinx 7 feet long. Behind is a court 80 feet long, and 45 feet wide, also flanked by galleries of columns. On the right, behind the columns, is a suite of cells 10 feet deep, and on the left a private dwelling, composed of a portico at each end, and of three rooms of various dimensions, communicating one with another, and opening to the porticos; this is the only building that Denon ever saw of the kind. Two other môles serve as the portal to the most beautiful and regular part of the edifice; this is a species of portico, decorated by 10 columns and 8 pilasters 4 feet in diameter, as magnificent as they are elegant; the columns and walls are covered with sculptures, the ceilings are either painted in astronomical tables, or with white stars on an azure ground. Beyond this again was the secret part of the temple, 60 feet by 30, divided into four rooms, one leading to the others; in these remote chambers it is supposed that the sacred birds and reptiles were kept.

"Besides this vast enclosure, in which these numerous temples were connected and grouped together by dwellings for the priests, there were two temples standing apart; the larger of the two I have already spoken of, the smaller is one of the most beautiful that can be conceived, in perfect preservation, and so small, that it almost gives one the desire of carrying it away. I found within it some remains of a domestic scene, which seemed to be that of Joseph and Mary, and suggested to me the subject of the flight into Egypt in a style of the utmost truth and interest."

We have now described several of the principal monuments belonging to this style of architecture, from which may be formed a very fair idea of the Egyptian method of arranging and adorning their temples. We have not touched upon the pyramids, although the subject can scarcely be said to be completed without some description of them; we have, however, already extended this article to a somewhat inconvenient length, and would rather defer their consideration to a later period, than treat them here in a summary and insufficient manner. The same reasoning applies to the description of the sphinxes, and such like. We refer the reader, therefore, to the articles under the heads Pyramid and Sphinx.

The subject we have been treating of is one of very considerable interest, and, although not of direct practical utility to the architect, is yet well worthy his careful consideration.

Egyptian-Hall, or Banqueting-Rooms. *See* Œcus.

Egyptian Pyramids. *See* Pyramids.

EIDOGRAPH, an instrument for copying designs, invented by Professor Wallace, of Edinburgh. The eidograph is an improvement on the pentagraph in common use, is much more correct, and can be used for purposes to which the latter cannot be applied.

EIDOLON, a likeness, image, or representation.

ELBOWS of a Window, the two flanks of panelled work, one under each shutter, generally tongued or rebated into the back, so that the two elbows and the back form a lining round the three sides of the recess.

ELEOTHESION, the anointing-room, belonging to the palestræ, called by the Romans *unctuarium*. *See* Palestræ.

ELEVATION, an orthographical projection, made on a plane perpendicular to the horizon. In architecture, as buildings are constructed with vertical faces or fronts, the plane of delineation is generally chosen parallel to a side, in order that the measure in every direction may be readily obtained. What is generally called a section, partakes as much of a geometrical projection or elevation, as a section. By the elevations and plans, all the measures of an original object may be ascertained, whether the lines or arrises represented be horizontal, vertical, or inclined. In orthographical projections, all straight lines perpendicular to the plane of delineation are projected into points, and all straight lines parallel to the plane of delineation, are projected into straight lines of equal lengths, and are alike situated with regard to the plane of delineation, as the straight arris in the original object is with regard to the naked face of the wall. Therefore, whatever lines are perpendicular to the elevation, they will be represented by points, and whatever arrises are parallel to the elevation, they will be represented by lines parallel to the original. *See* DESIGN.

ELIZABETHAN ARCHITECTURE. *See* TUDOR ARCHITECTURE.

ELLIPSIS, or ELLIPSE, in geometry, a conic section formed by cutting a cone entirely through the curved surface, neither parallel to the base, nor making a subcontrary section; so that the ellipsis, like the circle, is a curve that returns into itself, and completely encloses a space. See the definitions under the word CONE.

One of the principal and most useful properties of the ellipsis is, that the rectangle under the two segments of a diameter is as the square of the ordinate. In the circle, the same ratio obtains, but the rectangle under the two segments of the diameter becomes equal to the square of the ordinate:

Problem 1.—*The two axes of an ellipsis being given to describe the curve.*

Method I.—*Figure* 1. Let A C be the greater axis, DG the lesser, cutting each other in the centre H; and if with the radius A H, or H C, from the point B, an arc E F be described, it will cut A C, at E and F, the foci; fix two pins at E and F; take a thread equal in length to A C, and fix one end of it to E, and the other to F; then keeping a pencil at the point D, move such point forward in the same direction, so that the parts D E and E F may continue to be stretched during the motion, until the describent D come to the point whence it began to move.

Method II.—*Figure* 2. Find the foci E and F, as before; between E and F, take any point, 1; with the radii A 1, 1 C, and the centres E and F, describe arcs cutting each other at G, as also at H; then G and H are points in the curve; in the same manner, with the same radii, from the centres F and E, find the intersections I and K. In like manner, if any other point, 2, be taken between E and F; four other points, L, M, N, O, will be obtained, and thus as many more as will be requisite for drawing the curve by hand.

For by the construction of the ellipsis, E D + D F, (*Figure* 1) is equal to E C + C F, = E F + 2 F C; also E D + D F = F A + A E = E F + 2 A E; therefore E F + 2 F C = E F + 2 A E: consequently A E is equal to F C; hence E D + D F = E F + 2 A E = E F + 2 F C: that is, the sum of the two lines drawn from the foci, to any point in the curve, is equal to the transverse axis.

Method III.—*Figure* 3. *To describe an ellipsis with the ellipsograph, or trammel, as it is called by workmen, the axes* A B *and* C D *being given in position, bisecting each other in the centre* E.—In any piece of material, contained between any two parallel planes, cut two grooves, at right angles to each other, in one of the planes; then provide a rod with three pins, or points, so that at least two may be moveable, and in a straight line with the third: let H F G be the rod, with the points F and G moveable; making H G equal to the greater semi-axis; then placing the grooves over the axes, and putting the points F and G in the two grooves, move the point H round, keeping the point F upon the greater axis, A B, and the point G upon the lesser axis C D, until the describent H come to the point where the motion commenced; and the figure so described, will be an ellipsis. The trammel, used by artificers, consists of two rulers, with a groove in each, so fixed that both grooves may be in the same plane, and at right angles to each other, and that the opposite sides of the cross may be in a plane parallel to those of the grooves. The rod above, is a bar with two moveable cursors, the fixed end is made to hold a pencil, and each of the other two an iron point, made to fill the groove, but capable of sliding freely.

Method IV.—*Figure* 4. *Given one of the axis,* A B, *and an ordinate,* C D, *to describe the ellipsis.*—Bisect A B at I for the centre; through I draw E F, parallel to C D; with the distance I A, or I B, from the point D, describe an arc, cutting I F at G; draw the straight line D G H, cutting I A at H; then if H D G be conceived to be an inflexible line or rod, the points H, G, D, remaining at the same distance in respect to each other; and if the point H be moved in the axis A B, and the point G in the axis E F, while the describent D, is carried round the centre, I, until A come to the point whence it began to move; a curve D B E A F, will be described, which will be an ellipsis.

Demonstration.—*Figure* 5.

$$LF, \text{ or } BK : FG, \text{ or } DB :: LC, \text{ or } AB : CD;$$
$$\text{Therefore, } BK^2 : DB^2 :: AB^2 : CD^2;$$
$$BK^2 : BK^2 - DB^2 :: AB^2 : AB^2 - CD^2.$$
$$\text{But } BK^2 - DB^2 = BK + BD \times BK - BD = DH \times DK$$
$$\text{and } CD^2 = CL^2 - DL^2 = AB^2 - LD^2.$$
$$\text{Consequently, } BK^2 : DH \times DK :: AB^2 : DL$$

which is a most principal property of the ellipsis, but the demonstration which accompanies the following method, is quite general, for every two diameters.

Method V.—*Figure* 6. *A diameter,* K H, *and an ordinate,* D L, *of an ellipsis being given, to describe the curve by a continucd motion.*—Bisect K H at I, and through I, draw A I A, parallel to D L; draw D E C, and K D, at right angles to A A; from L, with the distance K B, describe an arc, cutting I A at F; draw L F C; through the points C and I, draw M N; then if the point C be moved in M N, and the point F in A A, the point L will describe the curve of an ellipsis.

Demonstration.

$$\text{For the triangles } LFG, \text{ and } LCD \text{ are similar } \therefore \quad LF : FG :: LC : CD;$$
$$\text{But because } FL = BK, FG = DE, \text{ and } LC = AI, \quad KB : DE :: AI : CD;$$
$$\text{Again, by similar triangles, } IKB, \text{ and } IDE \quad KB : DE :: KI : DI;$$
$$\text{Therefore, by equality of ratios} \quad KI : DI :: AI : CD;$$
$$\text{By duplication} \quad KI^2 : DI^2 :: AI^2 : CD^2;$$
$$\text{By division} \quad KI^2 : KI^2 - DI^2 :: AI^2 : AI^2 - CD^2.$$
$$\text{But } KI^2 - DI^2 = (KI + DI) \times (KI - DI) = DH \times DK;$$
$$\text{and } CD^2 = LC^2 - LD^2 = AI^2 - LD^2.$$
$$\text{Therefore by substituting } DH \times DK, \text{ for } KI^2 - DI^2, \text{ and } AI^2 - LD^2, \text{ for } CD^2;$$
$$\text{In the last analogy we have} \quad KI^2 : DH \times DK :: AI^2 : LD^2,$$

a well-known property of the ellipsis.

The method for describing an ellipsis, having two conjugate diameters given, may be found in the Marquis de l'Hospital's *Treatise of Conic Sections*, translated by Stone. But the author of the *Architectural Dictionary* has chosen to give the description and demonstration from a diameter and double ordinate instead of two conjugate diameters, as being more readily applied in perspective. It is strange, that this useful method has been neglected by all English writers that have fallen in our way. This property was discovered by the author, and demonstrated by him, many years before he met with the above work, in endeavouring to find out methods for describing the perspective representation by continued motion.

Method VI.—*Figure* 7. No. 1. Let A B be the greater axis, bisected in C, by the lesser semi-axis C D; take two rulers, C E and E F, of equal length, equal to the sum of the semi-axes C D and C B, moveable upon each other at E, and the end C of the rule C E, moveable upon the centre of the ellipsis. Make the part F G of the ruler, F E, equal to the semi-axis C D; now suppose C E and E F to coincide with each other, and with the axis C D; then move the point F from C, in the direction C B, until the describent G arrive at B: the point G will then have traced the quadrant D B of the ellipsis. The other quadrants will be described in the same manner, by reversing and inverting the rulers.

Figure 8.—Another variation of this: Let A B be the greater, and C D the lesser semi-axis, as before; take the straight line H I, equal to the greater semi-axis, A C or C B; from I H cut off I K, equal to the lesser semi-axis, C D, and divide H K into two equal parts at I; then place the joint rule C E F in the following manner, viz., make C E and E F each equal to H L, or L K; the part C E being moveable round the centre, C, of the ellipsis, and the two rules C E and E G being moveable round E; now let C E and E G coincide with C D, and the point F to coincide with C, and consequently G with D; then move the point F towards A, keeping it in the semi-axis C A; and when C E and E F come in the same straight line, the point G will have described the quadrant of an ellipsis; the lesser axis (*see Figures* 7 and 8) is equal $2 \times$ F G, and the greater $= 2 \times$ C E $+ 2 \times$ E G.

Demonstration.—*Figure* 7, No. 2. Draw G I parallel to C F, cutting C E at I, and draw E L perpendicular to C F, meeting C B at L; produce C E to H, and make C H = C B; join H G, and produce it to K.

Now by the general demonstration, accompanying the article CYLINDER, we have C B^2 : C D^2 : : A K $\times$ K B : K G^2; but by the property of the circle K H^2 + A K + K B; therefore C B^2 : C D^2 : : K H^2 : K G^2; consequently C B : C D : : K H : K G, a property of the ellipsis.

But C E is the half sum of the two axis, and C I, or F G, equal to the lesser axis; then I E, or E G, is equal to the difference between the half sum of the two semi-axes and the lesser semi-axis; therefore I E = half the difference between the two semi-axes, and I H = the whole difference; consequently I E = E H.

Then because I G is parallel to C F, we have E C : E F : : E I : E G; but E C = E F; therefore E I = E G; and because E I = E H, E G is also equal to E H: then since the angle E P G is a right angle, the angles P E G and E G P, are together equal to a right angle; but the angles E G H and G E P are alternate; therefore E G H = G E P; add to each of these equal angles, the angle E G P, then will E G H + E G P = G E P + E G P equal to a right angle; consequently I G is parallel to C K, and the triangles C K H and I G H are similar.

Therefore C H : C I : : K H : K G; but C B = C H, and C D = C I; C B : C D : : K H : K G, the above property of the ellipsis.

Method VII.—*Figure* 9. Find the foci E and F, as in Methods I. and II. let the ends E and F of two rules F I and E K be moveable, the one round E, and the other round F, and let each be equal in length to A B, the greater axis, intersecting each other at E; let the ends I and K be connected by a bar, I K, equal in length to E F, so as to be moveable round the points I and K; then if the point I or K, be carried round G, the whole instrument will be in motion, and the point A will describe the curve of an ellipsis.

Demonstration.—Join E I; then, because the triangles I K E and I F E have the two sides, I K and K E, equal to the two sides E F and F I, and the base I A common to both, the angles I K E and I F E are equal; therefore the sides I H and H E are equal; therefore I F = A B = E H + H F, which is a property of the ellipsis.

Method VIII.—Another method will be found under the article CONE, by the equal divisions and intersections of straight lines.

Method IX.—*Figure* 10. *To find any number of points in the curve.*—On the transverse axis, A B, describe a semicircle: take as many points in the circumference of the semi-circle, as may be necessary for constructing the elliptic curve; draw straight lines perpendicularly to the axis cutting it, and let one of these lines, C D, pass through the centre; let E F be any other perpendicular, cutting the axis in F, and let C G be the lesser semi-axis; find the point H, so that F H may be a fourth proportional to C D, C G, F E, and the point H will be in the curve of the ellipsis required: in the same manner, a point may be found in each of the other perpendiculars. The finding of points in the curve by this method being entirely in proportion, the whole may be very readily obtained, by making I K = C D, I L, equal to the lesser semi-axis of the ellipsis; join K L; on I K make I *l*, *e m*, I *n*, equal to the perpendiculars; draw *l o*, *m p*, *n q*, parallel to K L, cutting I L, at *o*, *p*, *q*; then I *o*, I *p*, I *q*, are the ordinates of the ellipsis, to be applied respectively upon the perpendiculars, from the greater axis. This may very easily be described by means of the proportional compass, or the sector.

Method X.—*Figure* 11. Let A B be the greater axis, C D the lesser semi-axis. On the diameter A B, describe the semi-circle A E B, and with the radius C D describe the semicircle F D G; take any number of points, *h*, *i*, &c. in the circumference A E B, and draw *h* C, *i* C, &c. cutting the semicircle F D G, at *k* and *l*; from the points *h*, *i*, &c. draw lines *h m*, *i n*, &c. perpendicularly to A B; also from the points *k*, *l*, &c. draw lines *k m*, *l n*, &c. parallel to A B; then the points *m*, *n*, &c. are in the elliptic curve. When the points for half the curve are found, the corresponding points for the other half will be readily obtained, by producing the perpendiculars to the other side of C B, and making the ordinates on the one side equal to those on the other.

Method XI.—*Figure* 12. *Any two conjugate diameters,* A B *and* C D, *being given, to describe an ellipsis through points found in any diameter, taken at pleasure.*—Through D draw P Q parallel to A B; from D draw D F, perpendicular to P Q; make D F equal to E A, or E B, upon F; with the distance F D, describe the circle *n* D *k*; through the centre, E, draw the lines P E N, *t* E M, *s* E L, indefinitely cutting the tangent P Q, at P, *t*, *s*, &c.; join P F, *t* F, *s* F, &c. cutting the circle *n* D *k*, at the points *n*, *m*, *l*, &c.; also join E F, if necessary, and draw *n* N, *m* M, *l* L, &c. parallel to it, cutting the diameters N N, M M, L L, &c. at N, M, L, &c. and these points will be in the curve of the ellipsis required: if the diameters are produced to the opposite sides, at N, M, L, &c. and the distances E N, E M, E L, &c. are made respectively equal to their opposite corresponding distances E N, E M, E L, &c.; then the points N, M, L,

on the under side of the diameter A B, will also be in the curve.

This method may be very easily applied in perspective: by having the representation of a diameter of an original circle perpendicular, and that of another parallel to the picture, we have a diameter and double ordinate: the diameter of the ellipsis, or representation, is the diameter of the circle perpendicular to the intersecting line of its plane; thus it is only finding the conjugate diameter, and drawing as above.

Figure 13.—*The axes* A B *and* C D *of an ellipsis being given, to describe its representation by means of circular arcs.*—Draw B P parallel and equal to E C; bisect it at 1; draw 1 C, and P D, cutting each other at K; bisect K C, by a perpendicular meeting C D at O; on O, with the radius O C, describe the quadrant C G Q; through A and Q draw Q G, cutting the quadrant at G; draw G O, cutting A B at M; make E L equal to E M, and E N equal to E O; from O, through M and L, draw O G and O K; from O, complete the arc G K; from N, with the same radius, equal to the distance N D, describe the opposite arc H I; from M with the radius M G, describe the arc G H, at the extremity of the longer axis; and lastly, from L, with the same radius, equal to L B, describe the opposite arc K I; then A G C K B I D H A is the representation required, made to pass through eight points in the curve.

Figure 14.—*To find the representation of an ellipsis, by means of circular arcs, passing through twelve points in the curve (a more accurate method than the former) the axes* A B *and* C D *being given.*—Draw A 3 parallel to E C; divide it into three equal parts; draw 2 *c* and 1 *c*; divide A E also into three equal parts, and through the points 1, 2, draw D Q and D P, cutting the former in Q and P. Bisect C P by a perpendicular, meeting C D, produced at S; and join P S, cutting A E at X; make E W equal to E X, and E U equal to E S; draw P X S, O W S, K X U, and L W U. Bisect P Q by a perpendicular, meeting P S at F, and draw Z F parallel to A B. With the radius F Q describe the arc Q Z, cutting F Z at Z; join Z A, and produce it to meet the arc at Q Z, at *y*: join *y* F, cutting A B at V; make X I equal to X F, also W H, and W G, equal to X F; make E T equal E V, and draw I V R, H T M, and G T N; then, with the centre S, and distance S C, describe the arc P O; with the centre U and distance U D, equal to the former, describe the opposite arc K L; with the centres I, F, G, H, describe the arcs K R, P Q, N O, and L M; and, lastly, with the centres V and T, describe the arcs Q R and M N, at the extremity of the longer axis; and A C B D is the representation passing through the twelve points A, Q, P, C, O, N, B, M, L, D, K, B, as required.

This method differs so little from a true ellipsis, that it may be used in preference to any instrument for describing the curves of very large arches of bridges, and in finding the joints of the stones, as was the practice of the celebrated French engineer Perronet.

Another method of describing an ellipsis, by means of an instrument, constructed upon the principle of the oval turning lathe.—As we have never seen any investigation of this method, upon simple principles, the Author offers the following to the public, which has only been given in his *Mechanical Exercises.*

Definition.—If there be any plane figure, and two inflexible straight lines at right angles to each other; and if the plane be fixed to an axis at right angles thereto; and if the two inflexible lines be made to coincide with the plane, and be so moveable on its surface, that one of them, which we shall call *the primary line*, may always pass through two fixed points in the plane, and through the point where the plane is intersected by the axis; and if the other transverse line be made to pass or slide along a given point, which is not attached to the plane, but would remain stationary, even though the plane were in motion; and if a secondary plane be fixed to the inflexible lines parallel to the primary plane: then if the axis be carried round while the point in the transverse line is at rest, the primary plane will also be carried round, and every point in it will describe the circumference of a circle: the secondary plane will likewise be carried round, and perform its revolutions in the same time as the primary plane and the axis, but being immoveably fixed to the rectangular lines, they will cause it to have both a progressive and retrogressive motion, in the direction of the primary line, in each revolution; and, lastly, if another point at rest be held to the surface of the secondary plane while in motion, it will either describe an ellipsis, a circle, or a straight line. Hence the describing point will always be at the same distance from the centre, or point where the axis intersects the primary plane.

The eccentricity of the ellipsis, or the difference of the axis, will be double the distance between the stationary point in the transverse line and the axis.

Instead of the stationary point, a circle may be placed with its centre in this point, and its plane perpendicular to the axis, and instead of the inflexible line moving backward and forward upon two fixed points in the plane, the diametrically opposite parts of the circumference may always touch a pair of parallel lines on the revolving plane.

Illustrations.—*Figure* 15. Let A B and E F, No. 1, 2, 3, 4, 5, 6, 7, 8, be the two inflexible lines intersecting each other in I, at right angles, and let C D be the two fixed points. Let A B be denominated *the primary line*, and E F *the secondary line*, and let the lines A B and E F at right angles, taken as a whole, be called *a transverse;* also, let C represent a primary point, and let the describing point be taken at O, in the line drawn through C D produced; now, in all positions of the chuck, the primary line A B is always upon the point C, and E F upon D. Having premised this in general, suppose, before the machine begins to start, that E F, No. 1, the secondary line, coincides with E G, and the point G with *o*, *o* being in the plane of the figure to be described; then because A B always passes through C, the points I and C will be coincident, A B being then at right angles to E F. Let us now suppose the motion to commence, and let it perform an eighth part of a revolution, as at No. 2, the describing point G, still remaining in the same position with respect to C and D, viz., in the right line C D G; then the point *o* will be at a distance from the point G, and a part, G *o*, of the curve will be described by the fixed point G, and the point I will be above the line C D G; now let the motion proceed, and describe another eighth, as at No. 3, then, the point *o* being always in the line E F produced, E F will be at right angles to the fixed line C D G, and A B coincident with C D G and the point which was last at G, will now be at I. In like manner, when another eighth has been performed, as at No. 4, the point *o* has performed three-eighths of a revolution, the point 1 is in a line drawn from the point C perpendicular to the fixed line C D G, and the point 2, which was at G, in No. 3, is situated between 1 and G. In this manner, by continuing the motion, the whole curve will be generated. No. 5 shows the curve when half a revolution has been described; No. 6, five-eighths; No. 7, six-eighths, or three-quarters; and No. 8, seven-eighths.

Here it may be proper to observe, that the angles performed by the revolution of the machine, are very different from the corresponding angles, formed by lines drawn from the centre of the ellipsis to the describing point, and to the extremity of the curve at its commencement.

From what has been said, it is easy to conceive, that the operation of elliptic turning is nothing more than that of the ellipsograph, or common trammel, with this difference, that in the operation of turning, the ellipsis is described by moving the plane, and keeping the point steady, but in forming the curve by the ellipsograph, the plane of description is kept steady, while the point is in motion. The transverse A B E F is the same as the grooves in the trammel-cross, and the line C D G the trammel-rod: here the cross and plane of description move round together, but fixed to each other, and the trammel-rod C D G is held still or immoveably confined: in the trammel, the board and cross are fixed together, and held while the trammel-rod C D G moves with the points C and D in the grooves.

To set this machine, therefore, it is only to make C D equal to the difference of the axes.

Figure 16.—No. 1, 2, 3, and 4, show the relation between the foregoing diagrams and the chuck. Let K L M N be the face of a board representing the plane, which is fixed to the axis of the machine; and let O P Q R be another board, made to slide in the board K L M N: each two points, O and K, L and P, M and Q, N and R, coinciding at this moment, K L M N will therefore represent a wide groove in the board; as this groove may be of any width, we may conceive the breadth to be very small, or nothing; it may therefore be represented by a groove, or by the line A B parallel to K N and L M, and in the middle of the distance between them. Instead of supposing the point D always moving backward and forward on the line E F, we may suppose a circle, or the end of a large cylindric pin, moving in a very wide groove, T U V W, across the slides O P Q R. Now, all the differences between these diagrams and those in the former Plate, are only wide grooves in place of lines passing longitudinally through the middle: for the line A B is always conceived to move reciprocally from one side to the other of the board K L M N; and it is the same thing whether one straight line slide longitudinally upon another fixed line, or whether a bar of any breadth move in a groove of the same breadth, or whether a straight line in reciprocal motion always pass through two fixed points.

No. 1, shows the chuck, as in the first diagram of the last Plate: No. 2 as No. 2, No. 3 as No. 3, and No. 4 as No. 4, of the said Plate. Any farther explanation is conceived to be unnecessary.

Problem 2.—*An ellipsis*, A B D C, *being given, to find the transverse and conjugate axes.*

Draw any two parallel lines A B and C D, cutting the ellipsis at the points A, B, C, D; bisect A B at *e*, and C D at *f*; draw G *e f h*, cutting the curve at G and H; bisect G H at I, which gives the centre; from I, with any radius that will cut the curve, describe a circle, *k l n m*, and join *k l* and *m n*; bisect *k l*, or *m n*, at *o* or *p*, and draw Q *o* I *p* R, meeting the curve in Q and R: then Q R is the greater axis; draw S T at right angles therewith, meeting the curve in S and T, and S T will be the lesser axis.

Problem 3.—*Any diameter*, A B, *being given, and an ordinate* C D, *to find the conjugate diameter of the ellipsis.*

Draw C I perpendicular to A B; bisect A B in F, and draw F H parallel to C D; on F, with the distance F A, or F B, describe the semi-circle A I B, cutting C I at I; make A E equal to C I, and draw E G parallel and equal to C D; through G and A, draw A H, cutting F H at H, then F H is the semi-conjugate diameter.

This problem is useful in perspective, in the representation of the circle: for, having the representation of a diameter of the circle perpendicular to the intersecting line, and the representation of a diameter of the circle parallel to it, the former representative diameter of the circle will be a diameter of the ellipsis, and the latter will be a double ordinate of the same; find the conjugate diameter by this problem; then, having the two conjugate diameters, the curve may be described as in *Method* XI; or the axis may be found as in the next problem, and thence this curve described.

Problem 4.—*Any two conjugate diameters*, A B *and* C D, *being given, to find the axis.*

Through D draw E F parallel to A B, and D I perpendicular to E F; make D I equal to M A, or M B; with the radius I D describe from I the arc *g* D *l*, and join I M, which bisect by a perpendicular, meeting the tangent E F at N; with the distance N I describe from N a semi-circle, E I F; join E M and F M, which produce to H and K; and join I *g* E and I *l* F; parallel to I M, draw *l* L and *g* G, cutting H E and K F at G and L; make M H equal to M G, and M K equal to M L; then will G H and K L be the two axes required.

In like manner, if G H had been a diameter, its conjugate would have been thus found: produce H G to E, and join E I; draw E V at right angles to E I; then draw *g* G, and complete the rest as before.

This problem may be readily applied in perspective; for, by the last problem, two conjugate diameters will be found, and having the two diameters, the axes may be found by this, and the curve be described geometrically by an elliptic compass, or by traversing the curve with an ivory, pasteboard, or strong paper slip.

Problem 5.—*An ellipsis and its foci* F *and* G *being given, to draw a tangent through a given point*, H, *in the curve.*

Join F H and G H, and produce the latter to I; bisect the angle I H by the straight line L H, and L H is a tangent to the curve.

This problem is very useful in masonry, for finding the joints of elliptic arches. Thus, find a tangent in the curve, at the lower end of the joint, and from the point of contact, draw a line perpendicular to the tangent; and the line thus drawn will be the joint.

Problem 6.—*Two conjugate diameters*, A B *and* C D, *and the centre*, H, *being given, to draw two tangents to the ellipsis, from a given point*, E, *without the curve.*

First, let the point E be in D C, produced; make H I equal to H C, and join I E; through C draw C K, parallel to I E, cutting H A in K; make H L equal to H K, and through L draw F G parallel to A B; find the extreme points F and G, by *Problem* 3, and draw E F and E G, which are the tangents required.

But if the point E be in neither of the diameters, A B or C D, when produced, draw a line from the given point E, through the centre, so as to be terminated by the curve; and the portion thus intersected will be a diameter; then find a conjugate to this diameter, as in *Problem* 4.

This problem will be very useful in the perspective representation of a cone, for drawing the contour of the sides with the utmost exactness; the diameters being found by the preceding problem.

Problem 7.—*To describe an ellipsis similar to a given one* A B C D, *through a given point*, P, *having the same centre, and the axes in the same lines.*

If the two axes, A D and B C, are not given, find them as in *Problem* 4; and the point E, where they intersect, is the centre; through the given point P, draw F E, to meet the curve in F; join A F and F B; parallel to F A draw P G cutting A E at G; and parallel to F B draw P H, cutting E B at H; then will E G be the greater semi-axis, and E H the lesser semi-axis.

Problem 8.—*Through the angular points*, A B C D, *of a given rectangle, to circumscribe an ellipsis, which shall have its axes in the same ratio as the sides of the rectangle.*

ELLIPSIS.

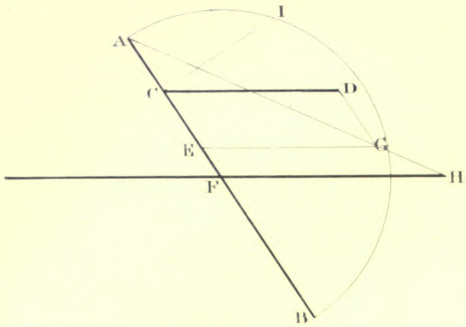
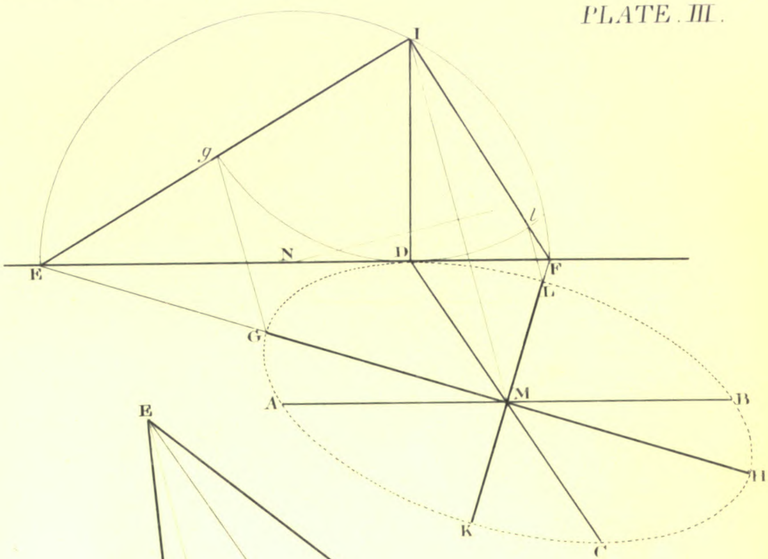
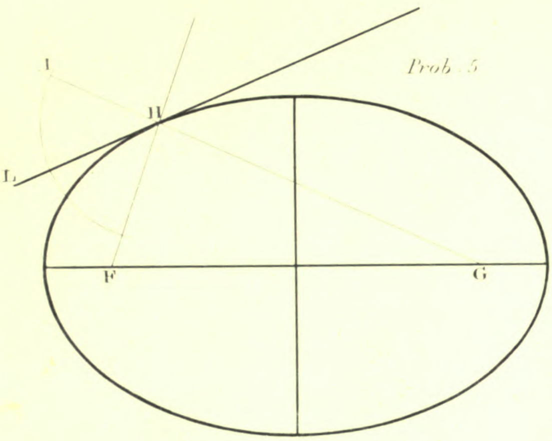
Prob. 3.



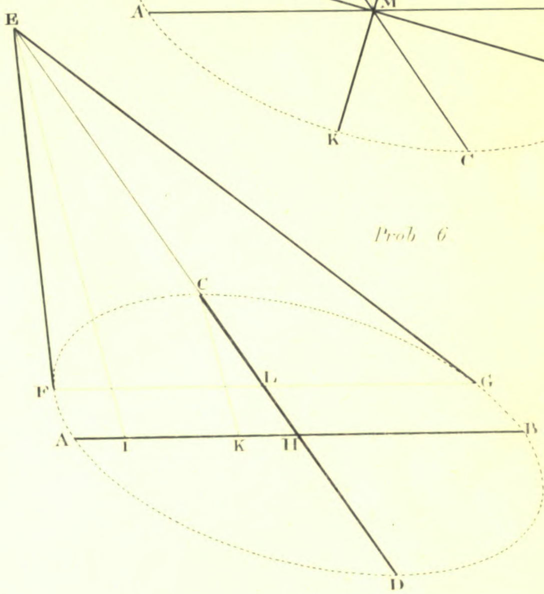
Prob. 4.



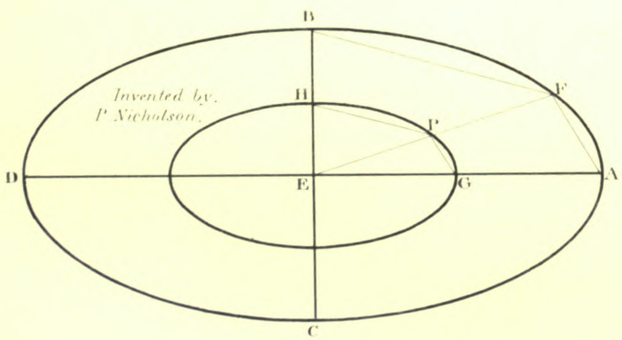
Prob. 5.



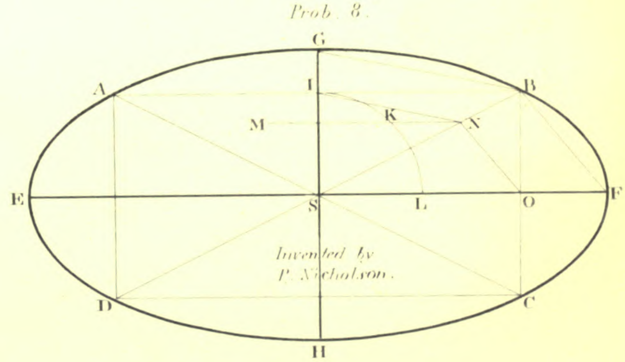
Prob. 6.



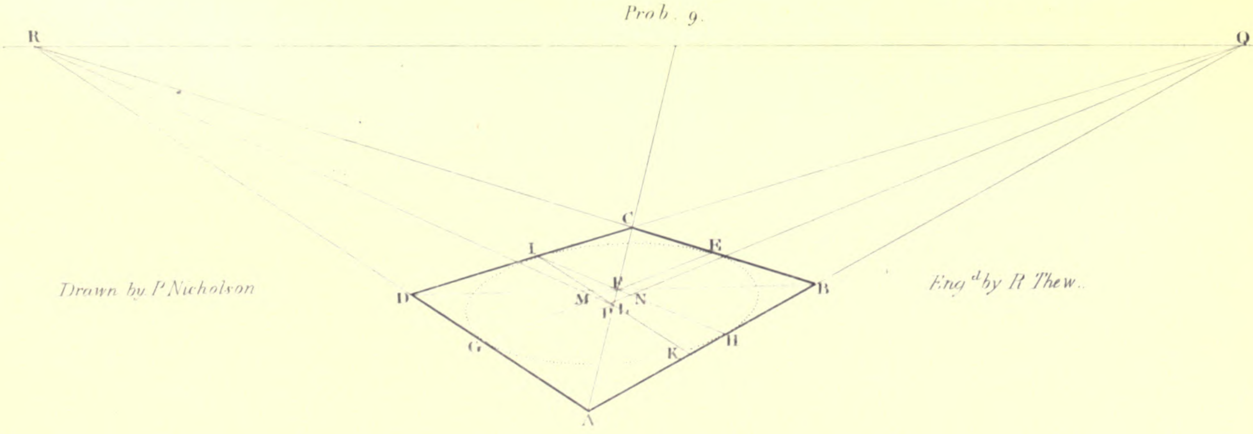
Prob. 7.



Prob. 8.



Prob. 9.



Drawn by P Nicholson

Eng^d by R Thew.

Draw the diagonals A C and B D, cutting each other at S, the centre; through S draw E F and G H, respectively parallel to A B and A D; upon S, with the radius S I, equal to the half of A D or B C, describe the quadrant I K L, cutting E F at L; bisect the arc I K L at K, and through K draw M N parallel to E F, cutting the diagonal B D at N; join I N, and through B draw B O parallel to it, cutting G H at O, and make S H equal to S O; join N O, and through B draw B F parallel to it, cutting E F at F; make S E equal to S F, and E F and G H are the two axes; then the curve may be described by any of the methods shown in Problem 1.

Problem 9.—*A trapezium,* A B C D, *being given, to inscribe an ellipsis therein.*

Produce the sides B A and C D to Q; also the sides A D and B C to R; draw the diagonals A C and B D, meeting each other at F; through F draw R I H, cutting the sides of the trapezium at I and H; also, through F draw Q E G, cutting the other two sides of the trapezium in E and G; bisect I H at N, and E G at M; draw Q N P and R M P; join I P, to which produce K: make P K equal to P I; draw G L parallel to C D, cutting I K at L; then I K is a diameter bisected by P, the centre, and L G is an ordinate.

This problem might have been constructed, as in the *Principles* (see Vol. I. *Problems* XVIII. XIX. and XX.) by having one of the points of contact given; but it is here much simplified, and reduced into one problem, by which it is much better adapted to perspective.

Problem 10.—*To find the area of any segment of an ellipsis.*—Let t = the greater axis,
c = the lesser,
y = D H, the ordinate,
and x = A D, the abscissa.

Then by the property of the curve, we have $y = \frac{c}{t} \times x\,(a x - x^2)^{\frac{1}{2}}$ but $\frac{c}{t} \times \dot{x}\,(a x - x^2)$ is a fourth proportional to t, c, and $\dot{x}\,(a x - x^2)^{\frac{1}{2}}$ for $t : c :: \dot{x}\,(a x - x^2)^{\frac{1}{2}} : \frac{c}{t} \times x\,(a x - x^2)^{\frac{1}{2}}$; and since $\dot{x}\,(a x - x^2)^{\frac{1}{2}}$ is known to be the fluxion of the semi-segment of the circumscribing semi-circle A E B, (see the article SEGMENT;) therefore, as the transverse axis, or the diameter of the circumscribing circle, is to the conjugate, or diameter of the inscribed circle, so is the area of the semi-segment of the circle to the area of the elliptic segment A H D; but the ordinate F D of the circle is to the ordinate H D of the ellipsis, as the diameter of the circumscribing circle is to the diameter of the inscribing circle; therefore, circular and elliptic segments upon the same base, and between the same parallels, are to one another as their bases, when the greater axis of the ellipsis is equal to the diameter of the circumscribing circle.

It is therefore evident, that, whether we know the specific measure of the greater axis of the ellipsis, or the diameter of the circumscribing circle, or not, we still can obtain the area of the elliptic segment, by a circular segment; provided it be known, that the greater axis of the ellipsis is equal to the diameter of the circle. In architecture, this circumstance is frequently known: suppose, for example, that in a groin, one side is the segment of a circle, and the other the segment of an ellipsis; it follows, from the construction of the groin, that both the vertical diameter of the circular side, and the vertical axis of the elliptic side, are equal; and therefore, if the width of each side of the groin, which is the chord of its arc, be given, and the height of the arch, we have nothing more to do than to find the area of the circular section or side, and the area of the elliptic side will be found by the rule of proportion. For practical use, take the following rule:

First.—*To measure the circular segment.*—To two-thirds of the area of the base, multiplied by the height, add the cube of the height, divided by twice the base of the segment, and the sum is very nearly the area of the circular segment; then *To find the area of the elliptic segment,* say, As the chord of the circle is to the chord of the ellipsis, so is the area of the circular segment to the area of the elliptic segment.

Example.—What is the area of the elliptic end of a groin which rises 5 feet, and extends at its base 15 feet, supposing the base of the circular end to be 18 feet?

$2 \times 15 = 30$, twice the length of the segment.

18	5
15	5
90	25
18	5
3)270	3,0)12,5
90	4.166, &c.
90	

180 two-thirds of the product of the base and height.
4.166 cube of the height, divided by twice the base.

184.166 area of the circular segment.

Then 18 : 15 : : 184.166
15
920830
184166
18)2762490(153.471 the area of the elliptic segment.
18

12

To have wrought this example according to the series, would have been too operose for practical purposes.

The above method for finding the area of the segment of a circle, was discovered, or invented, by the author, in the year 1794, and published in his *Principles,* in 1795.

It is evident, that whatever takes place in the segment, must also occur through the whole curve; therefore, in an ellipsis having its greater axis equal to the diameter of a circle, it will be, As the diameter of the circle is to the lesser axis of the ellipsis, so is the area of the circle to the area of the ellipsis.

Example.—What is the area of an ellipsis, the greater axis of which is 24, and the lesser 18?

```

```

But the proportion of 18 to 24, is as 4 to 3: therefore the above might have been considerably abridged; we were, however, desirous of working the operation at full length, as would unavoidably happen in case of incommensurable numbers, in order to compare it with the following operations.

Now let us try whether we cannot find a more practical rule for the area of an entire ellipsis, than that above.

Let $p\,d^2$ be the area of a circle circumscribing an ellipsis, where

$p = .7854$, and $d =$ the diameter of the circle or greater axis of the ellipsis,

and $c =$ the conjugate, or shorter axis;

then we have $d : c : : p\,d^2 : \frac{p\,d^2\,c}{d} = p\,d\,c$ the area of the entire ellipsis; we have therefore the following neat rule.

Multiply the two axes together, and the product by .7854, and this second product will be the area.

Suppose now, for the sake of comparison, that we take the former example, viz., the greater axis 24, and the lesser 18.

In the same manner, may the half, or the quarter, be found, viz., by multiplying the two dimensions together, and the product by .7854.

Example.—In a semi-ellipsis upon the greater axis. Let the greater axis be 24, as above, and the lesser semi-axis 9, the area is required.

           84. 8232 the area of the quad-
```

rant of the ellipsis, being one quarter of the area of the entire ellipsis, in the foregoing example. The area of an ellipsis is a mean proportional between the area of the circumscribing and inscribing circle.

For $p\,t^2$ is the area of the circumscribing circle; and $p\,c^2$ is the area of the inscribing circle:

Now $p\,t^2 : p\,t\,c : : p\,t\,c : \frac{p^2\,t^2\,c^2}{p\,t^2} = p\,c^2$; and therefore the proposition is manifest.

To find the periphery of an ellipsis.

Let $a =$ the greater semi-axis A C;

$c =$ the lesser semi-axis;

$x =$ the distance C D from the centre, the abscissa;

$y =$ D H, the ordinate;

$z =$ E F, the arc:

then will A D $= a - x$ and D G $= a + x$, therefore A D $\times$ D G $= a + x \times a - x = a^2 - x^2$.

Then by the property of the ellipsis,

A C^2 or C B^2 : C G^2 : : A D $\times$ D B : D H^2; that is

$$a^2 : c^2 : : a^2 - x^2 : y$$

consequently $y^2 = \frac{c^2}{a^2}(a^2 - x^2)$

and therefore $y = \frac{c}{a}(a^2 - x^2)^{\frac{1}{2}}$

and $\dot{y} = \frac{-c\,x\,\dot{x}\,\frac{1}{2}}{a(a - x^2)}$ Therefore $\dot{z} = (\dot{x}^2 + \dot{y}^2)^{\frac{1}{2}} = \frac{\dot{x}\,(a^2 - \frac{a^2 - c^2}{a^2} \times x^2)^{\frac{1}{2}}}{(a^2 - x^2)^{\frac{1}{2}}}$; but by substituting d for $\frac{a^2 - c^2}{a^2}$ in this last expression we obtain $\frac{\dot{x}\,(a^2 - d\,x^2)^{\frac{1}{2}}}{(a^2 - x^2)^{\frac{1}{2}}}$ for the value of $\dot{z}$. But

$$\frac{\dot{x}\,(a^2 - dx^2)^{\frac{1}{2}}}{(a^2 - x^2)^{\frac{1}{2}}} = \frac{a\,\dot{x}\left(1 - \frac{d\,x^2}{a^2}\right)^{\frac{1}{2}}}{(a^2 - x^2)^{\frac{1}{2}}} = \frac{a\,\dot{x}}{(a^2 - x^2)^{\frac{1}{2}}} \times \left(1 - \frac{d\,x^2}{a^2}\right)^{\frac{1}{2}}.$$

Then by throwing the factor $\left(1 - \frac{d\,x^2}{a^2}\right)^{\frac{1}{2}}$ into an infinite series, we obtain $\dot{z} = \frac{a\,\dot{x}}{(a^2 - a^2)^{\frac{1}{2}}} \times \left(1 - \frac{d\,x^2}{2\,a^2} - \frac{d^2\,x^4}{2.\,4\,a^4} - \frac{3\,d^3\,x^6}{2.4.6\,a^6} \&c.\right)$ But the fluent of $\frac{a\,\dot{x}}{(a^2 - x^2)^{\frac{1}{2}}}$ is equal to the corresponding arc, E F, of the circumscribing circle. Therefore, taking A equal to the circular arc, we obtain the fluent of $z = \text{A} - \text{B}\frac{d}{2\,a^2} - \text{C}\frac{d^2}{2.4\,a^4} - \text{D}\frac{3\,d^3}{2.4.6\;a^6}$ where $\text{B} = \frac{a^2\,\text{A} - x\,(a^2 - x^2)^{\frac{1}{2}}}{2}$, $\text{C} = \frac{3\,a^2\,\text{B} - x^3\,(a^2 - x^2)}{4}$, $\text{D} = \frac{5\,a\,\text{C} - x^5\,(a^2 - x^2)^{\frac{1}{2}}}{6}$ &c., but when x becomes $= a$, then $(a^2 - x^2)^{\frac{1}{2}} = 0$, consequently the values B, C, D, become only as follows, viz.,

$$\text{B} = \frac{a^2}{2}\text{A}$$

$$\text{C} = \frac{3\,a^2}{4}\text{B} = \frac{3\,a^2}{4} \times \frac{a^2}{2} \times \text{A} = \frac{3\,a^4}{2.4}\text{A}$$

$$\text{D} = \frac{5\,a^2}{6}\text{C} = \frac{5\,a^2}{6} \times \frac{3\,a^2}{4} \times \frac{a^2}{2} \times \text{A} = \frac{3.5\,a^6}{2.4.6}\text{A}$$

These values being substituted in the above series, give the quadrant $z = \text{A} \times \left(1 - \frac{d}{2.2} - \frac{3\,d^2}{2.2.4.4} - \frac{3.3.5\,d^3}{2.2.4.4.6.6}\right)$ &c. Now by putting $\text{B} = \frac{d}{2.2}$, $\text{C} = \frac{3\,d^2}{2.2.4.4}$, $\text{D} = \frac{3.3.5\,d^3}{2.2.4.4.6.6}$, &c. we obtain $z = \text{A} \times \left(1 - \frac{d}{2^2} - \text{B}\frac{1.3.d}{4^2} - \text{C}\frac{3.5.d}{6^2} - \text{D}\frac{5.7.d}{8^2}\right)$ &c. Therefore, to find the circumference of an ellipsis, we have the following

RULE. Multiply the circumference of the circumscribing circle by the sum of the infinite series $1 - \frac{d}{2^2} - \text{B}\frac{1.3.d}{4^2} - \text{C}\frac{3.5.d}{6^2} - \text{D}\frac{5.7.d}{8^2}$, &c.

Example.—Required the periphery of an ellipsis, the transverse axis of which is 50, and the conjugate 40, then will $d = 1 - \left(\frac{40}{50}\right)^2 = 1 - \left(\frac{4}{5}\right)^2 = 1 - \frac{16}{25} = 1 - .64 = .36$

Therefore 2) .36 = d

2) .18

.09 = $\frac{d}{2.2}$ = A
1

4 5139 0471 5
135 4171 4145

141.8088 3052 64400 = the periphery of the ellipsis required.

But as this rule would be much too laborious for practice, we must content ourselves with some easy method of approximation: It will be very serviceable, however, in comparing the results obtained by such approximations, in order to ascertain the degree of dependence that may be put on them. Let us therefore try the following Rule, for the periphery of the whole, the half, or the quadrant of the curve.

RULE.—Multiply the square root of the half sum of the squares of the two axes by 3.1416, and the product will be the circumference, nearly.

Example.—Let the greater axis be 50, and the lesser 40, as before: the entire periphery is required.

50	40
50	40
2500	1600
1600	

2) 4100

20.50 (45.27692, the root.

9055382) . 23263900
18110764

.5153136

45.2 7692
3.1416

271 6 6152
452 7 692
1 8110 7 68
4 5276 9 2
135.8307 6

142.2419 7 1872

The above, though agreeing only in the two first places of figures, is sufficiently near for most practical purposes in measuring; the difference in four places of figures is only four more than the truth.

The investigation of this rule is as follows:
Let t = the greater axis,
and c = the lesser,

then $p\left(\frac{t^2 + c^2}{2}\right)^{\frac{1}{2}}$ expresses the rule;

out $p\left(\frac{t^2+c^2}{2}\right)^{\frac{1}{2}} = p\,t\left(\frac{1}{2}+\frac{c^2}{2\,t^2}\right)^{\frac{1}{2}}$

and since $d = 1 - \frac{c^2}{t^2}$

we have $\frac{c^2}{2\,t^2} = \frac{1-d}{2}$

therefore $p\,t\left(\frac{1}{2}+\frac{c^2}{2\,t^2}\right)^{\frac{1}{2}} = p\,t\left(\frac{1}{2}+\frac{1-d}{2}\right)^{\frac{1}{2}} = p\,t$ $\left(1-\frac{d}{2}\right) = p\,t\left(1-\frac{d}{2^2}-\frac{d^2}{2^3.4}-\frac{d^3}{2^4.8}-\frac{5\,d^4}{2^5.16}\right)$ &c. = the periphery; but the true periphery = $p\,t$ $\left(1-\frac{d}{2^2}-\frac{3\,d^2}{2^2.4^2}-\frac{3.3.5d^3}{2^2.4^2.6^2}\right)$ &c. Now this series agrees with the former in the first and second terms, and differs in the third only $\frac{d^2}{64}$; the rule is therefore an approximation.

The rule now delivered is still too long for practical uses; let us therefore try the following:

Rule.—Multiply the half sum of the two axes by 3.1416, and the product will be the periphery, nearly.

Example.—The same still as the preceding, viz., 50 and 40.

50	3.1416
40	45
2)90	15 7080
	125 664
45	
	141.3720 the periphery.

This rule is exceedingly easy, and sufficiently near for all practical purposes, where the eccentricity of the ellipsis is not very great. It gives the periphery nearly as much below the truth as the preceding rule is above; and, consequently, where great accuracy is required, if the result be found by both methods, the half sum will be exceedingly near. To show this by an example:

The result by the first rule	142.241971
The result by the last rule	141.3720
	2)283.613971
The half sum of both	141.806985

which is very near the truth, as it agrees in five places of figures with the result by the series.

ELLIPSOGRAPH, an instrument usually constructed of brass, for describing a semi-ellipsis at one movement of the index. *See* Ellipsis, *Problem* 1, *Method* 3.

ELLIPSOID, a solid, generated by revolving a semi-ellipsis round either of its axes. This solid is understood by some to be the same as spheroid. *See* Spheroid.

Elliptic Arch, a portion of the curve of an ellipsis, employed as an arch. This curve has some advantages over circular arcs, in bridge-building, as it leaves a greater space at the haunches for the passage of vessels, and, consequently, saves a considerable quantity of materials in the construction.

Elliptic Compasses. *See* Ellipsograph.

Elliptic Conoid, the same as Ellipsoid.

Elliptic Winding Stairs, a winding stair, having an ellipsis for its plan. *See* Stairs and Winding Stair.

EMBANKMENT, a large body, mound, or bank of earth, constructed or thrown up in different ways, according to circumstances. Embankments are of various kinds, according to the purposes for which they are designed, as Railway Embankments, which carry a line of railway over valleys and low ground at the elevation required for the level of the rails; Canal Embankments, for confining the water of a canal or reservoir, or upon which a canal or aqueduct is formed; and Embankments constructed with the view of guarding, protecting, and defending lands on the borders of the sea, rivers, and lakes, from being inundated and injured by them, and for reclaiming lands from the sea.

We shall treat first of the latter description of embankments. These are of different kinds and forms, according to the nature of the situations and the materials of which they are constituted. In embanking against the sea and large rivers, where the slopes next them are naturally gentle and easy, they are mostly of the earthy description, being well put together, and covered on the surface with turf cut from the tough sward of the land in the neighbourhood; but in cases where the banks, borders, and shores, are steep and bold, they are usually of a more hard and solid nature: as of stone, brick, gravel, sand, shells, and other similar substances, laid closely in some sort of tenacious material, such as clay or mortar, and other matters of the same quality. Timber is also frequently employed in their construction, in a variety of forms.

In works of this sort, very much depends upon the form in which they are constructed, and the nature and management of the materials made use of. In respect to the first it may be remarked, that banks of these kinds are commonly constructed with too narrow bases for the heights which are given them; from which circumstance, the sides which are opposed to the effects of the water become too steep and upright; consequently, in cases of high tides or floods, they are utterly incapable of resisting their weight, which has equally a lateral and downright pressure. Besides this, there is another disadvantage attending this method of forming them, which is, that the floods, as well as the tides, in ebbing and flowing, have a more continued action on one part than would be the case, if the slopes were more gentle and gradual: consequently, they have a much greater tendency to break down and destroy the superficial parts of the banks. With some variations in the forms, most of the embankments in this country are, however, made in this way. They may succeed in some particular instances; but, in general, it is found that breaches are frequently taking place in them, from the effects of the sea or floods, which are not capable of being filled up or repaired without considerable difficulty and trouble; and which, if suffered to continue even for a short space of time, endanger the whole embankment.

The common form of embankment is shown at *Figure* 1, and the improved form pointed out at *Figure* 2.

The angles or slopes of these sorts of works are made very different in various cases; but that shown in the above figure seems, in general, well calculated for the purpose of resisting the impression of heavy tides, or the waters of floods. The greater breadth they have, in proportion to their height, the more effectual they must be in resisting the power of the waters which come upon them. In regulating the heights of embankments, it is necessary to ascertain the greatest depth of water at the highest tides or floods; making the summits of them about two feet higher than the points to which they rise at such times. By some, a less height than this above the highest mark of the tides or floods has, however, been considered sufficient; but it is always proper to be on the safe side, as the consequences of an overflow are very serious.

In forming embankments with stones, or other similar materials, which, as has been seen, is essential in bold steep banks or shores, it is necessary that they be laid in proper materials, and be closely jointed next the sea, or the rivers, so as to be fully capable of resisting the entrance of water. Great care is requisite in doing this, or the bank will not stand, for the water, insinuating itself between the openings, will sink down among the stones, softening and loosening the clayey or earthy matters underneath, by which portions of them will be forced out and washed away. Hollows being formed in that way below, the stones naturally sink down; and the waters, rushing into the cavities with considerable impetuosity, quickly displaces others, and the whole embankment is soon destroyed. This very frequently takes place with the heads thrown across rivers, and such paved or causewayed banks as are formed with the view of protecting and preserving bold and open shores. Such shores are especially liable to be undermined and carried away by the washing operation of the waters which come against them. In order to render the embankments perfectly secure in such cases, they should be laid with good mortar, and be pointed with a strong cement. A good coat of gravel, in some cases of this kind, is even found far superior to paving with stones.

It sometimes happens that rivers, near their mouths, form shallow estuaries, and occupy much ground which might be usefully employed. In this case, an entirely new outlet may sometimes be made, through which the river may at once discharge itself into the sea; and the whole course will, probably, be soon filled up by the deposition of soil and mud brought in by the tides; for it is the current which clears the channel, and when this is taken away the channel soon fills up. In the course of a short time the old mouth of the river will be so filled up as scarcely to admit the tide; and an embankment across it may lay a large fertile track of land quite dry.

In constructing embankments of the quay, or other similar kinds, a mortar formed from powdered unburnt lime-stone and coarse sharp sand is employed; the whole being pointed with puzzolana earth, by which they become as solid as rock, and fully resist the effects of water. The lime of particular sorts of lime-stone is found more proper for forming this sort of mortar-cement than that of others: thus, that found at Dorking, in Surrey, is supposed to constitute the most durable substance of this kind of any in the kingdom; and has been employed in many works near London. And an excellent sort of lime-stone, for the same purpose, has likewise been discovered near Worsley, in Lancashire, which is there termed *Sutton lime*.

An excellent cement for this use, which hardens under water, may be composed by having four parts of blue clay, six of the black oxide of manganese, and nine of carbonate of lime, submitted to a white heat, and then well incorporated with sixty parts of sand, and as much water as may be necessary to form it into a mortar. *See* CONCRETE.

It is invariably found, in examining the shores of the sea, and the banks of rivers, that such as have easily and gently declining slopes from their beds to their borders or banks, and those which are formed in a steep upright manner, of rocky materials, such as are shown at *Figures* 3 and 4, are the least exposed to injury from the effects of the waters: the two former being the most secure when spread over or coated with good coverings of sand or gravel, or uniformly turfed over quite down to the water-side with the sward of a tough old pasture. The strength and firmness of their banks are in proportion to the extent of the slope; and their durability depends on that of their being made uniform on their surfaces, both in respect to hardness and smoothness: as, in the former case, from the great length of slope, the flows and decreases of the waters act more momentarily on their different parts, and their greater weight renders their banks more firm; while, in the latter case, by the equality of their surfaces, the power of the water is rendered the same on one part as another, and no obstacles are left for the producing of eddies, or other means of forming holes or breaks in them.

In the latter, or those of the bold, upright, rocky kind of banks, their strength chiefly depends on the resistance of the large quantity of materials by which they are backed, and not on the manner in which they are disposed, as in the former case; and their durability, on that of the uniform compactness of texture in the parts opposed to the effects of the waters: as, where these have fissures in them, or are softer in some parts than others, the waters are liable to enter and break down the banks in time, according to the particular nature of the cases.

It is, therefore, of importance, that the modes and forms of embankment, which are thus naturally presented, should be improved upon by art. It is evident, that if a cut were formed behind the embankment, as in *Figure* 5, at the letter *x*, the shores or banks, though, in this case, as it were, detached from the land, would be found equally strong, and capable of resisting the pressure of the waters, as in their original state. Hence, if a mound or bank were formed, and placed out at the distance of one, two, or three miles from the shore or other embankment, within the bed of the sea or other waters, as at *y* in the same *Figure*, it would be equally capable of resisting them as in the former instance, and not more liable to be broken down by their pressure than in its former station; and would also defend them as completely from the intermediate space of land, as it did before from the narrow trench. Consequently, on this principle, vast tracts of land may, in different parts of the kingdom, be obtained by judicious embankments.

Though the shores of bold steep coasts may not afford examples equally capable of being followed with advantage as the above, they nevertheless suggest useful hints for the purpose of defence, in cases of bold, abrupt, broken shores, constituted of earth, or of that material and rocky substances intermixed. It readily presents itself to the mind, that the raising a good perpendicular stone wall against such banks, renders them nearly as strong and lasting as those formed by nature of steep solid rocky bodies. This sort of walled bank is exhibited at *Figure* 6; but though this method may be practised, in cases of the above kind, with great advantage, it is not, by any means, applicable in general to rivers; as, with them, the waters, during the periods of floods, stand in need of room to spread, which is the great use of giving their banks a sloping form; while, in this way, it would have the effect of doing more injury than was the case before. The increased rapidity of the current, caused by its being so confined, doing greater damage to the banks. Instances may, however, happen in which it may be had recourse to with propriety, in defending a part of the bank of a river, without giving it a sloping direction, or for protecting one part of a bank at the risk of that which is opposite to it; but well-constructed piers, in such cases, are preferable, and attended with less expense to maintain. But instead of these, art may suggest one that may answer in some respect more perfectly; as, in place of bringing together such a mass of earthy or other substances, as may be proper for constructing such banks as are shown at *Figures* 1 and 7, it may be more advantageous to have one formed, such as is shown at *Figure* 8, the side of which, next the water, forms, with the base, an angle of about 45 degrees. This will be capable of bearing all the weight or pressure of water that can possibly be brought upon it, equally well with that of *Figure* 1, except that the operation of the tides would break the superficial part of the side next the sea, unless prevented by coating it with some durable substance, such as paving stones, bricks, or other similar materials.

Banks of various kinds, between this and the first natural kind, may be invented, differing only in the degree of inclination which they have towards the sea; that which slopes in the highest degree, as *Figure* 1, having the surface covered over with sand or gravel; and that which has the least slope, as *Figure* 8, may be covered with pavement; the different intermediate slopes being protected by materials which have a quality between the two, such as coarse gravel, chalk-stones, brick, and sand. The embankment, shown in *Figure* 9, is wholly constructed of a sandy loam deposited upon a soil of the same quality; but as it would not, for some time after being formed, be sufficiently impervious to water, a column of clay is carried upright in the middle, from the clayey substratum of the soil underneath, as is shown at *x x*, in the section. This is called *Puddling*.

In cases where the shores are of a very sandy nature, embankments may be made wholly of a sort of wicker-work. Thus three or four rows of paling are put down, of different heights, and the vacant spaces between them well filled, by forcing in furze, brush-wood, or even straw, as represented at *Figure* 10. These substances, by detaining the mud and sand, as the tide passes through them, or during high floods, soon forms a sort of embankment, such as that shown in the above representation. It should afterwards be covered with some plant, which is capable of binding and giving it solidity, such as the *elymus arenarius*. An embankment, so constructed, would continue, during extraordinary tides, to retain still larger quantities of the sandy materials, until, ultimately raised above the range of the highest floods, a safe bank would be formed. By banks formed in this way, large quantities of land might be gained in a very few years, in different parts of the rivers Severn, Humber, Frith, &c.

In all cases of embankment, however they may be formed, tunnels and sluices of a proper kind, with valves towards the sea or rivers, must be occasionally placed, according to circumstances, so as to permit the water that may be collected within to pass away, and that of the sea or rivers, to flow up, with different intentions in the view of improving the land.

The utility of projecting points is very considerable, in different cases, on the sea-coasts and rivers, in defending the bays and inlets of the former, as well as guarding the banks of the latter, by diverting their streams or currents to the opposite sides. Hence arises the formation of piers, which become highly beneficial in defending embankments, as well as the borders of rivers and brooks. In the first of these cases, they may generally be constituted and coated over with the same sort of material as that of which the embankment is formed; while, in the latter, they should be formed of some sort of stony matter, being constructed in such a way as to decrease in every direction as they advance outwards, as represented in *Figure* 11. In each of these cases, they are, however, capable of being constituted of brush wood, secured by means of stakes, often with more perfect success. And it frequently happens, that a simple rude wicker-work fence, of not more than three or four yards in length, may be fully sufficient for the purpose. Embankments formed of stone, unless constructed in the manner represented at the above figure, are apt to cause eddies below them; while those formed of brush-wood cannot have this effect.

It is obvious, that considerable attention must be required in deciding the most proper situations for constructing this sort of projection in, and the distances to which they should extend into the rivers; as a too extended projection may be highly dangerous to the opposite bank, and of course do harm, instead of being beneficial; while not carrying them out sufficiently far may prevent the effect which is wanted. In cases where piers are to be formed of stone, as in rivers where the bottoms are of a rocky nature, the plan represented at *Figure* 11, is a good one, as it will scarcely cause any eddy, and be nearly similar to that of the wicker-work, in the effect which it produces. Different works of these several kinds have been constructed in the northern parts of the island with much success.

Proper Materials for Embankments.—It will be obvious, that different sorts of materials may be made use of in different situations and kinds of works of this nature, with more advantage than others, both in so far as duration and expense are concerned.

Those steep upright embankments, which are constructed with the view of protecting bold shores, or coasts, and the banks of particular rivers, may probably be best formed of good brick, rubble, or ashlar work, in the manner of a wall, as seen at *Figure* 6, in the Plate, the materials being laid in the strongest mortar that can be made. But where this is not the case, they may be built in the common way, and pointed with puzzolana earth, or what is termed the Roman cement, prepared by Messrs. Parker and Co., London. Concrete has been used most successfully and extensively for the purpose of embankments, as we have shown under that article.

The different kinds of sloped embankments may be formed either with common earthy materials, clay, mud, or a mixture of these several different substances; and any other matters which are capable of uniting into a solid, firm, compact mass, may be had recourse to for the same purpose. Where the sides next the sea or other waters form angles of from 20 to 30, or even 35 degrees with their bases, they may be coated with sand, the shells from the sea, or coarse gravel from the borders of the shores. And stones, broken down to uniform sizes of a few pounds in weight, may be employed in a similar manner. Where none of these substances can be procured in sufficient abundance, a method practised in Holland, of covering them with such perishable materials as mats, reeds, straw, bark, and others of the same nature, may be had recourse to; but these are obviously disadvantageous, as requiring very frequent renewal. They might likewise be protected by a low fence of brushwood fixed in an erect manner all along at the bottom of the bank, of an equal height, as tending to break off the violence of the waves. Another method might also be employed, which is that of covering the whole front of the bank with brushwood, either made into bundles, or in the manner of wicker-work, or fixed down in a neat manner by means of long poles and strong hooked stakes. And farther, they may be laid in the form of a causeway, with stones in moss, or covered with wicker-work applied upon the mossy material when spread out over the bank. Many other modes also may be adopted under particular circumstances.

In all cases where the sides and slopes towards the sea constitute angles of from 35 to 45 degrees with their bases, as in *Figure* 8, recourse may be had to stones of the flag kind, as coverings, which should be jointed with cement mortars formed in some of the ways we have mentioned above. And where these sorts of stones cannot be provided, if clay can be found, proper kinds of bricks may be made, and used in the same way as the stones. Where the slopes or inclined planes are from 40 to 45 degrees, it is frequently more cheap and economical to have them covered with stones of about six or eight pounds in weight, applied to the thickness of a foot and a half, or nearly two feet; or these may be used on a bed of common moss of three inches, or of peat-moss of the flow kind, of six inches in thickness, spread upon the banks, only to the thickness of six or eight inches. Stones of these kinds may likewise be formed into a sort of causeway, or be laid in strong clay, and their surfaces jointed with lime or a strong cement mortar, which has the property of quickly hardening, and of enduring the operation of the air and tides, which alternately act upon it.

There may likewise be cases in which it may be the most advantageous practice to have the sides next the sea or rivers protected by coverings of wood only, in which case, larch may be the most proper, or such others as are durable, having their surfaces covered over with pitch and some sort of sharp sand. And old sail-cloth, or oil-cloth pitched and coated over with sand in the same manner, or even thin plates of metals, have been suggested as useful in particular instances.

In a paper read before the Institution of Civil Engineers in May, 1841, the Hon. Mr. Stewart gave a very interesting account of the application of peat to the purpose of building "sea walls." The author described some embankments constructed with it on the estates of his brother the Earl of Galway, to reclaim various portions of land, to the amount of many hundred acres, and stated that it had been found to answer extremely well, for several reasons, the most prominent of which were, that the blocks of peat, when well rammed down, grew together, thus forming a complete "puddle" wall; and that from its spongy nature it was not liable to crack in dry weather like clay, when any portion of it was in water, as moisture was in that case drawn up to all parts of it.

It is evident that great quantities of land might in many situations be obtained from the sea and large rivers, by the forming of proper embankments. Some notion of this may indeed be formed by a careful examination of such lands as lie along their shores and banks, by ascertaining the distances to which the waters ebb out at common tides, as it is found by experience, that at least one-half of the extent of land, thus uncovered in any particular situation, may be gained; hence, throughout the whole kingdom, it could hardly be estimated at a less quantity than from two to three millions of acres, but it is probably much more than even the last quantity, if it were capable of being ascertained with any degree of accuracy or correctness.

Importance of embankments.—When the extent and the value of the lands which are capable of being gained by these means are fully considered, there can be no doubt of their being of the greatest consequence to the interests of the country. It has been well remarked by a late writer on this subject, that there are numerous places in the kingdom where vast improvements may be effected by the judicious application of these means. Vast tracts of land of the best kind may not only be gained from the sea, but likewise from the large rivers and lakes, besides the beneficial consequences which must necessarily arise from the prevention of such rivers from overflowing their banks, and injuring the level grounds in their vicinity by such inundations. In some cases, it is supposed, that by raising a bank of only three or four feet in height, at a very small expense, some thousands of acres might be prevented from being overflown, the crops from being carried away, and much other mischief from being produced. In other instances, the forming of very trifling banks might be the means of obtaining much extent of country, which in its present state is of but very little value; yet so indifferent are people in general about improvements of this description, that though immense tracts are year after year overflown, and the most dreadful devastations committed, they have recourse to no means of prevention; nay, even though the sea itself, says the writer, as if to rouse them from their inaction, presents to their view twice every twenty-four hours, large tracts that might by proper means be made of very great value, yet these repeated invitations are disregarded, and no attempts are made to possess what might, in many cases, be so easily and so advantageously acquired. It is certainly extraordinary and unaccountable that the acquiring of distant possessions should be eagerly sought after, and considered of so great importance to us as a nation, when the addition of land in our own country by the reclamation of it from the waters, must be in every point of view so much more valuable.

The acquisition of additional territory at home should, therefore, be more attended to, and have more expense bestowed upon it than has hitherto been the case. In particular situations, indeed, a few active and enterprising persons have taken advantage of the opportunities which have been presented; as in the counties of York, Lincoln, Cambridge, and others, many hundred thousands of acres have been gained by embankments. In Norfolk, too, a considerable extent of land has been gained in this way. In the neighbourhood of Chester, the River Dee Company have likewise gained several thousands of acres from the sea, which have since been divided into different beautiful farms, the whole of which pay in rent more than 2,000 pounds per annum. And in Holland the whole country has, in a great degree, been obtained by these means.

It is stated by Mr. Beatson, in the second volume of *Communications to the Board of Agriculture*, that large sums have been expended in some places by individuals with a view of guarding against inundations, but, owing to the embankments they have made being injudiciously placed, and as badly constructed, the desired effect has not always been produced, particularly in the northern parts of Cheshire, on the banks of the river Mersey, where works of this kind have been thrown up at a great expense, which, from the manner of their being placed, may, in some cases, by confining the course of the river, do more harm than good. By the appearance of that part of the country, so far as he could judge from the cursory view he had of it, it seemed to him that the inundations from that river might have been effectually prevented at a much easier rate, if a proper method had been taken at first; but from a certain ill-judged and mistaken tenaciousness of property, the embankments are constructed so close upon the sides of the river, that, in many places, it is confined to a space not more than 20 yards over. Owing to this, and to an aqueduct across the river, with only one arch instead of two, which it ought at least to have had, the water sometimes, in great floods, rises, he was informed, to the height of about 20 feet above its ordinary level, and overflows the embankments, although now, by frequent additions, they are about that height. Instead of 20 yards, had these embankments been 80 or a 100 yards distant from each other, and the river widened in the narrowest places, one-third or one-fourth of their present height would have been quite sufficient. They would have been much easier made, and less liable to damage by the floods; a great deal of money also would have been saved, not only in the first construction, but in keeping the banks afterwards in repair. The space of ground between the embankments and the river thus left, would have produced the richest pasture, or meadow-hay, by its frequent manurings with the fertilizing particles left upon it, when flooded by the swelling of the river; and in those places, if any, that are unfit for pasture or hay, willows or other aquatics might have been planted to great advantage;

and thus it might have been of more value perhaps than at present, while the interior grounds would have been more effectually secured from the ravages of sudden floods. Notwithstanding the general indolence shown in most parts of the country, respecting the acquisition of land by embanking, and the seeming aversion that most people have to engage in such undertakings, there have been, however, some ingenious and enterprising projectors, whose ideas upon that subject have soared far beyond the bounds allotted to common understandings. From the speculations of such people, the most important advantages are sometimes produced; and surely the man who is possessed of a speculative turn of mind, and who considers no obstacles insurmountable, is a much more useful member of society than he who is perpetually starting difficulties against every new project, and is for having all things remaining *in statu quo*, that is, for leaving the world as he found it.

The idea of reclaiming land from the sea, for example, would have appeared to a torpid genius of this kind, as a matter too visionary for sober-minded men. A thousand difficulties would have started up at such a proposal; and obstacles, which to a more expanded mind, would seem perfectly practicable to overcome, would have presented to him impediments insuperable.

What would such anti-projectors think of proposals to exclude the sea entirely from extensive bays, many miles across, and exposed to the full sweep of the winds and the waves? Such was the proposition to carry a railway embankment across Morecambe Bay, and the estuary formed at the mouth of the Duddon, the embankments on Lough Foyle in Ireland, and other similar works.

That there are many large tracts of land in different parts of the kingdom, both on the sea-coasts and on the sides of lakes and rivers, easily attainable, there cannot be the smallest doubt. It is, therefore, an object worthy of the attention of those who are so fortunate as to possess property of this nature, to have it ascertained by persons of experience in such matters, how far the acquisition of additional portions of land may be adequate to the expense which it may be necessary to incur in procuring it. But embankments are important in other views than those of gaining ground by them. When rivers are concerned, one material advantage is the deepening of their courses, by which vessels of greater burden than they admitted formerly, may be permitted to navigate them.

And farther, as embankments become more frequent on the borders of rivers and sea-shores, the intervening distances may become a sort of bays, in which accumulations of shell, mud, sand, gravel, and other matters, may take place by the influx of the tides; and these, however difficult they may be at first to embank, will in time be as easy to perform the work on, as the natural bays and creeks are at this period. In this way many rivers, which in their present state are eight or ten miles in width at their junction or influx with the sea, may in the course of years be reduced to less than half these distances. Consequently, such embankments would be equally beneficial to the proprietors of land, and the merchant or manufacturer, as many rivers would become more easily navigable, and those obstacles which interrupt their mouths be wholly removed.

In embanking against the encroachments of the sea, it is necessary to ascertain, with great accuracy, the maximum height to which the water rises; the methods of doing this have been already shown. But as new works of this sort, especially where the banks are large, are liable to subside too much, it may be a proper precaution to take the levels frequently for some time after they are completed, in order to guard against any mischief which might arise in this way. Where the banks are low, this is not, however, so necessary, as in higher ones, as the settling is always more or less according to their height; in low banks it will of course be very little. In the making of such embankments, it is scarcely possible to lay down any general rule in regard to their size or dimensions, as these must be directed by situation and circumstances, under the management of an expert engineer. In cases where the embankment to be formed is to exclude the sea from a piece of low marshy ground, over which it only flows at spring-tides, the work is easy, and capable of being accomplished at no great expense. But where it is intended to reclaim a portion of land which is covered every tide, in some bay or creek, or on the sides or windings of some large river in which the tide ebbs and flows, the business will be in some degree more difficult, according to the depth and rapidity of the current of the water. And where it is proposed to exclude the sea from an exposed situation at the mouth of a river, or in a bay, or inlet, which is uncovered every tide, the operation will be the most difficult and expensive of all, according as it is exposed to prevalent winds, and the depth of the water to be resisted. Each of these situations, therefore, requires a different method of management.

The business of embanking against the sea, when at any considerable distance within high-water mark, is not only the most tedious, but at the same time the most difficult; as, when the materials are not very good and the work not well performed, the force of the water at every flowing of the tide will quickly undo all that has been effected, especially if the soil be of a sandy nature, as is often the case in such situations. If it be a strong clay, as is sometimes the case in marshy places, there will be the less risk of its being washed away. In sandy situations it has been advised by some to lay bundles of straw or reeds well fastened down, or any other impediment, to hinder the soil from being carried away by the ebbing tide. Where a sufficient supply of good strong turf cannot be had, other expedients may be tried; but where such turf can be provided, as is the case in most marshy situations, and where the embankment required is not to exceed the height of four or five feet, it is best to finish the slope with good turf as expeditiously as possible, as the work proceeds; that is, supposing the length of 30, 40, or 50 feet or yards of it can be completed in a tide, it is better to finish that length to its intended height, than to trace out or begin a greater extent than can be finished before the tide returns, by which a great deal of the soil might be carried away, and much of the work demolished, which is not so likely to be the case when the slope is finished. Turf which contains the roots of bent or rushes is very good for this use.

In commencing a work of this kind, however, the first thing to be done is to strike out the intended line of it, setting out the breadth at the base, also the width of the excavation or trench to be made in the inside, from which most of the materials that compose the bank are to be taken: this trench serving also as a drain to keep the grounds within dry. There should also be trunks or sluices at different parts of it, to shut off themselves against any external water, and to open when the tide ebbs, to let out any water from within. The width of it should be proportioned to the quantity of materials required from it, for the raising of the embankment, as eight, ten, or fifteen feet wide, and three or four feet deep, leaving a *berme*, or space, between the edge of the trench and the inner bottom of the embankment. If the soil be strong, one foot or eighteen inches will be sufficient for this purpose; but if loose or sandy, three or four feet at least will be required. The more easy and gradual the external slope is made, the less sudden the resistance against the sea will be, as has been seen above, and of course the embankment be less liable to injury; this slope should therefore be formed according to the exposure of it to the winds and tides: a contrary opinion has, however, been held by some engineers, and the formation of upright walls properly faced has by them been considered better adapted to resist the action of the water. *Figure* 12, is supposed to be a section of an embankment in which the base or horizontal line *g h* should at least be three times the perpendicular height *h i*; but *l m*, the inside slope, need not be more than three-fourths of the perpendicular height, that is, nine inches for every foot of rise. The inside slope should be faced with turf likewise, laid with the green side downwards, as in common sod walls. Some expert sodders can finish this sort of work extremely neat by setting the sod on edge, according to the slope intended to be given, and with proper mallets and beetles ramming the earth hard behind, which consolidates the work as it advances, and tends to render it durable. As soon as the first or lower course is finished, the upper edge of the sods is pared with a sharp knife quite even, by laying a rule to them, and then they go on with the second course, which they finish in the same manner, and thus proceed until the whole height is completed, which, when properly finished, has a smooth and beautiful appearance, not a joint between the turfs being seen. Where turf is used in covering the outside slope, it should all be laid with the grass uppermost, as already noticed, and be well beaten down with a flat sod-beetle for the purpose, and in order the better to secure them, it may be proper to drive small stakes, about eighteen inches in length, through every sod. In cutting sods for this use, they should be taken up in a careful manner, and be all traced by a line of the same breadth; their edges being cut as even as possible, that they may make the closer joints, which will tend very much to their security, until they are grown properly together. In laying the different courses of such sods, care should also be taken that the joints of the one be covered by the other, in the manner that good brickwork is made.

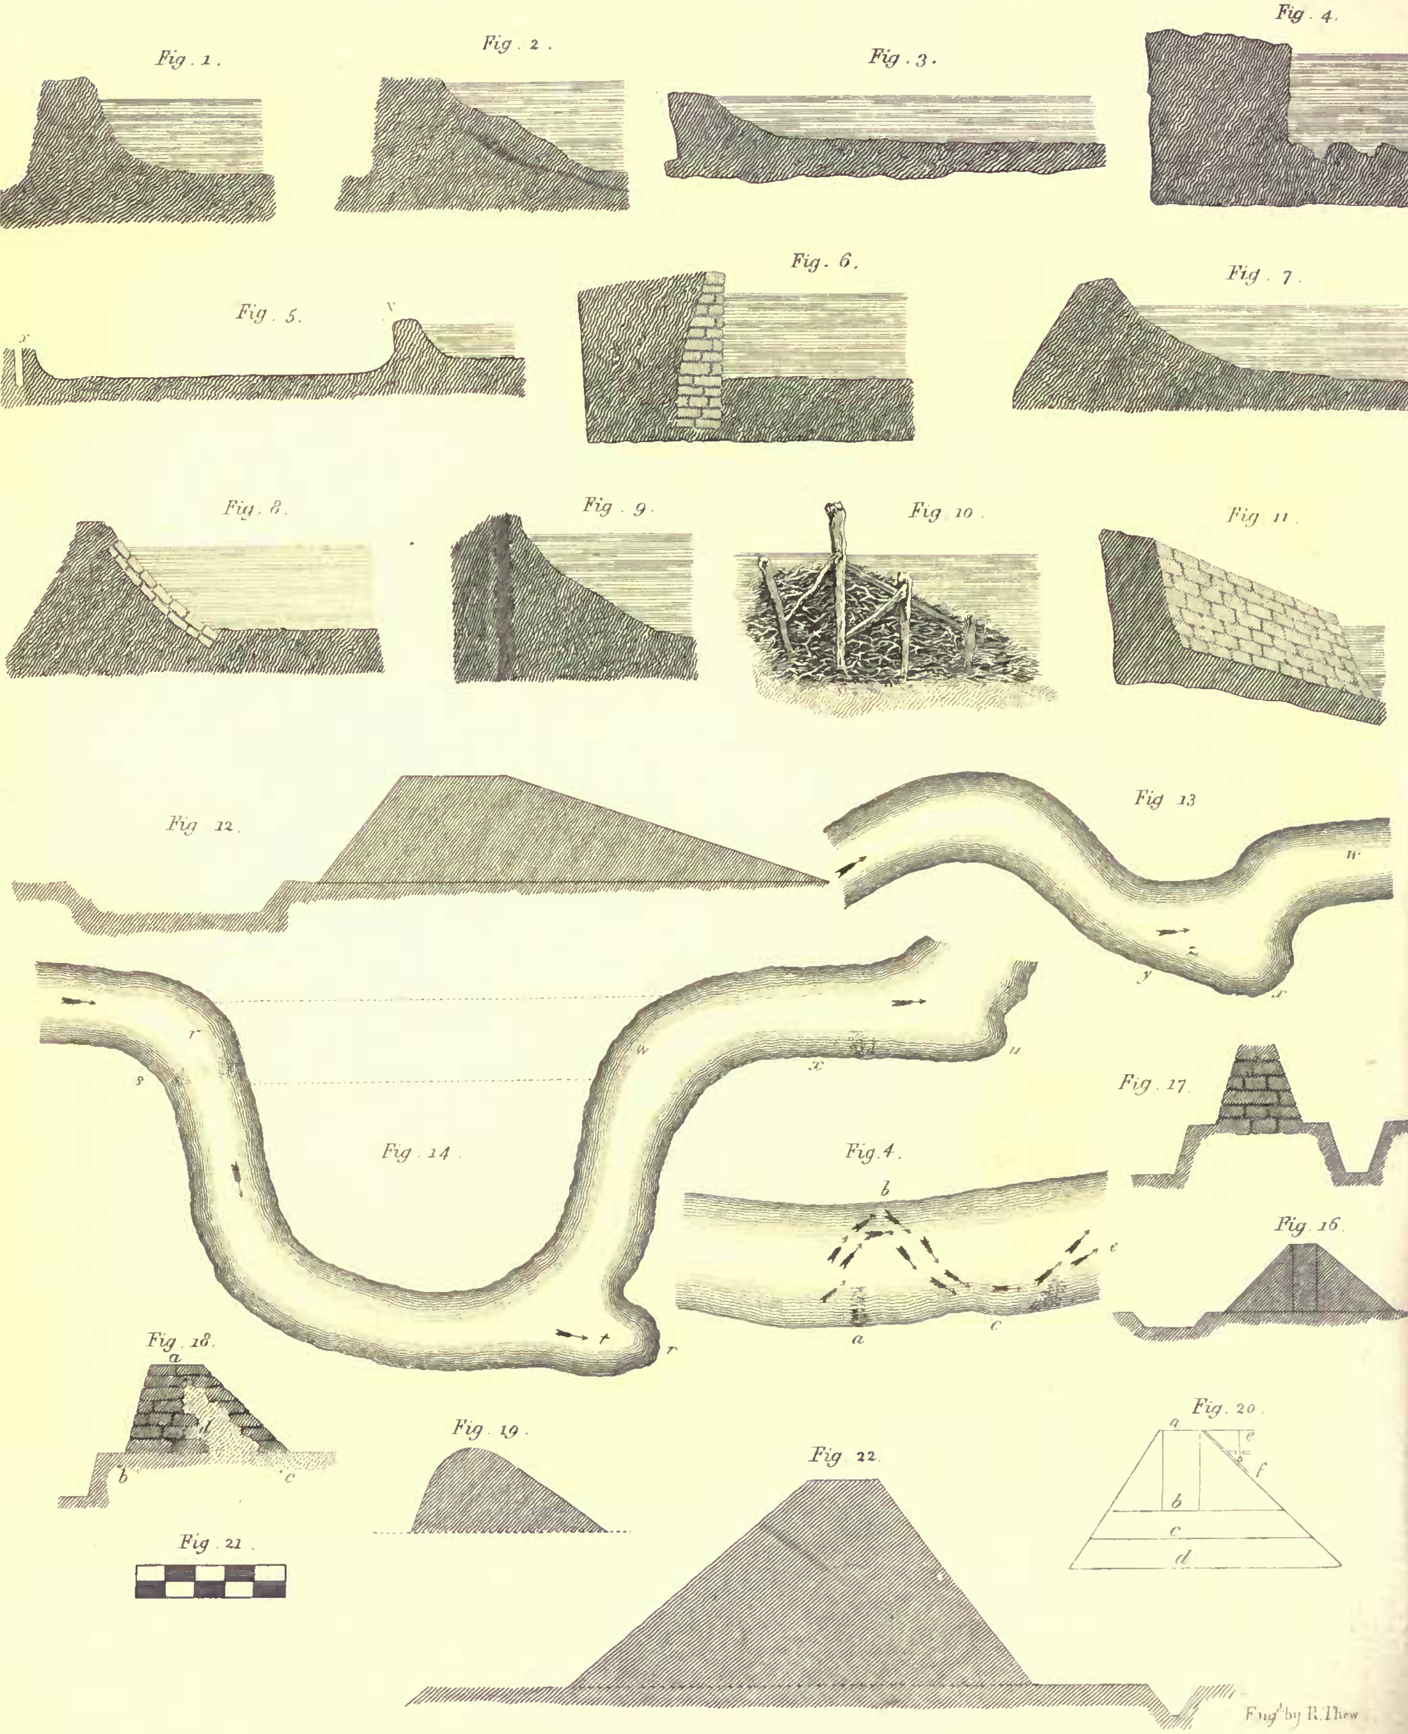
Where it is proposed to reclaim a piece of land, upon which the sea ebbs and flows every tide, to a greater depth than in the foregoing case, as in a creek, or on the side of a large river, a different mode of proceeding must be pursued, according to the soil, and the nature of the materials to be employed. Where plenty of stones can be readily procured, a bank may be formed of them, with a mixture of clay, either by means of land-carriage, or, which in some instances is better, by conveying them in flat-bottomed boats, or punts, and throwing them over-board until the bank is formed. Where stones cannot be easily had, clay, or other materials proper for the business, may be thrown in, in sufficient quantity, in the same manner, with perhaps nearly equal success. It is supposed that most of the embankments in Holland were formed in this way, the clay dug from the canals being made use of for the purpose. In either case it is requisite to fix up strong poles before the work is begun, as guides for laying down the materials. Proper sluices must likewise be laid in suitable direction for taking off the back-water when the tide ebbs, under the inspection of the engineer. Much, in all cases of this sort, depends on a skilful engineer, who is capable of suggesting and contriving various means of facilitating the business, and of obviating the difficulties that may arise in its execution. A person of real genius is often capable, by his different contrivances, of rendering the accomplishment of a great undertaking comparatively easy, which to others would be almost impracticable, or carried on at such a heavy expense as to counterbalance the advantages to be drawn from it. In cases of the kind just noticed, he might suggest the erection of stages or platforms, in such a manner as to carry on the work at all times of the tide, which would be an immense saving, as the delays caused by the tides in this sort of business are both tedious and expensive. Waggons might likewise be contrived in such a way as to carry on such platforms large quantities of materials at once, which could be easily emptied and filled; and at the same time be drawn by machinery, in such a manner as to save much labour and expense, both in carriage and tidework.

There is another species of sea embankment, which is, perhaps, the most important of any; as there are few estuaries, or mouths of rivers, in which large tracts of land may not be gained by it. The shoals or flats formed at the entrance of such rivers, are mostly composed of the richest and most fertilizing particles, brought down from the towns and circumjacent country through which they pass. Such shoals and flats may, therefore, under proper management be in most cases readily converted into the most fertile plains. In these situations the first object is that of collecting the whole river into one stream, and preventing its overspreading a wider extent than is merely sufficient for its discharge; or it may be better, perhaps, to alter its course altogether, and cause it to be discharged at some other outlet. It has been found by experience, that where the course of a river is changed in such a manner as to make it discharge itself into the sea at a different place to that where it did before, the former place will in a few years, by the continued accumulation of sand and mud brought in at every tide, be so choked up, and raised above its former level, as to form of itself, in the course of time, a bank, that with a very little assistance, will exclude the sea; for as the current of the river before carried away all that sediment which the motion of the waves naturally stirred up, from its being now removed, it is obvious that all or most of the muddiness will not only be carried farther up the old channel of the river, but a great part of it be deposited there as the tide recedes. It has been found that in spring-tides and particular winds, this sediment is deposited in larger quantities than at other times, and on making a perpendicular cut in the ground under reclamation, the different layers are found to be so distinct, that those made at spring-tides can be easily distinguished from the rest. This curious fact is well deserving of the attention of all those who have lands situated at the mouth of rivers, as there may in many such situations be considerable tracts gained at a very light expense. But though this fact may exist in some places, as has been proved by experience, nevertheless it is supposed that the effect cannot be the same in all situations. Where there is a great extent of flat or muddy shores, the motion of the waves will no doubt stir up the mud and sand, and carry great quantities of them along with the current on the flowing of the tide; and when the tide ebbs, though some of the lighter particles will be carried away again, yet it is reasonable to suppose the heavier ones will be left behind. If the shores are bold and rocky except just near the entrance of the river, there will be less of this mud; but on such shores there can, indeed, be little or no occasion for embanking, unless perhaps in some creeks, narrow at the entrance and spreading out wide above. If the sea were excluded from such creeks, a great deal of land might probably be gained.

In the marshland district of the county of Norfolk, lying between the rivers Wyn and Ouse, immense tracts of the most rich land, such as is composed of the muddy depositions left by the tides and floods, which is there called *silting*, have been obtained by means of embanking. This kind of work has sometimes been undertaken by the tenants on a low piece of marsh, in consideration of having the land free for twenty-one years. But in these cases the banks have often been very

EMBANKMENTS

PLATE .



Engd by R. Thew

imperfectly made, not having cost more than forty shillings a rod. And those which were constructed by the landlords were indeed frequently but little better, being mostly deficient in not having slope enough given them towards the water. Count Bentinck, and his son, who succeeded him in the estates, undertook the drainage of the marsh lands upon a scale never practised in that part of the island before, and by their successful operations have increased the old estates by more than 1,000 acres.

The base of the embankment, in this case, is about 50 feet, the slope to the sea 36 feet, forming an angle, of about 25 or 30 degrees. The crown is 4 feet in width, and the slope to the fields 17 feet, in an angle of about 50 degrees; the slope towards the sea being very nearly turfed over. The first expense incurred in forming this bank was £4 per rod, but a very high tide coming before it was finished, not only made several breaches, but occasioned an additional height and slope to be given to several different parts, in order to bring it to the dimensions mentioned above, all of which made the gross expense to amount to about £5 the rod. The whole cost was something more than £5,000. The expense of the houses, farm buildings, and other things, was about as much more, for five new farms, which was a greater expense than was necessary, as the land would have let as well in two or three as five farms. Supposing, therefore, the expense at £10,000 and the new rental at £1,000 a year, it is just 10 per cent for the capital laid out. The expense here, however, seems to have run too high, when the necessary repairs of the bank are taken into the account. The representation, given at *Figure* 22, in the Plate, fully explains the nature of the embankment formed in this case.

In another new embankment, in which 273 acres of marsh land, and 18 of bank, were gained, the men were paid 4s. 6d. a floor of 400 cubical feet, finding wheeling planks, barrows, trussels, &c. When it is thus formed, the front slope is sodded, for which they are paid in addition 4s. a floor of 400 square feet, earning from 5s. 6d. to 7s. a day, and there is some little further expense necessary for beating it down in a firm manner. The whole of the expense of the bank, sluice, and every thing else, was about £3,300. The land was immediately offered to be rented at four pounds an acre for four years, or three pounds an acre for six years; which, in the former case, would amount to £4,368 in that length of time, or 1,000 guineas more than the whole of the capital laid out on the undertaking.

On this coast the operation of *silting* up, or raising the surface of the marsh-land by the repeated depositions of muddy matters from the sea, is performed in a more rapid manner than in many others; and the little hollows and creeks are found from experience to silt up much faster where the tide-waters are speedily taken off by proper cuts and channels formed for the purpose, than where the contrary is the case.

One of the most extensive reclamations of land in England, is the large tract of country known by the name of the Great Bedford Level. This great expanse of rich and fertile country is bounded by the high lands of the counties of Norfolk, Suffolk, Cambridge, Huntington, Northampton, Lincoln, and the Isle of Ely, and contains upwards of 300,000 acres of fen-land, beyond which are about a dozen very large marshes also similarly reclaimed. The drainage of the whole level is effected by innumerable dikes and drains of all sizes communicating with, or gathered together into three great channels, forming the main outfalls into the sea. One of these outfalls is at Boston, in Lincolnshire; one at Wisbeach, in Cambridgeshire; and the other at Lynn Regis, in Norfolk.

In Holland, however, is exhibited the most prominent illustration of the successful redemption of land from the sea; and probably in no part of the world has it been carried to so great an extent. Indeed, the whole country has been rescued, as it were, from the waves of the ocean, and has been secured and held only by the constant care and superintendence of the persevering conquerors.

There is little doubt that the inhabitants of Holland were obliged, in the first instance for their own preservation, to erect barriers against the encroachments of the sea. On the invasion of their country by the Danes and Normans, the latter soon discovered the superiority of these lands to those adjacent to them, and at once applied all their energies to the proper reclaiming of so fertile a property. Thus, by the steady perseverance of ages, has Holland become pre-eminent for the extent of her drainage works, though the manner in which their embankments are constructed is very far from equal to similar works executed in this country. It is said by those who have made it their business to examine the mode of making these banks, that in those made of stone, the materials are not economically distributed, but are heaped so confusedly on each other, as not only to weaken the bank, but occasion great waste. They have, however, a very ingenious method of facing their banks where there is a scarcity of stone, with straw, formed into ropes, about an inch or two in thickness, laid in regular courses. These courses fit closely together from top to bottom, and are fastened down to the bank with wooden *falks*.

In Ireland the attempt to bring into cultivation the immense tracts of bogs or flats partially covered with water, a few years ago attracted the public attention; and a board of commissioners was appointed to inquire into the nature and extent of the bogs in Ireland, and the practicability of reclaiming them.

These commissioners have published reports containing much interesting and instructive matter, exhibiting the present state of the wastes in certain districts, and evincing clearly the practicability of converting them at a comparatively small expense, into rich arable and pasture land.

On the north and west coasts of Ireland there are a great number of deep bays or inlets of the sea, presenting great facilities for embanking. Amongst these the estuaries called Lough Swilly and Lough Foyle, in the counties of Donegal and Derry, seemed to offer to some enterprising speculators a tract of land peculiarly adapted for embanking.

Sir John Macneill having been consulted on the scheme for the drainage of these loughs, employed Mr. J. W. Bazalzette to make the necessary surveys for the purpose, and the latter has furnished to the Institution of Civil Engineers a valuable paper on the subject from which the following observations have been extracted.

Lough Foyle is described by Mr. Bazalzette, as not entirely insulated from the Irish Channel, but as having a narrow mouth communicating with it. Above this mouth the waters spread over a wide tract of land, and then again contract into a narrow channel. The effect of the tide rising through so small a passage has been to scour the *narrows*, and throw up the deposits on the sides of the Lough. By the accumulations of years these deposits have at last become immense banks of rich alluvial soil extending for some miles and covered only at high water. To reclaim this land it was proposed to construct an embankment or sea-wall, a little below low-water mark, for fourteen miles in length, by which about 25,000 acres of land would be enclosed.

Lough Swilly is less extensive than Lough Foyle, but presents greater difficulty in the construction of the works, from the scarcity of the necessary materials. It is wider at its mouth (which opens into the Western Ocean,) than in any other part, and in its whole extent is extremely exposed to the winds. It was proposed to construct here three embankments, the first 1,100 yards, the second 1,133 yards, and the third 633 yards in length. The position of these banks being fixed by careful measurements and soundings, the proposed method of formation was as follows :

Each bank was to be 4 feet in perpendicular height above the highest spring-tides, which here rise to 18 feet : and to have a slope on the sea-face of 3 to 1, except in the most exposed part, where the slope was to be 4 to 1. The materials available for the work were stone, clay, earth and gravel, taken from the adjoining lands, and the banks were to be faced with rough stones on both sides, laid as close as possible with the edge outwards, in courses not exceeding 4 feet in height. In the centre of each bank was to be built a culvert of masonry, with proper sluices and flood-gates. These culverts were to rest on a foundation made by driving piles into the soil, which from its alluvial character could not be depended upon in itself. The sluices being self-acting, the drainage would be effected in the following manner. At high water, it being supposed that the whole of the *slob* (as it is termed in Ireland,) is covered on the receding of the tidal water, the sluices would shut of themselves, retaining the water within the banks. When the flood-tide came on, the pressure on the sluice-gates from within, would prevent their opening to admit it, and the retained water would soon evaporate, leaving the rich slob dry, and to be in a short time fit for agricultural purposes.

The extent of the slob thus enclosed by these three walls would be about 2,000 acres, and the value of it may be estimated by the fact that a large quantity of land has already been reclaimed near this part of the Lough. This land now lets at £5 per acre, and is considered the richest soil in the neighbourhood. Indeed, in every case, where a proper selection of land has been made, and the works performed judiciously, similar success has been the result.

It has been remarked by Mr. Beatson, whose observations on this subject we have before noticed, that in the lakes or *mires* of the north, and the *Loughs* of Scotland and Ireland, the business of embanking is both simple and easy. In these situations the waters generally subside during the summer months, rising considerably in winter, and whenever the season is very wet. In particular cases the extent of surface which is overflown in the winter season, so far exceeds that which it covers during the summer, that it would be an object, and sometimes a considerable acquisition, to confine the water within its summer boundaries, or to cut off some of its parts. To accomplish this the principal outlet must be carefully examined, and be considerably widened and enlarged; which will prevent the water from rising so high as was formerly the case. Where the levels will not admit of much depth being had, or where the ground is of a rocky nature, and would of course be difficult and expensive to deepen, the breadth should be increased as much as possible, and all obstacles cleared away, that the water may run freely in a shallow stream. Where it is required to ascertain with exactness, or, to fix with certainty, the future limits of the water, a section of the greatest quality running out during a flood should be taken. Suppose this section, for example, be 10 feet in width and 4 feet in depth, by making it 40 feet in width, the same quantity of water will not rise above 1 foot : consequently, by this means alone, 3 feet in height will be gained all round the lake, which, in case of embanking it, would be a great object. During the summer season, when the water is lowest, is the most proper time for carrying on these, as well as other embankments. When, however, any materials are to be brought from a distance, they may be laid down, or prepared at other seasons, with the exception of turf, which should always be used as soon as possible after it is cut. The manner of constructing embankments of this kind may be sufficiently understood, from what has already been said in the other description of embankments: observing, however, as a general rule, that when the materials on the spot will answer the purpose, they should invariably be made use of, although at the expense of digging a trench larger and deeper than would otherwise be necessary. It should constantly be attended to, in executing all sorts of embankments, that the greatest care be taken to make them perfectly firm and solid, by continually beating them, and examining them carefully, during the whole of the time they are in a state of being formed.

The following account of embankments on the Continent, is taken from the "Dictionary of Terms of Art," part of the very useful rudimentary treatises published by Mr. Weale.

"On the banks of the Po, two sorts of dykes are used to prevent the river from overflowing during the winter, or the flood season. They are called 'in froldi,' when immediately upon the banks of the river, and 'in golene,' when at any considerable distance, as it is sometimes found advisable to allow the river to spread over a large surface of the adjacent valley, either for the purpose of admitting it to deposit the mud in suspension, or to allow it to lose its torrental character. The maintenance of the works of these dikes is confided to the government engineers, who are under the control of a syndicate of the proprietors of the property most liable to be affected by inundations. When the river passes from one state to another, as from Piedmont to Modena, a mixed commission is charged with the joint superintendence.

"The Haarlem lake, besides the very remarkable steam-engines described by Mr. Dempsey, merits observation for the extensive works executed for the defence of the land, and for the canals reserved for the navigation. The enclosure dike is 50,000 metres long, or rather more than 31 miles. It has two outfall dikes, which serve for the navigation, 9,000 metres, about 5½ miles ; one half of which is 40^{m} (131 feet 2 inch) wide at the bottom or floor line ; the other 43^{m} 20 (141 feet 10 inches.)

"The ordinary tides are at the flux, 2 feet 4 inches above the scale or datum line at Amsterdam ; at the reflux 2 feet 8 inches below the same datum : the difference between high and low water is then, on the average, about 5 feet. With violent winds from the N. W., however, the tides rise sometimes 6 feet 6 inches above the average. The tides of the Y, near the lake, are $+ 16^{c}$ (or 6½ inches) and -23^{c} (or 9 inches), giving a total variation of 1 foot 3½ inches.

"The estimated cost of reclaiming the 18,000 hectares, was 8,000,000 of florins, or £667,000 English, nearly about £13 per acre. Previously to undertaking this colossal work, the Zind Plas, of 4,000 hectares superficial, (nearly 11,500 acres) had been reclaimed at a cost of 3,000,000 of florins, or £250,000 ; not far from £22 per acre. The heights of the enclosure dike are + or — the datum line at Amsterdam, or the mean level of the sea in that port.

Embankment of the flooded part of the Amsterdam and Haarlem railway.—The bottom part consists of treble ranges of fascines, tied down by longitudinal poles 1 metre apart from centre to centre, and 0.25^{c} diameter; two double stakes at each end of the poles, and two ties in the intermediate distances. The interstices of the fascines and the space between the rows, are filled in with sand. The upper part, forming the encasement for the ballast, is made of three rows of treble fascines, well staked and wattled together.

"A core of sand or clay, faced with step fascines, is made up to low-water mark. Upon this a bed of rushes, fastened down by stakes and wattles, is laid; and the upper portion of the bank is faced with fascines of a regular slope of 1 to 1."

Embankments against rivers may be divided into two kinds; namely, such as are for preventing their encroaching on the adjacent lands, and for protecting those lands and the neighbouring level country from being overflown, when the water rises above its ordinary level. It may be remarked, that where the course of a river is a straight line, or nearly so, it hardly ever makes any encroachment upon its banks, unless, perhaps, in very large rivers, when they rise above their common level, either owing to an increase in the waters, or to their being, in some degree, affected by the tides. In either case, the waves occasioned by a strong wind, where the river is wide, will moulder away the banks on that side upon which it blows, unless prevented in proper time. This may be done either by securing the bank properly with stones, or by driving a row of long piles pretty close together at a little distance from the shore, the piles being of such a length, and so driven, that their tops may be always above the highest rise of the water. It is surprising the effect that piles driven in this manner have in resisting the power of the waves in such situations.

Some years ago, when Mr. Beatson was on duty as an engineer at a fort near Portsmouth, built on a point of land much exposed to the sea, the waves made such havoc, that the walls on that side were constantly giving way, although built in the most substantial manner; and having bulwarks of large heavy stone besides, to protect the foundation: however, all would not do; those bulwarks were soon knocked to pieces, and several times the wall itself. At length it was proposed to drive a number of piles at about 40 or 50 yards from the fort. These piles were 12 or 15 inches in diameter, and driven about one diameter from each other nearly in a straight line, parallel to the wall where the waves did so much damage. They were driven into the ground with a pile-engine till perfectly firm, perhaps 8 or 9 feet deep, and about 2 feet or the top of them left above the level of high-water mark. After this was done, the wall received no farther injury, the space between the piles and the fort being always perfectly smooth, however tempestuous the waves might be without. The same simple method might, it is supposed, sometimes protect the banks of large rivers, if exposed to the waves, when other methods might fail.

But it is suggested, that the most common cause of rivers encroaching on their banks, is the resistance occasioned by a sudden bend. In flat countries, apt sometimes to be overflown, where there are any such bends or windings in the rivers, it would be of great advantage to straighten the course as much as possible; for, as every impediment or obstruction will naturally cause the water to rise higher than it otherwise would do, and as such bends have that effect, consequently, in the time of a flood the waters will overflow a greater extent of country, and to a greater depth, than if the river had a free and uninterrupted course straight forward. If the windings of the river cannot be altered, and encroachments are making on some part of the banks, it must first be considered, whether the force of the water can be driven to another place where no injury can be done. If, for example, a river is encroaching on its banks at *x*, *Figure* 13, a jetty of stone, a little way up the river, in the direction *y z*, would throw off the current towards *w*, and might totally prevent any farther encroachment. On the river Nith, in Dumfriesshire, it is stated, that a good deal has been done in this way by Mr. Millar, of Dalswinton, a gentleman of the most enterprising genius and most liberal mind, who has paid more attention, and laid out more money, in making important and useful experiments, than almost any other private individual. The course of the river, where Mr. Millar has been carrying on his operations, is said to be nearly as shown at *Figure* 14, by *r s t u;* at *t*, it was encroaching most rapidly, and seemed inclined to take a new course towards *v*, which would have destroyed some very fine land, and done a great deal of mischief in that part of the country. To prevent this, Mr. Millar made a large cut, about 400 yards in length, from *w* to *r*, and threw in a great quantity of stones quite across the river at *s*, to direct its course in a straight line from *r* to *w*. This had, in a great measure, the desired effect, by totally preventing its progress at *t*, but now it began to encroach on its banks at *u*. He at first endeavoured to prevent this by driving in, at a considerable expense, a number of piles at a little distance from the bank, and wattled them with willow branches, &c., thinking thereby to protect the bank. The piles were driven in with heavy mallets, apparently firm into the ground; they continued so for some months, till a heavy fall of rain came on, which swelled the river, undermined the piles, and carried them all away. But, indeed, it is in vain to think of piles doing any good in such a situation, unless firmly driven in by a pile-engine; for it is not possible to drive them in properly with mallets; this must have been the cause of their giving way so soon. The piles not succeeding, Mr. Millar was resolved to try another plan; several of his adjacent fields being covered with an immense quantity of stones, he ordered them to be gathered and thrown into the river, so as to form a jetty at *x*, a little way above the injured bank. Being obliged to go from home about that time, and to leave the execution of the work to some country-people, they carried out this jetty too much at right angles to the stream. It had not, therefore, the desired effect, but rather made the matter worse than before; for, if a jetty is carried out at right angles, as at *a*, in *Figure* 4, the current will be forced from *a* to the opposite side of the river at *b*, and from thence it will rebound towards *c*, more violently that it did before. But if a jetty be placed obliquely, as at *d*, it will force the current gradually towards *e*, in which position one jetty may do more good than several placed improperly at right angles. Mr. Millar was, therefore, under the necessity of making other jetties in this way, and at length had the satisfaction to find that they answered the purpose intended. Those he made laterally formed a sort of convex slope, the convexity being parallel to the current. Strong planks were also firmly set on edge among the stones, their ends pointing towards the river, so that if ever any current came so rapidly as to move any of the stones, it must move them all in a body the whole length of the plank. Perhaps this precaution was unnecessary; for although stones are thrown into a river loose in this manner, the slush, sand, &c., that come down the river will soon fill up all the cavities, and render it as firm and solid as a regular-built wall. Mr Beatson has been the more particular in this description, he says, in order to show the errors that Mr. Millar at first fell into, and the great expense they occasioned, whereas, had he been on the spot himself, and got the work executed as he intended, it would have saved a great deal of unnecessary labour as well as money.

It is stated by the same writer, that the next sort of embankments against rivers, are those to prevent them overflowing their banks, and inundating large tracts of country. This may be considered as the simplest and easiest of all sorts of embanking, if judiciously executed. It is, therefore, the more inexcusable to see, in some places, extensive tracts of the richest meadows completely overflown by every flood, for want of them.

Two ordinary-sized rivers rise no more, even in the greatest flood, than five or six feet above their common level, unless when they meet with some considerable interruption or confinement in their course. But if interrupted or confined, they will rise twenty feet or more, as is the case with some parts of the river Mersey, already mentioned. If, for example, a given quantity of water is six feet deep, when running over a space twenty feet wide, it is clear, if that space were only made ten feet wide, the water would rise to twelve feet, and if it were made forty feet wide, the same quantity of water would only rise to the height of three feet. It is, therefore, of great consequence, in preventing inundations, to give the river as much width as possible, by widening every narrow place. All kinds of obstructions should also be removed, whether occasioned by windings, shoals, stones, trees, bushes, or anything else. In some cases this may even preclude the necessity of embanking; but where embanking is necessary, let the banks by all means be at a sufficient distance from each other, to contain with ease, between them, the largest contents of the river in great floods. The distance and height of the banks may easily be ascertained by measuring a section of the river when at its highest, or when the flood-mark is visible. By not attending to this, a great deal of money has been thrown away on the embankments on the river Mersey, and after all they do not effectually answer the intended purpose; a great part of the country being still overflown every time the river rises to any considerable height.

Where a sufficient distance is allowed between the embankments, their height need not exceed from four to six feet. If irremoveable obstacles are in the way, which cause the river to rise higher, the banks must be higher in proportion. In either case, however, the slope of these kinds of banks on each side may be equal to its perpendicular height, and the breadth on the top about one-third of that height, which, supposing the bank six feet high, the base would be fourteen feet, and the breadth of the top two feet, as shown at *Figure* 16, in the Plate.

The materials for making these banks should be taken as much as possible from the sides of the river, which will have the double effect of widening the river and forming the embankments; and there should be a trench on the inside (from which materials may also be got) with some sluices, as formerly directed, to drain off any water from within; also sluices to let in water from the river, if required, which would very much fertilize the meadows, if properly laid out for that purpose.

Such farms as are situated on the borders of rivers are frequently, it was observed by a late writer, liable to much injury and inconvenience from them: 1st. From part of the soil being carried away in times of flood. 2nd. From their overflowing their banks. 3rd. From their flowing back in times of flood into the channels of the rivulets and streams that conduct the water from the more elevated and distant grounds to the rivers, whereby these rivulets and streams are made also to overflow their banks.

In respect to the first, the danger of the soil being carried away in time of floods, it is increased or decreased according to circumstances, as the form of the banks, the nature of the soil, the rapidity of the river, and the quantity of water that lodges on the margins of the banks, or falls over them into the river. Where the banks of a river are perpendicular, especially if the soil be of a rich mouldering nature, the danger of part of them being carried away by floods is much greater than where they slope gently from the surface of the field to the bed of the river, as has been already fully seen.

Where that is not the case naturally, they ought to be moulded into that form by art; as when a river, in place of being confined in its progress, has a power of efflux and reflux, the damage to be apprehended is inconsiderable, compared with what is likely to happen when, being restrained within too narrow limits, it is constantly struggling for an extension of space. Where the soil is rich free mould, and the under stratum, opposite to the greatest force of the water, sand or gravel, this struggle never fails to be attended with bad consequences. If the soil and subsoil be one entire mass of clay or strong loam, and the current of the river does not press more upon one part than another, a most substantial improvement may be effected by sloping the bank, so that the declivity may be one foot in three or four from the surface of the field to the bed of the river. This some may object to, as sacrificing a certain portion of valuable land; but it should rather, it is thought, be considered as a premium paid for the insurance of the remainder, than as a total loss. If gravel, mixed with small stones, can be conveniently procured, spreading these materials on the sloping bank to the depth of eight or ten inches, and till beyond the flowings of the river, will prove a good security against farther damage; and if the bank be planted thick with any sort of willow, especially the Dutch willow, it will in a short time become an impenetrable fence, while the annual cuttings of wood will soon be equal to the heritable value of the land thus apparently sacrificed. Where no gravel can be procured, the new sloped bank should be immediately covered with well swarded turf, pressed down as hard as possible, either with the back of a spade, or with wooden mallets. If this be done in the beginning of summer, and willows planted the following autumn, the improvement will be both effectual and permanent. In case the river run with extraordinary violence against any one particular part of the bank, it may be necessary to make a fence or bulwark of stone in the front of that place; the best way of doing which, is, in place of building a wall, to drop the stones in a careless manner, but so as they may lie close together on the sloped bank, as already suggested.

This is a much more secure mode of fencing, if the bank be made with sufficient declivity, than any stone wall that ever was built for the purpose, and while it is the most secure, it is also the least expensive; but care should be taken to lay the stones all the way from the bed of the river, till considerably beyond where the river flows in common. Where the soil is of a strong adhesive nature, and the under stratum is sand or a pebbly gravel, it becomes in a much greater degree necessary to slope the banks. The water, when rushing violently along, has a powerful effect in undermining the bank; so that the soil, having nothing to support it, naturally gives way, and frequently in such quantities as to occasion very serious loss both to proprietors and tenants. In all such cases, the slope should be made much more gradual than where the soil and subsoil are of the same quality, and such as will nourish aquatic plants. The banks, having been sloped according as circumstances require, a thick coat of gravel, mixed with small stones, where such can be procured, should be laid on, so as to form a kind of natural beach, over which the river, when in flood, may have power to extend itself at pleasure. Should it be difficult or impossible to procure such materials as are proper for forming this best of all defences, strong thick sods should be placed on the surface, in the manner before directed: these, if laid on in spring, or early in summer, will have time to unite, and to become one compact body before the autumnal floods (which are those whence the greatest danger is to be expected) begin to flow. If the subsoil be of a nature unfavourable to the growth of willows, such sods as are full of the roots of rushes should be made choice of in preference to all others; as, where these plants thrive and spread over the surface, it becomes in a great degree impenetrable by water, even in great floods, and when the river runs with considererable violence and rapidity.

The directions above given will, it is supposed, be found more or less practicable and useful according as the river on ordinary occasions runs with greater or less rapidity. In level, or nearly level districts, all that is necessary is to secure full scope for the rivers to overflow their usual bounds without interruption; when that is secured by either of the methods before mentioned, floods, unless very violent, seldom do any material damage to the banks of rivers in such situations. It becomes in many cases extremely difficult to fence rapid running rivers in such a manner as to prevent part of the banks from being carried away by inundation. Sloping the banks would be attended with no good consequences. Even strong bulwarks made of stone are often swept away by the overpowering flood. A method has, however, been suggested, of fencing the sides of a rapid running river, which has been practised with success, after several other attempts had failed: it is by means of a sort of large baskets, provincially termed *creels*, formed of hazel, willow, &c., into a kind of open network, which being placed along the bottom of the banks, are filled with stones. This is a very simple, and by no means an expensive expedient; and as these baskets may be made to contain two or three tons of stone, it can only be on few occasions, and in very particular situations, that a basket, containing such a weight, can be displaced or carried away. Such a mode of fencing as this, it is imagined, would prove effectual in many parts of Scotland and Wales, where the rivers run with uncommon rapidity. Owing to inattention, or rather to not being aware of the consequences, much damage is often done to the banks of rivers in level districts, especially if the banks be perpendicular, and of a considerable height, by allowing the land-floods to fall over them into the river. As the water from the furrows approaches the bank, it is frequently stopped in the furrow of the head ridge, which becomes for a time a kind of reservoir; the consequence of which is, that a considerable proportion of water sinks and filters through the earth, which being thus softened and swelled, is more easily undermined and carried off by the river. Sometimes little cuts or openings are made for the furrows across the head ridge, for the purpose of conducting the rain-water into the river; here, again, the consequences are equally bad. Whoever will examine the bank of a river where this mode of management is adopted, and it is very common, will observe, that at every one of these cuts or openings a little creek is formed, in consequence of the bank having been more softened, and by that means having become a more easy prey to the river when in flood. To prevent these evils, it is necessary, besides sloping the banks, to devote a part of the lands adjoining, to the breadth of 20 or 30 yards, for instance, either to pasturage or the growth of trees, and to form a drain at a proper distance from, and parallel to the bank, for the purpose of collecting and carrying off the water from the furrows. Were this done, and were the water from this drain conducted into the river by conduits formed a little above its ordinary level, much land, which is annually lost by neglecting this simple precaution, would be saved, and preserved in a proper state.

In the second case, it is evident that injuries, although of another nature, are often sustained by farmers, from rivers overflowing their banks. Sometimes the farmer is prevented from sowing his field; at other times the crops of grain and grass are greatly injured, by being covered for a considerable time with water; and at others again, the whole produce of the year, the hay and corn crops, are swept away. To prevent evils so complicated, and so serious in their nature, is certainly the business of every man, who, from the situation of his farm, has reason to apprehend, that, without using proper precautions, he may be subjected to such visitations. These damages can only happen in level tracts, where the banks of the rivers are low, and where the course is not of sufficient breadth to contain the water in time of flood. Some people, although very improperly, raise mounds of earth close to the top of the bank, and of a height exceeding that to which the river can be expected at any time to rise. These mounds, from being placed so near the river, are unable to resist the pressure of the water, and by giving way, frequently admit a current into the fields, which proves much more injurious in its course than if no mound whatever had been erected. Were a mound of earth formed on the side of the drain, proposed to be made for carrying off the land-water, and were that mound well sloped on the side towards the river, it would be the most secure and effectual guard against rivers doing injury to the adjoining lands, of any that could be adopted. By these mounds being placed at a distance from the river, the force of the stream would be much lessened, and the natural boundaries of the river greatly enlarged; as, in proportion as the mounds are removed from the centre of the current of the river, in like proportion will they become more secure, as being less liable to violent pressure. The propriety of erecting these mounds at a proper distance must, therefore, be sufficiently evident; as, when mounds are erected near the top of the bank, which can only be owing to ill-judged parsimony, they form as it were a part of the bank, and are liable to be undermined and swept away. Whereas, when they are placed at the distance of 20, 30, or 40 yards, they serve rather as a boundary to confine the overflowing waters which glide along the bottom, than as a barrier to prevent the encroachments of an impetuous river during the time of floods.

In regard to the third case, it is observed, that farmers who possess lands in low situations often sustain damage from rivers, in time of flood, by their flowing back into the channels of the rivulets and streams that conduct the water from the more distant and elevated grounds to the rivers, whereby these rivulets and streams are made also to overflow their banks.

The only precaution that can be adopted, in such a case, or at least the one which appears to have the greatest probability of answering the purpose, is to erect mounds at a distance from the banks, and of a size proportioned to the quantity of water, which, from the cause now mentioned, may be supposed at any time to stagnate in these channels. This may be done at a very trifling expense either in money or land. If the proprietors do not choose to ornament the country and improve their own estates, by planting trees on the borders of the rivulets and streams, the farmers may so construct these mounds, as that they may become fences to their arable fields, while that portion of the farm, necessarily and properly cut off for the protection of the remainder, may be devoted to pasturage.

Several different embankments of a successful kind have been effected in the northern parts of the kingdom. An important work of this nature was some years since executed on the estate of Lord Galloway, situated on the mouth of the river Cree, near Cree-town, by his lordship's tenant, Mr. Thomas Hannay, who states, in the third volume of the "Farmer's Magazine," that at the time he entered on the farm, upwards of 100 Scottish statute acres were regularly flooded by the highest spring-tides, excepting about three months in summer, when the tides were lower. They were seldom, however, covered above the depth of one or two feet, and never above four or five. Eighty acres of the above consisted of a rich sea marsh, or *ings*, as they call them there, almost a true level, excepting where hollows were formed by the egress and regress of the tides, and the passage of fresh water from the higher grounds; and about 4 or 5 acres, which were about 16 inches lower, being a younger marsh, and nothing but what they call ink-grass growing upon it; other grasses, such as clover, rib-grass, &c., grew on the rest of the marsh, forming a very beautiful close cover in the summer. The other 20 acres were on an average about 18 inches higher; consequently the sea did not cover them so often. It had formerly been ploughed, but not for about 20 years past. Last time it was in corn, it was flooded immediately after being sown, which rendered the crop almost entirely useless, and deterred former tenants from ploughing it again. Mr. Hannay began to bank this field in the autumn of the year 1798, by making a dike along the side opposite to the river, in a direct line facing the east. This dike was made, at an average, about 3½ feet high, and 6 feet broad at bottom, and 20 inches at top, built after the same manner with that mentioned below. He enclosed, along with the said fields, he says, 4 acres of the marsh adjoining, by making a dike 5 feet high, and 5 feet in bottom, almost wholly of solid feals or sods, with a very little stuff, properly beat, in the heart of it, which makes an excellent fence, and promises to be a very durable one. This dike, together with two small drains, one on each side of it, about two feet deep, cost 3d. per yard. The division-dikes of the whole marsh, which now, divided into 4 parts, are all built after the same manner, only that there is no loose stuff in the heart of some of them, but all of solid feal, jointed like bricks, as may be seen at *Figure* 17, which represents an end view, or section of it. This dike, meant as a permanent fence, answered as a temporary bank, and enabled him to plough that field in spring, 1799, although the bank round the whole marsh was not finished till the winter following. He sowed oats on this field, and, considering the badness of the season, had a very good crop; particularly so on that part which had not been ploughed formerly. On farther consideration, he altered the plan of the bank round the marsh, (which extends in a circular direction facing the north) by making it, at an average, about four feet and a half high, and allowing about two feet in the base for one in height, as at *Figure* 18, where *a b c* represents an end view, or section of it, every small span representing the section of a feal or sod; *a b* shows the inside of the bank, with the green side of the feal down; *b c* the base; *a c* the side next the water, with the green side of the feal out, (which adds greatly both to the strength and beauty of the bank;) and *d* the heart of the dike, made up with stuff properly compressed with a rammer. The stuff was taken from a ditch, in the inside of the bank, leaving a casement of a foot, which ought to have been three at least; and, where the ground is of a sandy nature, more; as the fresh water, running in the inside, was likely to undermine the bank, had he not prevented it, by cutting a new drain, and filling the old one with the stuff cast from it. The only creek worth noticing, through which the bank passed, was about 40 feet wide and 9 feet deep, in the bottom of which a wooden pipe, with a stopper, was laid through the bank.

There are now about 50 acres of the same kind of marsh-land adjoining his; and also about 100 acres on the other side of the river, banked in, all nearly in the same manner as represented in the figure. The bank on a farm on the side of the river opposite to his, was made almost a complete wreck, by an extraordinary tide, owing to its lying quite exposed to the south-west winds, which always send up the highest tides; but on his side, though suffering some injury from the same high tide, he was not affected by those winds, as they blew right over the bank. In his opinion, the bank on the other side of the river, in order to be durable, would require to be 30 feet broad, and 8 feet high, covered with feals, with the green side out; and that no stuff should be lifted within 6 or 7 feet of it, the ground being of a sandy nature. It might be made after the form shown at *Figure* 19. The whole of this turned out most excellent land, and continues to produce to this day some of the finest crops in that part of the country.

Another improvement of the same nature was accomplished on what in Scotland is termed *carse land*, on the farm of Netherton of Grange, belonging to James Peterkin, Esq., by Mr. John Hoyes, his tenant. The work was undertaken under an agreement with the proprietor, to allow one year's rent, of £195 sterling, with the farther allowance of ameliorating the farm-houses to the extent of £150 more. The method adopted for carrying on the operations was this:—After looking over the carse, and marking out the line or dike, the length of which is 1,400 yards, mostly in a right line, except an angle at the distance of 300 yards from the west end, and a segment of a circle at about 250 from the south-east end, it was resolved to make the embankment 6 feet high in the highest part of the ground, and to allow 2 feet of breadth in the bottom of every foot in height, as seen by the draught of the mould at *Figure* 20. After taking the level of the carse, it was found that where the ground was low, and a good deal of it broken by runs of the sea and outlets for the water, the dike would require to be 8 and 10 feet high, to have it on a level at the top; so that the average would be 9 feet high. The embankment was built in the following manner: It was begun on the highest ground, near the west end, and two moulds set up at the distance of 70 or 80 yards; the height, 6 feet, by 12 broad in the base; the slope on the outside 6 feet, on the inside 4 feet, and the breadth at the top 2 feet; the sides made up with feal from the broken ground on the outside of the dike, which were laid with the grass-side down, two feal deep on each side of the dike; the outside feal of the first course with the ends out and in, and the other running along; the next course, the outside feal running along, and the outside out and in, and so on alternately, each course consisting of a head and runner; the body of the dike being made up of the carse ground from which the feal had been cut, and packed down by men with beaters. When this was brought to the height of 4 or 5 feet, another piece was begun, leaving an intermediate space, where there were any water-runs, for the egress of the tide: this was found necessary, to draw off the water from the low parts of the carse, which would have been filled up in spring tides; and, by coming in at the end and over the high ground, would have been prevented from getting out by the dike, if it had not been done in that way; so that the embankment was all in detached pieces, till it was brought near the height. These intermediate spaces were then filled up, between the fall of one and rise of next spring-tide, after laying down wooden pipes with stoppers in the dike, to carry off the sink-water. In carrying on the work, they had in some places to cross over lakes and runs made by the tides, which required vast quantities of materials, the dike being in some places upwards of 10 feet high, and 22 broad in the base; the greatest part of the dike being 16 to 18 feet broad. There was one lake of 150 feet in length, and 50 feet in breadth, filled up with earth, clay, and sand, to the height of 5 feet; on which the dike was then built. This forms a mound, on the outside of the dike, of 15 or 16 feet broad; and through this there are pipes laid, to carry off the sink-water. A stream of water was also turned by the west end of the farm, by cutting a canal, which conveyed the water through the embankment there, by means of an outlet built of stone, with a sluice on the inside, raised to the level of the running water, and a folding door on the outside, to be shut by the spring-tides. At this place, a road, that formerly led to Findhorn at low water through the carse, is carried over the top of the dike, by making a mound of earth at each side, with a gradual approach and descent.

In *Figure* 20, *a*, is the breadth of the dike at the top, when finished; *b*, the breadth of dike at the bottom, being twelve feet, when it is six feet high; *c*, the breadth when eight feet high; *d*, the breadth when ten feet high; *f*, the slope on the sea-side of the dike, which is always equal to half of the breadth of the bottom: the inside slope, and breadth of the dike at the top, is equal to the other half; and *e* is the plumb-rule in a frame, made to apply to the mould or dike: the intention of it was, to find if the dike was kept on the proper slope, where a line could not be applied from one mould to another, as in a round or turn, or when the moulds were obliged to be taken down; but this one only answered for the sea-side, another being used for the inside, to fit its slope." *Figure* 21, is a scale of the mould, one-eighth of an inch to a foot.

A curious, useful, and highly ingenious method of embanking, and preventing the waters of the tides from soaking through the porous banks, made in the fen-lands, and low marshy grounds, was described by Mr. John Smith, in the fourth volume of "*Communications to the Board of Agriculture*," who begins by "concisely observing, that the great land of the fens is divided into three large levels; and that each of these levels is subdivided into numerous districts by banks: but as these banks are made of fen-moor, and other light materials, whenever the rivers are swelled with water, or any other district is deluged either by rain, a breach of banks, or any other cause, the waters speedily pass through these light, moory, porous banks, and drown all the circumjacent districts. The fens have thus sometimes sustained £20,000 or £30,000 damages by a breach of the banks, though these accidents seldom happen in the same district twice in twenty years. The water, however, soaks through all fen-banks every year, in every district; and when the water-mills have lifted the waters up out of the fens into the rivers in a windy day, a great part of the water soaks back through the porous banks, in the night, upon the same land again." And he adds, that "this water that soaks through the bank drowns the wheat in the winter, washes the manure into the dikes, destroys the best natural and artificial grasses, and prevents the fens from being sown till too late in the season. This stagnant water lying on the surface, causes also fen-agues, &c. Thus, says he, the waters that have soaked through the porous fen-banks have done the fertile fens more real injury than all the other floods that have ever come upon them."

Having been much concerned in fen-banking from his youth, he had some time since devised the plan which he now finds to answer so well; but found it difficult to prevail with any gentleman, who had a proper extent of this sort of land, to give it a fair trial. However, during the last autumn, he prevailed with a person in the parish where he lives to try it, which showed it to be equal to his highest expectations.

The improved method of embanking proposed by this gentleman, consists chiefly in this: that "a gutter is cut eighteen inches wide, through the old bank down to the clay (the fen substratum being generally clay;) the gutter is made near the centre, but a little on the land-side of the centre of the old bank. This gutter is afterwards filled up in a very solid manner with tempered clay; and to make the clay resist the water, a man in boots always treads the clay as the gutter is filled up. As the fen-moor lies on clay, the whole expense of this cheap, improved, and durable mode of waterproof banking costs in the fens only sixpence per yard. This plan was tried on a convenient farm, and a hundred acres of wheat were sown on the land. The wheat and grass lands on this farm were all dry, whilst the fens around were covered with water. This practice is, after all, nothing more than making a *puddle-bank*, well known to all engineers, or those engaged in forming canals.

The term embankment in canal-making is applied to any large mound of earth, either for confining the water of the canal or reservoir, or for carrying the former across a valley or low piece of ground. The method of constructing such embankments is nearly the same as in those for railways, except that in the former the sides have puddle-trenches formed near the canal, to prevent leakage.

The embankments on some of the great lines of railway in this country are of immense magnitude, on the London and Birmingham railway, for instance, the total of embankments amounted to about 11 millions of cubic yards. The following extracts from specifications for works of this kind will show the usual mode of construction.

"The whole of the embankment in this contract shall have slopes of two to one (that is to say) where the base of the slope is two feet, its height shall be one foot only, and they shall be thirty-three feet wide at the level of the red line in the section, neither more nor less.

"Each of the embankments shall be uniformly carried forward as nearly as the finished heights and width as the due allowance for shrinking of materials will admit of, and this allowance shall not exceed or fall short of the quantity deemed necessary by the engineer. In all cases, this must be carefully and strictly attended to, in order to avoid the necessity of making any subsequent addition, either to heights, or the width of the embankment, to bring them to their proper level and dimensions.

"The surface of the embankment shall be kept in such form or be intersected by such drains, as will always prevent the formation of pools of water upon them, and insure the embankment being kept as dry as possible.

"Whenever the material, teemed over the end of the embankment, shall not form the proper slope, it shall be carefully trimmed to its required form; and this operation must proceed at the same time with the end of the embankment, so as to obviate the necessity of any future addition of material to the sides of the embankment.

"As the embankments advance, and become consolidated, the slopes shall be carefully trimmed into planes having the proper slope, and be neatly covered with a uniform substance of turf, of not less than eight inches in thickness, and laid with the green sward outwards; the turf must be taken from the ground to be occupied by the base of the embankment, and cut square, so as to be laid on the slopes in the form of flags; and where the land is arable, the slopes of the embankment shall be covered with soil. It must be uniformly laid on, of the thickness of six inches, and sown with rye-grass and clover-seed, as soon as the proper season will admit of its being done, not less than one pound and a half of clover-seed, and one pound and a half of rye-grass seed, to be sown to each acre.

"When the material, brought to the embankment, consists of large lumps, they shall be broken into pieces of not more than six inches in diameter."

Expense of forming embankments.—This must obviously be very different in different situations and circumstances, according to materials and the price of labour, but though in general pretty considerable, it is seldom so high as is commonly supposed. It is probable, that in cheap districts, and where the materials are plentiful, the expense of forming an earth-bank, covered with sand or gravel, such as that shown at *Figure* 1, could not be less than from fourpence or sixpence, to tenpence or a shilling, the cubic yard. And such as have more steep and bold slopes, as from thirty-five to forty degrees, and are formed with pavement on the surfaces, cannot cost less than from ninepence to one shilling the cubic yard. One made on the plan of that shown at *Fignre* 6, could not be constructed for less than from twelve or fifteen to thirty pounds for every thirty-two yards. And one constructed of brushwood, in the same method, for soft ground, which will not admit of a wall, would not be lower than from sixpence or eightpence, to six or seven shillings for each foot forward in a lineal manner. In many situations, the ezpenses would, however, in all sorts of embankments, stand a great deal higher than these.

In some districts, embankments are formed by the rod and the floor, the former being from four to five pounds, and the latter about four shillings and sixpence, the workmen finding all sorts of necessary things for the business.

EMBATTLED BUILDING, a building with embrasures in the parapet, resembling a castle or fortified place.

Embattled Line, a straight line bent into right angles, so that if there be two sets of parts, the parts of each set may be in the same straight line, and parallel to the parts of the other.

Embattled Aronade, is partly the same as the Embattled Line, the difference consisting of a semi-circle raised in the middle of each part which forms the continuation of one of the straight lines, the semi-circle presenting its convexity towards the parts which form the other straight line.

Embattled Battled Line, a straight line bent into right angles, so that if there be three sets of parts, one set may be parallel to those of the other two.

EMBLEMATA, a kind of inlaid or mosaic work, used by the Romans in flooring, panelling, &c.

EMBOSSING, the act of forming work in relievo, whether it be cast, moulded, or cut with a chisel.

Embossing, in architecture, that kind of sculpture in which the figure stands in relief beyond the plane, or other surface from which it seems to rise. The several kinds of sculpture formed by embossing are, *low relief, mean relief,* and *high relief.*

EMBRASURE, an enlargement or splay of the aperture of a door or window, generally withinside the wall, for the admission of a greater quantity of light; when the wall is very thick, an enlargement is also made on the outside of the wall.

Embrasure, is also applied to the apertures of an embattled parapet. It is another term for the crenelles, or intervals between the merlons.

EMBROIDERY, the enrichment of woven fabrics by the introduction of devices in needlework. Embroidery was a kind of work very usually employed in ecclesiastical hangings, vestments, and the like, and, in such cases, is of the most gorgeous and elaborate description.

EMPLECTON, a kind of walling, used by the Greeks, and the Roman villagers, consisting of rubble masonry, with facings of wrought stones laid in regular courses. *See* Walls.

ENAMELLING, a method employed to enrich metal-work by the introduction of colour, much used in the works of the middle ages. Specimens of enamel of an early date are to be seen on the envelopes of Egyptian mummies, also in Greek and Roman work, &c.

ENCARPUS, sculptures of fruit or flowers, such as those employed in the decoration of friezes.

ENCAUSTIC, a term applied to paintings, in which the colours are fixed by means of heat. *Encaustic tiles*, are those in which coloured devices are introduced, the colours being burnt in during the process of manufacture.

ENCHASING, that mode of decorating metal-work in which the devices are represented in low relief.

ENDECAGON. *See* Hendecagon.

END-IRONS, otherwise *and-irons*, standards, usually of metal, and of various forms, used in fireplaces previous to the employment of coal for fuel, to support the logs of wood.

ENDS of a Stone, the two parallel sides, which form the vertical joints.

ENGAGED COLUMN. *See* Column.

ENGINE, *Pile*. *See* Pile Engine.

ENGLISH ARCHITECTURE, a term applied by some to the styles of Gothic architecture as developed in England. *See* Gothic and Domestic Architecture.

ENGLISH-BOND, in bricklaying, a disposition of bricks, wherein a course of headers succeeds a course of stretchers alternately. In the north, bricklayers frequently run three or five courses of stretchers to one of headers.

ENGLISH OAK, oak timber of the native produce of England. It is much used in the country for rustic buildings, and is particularly useful in the truss-posts of roofs, as being less liable to compression, and possessing a greater degree of tension, than fir.

ENNEAGON, a figure of nine sides and angles.

ENSEMBLE, (a French word, signifying *together*, or *one with another*, formed of the Latin *in* and *simul*,) the work or composition of a building, considered as a whole, and not in parts.

ENTABLATURE, (French, from the Latin *tabulatum*, a stage, or story,) that part of an order which is supported by the column or columns, and forms the covering or shelter to the edifice. It consists of three principal divisions, viz., the architrave, which rests upon the capitals of the columns; the frieze immediately above it; and the cornice at the summit. These divisions, according to Vitruvius, represent the principal timbers used in the roof of the timber-building, which he supposes to have been the origin and type of erections in stone. This subject has been already referred to under the title Doric Architecture. The entablature either finishes the whole edifice, or so much as has the order applied to it; and in strictness ought to terminate either in a level cornice, or in a pediment formed of two equally inclined cornices. This rule, however, was not always adhered to by the Romans: for in many of their buildings, we find the ordonnance crowned with an attic or blocking course. The edifices of Balbec and Palmyra were often finished in this manner; as were even some of the Grecian structures, after Greece had become a Roman province.

The general height of the entablature is equal to two diameters of the column; though some authors make the Doric entablature one-third of the height of the column; and the entablature of the Ionic one-fourth, and that of the Corinthian or Composite, each one-fifth of the respective columns. Vignola makes the entablature one-quarter of the height of the column, in each of the orders; but the former proportion of twice the breadth of the base agrees much better with the ancient Grecian examples than the other two. It must be recollected, that in ancient examples of the same Order, the height of the entablature is in some instances more, in others less, than two diameters. In the temple of Minerva, at Athens, which is one of the most chaste of the Grecian Dorics, the entablature is almost precisely two diameters of the column. In the Corinthian or Composite, where the column is ten diameters in height, the proportion found in some ancient examples of later date, one-fifth of the said height, is exactly two diameters of the foot of the shaft.

To find the proportions of the different parts of the entablature, divide the total height into ten parts, of which give three to the architrave, three to the frieze, and the remaining four to the cornice. This will stand as a general rule, but in the Doric order the proportions are somewhat different, the architrave containing two-eighths, and the frieze and cornice three-eighths each.

The entablature is also called *trabeation;* and by Vitruvius and Vignola, *ornament.*

ENTABLATURE, or ENTABLEMENT, is sometimes used for the last row of stones on the top of the wall of a building, whereon the covering rests. As this is frequently made to project beyond the naked of the wall, to carry off the rain, some authors call it, in Latin, *stillicidium,* or *drip;* but such an entablature does not stand out far enough, but permits the water to fall on the foot of the wall.

ENTAIL, a term used in the middle ages to designate all kinds of sculpture and carved decoration, but more especially applied to the more elaborate enrichment.

ENTASIS, the swell observable in the shafts of Grecian columns, and more particularly in those of the Doric order. Amongst the modern Italian architects, the practice has been carried to an absurd excess. Several methods of describing the curve will be found under the article COLUMN.

ENTER, (from the French *entrer,* to go in,) in carpentry and joinery, to insert the end of a tenon in the mouth or beginning of a mortise, previous to its being driven home to the shoulder.

ENTRESOLE, (French,) an intermediate story; a low floor introduced between two principal ones. *See* MEZZANINE.

ENTRY, (from the French *entrée,* a passage,) a door, gate, passage, &c., for admission into the interior of an enclosure, house, or apartment.

ENVELOPE, (French,) the covering of a portion of the surface of a solid, by means of a thin pliable substance, which comes in contact in all points or parts with such surface.

To develope the surface of a solid, is to find the envelopes that will cover its different parts.

A few examples of the developement of surfaces will be here given, and for further information we refer the reader to the article SOFFIT.

Problem I.—*To develope that portion of the curved surface of a cylindroid, which is contained between two parallel planes, and another plane passing through the axis at right angles with the parallel planes.*

Plate I. *Figure* 1.—Let M N L C be the plane passing through the axis, terminated at M C and N L by the parallel planes, and by the surface to be developed, at M N and C L; the four lines M C, C L, L N, N M, forming a parallelogram, M C, L N. Draw C A C_8 at a right angle with C L, and produce N M to A; then A C is one of the axes of the elliptic section, at right angles to the axis of the cylindroid. On A C describe the semi-ellipsis A B C, having its other semi-axis equal to that of the cylindroid; divide the curve A B C into any number of equal parts, say eight, and extend them from A to C_8, which coincides with the termination of the eighth part, marking the respective points as 1, 2, &c., at *e*, *g*, &c. Through the points of division, 1, 2, 3, &c., in the arc, draw the straight lines 1 E F I, 2 G H K, parallel to A M: also, from the points *e*, *g*, &c., draw lines *e f i*, *g h k*, &c., parallel to A. M. Transfer the distances, E F, G H, &c., to *e f*, *g h*, &c.; through the points M, *f*, *h*, &c., to C_8 draw a curve; and C_8 M N *l* will be the envelope required.

Problem II.—*To develope the surface of a cylinder contained between two other concentric cylindric surfaces and a plane, in such a manner that the axes of the two cylindric surfaces may cut the axis of the first cylinder at right angles, and that the plane may pass along the axis of the first cylinder, and cut the axes of the two cylinders at right angles.*

Figure 2.—Let A C L N be the plane terminated by the arcs A C and N L, which are the intersections of the concentric cylindric surfaces, and by the parallel straight lines A N and C L, which are formed by the curved surface of the cylinder intersecting the plane.

Proceed in every respect as in *Figure* 1, and the envelope will be obtained; the referring letters being alike in both *Figures.*

Problem III.—*To develope that portion of the surface of a cone contained between two parallel planes and a third plane, so that the axes of the code may be cut at right angles by the parallel planes, and that the third plane may pass along the axis of the cone.*

Figure 3.—Let A E F C be the plane passing along the axis, terminated at A C and E F by the parallel planes, and at A E and C F by the curved surface of the cone. A B C is a section of the cone, perpendicular to the axis. Produce A E and C F to meet in D; and with the radii D E and D A describe the arcs E G and A C; extend the semi-circumference of A B C on the arc A C, from A to C, and draw C G D; and A C G E will be the envelope required.

Problem IV.—*To develope that portion of the surface of a cone contained between two concentric cylindric surfaces and a plane passing along the axis, so that the plane may cut the common axis of the cylindric surfaces at right angles.*

Figure 4.—Let A I K C be the portion of the plane passing along the axis, and the arcs A C and I K the intersections of the cylindric surfaces; the straight lines A I and C K, the intersections of the conic surface. A B C is a section upon the chord A C. From D, with the radius D A, describe the arc A M; divide the semi-circumference A B C into any number of equal parts, and extend them upon the arc A M, from A to M, at the points 1, 2, 3, &c. to M: draw 1 D, 2 D, 3 D, &c. to M D included; also, through the points 1, 2, 3, in the arc A B C, draw lines perpendicular to A C, cutting it in as many points: from these points, draw lines to D, cutting both the concave and convex curves; from the points so cut, draw lines parallel to A C, cutting A D; then from the points of intersection, made by the parallels drawn from one of the curves, describe the several arcs drawn from the point D, to cut the respective straight lines. Proceed in the same manner with the other curve, and through the points so obtained, draw the two curves; and A M L I will form the envelope required. But to show more particularly how the successive points in the curve of the envelope are found, we shall only describe a single point, and the remaining points will be obtained in the same manner; thus, to find the point H in the envelope, draw 2 E perpendicular to A C, cutting it at E; draw E D, cutting the curve A C at F; draw F G parallel to A C, cutting A D at G; from the centre D, describe the arc G H, cutting 2 D at H, which is a point in the curve, as before stated; but by drawing the several systems of perpendicular lines, of lines going to a centre, and parallel lines, at once, much time will be saved in the operation.

Problem V.—*To develope the surface of a cuneoid contained between two parallel planes, and a plane passing along the axis of the cuneoid, so that the parallel planes may be perpendicular to the plane passing along the axis, the section of one of the parallel planes being given.*

Figure 5.—Let A B C D be the plane passing along the axis, terminated by the straight lines A D and B C, which are the intersections of the parallel planes, and by the straight lines A B and C D, which are the intersections of the cuneoidal surface. Let the section B E C, standing upon D C, be a semicircle, and, consequently, the section A F D formed by the other parallel plane, will be a semi-ellipsis of the same altitude.

Produce A B and D C to meet in G, divide the arc D E, which is the half of the semi-circumference, into any number of equal parts, say four, from the points of division, draw the perpendiculars 1 H, 2 I, 3 K, E L, cutting B C at H, I, K, L: draw G P perpendicular to A G; on G P make G *m*, G *n*, O *o*, and G P respectively equal to H 1, I 2, K 3, and L E; from the points *m*, *n*, *o*, P, as centres, with the respective distances G H, G I, G K, and G L, describe the arcs *h r*, *i t*, *k v*, and *l x;* extend the arc B 1, or 1, 2, which is the eighth part of the semi-circumference, from B to *h*, from *h* to *i*, from *i* to *k*, and from *k* to *l;* then drawing the curve B *h i k l*, will give the half of the envelope, which will coincide with the arc H E, when the semi-circle H E C is turned perpendicular to the plane, A B C D, upon its base B C: and since *l* P is the middle line, the other half, or counter part, will easily be found. To develope the elliptic edge, join *m h*, *n i*, *o k*, and P *l*, and produce them to *u*, *s*, *t*, *f:* transfer H U, I S, K T, to *h u*, *i s*, *k t*, *l f*, and through the points A, *u*, *s*, *t*, *f*, draw a curve A *u s t f*, which will be the envelope of the arc A F, the half of the semi-ellipsis A F D; then the counter part being found, will complete the envelope A B C *d* of the curved surface, standing over A B C *d.*

Problem VI.—*To develope that portion of the surface of a cuneoid terminated on two sides by a plane passing through the axis, and by two concentric cylindric surfaces whose axis is perpendicular to the plane given; given that portion of the plane terminated by the curved surface of the cuneoid, and by the intersections of the two cylindric surfaces; also, the semicircular section of the cuneoid.*

Figure 6.—Let A E and D G be the intersections of the cuneoidal surface, and the arcs A E B and E F G the intersections of the concentric cylindric surfaces.

Let D C be the intersection of the section, which is a semicircle, then find the envelope for the semi-circumference, as in the last problem for parallel planes; then the lengths of the intermediate lines contained between the base of the circular section, and the intersections of the cylindric surfaces, being transferred upon the corresponding lines from the semicircular envelope, will form the covering of the cuneoidal surface, as defined.

The reader will observe, that the two last constructions in *Problems* V. and VI., are only approximations near to truth; it is, we believe, impossible to find the true envelope by means of straight lines, or perhaps even to extend the true cuneoidal surface on a plane at any event, any more than that of a sphere, which can only be represented by means of projections. The only surfaces which can be extended on a plane, are those to which a straight edge will everywhere apply through a certain point, or in parallel directions to a given line; of this description are the surfaces of planes, cones, and cylinders: a straight line will apply to all parts of the surface of a cone through the vertex, and to all parts of a plane through any given point, and to all parts of the surface of a cylinder parallel to the axis.

The envelopes of all solids, to which a tangent plane to its surface parallel to the given plane will apply, have the same curvature or straight line at the edge, where the plane becomes a tangent, as the corresponding part of the edge of the given plane.

In describing the envelopes of solids, the whole or a portion of the section passing through the axis, is always supposed to be given, as also a section of the solid, making a given angle with the said plane, and the intersection in a given position.

If only a portion of the section passing along the axis be given, it is always supposed to be terminated by the same surfaces, which also terminate the surface to be covered.

The following is a more general method of finding the envelope of a solid by means of points.

In this description it will only be necessary to have the seats of three points given on the base, and the heights of the points on the cylindric surface from their seats. Let A B C (*Plate* II. *Figures* 1, 2, 3) be the part of the base of the cylinder, and A, B, C the seats of the three points; join A C; draw C E and A D perpendicular to A C; make A D equal to the height of the point above A, C E equal to the height of the point above C, and C F equal to the height of the point above the seat B; join E D; draw F G parallel to C A, and G H parallel to C E, cutting A C at H; and join H B; produce A C to I; divide the curve A B C into any number of equal parts; and extend those parts upon C I; through the points of division in the curve, A B C, draw lines parallel to B H, intersecting B C; from the points of intersection in A C draw lines parallel to G H, to meet D E; from the points of intersection draw lines parallel to A C; and from the divisions in C I draw lines parallel to C E, so as to intersect the other parallels last drawn; through the points thus found, draw the curve C I K E C, and it will be the envelope required.

Figure 1, is the case where the rectangular plane makes a right angle with the elliptic section:

Figure 2, that where the angle made by the rectangular plane and the elliptic section is acute:

Figure 3, where the angle formed by these two planes is obtuse.

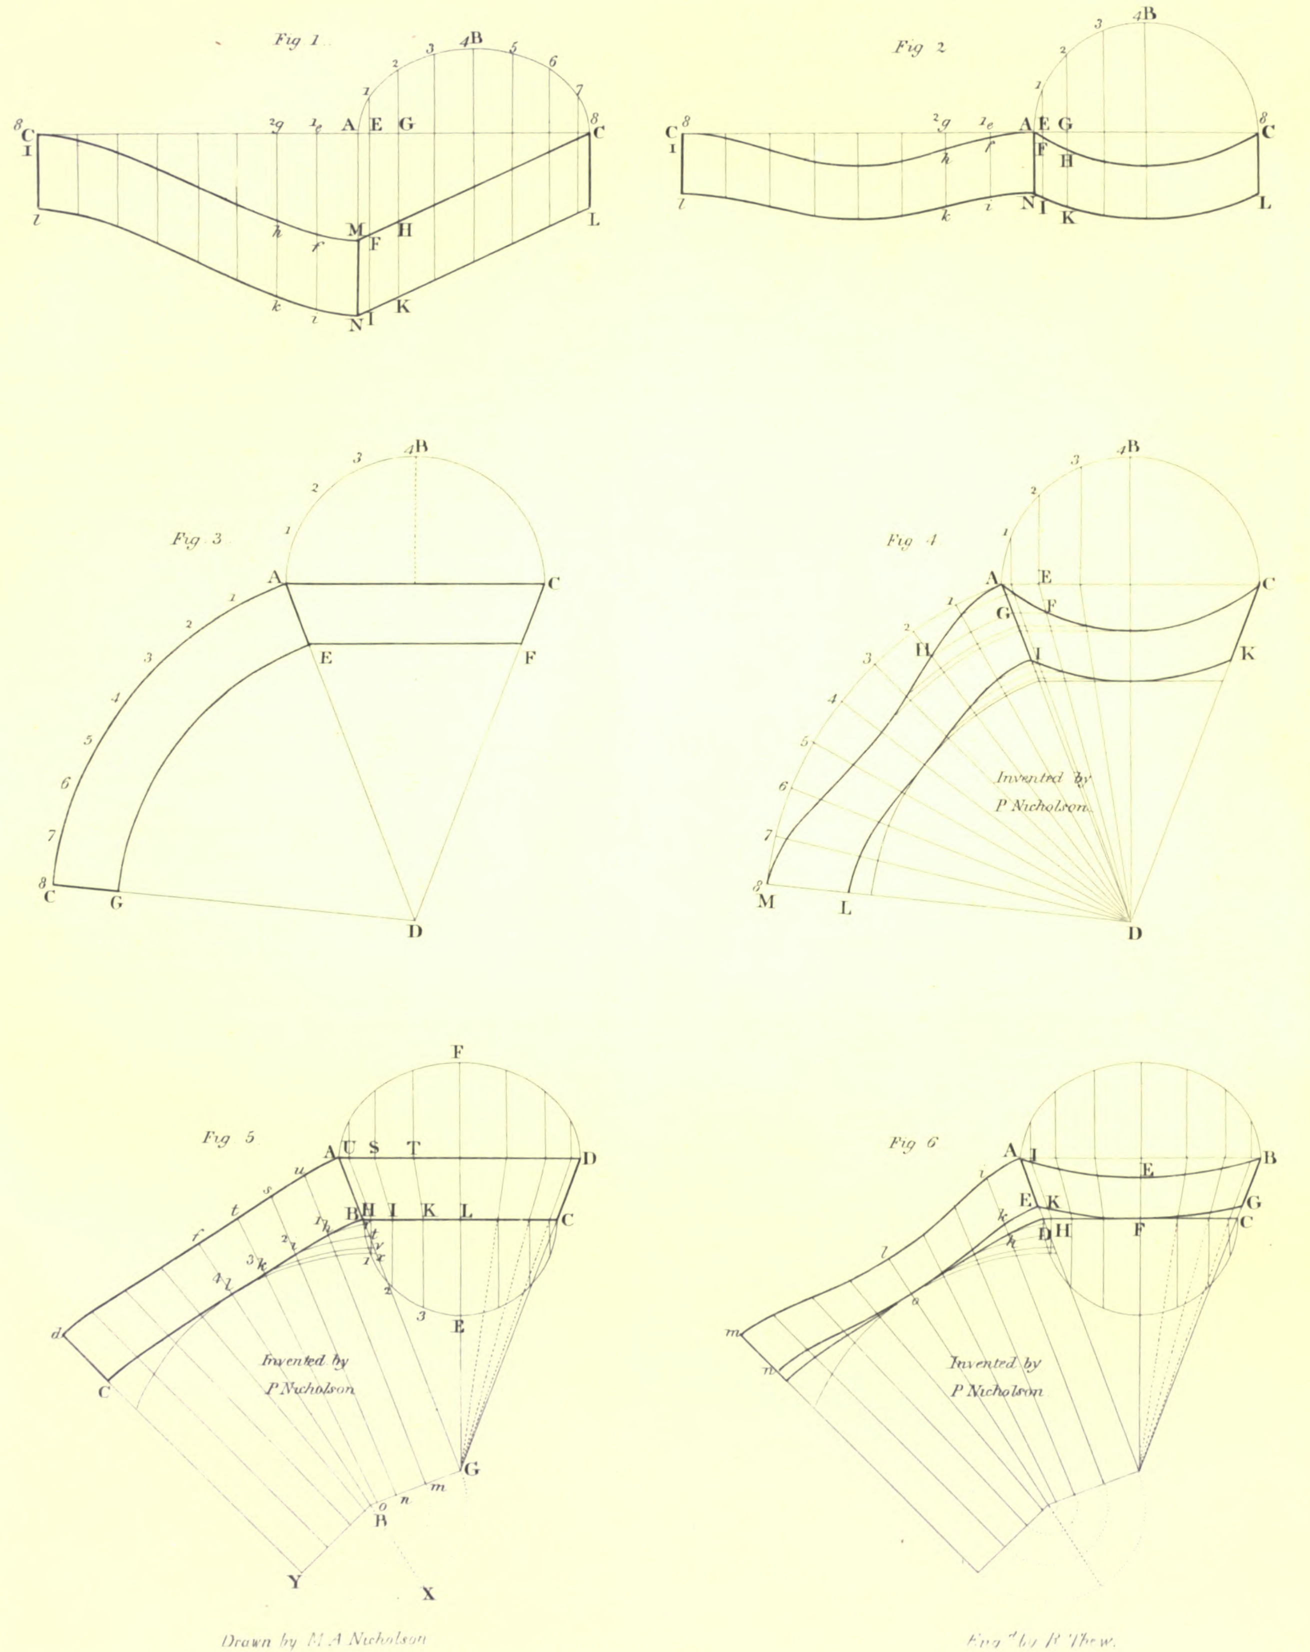
In *Figures* 2 and 3, D M E is the orthographical projection of the curve; with which the curve, E K, of the envelope would coincide. This is found by drawing parallels to G H through the points of division in the curve A B C, to meet the parallels of A C, as shown by the dotted lines.

EPHESUS, an ancient city of Ionia, formerly the metropolis of Asia Minor, now in ruins. The celebrated temple of Diana, in this city, was deemed one of the seven wonders of the world. In the time of Pococke, the remains of this renowned metropolis consisted of the temple of Diana; a circus; a gymnasium; a large theatre, and two of smaller dimensions; an odeum, or music theatre; a building, called the *Athenæum;* another, called the *Hypelæum*, of which there are yet considerable remains; with some vestiges of an aqueduct, and other fragments. A great part of the ancient walls are still entire, but in some parts the foundations only remain, from which it appears they were ten feet thick. Most of these vestiges are represented in Pococke's *Travels in the East.* The situation of this city was very favourable to the procuring of materials, being in the vicinity of Mount Lepre, which consisted of rocks of stone and marble, whose elevated situation afforded the means of an easy transit of the stones or blocks for building, to the site of the intended fabric.

EPICYCLOID, in geometry, a curve generated by the revolution of a point in the circumference of a circle, while it is moved round the circumference of another quiescent

ENVELOPES OF SOLIDS.

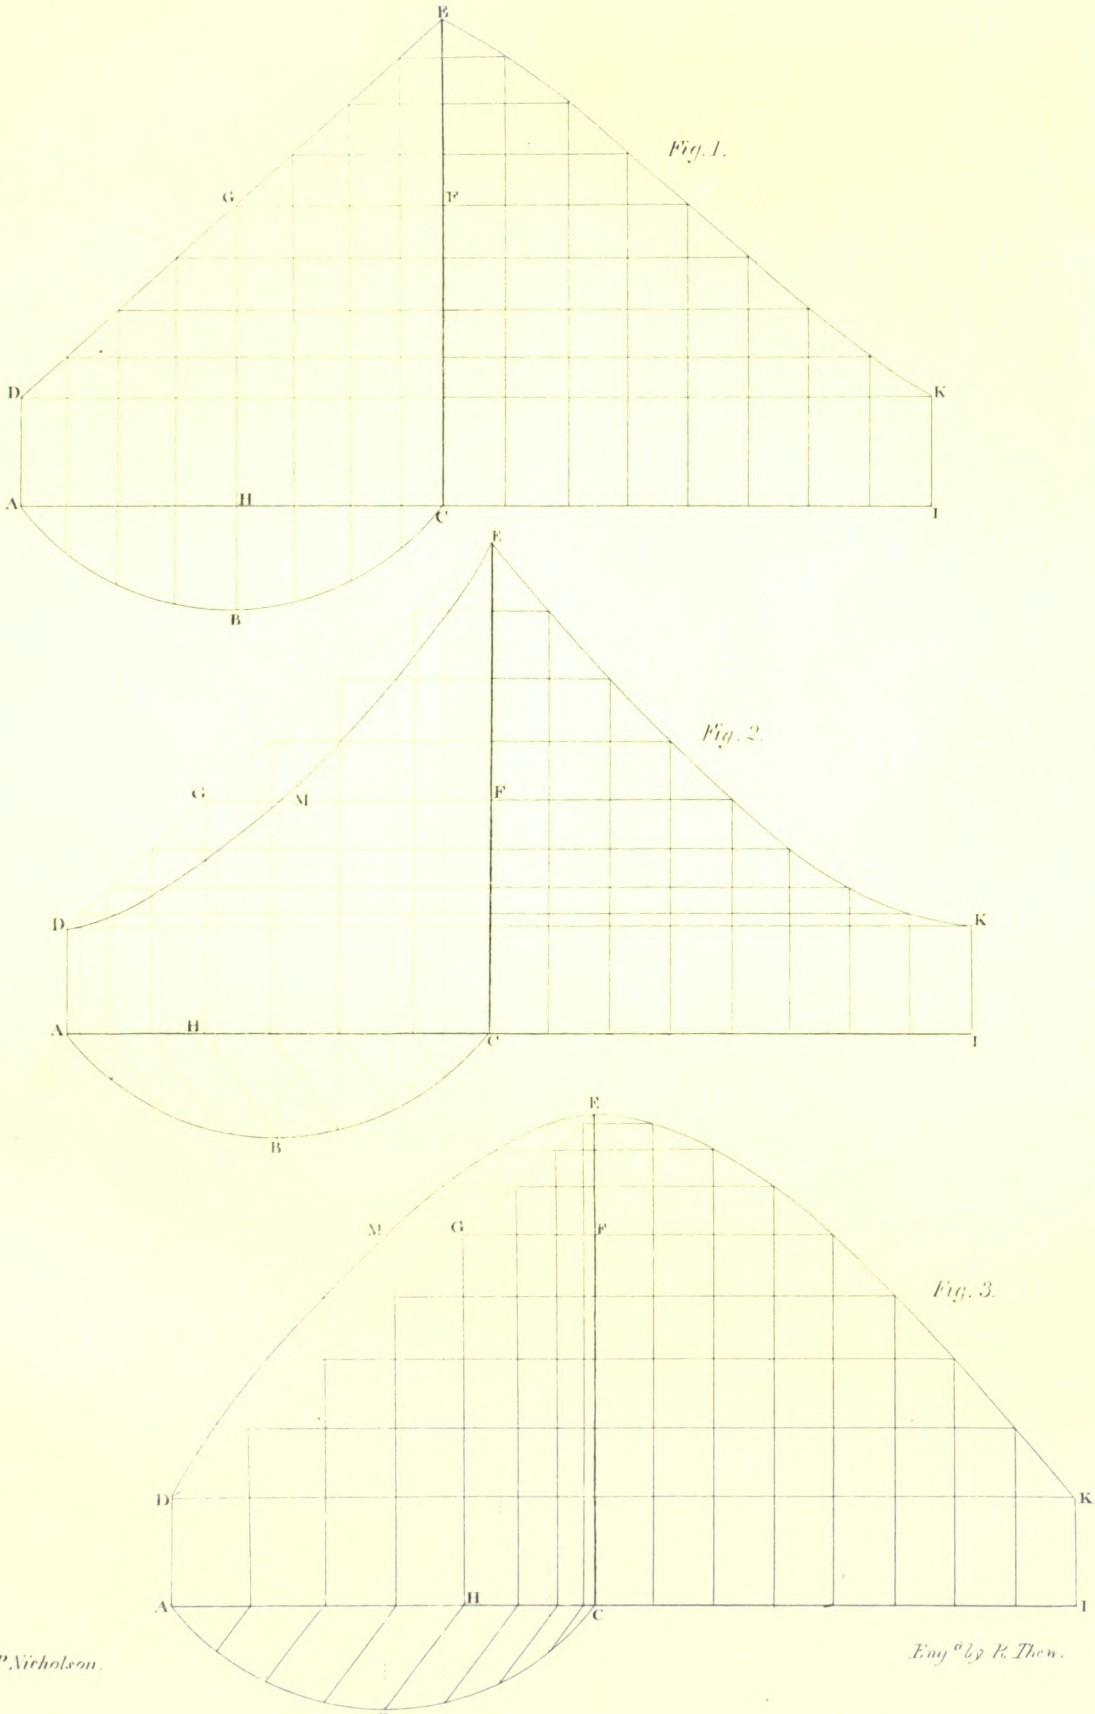
PLATE I.



Drawn by M. A. Nicholson

Engd by R. Thew.

ENVELOPE.



Drawn by P. Nicholson.

Eng.d by R. Thew.

circle in the same plane, so that in each circle, the distance between the point of contact at the commencement of the motion, and the point of contact at any instant while in motion, is equal one to the other. Hence if the circumferences are equal, all parts of the circumference of the moving circle will have been in contact with all the parts of the circumference of the quiescent circle.

If the generating circle proceed along the convexity of the periphery, it is called *an upper*, or *exterior epicycloid:* if along the concavity, *a lower*, or *interior epicycloid.*

The part of the quiescent circle which the generating circle moves along, is called *the base.*

The length of any part of the curve, which any given point in the revolving circle has described from the time of its first being in contact with the quiescent circle, is, to double the versed sine of half the arc, as the sum of the diameters of the circles, to the semi-diameter of the quiescent circle; provided the circumference of the moving circle be carried along the convex side of the quiescent circle; but if upon the concave side, as the difference of the diameters to the said semi-diameter.

Dr. Halley gives us a general proposition for the measuring of all cycloids and epicycloids: thus, the area of a cycloid or epicycloid, either primary, contracted, or prolate, is to the area of the generating circle, and also to the areas of the parts generated in these curves, to the areas of the analogous segments of the circle, as the sum of double the velocity of the centre, and the velocity of the circular motion, to the velocity of the circular motion. The demonstration hereof, *see Phil. Trans.* No. 218.

The areas of epicycloids may be determined by the following proportion: As the radius of the circle of the base is to three times that of the radius, together with twice that of the generating circle, so is the circular segment to the epicycloidal sector, or the whole generating circle to the whole area of the epicycloid.

As to the tangents, it is known from the time of Descartes, that a line drawn from any point to that of the base, which touches the circle, whilst this point is described, is perpendicular to the curve, and consequently to the tangent.

Maupertius, discussing this subject, conceived a polygon to revolve upon another, the sides of which are respectively equal; one of the angles described a curve, the periphery of which is formed of arcs of circles, and the area is composed of circular sectors, and right-lined triangles. He determined the proportion of the area, and of the periphery of this figure to those of the generating polygon. He also supposed those polygons to become circles, the figure described to become an epicycloid, and the above-mentioned proportion, modified agreeably to this supposition, gave him the area and periphery of the epicycloid. *Mem. de l'Acad.* 1727.

It does not appear that any writer published an account of epicycloids, before the celebrated Sir Isaac Newton, who, in the first book of his *Principia*, proposed a general, and a very simple method of rectifying these curves. After him, Bernouilli, during his residence at Paris, showed how, by means of the integral and differential calculus, to determine their area and rectification. The invention of epicycloids is, however, ascribed to M. Reaumur, the celebrated Danish philosopher, during his residence at Paris, about the year 1674. These curves appeared to him to be such as best suited the teeth of wheels, constructed so as to diminish their mutual friction, and to render the action of the power more uniform; hence he was led to consider them, and to this purpose they have been applied. However, M. de la Hire makes no mention of Reaumur, and seems to claim the merit of this geometrical and mechanical invention. But M. Leibnitz, who resided at Paris in 1674, and the two following years, says, that the invention of epicycloids, and their application to mechanics, was the work of this Danish mathematician, and that he was esteemed the author of it.

EPISTYLE, (from *επι*, *upon* *ςυλος*, *column*) in ancient architecture, a term used by the Greeks for what we call *architrave*, viz., a massive stone, or a piece of wood, laid immediately over the capitals of columns, from one to the other.

The epistyle is the first or lowest principal division of the entablature.

EPISTYLAR ARCUATION, a term applied to that method of building in which arches are thrown from column to column, instead of horizontal architraves.

EPITITHEDAS, (Greek *επι τιθημι*) a word used by the Greeks, to express the simæ, or cymatium, or crowning moulding of the entablature. By some the term is restricted to the upper member of a raking cornice.

EQUAL ANGLES, are those whose containing lines are measured by equal portions of equal arcs, described from the meeting of the two containing lines.

Equal Arcs. *See* Arcs.

Equal Circles, are those whose diameters are equal.

Equal Curvatures, are such as have the same, or equal radii of curvature. *See* Curvature and Curve.

Equal Figures, are those whose areas are equal, whether the figures be similar or not.

Equal Solids, are those which comprehend, or contain as much as the other, or whose solidities or capacities are equal.

EQUIANGULAR FIGURES, such as have equal angles.

EQUIDISTANT STRAIGHT LINES, are a series of parallels with equal intervals.

Equidistant Solids, are those whose intervals are terminated by parallel planes, at equal distances on the corresponding sides, comparing that of any two adjoining solids, with that of any other two adjoining solids.

EQUILATERAL (from *æquus*, equal, and *latus*, a side) having equal sides.

Equilateral Figure, that which has all its sides equal.

Equilateral Hyperbola, that in which the asymptotes are at right angles to each other.

EQUILIBRIUM, in mechanics, the equality of forces in opposite directions, so that they mutually balance each other; equipoise.

ERGASTULUM, among the ancients, a house of correction, or workhouse, where slaves, by the private authority of their masters, were confined and kept at hard labour for some offence. It was likewise called *sophronisterium.*

ESCAPE, a concave quadrantal moulding used to join two parallel members of different projections, as the shaft of a column with the fillet at its foot and junction with the capital.

ESCUTCHEON, a shield charged with armorial bearings. Decorations of this kind were much used in the later periods of Gothic architecture, carved on bosses, dripstones, spandrels, &c. The term is also applied to the metal plate on doors surrounding the key-hole, and to that from which the handle is suspended. Beautiful specimens, of excellent design and workmanship, are to be found in old mediæval buildings.

ESCURIAL, the palace or residence of the kings of Spain. The word originally signified a little village in Spain, situated in the kingdom of New Castile, twenty-two miles to the N. W. of Madrid. Here king Philip built a stately monastery, of the order of St. Jerome, held by the Spaniards as one of the wonders of the world. It was begun in 1557, and finished in about 22 years, at the expense of 6,000,000 of piastres. The plan of the work resembles a gridiron, in memory of St. Quintin, who suffered martyrdom with that instrument.

The king and queen had their apartments there, the other parts were possessed by the monks.

The length of this superb palace is an oblong 740 by 580 Spanish feet, besides 460, for what may be termed the handle of the gridiron. The height of the roof is 60 feet, and every angle has a square tower 200 feet in height. The west front has 200 windows, and that of the east 366.

The Escurial has a very fine church, crowned with a dome, which is 330 feet, supported by four rows of pillars, and paved with black marble; containing 40 chapels, and 48 altars. To this church, Philip IV. annexed a beautiful mausoleum, called the *Pantheon*, or *Rotunda*, built on the plan of the temple of that name at Rome. It is 36 feet in diameter, and incrusted with marble; in which the kings and queens of Spain, who leave any posterity, are interred; the rest being laid in another vault of the same church, together with the infants and other princes.

ESTIMATE, a calculation of the expenses of a building, or other parts thereof, by measuring the drawings with a compass from a scale, and calculating the amount upon materials and workmanship. *See* Brickwork, Carpenters' work, Joiners' Work, &c.

ESTIMATION, the act of estimating a building, *See* Estimate. A quick mode of estimating, or rather guessing at the expense of a building, is, to throw the whole into cubic feet, as if all the parts within the walls and roof were really solid, and calculating the whole at a certain rate per cubic foot; but this is so different in different places, and even in different times in the same place, that no certain ratio can be established: but where things are finished in the same way, in the same place, and at the same time, it frequently comes nearer to the truth than many real estimates, which are accepted far below value, in order to obtain the work. Though estimates sometimes come very near each other, yet the difference at other times is so preposterous, as to be one-fourth, or one-third of the whole amount, either owing to articles being overlooked, or to a difference of rates, or both.

ESTRADE (a French term, signifying a public road or highway) in building, a little elevation of the floor of a room, frequently encompassed with an alcove or rail, for receiving a bed; or sometimes, as in Turkey, it is only covered with fine carpets, for the accommodation of visitors of distinction.

ETRUSCAN ARCHITECTURE. The method of building practised by the ancient inhabitants of Etruria; from which it is supposed many of the peculiarities of Roman architecture took their rise, and the Tuscan order was borrowed. The origin and history of this people is involved in obscurity, as is also, to a great extent, their architecture. They seem to have been a mixed race, composed of Siculi or Umbri, of Pelasgi, and of a third race, of Lydian extraction, and to have attained to considerable eminence in the scale of nations, both in power and civilization. Although they had brought the arts to a great degree of perfection, we had, until recently, but little evidence of the fact; and, as regards their architecture, examples are still so scanty, as to afford us no precise notion of its character. We have no remains of temples, or other buildings of the kind; all such information is to be derived solely from their hypogæi or sepulchres, and the representation of buildings, to be found on the various utensils discovered therein. The remains above ground consist almost solely of ruins of walls surrounding the different cities, which remind us of the Cyclopæan erections at Tiryus and Mycenæ, consisting, as they do, of lofty heaps of stones of enormous size, fitted together in a compact form, but without either cramps or cement. Ruins of this nature exist at Cortona, Volterra, Fiesol, &c., in the first of which are some stones more than twenty-two Roman feet in length, and about five or six feet in height. The walls of Volterra are of a similar description. In the earliest examples, the stones are of an irregular polygonal shape, and in building were so laid as to have all their sides in close contact with the surrounding stones; remains of this kind of work are to be found at Cora near Velletri. Generally speaking, the stones were of rectangular form, and of various sizes, disposed in horizontal courses. There is at Volterra a gateway, called the Gate of Hercules, which has a fine arch composed of nineteen large stones. This leads us to remark, that the origin of the arch is very generally ascribed to Etruria, from whence it is said to have found its way into Rome. Be this as it may, the Etrurians were certainly aware of its principles, specimens of true arches and vaulting having been found in the remains, some of which are probably of early date. In a tomb at Cerœtri is a wall carried up somewhat after the shape of a Gothic arch gradually converging towards the top, but not meeting at the apex, a square channel being left between the two sides of the arch, which is covered over with a block of nenfro. This, however, is not a true arch, but is similar to those to be found in Egypt and Greece, the building to which it belongs is on all hands allowed to be of very great antiquity.

From the description of Etruscan temples given us by Vitruvius, we learn that they were of an oblong form, the length being occupied by three chapels, of which the central one was the principal. The façades were similar to those of Greece, adorned with columns, pediments, &c., and the latter with sculptures in terra cotta. From the same author we likewise learn, that their private houses were buildings of some importance, having external porticos and vestibules like those of Rome; indeed, it is supposed that the atrium was borrowed from them by the Romans. Amongst the structures for which the Etrurians were eminent, are their tunnels, canals, and sewers, for the purposes of drainage and irrigation; roads, fortifications, and other works of an equally useful character. Remains of a cloaca have been discovered at Tarquinii, in which the arch is employed, and which is altogether similar to that at Rome; and at Volaterra are the ruins of a subterranean reservoir, 24 Roman feet high, 56 long, and 29 broad.

We have now only to notice the sepulchral buildings; which form by far the principal portion of the remains, and are found in great numbers, fresh ones being constantly opened at the present day. They seem to have been equally as numerous as the cities, and it would appear to have been an universal rule, that each city should have a place of burial for its dead in its immediate vicinity. To such an extent is this the case, that a modern writer lays it down as an axiom, that wherever there stood an ancient town, there you will find a cemetery; and wherever you find a cemetery, there will have stood likewise an ancient city. These sepulchres are, however, not all alike, their forms and situation varying according to the geographical, geological, and other characteristics of the site; in some cases they are cut out of cliffs below the city wall; at others out of more yielding soil, and, in cases where requisite, lined with masonry on the inside. Besides these excavated sepulchres, we have some of a more primitive and less imposing character, being nothing better than graves sunk a few feet below the surface, and covered with unhewn masses of stone. They are very similar to the Druidical cromlechs; which fact would intimate some connection between the Celts and Etruscans. Again, we find tumuli, another form of sepulchral monument, which is common to all parts of the world.

Amongst the cemeteries which have been explored, that at Vulci is one of the more important, and this, like many others, was discovered by mere chance, and was found to contain a vast number of antiques of various kinds. Those of Norchia and Castel d'Asso, the façades of which are covered with sculpture, were discovered in 1810; those of Bomarzo and Orte from 1830 to 1837. Of still later date are the discoveries of Savona by Mr. Ainslie, and of several others by Mr. Dennis, who has published a very interesting work upon the subject. There seems to be no scarcity of such monuments, for new discoveries are being brought to light every year, and would lead us to suppose that vast tracts of country were completely undermined by them. The cemeteries vary in size, some of them being of very great extent, and laid out like a city in streets and squares. Each has its peculiar kind of tomb, the most simple of which consist of mere conical pits about eight or nine feet in depth, and six in diameter. Next to these come the tombs, with a simple doorway opening in the side of the cliff, and leading into a small vestibule about five feet square, with a shaft carried up from the roof to the ground above, the opening of which is frequently covered over with a large stone. The vestibule gives access to the tomb, which is an apartment from twelve to twenty feet square, cut out of the rock, and supported in the centre by a low massive quadrangular pillar, or in larger tombs by four or more similar piers, as is shown in Inghirami's plates. Sometimes the tomb is divided into two parts by a thick wall cut out of the rock, which forms a means of support in place of pillars. In the side-walls of the tombs, and sometimes in the piers and partition walls, are two or more tiers of long horizontal niches in which the bodies were placed. Tombs of this kind exist near Corneto, Ferenti, and Cervetri.

Cemeteries of more imposing character are to be seen at Castel d'Asso, and the places to which we have above referred; of the former we give the following description from a popular work of the day. "At Castel d'Asso the tombs rise upon each side of a narrow glen, facing each other like the houses in a street. Each tomb being detached, and the cliffs in which they are hollowed being hewn to a smooth surface, and formed into square architectural façades, with bold cornices and mouldings in high relief, they bear a strong resemblance to dwelling-houses, their façades extending the whole height of the cliffs, which in some places rise as high as 30 feet. In the centre of each façade is a rod-moulding, describing the outline of a door, in many cases having panels recessed one within the other. This, however, is but the false semblance of an entrance, the real one being in the lower part of the cliff, which having been left to project when the façade was smoothed down, has been hollowed into a kind of small vaulted antechamber, open in front. The form of these monuments, as well as of the false door in the façade, tapers upwards, and the front recedes slightly from the perpendicular. Along the top of the façade runs a massive horizontal cornice, but receding from the plane of the façade. On many of the tombs there are inscriptions, some of which are still legible, graven deep in the smooth surface of the rock above the simulated doorway. On the inner wall of the little entrance-chamber, and immediately below the one in the façade, is a second false door, moulded like the former, but with a niche in the centre; and directly below this again is the real door leading into the sepulchral chambers, which, neither in grandeur of dimensions, nor elegance of details, answer to the external appearance of the tombs. They are quadrilateral, of various sizes, and rudely hollowed in the rock, having a flat or slightly-vaulted ceiling and ledges of rock against the wall for the support of sarcophagi. In some cases the sarcophagi have been sunk in the rock in two rows, side by side, with a narrow passage between them, and seem to have been originally covered over with tiles. In the interstices which separate the monumental façades, there are in many cases flights of steps cut in the rock, and leading to the plain above."

Tombs of a more decorative character exist at Norchia, adorned with pediments filled with sculpture, and Doric friezes, and bas-reliefs on the inner walls of the portico. The interiors, however, are of similar character to those at Castel d'Asso. At Bieda, are tiers of tombs hewn in terraces one above the other, and connected by flights of steps cut in the rock. Here also another peculiarity is presented, the tombs standing out from the rock completely isolated, and of similar form to dwelling-houses, having roofs sloping down on either side with overhanging eaves at the gable. The internal arrangement likewise bears a very great resemblance to that of dwelling-houses.

The tombs near Cervetri, opened in 1836, were originally covered with a large conical mound, and contain two apartments, an inner and outer one, separated by a partition, the latter being somewhat the largest, and the length of the two together measuring about 60 feet. On each side of the first chamber is a small cell cut out of the rock, the chamber itself being lined with masonry, and roofed over with a kind of Gothic vault, which springs at about three feet from the ground. Of this vault we have spoken above.

A curious range of sepulchres has been discovered at Chiusi, which, from the winding passages which lead from one tomb to another, presents the idea of a labyrinth, and caused it at one time to be considered a portion of the tomb of Porsenna, a description of which is given by Varro.

The following account is taken from the publication before referred to:—"The tombs to which we allude, are excavated in the conical crest of a broad hill, surrounded by a fosse about three feet wide, and lined on the inner side with large blocks of travertine, which thus form a wall measuring about 855 feet, this being the circumference of the base of the enclosed tumulus. The chief sepulchres open from the encircling wall; the largest, a circular chamber facing the south, and supported in the centre by a huge pillar hewn in the rock, is connected with the fosse by a passage of about 50 feet in length. Towards the south-east is a group of smaller chambers; close upon the fosse, and facing the south-west, is another, connected with the former by a passage about 45 feet long; while other smaller ones again, are situated all around, facing all the points of the compass.

"Above this tier is another, containing likewise several groups of chambers of different size and shape; and below the level of the fosse is a third tier, the chambers of which are, however, in a very ruinous state. Opening from the circular chamber facing the south, is a narrow passage, which winds by many a circuitous route towards the western group of chambers, and then turning again to the south, branches out into many side-passages. These passages were at first thought to form a regularly planned labyrinth, but their lowness being such as barely to allow a man to creep through on all-fours, the irregularity of their level, and the circumstance of the passage opening into the western group of chambers, breaking through one of the stone benches with which the walls of the chamber are lined, and on which the dead reclined, have subsequently led to the abandonment of this opinion, and of the idea of this being the site of the far-famed tomb of Porsenna."

We must not omit to mention that colour was used in these tombs as a means of decoration. At Tarquinii, they are all painted, but there is one, the Grotta Querciola, which in the design and execution of the pictures, surpasses all the others.

The walls are entirely covered with paintings illustrative of the social manners of the Etrurians, the colours of which, though now somewhat dim, must have been originally splendid. In the Grotta del Triclinio, hard by, the colours have retained their brilliancy, and the effect is described as perfectly dazzling by those who have beheld them in a bright light.

The Etrurians do not seem to have been a people of any great native taste, and are not to be compared with the Greeks in this respect; they preferred utility to beauty, and convenience to decoration. Some assert that all that is really beautiful in their monuments, emanates solely from Greece; but this we cannot suppose; they were destitute indeed of the creative imagination of the Greeks, and probably borrowed very largely from them, but at the same time we cannot suppose them to have been entirely devoid of originality.

For further information on this subject, we would refer to Michali and Inghirami, as also to the recent work of Mr. Dennis on the Cities and Cemeteries of Etruria. *See* Roman Architecture.

EUANTHI COLOURS, in painting, a term used by the Greeks, to express what the Romans called the *floridi colores*, or such as had remarkable brightness: the duller and coarser colours, the Romans called *austeri colores*, and the Greeks *bathyci*. Of the first sort were cinnabar, lapis arminus, chrysocolla, minium, indigo, purpurissa, according to the Romans; but the Greeks, as we find by Dioscorides, made cinnabar one of the austere colours.

EVOLVENT (from the Latin *evolo*, to unfold) in geometry, the curve resulting from the evolution of a curve, in contradistinction to the evolute, which is the curve supposed to be opened or evolved.

EVOLUTE, or Evoluta, in the higher geometry, a curve first proposed by Huygens, and much studied by the later mathematicians: suppose a string, or flexible line, be unwound, so that the part unwound may be kept straight and in the plane of the curve, the extremity will describe a new curve, of which the first turn is the evolute.

The radius of the evolute, is the part of the thread contained between any point where it is tangent to the evolute, and the corresponding point, where it terminates in the new curve.

Every curve may therefore be considered as the evolution of another.

EURYTHMY, (from the Greek εὔρυθμος, *harmony*,) a certain majesty or elegance in the composition of the different parts of a building.

The word is Greek, and signifies literally a consonance or fine agreement; or, as we call it, *harmony*, of all the parts: it is compounded of ευ, *well*, and ρυθμος, *rythmus*, *cadence*, or agreement of numbers, sounds, or the like.

EUSTYLE, (from the Greek, ευ, *bene*, *well*, and ϛυλος, *column*) a disposition of columns in which the intervals are exactly two diameters and a quarter. This intercolumniation was most approved of by the ancients, as being a medium between the pycnostyle and areostyle.

Vitruvius, lib. iii. chap. 2. observes, that the eustyle is the most approved of all the kinds of intercolumniation, and that it surpasses all the rest in conveniency, beauty, and strength.

EXAGON, *See* Hexagon.

EXCAVATING MACHINES, for digging and removing earth in extensive excavations, have occupied the attention of many ingenious men, and various machines for the purpose have been proposed and tried with different degrees of success. The great difficulty seems to consist in adapting any peculiar arrangement of mechanism which shall be capable of digging into the various sorts of earth. Were it only to operate upon a uniform mass, the task would be of comparatively easy accomplishment.

Amongst others who have devoted much time and capital in the attempt to overcome these difficulties, Mr. G. V. Palmer applied himself to the construction of machines of this kind. In 1830 he took out a patent "for a machine to cut and excavate the earth." This invention is designed, by the application of steam-power, to loosen, dig up, and remove into a cart, earth from a canal or other cavity, and to move itself forwards as the excavation proceeds. In principle, its leading arrangement resembles the dredging-machines employed in clearing the beds of rivers and harbours; but it has several appurtenances, such as *picks*, for loosening the earth; *cutters*, for separating it; and *scrapers*, for filling it into scoops or elevators; the latter convey it into the cart by which it is carried away. The machine is mounted upon four wheels, and gradually moves forward upon a temporary railway, as the excavation proceeds. The moving power is applied to the axis of a fly-wheel, and to the same axis is fixed a drum or pulley, around which passes an endless pitched chain, giving motion to another drum or pulley, which revolves in bearings fixed to the upper ends of two long cheeks or supports. Around this second drum passes another endless chain, by which a third drum or pulley, of a quadrangular figure, is set in motion, and which turns on an axis in the lower ends of the long cheeks; to this last-mentioned chain are fastened a series of earth-scoops, which are successively brought into operation in taking up the earth. So far, the machine resembles the common ballast-engine; we have now to describe how the several actions of picking, digging, and projecting the earth are effected. A third endless chain is actuated by the drum on the main axis, and gives motion to a spur-wheel; this spur-wheel drives another toothed wheel attached to the fore-wheels of the carriage, and thus the carriage gradually advances. By an ingenious system of levers, connected to a crank on the main axis, a row of pick-axes, a row of cutters, and a row of scraping-shovels, are alternately brought into action. When the pickers have descended and loosened a portion of earth, the cutters follow, and separate it from the mass, and this separated portion is immediately afterwards drawn forwards by the scraping-shovels into the scoops, which, by the action of the machine, are brought into the required position on one of the sides of the revolving quadrangular drum; and filled scoops thence proceeding to the top of the machine by the revolution of the attached endless chain, discharge their contents into a cart or waggon to be conveyed away. The same gentleman patented another engine for this purpose in 1832. This consisted of an excavated cart and plough united, to be worked by horses or other power. The cart-wheels are made considerably wider than those in common use, and the interior portion of the ring of each wheel is made into a series of earth-boxes; these earth-boxes are made to open inwards, and also towards the centres of the wheels. Underneath the cart, immediately adjoining each wheel, is placed a plough, for raising and turning the earth into the boxes, as the cart is moved forwards; the wheels at the same time turning round, bring up the earth, and deliver it into the body of the cart. When a sufficient load has been thus deposited in the cart, the ploughs are raised from the ground by means of a lever, and then the cart can be drawn in every respect as a common cart, to the place intended for the deposition of the excavated earth, where it is to be unloaded by withdrawing a pair of bolts, which allow the bottom of the cart to fold downwards sufficiently to permit the earth to escape. There are many circumstances where the application of excavating machines of this kind might be employed to advantage, but though the use of them in the extensive excavations of railway works has been many times attempted, they have not been found to answer so well in practice as to bring them into general employment.

EXCAVATION, (from the Latin *ex*, out, and *cavus*, hollow) the act of hollowing or digging a cavity, particularly in the ground.

The excavation for the foundation of a building, by the Italians called *cavatione*, is settled by Palladio at a sixth part of the height of the building, unless there be cellars under ground, in which case he would have it somewhat more.

But this proportion is vague, and contrary to experience and reason. Good firm gravel, clay, or rock, forms as good a foundation at a foot or 18 inches from the surface, as at any greater depth; while swampy or boggy land is not good at any depth. *See* Digging and Foundation.

EXCHANGE, a building where merchants resort to transact business. The principal commercial cities of Europe and America have edifices appropriated for this purpose, and the Bourses of Paris, Amsterdam, Antwerp, and other continental cities, and the Exchanges of London, Liverpool, New York, &c., are distinguished for their beauty and convenience. In London there are three buildings of this kind; the Corn Exchange—the Coal Exchange—and the Exchange of London, *par excellence*, the Royal Exchange. The two first are appropriated to the particular branches of commerce indicated by their names, and are more especially resorted to by persons therein engaged; the Royal Exchange is the general place of assembling, at a certain hour of the day, of the merchants and traders of London. Here meet together men from all parts of the world, and here are settled transactions of commerce of a magnitude inconceivable by those unacquainted with the subject. There are few merchants in the city but make it a rule to attend the Exchange daily, or, as it is termed in commercial phraseology, "to go on 'Change." We propose to give a brief description of each of these places of mercantile rendezvous.

The Corn Exchange is situated in Mark Lane, and consists, in fact, of two buildings adjoining each other, and known respectively as the Old and New Corn Exchange. Business, however, is carried on in both, and together they are considered as the "Corn Exchange."

The new building, as we have before observed, immediately adjoins the older one, which still continues to be made use of, and which may therefore with propriety be briefly described here, if only for the purpose of affording some kind of comparison between the two. "The lower part of the structure is an open colonnade, whose pillars are of the modern Doric kind, but the entablature has a plain frieze, and its architrave is singularly narrow for the order, or indeed for any order whatever. There are eight columns, with an iron palisading between them; displaying, however, a very peculiar arrangement, four of them being placed in pairs, but in such a manner, that, beginning to reckon from the south end, we find them placed thus: first, a pair of columns at that angle, then three single columns, then another pair, and at the north angle another single column, forming altogether five inter-columns, corresponding with which are as many windows in each of the two stories forming the upper part of the building over the colonnade; which are quite plain, with the exception of the centre one on the first floor, which, in addition to other dressings, has a pediment."

There is no wall behind these columns, and the space within is open to the street, forming a court rather than a hall, the centre space of which is not covered by a roof. With this difference, it resembles the similar part of the plan in the new building, having, as that has, three intercolumns at each end, and five on each side; and it further resembles it in the great depth of the ambulatory around it. The building, though making little pretension to architectural character, except what it derives from its columns and their arrangement, has, in its general effect, a degree of picturesqueness both unusual and pleasing, especially as there is a second range of columns between those in front and the area of the Exchange itself.

The New Corn Exchange was erected in 1828, from the designs of Mr. G. Smith, the architect of St. Paul's School, and exhibits a very tasteful and appropriate application of the *Grecian* Doric.

In point of design, this facade merits investigation, because, whatever else may be alleged against it, no one can object to it, that it is either a direct copy, or an assemblage of copies, that is, of parts entirely borrowed from other buildings, without other novelty than what they derive from their combination with each other.

The colonnade forming the centre, (which being an hexastyle in antis, gives the same number of intercolumns as an octostyle,) does not constitute a loggia, or even a mere corridor; for, as may be seen by the plan, the space between the columns and the wall is occupied, except where the entrances occur, by a sunk area screened by the stylobate. This area being barely equal to one diameter, the colonnade is much shallower than usual, and therefore likely to be censured, on that account, by those who consider a certain depth of space behind the columns to be an indispensable requisite for their proper effect, and invariably demanded in all situations and under all circumstances.

In the present instance, the very moderate distance at which the wall is placed behind the columns, occasions greater breadth of surface, as the light falls upon that as well as on the columns themselves; which would not be the case were the wall so far back that the columns would relieve themselves entirely against the shadow of the parts beyond them. At the same time, the columns receive a greater portion of reflected light, and thus contrast more distinctly with the shadows which they cast on the wall itself, and which produce an agreeable variety and equipoise of light and shade, according to the sun's elevation, when it shines on this (the west) side of the building. But that to which, more than anything else, this façade is indebted for its classical air and architectural beauty, is the entire absence of windows within the colonnade. Not only do such apertures—unless introduced very sparingly indeed—destroy repose, by frittering what requires to be preserved nearly an unbroken surface, but they show themselves in a situation where their serviceableness is greatly lessened. Besides which, the colonnade or portico itself seems misplaced, being overlooked by the rooms behind it.

To return to the immediate object of our description: we may observe, that the wall is not entirely plain, it having slightly projecting antæ or pilasters corresponding with the columns, and the faces of those in the centre serve partly as a ground upon which the jambs of the large door are raised. This door is a feature not only important for its size, but tasteful in design—bold and simple, yet at the same time carefully finished.

In the frieze, wreaths composed of ears of corn are substituted for triglyphs; and even had they not elegance of form as well as novelty to recommend them, they would still have a propriety and significance which we rarely meet with in those similarly-shaped decorations of laurel transferred to modern buildings, from the entablature of the monument of Thrasyllus.

The cornice here given to the order is rendered less cold and scanty than usual by the addition of a cymatium above the corona, ornamented with lions' heads, that slightly break its upper line. Much of the peculiar character arises from the unusually lofty blocking-course, surmounted in the centre by a podium bearing the following inscription:—'Corn Exchange, erected 1828, according to act of parliament, 7th George IV. Chap. 33.' This podium is, in turn, surmounted by a piece of sculpture representing the royal arms, grouped with implements symbolical of agriculture. Thus the upper part of the front acquires considerable variety of outline, and somewhat of a pyramidal form, together with distinctly marked individuality of character. Instead of being at all at variance with the style adopted, the part we are now considering is not only consistent with, but seems to give additional expression to all the rest; at the same time that it takes away from it that air of direct imitation which it is so difficult to avoid without endangering, if not destroying, the classical physiognomy intended to be preserved.

Whether, in his treatment of the wings, the architect has successfully overcome this last-mentioned difficulty, is what we have now to inquire. As far as regards the order itself, that is kept up with sufficient strictness, and the mode in which the antæ are applied, deserves commendation. Had these been merely coupled, after the usual fashion, the effect would have been rather formal and monotonous; besides which, it might not improperly have been objected, that such duplication was at variance with the arrangement of the columns. But by compounding, instead of pairing them, and placing the broader anta at the outer angle, while the other is made to project slightly upon it, both a due expression of strength and solidity is kept up, a certain degree of play and variety is obtained, although there appears to be nothing at all new in the idea itself, except that here the two united faces are of unequal breadth—an irregularity converted into a merit by its obvious propriety.

"The windows, which entirely occupy the space between the antæ, may be considered as assuming the character of small loggiæ, whose intercolumns are filled in with sashes. In style, therefore, they harmonize with the general design far better, perhaps, than anything else that could have been devised for the same purpose; the chief objection to be made in regard to them is, that somewhat less plainness—not to call it severity of style—would not have been amiss, and would have prevented the small antæ of the windows from appearing a repetition of the larger ones on a diminished scale.

"The upper story of the wings, to which we now come, display more invention and decided novelty than any other part of the building; and although exhibiting somewhat of unusual forms and combinations, the style here preserves its characteristic energy, boldness, and breadth. Although, too, the parts themselves are simple, they acquire much picturesque complexity from the lofty position in which the windows are placed, being thrown further back, owing to which the pedestals detach themselves with considerable projection. In addition to the variety thus produced, we have that arising from the attic itself, if it may so be termed, being both loftier than the pedestals, and narrower than the compartment of the front below; from both which circumstances result great contrast and diversity of outline.

"The interior calls for very little description or remark, the walls being perfectly plain, and their being no other decoration of any kind than the columns, which are of very slender proportions, and have deep capitals, composed of ears of wheat. Above the centre space within the columns, is a lantern with vertical lights; and those on each side have seven skylight compartments in their ceilings. The north wing contains a tavern and coffee-room, and the opening in the south wall of the other wing communicates with the old Corn Exchange."—*Public Buildings of London.*

The Coal Exchange is a new building erected in Thames-street, near the Custom House, and completed so lately as the month of November, 1849.

The importance of the vast trade in that precious mineral to which Great Britain owes so much of her prosperity, may well demand that the merchants and others trading in coal, should have their own Exchange. The enormous extent of this trade can hardly be conceived, or its value in a pecuniary sense estimated.

"In respect to its natural supply of coal," says McCulloch, "Britain, among the nations, is most singularly favoured; much of the surface of the country conceals under it continuous and thick beds of that valuable mineral, vastly more precious to us than would have been mines of the precious metals, like those of Peru and Mexico; for coal, since applied to the steam-engine, is really hoarded power, applicable to almost every purpose which human labour directed by ingenuity can accomplish. It is the possession of her coal-mines which has rendered Britain, in relation to the whole world, what a city is to the rural district which surrounds it—the producer and dispenser of the rich products of art and industry. Calling her coal-mines the coal-cellars of the great city, there is in them a supply which, at the present rate of expenditure, will last for 2,000 years at least; and therefore a provision which, as coming improvements in the arts of life will naturally effect economy of fuel, or substitution of other means to effect similar purposes, may be regarded as inexhaustible."

The former Coal Exchange being quite unfit for the purposes required, and the inconvenience felt by the merchants frequenting it much complained of, an enlarged site was purchased by the corporation of London, for the erection of a new Exchange. This site afforded a frontage next Lower Thames-street of 113 feet, and a similar frontage next St. Mary-at-Hill. The building is erected from the designs of Mr. Bunning, the architect to the corporation, and is so arranged as to give an increased width to the two thoroughfares above-named. It presents two distinct elevations, connected by a tower, placed within the re-entering angle formed by the two fronts.

The façades of the building are of very simple, yet bold and effective design; and, with the exception of the cornice, but few projections are introduced. The fronts in Thames-street and St. Mary-at-Hill, are respectively about 112 feet in width, by 61 feet in height. The unequal form of the plot of ground on which the Exchange stands, is skilfully masked at the corner by breaking the mass of building, and introducing the circular tower before mentioned. This tower is 109 feet high to the top of the gilded ball, and 22 feet in diameter at the lowest part, and is divided into three stories. The lowest story, containing the entrance vestibule, is of the Roman-Doric style of architecture; and presents a striking peculiarity in the arrangement, to which we must advert. The wall of the tower not only contains the vestibule by which entrance to the hall or rotunda is attained, but serves also as a centre to flights of steps, which lead, on either hand, to a landing on the first story of the building. From this landing, a spiral staircase is carried up in the tower to the other stories. The first story is of the Ionic order, carrying an entablature, and is lighted by windows. The top story, 15 feet in diameter, is ornamented by pilasters, with windows between; the roof rising to a cone, and being crowned with a gilded ball. The front of the whole is faced with Portland stone. Entering the rotunda, the attention of the visitor is immediately arrested by its beautiful effect, and extremely novel arrangement. It forms a circle of some 60 feet in diameter, and is crowned with a dome, or, in fact, double dome, as a lesser cupola rises from the eye of the great dome to the height of 74 feet from the floor. The dome rests on eight light piers, the space between each pier being divided by stanchions into three compartments. There are three galleries, and from these galleries, entrance is obtained to the numerous offices in the building. The galleries are peculiarly constructed, and entirely composed of iron, embellished with symbols of the coal trade. Iron, indeed, has been most extensively made use of; the stanchions, brackets, ribs, and eye of the dome, are all of iron, and above 300 tons have been used in the building in the several parts. Each rib, of which there are 32, is 42 feet 6 inches long, is cast in one length, and weighs on the average two tons. The arrangement of pateræ in the stanchions, brackets, and soffits of galleries, is original and good. The ornament chiefly used is a cable, twisted about in various patterns, and the balustrade to the galleries is of loops of cable, broken at intervals by the introduction of the City arms. This rope-ornament has perhaps been used in too great profusion, for it is displayed on the stanchions, gallery-railings, soffits, and every place where it could possibly be introduced. The frame-work to the offices is of wood, and panelled with rough plate-glass. By this means, they receive light from the great dome of the hall. The dome itself is glazed with large pieces of ground plate-glass of great thickness, the glass of the small upper dome having an amber tint. The chief public offices surrounding the Rotunda are those appropriated to the offices of the corporation, whose business it is to collect the coal dues; the factors' board-room, the weighers' society, and the merchants' and factors', among whom Sir James Duke, lord-mayor of London at the time of the opening of the Coal Exchange, holds a very prominent position.

The floor of the Rotunda is composed of inlaid woods, disposed in form of a mariner's compass, within a border of Greek fret, and in its appearance is beautiful in the extreme. In its construction are employed upwards of 4,000 pieces of wood of various kinds, comprising black ebony, black oak, common and red English oak, wainscot, white holly, mahogany, American elm, red and white walnut, and mulberry. The whole of these materials have been prepared by Messrs. Davison and Symington's patent process of seasoning woods, to which we have alluded under the word Desiccation.

The same desiccating process has been applied to the woodwork throughout the building. The black oak introduced is part of an old tree which was discovered imbedded in the river Tyne, where it had unquestionably lain between four and five centuries. The mulberry wood, of which the blade of the dagger in the shield of the City-arms is composed, is made of a piece of a tree planted by Peter the Great, when he worked as a shipwright in Deptford dockyard.

The coloured decorations of the Exchange are peculiarly characteristic, and the entrance vestibule, in particular, is extremely rich and picturesque in its embellishments. Terminal figures, vases with fruit, arabesque foliage, &c.; all of the richest and most glowing colours, fill up the vault of the ceiling, through an aperture in which is seen that of the lantern, adorned with a figure of Plenty scattering riches, and surrounded by *figurini*. Over the entrance-doorway, within a sunk panel, are painted the City-arms. Within the Rotunda the polychromatic decorations immediately arrest the eye. The range of panels at the base of the dome, and the piers which carry the dome, are all fully and harmoniously decorated. Commencing with the piers in the lowest story:— It will be seen that the Raffaelesque decorations are very rich in character. In each pier a scroll supports and encircles four compartments; the lowest are semi-circular panels, within which are painted symbolic figures of the principal coal-bearing rivers in England: the Thames, the Mersey, the Severn, the Trent, the Humber, the Aire, the Tyne, &c. Small oblong panels, with marine subjects, are a little above the symbolic figures just described; and above these again, within borders of flowers of every kind, are figures symbolical of Wisdom, Fortitude, Vigilance, Temperance, Perseverance, Watchfulness, Justice, and Faith. These figures are the most prominent objects in the decorations of the piers in the lower story, and in circles above them are painted groups of shells; whilst at the top, in semi-circles corresponding with those at the base of the piers, snakes, lizards, and other reptiles, are introduced. In the first story, the leading feature in the arabesques is a series of views of coal-mines, including the air-shaft at Wallsend, Percy Pit Main Colliery, Wallsend Colliery, Regent's Pit Colliery, &c. Groups of fruit and flowers are in small circles just above the views, and in oblong panels beneath the latter the series of nautical "bits" is continued. At the base, in each pilaster, are representations of different specimens of Sigillaria—a fossil found in coal formations. In the second story, the largest panels contain figures of miners engaged in different parts of their labours, but these figures we think are not so well executed as other portions of the decorations. Nautical subjects, clusters of fruit and flowers, are introduced among the arabesques. The third story contains, within oval panels, miners at work, picking the coal, &c.: flowers and small landscapes add to the richness and variety of the decorations on this floor; and both in this and the lower, *calamites*, (fossils from the coal formations,) are depicted amongst the arabesques. The twenty-four panels at the springing of the dome, of which we have before spoken, have oval compartments painted in them, surrounded by a gracefully flowing border of extremely rich and varied design, being light ornaments on a dark ground. The spaces within the oval borders are coloured of a turquoise blue tint, on which is painted a series of representations of different fossil plants met with in the coal formations. This portion of the decoration is extremely striking and appropriate; and, we need scarcely say, the representation of the plants are strictly correct. These were painted in encaustic by Mr. Sang, from the drawings of Mr. Melhado, (a pupil of the architect,) taken from specimens in the British Museum. A staircase leads to the hypocaust, which was discovered in excavating for the foundation, a remnant of the time when the Romans ruled here. A visit to this will amply repay the lovers of antiquity, and its minute agreement with the details of such constructions given by Vitruvius, should be noticed.

The artificers' work generally were performed by Mr. Trego; the iron-work by Messrs. Dewer; and the woodwork was seasoned by Messrs. Davison and Symington's patent desiccating process. The floor of the merchants' area was laid down by the first-named of these gentlemen, Mr. Davison.

The cost of this Exchange was about £40,000.

The Royal Exchange, in general, has been fortunate in finding historians, still the current descriptions are, for the most part, imperfect and incorrect, and utterly without the sanction of official authority.

Like everything in the City, the existence of the Royal Exchange is owing to individual enterprise. This is the spirit and essence of commercial prosperity. The merchant is generally the architect of his own fortune; his pursuits necessarily bring him into contact with his fellow-men; and thus, while the principle of association obtains with him, and expresses itself in the guild and the corporation, in his own person he maintains a special individuality. To him who would indulge personalities, and portray characteristics, a visit to the City would afford many examples—some strange and odd enough, but all striking and strongly marked. In other pursuits of life there is more or less of a professional costume, which sinks the man in the official; but the merchant pleases himself, or acts upon early associations, in his dress and conduct. His success mostly depends, indeed, upon the personal. Gresham, the founder of the Royal Exchange, is an illustrious example of the truth of these remarks, and another instance of the great works that may be accomplished by the zeal, activity, and perseverance of an individual.

To Sir Richard Gresham, however, father of the Sir Thomas Gresham, whose name has become a "household word" to the citizens of London, the merchants of this great metropolis are indebted for the first serious attempt to found an Exchange. Before this time, the merchants met together in the open air in Lombard-street, exposed to the many inconveniences of such a place of assembling. In the reign of Queen Elizabeth, Sir Thomas Gresham, who determined to carry into effect what his father had been unable to do, proposed to the corporation, in 1564, "That if the City would give him a piece of ground in a commodious spot, he would erect an Exchange at his own expense, with large and covered walks, wherein the merchants and traders might daily assemble, and transact business at all seasons, without interruption from the weather, or impediments of any kind." This offer was accepted, and the new building, when completed, was visited by the Queen, who "caused the same to be proclaimed by sound of trumpet, the *Royall Exchange*, and so to be called from thenceforth, and not otherwise." Sir Thomas Gresham, who died in November, 1579, bequeathed the whole of this edifice, and its various appurtenances, after the death of his wife, "jointly for ever to the corporation of London and the Company of Mercers," upon trust for various purposes.

The fabric erected by Gresham was almost entirely destroyed by the great fire of London in 1666. Measures for the erection of a new building were, however, promptly taken, and in October 1667, King Charles II. laid the base of the column on the west side of the north entrance of the second Exchange; and, on the 31st of the same month, the first stone of the eastern column was laid by his brother, the Duke of York.

The popular notion has always been that Sir Christopher Wren was the architect of this Exchange; this is not the fact, the architect was Edward Jerman, one of the surveyors to the City in 1666. As this is a matter on which much difference of opinion has existed, we think the insertion of the following evidence from a letter in "The Builder," will definitively settle the question. The writer states, that the extracts we have given below, were taken from the records of the City, and of the Mercers' Company, and from them are obtained the following facts, which leave no doubt whatever that Jerman, and not Wren, was the architect of the late Royal Exchange.

"That on the 19th———1666, the commissioners appointed to the work, summoned to their assistance, Mr. Mills and Mr. Jerman, the City surveyors. Again at a joint committee, held on the 25th April, 1667, the following minute is recorded:—

"The committee, concluding it very necessary at this meeting, to make choyce of a surveyor for directing and overseeing the building of the Royal Exchange, and assisting them in carrying on that designe to the best advantage, as to substantiallnesse, ornament, and frugality; and forasmuch as Mr. Mills, the City surveyor, hath declared that hee cannot perform that worke alone, and the committee being very sensible of the greate burden of businesse lying upon him for the City all this time; and considering that Mr. Jerman is the most able knowne artist (besides him) that the City now hath: therefore the committee unanimously made choice of Mr. Jerman, to assist the committee in the agreeing for, ordering, and directing, of that worke; and, having declared the same unto him, hee, after much reluctancy and unwillingness (objecting, it might bee thought an intrenchment upon Mr. Mills his right,) at length accepted, being assured first by the Lord Mayor and the committee, that itt was no intrenchment, that this wholle committee, at all times, would acquit him from any scandall in that behalfe; then the committee ordered the clerke to acquaint Mr. Jerman with all the proceedinges of this committee about the said building."

After this appointment Mr. Mills's name does not occur again, and the works evidently proceeded with great rapidity, for they were finished within three years and a half from the period of Jerman's appointment.

On the 9th December occurs the following entry. "The committee considering that Mr. Jerman, who was chosen surveyor for rebuilding the Exchange in April last, hath not yet received any gratification for drawing drafts and directing the building; they therefore ordered that £50 shall be payed him upon account until further consideration of his merits."

These extracts, I think you will agree with me, prove that Edward German (or Ierman as sometimes spelt) was the sole architect. In these records Sir Christopher Wren is spoken of, under date of the 7th Jan., 1670, as "Dr. Wren, Surveyor-general of His Majesty's workes."

The building erected by Jerman, was publicly opened for business on the 28th of September, 1669, the expense of its construction having amounted to £80,000, which was defrayed in equal moieties by the City and the Mercers' Company.

This structure also was doomed to fall by the same element which had proved fatal to its predecessor, for on the night of the 10th of January, 1838, it was discovered to be on fire, and in the course of the night, though not entirely destroyed, was so much damaged, that for all purposes of usefulness the destruction may be said to have been complete.

The architecture of the building thus destroyed has been variously estimated; by some decried, by others praised; but probably it merited the extravagant praises of the one party as little as it deserved the severe criticism of the other.

The four orders of the quadrangle were richly decorated, with the basements, arches of the walks, the cornices over them, the niches, statues, pillars, circular windows, entablature, pediments, and balustrade, all in correct proportion and arrangement. Its principal front was towards Cornhill; and on each side there were Corinthian demi-columns, supporting a compass pediment; within each of which were niches containing statues of Charles I. and II. in Roman habits, by Bushnell. Within the quadrangle there were twenty-four niches in the intercolumns, with statues of English kings and queens, most of the kings before Charles II. being sculptured by Cibber. The centre of the area had for some time a statue of Charles II. by Grinlin Gibbons, which was subsequently displaced for one by Spileer, habited in the Roman style. In an obscure position under the piazza, the statue of Gresham, too, had its niche; and nigh to it, that of one, whose modesty would have been better content had his merit received no such acknowledgment—Sir John Bernard; to whom, in his lifetime, the memorial was erected as a mark of civic respect, but who could never bring himself to visit the walks afterwards.

The destruction of this building having deprived the merchants of London, for the second time, of their great place of resort, they were obliged temporarily to assemble in the space attached to the Excise Office, in Old Broad Street. This was, of course, attended with much inconvenience to those accustomed to attend 'Change, and it became therefore a matter of pressing importance to remove that inconvenience by the erection of a new building, fitted in every respect for its purpose, and worthy the merchant-princes of the first metropolis in the world.

In preparing to re-erect the Royal Exchange, many interests had to be considered—those of the Underwriters of Lloyd's, the Royal Exchange Assurance Company, and the shopkeepers who had occupied the ground-floor. An act of parliament was also necessary; this was applied for, and obtained. By this act, which received the Royal assent on the 10th of August, 1838, the Joint Gresham Committee were empowered to purchase and remove all the buildings to the eastward, extending nearly to Finch Lane, and to raise a sum of £150,000 upon the credit of the London Bridge Trust.

After considerable delay, the Gresham Committee issued their advertisements for designs for the new building, but in doing so, unfortunately did not avoid the errors into which so many similarly-constituted public bodies have fallen, under similar circumstances. There is little doubt but that the Committee intended a fair and honest competition, but with *not singular* bad management, they so contrived matters, as to bring down on themselves a storm of indignation from all sides, and to disgust not only the competitors, but the public in general.

The system pursued of late years in the management of architectural competitions, has been attended with manifest evils, and fraught with gross and palpable injustice to the profession. Hastily and inconsiderately commenced, under the control of persons unfitted to sit in judgment on the various designs referred to their decision, they have in too many instances been attended by results, as injurious to the best interests of art, as unfair and unjust to its professors.

In making these remarks it is not intended to attack the principles upon which competitions are based; properly conducted, their tendency is unquestionably, not only to call out the talent and genius of the experienced artist, but to rouse a spirit of emulation in the young professor, as an assistance in encouraging rising merit, which without such a stimulus might possibly remain undeveloped, or, without such a means of exercise, unknown and unappreciated.

There may be many advantages attending architectural competitions, but there is so total a want of security, under the operation of the present defective system, so general an impression existing, whether justly or not, that fairness and impartiality in the decisions cannot always be relied upon, that the great body of the profession hold themselves aloof from entering an arena where fair play is, to say the least, doubtful. The competition for the Royal Exchange, it is to be lamented, afforded another proof, if proof were wanting, of the truth of those observations.

It is not our purpose to enter on a discussion of the merits of a controversy which filled many pages of the periodicals more especially devoted to recording matters connected with architecture and building, but we think we cannot pass to a description of the New Exchange without slightly noticing the manner in which the design for it was selected, or its architect appointed.

The following are extracts from the—

"*Resolutions of the Gresham Committee, as to Instructions to the Architects.*

"1. That architects be invited to offer designs for the rebuilding of the Royal Exchange, in general competition, and that premiums be offered for three designs adjudged by the Committee to be the best.

"3. That the new building be of the Grecian, Roman, or Italian style of architecture, having each front of stone of a hard and durable quality.

"6. That a specification be required to accompany each design, giving a general description of the building, and such other information as cannot be clearly shown on the drawings, stating also what stone, or other material, are proposed for use in the different parts of the building, and specifying particularly the estimated expense of carrying the designs into execution in the most substantial and complete manner in every respect for occupation, the expense not to exceed £150,000.

"10. That for the design for which the Committee shall award the first premium, the sum of £300 shall be given; that for the second design the sum of £200; and for the third the sum of £100. The successful competitor, to whom the first premium is awarded shall not be considered as having necessarily a claim to be entrusted with the execution of the work; but if not so employed, and his designs are carried into execution, a further sum of £500 shall be paid to him—the Committee retaining possession of all the drawings for which the premiums have been given.

"11. That if reasonable doubts should arise in the minds of the Committee as to the practicability of carrying into execution the successful design for the amount of the estimated expense of the building, the Committee shall be at liberty to call upon the party to give sufficient and satisfactory proof of the accuracy of the calculations, and to withhold the premium, and reject the designs unless such proof be furnished."

After issuing these Instructions, the Committee appointed three architects—Sir Robert Smirke, Mr. Gwilt, and Mr. Hardwick, to examine and advise on the designs which might be sent in. Above fifty competitors appeared, and the above gentlemen, after due examination, made a report to the Committee, from which we extract the following passages.

"In the first class, those that we think may be executed for £150,000, we beg to report as follows:—

First	No. 36
Second	„ 43
Third	„ 37
Fourth	„ 33
Fifth	„ 57

"In the second class, or that in which we consider the cost would vastly exceed the sum of £150,000, equal impracticabilities of execution with those of the first class are to be found; and, notwithstanding the very great talent they exhibit, there are circumstances of inconvenience and unsuitableness which would bring them, as we conceive, into the predicament of being unadvisable for adoption. We wish it, therefore, to be understood, that we report on them respectively as the works of very clever artists, who have produced pieces of competition in which, besides the circumstances above-mentioned, stability arising from solid bearings for upper apartments, and other essential matters, have been sacrificed to grand architectural features.

"The designs in the second class, in our estimation of their order of merit, are as follows:—

First	No. 50
Second	„ 46
Third	„ 27

"We again venture to state to the Committee the difficulties which have attended the making of the report herewith submitted, and which, but for the unanimous decision at which we have arrived, we confess, might have left doubts in our minds, if our view had not been confined by the Committee to the expenditure of a given sum."

On receiving this report, the Joint Committee met at Mercers' Hall on Friday, the 18th October, to consider the report, and again inspect the designs, and came to the following resolutions :—

"Resolved,—That the premiums be awarded to the architects who have produced the plans numbered as under—

No. 36 the first premium . . . £300
„ 43 the second „ . . . £200
„ 37 the third „ . . . £100

being those reported by the architects as the three best designs.

"And it was resolved, that Sir R. Smirke, and I. Gwilt, and P. Hardwick, Esqrs., having stated in their report upon the respective merits of the plans selected by them, that they cannot recommend any one to be carried into execution, this Committee doth request them to take the 1st, 2nd, and 3rd plans, as selected by them, into consideration, and prepare a plan and specification for a new Royal Exchange, such as in their judgment should be carried into execution, having reference, at the same time, to the printed instructions issued by this Committee to the architects."

The following were the architects to whom the premiums were adjudged.

No. 36, £300, to Mr. William Grellier, district surveyor, 20, Wormwood-street.

No. 43, £200, to M. Alexis De Chateauneuff, of Hamburgh ; and Mr. Arthur Mee, of Carlton Chambers.

No. 37, £100, to Mr. Sydney Smirke, of Carlton Chambers.

The architects of the remaining designs of the first class.

No. 33, Messrs. Wyatt and Brandon.
„ 46, Mr. Pennethorne.

The architects of the second-class designs, which were considered too expensive.

No. 50, Mr. T. L. Donaldson.
„ 46, Mr. Richardson.
„ 27, Mr. David Mocaotta.

The next step taken by the Committee was to appoint Mr. George Smith, the City-surveyor, and Mr. Tite, to inquire into the eligibility of some one of the designs selected by the umpires for the premiums. Mr. Tite, however, refused to act, and the onus devolved on Mr. Smith alone. This gentleman submitted a report to the Committee, in which he advised the rejection of the whole of the designs; and the Committee acting on this advice, without ceremony threw the supposed successful candidates overboard, and boldly selected six other architects, whom they requested to send in designs for the contemplated building. The gentlemen so honoured by the Committee were Sir R. Smirke, Mr. Barry, Mr. Gwilt, Mr. Hardwick, Mr. Cockerell, and Mr. Tite, the whole of whom, excepting the two last, declined accepting the invitation, being doubtless influenced to such course by the bad faith observed to all parties by the Committee. What also added to the public dissatisfaction, was that rivalry or competition between Mr. Cockerell and Mr. Tite was considered out of the question, from their previous connection. Thus the whole matter evidently settled down in Mr. Tite being selected finally to prepare the design for the new Royal Exchange.

That design we shall now proceed to describe, as given by Mr. Tite, himself, in his explanation to the Committee :—

Extent and Site.

The total length of the building is 293 feet 6 inches, from the columns of the portico on the west, to the pilasters at the east end ; the width of the portico is 89 feet 6 inches ; the extreme width at the east end, at the broadest part, is 175 feet, and the width through the centre, from north to south, is 144 feet.

The building is placed in the centre between the south front of the Bank, and a mean line of the irregularities presented by the houses on the south side of Cornhill ; the east and west fronts are at right angles to the centre line, and, of course, the angle formed by the intersection of the north and south fronts, with the east and west fronts, is the same ; by this means the building, though not rectangular, is regular in the plan.

Arrangement.

Gresham College occupies the north-west angle of the building on the principal story, and is entered from the north.

The Royal Exchange Assurance occupies the south-west angle, and the space over the west end of the colonnade, on the one-pair floor, and is entered from the south side of the loggia, under the portico.

The London Assurance occupies the greater part of the south front on the principal story and is entered from the south.

Lloyd's fills up the remainder of the east and north fronts of the principal story, and is entered in three places, viz., from the east and the north-east corner, and from the north.

There is a small additional staircase and entrance to the principal lecture-room of the Gresham College (which I propose to use for the exit from the lectures only) and this opens into the loggia under the portico.

The commercial room proposed to be attached to Lloyd's, and which, in a letter from Mr. Barnes, of the 26th February, I am requested so to manage as that it might be appropriated for offices, if not eventually required for the above purpose, has been accordingly placed by me on the principal story on the north side. If not required by Lloyd's, I should propose to convert this room into a double range of offices, one lighted from the street, and the other lighted from the area of the Exchange, each office having a room over in a third floor; the access to these rooms would be by a distinct staircase and entrance on the north, for which a distinct shop must be taken. The mean width of this commercial room is 39 feet, and its length 96 feet; allowing, therefore, for an 8 feet passage in the middle, it would provide for 12 sets of offices, each 16 feet by 15 feet.

The shops and offices are very material features of any design for this building, for, under the 62nd section of the act for providing a site for the Royal Exchange, the Gresham Committee are bound to compensate any party holding a lease in any part of the old Royal Exchange, unless the owner or lessee is reinstated. As regards the offices this would probably only be the value of the difference between the reserved rent and the actual rent, and not a matter of much importance ; but unless the valuable trades and occupations round the Exchange are reinstated, the question would become a very important one, because it would involve the good-wills of the parties. The mere question of reinstatement, however, is not the only one ; for it is clear the revenue to be obtained from the shops, after the expiration of the present leases, must form a very important item in any income to be derived from the building. In order to meet these requirements, and still, I hope, in no way to injure the design, I have placed the shops or offices on a level with the street, round the north, south, and east sides; and, inasmuch as I found that in the old Royal Exchange there were shops in three of the entrances, and as I could very conveniently arrange a few in the east entrance of my design, I have placed six there. Let the claims, however, arise as they may, with this plan now under discussion, there could be no difficulty in meeting them all, for the area of all the shops and offices of all descriptions, in the ground-floor of the Old Exchange, amounted to 8,106 feet only, whereas, in this plan, the shops and offices provided, exclusive of the part appropriated to Lloyd's, to the Gresham College, the London Assurance, and the Royal Exchange Assurance, exceeds this quantity by 1,087 feet, the total being 9,217 feet. The increased value of all this, and the exact nature of the accommodation, will, however, be further explained under other heads of this descriptive particular.

Accommodation.

Gresham College.—In considering this department of the building, I was placed in considerable difficulty, not only from the total absence of instructions, but because I found, as well amongst the committee as in society, very considerable differences of opinion on the subject.

After much reflection, I have, however, arranged what I hope will be considered a complete establishment for most purposes, and it is as follows:—On the north side of the Exchange, about 45 feet from the west end, is an entrance with a small hall and staircase. In this hall a porter would be placed, who would prevent the admission of improper persons.

The entrance-doorway is large, and over it is placed a shield containing the arms of Sir Thomas Gresham. This entrance and hall are also quite distinct, and, like all the other parts or distinct portions of the design, it is separated by party-walls. On the first landing of the staircase is a porter's room, which would also serve for umbrellas, coats, or cloaks.

On the one-pair, or principal floor, is a lecture-room or theatre, of a horse-shoe form, the dimensions being 46 feet, 6 inches, by 36 feet. To this is added a library or lesser lecture-room, 25 feet by 24 feet; a lecturer's or librarian's room, 19 feet by 15 feet 6 inches; apparatus-rooms, 16 feet 3 inches, by 11 feet: with a water-closet and washing-room; and two rooms over the librarian's, and apparatus-rooms for some resident servant.

The theatre would seat 250 persons on the floor, and 200 more might be conveniently seated in the gallery. It is probable, however, that for many lectures or continuous courses, this might be too much, but for some it might be too little. I have, therefore, placed the library at the back of the theatre, by which, in the latter case, the accommodation might be increased, or in the former it might be sufficient in itself for such purposes. The result, therefore, is this, that for an auditory of 40 or 50 persons, the library would be sufficient; beyond that number, and up to 450 persons, the theatre would be the proper place; if a larger number were expected, the partition dividing the library from the theatre might be removed, (as is shown in the plan) by sliding it into the wall, when, by removing the lecture-table a little further back, 50 persons more might be accommodated. Beyond this extent of 500 persons, it is probably undesirable to carry it further.

If, however, I have erred altogether, and have provided too much, it is easy to diminish it; or if it is determined to abandon this site for this purpose, the space so complete and isolated would readily let by itself, or might be combined with the unappropriated offices in the north-west angle immediately under the theatre. It remains to be added, that I have also provided ample vault-room in the basement of this establishment, and a second staircase connected with the theatre, and only intended to be used on a crowded occasion, for the dismissal of so large an audience as 400 or 500 persons, and for a private approach or retreat for the lecturer.

Royal Exchange Assurance.—This establishment in the old building occupied apartments in the mezzanine, and on the one-pair floor. The net area being 5,235 feet, exclusive of passages, staircases, water-closets, kitchen, and rooms in the roof. I have had many meetings with the governor on the subject, and at length I received, so late as the 4th instant, a list of the rooms, of which I have attached a copy to this description.

The total area in this is 6,284 feet, but omitting the store-rooms and kitchen for the sake of comparison, the net quantity is 5,894 feet. My plan gives this so nearly, and the dimensions of the rooms also correspond so generally with the requirements, that I need not occupy the time of the Committee with any further description; but, in addition, I have added what appears to me obviously necessary, viz., strong rooms and cellars in the basement.

As the heights of the floors of this part of the building differ in some respects from the general section, I beg to add them here, and they are as follows, viz.: The ground-floor is 2 feet 6 inches above the level of the floor of the Exchange, and 6 feet above the street; under this is a lower ground story, the height being 10 feet with vaults under.

The ground-floor will be 13 feet, high, the mezzanine 10 feet, the one-pair floor is 18 feet, except where there are rooms over, when this will be 13 feet.

London Assurance.—I attach a copy of the instructions received from this company to my letter of the 6th March, addressed to Mr. Barnes. The total quantity of space required is 5,553 feet, exclusive of waiting-rooms, water-closets, &c.; as some of the rooms seemed extravagant in size, I have arranged them somewhat less, and the company express themselves satisfied with my dimensions, the total being 4,834 feet.

Lloyd's.—With regard to this very important establishment, I beg a reference to my letter to Mr. Barnes, of the 6th instant, to which I attach a copy of the new instructions forwarded by their architect. The total quantity of space occupied in the old Exchange by this company, exclusive of staircases, was 7,914 feet. The space now required is 13,781 feet, exclusive of passages, staircases, water-closets, urinals, &c.; but this includes the commercial room, which is 4,050 feet. The dimensions of the several apartments in my plan are very nearly consistent with their requirements, and the total result the same.

The arrangement of the rooms is best understood by a reference to the plan of the one-pair floor, and I believe it to be quite in accordance with the wishes of the Committee.

Shops.—I propose that each shop shall have a cellar below, and, with very few exceptions, a mezzanine over. The average height of the shops will be 14 feet, the basement-floor 12 feet, and the mezzanine 10 feet. Each shop will be secured by party-walls, and roofed with iron beams and arches under the one-pair floor. The water-closets will be in the basements, there will be a separate flue in each shop, and room for the fire-places; and I propose that each shop and room shall be warmed by an open, or Arnott's stove, of the same pattern.

The staircase will be circular, and of cast-iron. Staircases of this kind, though not much known here, have been extensively used in Paris, and are admirably adapted for such purposes. I have paid every attention to the mode of lighting the deeper shops, and I hope I have succeeded in obviating all reasonable apprehension on that subject. The shops without mezzanines, are one in the south front, one in the north front, and four in the eastern entrance to the Exchange. In the area, in the latter case, they are left out, to allow of light being obtained over the shops to the back parts of the other premises.

Exchange.—The Exchange is entered from four arched openings in the centre of each side; the form is a parallelogram, and the inner area exactly a double square. This form has many advantages, both in point of convenience and elegance over the old form, and is also better adapted to the shape of the ground.

As to the level of the floor of the Exchange, I have heard many opinions; but it appears to me to be of the greatest importance, that it should be as nearly level with the street as possible. From the natural fall of the ground, however, which is quite gradual, but amounts to 3 feet 6 inches in the length of the building from east to west, it is impossible to avoid a few steps at the north, south, and west entrances. This is an advantage at the west end, as it gives height and character to the façade or portico; the exact effect and extent of this fall of the ground is shown in my north and south elevations. In the shops the steps are avoided, because they can follow the natural inclination of the ground.

Basement.—Much of the basement (or vaults,) is occupied by the establishments over the respective divisions, and I have added some to the lesser shops, but there is still a large space which may be let off, as the basement of the old building was. I have lighted the basement by area gratings in the pavement of the Exchange, exactly as formerly.

The public vaults are approached by two staircases, which are placed in the eastern entrance. The central area is proposed to be left without a basement; it would be difficult to keep it dry, and I do not know any use to which it could be applied which would pay for the cost.

Style of Architecture.

This is naturally one of the most important considerations in the design, and one in which I have most to regret the limited time I have had to consider this most extensive and difficult composition. It appears to me, that a building for essentially commercial purposes should present the character of grandeur, simplicity, and usefulness. In this way, the universally acknowledged good effect of the Bourse at Paris has been obtained. In that building the lines are simple and unbroken, and the large arched windows surrounding the walls behind the columns have all the character of shops or offices. The west front of the Exchange of London, as in that of Paris, must be the principal feature, the other sides being bounded by buildings.

Another difficulty arises from the shape of the ground; because any tower placed to agree with the lines of the south front must disagree with the lines of the east and west fronts, which are in different planes; and such an object, when seen from a distance, or from the area of the Exchange, would produce an effect that would be discordant and unarchitectural, because it would bring into distinct notice a fact which it should be the business of the architect to conceal. For a long time I contended with this difficulty, because I was anxious to place the tower or towers in the south front, but it was impossible to get over the irregularity; it would, indeed, have been easy to have concealed this defect in the drawings, or have kept it out of notice, but the result, when built, would only have ended, in my judgment, in disappointment and failure. For these reasons, and with these views, I have composed my design as it is now exhibited. I have placed a portico at the west end, and the tower at the east. The south and north fronts exhibit unbroken lines of entablature, with a repetition of arches of the same character for the shops, offices, and entrances. We are deficient in England, of specimens of architecture of this unbroken kind: were I to adduce instances, I should quote the National Gallery, as affording an illustration of the bad effect of broken and detached masses, and the Reform Club, of the excellent effect of continuous and unbroken ones.

The portico would be very superior in dimensions to any in this country, and not very inferior to any in the world. The width, from outside to outside of the 8 columns, is 90 feet, and the height, from the ground to the apex of the pediment, is 74 feet 6 inches. The portico of St. Martin's Church is 64 feet wide and 58 feet high; that at the Post-Office 76 feet wide and 67 feet high; and from these dimensions a fair comparison may be made of the relative size of the two porticos.

The height of the order used in this edifice is 50 feet, and the height of the tower, to the top of the vane, is 170 feet. From the point of view prescribed by the instructions, the tower is not seen. Had I been at liberty to have removed the station further to the westward, as to Mansion-House-street, or the Poultry, the tower would have been seen over the portico, and the effect of the composition thereby greatly improved. The sections and view show the exact character of the interior of the Exchange, the lower story is a colonnade of the Doric order, the columns are 34 inches in diameter; the upper order is Ionic.

Specification of the nature of the work.—The examination of the foundations, which I ventured to suggest, has proved that the nature of the sub-soil is of the best kind for supporting a large building. At an average of fifteen feet from the surface, a very compact gravel is found. For the sake of perfect uniformity, I should excavate sufficiently for a few feet below this; and by a uniform bed of concrete, of the thickness of six feet over the whole surface, a most certain and safe foundation would be made. The gravel is full of water, and therefore the drainage must be carefully considered.

Your conditions require a general specification, but, without going into full technicalities, I am at a loss to furnish a specification of any value. I intend everything to be executed in the best manner. All external work to be faced with Portland stone; all the horizontal divisions that require it, for the purpose of security from fire, to be constructed with iron beams and brick arches; and the ceiling and floor over the colonnade constructed in the same manner. The timber used to be all Baltic timber, English oak, or African teak. Everything to be sufficiently and completely finished in all respects.

Sculpture.—I have not introduced much sculpture into this design, because the estimate would not allow of it; and I have, therefore, aimed at a style which did not require it to any extent. The sculpture introduced as essential to the architecture, embraces the five panels in the attic of the south front, and the two figures at the west end. The panels in the south front are intended to represent Britannia, supported by the principal cities of the empire receiving the representatives and productions of the four quarters of the world; the two seated figures in the west front, are emblematical of Peace and Abundance. There are several shields of arms, which though not falling exactly under the head of sculpture, I think it desirable to mention, and they are as follows:—the escutcheons on the key-stones of the three great arches of the west front, are the arms of Queen Elizabeth, Charles the II., and Queen Victoria. These arms are repeated in the panels of the attic at the east end. In the north and south fronts, on the keystones of the centre arches, the arms are those of the City, the Mercers' Company, and Sir Thomas Gresham.

Estimate.

I estimate the cost of this edifice, as thus described, including the sculpture, at the sum of £143,800.

Income.

I have estimated with great care the income to be derived from the various shops, offices, and public establishments, proposed in the several floors of the building, by comparing dimensions and other circumstances, with the previous lettings, and by the actual value derived from my own experience; and I am of opinion that the total net annual value, if let on lease, would amount to the sum of £8,718 per annum. In addition to this, if the space allotted to Lloyd's commercial room on the north side, and that to the London Assurance on the south side, were arranged as offices, each set having two rooms, one over the other, as suggested in an early part of this statement, though the estimate would be increased £3,000, I have no doubt this annual income might be raised to the extent of £800 per annum, making a total income of £9,500 per annum.

In the drawings themselves, I have carefully laboured to follow out the instructions under which I undertook this competition. The views are strictly confined to the points of view prescribed: in the colouring of the views themselves, and in the drawings of the adjoining buildings, I have laboured to be accurate, and to give as nearly as I could, the actual effect of this edifice, if it were constructed. I cannot but feel that a more elaborate style of architecture would have been productive of more picturesque effects, and it would have been easy to have produced them; but I have ventured to come to the conclusion, that nothing but plain grandeur and elegant simplicity is consistent, either with the means at the disposal of the committee, the purposes and uses of this building, or its situation in the very heart of the City of London.

We have given at length Mr. Tite's own description of the building, as affording the most perfect and complete explanation of every particular connected with it, and also as showing the many requirements he had to meet, and the various interests he had to provide for. It is due to him to say, that he has certainly succeeded in satisfying all parties, in the convenience of his arrangements for individual benefit, while he has added to the public buildings of London an edifice in every respect worthy the first community in the world. On one part of the design much discussion took place at the time, viz., whether the area of the new Exchange should or should not be an open court, as in the old building. In the instructions issued to the competing architects by the Gresham Committee, this was insisted on, and, as we are informed, in compliance with the general opinion of the merchants and bankers of London. With submission, however, we are strongly inclined to believe that the merchants and the Gresham Committee might have left this matter, with benefit, to the discretion of the architects offering designs, with whom it would have remained to demonstrate the advantage or defects of either mode of construction, whether open or covered.

It is worthy of remark that the Bourse at Paris, and at St Petersburg, the Exchanges of Dublin and Glasgow, and almost all modern structures erected for a similar purpose, are, we believe, roofed in; one advantage of which is, that the whole of the area is available, let the weather be as unfavourable as it may, consequently, the same superficial extent can accommodate a far greater number of persons than where it is only partially sheltered, and where a considerable portion must frequently be altogether useless, as far as actual serviceableness is concerned. The present arrangement therefore is to be approved of only where what is thus sacrificed, with regard to mere convenience and utility, is amply atoned for by what is gained as to architectural character and effect.

We do not deny that a *cortile*, whether surrounded by columns or by arches, and whether partially or entirely so, is favourable to scenic effect and display, and, farther, admits of very great variety as to plan and design. This is sufficiently testified by examples in Italian buildings, where cortiles frequently constitute the most striking and beautiful parts, generally picturesque and piquant, though not always unexceptionable in design. But then it does not exactly follow, that because a cortile is beautiful as such, it is eligible for a purpose requiring more than a sheltered corridor around the open part; for, although that kind of shelter is sufficient for a place of *passage* to and fro, it certainly does not seem to be sufficient for one intended for the assemblage of a concourse of persons, not on particular occasions, when, in case of the weather proving unfavourable, the company may be protected from it by awnings provided for the emergency, but daily, throughout all seasons of the year. When a place of the kind already exists, it may conveniently and properly enough be applied just as it is to the purpose of an Exchange; its inconvenience may, then, be put up with as unavoidable. But there is no qualifying circumstance, to reconcile us to a defect studiously adopted, voluntarily and with premeditation, to the exclusion not only of positive convenience, but likewise of originality of design. Either our climate is most unjustly reproached, not only by foreigners, but by ourselves, or it ought at once to have banished all idea of rebuilding the Royal Exchange upon the plan of the former one, as regards that very principal part of it where the merchants will daily assemble, and to which all the rest is to be considered as merely supplementary.

Be it any improvement or not, all our lately built markets are floored with flagstone pavements, and covered in from the weather, shaded from the burning sun in summer, as well as sheltered from rain and snow in winter; nor do we believe that either the occupiers of them, or their customers, at all regret the change which has taken place. Nevertheless, with instances of that kind before their eyes, not in the Metropolis alone, but at Liverpool, Newcastle, and other places, the merchants of London have decided that they are to meet for business as heretofore, within an area only partially and imperfectly protected from the weather. Even beneath the colonnades, they must be more or less exposed to wind and rain, and be inconvenienced by the throng of persons; whereas, by converting the central space into the part more particularly appropriated to the transaction of business, the sides, which might still be separated from it by colonnades, would be left free for persons passing in or out, without interruption to those engaged in business.

There may possibly be contrary reasons for not adopting a mode of building securing the advantages here pointed out by us; but they have not been brought forward by others, nor can we divine what they can be. Hardly can it be objected, that any plan of the kind would destroy all peculiarity of character, by converting the Exchange itself into merely a spacious hall, lighted from above, which, however it might be decorated, would, in its general effect, resemble any other public apartment of the same dimensions; because, although it would no longer be a cortile—an open space enclosed by façades of external architecture—it might be kept altogether different from anything we are accustomed to, in interior architecture, and appropriately rendered *sui generis.*

It will appear a very singular pendent to the above observations, that we should have to insert the following petition to the Gresham Committee, from the very parties to oblige whom this "uncovered" area was insisted on.

"The undersigned Merchants of the City of London are of opinion, that, in the construction of the new Royal Exchange, sufficient attention has not been paid to the comfort of those who attend the same, and beg most respectfully to submit to the Gresham Committee the following alterations, which are necessary before they can assemble there without danger to their health and personal comfort. The alterations suggested are:—1. That the area be covered in. 2. That some remedy be provided to remove the cold damp from the pavement. 3. That a remedy be also provided to protect them from the currents of air."

The above petition has been signed by Messrs. Barings, Rothschilds, Heath, Morris Prevost, Doxat and Co., Lemme and Co., and some hundreds of the first firms in the city. After much discussion in Committee, the clerk was directed to communicate to the memorialists:—

"That in the month of September, in the year 1838, before the Gresham Committee took any steps whatever as to the erection of a new building, they applied by circular to most of the leading merchants and brokers, requesting their opinion as to whether the new Exchange should be a covered hall, or partially open, as in the original Exchange of Mr. T. Gresham, and in the one recently destroyed; that besides, the Committee took every opportunity, by personal inquiry, of ascertaining the wishes of their fellow-citizens on the subject; that the result of the circular, and of these inquiries, was, that a large majority wished the Exchange to be partially open, as heretofore, alleging the great noise in the Bourse at Paris, and the necessity for ventilation of the most free kind, as their reasons for the decision; that in consequence of this determination, they directed a part of the merchants' area to be left uncovered as before, but that, for greater shelter, they further directed that the covered space should be increased from one-half, (the proportion of the space covered in the late building,) to two-thirds; and that the architect of the present edifice had strictly followed out these instructions; and, for these reasons, the Committee could not comply with the wishes of the merchants; that, with regard to currents of air, the committee had directed such inner doors to be put up, at the north and south entrances, as might check the draughts, at the same time providing that such doors should not interfere with the extensive uses of the area of the Exchange, as a thoroughfare to all the neighbouring streets, the Bank, the Stock Exchange, and other important public and private buildings of the neighbourhood."

We have given the above, as *apropos* to the question of a roofed or unroofed area, though this is hardly the proper place for a petition delivered some months after the Exchange had been opened for business. Such a petition, however, proves clearly the justice of the observations we, in common with the great body of the profession, have urged to the central space of the building having been left uncovered.

To return from this apparent digression.—After much consideration as to whether the material employed should be magnesian limestone, similar to that used for the Houses of Parliament, it was determined that the whole of the exterior of the building, with the exception of the socle or stylobate (which was to be of granite) should be Portland stone of the best quality. This point having been decided, the Gresham Committee at length found themselves in a position to enter on the contracts for the new structure. About fourteen of the principal builders were applied to, and sent in tenders; and those of Messrs. Webb for the first contract, (the excavation and concrete foundation); and of Mr. J. Jackson for the second (the super-structure),—were accepted. The first was for £8,000—the last for £115,000.

In excavating the merchants' area, (originally intended to have been left solid,) for the purpose of extending the basement beneath that part of the plan: a number of antiquities were discovered, beneath what was the west wall of the former building; in particular, the remains of some Roman structure were found, which proved, on examination, to have been built on a very large pit or pond, irregular in shape, but about 50 feet in length from north to south, 34 in breadth, and 13 in depth. This pit was filled with hardened mud, in which were immense quantities of bones of sheep, of bones and horns of stags, also numerous fragments of the red Roman pottery, usually called Samian ware, pieces of glass, and glass vessels, broken lamps, &c., and several copper coins, two of the emperor Vespasian, the remainder of Domitian—all of which antiquities were, by the terms of the contract, reserved for the Gresham Committee. On Monday the 17th January, 1842, the first stone was laid by His Royal Highness Prince Albert, with much state and ceremony, a full description of which appeared in the newspapers of the day; and the works then proceeded with such rapidity, that in three years from that date the new Royal Exchange was completed—a very brief space of time for such a work, especially considering that it consists entirely of stone.

On Monday the 28th of October, 1844, the Exchange was opened by Queen Victoria in person. The "pomp and circumstance" of such a ceremonial are not for a work like the present, they have been duly chronicled by those publications which record so faithfully and so minutely events like these: but the following observations, which appeared in one of the newspapers at the time, seem so pertinent to the subject, that we think their insertion here not inappropriate. "The present ceremonial," says the writer, "will, in many things, resemble that which was presided over by the 'Virgin Queen:' for state and its observances partake of the traditional, and are transmitted down with comparatively slight changes. But in all else how different! What an empire! and what a metropolis! How vast the increase in all that constitutes the strength of nations, in the England of Victoria, since it was the England of Elizabeth! The empire is one of many tongues and nations; the population of its chief city is counted, not by thousands, but by hundreds of thousands; and as for the commerce of the realm and city of Gresham's royal mistress, it was, as compared with that of the England and London of to-day, but as the rivulet to the ocean; its development has been as vast as that which could bring 'Dodona's forest from an acorn cup.' Between the day on which a Queen of England passed through the Temple-Gate to open the first Royal Exchange—and the hour which will see another Queen of the same fair land pass along the same road on the same august errand—great has been the destiny of England among the nations of the world! At this point the mind naturally goes forward to the future, and asks itself the question, what will be the state of this 'crowning city,' of the traffickers of the earth, when three centuries shall have passed over the now white walls, the fair chambers, and sculptured portico, of the new Exchange? What will be the condition of the empire, when the generation that gazes on the pageantry of to-day, shall—with many succeeding ones—be mingled with the dust? They are solemn questions; and, happily for us, can find no answer from human intelligence. The misery of Adam, when the angel, in Milton's immortal epic, revealed to him the doom of the future race of man, is but a type of what would be felt by all, if the coming time were not, with infinite wisdom and mercy, hidden from our ken. The past we know; the present we can govern; for the future we can only hope, making our actions such as to render a cheerful hope justifiable. Let the spirit of commerce, then, when it takes up its new abode, work with the energy and activity that have always marked it. Above all, let it preserve that integrity and commercial honour which have been so long the pride of the English merchant, and then will it have done the best to secure a still further development of the wealth, extent, power, and numbers of that realm over which Elizabeth watched, and which Victoria now rules; queens, who, differing in much, yet resemble each other in the extent to which they have commanded the loyalty and affection of the people; and in this also—that the commercial activity of their respective ages received the countenance of both. In its reference to our history, the opening of the New Royal Exchange by Queen Victoria, is one of the most interesting events of modern times."

We must not conclude our description of this magnificent building, without reference to the sculpture with which the new Royal Exchange has been adorned. That by Mr. Richard Westmacott, in the tympanum of the pediment at the west front, deserves the earliest and highest mention, both from its position and its merit. Allegorical in subject, it nevertheless avoids the objections to which such compositions are generally liable. It consists of seventeen figures, carved in compact limestone, and, with two exceptions, modelled as entire and detached figures. The centre figure, which is ten feet high, represents Commerce; with her mural crown, her cornucopia, bee-hive, and other accessories. Her left hand holds the charter of the Exchange, her right rests on part of a ship; two dolphins and a shell forming her pedestal. The groups on either side consist, on the right, of three British merchants in their civic robes—as lord-mayor, alderman, and common-councilman; two Asiatics, a Hindoo, and a Mahommedan, in appropriate costume; a Greek bearing a jar; an Armenian scholar, and a Turkish merchant; and, on the left, of two British merchants examining some woven fabric shown to them by a Persian; a Chinese; a sailor of the Levant; a negro; a British sailor cording a bale of cotton, &c.; a super-cargo, or factory agent. The opposite angles are filled with anchors, jars, packages, and other nautical and commercial emblems. The arches of the upper story are decorated with the arms of various nations, according to the order determined at the congress of Vienna—the arms of England occupying the centre of the eastern side. The sheltered walk for the merchants also has the ceiling and sides panelled, painted, and emblazoned with the arms of countries and monarchs; namely, Edward the Confessor, Edward III., Elizabeth, and Charles II. In the south-east angle there is a statue of Queen Elizabeth, and in the south-west a statue of Charles II.

It only remains now to speak of the statues of Queen Victoria inside the building, and of the Duke of Wellington without. The latter is a bronze equestrian figure, by Chantrey, and was composed of the metal of the guns taken in battle, contributed by the government, and valued at £1,500. The cost of the statue itself was £900. It was completed on the anniversary of Waterloo, the 18th June, 1844, when the inauguration took place, at which the King of Saxony, who was in England at the time, attended. The marble statue of the Queen, by Lough, in the centre of the merchants' area, was not placed on its pedestal until the 27th of October, 1845. An interesting fact is recorded by historians respecting the statue of Gresham. During the raging of the great fire of 1666: "When the fire was entered," writes the old chronicler, "how quickly did it run round the galleries, filling them with flames; than descending the stairs, compasseth the walks, giving forth flaming volleys, and filling the court with sheets of fire. By-and-by the kings fell all down on their faces, and the greater part of the stone building after them, *the founder's statue alone remaining*."

It is a remarkable fact, that this statue was again saved in the fire of 1838.

The gates of the Exchange are exceedingly handsome. They are made of wrought-iron, the decorations being cast-iron. In the centre of the gates, on either side, are the arms of the City of London, and of the Mercers' Company, with the cipher of Sir Thomas Gresham, (T. G.,) very ingeniously introduced. In the ornamental heads of the gates, the rose, thistle, and shamrock appear entwined.

After the publication of the first portion of this article, the following paragraphs appeared in *The Times;* and we think we cannot better conclude our account of the Exchanges of London, than by recording so high and so well-deserved a compliment, to the designer of the Coal Exchange:—"A piece of plate, weighing 222 ounces of silver, was presented to the City architect, for services which are sufficiently indicated by the inscription: 'Presented to I. B. Bunning, Esq., by the coal-factors and merchants of the City of London, as a testimonial of their admiration of his genius and judgment in the erection of the Coal Exchange, and of his urbanity throughout the progress of the structure; which is not more approved of by those for whose use and convenience it was designed, than by the public at large, for its taste and elegance as a work of art. Anno Domini M.D.CCCL.' The plate was presented by Mr. Harris, as the organ of the coal-factors, with an appropriate speech. In addition to this pleasing compliment to Mr. Bunning, the coal-factors and merchants have signed a declaration, for presentation to the Corporation of the City, of their satisfaction of all the accommodations provided for them by means of the New Coal Exchange, which they attribute to a union of talent on the part of the architect, which has enabled him to produce an edifice which, whilst it embodies all the requirements of the coal-factors and merchants as men of business, is, at the same time, in design, taste, and judgment, the admiration of the numerous strangers who daily visit it, as one of the chief objects of interest and of Art in the City of London."

EXEDRÆ, (from the Greek εξεδραι, *a parlour*) among the ancients, places wherein the philosophers, sophists, and rhetors, held their conferences and disputes. They are supposed to have been recesses in the walls, or little chapels, answering to what we call *chapters* in the cloisters of monks, or collegiate churches.

Also applied to an apse or recess in a building, or to a projecting porch, in short, to any addition to a building. In the early Christian church, the term is applied to all the buildings within the consecrated enclosure which were detached from the church. Such were the baptisteries, vestries, diaconica, schools, libraries, and such like.

EXENTRIC, or Eccentric, (from the Latin *eccentricus*) in geometry, a term applied to two circles or spheres, in which, though in some measure the one is contained within the other, yet the two have not the same centre, and consequently their surfaces are not parallel. The word is opposed to *concentric* where they are parallel, and have the same centre.

EXOSTRA, in the ancient theatre, a place where such parts of the play were recited as were supposed to be acted privately in the house.

EXPANSION, (from the Latin, *expando*) that degree of increment, which a body is susceptible of extending, in one or more of its dimensions by heat. Bodies of every kind, as far as we are acquainted with them, are expanded in bulk by heat, and are contracted by cold; and to this law there are but few exceptions, which will be noticed in due time. The expansions, or the increments of bulk, are not exactly proportional to the increments of heat in the same body; nor are different bodies expanded alike by the like elevation of temperature. Thus, if a quantity of water be increased one inch in bulk by the communication of ten degrees of heat, the communication of twice or thrice as much more heat will not cause it to expand two or three inches more. Also, if a rod of gold, and another similar rod of glass, be heated to the same degree, their increments of bulk, arising thereby, will not be equal, the gold expanding more than the glass.

Of the three principal states of natural bodies, viz., solids, liquids, and elastic fluids, the solids are expanded least; the liquids are expanded more than the solids; but the elastic fluids are expanded a vast deal more than the liquids. The knowledge of the precise quantities of these expansions of bodies is of great use in philosophy, in mechanics, and in other scientific subjects; hence no pains have been spared by philosophers to investigate and ascertain them; various instruments have been contrived for that purpose; innumerable experiments have been instituted; and a great many useful results have been obtained. Of these results we shall now endeavour to give a regular and distinct account.

The instruments which have been contrived for the purpose of measuring the expansions of solids arising from an elevation of temperature, are called *pyrometers*. The objects which must be had in view in the construction of pyrometers, are to form a steady frame, wherein solids of a certain length may be applied either successively, or several of them at the same time; some contrivance by which those metallic bodies may be heated to any required degree; and a mechanism capable of measuring the increase of bulk which is caused by the heat; and this may be accomplished by means of multiplying wheels, by levers, by screws, by a microscopical micrometer, or otherwise.

Some of the first determinations of the expansion of bodies, that may be considered as being sufficiently accurate, were made by Mr. Ellicot, with a pyrometer of his contrivance. Mr. Ellicot determined the proportional expansions of seven metallic bodies by the same elevation of temperature. They are as follow:—

Gold.	Silver.	Brass.	Copper.	Iron.	Steel.	Lead.
73.	103.	95.	89.	60.	56.	149.

Mr. Smeaton contrived a much better pyrometer, and with it he determined the expansions of several solids. M. De Luc also contrived a pyrometer of a peculiar construction; but Mr. Ramsden's pyrometer is superior to any other contrivance of the kind.

The following table shows, in parts of an inch, how much one foot's length of different substances is expanded by 180° of heat, Fahrenheit's scale, between the freezing and the boiling points of water. To the first seven substances (which were examined in Mr. Ramsden's most accurate pyrometer) there are added the expansions for a single degree of heat. The others were determined by Mr. Smeaton with his pyrometer.

	Fahrenheit's Scale. By 1°	Fahrenheit's Scale. By 180°
Standard brass scale, supposed to be Hamburg brass	0.0001237	0.0222646

Zinc hammered half an inch per foot		0.0373

Iron, instead of being condensed into a smaller bulk, expands in its transition from a fluid into a solid state; so that a quantity of iron occupies more room in the solid form than it does in a fused state.

Dr. Wollaston, in order to form some estimate of the comparative rate of expansion of platina and palladium, says, "I riveted together two thin plates of platina and palladium, and observing that the compound plate, when heated, became concave on the side of the platina; I ascertained that the expansion of palladium is in some degree the greater of the two. By a similar mode of comparison I found that palladium expands considerably less than steel by heat." *Phil. Trans. for* 1805.

It must be remarked, with respect to the expansion of glass, that sometimes glass tubes are extended more than solid glass rods; their dilatation, however, is not constant; for tubes of different diameters, or of different sorts of glass, are expanded differently by the application of like degrees of heat.

Wood is not much expanded longitudinally, that is, in the direction of its fibres, by heat; and this is particularly the case with deal and other straight-grained wood. Probably, upon the whole, the longitudinal expansion of wood is less than that of glass. It has been observed, (especially by Dr. Rittenhouse, *Trans. of the American Phil. Society*,) that very dry and seasoned wood, if not exposed to a very high or to a very low temperature, will expand in length pretty regularly; otherwise its expansion by heat, and its contraction by cold, are very irregular; for they seem to depend partly upon the heat, and partly upon the moisture, which the wood acquires in certain circumstances, and is deprived of in others. It is hardly necessary to mention, that the solids of the preceding table contract their dimensions by cooling, as much as they are expanded by heating; thus, for instance, if a yard's length of any particular metallic body, by being heated 100 degrees above the actual temperature of the atmosphere, be lengthened one-fiftieth part of an inch; afterwards, when cooled down to the temperature of the atmosphere, it will be found to have lost exactly that fiftieth part of an inch which it had acquired by heating.

From the experiments hitherto made on the expansions of solids by heat, no correspondence has been observed between the expansions and the quantities of caloric they are capable of absorbing. The fusibility of metals seems to coincide with the dilatations; platina, the least fusible of the metals, dilates the least; lead dilates most; and the most fusible glass is also the most dilatable. We may therefore conclude with M. Berthollet, that bodies are so much the more expansible, the less caloric they require, to change their constitution from solid to liquid, and from liquid to gases or vapours.

There is a substance which expands when heated, but does not contract when cooled; and of this singular property Mr. Wedgwood availed himself for the construction of his ingenious thermometer for measuring the highest degrees of heat; viz., those degrees which exceed the scale of the mercurial thermometer. The substance alluded to is the argillaceous earth or clay, and it appears that the above-mentioned property belongs, more or less, to argillaceous bodies of every kind. This property may at first sight appear to be an unaccountable exception from the general law: the difficulty, however, will vanish, if it be considered that bodies of the argillaceous genus contain a considerable quantity of water, and that the contraction of these bodies, when exposed to the action of a strong fire, is in a great measure due to the escape of the water, and hence they do not contract by subsequent cooling.

EXPERIENCE, knowledge derived from trials, long use, practice, or a series of observations. Experience consists in the ideas suggested by what we have seen, read, or done: we reflect on these things, and the judgment forms for itself a rule or standard, which standard is experience.

Authors make three kinds of experience: the first is the simple uses of the external senses, whereby we perceive the phenomena of natural things, without any direct attention thereto, or making any application thereof.

The second is, when we premeditatedly and designedly make trials of various things, or observe those done by others, attending closely to all effects and circumstances.

The third is that preceded by an apprehension of an event, and determines whether the apprehension were true or false; the two latter kinds, especially the third, are of great service in philosophy.

EXPERIMENT, (from the Latin *experimentum*,) a trial, an act, or operation designed to discover some unknown truth, principle, or effect, or to establish it when discovered. In philosophy, it means the result of certain applications, dispositions, or combinations, of natural bodies, made with some particular view. The history of physical science from the commencement of the present century, strikingly demonstrates how powerful an instrument experiment is in the discovery of facts. Experiments are said to be mechanical, or chemical, or electrical, or magnetical, &c., according to the subject to which they more immediately belong. The object of making experiments is to ascertain either certain causes or certain phenomena; and for the proper attainment of these objects, care must be had to institute experiments that admit of no equivocal result, and so as to answer the purpose in the quickest and most direct way. The main object, however, of the inquiry can seldom be determined by a single decisive experiment; hence, in most cases, it becomes necessary to divide the question into parts, and to ascertain each part separately by one or more appropriate experiments. When the experiment is so prescribed, as to decide the question without any possible doubt or equivocation, it has in that case frequently been called *experimentum crucis*; a *crucial experiment*, meaning a capital or decisive experiment; such as supersedes the necessity of instituting more experiments for the same purpose. The origin of the expression *experimentum crucis* has by some been derived from its being a kind of torture, whereby the nature of the question is, as it were, extorted by force. It has been also attributed, by others, though with less apparent probability, to the guide or instruction which it affords, like that of a direction-post, which is shaped somewhat like a cross.

It is not practicable to give any instructions for the right performance of experiments in general; for not only every subject, but every particular question belonging to any subject, must be determined by a particular mode of investigation. The experimenter can only be instructed by practice. The nature of the subject, a strict attention to every apparent circumstance, an accurate statement of particulars, and an unprejudiced mode of reasoning, will easily suggest a proper train of experiments which the subject in question may admit of. It deserves to be remarked, that though in the investigation of any subject, the philosopher proposes a certain order of investigation, (and it is always proper to propose to oneself some such plan or train of experiments;) yet it is but seldom that the proposed plan can, or deserves to be, strictly executed; for the result of the first or second experiment frequently points out a new tract, or a more promising road; in consequence of which, new and different trials must be instituted; it is in the ready adoption of such plans as may be best suited to the last indications, that the genius of the philosopher is rendered conspicuous.

Such mode may suffice for the determination of any doubtful point; but when a discovery has been made, and is to be explained to other persons, then it is of use to show the same result by different experiments; for it is not only a satisfaction to have several concurring proofs of the same proposition; but it is also rendered intelligible to a greater number of readers or hearers; it being seldom the case, that the same experiment conveys an equal degree of conviction and satisfaction to the mind of everybody.

EXPERIMENTAL PHILOSOPHY. Philosophy, from the Greek *philosophia* (φιλοσοφια,) literally signifies "love of wisdom or knowledge," and a philosopher, (φιλοσοφος,) is a lover of wisdom. Pythagoras is said to have been the first person who called himself philosopher, from which appellation the word philosophy was derived, meaning the love of general knowledge. The terms philosophy, philosophical, philosopher, are often used in our language apparently with no great precision, though it is not difficult to deduce from the use of these terms the general meaning or notion which is attached to them. We speak of the philosophy of the human mind, as being, of all philosophies, that to which the name philosophy is particularly appropriated; and so also, by using qualifying terms, we speak of natural philosophy, experimental philosophy, &c.

If this knowledge or philosophy relate to the manners, the duties, or the conduct of human beings, considered in a rational and social light, it is called *moral* philosophy; if to the phenomena of natural bodies—*natural* philosophy. Experimental philosophy, as will be shown hereafter, may be defined as the philosophy of *proof*, in contradistinction to the philosophy of opinion, to the manners, the duties, and the conduct of human beings, considered in a rational and social light, or to the phenomena of natural bodies, so it has been called either *moral philosophy* or *natural philosophy*.

The philosophers of the primitive ages, among the Greeks, Romans, &c., in explanation of the phenomena of nature, such as the motions of the celestial bodies, the rain, snow, frost, thunder and lightning, the rainbow, the combustion of fuel, the production of animals and vegetables, and so forth, generally offered the inadequate suggestions of their imaginations, which, though mostly unintelligible, and frequently in the greatest degree absurd, were nevertheless received with deference by their scholars, and were propagated with fidelity and diligence from one generation to another. Their acquiescence rested merely on the authority of the teacher. That these explanations were generally inadequate and absurd, is easily evinced by observing, that different contemporary philosophers entertained and taught opinions diametrically opposite to each other, though they related to the very same question; and that subsequent philosophers have, by actual observations, and unerring demonstrations, shown their fallacy. It may amuse an inquisitive mind to observe, that whilst the exertions of the early mathematicians, whose productions have obtained the admiration of subsequent generations, were strictly rational and correct, the investigations of their contemporary philosophers were conducted in a manner altogether slovenly and superficial. This method of philosophizing prevailed for a very long period, and several centuries elapsed, during which the knowledge of nature made no progress deserving of notice, excepting a few rare and accidental discoveries.

The 15th century, which was productive of the greatest events and the most consequential discoveries that history can record, seems to have given a new turn to the subject of natural philosophy. The old tenets began to be doubted, and the energies of the human mind began to manifest their unfettered powers. In the next century, the incoherent dogmas of the preceding ages were freely combated; the authority of names and sects was disregarded, and, in lieu of opinions, the explanation of natural phenomena was referred to the evidence of actual experiments. Then was introduced the appellation of *experimental philosophy*, by which is meant, the knowledge of natural powers and natural effects acquired by means of experiments or trials. The least reflection readily showed the superiority of this new method of philosophizing; but, independent of any other consideration, its establishment is principally due to the success with which it was attended, and which exceeded even the most sanguine expectations of its first promoters. No sooner was it adopted, than discoveries of importance were made, old-established errors were detected, and the subject of philosophy assumed an entirely new aspect.

It is undoubtedly true, that in this mode of investigation the experiments must be preceded by hypothesis, or supposition; for a man cannot begin to make experiments without the previous formation of a certain plan; but then the plan, the supposition, or the hypothesis, goes no farther than to propose something, the confirmation or refutation of which is referred to the result of experiments, assisted by mathematical calculation. In the 13th century, the necessary preliminaries for the improvement of natural knowledge began to be made; viz., collections of what then prevailed under the denomination of scientific knowledge, natural knowledge, secrets of nature, and the like; and the farrago of truths, errors, inconsistencies, doubts, and perplexities, which these works contain, is strange indeed. Among the few who effectually began to work in the experimental mode of investigation, during that century, Friar Bacon held the most distinguished place. His desire of information was great; his views extensive; his mind clear and capacious; and he is said to have spent about £2,000 (a sum very considerable at that time) in the performance of his numerous philosophical experiments. Baptista Porta also distinguished himself for similar pursuits in Italy. This inquisitive person lived at Naples, and about the year 1560 formed a society of scientific persons, who met in his own house. The great Galileo, who was born in Italy, in the year 1564, became famous as a philosopher and a mathematician, towards the latter end of that century and the beginning of the next. His genius, superior to the prejudices of the times, investigated and established several leading propositions in natural philosophy; and his success, his example, and his precepts disseminated a universal ardour for the true mode of investigating the powers and the effects of natural bodies. His successor, Torricelli, was not unworthy of a most distinguished rank amongst the philosophers of the age; and the Torricellian tube, or the barometer, is a magnificent monument of his experimental inquiries.

In England, as we have already mentioned, Friar Bacon was the first promoter of true knowledge; but a great part of the work of philosophical reformation was accomplished by another inquiring genius of the same name. Francis Bacon, lord-chancellor of England, gave a fresh and vigorous impulse to the progress of experimental inquiry. He recorded a vast number of facts, proposed and executed a great many experiments, and nothing that related to nature seemed to be below his notice.

These early reformers of philosophy, besides other obvious difficulties, were obliged to struggle against, and the success of their labours was much impeded by, the erroneous notions which then prevailed, and which had been long rooted in the minds even of the most able persons then living. Galileo was oppressed by the ignorance and prejudices of the clergy. Crichton, who flourished about the latter end of the 16th century, wrote an able book expressly against the vain philosophy of Aristotle, which had long been read in the schools. The two Bacons, and other able writers, frequently allude to, and strenuously endeavour to remove, the absurd and fanciful notions of their contemporaries. In short, the demolition of the old defective fabric, proved nearly as laborious as the erection of the new structure.

The reform which had been begun by the above-mentioned, and other worthy persons, was soon after completed by the extraordinary genius of Newton. This truly great man, like a luminary of the first magnitude, illustrated whatever came within the limits of his notice, and his notice was employed in the greatest and most admired works of the creation. His method was to institute experiments, to examine the phenomena with accuracy, and to ground upon them the strictest mathematical reasoning. The conviction which such a rational method conveyed, and the numerous discoveries with which it was attended, completely exploded the old tenets, and established the only true method of investigating nature.

The progress of experimental philosophy might have been interrupted by the death of a single individual; for it does but seldom occur that genius, health, opulence, and other opportunities, concur in the qualification of an experimental philosopher; but the danger was in great measure averted by the institution of philosophical societies. These societies, by bringing together learned men, and concentrating, as it were, their efforts against the ignorance and prejudice of the age; by uniting the efforts of several ingenious labourers, by furnishing in great measure the means of investigation, by encouraging improvements, and by recording and propagating the results, at length succeeded in establishing the progress of knowledge in a regular and permanent channel.

The first society of the kind which we find recorded, is that which we have already mentioned at the house of Baptista Porta, in Naples, towards the latter end of the

16th century. It was called "Academia Secretorum Naturæ." Next to this, and before the end of the same century, the academy, called the Lyncei, was founded at Rome, and was rendered famous throughout the world, principally by the renown of one of its members, the great Galileo. The Academy del Cimento, and several other associations of scientific persons, were established in the succeeding, viz., the 17th century. Amongst those associations the first rank must be assigned to the Royal Society of London. This most learned and distinguished society had its origin soon after the middle of the 17th century. A few men of learning began to meet at stated times at Wadham college, Oxford; and among those persons were the following conspicuous characters: viz., Dr. Ward, Mr. Robert Boyle, Dr. Wilkins, Sir William Petty, Mr. Matthew Wren, Dr. Wallis, Dr. Goddard, Dr. Willis, Dr. Bathurst, Dr. Christopher Wren, and Mr. Rooke. From Oxford this association transferred its meetings in the year 1658, to Gresham college, in London. There they increased their number; and soon after the restoration of Charles II., the society received a royal charter, which established it in the form that has been continued ever since.

The objects of the universe, or the natural bodies which affect our senses, become known and useful to us by their properties, some of which affect one of our senses, whilst others affect some other sense. Thus we perceive luminous bodies through our eyes, sound through our ears, heat or cold by the touch or feel, &c. Some of these properties are called general, like gravity and extension, because they belong to all bodies; and others, like transparency and fluidity, are called particular, because they belong to certain bodies only. The better we become acquainted with the properties of natural bodies, the more extended the sphere of our powers and of our advantages becomes; and it is for the discovery of these properties, either in simple or in compound bodies, that experimental inquiries are instituted.

In the acquirement of knowledge, the human being has no other assistance besides that of his senses, and of his reasoning faculty. By the first he observes and acquires ideas of self-evident propositions, or properties of natural bodies; such as the human mind cannot dissent from without manifest violence to its perceptions; by the second he is led from one of these evident simple propositions, to another strictly depending upon the first, then to a third strictly depending upon the second, and so on, to the acquisition of some idea more complex, and less apparent at the first annunciation. The constant observation of philosophers, with Sir Isaac Newton at their head, and the dictates of plain reasoning, have furnished certain axioms and certain rules of philosophizing, the propriety of which is too evident to be objected to.

The axioms of philosophy, or the axioms which have been deduced from common and constant experience, are so evident, and so generally known, that it will be sufficient to mention a few of them only.

1. Nothing has no property ;. hence

2. No substance, or nothing, can be produced from nothing.

3. Matter cannot be annihilated, or reduced to nothing.

The propriety of the last axiom may perhaps not be readily admitted by certain persons; observing that a great many things appear to be utterly destroyed by the action of fire; also that water may be caused to disappear by means of evaporation; and so forth. But it must be observed, that in these cases the substances are not annihilated; they are only dispersed, or removed from one place to another, and by being divided into particles very minute, they elude our senses, and escape our immediate notice. Thus, when a piece of wood is placed upon the fire, the greatest part of it disappears, and a few ashes only remain, the weight and bulk of which do not amount to the hundredth-part of the weight and bulk of the original piece of wood. In this case the piece of wood is divided into its constituent principles, which the action of the fire drives different ways. The fluid part, for instance, becomes steam, the light coaly part either adheres to the chimney, or is dispersed through the air, &c., so that if, after the combustion, the scattered materials were collected, (which may in a great measure be accomplished,) the sum of their weights would equal the weight of the original piece of wood.

4. Every effect has, or is produced by, an adequate cause, and is proportionate to it.

It may, in general, be observed, with respect to these axioms, that we only mean to assert what has been constantly shown, and confirmed by experience, and is not contradicted, either by reasoning, or by any known experiment. But we do not mean to assert that they are as evident as the axioms of geometry; nor do we in the least presume to prescribe limits to the agency of the Almighty Creator of every thing, whose power and whose ends are too far removed from the reach of our finite understandings.

Having thus stated the principal axioms of philosophy, it is in the next place necessary to mention the rules of philosophizing, which have been formed, after mature consideration, for the purpose of preventing errors as much as possible, and of leading the student of nature, along the shortest and safest path, to the attainment of true and useful knowledge. These rules may be reduced to four, viz.

1. We are to admit no more causes of natural things, than such as are both true, and sufficient to explain the appearances.

2. Therefore, to the same natural effects we must, as far as possible, assign the same causes.

3. Such qualities of bodies as are not capable of increase, or of decrease, and which are found to belong to all bodies within the reach of our experience, are to be esteemed the universal qualities of all bodies whatsoever.

4. In experimental philosophy we are to look upon propositions collected by general induction from phenomena, as accurately, or very nearly true, notwithstanding any contrary hypothesis that may be imagined, till such time as other phenomena occur, by which they may either be corrected, or may be shown to be liable to exceptions.

With respect to the degree of evidence which ought to be expected in natural philosophy, it is proper to remark, that physical matters are not, in general, capable of such absolute certainty as the branches of mathematics. The propositions of the latter science are clearly deduced from a set of axioms so very simple and evident, as to convey perfect conviction to the mind; nor can any of them be denied without a manifest absurdity. But in natural philosophy we can only say, that because certain particular effects have been constantly produced under certain circumstances, therefore they will most probably continue to be produced as long as the same circumstances exist; and likewise that they do, in all probability, depend upon those circumstances. And this is what we mean by *laws of nature*, viz., certain effects which are, or have been uniformly, produced by certain causes, as far as our observations reach.

We may, indeed, assume various physical principles, and by reasoning upon them, we may strictly demonstrate the deduction of certain consequences. But as the demonstration goes no farther than to prove, that such consequences must necessarily follow the principles which have been assumed; the consequences themselves can have no greater degree of certainty than the principles are possessed of; so that they are true, or false, or probable, according as the principles upon which they depend are true, or false, or probable.

The foundations of experimental philosophy, as we have already observed, are the properties of natural bodies, viz., of all these bodies, either solid or fluid, which in any way affect any of our senses; and since our senses are affected by the properties of these bodies, viz., by their extension, colour, hardness, transparency, &c., we cannot know any more of these bodies than what is manifested to us by such properties only as we are able to perceive. Were we furnished with other senses, doubtless we might discover other properties which would make us more intimately acquainted with the nature of such bodies.

Human art has not been able to discover more senses than those which everybody knows; but it has, in great measure, improved some of those which we possess, and this alone is sufficient to point out the limited nature of our perceptions. Thus, for instance, the discovery of the microscope and the telescope have shown us wonders, of which our forefathers were utterly ignorant; and the number and variety of these wonders have increased, in proportion as the above-mentioned instruments have been improved. The improvements of these instruments have been suggested by the discoveries that have been made respecting the refrangibility of light, and the properties of transparent bodies, and these have been made in consequence of the innumerable experiments that have been instituted by various intelligent persons. Thus it appears, that by means of trials and observations, new facts are ascertained, which, besides their being immediately useful to the human species, furnish, at the same time, the means of making farther discoveries; and the treasures of the natural world are far, indeed, from a state of exhaustion. Hence the improvements and the discoveries of experimental philosophy proceed in a kind of increasing geometrical progression; unless they are impeded by some extraordinary occurrence.

In contemplating the intimate nature of natural bodies, when our mind goes beyond the bounds of our senses, (and our senses, even with the assistance of instruments and reasoning, are only capable of perceiving a few properties of those bodies;) we wander in the boundless field of probability and conjecture. Two principal hypotheses have been entertained with respect to the primitive component particles of bodies. One is, that the particles of each peculiar species of bodies are different from the particles of another species of bodies. Thus the primitive particles of gold are supposed to be different from the particles of calcareous earth, different from the particles of water, &c. The other hypothesis is, that there is one kind of primitive, or original particles of matter, and that from the different arrangement of those ultimate particles, the various bodies arise. Experience shows, that certain bodies, which at first sight appear to be absolutely different from each other, are, upon farther examination, exactly of the same nature. On the other hand, a vast number of bodies are so distinct from each other, that no art has been able to form one of them from the particles of the other; thus gold cannot be converted into a diamond, iron cannot be converted into lead, &c. The former of these observations seems to favour the second hypothesis; the latter seems to favour the first hypothesis; but it is not in our power to determine the real state of the matter.

With respect to the number of bodies, which, by our not being able to change one of them into the other, are called elementary, or primitive and distinct; it may be remarked, that new bodies are frequently discovered in proportion as new instruments, and the improvements of science in general, furnish us with the means of discriminating them from others. We are thus naturally led to conclude, that in all probability there exists a vast number of other bodies, of which we at present have not the least suspicion. Some of these may perhaps be discovered hereafter, others may remain utterly unknown to the human species for ever.

The properties of natural bodies, which are the objects of research to the experimental philosopher, are either general, or particular. The general properties, which belong to all kinds of bodies, are, as far as we know, not more than six; viz., extension, divisibility, impenetrability, mobility, vis inertiæ, or passiveness, and gravitation. We have said that these are the general properties as far as we know, because matter in general may possess other properties with which we are yet unacquainted. And the same observation may be made with respect to the universality of these properties: for they are said to be general, because nobody was ever found which wanted any one of them. But mankind are not acquainted with all the bodies of the universe, and many which are known to exist, cannot be subjected to experiments.

The peculiar properties, viz., those which belong to certain bodies only, and not to others, are density, rarity, hardness, softness, fluidity, rigidity, flexibility, elasticity, opacity, transparency, the properties of light, the properties of heat, the properties of electricity, the properties of magnetism, and three other kinds of attraction, (independent of gravitation, of electricity and of magnetism,) viz., the attraction of aggregation, which the homogeneous parts of matter have towards each other, or by which they adhere together; and such is the power by which two small drops of mercury, when placed contiguous to each other, rush, as it were, into each other, and form a single drop; the attraction of cohesion, or that power by which the heterogeneous particles of bodies adhere to each other without any change of their natural properties, such as the adhesion of water to glass, of oil to iron, &c.; and the attraction of composition, or of affinity, which is the tendency that the parts of heterogeneous bodies have towards each other, by which they combine, and form a body, differing more or less from any of its components.

It is to be remarked, that of all these properties we know their existence only, and some of the laws under which they act; but we are otherwise utterly ignorant of their nature and dependence.

The investigation of some of the above-mentioned properties, whether general or particular, has been carried much farther than the investigation of other properties. The results of these investigations have likewise been various, both in point of extent and of application. Some of them are so very extensive and so useful, as to form the foundations of very important branches of science, or of art, under peculiar appellations. Thus, upon the mobility, and the vis inertiæ of bodies, the doctrine of motion, or dynamics, is grounded, which comprehends mechanics, hydrostatics, or the mechanical properties of fluids, pneumatics, &c. Transparency and the properties of light form the important foundation of optics. The attraction of affinity is the foundation of chemistry, as well as of various arts; and so forth.

The phenomena of the universe, are the appearances which take place in consequence of the above-mentioned properties of natural bodies, together (respecting some of them at least) with some original impulse. The phenomena which take place amongst the luminous celestial bodies, properly so called, such as the stars, the planets, &c., are examined by a particular science, called astronomy; the meteors, or the phenomena which take place within the limits of the terrestrial atmosphere, such as shooting stars, northern lights, halos, rain, fogs, hail, winds, &c., form the subject of meteorology.

EXPLOSION, in natural philosophy, a sudden and violent expansion of an aërial or other elastic fluid, by which it instantly throws off any obstacle that may be in the way. It differs from expansion, properly so called, in this, that the latter is a gradual and continued power, whereas the former is always sudden, and of only momentary duration.

Explosion, in military engineering. It is a matter of great moment, so to load, and indeed to construct a mine, that it may explode with the greatest precision, and with the maximum effect. Numerous theories have been given upon this subject, but it would be out of place to notice the whole of what appertains thereto in a work like this.

In commencing operations, it is necessary in the first instance to ascertain, so nearly as may be practicable, what depth, and what weight of soil is to be removed by an explosion. This being done, the mine is formed, by constructing a gallery leading to the chamber in which the powder is to be placed. This must be deposited in a very strong chest, let into a recess, and firmly secured in every part. Now, it being the nature of rarefied air to escape by that part which may be the weakest, it is evident, that if a mine is made under a rampart, so as to be within six feet of the surface, while all the sides are thicker by far than that measurement, the explosion will be directed towards that part which is thinnest, and which, from that circumstance, is called "the line of least resistance."

But, in order to direct the explosion to that part, it will be necessary to consider whether the soil be everywhere alike; for if the superincumbent portion should be part of a large stratified rock, while the sides are of a loose, inadhesive substance, the latter, though measuring more in diameter will give the line of least resistance, which, in such case, would follow the intenacity, and create a false explosion. For it must be recollected that explosions may be lateral as well as vertical.

It was formerly supposed, that the diameter of the *entonnoir*, or explosion, was equal to double the line of least resistance; but we find that six times that line may be exploded, by allowing a load of 300 lbs. of gunpowder, duly concentrated, and fired in the middle of the mass, for every foot of the line of least resistance. We are not to infer from this, that 300 lbs. will be requisite to lift one foot of soil; far from it; for as a cubic foot of excavation will contain only 75 lbs. of powder, the above quantity (300 lbs.) would require a space of exactly four cubic feet; the proportion would therefore be preposterous. But when we calculate upon large masses of soil, such as those prodigious cones thrown out from entonnoirs of great extent, we then find, that, to produce the completest explosion, an immense quantity of powder must be supplied.

It is self-evident, that the power of the powder, according to the above scale, is only computed to that extent which may be necessary towards the ordinary purposes of military devastation; for if we were to contribute, *ad infinitum*, 300lbs. of gunpowder for every foot in the line of least resistance, we should be accumulating power only in arithmetical proportion, while the resistance would be increasing in a geometrical ratio: of course the power must be in a regular state of comparative diminution, in proportion as the line of least resistance is increased; and this must, after a while, occasion the powder to be inert; or, if there should be any explosion, it could only follow the track of the train. Its ignition, to be sure, might be felt partially, like that of a slight earthquake, but no superficial effects would be observable.

It has been already stated, that the powder must be lodged in bulk; and that it should be ignited at the centre. This may, perhaps, appear superfluous; but all military men know, that much powder is blown out of the muzzles of pieces without ever being ignited; and we have a most remarkable fact in modern times, one indeed, which shows, that, unless in bulk, powder is not always sure to be fired *in toto*. The incident alluded to is as follows:—

In the month of March, in the year 1809, a barge was proceeding along the new cut, from Paddington, laden with casks of spirits and barrels of gunpowder. One of the crew, it is supposed, allured by the former, bored a hole for the purpose of drawing off a little wherewith to tipple. Unhappily the action of the gimblet set fire to the contents of that barrel, which the dishonest navigator had mistaken for one of spirits. The barrel exploded, and drove eleven other barrels, filled with gunpowder also, to the distance of near a hundred and fifty yards. It is curious, that although the whole of the powder-barrels were together, indeed, in contact, only that in question exploded.

Vauban gives us the following scale for exploding soils of various descriptions. He calculates, or perhaps found from experience, that for a cubic fathom (six feet) of soil, measuring in all 216 solid feet, the following proportions of gunpowder were needful.

	lb.
1. Light earth, mixed with sand	11
2. Common earth	12
3. Strong sand	15
4. Clay, or fat earth	16
5. Old, and good masonry	18
6. Rock	20

In following this calculation, we are to consider the entonnoir to be in diameter equal to only double the line of least resistance; and not according to a maximum explosion.

A new substance, gun-cotton, which is cotton wool steeped in nitric or nitro-sulphuric acid, and dried, by which it becomes explosive, has been lately introduced as a substitute for gunpowder in blasting. It is not yet sufficiently understood to have come into extensive use.

EXPONENT, in algebra, is a number placed over any power or involved quantity, to show to what height the root is raised; thus 2 is the exponent of x^2 and 4 is the exponent of x^4 or $x\,x\,x\,x$.

EXPONENTIAL CURVES, those curves which partake both of the nature of algebraic and transcendental ones. They are algebraical in their nature, because they consist of a finite number of terms, though these terms themselves are indeterminate, and they are in some measure transcendental, because they cannot be algebraically constructed.

EXPOSURE, the act of exposing or laying open to view; as we say a building, a garden, or a wall, had a northern or a southern *exposure*, and we speak of its exposure or exposition to a free current of air, or to the access of light.

EXTEND, to stretch in any direction, to continue in length as a line, to spread in breadth.

EXTENSION, in philosophy, one of the general and essential properties of matter; the extension of a body being the quantity of space which the body occupies, the extremities of which limit or circumscribe the matter of that body. It is otherwise called the *magnitude*, or *size*, or *bulk* of a body.

A quantity of matter may be very small, or so as to elude the perception of our senses, such as a particle of air, a particle of water, &c.: yet some extension it must have, and it is by the comparison of this extension, that one body is said to be larger than, equal to, or smaller than, another body. The measurement of a body consists in the comparison of the extension of that body with some determinate extension, which is assumed as a standard, such as an inch, a foot, a yard, a mile; hence it is said, that a body is a foot long, or three inches long, &c.

The extension of a body is measured three different ways; or a body is said to have length, breadth, and thickness. Thus an ordinary sheet of writing paper is about 16 inches long, about 14 inches broad, and nearly one hundredth part of an inch thick. Either of these dimensions might be called the length, or the breadth, or the thickness; but, by general custom, the greatest extension is called the length, the next is called the breadth, and the shortest is called the thickness. The outside of a body, its boundary, or that which lies contiguous to other bodies that are next to it, is called the *surface* of that body, and this surface has two dimensions only, viz., length and breadth; but it has no thickness, for if it had, it would not be the outside of the body; yet a surface by itself cannot exist. In mathematics, however, surfaces are mentioned, and are reasoned upon, abstractedly from matter. But in these cases the surfaces exist in the imagination only, and even then our ideas have a reference to body, for our senses cannot perceive a surface without a body.

As a surface is the outside or boundary of a body, so a *line* is the boundary of a finite surface. Suppose, for instance, that a surface is divided into two parts, the common boundary of the two parts is called a *line;* this has one extension only, viz., it has length.

The beginning or the end of a line, or the intersection of two lines which cross each other, is called a *point*, and this has no dimensions; or, according to the mathematical definition, a point is that which has no parts or magnitude, its use frequently is to mark a situation only as a point upon a surface by the intersection of two lines, &c. Thus, if you divide a line into two parts, the division or boundary between the two parts is a point.

Our senses are only capable of perceiving bodies which have three dimensions; or rather the surfaces of bodies, which surfaces have two dimensions, but a surface cannot be represented nor perceived without a body, and of course neither a line nor a point can be perceived without a body. In the study of geometry, and in a variety of other branches, surfaces, lines, and points are represented upon paper, or upon something else; but in those cases, the paper, or that something else, is the body whose surface we perceive, and the surface of a particular figure is circumscribed, not by real lines, but by a narrow slip of surface, which is sufficient to direct our reasoning with respect to the geometrical properties of lines and surfaces. Thus also, when points are represented by themselves, the marks are not real points, but very small portions of the surface of a body.

There is a case in which extension is often said to be perceived without the existence of a body, and this is the extension between two bodies. But, upon consideration, it will easily be comprehended, that we may perceive the two bodies, and that they are separate from each other; but we cannot perceive anything positive between them. So that in this case the word extension is used in a figurative manner, as if some other body existed between the two bodies.

The particular extension, whether under the name of inch, foot, yard, metre, league, &c., with which other extensions are compared, or by which they are measured, is established only by the common consent or agreement of persons of a certain nation, or profession, and used as standard measure by them only. Hence, the measures of different nations, though sometimes they have the same name, differ considerably from each other. Great endeavours have been made by divers ingenious persons, at different times, for the purpose of determining an unalterable universal standard of measures; those endeavours, and the results with which they have been attended, will be found described under the article STANDARD *of Measures.*

Extension is usually described as consisting in the situation of parts beyond parts; but to this definition some authors object, maintaining, that we can conceive absolute extension without any relation to parts.

If a man consider the distance between two bodies abstractedly, and without any regard to bodies which may fill that interval, it is called space; and when he considers the distance between the extremes of a solid body, it is called extension.

Extension is frequently confounded with quantity and magnitude; and, for what we can perceive, without much harm, the thing signified by them all appearing to be the same; unless we admit a distinction made by some authors, that the extension of a body is something more absolute, and its quantity and magnitude more respective, or implying a nearer relation to much and little. The infinite divisibility of extension has been a famous question in all ages. It is not easy to reconcile the doctrine of mathematicians on this head with the tenets of some philosophers. Those who hold that all extension and magnitude are compounded of certain *minima sensibilia;* and that a line, for instance, cannot increase or decrease, but by certain invisible increments or decrements only, must, consistently with themselves, affirm, that all lines are commensurable to each other. But this is contrary to the tenth book of Euclid, who demonstrates that the diagonal of a square is incommensurable to its side. And further, if all lines were composed of certain indivisible elements, it is plain one of those elements must be the common measure of the diagonal and the side.

Bishop Berkeley observes, that the infinite divisibility of finite extension, though it is not expressly laid down, either as an axiom or theorem in the elements of geometry, is yet throughout the same everywhere supposed, and thought to have so inseparable and essential a connection with the principles and demonstrations in geometry, that mathematicians never admit it into doubt, or make the least question of it. And as this notion is the source from whence do spring all those amusing geometrical paradoxes, which have such a direct repugnancy to the plain common sense of mankind; so it is the principal occasion of all that nice and extreme subtilty which renders the study of mathematics so difficult and tedious. Hence, says he, if we can make it appear, that no finite extension contains innumerable parts, or is infinitely divisible, it follows, that we shall at once clear the science of geometry from a great number of difficulties and contradictions which have ever been esteemed a reproach to human reason, and withal, make the attainment thereof a business of much less time and pains than it hitherto hath been.

Every particular finite extension, which may possibly be the object of our thought, is an idea existing only in the mind, and consequently each part thereof must be perceived. If therefore, says this author, I cannot perceive innumerable parts in any finite extension that I consider, it is certain they are not contained in it; but it is evident, that I cannot distinguish innumerable parts in any particular line, surface, or solid, which I either perceive by sense, or figure to myself in my mind; wherefore, I conclude they are not contained

DETAILS, PLATE 6.

Nº. 1. Fan tracery Vaulting. Nº 4. Flying Buttress. Nº 8. Gargoyle. Nº 11. Hip knot.

in it. Nothing can be plainer to me than that the extensions I have in view are no other than my own ideas; and it is no less plain, that I cannot resolve any one of my ideas into an infinite number of other ideas; that is, that they are not infinitely divisible. If by an infinite extension be meant something distinct from a finite idea, I declare I do not know what that is, and so cannot affirm or deny anything of it. But if the terms extension, parts, and the like, are taken in any sense conceivable; that is, for ideas; then to say a finite quantity or extension consists of parts infinite in number, is so manifest a contradiction, that every one at first sight acknowledges it to be so.

On the other hand, it is observed by an eminent mathematician, that geometricians are under no necessity of supposing that a finite quantity of extension consists of parts infinite in number, or that there are any more parts in a given magnitude than they can conceive or express: it is sufficient that it may be conceived to be divided into a number of parts equal to any given or proposed number; and this is all that is supposed in strict geometry concerning the divisibility of magnitude. It is true, that the number of parts into which a given magnitude may be conceived to be divided, is not to be fixed or limited because no given number is so great, but a greater than it may be conceived and assigned: but there is not therefore any necessity for supposing that number infinite; and if some may have drawn very abstruse consequences from such suppositions they are not to be imputed to geometry. Geometricians are under no necessity of supposing a given magnitude to be divided into an infinite number of parts, or to be made up of infinitesimals; nevertheless they cannot so well avoid supposing it to be divided into a greater number of parts than may be distinguished in it by sense in any particular determinate circumstance. But they find no difficulty in conceiving this; and such a supposition does not appear to be repugnant to the common sense of mankind, but, on the contrary, to be most agreeable to it, and to be illustrated by common observation. It would seem very unaccountable not to allow them to conceive a given line, of an inch in length for example, viewed at the distance of 10 feet, to be divided into more parts than are discerned in it at that distance: since by bringing it nearer, a greater number of parts is actually perceived in it. Nor is it easy to limit the number of parts that may be perceived in it when it is brought near to the eye, and is seen through a little hole in a thin plate; or, when by any other contrivance it is rendered distinct at small distances from the eye. If we conceive a given line, that is the object of sight, to be divided into more parts than we perceive in it, it would seem that no good reason can be assigned why we may not conceive tangible magnitude to be divided into more parts than are perceived in it by the touch; or a line of any kind to be divided into any given number of parts, whether so many parts be actually distinguished by sense or not. In applying the reasonings and demonstrations of geometricians on this subject, it ought to be remembered, that a surface is not considered by them as a body of the least sensible magnitude, but as the termination or boundary of a body; a line is not considered as a surface of the least sensible breadth, but as the termination or limit of a surface; nor is a point considered as the least sensible line, or a moment as the least perceptible time; but a point as a termination of a line, and a moment as a termination of a limit of time. In this sense they conceive clearly what a surface, line, point, and a moment of time, is; and the postulata of Euclid being allowed and applied in this sense, the proofs by which it is shown, that a given magnitude may be conceived to be divided into any given number of parts, appear satisfactory; and if we avoid supposing the parts of a given magnitude to be infinitely small, or to be infinite in number, this seems to be all that the most scrupulous can require.

Dr. Reid, in his "Inquiry into the Human Mind, on the Principles of Common Sense," considers that it is absurd to deduce from sensation the first origin of our notions of external existence, of space, motion, and extension, and all the primary qualities of bodies; they have, he says, no resemblance to any sensation, or to any operation of our minds, and therefore they cannot be ideas either of sensation or reflection; nor can he conceive how extension, or any image of extension, can be in an unextended and indivisible subject like the human mind.

EXTERNAL, or Exterior, (from the Latin *externus*, outward,) a term of relation, applied to whatever is on the surface or outside of a body, and opposed to *internal* or *interior*.

External or Exterior Angles. *See* Angles.

EXTRADOS, (from the Latin, *extrà*, outer, and *dorsus*, the back,) the external surface of a vault. The surface on the upper side of the voussoirs of an arch. *See* Arch, Bridge.

EXTREME, (from the Latin *extremus*, utmost,) whatever finishes or terminates on one side of a thing. The extremes of a line are points.

EYE, (from the Saxon,) a circular window in a pediment, attic, the reins of a vault, or the like.

Eye, *Bullock's*, (in French, *œil de bœuf*) a little skylight in the covering or roof, intended to illuminate a granary, &c. It is also applied to the little lanterns in a dome, as at St. Peter's at Rome, which has forty-eight, in three rows.

Eye of a Dome, the aperture at the summit, as that of the Pantheon at Rome, or of St. Paul's, London.

Eye of a Volute, the circle at the centre, from the circumference of which the spiral line commences. *See* Spiral and Volute.

Eye, in perspective, the point where the organ of vision is fixed, in order to view the object.

Eye-Brow, the same as Fillet, which see.

F.

FABER, a workman, the Romans gave this name to artisans or mechanics who worked in hard materials.

FABRIC, (from the Latin, *fabrica*, French *fabrique*, originally the workshop of a mechanic, *a smith's shop or forge*) the structure or construction of anything, particularly a building.

In Italy, the word is applied to any considerable building; in France, it rather signifies the manner of building.

FAÇADE, or Face, (from the Latin *facies*, the front) the face or front view of an edifice; that portion of the surface of a building which presents itself to the eye. Façade was used originally to denote the principal front of a building; and the term Facciata, used by the Italians, is, for the most part, applied to such fronts as have a principal entrance. The word is now generally made use of when speaking of architectural buildings, as the façade of the Louvre, or the façade of St. Peter's, &c.

FACE, or FACIA (from the Latin) a vertical member in the combination of mouldings, having a very small projection, but considerable breadth; such as the bands of an architrave. *See* FASCIA.

FACE MOULD, in the preparation of the hand-rail of a stair, a mould for drawing the proper figure on both sides of the plank; so that when cut by a saw held at a certain inclination, the two surfaces of the rail-piece will be every where perpendicular to the plan, when laid in their intended position.

FACE OF A STONE, the surface intended for the front of the work. The face is easily known when the stone is scalped, as being opposite to the back, which is rough as it comes from the quarry. The surface of the splitting grain ought always to be perpendicular to the face.

FACET, or FACETTE, a flat projection between the flutings of columns.

FACIA. *See* FASCIA.

FACING, in engineering, a small thickness of common earth, soil, or stuff of a canal, laid in front of the side lining or puddle on the sloping sides. It is of use to hold up the puddle while working and chopping, in the act of puddling, and afterwards to guard the puddle from being penetrated by the hitchers and poles used by the barge-men.

FACING, a thin covering of a better material, to improve the appearance, or add to the strength of anything. Thus the thin covering of polished stone, or the stratum of plaster, or cement on a brick or rough stone wall is called a facing.

FACING, FAÇADE, or REVETEMENT, in fortification, the portion of masonry, or rather building, given to ramparts, with a view to prevent the soil of which they are composed from crumbling or giving way. When the wall is of masonry, it should be 5 feet thick at the top, with tresses, called *counterforts*, at about 15 feet apart, to strengthen the facing. In order to prevent escalade, the facing is generally made full 27 feet high, from the bottom of the ditch to the cordon. When the facing is carried up as high as the soles of the embrasures, it is called a *whole revetement;* but when confined to the ditch only, it is called a *half revetement.* These must depend upon the nature of the soil, the facility of obtaining materials, the time that can be allowed, the importance of the post, &c. When difficulties occur, as also in temporary works, the facings are made with turf, in which case they are said to be *gazoned.* For field-works, and particularly in the conducting of sieges, fascines or faggots, made of various materials, are very generally employed, and answer the intention.

FACINGS, in joinery, all those fixed parts of wood-work which cover the rough work of the interior of walls, and present themselves to the eye in the completion.

FACTABLING. *See* COPING.

FAIR CURVE, in ship-building, a winding line, used in delineating ships, whose shape is varied according to the part of the ship which it is intended to describe.

FAHRENHEIT, the presumed inventor of the thermometer which bears his name. It is quite unknown on what grounds he made choice of the fixed points on his scale, or of the number of graduations between them, but it is supposed that one of the fixed points was that of boiling-water, and that the other, the *zero* of the scale, was that at which the top of the column stood, when the instrument was exposed to an intense cold in Iceland, in 1709. The extent of the scale between this last point, and that of boiling-water, is divided into 212 parts, and the point of freezing water is at the thirty-second division from the zero point.

FALD-STOOL, a portable folding seat of wood or metal, often of elaborate workmanship, and covered with rich hangings of silk or other material. The term is applied to the Litany stool, or low desk, used in churches, from which the Litany is said. Its position is in the middle of the choir, near the steps of the altar.

FALL. *See* MEASURE, and WEIGHTS AND MEASURES.

FALLING MOULDS, the two moulds which are applied to the vertical sides of the rail-piece, one to the convex, the other to the concave side, in order to form the back and under surface of the rail, and finish the squaring.

FALLING SLUICES, in engineering, gates contrived to fall down of themselves, and enlarge the water-way, on the increase of a flood, in a mill-dam, or the pond of a river navigation.

FALSE ROOF, of a house, that part between the upper room and the covering.

FANE. *See* VANE.

FAN-SHAPED WINDOW, a window consisting of rather more than a semi-circle, the circumference of which is cut out in circular notches.

FAN-TRACERY VAULTING, a mode of vaulting very much in use in late Perpendicular buildings. In this vaulting, all the ribs and principal lines diverge equally in every direction from a point at the springing of the vault; every rib preserving the same curvature; the spaces between the ribs are piled up with panelling and rich tracery. The name is applied from the similarity of this kind of roof to an open fan. Beautiful specimens exist at King's College Chapel, Cambridge; St. George's, Windsor; and Henry VII.'s Chapel, Westminster; also in many smaller erections, such as chantries, tombs, &c.

FANUM, among the Romans, a temple consecrated to some deity. The deified mortals, among the heathens, had likewise their *fana:* even the great philosopher, Cicero, erected one to his daughter Tullia.

FANUM JOVIS, a temple of Jupiter, in Asia Minor, near the Thracian Bosphorus and the Syrnæan promontory.

FARM. It is not within our province to enter on the subject of the mangement of a farm; but as the construction of the buildings belonging to one is frequently entrusted to architects and surveyors, especially in a country practice, it is desirable to offer a few observations respecting farm-buildings. The directions of Vitruvius are as follow:—"The magnitude of the buildings must depend wholly on the quantity of land attached to them, and upon its produce. The number of courts and their dimensions must be proportioned to the herds of cattle and quantity of oxen employed. The kitchen should be situated in the warmest part of the court, and the stable for the oxen contiguous to it; the stalls should be made to face the hearth and the east, because when oxen are constantly exposed to light and heat they become smooth-coated. No husbandman, however ignorant, will suffer cattle to face any other quarter of the heavens than the east. The width of the stables ought not to be less than 10, nor more than 15 feet, their length proportioned to the number of yokes, each of which should occupy an extent of 17 feet. The scalding-rooms should adjoin the kitchen, in order that the operation of cleansing the utensils may be performed upon the spot. The courts for sheep, &c., should be so spacious as to allow not less than 4½, nor more than 6 feet, to each animal.

"The granaries should be above ground, and made to front either the north or the north-east, in order that the grain may not be liable to ferment; but, on the contrary, by exposure to a cold atmosphere, may be preserved a long time: all other prospects encourage the propagation of worms and insects destructive to grain. The stables should be built in the warmest part of the villa, most distant from the hearth; because when horses are stalled near fire they become rough-coated. It is likewise expedient to have stalls for oxen at a distance from the kitchen, in the open air; these should be placed so as to front the east, because if they are led there to be fed in winter, when the sky is unclouded, they will improve in appearance. The barns, the hay-yards, the corn-chambers, and the mills, ought to be without the walls, so that the farm may be less liable to accidents by fire." An excellent work on farm-buildings has been written by Mr. G. A. Dean, of Stratford.

FASCIA, FACIO, or FACE (from the Latin, *facia*) a vertical member, of considerable height, but with a small projection, used in architraves and pedestals. In the Grecian Doric, the architrave under the band consists only of a single face; as does also the Ionic on the temple of the Illysus, in Attica. The Ionic on the temple of Erechtheus, at Athens, has three fasciæ; as have several celebrated examples of the latter order. Vitruvius allows only a single face to the Tuscan and Doric orders: that is, he makes it all plain, without any divisions or cantoning into parts or fasciæ.

In brick buildings, the jutting out of the bricks beyond the windows in the several stories, except the highest, are called *fascias* or *fasciæ*. These are sometimes plain, and sometimes moulded; but the moulding is only a sima reversa, or an ogee, with two plain courses of brick over it, then an astragal, and lastly, a boultine.

FASCINE, (from *fascis*, a bundle,) in fortification, a number of small sticks of wood, bound at both ends and in the middle, used in raising batteries, in filling ditches, in strengthening ramparts, and making parapets. Smeaton and other engineers have used wattled wood or hedge-work for groins, &c., to retain the pebbles or beach, and break the waves on the shore.

FASTIGIUM, (Latin, *a top* or *ridge*) the upper or crowning member of a building. The term is also applied to PEDIMENT; which see.

FATHOM (from the Saxon) a long measure of six feet, taken from the extent of both arms, when stretched in a right line. It is used in measuring the depth of water, quarries, wells, and pits. It is also always used in nautical matters, as in heaving the lead, &c.

FAUX, a narrow passage used as a means of communication between the atrium and peristylium, the two principal divisions of a Roman house.

FAVISSA (Latin) a hole, pit, or vault under ground, to keep something of great value.

FEATHER-EDGED BOARDS, those of a trapezoidal section; that is, thicker on one edge than on the other: they are used in the facing of wooden walls, and sometimes for the covering of an inclined roof, by lapping the thick edge of the upper board upon the thin edge of the lower one: boards of this description are also employed in fence walls, but are then most frequently placed vertically.

FEATHER-EDGED COPING. *See* COPING.

FEATHERING, an ornament in use in Early English, and the later periods of Gothic architecture, consisting of an arrangement of small arcs in juxtaposition, and forming, at their intersection, projecting points or cusps. Sometimes we find a second and even a third series of these ornaments, one within the other. *See* FOLIATION.

FEEDER, in engineering, a cut or channel, sometimes called a *carriage* or *catch-drain*, by which a stream or supply of water is brought into a canal: sometimes the stream of water itself thus supplied, is called a *feeder*.

FEEDING-HOUSE, or SHED, a building in a farm, for the purpose of fattening neat cattle. It should have a dry warm situation, capable of free ventilation, and be well supplied with proper conveniences for the reception of food and water.

FELLING, of timber, the cutting of trees close by the root, for the purpose of building: the proper season for this purpose, is about the end of April.

FELT-GRAIN: when a piece of timber is cloven or split towards the centre of the tree, or transversely to the annular rings or plates, that position of splitting is called the *felt-grain;* and the transverse position, or rather that which is in the direction of the annular plates, is called the *quarter-grain.*

FELTING, the splitting of timber by the *felt-grain.*

FEMUR, the plane space intervening between the channels in the triglyphs of the Doric order.

FENCE, (from the Latin *defendo*, to defend) any sort of construction for the purpose of enclosing land; as a bank of earth, a ditch, hedge, wall, railing, paling, &c.

FENCE, the guard of a plane, which obliges it to work to a certain horizontal breadth from the arris: all moulding planes, except hollows, rounds, and snipes' bills, have fixed fences, as well as fixed stops; but in fillisters and plows the fences are moveable.

FENESTELLA, a niche on the south side of the altar in churches, in which the piscina and sometimes credence table also is placed. These niches are of various forms and degrees of ornamentation; some of them are very richly finished. In some instances a double niche is found, one for the piscina and the other for the credence table. *See* PISCINA, CREDENCE TABLE, CHANCEL, &c.

FENESTRATION, the arrangement of windows in a building. The term is also used in contradistinction to *columniation*, when speaking of the design and composition of a building generally; the former term being used in reference to an edifice in which windows form the principal feature, the latter to that in which the columnar arrangement is adopted. Buildings in which both windows and columns are employed, are termed *columnar-fenestrated.*

FERETORY, (Latin *fero*, to carry,) a bier, coffin, shrine, or tomb. The term is more properly applied to portable shrines.

FESTOON, a representation in sculpture of bands of flowers, drapery, foliage, &c., looped up or suspended at regular intervals. This decoration was used by the ancients in friezes, &c.

FETCHING THE PUMP, the act of pouring water into the upper part of a pump, to expel the air contained between the lower box, or piston, and the bottom of the pump.

FIGURE (from the Latin *figura*, likeness) in a general sense, the terminating extremes, or surface of a body.

No body can exist without figure, otherwise it would be infinite, and consequently all space would be solid matter.

FIGURE, in geometry, any plane surface comprehended within a certain line or lines.

Figures are either rectilinear, curvilinear, or mixed, according as the perimeter consists of right lines, or curved lines, or both.

The superficial parts of a figure are called its *sides*, or *faces*, and the lowest side its *base;* if the figure be a triangle, the angle opposite the base is called the *vertex*, and the height of the figure is the distance of the vertex from the base.

FIGURE, in architecture and sculpture, representations of things made of solid matter, as statues, &c., thus we say, figures of brass, of marble, of stucco, of plaster, &c.

Figures, in architecture, are said to be *detached* when they stand singly, in opposition to those compositions called *groups.*

Figure, in conics, the rectangle under the latus rectum and transversum, in the hyperbola and ellipsis.

Figure, in fortification, the interior polygon, which is either regular or irregular. It is called a regular figure, when the sides and angles are all equal.

Figures are either Circumscribed or Inscribed, Equal, Equilateral, Similar, Regular, or Irregular. *See* these words.

Figure of the Diameter, a name given to the rectangle under a diameter and its perimeter, in the ellipsis and hyperbola.

FILLET, (from the French *filet*, a band) a small member, consisting of two planes at right angles, used to separate two larger mouldings, to strengthen their edges, or to form a cap or crowning to a moulding, or sometimes to terminate a member, or series of members.

The fillet is one of the smallest members used in cornices, architraves, bases, pedestals, &c.

It is called by the French, *reglet*, *bande*, and *bandelette;* by the Italians, *lista* or *listella.*

Fillet, in carpentry or joinery, any small timber scantling, equal to, or less than, battens: they are used for supporting the ends of boards, by nailing them to joists or quarters, &c., as in sound-boarding, and in supporting the ends of shelves.

Fillet Gutter. *See* Guttering.

FILLING - IN PIECES, in carpentry, short timbers, less than the full-length, fitted against the hips of roofs, groins, braces of partitions, &c., which interrupt the whole length.

FINE-SET, when the iron of a plane has a very small projection below the sole, so as to take a very thin broad shaving, it is said to be *fine-set.*

FINE STUFF, in plastering. *See* Plastering.

FINIAL, (from the Latin, *finio*, to finish,) in the pointed style of architecture, a termination to a building, or principal part, in the form of a flower or knop of foliage; used in high-pointed pediments, canopies, pinnacles, &c. It is usually in the form of a lily, trefoil, acorn, pomegranate, endive, &c., or consists of four or more of the leaves which compose the crockets tied up in one bunch.

FINISHING, a term frequently applied to the termination of a building, as also to the interior, in the plaster-work, in giving the last coat; and very frequently to the joiner's work, as in the architraves, bases, surbases, &c.

Finishing, in plastering. *See* Plastering.

FIR, (from the Welsh *fyrr*,) a species of timber much used in building. The native fur of this country is called *Scottish fir*, which is chiefly employed in out-houses, offices, &c. It is much inferior to the Baltic timber, which is used wherever durability is required. *See* Timber.

Fir, *Wrought*, that which is planed upon the sides and edges.

Fir, *Wrought and framed*, such as is both planed and framed.

Fir, *Wrought*, *framed*, *and rebated*, is what its name imports.

Fir, *Wrought*, *framed*, *rebated*, *and beaded*, is what its name imports.

Fir-Boards, the same as deal-boards. *See* Deal.

Fir-framed, is generally understood of rough timber framed, without undergoing the operation of the plane.

Fir-in-bond, a name given to all timber built in a wall, as bond-timbers, lintels, wall-plates, and templets.

Fir-Poles, small trunks of fir-trees from ten to sixteen feet in length, used in rustic buildings and out-houses.

Fir-no-labour, rough timber employed in walling, without framing or planing.

FIRE-BRICKS, are made from a natural compound of silica and alumina, which, when free from lime and other fluxes, is infusible under the greatest heat to which it can be subjected. Fire-bricks are brought to London from Stourbridge and from Wales; they are also made near Windsor: *See* Brick, and Windsor Bricks.

Fire-Engine, a term formerly applied to the steam-engine, but now confined to those machines which extinguish fires by throwing water from a jet upon the burning materials.

Fire-Escape, a machine for escaping from windows when houses are on fire.

Fire-Place, that space in an apartment where the fuel is consumed in communication with a flue through which the proceeds of combustion are carried away. In modern houses the fire-place is usually taken out of the space within the apartment, and flanked by projecting walls, upon which is carried up a flue, also projecting within the apartment, but in ancient houses the fire-place and flue were often taken out of the thickness of the wall, or projected outwards on the exterior of the building.

The most ancient fire-places in England, now existing, are those at Rochester and Conisborough Castles, which date of the twelfth century. The former is deeply recessed, with a semi-circular back, while the back of the former is flat, and not recessed at the level of the floor, but slopes backward as it rises; the hearth consequently projects into the room, but is covered by a hood which projects from the wall to collect the smoke. We have not many specimens of Early English work, but in the later styles they are more frequent. In Early English and Decorated buildings fire-places are not often very deeply recessed, and sometimes not at all, but they are frequently covered with projecting hoods. In the Perpendicular style they are generally entirely recessed, and in that case are without the hood; some specimens of this period are of a very ornamental description.

Fire-proof Houses, such as are built without the use of any combustible matter: for this purpose, vaulted or cast-iron floors and roofs should be employed in every apartment. Vaulting is well adapted to the lower story of a building, but if used in the upper stories, the walling must be carried up very thick, in order to resist the thrust of the arches; and this extra substance not only darkens the apartments, but occasions an enormous expense. The builder is therefore obliged to have recourse to other modes of construction for common purposes. The most convenient substitute is cast-iron joists, vaulted between with brick, or covered with cast-iron boards flanged and keyed together.

Mr. Bartholomew strongly recommends that roofs should be so constructed as to lessen as much as possible the possibility of fire. "It should be," he observes, "the architect's study, in all roofs, to have as little as possible that will either burn or rot; if the roof-trusses were made of cast-iron, as Mr. Gwilt has made those to his restoration of the choir of St. Saviour's Church, Southwark; and if slight horizontal rafters, reaching from truss to truss, supported tiles of the ornamental description above referred to, (tiles made of burnt earth, moulded in the form of leaves, &c.,) all combustible materials might be banished from our invaluable cathedrals."—We quite agree with Mr. Bartholomew in principle, but, in such cases, would beg to recommend a vaulted stone roof in preference to one of iron.

The late Sir John Soane constructed nearly all the apartments of the Bank of England fire-proof, and without any carpentry whatever; in his arches and domes, making use largely of hollow pots or cones of coarse earthenware; these, while strong enough not to crush, by their lightness relieve the walls in a great measure, both from the lateral thrust, and the perpendicular pressure, caused by the use of heavier materials.

A method of rendering the floors of houses fire-proof, has been adopted with success in many parts of France. After the joists are laid they are boarded over with rough boards, and these covered with a coating of plaster of about eight inches in thickness, above which are laid tiles of an ornamental description, or sometimes a floor of parquetry. In some instances, the boards on which the plaster is laid, are omitted altogether, and the plaster inserted between the joists. The staircases likewise are made of brick-nogging, and covered with tiles.

It is a cause of wonder and regret, that these or similar means for rendering buildings fire-proof, are not adopted in London, where so great a loss is annually sustained by neglect on this head: the immediate outlay would not be very much greater than at present, and in the end the practice would assuredly prove the more economical. Our timber partitions, roofs, and staircases would seem to be made for the purpose of burning; and when once a portion of a building takes fire, there is little chance of saving the remainder; whereas if the chambers, or at least the floors, were isolated by fire-proof partitions, a fire could readily be confined to that part of the building where it commenced.

But perhaps of all parts of a house, that which requires the greatest care in this respect is the staircase; it is no easy matter to calculate how great a loss of human life has been occasioned by recklessness on this point. The staircase forms a shaft to carry up the flames, and is one of the first things to be destroyed, thus cutting off the means of escape from persons above the ground-floor: if nothing else be attended to, surely our staircases should be rendered fire-proof.

Iron has of late years been much used for the purpose of rendering buildings more safe from the effects of fire, but we are inclined to think the success of this application doubtful. This material is generally used as a substitute for summers, girders, or bond-timber, in which instances wood is almost as secure as iron; for in the former cases, the timbers are of too great scantling thoroughly to ignite, and in the latter they are well protected, and will be seldom found more than charred on the exposed surfaces. Besides this, iron has its disadvantages, for it is liable to expand and contract under the influence of heat and cold, and is known by this means to destroy the brickwork.

FIRE-STONE, is used in joinery, for rubbing away the ridges made by the cutting-edge of the plane.

FIRMER,
FORMER, } *See* Tools.
FURMER,

FISH-POND, a reservoir of water, for breeding, feeding, and preserving fish.

FISTUCA, (Latin) in antiquity, an instrument of wood, used in driving piles. It had two handles, and being raised by pullies fixed to the head of large beams, was let fall directly on the piles; sometimes it was wrought by hand only.

FIXED AXIS, in geometry, the axis about which a plane revolves in the formation of a solid.

Fixed Points, in carpentry, the points at the angles of a piece of framing, or where any two pieces of timber meet each other in a truss. If a third piece join the meeting of the two, it may be pushed or drawn in the direction of its length, without giving any cross strain.

Fixed points are of the utmost use in shortening the bearings of the exterior timbers of the frame; neither is there any other method by which this can be so effectually done. When two sides of a frame are similar, any points in the length of the pieces may be supported by as many beams, extending between the opposite points: though this will keep the frame in *equilibrio*, it will not prevent it from being shaken by heavy winds, or lateral pressure.

FLAGS, thin stones used in paving, from one and a half to three inches thick, and of various lengths and breadths, according to the nature of the quarry.

FLAKE WHITE, in painting, lead corroded by the pressing of grapes, or a ceruse prepared by the acid of grapes. It is brought to England from Italy, and far surpasses, in the purity of its whiteness, and the certainty of its standing, all the ceruses of white-lead made with us in common. It is used in oil and varnish painting, for all purposes where a very clean white is required. Flake white should be procured in lumps, as brought over, and levigated by those that use it; as that which the colourmen sell ready prepared, is levigated and mixed up with starch, and often with white-lead, or even worse sophistications.

FLAMBOYANT, a name applied to a style of Gothic architecture prevalent in France in the 15th century, from the circumstance of the principal lines of the tracery converging together in the shape of flames. This undulating distribution of lines is the characteristic of the style, if it may be so termed. The tracery is frequently of a very elaborate character, and the ornamentation intricate and redundant, while at the same time the mouldings are meagre. These consist usually of large hollows separated with small and insignificant members of different contour, which gives the whole an appearance of poverty, ill contrasting with the richness of the tracery. The centre moulding in the mullions of windows, and similar positions, projects often to an unusual extent, so as to give it the appearance of weakness. Pillars, piers, jambs, and such like, are often devoid of capitals, the mouldings of arches which abut against them, dying into them without any finishing ornament. The more ornamented parts, such as foliage, &c., are very rich, and delicately carved, but are frittered away by the minuteness of their parts, thus losing all boldness and even distinctness of outline.

FLANK, (from the French, *flanc*,) that part of a return body which adjoins the front; as flank-walls. In town-houses, the flank-walls become party walls.

FLANK WALLS, in engineering, the same as the wing or return walls of a lock or bridge.

FLAPS, folds or leaves attached to the shutters of a window, which are not sufficiently wide of themselves to cover the sash-frames, or to exclude the light.

FLASHES, in engineering, a kind of sluices erected upon navigable rivers, to raise the water upon any shoals therein, while the vessels or craft are passing.

FLASHINGS, in plumbery, pieces of lead inserted in a wall for covering other pieces laid down for gutters, &c.

FLAT CROWN. *See* Corona.

FLATTING, in house-painting, a mode of painting in oil, without any gloss on the painted surface when finished. The paint is prepared with a mixture of oil of turpentine, which secures the colour; and when used in the finishing, leaves the paint quite dead, without gloss. This is of great importance to those who are desirous to have their rooms continue white. Flatting is only used for inside work, and rarely for any but principal rooms. Nut oil is sometimes used for the purpose, but not often, on account of its high price.

As useful a flatting as any, is such as is ground in poppy oil. It is pleasant in working, and leaves a beautiful white for some years; but it is rather expensive.

FLEMISH BOND, that method of laying bricks in which headers and stretchers appear alternately in the length of each course. The appearance of this work is generally preferred to that of English bond, for the external facings of walls, but the method of laying is much more complicated, and requires the insertion of a number of small pieces in carrying up the work, to fill up the interstices between the bricks. *See* BRICKLAYING.

FLEMISH BRICKS, in bricklaying, strong bricks, of a yellowish colour, used in paving; their dimensions are about $6\frac{1}{2}$ inches long, $2\frac{1}{2}$ broad, and $1\frac{1}{2}$ thick; 72 set upon their widest sides, or 100 on edge, will pave a yard square, allowing a quarter of an inch for the joints.

FLEXURE, or FLEXION, (from the Latin) the opposition of curvature at a given point, where a straight line becomes a tangent, having the curve on both sides of it, one portion of the curve being concave, and that on the other side of the point of contact, convex.

FLIGHT, in staircasing, a series of steps, whose treads are parallel, and terminate against a straight wall.

FLIGHT, *Leading*, } *See* STAIRCASING.
FLIGHT, *Returning*, }

FLIGHT, is also used in London for a whole stair, between two adjoining floors.

FLOAT, in plastering. *See* PLASTERING.

FLOAT-BOARDS, the boards fixed to undershot water-wheels, to receive the impulse of the stream.

FLOAT-STONE, among bricklayers. *See* BRICKLAYERS.

FLOATED LATH AND PLASTER, set fair for paper. *See* PLASTERING.

FLOATED, RENDERED, and SET, in plastering. *See* PLASTERING.

FLOATING, in plastering. *See* PLASTERING.

FLOATING BRIDGE. *See* BRIDGE.

FLOATING RULES, in plastering. *See* PLASTERING.

FLOATING SCREEDS, in plastering. *See* PLASTERING.

FLOOD-GATE, a gate or sluice, that may be opened or shut at pleasure, to give passage to, or retain the water of a river liable to be swollen by floods. Flood-gates are necessary in many situations; as, upon rivers where the water is retained for the service of mills, canals, navigations, docks, &c.

FLOOR, (from the Saxon) the lowest horizontal side of an apartment, for walking, or for performing different operations upon.

Floors were formerly covered with rushes, carpets being seldom used for such purposes, even at the close of Elizabeth's reign. In much earlier times, however, tapestry-cloths were occasionally used to rest the feet upon. Most of the old dramatists have frequent allusions in their works to the practice of strewing rushes in the principal apartments.

Floors are of various kinds, according to the materials of which they are constructed. Those made of brick and stone, are called *pavements;* those of earth are called *earthen floors;* those of plaster, *lime floors;* and those of timber are called *timber floors.*

FLOOR, in carpentry, includes not only the boarding for walking upon, but all the timber-work for its support. Boarded floors should never be laid till the building is properly covered in, nor indeed till the windows are glazed, and the plaster dry. Previous to the lying of such floors, the boards ought to be rough-planed, and set out to season, a twelvemonth at least, before they are used; that the natural sap may be thoroughly expelled, and the shrinking prevented, which so frequently takes place when unseasoned timber is used. The best timber for flooring is yellow deal, well-seasoned. The quality of this material is such, that when laid, it will be easily kept of a good colour; whereas white timber is liable to become black in a very short time.

Narrow boards are called *battens;* these should never exceed seven inches in width, nor be less than an inch in thickness.

Floors are nailed either at both edges, or at one edge; the longitudinal joints, or those in the direction of the fibres, are either square, ploughed and tongued, or rebated and lapped upon each other. Ploughed and tongued, and rebated joints may be used where the apartment is required to be air-tight, and where the stuff is thought not sufficiently seasoned. The heading-joints are either square or ploughed and tongued. In square longitudinal jointed floors, it is necessary to nail the boards on both edges: but where the boards are dowelled, ploughed and tongued, or rebated, one edge only may be nailed, as the grooving and tonguing, or lapping, is sufficient to keep the other edge down.

Battens used in flooring are of three kinds, and are denominated *best, second best,* and *common.* The best battens are those that are free from knots, shakes, sap, and cross-grained fibres; the second best are those free from shakes and sap, but in which small knots are suffered to pass. The common kind are such as remain after taking away the best and second best.

The best floors are dowelled and nailed only at the outer edge, through which the nails are made to pass obliquely into the joists, without piercing the upper surface of the boards, so that when laid no nails appear: the heading joints of such floors are most commonly grooved and tongued. Some workmen dowel the battens over the joists, but it makes firmer work to fix the dowels over the inter-joists. The gauge should be run from the under surface of the boards, which should be straightened on purpose.

In the most common kind of flooring, the boards are folded together in the following manner: supposing one board already laid, and fastened, a fourth, fifth, sixth, or other board, is also laid and fastened, so as to admit of two, three, four, five, or more boards, between the two, but which can only be inserted by force, as the capacity of the opening must be something less than the aggregate breadths of the boards, in order that the joints may be close when they are all brought down to their places; for this purpose a board may be thrown across the several boards to be laid, which may be forced down by two or more men jumping upon it: this done, all the intermediate boards are to be nailed down, and the operation is to be repeated till the whole is complete. This manner of flooring is called a *folded floor.*

In folded floors, less than four boards are seldom laid together. No attention is paid to the heading joints, and sometimes three or four joints meet in one continued line, equal in length to the aggregate of the breadths of the boards.

In dowelled floors, the distances to which the dowels are set, are from six to eight inches, generally one over each joist, and one over each inter-joist; and, as has been already observed, the heading-joints of this kind of floor are generally ploughed and tongued; and no heading-joint of two boards ought to be so disposed as to meet the heading-joint of any other two boards, and thereby form a straight line equal to the breadth of the two boards.

In common floors, the boards are always gauged from the upper side, then rebated from the lower side to the gauge lines, and the intermediate part adzed down, in order to bring them to a uniform thickness. In doing this, great care should be taken not to make them too thin, which is frequently the case, and then they must be raised with chips, which present a very unstable resistance to a pressure upon the floor.

Flooring is measured by throwing the contents into square feet, and dividing them by 100, which is called a *square of flooring;* the number of hundreds contained in the superficial contents in feet are squares, and the remainder feet.

The method of measuring floors, is by squares of ten feet on each side; the dimensions being multiplied together, cut off two figures from the right of the product, and those towards the left give the number of squares, and the two on the right are feet.

Example.—Suppose the length of a floor 28 feet, and the breadth 24.

```
 28
 24
———
112
56
———
6,72
```

The product gives six squares, seventy-two feet.

When a naked floor is squared, and the contents found, nothing is deducted for the chimney, because the extra thickness of the trimmers will make up for that deficiency.

Floor, in carpentry, the timbers which support the boarding, called also *naked flooring. See* Carcase Flooring, and Naked Flooring.

Floor also denotes any portion of a building upon the same level: as basement-floor, ground floor, one-pair floor, two-pair floor, &c., but when there is no sunk story, the ground floor becomes the basement; the expressions one-pair floor, two-pair floor, &c., imply the floor above the first flight of stairs above ground, the floor above the second flight of stairs above ground, &c.

The principal floor of every building is that which contains the principal rooms. In the country they are generally on the ground floor; but in town, on the one-pair-of-stairs floor.

Floor Joists, or Flooring Joists, such joists as support the boarding in a single floor; but where the floor consists of binding and bridging-joists, the bridgings are never called floor-joists.

Floors of Earth, or Earthen Floors, are commonly made of loam, and sometimes, especially to malt on, of lime, brook-sand, and gun-dust, or anvil-dust from the forge; the whole being well wrought and blended together with blood. The siftings of limestone have also been found exceedingly useful when formed into floors.

Earthen floors for plain country habitations may be made as follows: take two-thirds lime and one of coal-ashes, well sifted, with a small quantity of loam clay: mix the whole together, and temper it well with water, making it up into a heap: let it lie a week or ten days, and then temper it again. After this, heap it up for three or four days, and repeat the tempering very high, till it becomes smooth, yielding, tough, and gluey. The ground being levelled, lay the floor with this material about two and a half or three inches thick, smoothing it with a trowel; the hotter the season, the better; and when it is thoroughly dried, it will make a good floor for houses, especially malt-houses. But should it be required to make the floor look better, take lime made of rag-stones well tempered with whites of eggs, and cover the floor about half an inch thick with it, before the under flooring is quite dry. If this be well done, and thoroughly dried, it will appear, when rubbed with a little oil, as transparent as metal or glass. In elegant houses, floors of this nature are made of stucco, or plaster-of-paris, beaten and sifted, and mixed with other ingredients. Well-wrought coarse plaster makes excellent safe upper floors for cottages, out-houses, &c., when spread upon good strong laths or reeds.

Very dry and comfortable floors may be formed by covering the area of the rooms with a level stratum of concrete, consisting of dry screened gravel or pounded stone, mixed with a small quantity of ground stone lime, or Portland cement, and laid about six inches in thickness; over this, and before it sets, should be sifted a few ashes, or some fine gravel; which, if worked in and well finished, gives a hard and even surface. This description of floor is similar to those used in Devonshire, which are proverbial for comfort and durability. The ordinary red paving tiles, 12 inches square, make very good, dry, and comfortable floors, and they are easily kept clean. Claridge's asphalte of Seyssel, has also been used for the floors of basement stories, and answers very well, especially in damp situations. For stables, railway-stations, and places of a similar description, perhaps there is nothing better than wood. The wood-pavement of the Metropolitan Wood Pavement Company, has been used with great success for such purposes—in the dock-yards by government; and by the railway companies, for their stations, &c.

FLOORING-CRAMP, a machine invented by Mr. Andrew Smith, for laying down floors. This machine is used with great facility, and enables a person accustomed to it, to get through his work with rapidity and ease; making very tight and close joints in his floors, with much less trouble than by the ordinary method.

Flooring-Machine, a machine for preparing complete flooring boards with great dispatch, and in the most perfect manner: the several operations of sawing, planing, grooving, and tongueing, being all carried on at the same time, by a series of saws, planes, and revolving chisels.

FLOOR-TIMBERS, the timbers on which a floor is laid.

FLORID STYLE, in pointed architecture, that beautiful style which was practised in England during the reigns of Henry VII. and Henry VIII. Its general external character consists of large arched windows, with very obtuse angles at the summit, and with numerous ramifications, consisting of light cuspidated mullions, filled with a variety of polyfoils. The buttresses, instead of having always rectangular horizontal sections, frequently have those of polygons, as in Henry VII.'s chapel, and are crowned with cupolas. The walls are loaded with niches, pinnacles, and crockets, terminating in open mullion-work, forming a parapet, or kind of balustrade, finished with finials or spiracles. The walls are decorated interiorly with panelling, moulded string-courses, niches, canopies, and other kinds of tracery, vaulted over with fan-groins. *See* Gothic Architecture.

FLUE, a passage for smoke in a chimney, leading from the fireplace to the top of the shaft, or into another passage. *See* Chimney.

The same term is also applied to passages in walls made for the purpose of conducting heat from one part of a building to another.

Flues in hot-houses and vineries, frequently make numerous turns on the floor, and then ascend to the wall with several horizontal turnings.

In the construction of a stack of chimneys, particular care should be taken that the drawings show distinctly the turnings of the flues; this will prevent mistakes, and save the apartments from being incommoded with smoke.

FLUSH, a term among workmen, signifying a continuity of surface in two bodies joined together. Thus in joinery, the style, rails, and munnions are generally made flush; that is, the wood of one piece on one side of the joint does not recede from that on the other.

Flush, in masonry or bricklaying, signifies the aptitude of two brittle bodies to splinter at the joints, when the stones or bricks come in contact when joined together in a wall.

Flush and Bead. *See* Bead and Flush.

FLUTES, or Flutings, prismatic cavities depressed within the surface of a piece of architecture at regular distances, generally of a circular or elliptic section, meeting each other in an arris; or meeting the surface in an arris, and leaving a portion of the surface between every two cavities of an equal breadth; or diminishing in a regular progression; according as the surface is plane or curved, or applied to a prismatic or tapering body.

When a portion of the surface is left between every two flutes, that portion is called a *fillet*. When the flutes are parallel, or diminish according to any law, the fillets are also parallel, or diminish in the same degree.

The proportion of each fillet to a flute is from a third to a fifth of the breadth of the flute. That species of fluting, in which the flutes meet each other without the intervention of fillets, is generally applied to the Doric order; and that with fillets, to the shafts of the Ionic and Corinthian orders. The flutes most frequently terminate in a spherical or spheroidal form, particularly in those which have fillets. In the Ionic order of the temple of Minerva Polias at Athens, the upper ends of the fillets of the shafts of the columns terminate with astragals, projecting from the surface of the fillet: the astragals may begin at a small distance from the top of the shaft, ascend upwards, and bind round the top of the flute. In the Corinthian order of the monument of Lysicrates, at Athens, the upper ends of the fillets break into leaves in a most beautiful manner. In the Doric examples of the temple of Theseus, and of the temple of Minerva at Athens, and of the portico of Philip king of Macedon, in the island of Delos, the upper ends of the flutes terminate upon the superficies of a cone immediately under the annulets, in a tangent to the bottom of the curve of the echinus of the capital. The same kind of termination takes place in the temple of Apollo at Cora, in Italy: but in this example, the conic termination of the flutes is not under the abacus, but a small distance down the shaft, leaving a small part quite a plain cylinder, and thus forming the hypotrochelean or neck of the capital. In other ancient examples of the Doric order, the flutes terminate upon a plane surface perpendicular to the axis of the columns, or parallel to the horizon, as in the Propylea at Athens. Palladio, and other Italian authors, have terminated the flutes of the shafts of their designs of Doric columns in the segments of spheres tanged by the surfaces of the fluting.

In the temple of Bacchus, at Teos, in Ionia, the lower extremities of the flutes descend into the scape of the column.

The Greeks never applied fluting to any member of the Doric order, except the shaft, and this was their general practice.

Fluting was used by the Romans almost in every plane, and in every cylindrical surface. *See* a very fine specimen in the corona of the cornice of the temple of Jupiter Stator, at Rome.

The number of flutes in the Doric order is twenty, and in the Ionic, Corinthian, and Composite, twenty-four. Flutes are sometimes filled with cables or staves, except in the Doric order. The cables do not reach higher than one-third of the entire column. *See* Column, Cable.

FLUXIONS, in mathematics, the analysis of infinitely small variable quantities, or a method of finding an infinitely small quantity, which being taken an infinite number of times, becomes equal to a quantity given. The doctrine of fluxions, first invented by Newton, is of great use in the investigation of curves, and in the discovery of the quadratures of curvilinear spaces and their rectifications.

FLYERS, a series of steps whose treads are all parallel.

FLYING BRIDGE. *See* Bridge.

FLYING BUTTRESSES, in pointed architecture, arches rising from the exterior walls up to those of the nave of an aisled fabric, on each side of the edifice, for counteracting the lateral pressure of a groined or vaulted roof.

The contrivance of flying buttresses is due to the architects of the middle ages, and shows their skill in the application of mechanics to the science of architecture. *See* Buttress.

FOCUS, (Latin) in geometry, and in the conic sections, a point on the concave side of a curve, to which the rays are reflected from all points of such curve.

Focus, an altar, a hearth or fire-place: the Latin motto, *pro aris et focis*, is said to be derived from this word.

Focus, of an ellipsis, hyperbola or parabola, is particularly defined under the heads of Elliptic Curve, Hyperbolic Curve, and Parabolic Curve.

FODDER, Fudder, or Fother, (Saxon) a certain quantity, proportioned by weight.

The weight of the fodder varies, in different counties, from 19½ cwt. to 24 cwt. Among the plumbers in London, the fodder is 19½ cwt., but at the Custom House 20 cwt. of 112lb.

FOILS, the small arcs in the tracery of Gothic windows, panels, &c., which are said to be trefoiled, quatrefoiled, cinquefoiled, multifoiled, &c., according to the number of arcs which they contain. An arch with foils in its tracery is called a *foiled arch*. *See* Cusp and Foliation.

Foils, Foliations, the spaces between the cusps employed in the ornamentation of Gothic buildings.

FOLDED FLOOR. *See* Floor.

FOLDING DOORS, such as are made in two parts, hung on opposite jambs, and having their vertical edge rebated, so that when shut, the rebates may lap on each other. To conceal the meeting as much as possible, a bead is most frequently run at the joint on each side of the doors.

FOLDING JOINT, a joint made like a rule-joint, or the joint of a hinge.

FOLDS, or Flaps, of shutters, those parts that are hinged to the shutters, and concealed behind when the shutters are in the boxings, so as to cover the breadth of the window when the shutter and flaps are folded out in the breadth of the aperture. Folds are necessary when the walls are so thin as not to admit of shutters of sufficient breadth, when put together, to cover the opening.

FOLIAGE, in architecture, an artificial arrangement of leaves, fruit, &c. *See* Ornaments.

FOLIATION. *See* Foils.

FONT, (from the Latin *fons*) the vessel used in churches to hold the water consecrated for the purposes of baptism.

In the early church, the baptistery formed a separate building, numbered amongst the exhedræ or outbuildings which were detached from the church, but enclosed within the consecrated area. Within the baptistery was the font or reservoir. These separate buildings continued to prevail till the sixth century, when all occasion for adult baptism ceased, and fonts within the church became general. Many baptisteries, however, still exist in various parts of the

Continent, although there seem to be no specimens in England, unless indeed we consider as such the building surrounding the font at Luton church. This structure is octagonal, about twenty-eight feet high, having open arches at the sides, and a stone roof, the font being placed in the centre, thus forming a small oratory capable of holding seven or eight persons. A similar canopy occurs at Trunch, Norfolk, but it is of wood, and hexagonal.

The material in use for fonts, is for the most part of stone lined with lead, but we have some notice of fonts of metal; that at Canterbury is reported to have been of silver, and that taken from Holyrood Chapel and brought to St. Alban's was of brass. There is also a font at Chobham, Surrey, which consists of a leaden basin enclosed within a screen of oak panelling, the date of which is about A.D. 1600. The situation of the font is within the church, near the door, either in the aisle next the porch, against one of the piers between the aisle and nave, or in the nave near the west end.

The most rude fonts are in shape little better than large stones, without any definite external form, but having a space hollowed out at the top in the shape of a bason; such is that in the church of Little Maplestead. Norman fonts are either of a cylindrical or cubical form; but which shape is the earlier, it is not easy to decide. In some instances the cylindrical fonts taper towards the base; and at St. Martin's, Canterbury, the reverse proportion is adopted. Next to these forms came the square stone hollowed out in the centre, supported on a massive cylindrical stem, or on a central stem, and four smaller shafts, one at each corner, specimens of which form exist at Lincoln cathedral and Iffley church, Oxfordshire. In all these instances, the sides of the font are ornamented with rude sculpture in low relief, frequently of groups, and sometimes of single figures contained in shallow niches, as at Stanton Fitzwarren, Wilts. Symbolical representations are frequently introduced, as are also scenes from the Sacred Writings, especially of such events as relate to the subject of baptism. On the font at Castle Frome, Herefordshire, is a representation of the Baptism of Christ, which is a very favourite subject, the same occurring at Bridekirk, in Cumberland, and West Haddon, in Northamptonshire. Another usual subject is the Fall of Man, as at East Meon, Hants.

Early English fonts are in form very similar to those of the preceding style, but they are readily distinguished by their ornamentation, which consists of work peculiar to this style; the details also are of better execution. The octagonal was a new form introduced into this style. Decorated and Perpendicular fonts are for the most part octagonal, and most frequently supported on a central stem; many of them are of most beautiful form and workmanship. Those of the later period are usually covered with panelling, and have the sides filled up with armorial bearings. Hexagonal fonts are sometimes, though not commonly, found; we have instances at Carlisle cathedral, Farringdon, Berkshire; and Bredon, Worcestershire. Five and seven-sided fonts are extremely rare; of the former we have an example at Hollington, Sussex. At Patrington and Saddington, Leicestershire, we find fonts of twelve sides; and at Stainburn, Yorkshire, one of fifteen sides; but these are purely exceptions: the octagonal form is the most common, as it is also the most appropriate. The font is usually raised on one or more steps, the sides or risers of which are often in the later styles decorated with panelling, quatrefoils, &c. Fonts were furnished with covers, which Edmund, archbishop of Conterbury, A.D., 1236, ordered to be locked down. They were probably in the earlier periods merely flat lids of wood, but in later times they were carried up in the form of a spire to a great height, ornamented with pinnacles and buttresses, with crockets, finials, and other ornaments; and not unfrequently the whole of the sides were pierced with the most elaborate panelling.

FONTANA, DOMINIC, a distinguished architect, born in 1543, at a village on the lake of Como. Having acquired the elements of geometry, he went to Rome, where his elder brother John was a student in architecture. Here he applied himself most diligently to the study of the works of antiquity, and at length was employed by Cardinal Montalto, afterwards Pope Sextus V. Montalto had already begun to display the magnificence of his character, by undertaking the construction of the grand chapel of the Manger, in the church of St. Maria Maggiore. The pope, Gregory XIII., jealous of the munificence of his cardinal, took from him the means of his designs, and thus put a stop to the works. Fontana, with a spirit worthy of a great man, went on with the building at his own expense, which so gratified the cardinal, that when he was raised to the pontifical chair, he appointed Fontana to be his architect. The chapel and palace were finished in a splendid style; but this was a small part of the designs projected by Sextus. Besides completing the dome of St. Peter's, he resolved to contribute to its grandeur, by conveying to the front of its piazza the obelisk, of a single piece of Egyptian granite, which had formerly decorated the Circus of Nero.

This design had been contemplated by some of the predecessors of Sextus, but none had actually attempted it. Sextus summoned architects and engineers from all parts, to consult upon the best means of effecting his purpose; Fontana's plan obtained the preference, and he was able to execute what he had advanced in theory. This was regarded as the most splendid exploit of the age; and rewards and honours of the most magnificent kind were bestowed on Fontana and his heirs. He was afterwards employed in raising other obelisks, and in the embellishment of the principal streets of Rome. He built the Vatican library, and had begun to make considerable additions to that place; but they were interrupted by the death of Sextus. One of Fontana's great works was the conducting of water to Rome, the distance of fifteen miles, in an aqueduct supported on arcades. The successor of Sextus, Clement VIII., was prejudiced against the papal architect, and dismissed him; but his reputation caused him to be engaged by the viceroy of Naples as architect to the king. He accordingly removed to Naples, in 1592, where he executed many works of consequence. His last efforts were directed to a new harbour at Naples, but this he did not live to complete. He died at Naples in 1607, in his sixty-fourth year.

FOOT, (Saxon) a measure, either lineal, superficial, or solid. The lineal or long foot is supposed to be the length of the foot of a man, and consists of twelve equal parts called *inches;* an inch being equal to three barleycorns.

Thus the English standard foot (31 Edw. I.) is =12 lineal English inches, = 36 barleycorns, = 16 digits, = 4 palms, = 3 hands, = $5\frac{1}{3}$ nails, = $1\frac{1}{3}$ spans, = 1.5151 Gunter's links, = .938306 feet of France, = .3047 metres of France.

Geometricians divide the foot into 10 digits, and the digit into 10 lines, &c.

The French divide their foot, as we do, into 12 inches; and the inch into 12 lines. *See* MEASURES.

The foot square is the same measure, both in length and breadth, containing 144 square or superficial inches, = 2.295684 square links; and the glazier's foot in Scotland is = 64 square Scottish inches.

The cubic, or solid foot, is the same measure in all the three dimensions, containing 1728 cubic inches English =6.128 ale gallons=3.478309 cubic links=.0283 cubic metres or steres of France.

The foot is of different lengths in different countries. The Paris royal foot exceeds the English by nine lines and a half; the ancient Roman foot of the Capitol consisted of four palms, equal to eleven inches and seven-tenths English; the Rhinland, or Leyden foot, by which the northern nations go, is to the Roman foot as 950 to 1,000. The portions of the principal feet of several nations, compared with the English and French, are here subjoined.

The English foot being divided into one thousand parts, or into twelve lines, the other feet will be as follow:

	Th. Pts.	Ft.	Inch.	Li.
London . . . . . . Foot	1000	0	12	0
Paris foot, the royal, by Greaves	1068	1	0	9.7
Paris foot, by Dr. Bernard	1066	1	0	9.5
Paris foot, by Graham, from the measure of half the toise of the Chatelet, the toise containing six Paris feet	1065.416	1	0	9.8
By Monnier, from the same data	1065.351	1	0	9
From both these it may be fixed at	1065.4	1	0	9.4
Amsterdam . . . . . Foot	942	0	11	3
Antwerp	946	0	11	3.57
Dort	1184	1	2	2
Rhinland, or Leyden	1033	1	0	4
Lorrain	958	0	11	5
Mechlin	919	0	11	0
Middleburg	991	0	11	10
Strasburg	920	0	11	0
Bremen	964	0	11	6
Cologne	954	0	11	5
Frankfort on the Maine	948	0	11	4
Spanish	1001	1	0	0
Toledo	899	0	10	7
Roman	967	0	11	6
Bononia	1204	1	2	5
Mantua	1569	1	0	9
Venice	1162	1	1	11
Dantzic	944	0	11	3
Copenhagen	965	0	11	6
Prague	1026	1	0	3
Riga	1831	1	9	11

The Greek	1007	1	0	1
Old Roman	970	0	11	7.6
Roman foot, from the monument of Cossutius in Rome, by Greaves	967	0	11	7.2
From the monument of Statilius, by the same	972	0	11	7.9
Of Villalpandus, deduced from the congius of Vespasian	986	0	11	9.9

Mr. Rapier, who industriously collected a variety of authorities relating to the measure of the old Roman foot, determined the mean to be nearly 968 thousandth parts of the London foot. And by an examination of the ancient Roman buildings in Desgodetz's *Edifices Antiques de Rome*, Paris, 1682, he concluded that the Roman foot, before the reign of Titus, exceeded 970 parts in 1000 of the London foot; and in the reigns of Severus and Diocletian fell short of 965.

The Paris foot being supposed to contain 1440 parts, the rest will be as follow:—

Paris . . . . Foot	1440
Rhinland	1391
Roman	1320
London	1350
Swedish	1320
Danish	1403
Venetian	$1540\frac{2}{5}$
Constantinopolitan	3120
Bononian	$1682\frac{2}{5}$
Strasburg	$1282\frac{5}{4}$
Nuremburg	$1346\frac{1}{4}$
Dantzic	$1721\frac{1}{2}$
Halle	1320

In Scotland, this measure of length, though consisting of twelve inches, exceeds the English foot, so that 185 of the former is equal to 186 of the latter. Accordingly the Scottish foot = 12 Scottish inches = 12 $\frac{1}{15}$ English inches, according to some, and $12\frac{12}{185}$ English inches, according to others. The glazier's foot in Scotland = 8 Scottish inches.

For a farther account of the foot, ancient and modern, and its proportions in different countries. *See* MEASURE.

FOOT-BANK, or FOOT-STEP, in fortification. *See* BANQUETTE.

FOOT-BASE, the moulding above the plinth of an apartment.

FOOT-BRIDGE, a narrow bridge for foot-passengers. *See* BRIDGE.

FOOT OF THE EYE DIRECTOR, in perspective, that point in the directing line which is made by a vertical plane passing through the eye and the centre of the picture.

FOOT OF A VERTICAL LINE, in perspective, that point in the intersecting line, which is made by a vertical plane passing through the eye and the centre of the picture.

FOOT-IRONS, in engineering, pieces of iron plate, used by navigators, or canal-diggers, to tie upon that part of the sole of their shoes with which they strike the top of their spade or grafting tool, in digging hard soil.

FOOT-PACE, in hand-railing, a flat space in some stairs, always situated between the starting, or first step, and the landing. *See* STAIRCASING.

FOOT-PACE, the dais or raised floor at the upper end of an ancient hall.

FOOT-STALL, the base or plinth of a pillar.

FOOTING-BEAM, a term used in Cumberland, Westmoreland, Somersetshire, and perhaps in other counties, for the tie-beam of a roof.

FOOTINGS, in bricklaying and masonry, projecting courses of stone, without the naked of each face of a superincumbent wall, used as a base to the wall, in order to prevent it from sinking and rocking by heavy winds.

FOOTING DORMANT, the tie-beam of a roof; the term is used in Westmoreland.

FORCE, (from the Latin, *fortis*, strong) in philosophy, the cause of motion in a body, when it begins to move, or when it changes its direction from the course in which it was previously moving. While a body remains in the same state, whether of rest or of uniform and rectilinear motion, the cause of its so remaining is in the nature of the body, which principle has received the name of *inertia*.

Mechanical force is of two kinds: that of a body at rest, by which it presses on whatever supports it, and that of a body in motion, by which it is impelled towards a certain point. The former is called by the names of *pressure*, *tension*, *force*, *vis mortua*, &c., the latter is known by the appellation of *moving force*, or *vis viva*. To the first of these are referred *centrifugal* and *centripetal* forces because, though they also reside in the *vis viva*, they are homogeneous to weights, pressures, or tensions of any kind. For want of a true knowledge of the nature of force, we are accustomed to consider its measure by velocity, upon the supposition that, under precisely similar circumstances, the velocity is equal to the force; an hypothesis highly probable, though not easily demonstrable. Velocity itself is a compound idea, derived from a certain relation between time employed and space described. Thus, if two bodies be supposed to move uniformly upon two different lines, the distances which they describe upon their respective lines in any given time, may be measured and represented by some standard measure, from which we acquire an idea of their relative velocity or force; and considering velocity as an abstract number, it is said to be equal to the space, divided by the time; and thus we are led to consider velocity, or the space described in a given time, as the measure of force.

Force may also be expressed by other functions of velocity; for it may be proportional to the square or cube of the velocity; and La Place has very ingeniously proved that the difference between the proportionality of force to velocity, if any really exists, must be extremely small; whence he argues it is highly improbable that any does exist. If there were any material variation in this law, the relative motions of bodies on the surface of the earth would be sensibly affected by the motion of the earth; in other words, the effect of a given force would vary considerably, according as its direction coincided with, or was opposed to, that of the earth's motion. The effects of the same apparent forces would likewise vary in different seasons of the year; the velocity of the earth being less by about one-thirtieth in summer than it is in winter. But as no such variation is discernible, we may justly conclude the proportion between force and velocity to be as 1 to 1; that is, there is no difference. To illustrate this, suppose two bodies moving upon one straight line with equal velocities; by impelling one of them with a force which increases its original force, its relative velocity to the other body remains the same as if both had been primitively in a quiescent state. The space described by the body, in consequence of its original force, and of that which has been added to it, becomes equal to the sum of what each of them would have caused it to have been, described in the same time; therefore the force is proportional to the velocity.

This law, and that of *inertia* above alluded to, may be considered as derived from observation and experiment: they are simple and natural, and are sufficient to serve as a basis for the whole science of mechanics.

Early in the last century, a warm controversy arose relative to the measure of force, which was carried on with considerable acrimony, though it now appears that the question was rather about words than facts. Sir Isaac Newton had defined the measure of force to be "the mass of a body mutiplied into its velocity;" which definition was not only convenient for the philosophical investigation in which he was engaged; but was really mathematically just. But in another point of view, in which the effects of force may be said, without any impropriety, to depend on the mass multiplied into the square of the velocity, this product has been called the *vis viva*, and was considered by Bernouilli and Leibnitz as the true and universal measure of force, in opposition to Sir Isaac's definition; though it now appears that they were led into an error by not duly considering all the circumstances of the question at issue. The measure adopted by them, the *vis viva*, however, merits attention, as in all cases of practical machinery it is frequently the most accurate, and always the most useful; at the same time it implies no contradiction to the Newtonian definition. But the force thus measured ought to be distinguished by some appropriate name, *e. g.* the *vis mechanica;* the Newtonian measure being applied to the *vis motrix*, as suggested by Mr. Wollaston in the *Bakerian Lecture* for 1805.

Force, *Direction of*, the straight line which it tends to make a body describe.

Forces, *Composition of.* If two forces be conceived to act on a material point, it is evident that if they both act in the same direction, they will mutually increase each other's effect; but if they act in opposite directions, the point will move only in consequence of their difference, and it would remain at rest if the forces were equal. If the directions of the two forces make an angle with each other, the resulting force will take a mean direction; and it can be demonstrated geometrically, that if, reckoning from the point of intersection of the two directions of the forces, we take on these directions straight lines to represent them, and then form a parallelogram with such lines, its diagonal will represent their resulting force, both as to its direction and magnitude. The resulting force thus determined, which likewise represents the velocity of the moving point, may therefore be substituted as a force equivalent to the two component forces; and reciprocally, for any force whatever, we may substitute any two forces, which according to this rule would compose it. Hence we see that any force whatever may be decomposed into any two forces, parallel to two axes situated in the same plane, and perpendicular to each other. To effect this, it is only necessary to draw from the first extremity of the line representing the force, to other lines parallel to the axis, and to form with such lines a rectangle, whose diagonal will be the force required to be decomposed. The two sides of this rectangle, or parallelogram, will represent the forces into which the given force may be decomposed, parallel to such axis. If the force be inclined to a plane in position, a line in its direction may be taken to represent it, having one of its extremities on the surface of the plane, and the perpendicular falling from the other extremity will be the primitive force decomposed in the direction perpendicular to the plane. The straight line, which in the plane joins the other extremity of the line representing the force with the perpendicular (or the orthographic projection of the line of the plane) will represent the primitive force decomposed, parallel to the plane. This second partial force may itself be decomposed into two others, parallel to two axes in the same plane, perpendicular to each other. Thus we see that every force may be decomposed into three others, parallel to three axes perpendicular to each other; which axes are termed *rectangular co-ordinates.*

Hence we have a very simple mode of obtaining the resulting force of any number of forces supposed to act on a material point. This method was first adopted by Maclaurin, followed by La Grange, in the *Méchanique Analytique*, and also by La Place in the *Méchanique Céleste.* By decomposing each of these forces into three others, parallel to the given axes in position, and perpendicular to each other, we have all the forces parallel to the same axis reduced to one single force, which latter will be equal to the sum of the forces acting in the same direction, minus the sum of those acting in a contrary direction: so that the point will be acted on by three forces perpendicular to each other. From the point of intersection, or origin of the co-ordinates, take three right lines to represent them in each of their directions, and on such lines form a rectangular parallelopipedon, and the diagonal of this solid will represent the quantity and direction of the resulting force of all the forces acting on the point.

The principle of the composition of forces is of the most extensive utility in mechanics, and is in itself sufficient for determining the law of equilibrium in every case. Thus, if we successively compose all the forces, taking them by two's, and then take the result as a new force, we obtain one that is equivalent to all the rest, and which, in case of equilibrium, must equal 0, when the system under consideration has no fixed point; but if the conditions of the problem insist on an immoveable point, the resulting force must necessarily pass through it.

Though it is admitted by all writers on this subject, that the most abstruse propositions may be deduced from a few simple principles, yet few are found who entirely agree in their choice of such principles. The most advantageous, and indeed the most natural method, seems to be that wherein the relation between various forces in a state of equilibrium is first investigated, and then the consideration extended to a body in motion. If a body remain in equilibrium, at the same time that it is solicited by several forces, each force is supposed to produce only a tendency to motion, which is measured by the motion it would produce were it not checked by the power of the others: therefore, after expressing the effect of any one of the forces by unity, the relative force of the others may likewise be expressed by words or numbers.

La Place merely assumes the two foregoing principles, and speaks of them as experimental facts; while Dr. Young does not scruple to declare them capable of demonstration. (*See* his *Lectures.*) But this difference of opinion is of little importance, since the principles themselves are universally admitted.

La Grange has founded the whole doctrine of the equilibrium of forces on the well-known principle of the lever, the composition of motion, and the principle of virtual velocity; each of which we shall here notice.

The *principle of the lever* may be derived from the composition of forces, or even from much less complicated considerations.

Archimedes, the earliest author on record, who attempted to demonstrate the property of the lever, assumes the equilibrium of equal weights at equal distances from the fulcrum, as a mechanical axiom; and he reduces to this simple and primitive case that of unequal weights, by supposing them, when commensurable, to be divided into equal parts, placed at equal distances on different points of the lever, which may thus be loaded with a number of small equal weights, at equal distances from the fulcrum.

The principle of the straight and horizontal lever being admitted, the law of equilibrium in other machines may be deduced from it. Though it is not without difficulty that the inclined plane is referred to this principle; the laws relative to which have been but lately known.

Stevinus, mathematician to Prince Maurice of Nassau, first demonstrated the principle of the inclined plane by a very indirect, though curious mode of reasoning. He considers the case of a solid triangle resting on its horizontal base, whose sides then become two inclined planes: over these he supposes a chain to be thrown, consisting of small equal weights threaded together; the upper part of such chain resting on the two inclined planes, and the lower ends hanging at liberty below the foot of the base. His reasoning is, that if the chain be not in equilibrio, it will begin to slide along the plane, and would continue so to do, the same cause still existing, for ever; thus producing a perpetual motion. But as this implies a contradiction, we must conclude the chain to be in equilibrio; in which case, as the efforts of all the weights applied to one side would be an exact counterpoise to those applied to the other, and the number of weights would be in the same ratio as the lengths of the planes; he concludes that the weights will be in equilibrio on the inclined planes when they are to each other as the lengths of the planes; but that when the plane is vertical, the power is equal to the weight; and that therefore, in every inclined plane, the power is to the weight as the height of the plane to its length.

Virtual velocity is that which a body in equilibrium is disposed to receive whenever the equilibrium is disturbed; in other words, it is what a body actually receives in the first moment of its motion.

The principle of virtual velocity, in its most general form, is as follows: suppose a system in equilibrium composed of a number of points, drawn in any direction, by whatever forces, to be so put in motion, as that every point shall describe an infinitely small space, indicative of its virtual velocity; the sum of the forces being each multiplied by the space described by the point to which it is applied, in the direction of the force, will equal 0; the small spaces described in the direction of the forces being estimated as positive, and those in a contrary direction as negative. Galileo, in his *Treatise on Mechanical Science*, and in his *Dialogues*, proposes this principle as a general property in the equilibrium of machines; he appears to have been the first writer on mechanics, who was acquainted with it. His disciple Torricelli was the author of another principle, which seems to be but a necessary consequence of Galileo's. He supposes two weights to be so connected, that however placed, their centre of gravity shall neither rise nor fall; in every situation, therefore, they will be in equilibrio. He contents himself with applying this principle to inclined planes; but it equally applies to all machines.

Des Cartes deduced the equilibrium of different forces from a similar principle; but he presented it under another, and less general point of view, than Galileo had done; for he argues that to lift a given weight to a certain height, precisely the same force is requisite that would be sufficient to raise a heavier to a height proportionally less, or a lighter to a height proportionally greater; therefore two unequal weights will be in equilibrio, when the perpendicular spaces described by them are reciprocally proportioned to them. In the application of this principle, however, only the spaces described in the first instant of motion are to be considered; otherwise the accurate law of equilibrium will not be attained.

Another principle, recurred to by some authors in the solution of problems relative to the equilibrium of forces, arises out of the foregoing, *viz.* When a system of heavy bodies is in equilibrio, the centre of gravity is the lowest possible. For the centre of gravity of a body is the lowest, when the differential of its descent is 0, as can be demonstrated from the principle *de maximus et minimus;* that is, when the centre of gravity neither ascends nor descends by an infinitely small change in the position of the system.

J. Bernouilli first perceived the great utility of generalizing this principle of virtual velocity, and applied it to the solution of problems; in which he was followed by Varignon, who has devoted the whole of the ninth section of his *Nouvelle Mechanique* to demonstrate its truth and exemplify its utility in various cases in statics.

In the *Mémoires de l' Académie* for 1740, Maupertuis proposed another principle, originating in the same source, under the title of "The Law of Repose;" which was afterwards extended by Euler, and explained in the Memoirs of the Berlin Academy for 1751: and the principle assumed by Mons. Courtivron, in the *Mémoires de l' Académie* for 1748-9, is of the same nature: *viz.*, that of all the situations which a system of bodies can successively take, that wherein the system must be placed to remain in equilibrio, is that in which the *vis viva* is either a maximum or a minimum, because the *vis viva* is the sum of the respective masses composing the system, each multiplied into the square of its velocity.

Of all these methods, that of virtual velocity appears to be most generally useful; indeed all the others are derived from it, and are serviceable in proportion as they approach nearer to it. La Grange has given practical examples of the analytical processes for determining general formulæ or equations for the equilibrium of any system; and La Place has demonstrated the principle on which the calculus is founded.

In the foregoing observations, force is supposed to be the product of the mass of a material point, by the velocity it would receive if entirely free. By confining these considerations to the case of a single material point, the conditions of equilibrium will be found to be analogous to those above spoken of, but much simplified.

The most elementary equation to express the state of equilibrium of a material point, acted on by any number of forces, is, that every force, multiplied by the element of its direction, equals 0: thus, suppose the point to change its position in an infinitely small degree in any direction; then, in the case of equilibrium, if every force be multiplied by the elementary space approached to, or receded from by the point, the force being estimated in its direction, the product will be 0.

Here the point is supposed to be free; but if constrained to move on a curved surface, it will experience a reaction equal and contrary to the pressure which it exerts on such surface, but perpendicular to it, or in the direction of the radius of the curve. This reaction may be considered as a new force, which, multiplied by the elements of its direction, must be added to the former equation. But if the variation of position, instead of being taken arbitrarily, be taken upon the curve, so as not to alter the conditions of the problem, the preceding equation will still hold good, because the elementary variation of the radius is equal to 0, as is evident from inspection. Again, if the magnitude of any force, or its intensity, multiplied by the distance of its direction from any fixed point, be denominated its *moment*, relatively to such point, it will be found that the sum of the moments of the producing forces is always equal to that of the resulting force; and in case of equilibrium the sum of the moments of all the forces equals 0.

If the forces acting on a point, or on a system of points, be not so proportioned as to maintain the system in equilibrium, a motion must necessarily take place, the laws of which may be deduced from an extension of the principles laid down for investigating the state of equilibrium; a method pursued by La Grange, and after him by La Place. The former combines the principle of virtual velocities with that of D'Alembert, which is very simple, and, though long unobserved, may be considered as an axiom. It is as follows:

If several bodies have a tendency to motion, in directions, and with velocities, which they are constrained to change in consequence of their reciprocal reaction; the motion so induced may be considered as composed of two others, one of which the bodies actually assume, and the other such, that had the bodies been only acted upon by it, they would have remained in equilibrium. This theorem is not of itself sufficient to solve a problem, because it is always necessary to derive some condition relative to the equilibrium from other considerations; and the difficulty of determining the forces and the laws of their equilibrium, sometimes renders this application more difficult, and the process more tedious, than if the solution were performed upon some principle more complex and more indirect. To obviate this objection, therefore, La Grange attempted to combine the principle of D'Alembert with that of virtual velocity; in which he was so successful, that he was enabled to deduce the general equations relating to the forces acting on a system of bodies. His description of the method is as follows:

To form an accurate conception of the mode in which these principles are applied, it is necessary to recur to the general principle of virtual velocity, *viz.* When a system of material points, solicited by any force, is in equilibrium, if the system receive ever so small an alteration in its position, every point will naturally and consequently describe a small space; each of which spaces being multiplied by the sum of each force, according to the direction of such force, must equal 0.

Now, supposing the system to be in motion, the motion that each point makes in an instant may be considered as composed of two, one of them being that which the point acquires in the following instant; consequently, the other must be destroyed by the reciprocal action of the points or bodies upon each other, as well as of the moving forces by which they are solicited. There will therefore be an equilibrium between these forces and the pressures or resistances resulting from the motions lost by the bodies from one instant to another. Therefore, to extend to the motion of a system of bodies, the formulæ of its equilibrium, it is only necessary to add the terms due to the last-mentioned forces.

The decrement of the velocities, which every particle has in the direction of three fixed rectangular co-ordinates, represents the motions lost in those directions; and their increment represents such as are lost in the opposite directions. Therefore, the resulting pressures or forces of these motions destroyed will be generally expressed by the mass multiplied into the element of the velocity, divided by the element of the time; and their directions will be directly opposite to those of the velocities.

By these means the terms required may be analytically expressed, and a general formula obtained for the motion of a system of bodies, which will comprehend the solution of all the problems in dynamics; and a simple extension of it will give the necessary equations for each problem.

A great advantage derived from this formula is, that it gives directly a number of general equations, wherein are included the principles or theorems, known under the appellations of *conservation of the vis viva; conservation of the motion of the centre of gravity; conservation of equal areas;* and the *principle of the least action.*

Of these, the first, the *conservation of the vis viva*, was discovered by Huygens, though under a form somewhat different from that which we now give to it. As employed by him, it consisted in the equality between the ascent and descent of the centre of gravity of several weighty bodies, which descend together, and then ascend separately by the force they had respectively acquired. But by the known properties of the centre of gravity, the space it describes in any direction is expressed by the sum of the products of the mass of each body by the space such body has described in the same direction, divided by the sum of the masses. Galileo, on the other hand, has shown in his problems, that the vertical space described by a weighty body in its descent is proportional to the square of the velocity acquired, and by which it will reascend to its former elevation. The principle of Huygens is therefore reduced to this; that in the motion of a system of bodies, the sum of the masses by the squares of the velocities is constantly the same, whether the bodies descend conjointly, or whether they freely descend separately through the same vertical channel.

This principle had been considered only as a simple theorem of mechanics, till J. Bernouilli adopted the distinction, established by Leibnitz, between such pressures as act without producing actual motion, and the living forces, as they were termed, which produced motion; as likewise the measures of these forces by the products of the masses by the squares of the velocities. Bernouilli saw nothing in this principle but a consequence of the theory of the *vis viva*, and a general law of nature, in consequence of which, the sum of the *vis viva* of several bodies preserves itself the same, as long as they continue to act upon each other by simple pressures, and is always equal to the simple *vis viva*, resulting from the action of the forces by which the body is really moved. To this principle he gave the name of *conservatio vivium vivarum*, and successfully employed it in the solution of several problems that had not before been effected.

From this same principle, his son, D. Bernouilli, deduced the law of the motion of fluids in vases, which he explains in the *Berlin Memoirs* for 1748: a subject before but little understood.

The advantage of this principle consists in its affording immediately an equation between the velocities of the bodies and the variable quantities which determine their position in space; so that when by the nature of the problem these variable quantities are reduced to one, the equation is of itself sufficient for its solution, as in the instance of the problem relating to the centre of oscillation. In general, the conservation of the *vis viva* gives a first integral of the several differential equations of each problem, which is often of great utility.

The second principle above alluded to, *conservation of the motion of the centre of gravity*, is given by Sir Isaac Newton in his *Principia*, as an elementary proposition; where he demonstrates, that the state of repose or of motion of the centre of gravity of several bodies, is not altered by the reciprocal action of these bodies, in any manner whatever: so that the centre of gravity of bodies acting upon each other, either by means of cords or of levers, or by the laws of attraction, remains always in repose, or move uniformly in a direct line, unless disturbed by some exterior action or obstacle. This theorem has been extended by D'Alembert, who has demonstrated, that if every body in the system be solicited by a constant accelerating force, either acting in parallel lines, or directed towards a fixed point, but varying with the distance, the centre of gravity will describe a similar curve to what it would have done, had the bodies been free. And, it might be added, the motion of this centre will be the same as if all the forces of the bodies were applied to it, each in its proper direction. This principle serves to determine the motion of the centre of gravity, independently of the respective motions of the bodies; and thus it will ever afford three finite equations between the co-ordinates of the bodies and the times; and these equations will be the integrals of the differential equations of the problem.

The third principle, the *conservation of equal areas*, is more modern than the two former, and appears to have been separately discovered by Euler, D. Bernouilli, and D'Arcy, about the same period, though under different forms.

Euler and Bernouilli describe the principle thus: In the motion of several bodies round a fixed centre, the sum of the products of the mass of each body by the velocity of rotation round the centre, and by its distance from the same centre, is always independent of any mutual action exerted by the bodies upon each other, and preserves itself the same as long as there is no exterior action or obstacle. Such is the principle described by D. Bernouilli in the first volume of the *Memoirs of the Berlin Academy*, 1746; and by D'Alembert, in the same year, in his *Opuscula*. The Chevalier D'Arcy, also in the same year, sent his Memoir to the Academy of Paris, though it was not printed till 1752, wherein he says, "The sum of the products of the mass of each body by the area traced by its radius vector about a fixed point, is always proportional to the times."

This principle, however, is only a generalization of Sir Isaac's theorem of equality of areas described by centripetal forces: and to perceive its analogy, or rather its identity with that of Euler and Bernouilli, it is only requisite to recollect, that the velocity of rotation is expressed by the element of the circular arc divided by that of the time; and that the first of these elements multiplied by the distance from the centre, gives the element of the area described about it. It appears then that this latter principle is only the differential expression of that of the Chevalier, who afterwards gave the same principle in another form, which renders it more similar to the preceding, viz. The sum of the products of the masses by the velocities, and by the perpendiculars drawn from the centre to the direction of the forces, is always a constant quantity. Under this point of view, M. D'Arcy set up a kind of metaphysical principle, which he denominates the *conservation of action*, in opposition to, or rather as a substitute for, the principle of the least action.

But leaving these vague and arbitrary denominations, which neither constitute the essence of the laws of nature, nor are able to raise the simple results of the known laws of mechanics to the rank of final causes, let us return to the principle in question, which takes place in every system of bodies acting on each other in any manner whatever, whether by means of cords, inflexible lines, attractions, &c., and also drawn by forces directed to a centre, whether the system be entirely free, or constrained to move about it. The sum of the products of the masses by the areas described about this centre, and projected on any plane, is always proportional to the time; so that by referring these areas to three rectangular planes, we obtain three differential equations of the first order, between the time and the co-ordinates of the curves described by the bodies; and in these equations, the nature of the principle properly exists.

The fourth principle, that *of the least action*, was so denominated by Maupertuis, and has since been rendered celebrated by the writings of several illustrious authors. Analytically it is as follows: In the motion of bodies acting upon each other, the sum of the products of the masses by the velocities, and by the spaces described, is a minimum. Maupertuis has published two memoirs on this principle; one in the *Transactions of the Academy of Sciences*, for 1744; the other, in those of the Academy of Berlin, 1746; wherein he deduces from it, the laws of reflection and refraction of light, and those of the shock of bodies. It appears, however, that these applications are not only too partial for establishing the truth of a general principle, but they are in themselves too vague and arbitrary; so that the consequences attempted to be deduced become uncertain: this principle, therefore, deserves not to be classed with the three foregoing. There is, however, one point of view, in which it may be considered as more general and exact, and which alone merits the attention of geometricians. Euler first suggested the idea at the close of his *Treatise on Isoperimetrical Problems*, published at Lausanne, in 1744, wherein he shows that in trajectories described by central forces, the integral of the velocity multiplied by the element of the curve is constantly either a maximum or a minimum; but he knew of this property only as pertaining to insulated bodies. La Grange extended it to the motion of a system of bodies acting on each other, and demonstrated a new general principle, viz. That the sum of the products of the masses by the integrals of the velocities multiplied by the elements of the spaces described, is always a maximum or a minimum.

From a combination of this latter principle with that of the conservation of the *vis viva*, many difficult problems in dynamics may be solved; as exemplified by La Grange in the *Memoirs of the Academy of Turin*, vol. ii.

La Place, in the *Méchanique Céleste*, treats the doctrine of dynamics much in the same manner as La Grange, but he carries his investigations much farther. He agrees with that writer in adopting the principle of D'Alembert, and in resolving every motion into two; that which the particle had in the preceding instant, and that which would have maintained it in equilibrio: but he differs from him in not admitting the principle of virtual velocity to be assumed as a fundamental axiom; which he demonstrates by a regular train of inductions.

After having established nearly the same formulæ, or differential equations, and deduced all the general principles in the manner just described, he introduces others in the nature of corollaries, many of which merit peculiar consideration. From the principle of the conservation of areas, it follows, that in the motion of a system of bodies solicited only by their mutual attraction and by forces directed to the origin of the co-ordinates, there exists a plane passing through such origin, which possesses the following remarkable properties:

1. That the sum of the areas traced on the plane by the projections of the *radii vectores* of the bodies, and multiplied by their respective masses, will be the greatest possible.

2. That such sum is also equal 0 upon all the planes perpendicular to it.

As the principle of the *vis viva*, and that of areas, subsist relatively to the centre of gravity, even though the latter be supposed to have a rectilinear uniform motion, it follows, that a plane may be determined as passing through this moveable origin, on which the sum of the areas, described by the projections of the radii vectores, and multiplied respectively by their masses, may be the greatest possible. This plane being parallel to the one passing through the fixed origin, satisfies the same conditions; and another plane passing through the centre of gravity, and determined according to the foregoing conditions, will remain parallel to itself during the motion of the system; a circumstance of considerable utility and importance. To this we may add, that any plane parallel to the last-mentioned, and passing through any of the bodies, partakes of analogous properties.

La Place next examines how far these results would be changed, if other relations subsisted between the force and the velocity. Force, he observes, may be expressed in a great variety of ways relatively to the velocity, besides that of the simple law of proportionality, without implying any mathematical contradiction. Suppose the force to be some other function of the velocity, (analytically expressed by $F = \phi\, v$;) in this case the principle of the *vis viva* will be found to obtain in all the possible mathematical relations between the force and the velocity; the *vis viva* of a body being the product of its mass by double the integral of its velocity, multiplied by the differential of the function of the velocity indicative of the force.

The uniform rectilinear motion of the centre of gravity is preserved by the law of nature alone; by which also the conservation of areas subsists. But a principle analogous to that of the least action will be found to belong to every possible relation between force and velocity.

The principle of the least action is not so obvious as the others that have been mentioned, being more remote from the elementary theorems, from which they are all derived; nevertheless, if it be directly and mathematically deducible from the same simple principles, it must immediately be divested of all pretension to the dignity of a final cause; to which it can have no greater claim than any other remarkable numerical property; for the reverse would imply a mathematical contradiction. The fact, which is curious, may be thus analytically stated: Suppose a material point to move under the impulse of several forces from one point to another; the curve which it describes possesses the remarkable property of having the integral or continued product of the velocity (determined by previous considerations) when multiplied into the element of the curve, less than any other curve passing through the same points.

Maupertuis, who discovered this principle, carried it no further than to single bodies; Euler established its generality; and La Grange extended it to a system of bodies acting on each other, as already noticed. The principle of the least action being therefore admitted as an established theorem, it may be resorted to for the solution of problems, and for determining the trajectories of bodies moving in space; but in point of practical utility, the necessary calculations are so much more complex and difficult than the more usual methods of investigation, that the latter are greatly to be preferred to it.

Upon these leading principles of the doctrine of forces, as laid down by the most eminent writers on the subject, it is to be remarked, that they are for the most part mere developments of theorems easily deducible from the Newtonian laws of motion; and that many of them were even established by Newton himself. This generalization of mechanical principles possesses, however, the advantage of enabling us to take a more enlarged and comprehensive view of the subject, than we could do by the consideration of a single problem.

Forces, which become the subject of mathematical computation, may be appropriately divided into the three following classes:

1. Such as act instantaneously, or for a short interval of time, and impart uniform motion to a particle subjected to their action; provided it be not solicited by any force, and is free to move in any direction.

2. Such as, acting with a continued uniform intensity, oblige a material particle, at liberty to obey their impulse, to describe its path with a uniformly accelerated motion.

3. Those, whose intensities, perpetually varying, though according to some known law, produce a complicated action, whose circumstances can only be investigated by means of the integral calculus, or some analogous methods.

Forces whose mode of action is too arbitrary and uncertain to be included in either of these classes, may be considered as foreign to the present investigation.

The reader who wishes to have more scientific information on this subject, may refer to Gregory's Mechanics; Dr. Jackson's Theoretical Mechanics; and may also consult Marat's Mechanics, Wood's Mechanics, or Whewell's Mechanics. Professor Leslie also, (in his Elements of Natural Philosophy,) has given an excellent popular illustration, by supposing the threads to act on light spiral springs adapted to measure the forces, and commonly called spring steel-yards; but he acknowledges pulleys and weights have some advantages. By reversing the action of the springs, they might be applied, with much advantage, to show the relations of compressing forces, by lecturers on mechanical science.

Force, *Mechanical*. Desaguliers, in his *Experimental Philosophy*, has many curious and useful observations concerning the comparative forces of men and horses, and the best mode of applying them. And Dr. Young, in his *Lectures*, has given a table of a similar nature, compiled chiefly from the writings of Desaguliers and Coulomb, another writer, who has also displayed considerable ingenuity in pursuing the subject. The following extract cannot fail of being useful to all concerned in practical mechanics.

In his introduction to his Table, Dr. Young observes, that to compare the different estimates of moving power, it will be convenient to take an unit as the mean effect of the labour of an active man, and without impediment. This will be found, on a moderate estimation, sufficient to raise 10lb. to the height of 10 feet in a second, for 10 hours in a day; or to raise 100lb., which is the weight of twelve wine gallons of water, 1 foot in a second, or 36,000 feet in a day; or 3,600,000lb., or 432,000 gallons, 1 foot in a day. This we may call a force of 1 continued 36,000."

In a pile engine, $55\frac{1}{2}$lb. (French) were raised 1 foot (French) in 1″, for 5 hours a day, by a rope drawn horizontally. *Coulomb*....	.64	5h	.82
Robison says, that a feeble old man raised 7 cubic feet of water $11\frac{1}{2}$ feet in 1′, for 8 or 10 hours a day, by walking backwards and forwards on a lever. *Enc. Br*......	.837	9h	.753
A young man, weighing 135lb. and carrying 30lb. raised $9\frac{1}{2}$ cubic feet $11\frac{1}{2}$ feet high, for 10 hours a day, without fatigue. *Robison*..........................	1.106	10h	1.106
Wynne's machine enables a man to raise a hogshead 20 feet in 1 minute. *Young*..	1.75	1′	

"*Force of Horses.*

	Force.	Continuation.	Days' Work.
Two horses attached to a plough on moderate ground, exerted each a force of 150 (French.) *Amontons.* We may suppose that they went a little more than two miles an hour for 8 hours.................	5.4	8′	4.32
A horse draws with the greatest advantage when the line of direction is level with his breast; and he can draw with a force of 200lb. $2\frac{1}{2}$ miles an hour, for 8 hours in the day..........................	7.33	8h	5.87
With a force of 240, only 6 hours. On a carriage, indeed, where friction alone is to be overcome, a middling horse will draw 1000lb. *Desaguliers*................	8.8	6h	5.28
The mean draught of four horses was 36 myriogrammes each, or 794lb. *Regnier.* This must have been momentary. Supposing the velocity 2 feet in 1″, the action would have been...................	15.88	1″	
By means of pumps, a horse can raise 250 hogsheads of water 10 feet high, in an hour. *Smeaton's Reports*............	3.64	1h	

"A horse can in general draw no more up a steep hill than three men can carry, that is, from 450lb. to 750lb.; but a strong horse can draw 2000lb. up a steep hill, that is but short. The worst way of applying the force of a horse, is to make him carry or draw up-hill; for, if the hill be steep, three men will do more than a horse, each man climbing up faster with a burden of 100lb. weight, than a horse that is loaded with 300lb., a difference arising from the position of the parts of the human body being better adapted to climbing than those of a horse.

"On the other hand, the best way of applying the force of a horse, is in an horizontal direction, wherein a man can exert least force: thus a man, weighing 140lb., and drawing a boat along by means of a rope coming over his shoulders, cannot draw above 27lb., or exert above one-seventh part of the force of a horse employed to the same purpose.

"The very best and most effectual posture in a man, is that of rowing; wherein he not only acts with more muscles at once for overcoming the resistance, than in any other position; but as he pulls backwards, the weight of his body assists by way of lever.—*Desaguliers.*

"The diameter of a walk for a horse-mill, ought to be at least 25 or 30 feet.—*Desaguliers.*

"Some horses have carried 650lb. or 700lb. seven or eight miles without resting, as their ordinary work; and a horse at Stourbridge carried 11cwt. of iron, or 1232lb. for eight miles.—*Desaguliers, Exp. Philos.* vol. i.

"*Work of Mules.*	Force.	Continuation.	Day's Work.
Cazanel says, that a mule works in the West Indies two hours, out of about 18, with a force of about 150lb. walking 3 feet in a second..................	4.4	$2^h\ 40'$	1.2

Force, *Inanimate.* "According to M. Coulomb, a windmill with four sails, measuring 66 feet (French) from one extremity to that of the opposite sail, and 6 feet wide, or a little more, is capable of raising 1000lb. (French) 218 feet in 1′ and of working on an average 8 hours in a day. This is equivalent to the work of 34 men, as it has been above estimated, 25 square feet of canvass performing about the daily work of a man.

"Robison says, that 1 cwt. of coals burned in a steam-engine will raise at least 20,000 cubic feet of water 24 feet high; this is equivalent to the daily labour of 8.32 men. A steam-engine in London, with a 24-inch cylinder, does the work of 72 horses, and consumes a chaldron of coals in a day; each bushel being equivalent to two horses, and each square inch of the cylinder performing nearly the work of a man.

"If we calculate the quantity of motion produced by gunpowder, we shall find that this agent, though extremely convenient, is far more expensive than human labour; but the advantage of gunpowder consists in the great rarity of the acting substance. A spring or a bow can only act with a moderate velocity, on account of its own weight. The air of the atmosphere, however compressed, could not flow into a vacuum with a velocity so great as 1,500 feet in a second. Hydrogen gas might move more rapidly, but the elastic substance produced by gunpowder is capable of propelling a very heavy cannon-ball with much greater velocity.

"It is said, that nine tons of water, falling 10 feet, will grind and dress a bushel of wheat; consequently a man might do the same in 33′ 36″."

FORE-FRONT, the principal or front entrance of a building.

FORE-GROUND, that part of the field of a picture which is nearest the observer.

FORE-PLANE, in carpentry and joinery, the first plane used after the saw or axe. See Tools.

FORE-SHORTEN, in perspective, the diminution which the representation of the side or part of a body has in one of its dimensions, compared with the other, occasioned by the obliquity of the corresponding side or part of the original body to the plane of projection.

FOREYN, an ancient term signifying a cesspool or drain.

FORGE, a smith's furnace.

FORM (from the Latin, *forma*) the external appearance, or the disposition of the surfaces of a body; in which sense it is synonymous with Figure, which see.

Form, in joinery, the long seats or benches in the choirs of churches, for the priests, canons, prebendaries, &c. to sit on. Du Cange supposes the name derived from the backs of the seats being anciently enriched with figures of painting and sculpture, called in Latin *formæ et typi.*

FORMERETS, (from the French) the arches which are next the wall in Gothic groins; these are only half the thickness of those that divide the vault into compartments.

FORM-PIECES, the lower ends of the mullions of windows which are worked upon the sills. The same as Stool-pieces.

FORT, (Latin, *fortis* strong) a fortified building; a building strengthened by artificial means. The term is usually applied to small detached buildings.

FORTALICE, a small castle.

FORNIX, (Latin) an arch or vault. *See* Arch, and Vault.

FORUM, (Latin) in Roman antiquity, the market-place for transacting the business of the public revenue, bankers, merchants, &c. The following description of it is given by Vitruvius:

"The Greeks made their forums square, with large double porticos, the columns close together, and adorned with stone or marble epistyliums, making ambulatories in the upper stories: but the cities of Italy follow not the same method; because, by ancient custom, the shows of gladiators are usually given in the forum. For this reason the intercolumns around the area are made wider; and in the surrounding porticos the shops of the bankers are disposed, with galleries in the upper floors, properly adapted for the use and management of the public revenue.

"The magnitude of the forum should be suitable to the number of the people, that it may not be too small for use, nor on account of the scarcity of people, appear too large. The proportion is so determined, that the length being divided into three parts, two are given to the breadth; for thus it will be of an oblong form, and convenient for the use of the shows.

"The upper columns are made a fourth part less than the lower; because, as the inferior sustains the greater weight, it should be stronger than the superior: also because it is proper to imitate nature; for in straight-growing trees, such as the fir, cypress, and pine, there are none thicker at the top than at the root; and as they grow in height, they gradually diminish to the uppermost point. Following therefore the example of nature, it is proper that the superior should be made less than the inferior, both in height and thickness.

"The basilica should be joined to the forum on the warmest side, that the negociants may confer together, without being incommoded by the weather. The breadth is not made less than the third, nor more than the half of the length, unless the

the nature of the place opposes the proportion, and obliges the symmetry to be different. But if the basilica have too much length, chalcidicæ are made at the ends, as they are in the basilica of Julia Aquiliana. The columns of the basilica are made as high as the porticus is broad. The porticus is the third part of the space in the middle. The upper columns are less than the lower, as above written. The pluteum, which is between the upper columns, should also be made a fourth part less than the same columns, that those who walk in the floor above may not be seen by the negociators below. The epistylium, zophorus, and coronæ, are proportioned to the columns in the manner explained in the third book.

"Nor will basilicas of the kind of that at the colony of Julia of Fanum, which I designed and conducted, have less dignity and beauty; the proportions and symmetry of which are as follow: The middle testudo between the columns is 120 feet long, and 60 feet broad. The porticus around the testudo, between the walls and columns, is 20 feet broad. The height of the continued columns, including their capitals, is 50 feet, and the thickness 5, having behind them parastatæ 20 feet high, $2\frac{1}{2}$ feet broad, and $1\frac{1}{2}$ foot thick, which sustain the beams that bear the floors of the porticos. Above these are other parastatæ 18 feet high, 2 feet broad, and 1 foot thick, which also receives beams sustaining the canthers of the porticos, which are laid below the roof of the testudo: the remaining space that is left between the beams which lie over the parastatæ, and those which lie over the columns, is left open in the intercolumns, in order to give light. The columns in the breadth of the testudo, including those of the angles to the right and left, are four; and in the length, on that side which is next the forum, including the same angle-columns, eight. On the other side, there are but six columns, including those of the angles, because the middle two on this side are omitted, that they may not obstruct the view of the pronaos of the temple of Augustus, which is situated in the middle of the side-wall of the basilica, looking towards the centre of the forum and temple of Jupiter. The tribunal in this building is formed in the figure of a hemicycle: the extent of this hemicycle in front is 46 feet, and the recess of the curvature inward 15 feet, so that those who attend the magistrate obstruct not the negociants in the basilica.

"Upon the columns, the compacted beams, made from three timbers of two feet are placed around; and those from the third columns which are in the interior part, are returned to the antæ that project from the pronaos, and on the right and left touch the hemicycle.

"Upon the beams, perpendicularly to the capitals, the pilæ are placed, three feet high and four feet broad, on every side. Over these, other beams, well wrought from two timbers, of two feet, are placed around; upon which, the transtræ and capreols, being placed coincident with the zophorus, antæ, and walls of the pronaos, sustain one culmen the whole length of the basilica, and another transversely from the middle over the pronaos of the temple: so that it causes a double disposition of the fastigium, and gives a handsome appearance to the roof on the outside, and to the lofty testudo within. Also, the omission of the ornaments of the epistylium, and of the upper columns and plutei, diminishes the labour of the work, and saves great part of the expense. The columns likewise being carried in one continued height up to the beams of the testudo, increases the magnificence and dignity of the work."

Forum is also used for any place in which the governor of a province convened the people, to give judgment according to the course of the law.

Forum also meant a public standing-place in the city of Rome, where causes were judicially tried, and orations delivered to the people.

The Roman foræ were of two kinds—Fora Civilia and Venalia; the former were for law and political affairs, the latter for the purposes of trade. Of the Fora Civilia, there were at first only three, viz., Romanum, Julianum, and Augustum; but their number was afterwards increased to six, by the addition of the transitorium, called also palladium, the Trajanum, and Salusti.

The first and most eminent of these was the *forum Romanum*, called also *forum vetus*. In the time of Romulus, this forum was only a large open space, without buildings or other ornament. It was first enclosed by Hostilius, adorned with porticos by Tarquin the Elder, and at length, by the additions of succeeding kings, consuls, and magistrates, it became one of the most elegant and noble places in the world. It was called *forum Romanum*, or simply *forum*, by way of eminence, on account of its antiquity, in comparison with the other fora, and from its more general use in public affairs. It was also called *forum Latinum*, *forum magnum*, and *old forum*. The comitium, used sometimes for holding the comitia, was a part of this forum, in which stood the *rostrum*, a sort of pulpit, adorned with the beaks of ships taken in a sea-fight from the inhabitants of Antium. In this the causes were pleaded, orations were made, and panegyrics were delivered on the merits of the dead.

A very beautiful restored view of the Forum Romanum was made by Mr. C. R. Cockerell, and a reduced view was engraved and published, with his permission, in the second volume of the "Pompeii," published by the Society for the Diffusion of Useful Knowledge, to which we refer our readers for an accurate notion of the splendour of the accumulated architecture of the Forum and the Capitol, and its vicinity.

The Julian forum, called also *Cæsar's forum*, was built by Julius Cæsar with the spoils taken in the Gallic war. Its area alone, according to Suetonius, cost 100,000 sesterces; and Dio affirms, that it much exceeded the Roman forum.

Augustus's forum, built by Octavius Cæsar, was reckoned by Pliny among the wonders of the city. The most remarkable curiosity it presented was the statues in the two porticos on each side of the main building. In one were all the Latin kings, beginning with Æneas. In the other, all the kings of Rome, beginning with Romulus; most of the eminent persons in the commonwealth, and Augustus himself among the rest, with an inscription upon the pedestal of every statue, descriptive of the chief actions and exploits of the person it represented. This forum was restored by the emperor Adrian.

Nerva's forum was begun by Domitian, but finished and named by the emperor Nerva. In this forum Alexander Severus set up the statues of such of the emperors as had been deified, in imitation of what Augustus had done in his forum. This forum was called *transitorium*, because it lay very convenient as a passage to the others, and *palladium*, from a statue of Minerva which was set up in it. Scarcely anything remains of this forum except a decayed arch, which the Italians, by a strange corruption, call *Noah's ark*, instead of *Nerva's arch*.

Trajan's forum was built by the emperor Trajan with the produce of the spoils taken in his wars. The porticos, which were exceedingly beautiful and magnificent, were covered with brass, and supported by pillars of more than ordinary size, and of exquisite workmanship.

The forum of Pompeii, which was constructed in the Greek style, cannot, however, be altogether considered, if we are guided by the authority of Vitruvius, a truly Greek

Agora, which this author states was to be made square in form. It has, however, many Greek features. The Pompeian forum is of an oblong shape, surrounded on three sides with rows of columns, forming, with the advanced columns of the various buildings, a colonnade or ambulatory ; above this there was a second, if we may judge from the remains of stairs at several places at the back of the colonnade. The fourth side of the forum is enclosed with two arches placed on each side of a large hypætral temple, called the temple of Jupiter. On the west side are the prisons and the granary, before these, and the temple of Venus, and the Basilica, is an enclosed court. On the narrow side, opposite the temple of Jupiter, are three buildings, generally considered to be the Curiæ and Ærarium. On the east side is an enclosure, (the use of which has not been determined,) the Chalcidicum, the temple of Mercury, the Senaculum, and a building supposed to be a large eating-house, generally known by the name of the Pantheon, in front of which are the Tabernæ Argentariæ. The enclosed area of the forum was paved with large square pieces of marble, and the sides of the area were adorned with statues. Opposite the Curiæ, and a short way from them, is a small triumphal arch. The forum was closed at night with iron-barred gates, and it does not appear that chariots were admitted into it, as the pavement of the streets terminates at the back of the colonnade. The columns of the ambulatory are of the Greek Doric order, and were being restored in the same style, though with better materials, at the time the city was destroyed. The columns were aræostyle, and the architraves were most probably of wood, as we may infer from their being destroyed, while the frieze and cornice of stone remain.

The forum of Constantinople was erected by Constantine when he established the city on the commanding eminence of the second hill, where he pitched his tent during the siege and conquest of Byzantium. The edifice was of an elliptic form ; the two opposite entrances formed triumphal arches ; the porticos on every side were filled with statues, and the centre of the edifice was occupied by a lofty column, of which only a mutilated fragment is now left, and is degraded by the appellation of *the burnt pillar*. This column was erected on a pedestal of white marble, 20 feet high. It was composed of 10 pieces of porphyry, each of which measured about 10 feet in height, and about 33 in circumference. On the summit of the pillar, above 120 feet from the ground, stood a colossal statue of Apollo, of bronze, which had been transported hither from Athens, or from the town of Phrygia, and was supposed to be the work of Phidias. The artist had represented the god of day, or, as it was afterwards interpreted, the emperor Constantine himself, with a sceptre in his right hand, the globe of the world in his left, and a crown of rays glittering on his head. This statue was thrown down in the reign of Alexis Comnenus.

FOSSE, a trench or ditch excavated round a fortified place, to secure it from attack.

FOSSES D'AISANCES, a term used to designate the cesspools of Paris. These cesspools are constructed of materials sufficiently impermeable to filtration, so that the matter contained in them shall not penetrate through the walls, to the injury of the adjoining property. So strictly is this condition observed, that any infiltration to a neighbour's premises, according to the French law, gives a title to damages, and the architect and builder are held responsible for ten years, not only to the proprietor, but also to the neighbours, should any nuisance arise from imperfect execution of the work.

The *Fosses d'Aisances* are usually made about 10 feet long by about 5 feet 7 inches wide, and 5 feet in height to the springing of the semi-circular head. The material employed in their construction, has of late years been *meulière* or mill-stone, bedded in mortar made of lime and cement ; the inside being well pointed, and rendered throughout with the same. These cesspools are cleansed out when necessary, under the inspection and by the authority of the board of health of the city ; the carts employed, as well as all the *materiel* of the nightmen, being under the same surveillance. The work is done between ten o'clock at night and six o'clock in the morning. The contents of the cesspools are generally sufficiently fluid to allow of their extraction by pumps ; but when this is not the case, they are conveyed from below in small iron vessels ; and great care is taken to prevent, as much as possible, the escape of the noxious effluvia during the operations. When the soil is pumped into carts, a small furnace is placed over the bung-hole of the cart, to burn the gas as it rises ; and directly the cart is filled, the bung is plastered over. The lids of the vessels used to remove the more solid matter, are also plastered over in a similar manner, before they are brought out of the cesspools. For a fuller description of the Fosses d'Aisances, *see* SEWER, SEWERAGE.

FOUNDATION, (from the French) the trench or trenches excavated in the ground, in order to rest an edifice firmly upon its base. The word also means the superstructure of a stone or brick wall under the lowest floor of a building, contained within the trenches.

Foundations, according to Palladio, ought to be twice as thick as the walls to be raised upon them, so that both the quality of the earth and the greatness of the building are to be regarded, making the foundation larger in a soft and loose ground, or where there is a great weight to be supported. The plane of the trench must be as level as possible, so that the weight may press equally, and not incline more on one side than the other. For this reason the ancients were accustomed to pave the plane with Tivertine ; but the moderns most commonly lay planks or beams to build on. The foundations ought to diminish in width as they rise ; but in such a manner that the middle of the wall above may fall plumb with the middle of the lowest part ; this must also be observed in the diminution of walls above ground, because by that means the building becomes much stronger than by making the diminution any other way.

The various methods of treating the building of a foundation, according to the heterogeneous texture or uniformity of the ground, as may happen in the excavation, will be found under BRICKLAYING. Under the same head also will be found ample directions for making a foundation of CONCRETE, as now so generally used by builders. But should the foundation prove unsound, or of that character that dependence cannot be placed upon it, recourse must be had to piling, in the following manner. Good sound piles must be prepared, of such dimensions, that their thickness may be about a twelfth part of their length ; the distances at which those piles should be disposed, and the momentum requisite to drive them, will depend on the nature of the building to be erected ; and the weight they will have to bear ; the weight of the ram ought not to be more than sufficient for driving the piles, as the heavier the ram, the greater the number of men required to work it, and consequently the greater the expense. When the piling is completed, so as to be sufficient for supporting the intended structure, some builders lay a level row of cross bearers, called *sleepers*, ram the interstices with stone or brick up to the level of their faces, and then plank them over. This planking, however, may be dispensed with, if the piling be sufficiently attended to, and the expense of the foundation will thus be materially lessened. Timber should not be used with its thickness standing vertical, as it is liable to shrink, which will make the building crack or split at the junctions with the return parts.

Where the ground is not very soft, and where the wall is to be supported upon narrow piers, a piece of timber, or balk, is sometimes slit in halves, and those are either laid immediately at the bottom, or at the height of two or three courses from the bottom of the wall; which will frequently prevent settlements when the wall is to be so supported.

Forced earth, or made ground, remains unfit for the foundation of a wall, for a considerable time.

The breadth of a substructure should be proportioned to the weight of the superstructure, and to the softness of the ground on which it rests; if the texture of the ground is supposed to be constant, and the materials of the same specific gravity, the breadth of the foundation will be as the area of the vertical section passing through the line on which the breadth is measured; thus, for example, Suppose a wall 40 feet high, 2 feet thick, to have a sufficient foundation of 3 feet in breadth, what should be the breadth of the foundation of a wall 60 feet high, $2\frac{1}{2}$ feet thick? By proportion, it will be $40 \times 2 : 3 :: 60 \times 2\frac{1}{2}$: the answer$=5\frac{5}{8}$ feet. This calculation will give the breadth of the foundation of the required wall, equal to the breadth of the insisting wall itself; when the height of the required wall is equal to the ratio, which is the first term $(40 \times 2 = 80)$ divided by the second term $(3) = \frac{80}{3} = 26\frac{2}{3}$. Thus a wall of $26\frac{2}{3}$ feet would have the breadth of its foundation equal to its thickness above the foundation, and less than $26\frac{2}{3}$ feet would have a thinner foundation than even the superstructure. But though the calculation in this case gives the foundation less in breadth than the thickness of its superstructure, it must be considered that it only calculates the true breadth of the surface that should be opposed to the ground, in order to prevent the wall from penetrating by its weight: though the rule gives all the width that is necessary, on account of the weight of the insisting wall, yet the breadth of the footing should always be greater than that of the superstructure; as it will stand more firmly on its base when affected by lateral pressure, and be less liable to rock by the blowing of heavy winds. The least breadth that is commonly given to the bottom course of stone walls is one foot thicker than the superstructure. In damp situations, the superstructure should always be separated from the substructure by layers of lead, tarred paper, &c. Slate also may be used with advantage for such purposes.

FOUNTAIN, (from the French *fontaine*,) literally signifies a spring or issuing of water from the earth, but the word is also applied to a machine or artificial contrivance by which water is made to spout or dart up, called by the French a *jet d'eau*. There are various kinds of artificial fountains, but they are all formed by some description of pressure on the water, that is, the water of the fountain is made to spout up, by the weight of a head of water; by the pressure arising from the spring and elasticity of condensed air, or by machinery.

FOX-TAIL WEDGING, a method of fastening a tenon in a mortise, by splitting the end of the tenon and inserting a projecting wedge, then entering the tenon into the mortise, and driving it home; the bottom of the mortise will then resist the wedge, and force it farther into the tenon, which will expand in width, so as not only to fill the cavity at the bottom, but be firmly compressed by the sides of the mortise.

FRACTION, in arithmetic and algebra, is a part or parts of something considered as a unit or integer. Fractions are distinguished into vulgar fractions and decimal fractions. Vulgar fractions consist of two parts or quantities written one over the other, thus $\frac{2}{3}$, $\frac{3}{4}$, &c.; the quantity above the line is called the numerator, and that below the line the denominator. *See Decimal.*

FRAME, in carpentry, a combination of timber-work, composed of one or more triangular compartments, or of a mixture of triangles and quadrilaterals, the timbers being either joined together by joggles, or by being halved or let into each other.

Three pieces of timber are the least number that can constitute a frame, for the same reason that less than three straight lines cannot constitute a space. *See* the articles FLOORING, NAKED-FLOORING, PARTITION, TRUSS, and TRUSS-PARTITION.

FRAME, in joinery, an assemblage of various pieces of wood-work, forming certain compartments, according to the design, surrounding panels of wood, which are inserted in grooves made in every edge of each compartment of the frame, and thus filling up the interstices. This mode is a substitute for a board, which could not be procured in one breadth; and even if such a board could be obtained, framing would be preferable, as being much lighter, stronger, and less liable to warp. The stiffness of a frame in carpentry depends chiefly upon the triangles in its composition; but a frame in joinery depends upon the inflexibility of the joints, taking every two pieces separately, by which each joint is formed.

FRAMING, of a house, all the timber-work, *viz.*, the carcase-flooring, partitioning, roofing, ceiling, beams, ashlering, &c.

FRANKING, in sash-making, cutting a small excavation on the side of a bar for the reception of the transverse bar, so that no more of the wood be cut away than what is sufficient to show a mitre when the bars are joined to each other; by this means, the strength is impaired only in the smallest possible degree.

FRATERY, OR FRATER-HOUSE, the dining-hall of monastic buildings, otherwise termed REFECTORY.

FREEMASON, in ancient times was the term applied to a person supposed to be skilled in the art of building, more particularly in ecclesiastical construction. A freemason travelled from place to place, and by his learning in the science, and his taste in the construction of edifices, executed works celebrated for beauty and grandeur. In the present day the word is identified with the society of Freemasons, whose various ramifications are said to extend throughout the known world.

FREEDSTOOL, FRIDSTOOL, OR FRITHSTOOL, a seat placed at the east of some churches, near the altar, for those who sought the privilege of sanctuary. They were usually of stone, specimens of them in this material are still existing at Beverley and Hexham.

FREE-STONE. *See* STONE.

FREE-STUFF, that which works easily in the operation of planing, without tearing.

FREEZE, a part of the entablature of an order; more correctly spelt FRIEZE, which see.

FRENCH CASEMENTS, windows turning upon two vertical edges attached to the jambs, which when shut lap together upon the other two parallel edges, and are fastened by means of long bolts extending their whole height.

French casements are made in the form of the old English windows, the two meeting styles, which lap together, forming a munnion about four inches in breadth. The lower part only is moveable, the upper is fixed, and has a corresponding munnion, the lower rail of the fixed part and upper rail of the moveable part forming a transom.

FRESCO PAINTING, a peculiar mode of painting, performed by employing colours mixed and ground with water upon a stucco, or plaster, sufficiently fresh and wet to imbibe and embody the colours with itself. The term *fresco*, as applied to painting, is said to have been adopted because the practice of it is used in the open air; *andare al fresco* signifying "to take the air," or "walk abroad in the air:" but it seems more probable that another meaning of the word *fresco* has given rise to this particular adoption of it, viz., new, or fresh, relative to the state of the plaster on which it is wrought. Vitruvius (lib. vii. cap. 4.) calls it *udo tectorio.* It is very ancient, having been practised in the earliest ages of Greece and Rome.

The theory of the art of painting extends its principles to all modes of execution, because theoretic rules are drawn from nature, which is the object of all imitation, and are independent of the means employed in producing the intended effect. We propose, therefore, in this place, only to treat of the mode of execution, and of the materials employed in fresco painting; such observations as the recent revival of the art has rendered necessary, being deferred till after our description of the practice.

Previously to the commencement of a painting in fresco, it is necessary that a careful examination should be made of the fitness of the place to receive it. The artist must assure himself, therefore, in the first place, of the perfect construction of the walls, or ceilings, on which he intends to employ his genius, and entrust his reputation: above all, he must be careful to make it secure from damp.

Satisfied with the construction of the wall, it is then necessary the artist should see to the proper management of the first layer of plaster with which it is covered. The materials employed for building in different countries will vary according to the nature of those most easy to be obtained: and therefore it will, of course, be necessary to adopt means for rendering those not perfectly proper in themselves to receive fresco painting, more so by artificial means. Brick is certainly the one best calculated to hold the plaster perfectly; both on account of its absorbing quality, and from the smallness of the size of the bricks causing a number of interstices between them; which irregularity in the surface greatly assists in retaining the plaster in adherence. A wall built of rough stones full of holes may also be relied upon as a good foundation for fresco; but if, instead of that, it be constructed of smooth or polished stones, it will then be necessary to render it uneven by making holes in it, fastening nails, and small wedges of wood, to hold the plaster together, and prevent its falling off. These precautions are of the utmost consequence to prevent its bending or cracking, which the least alteration that happens to the materials, or even a change of weather, producing alternately wet or dry, may occasion.

The first layer of plaster may be composed of well-washed chalk made into a cement with pounded brick, or river sand; the last is better, being rather the coarsest, and producing thereby a roughness of surface which will better retain the second coat.

Tarras, composed of pounded sea-sand and chalk or lime, would perhaps be better still. The ancients had certainly a better compost for this purpose than that at present known; if we may judge from that which still covers many of their buildings; particularly the aqueduct they constructed near Naples, and the walls of the ruins of Herculaneum.

Before the second layer is given, the first must be perfectly dry, on account of a disagreeable and noxious vapour which issues from the lime in drying; but when it is so, and you proceed to give it the second coating, upon which the painting is done, it must be wetted with water, that the two may more completely incorporate. This layer, which requires to be more carefully prepared than the first, is made by mixing river-sand of an even and fine grain with chalk, which has been burnt several months before, and exposed to the air, as by that means the artist may be more sure of its general decomposition and freedom from stony parts.

It requires considerable skill in the person who prepares this ground, to lay it perfectly even, and he must be very careful in judging of the quantity proper to be laid on at once. This ought not to be more than the painter can cover and completely finish in a day; and it requires great skill and activity in spreading, to clean it from lumps and polish it evenly, so as to receive the painting with the promptitude requisite to leave the artist as much time as possible. The painter, however, should himself superintend this part of the process, for he alone can judge properly as to the rapidity with which he can work, or the advantages he may make of accidental occurrences.

The operation of laying on the ground is performed with a trowel, and in doing this, care must be taken to clean it properly, that the surface may be even, particularly in those parts most exposed to view. The mason's labour is finished by his polishing the surface to receive the painting; this is done by applying a piece of paper on the face of the wall, and passing the trowel over it. It is very necessary that this should be well done, for small inequalities in the surface might, in certain views, produce great irregularities in the drawing of the work.

When the second ground is thus prepared, cleaned, and polished, in the quantity, and on the part of the wall which the artist requires, he begins to trace his design upon it, and proceeds to the colouring of it; completely covering the quantity prepared, and finishing so much of the picture in the course of the day, in such a manner that he may not have occasion to re-touch it when the ground is dry. This is the characteristic peculiarity of painting in fresco, which, by this mode of operation, is incorporated with the mortar, and drying along with it, becomes extremely durable, and brightens in its tones and colour as it dries.

From the necessity there is in the progress of this style of art, that it should be executed with rapidity, and from the impossibility of retouching it without injuring the purity of the work; the artist, unless he be endowed with very extraordinary powers of imagination and execution indeed, is obliged to prepare a finished sketch of the subject, wrought to its proper hue and tone of colour, and so well digested, that there may be no necessity for making any essential alterations in the design. This, which is a very useful mode of proceeding in all historic works of painting, is absolutely indispensable in fresco, to those who are not determined to give the rein to their ideas, and leave as perfect whatever may first present itself. There is no beginning in this, by drawing the whole of the parts at one time, and correcting them at leisure, as is the custom in oil painting, where the artist may proceed to work without a sketch. Here all that is begun in the morning must be completed by the evening; and that almost without cessation of labour, while the plaster is wet; and not only completed in form, but also (a difficult, nay, almost impossible task, without a well-prepared sketch,) must be performed, viz., the part done in this short time must have so perfect an accordance with what follows, or has preceded of the work, that when the whole is finished, it may appear as if it had been executed at once, or in the usual mode, with sufficient time given to harmonize the various forms and tones of colour. Instead of proceeding by slow degrees to illuminate the objects, and increase the vividness of the colours, in a manner somewhat similar to the progress of nature in the rising day, till at last it shines with all its intended effect, which is the course of painting in oil; the artist working in fresco must at once rush into broad daylight; at once give all the force in light and shade and colour, which the nature of his subject requires. This, be it observed also, must be without the assistance (at least in the commencement) of contrast to regulate his eye; and therefore may be considered almost impossible, as we have before said, unless he be assisted by a well-digested and finished sketch.

The sketch being completed, the next process is to prepare a cartoon or drawing of the design on paper pasted together to the size of the intended fresco. This cartoon should be perfected in the outline to save time, and the artist has then nothing to do but to trace the line of the figures or other objects which the design may be composed of, on to the plaster, by either pricking with a pin through the paper, or by passing a hard point over the lines of the cartoon. By this means he saves himself the trouble of drawing the figures, and also the time which would be required for doing it, and proceeds at once to the painting; to facilitate the execution, and ensure the success of which, several precautions are requisite.

The colours being ground fine in water, and a sufficient quantity of the tints most likely to be employed prepared, they should be arranged in pots or basons, and several pallettes with raised edges should be ready at hand to work from, and assist in compounding the varieties of hues necessary for producing brilliancy and harmony. A few pieces of tile or brick, or of any absorbent stone, should also be provided, to prove the tints upon, because all colours ground in water become much lighter when dry, than they appear when wet. To be certain therefore of their hue, before he begins to use them on the picture, and to avoid the trouble and necessity of much changing or labouring them, (as the painters term the blending of colours,) the artist should apply some of each tint with his brush to the dry brick, &c., which, absorbing the water, the colours immediately appear very nearly of the same hue they will be of when the fresco is dry. Hence he may proceed with great security in his work, and is sure to have it much more fresh and vigorous in effect, than it would be if much labour had been employed to obtain the tone on the wall.

It will be requisite also to have at hand a vase or bason of water, or a wet sponge, and to take care not to begin to paint till the layer of mortar is hard enough to resist the impression of the finger: otherwise the colours would spread upon it, and prevent all possibility of neatness or clearness in the execution, which should be effected with great rapidity and lightness of hand.

With respect to the colours employed in fresco, they are fewer in number than those which may be used in oil painting, on account of the combined action of the lime and the air upon the component parts of many of the latter. Those most generally in use are the following, viz.:—

Lime-White.—This, when made of well-washed burnt chalk or lime, is the best and most simple white that can be used; it mixes freely with all the other colours, and works in itself with a full body. The preparation of it requires that the chalk should be slacked a twelvemonth before it is used, or at least, six months. It should then be dissolved in common water, and poured carefully off, (after letting it fall some short time,) into a vessel to settle.

Another white is made by mixing one-third of white marble powder with two-thirds of chalk; but it must be used with caution, as it is apt to change. If the proportion of marble dust be too strong for the chalk, it will become black. The artist will therefore do well to confine himself to chalk white, provided it has been well prepared, and kept a long time. As this, however, has frequently been used, we deemed it proper to be mentioned, that artists may, if they choose, make experiments upon its nature, and endeavour, if they find any peculiarly valuable quality in it, to ensure its continuance in clearness and perfection.

Egg-shell White.—There is also a third white, made of egg-shells, which, though it has not the full texture of the chalk, is yet very clear and good for use in fresco. It is made by boiling egg-shells in water with a little quick-lime. They are then put into a pot, and washed with pure water. Then pounded fine, washed again till no tint is given to the water, and then ground by the muller and stone to the degree fit for use; it is afterwards formed into little cakes, which are dried in the sun. Care must be taken not to let the powder of the shells remain too long in the same water, as it will exhale a fetid vapour almost insupportable, which cannot be dissipated but by roasting it in a close vessel, well luted.

Red—produced by burnt vitriol, in colour approaching to Indian red, and ground in spirits of wine, acts well with the lime, resists the action of the air, and mixes cleanly with the other colours. This forms an excellent preparation to receive the bright red of cinnabar or vermilion, when the whole wall is covered.

Colours of earthy textures, such as the ochres, whether burnt or not burnt, umber, both raw and burnt, Spanish red, Verd de Verona, Venice black, and blue black, made by bruising vine-stalks, or shells of peach-nuts, are all excellent for the purposes of fresco painting.

Blues.—The best is the ultramarine, as it never suffers any change. Smalt or enamel blue is good as to preserving its tone, and, if used early in the work, will adhere; but if the ground should become too dry before it is used, it is apt not to incorporate strongly with it, but to come off on the least friction.

White lead, lake, verdigris, masticot, Naples yellow, the orpiments, and bone black, are all unfit for this purpose, being liable to change.

Painting in fresco, when carefully executed, is of all others the most durable, and therefore the most proper to be employed in adorning public buildings. The use of it for this purpose appears to be very ancient. Norden speaks of paintings in Egyptian palaces 80 feet high, which Winkelman quoting, concludes they were in fresco, from the description given of the prepared grounds, and of the manner in which the colours appear to have been used. And all the paintings found at Herculaneum, at Portici, and at Rome, of ancient date, are of the same materials. No other kind of painting would so effectually have resisted the action of the air for so great a length of time, and more particularly the excessive aridity which those of Herculaneum must have endured, being shut up entirely from the light, and amidst glowing embers from Vesuvius, emitting of course, especially at first, an intense heat around them. That, however, in one point of view, was favourable to the preservation of those that escaped its immediate action; for damp is the most powerful destroyer of them, against which no caution taken can make them too secure. In this case of Herculaneum, damp must have been effectually excluded, first by the heat of the ashes, and afterwards, as the stratum of those ashes was so thick, water from above could not penetrate so low as to the pictures, particularly after the upper part was covered with the close cake formed by the decomposed parts, on and near the surface.

In ordinary situations, the choice of materials is the most important part, to secure the durability of the work, and particularly the greatest care is necessary in the preparation of the ground, and of the wall, to cause it to adhere.

Fresco painting has been chiefly employed in palaces, temples, and other public edifices. For large and important places no other kind of painting is so good. As the artist is obliged, from its nature, to proceed with rapidity in its production, it has necessarily more spirit and vigour in the execution, than paintings in oil, which may be repeated, and re-touched, as often as the artist fancies he can improve, or heighten their effect. In fresco there is not time to meddle, and disturb the freshness of the colour, or the fulness and freedom of the touch. But there can be no minute detail of forms, or extensive variety in the gradation of tints; the beauties of neatness, and delicacy of finishing, make no part of the excellencies of this branch of the art; it will not bear the close examination which well-finished pictures in oil do; there is something dry and rough in its appearance, unpleasing, to the common observer, on too close an inspection. It lacks the full rich sweetness of hue and texture which oil paintings possess; and though it has more freshness, and retains it, yet from the confined number of colours which can be employed in it, it is not equal to oil in the perfection of the imitation of nature.

Whoever seeks to be pleased with fresco painting, must learn justly to estimate the best, and not the most agreeable qualities of the art. Character, contour, expression, are within its powers; and are the points which the great artists who practice it, knowing its limits, will endeavour most to exhibit in their productions. Harmony of colouring, chiaro-oscuro, and the minute graces of execution, have never yet been rendered in it, or but very partially, in comparison with works in oil.

In the early part of the restoration of painting, a species of fresco was the only mode of practising the art, in use. A ground of chalk was prepared on tablets of wood, and the colours laid on it, ground and mixed in water only, or with some gluten soluble in it. The surface of the picture was afterwards covered with a varnish, to secure it from rubbing, and to give the tints more force and lustre.

"Fresco," observes a writer in *The Builder*, "was much used in England some four or five centuries since, in both ecclesiastical and civil structures of importance; the subjects being chiefly scriptural, with occasional deviations in favour of some legendary achievement, or as a pictorial record of some well-contested battle-field. With these bold and beautiful, but unresisting memorials of things sacred, and deeds that redounded to national glory, the fanatical spirit of the sixteenth and seventeenth centuries warred to extermination; neither the enrichments of the temple bestowed by the constant piety of our ancestors, nor the grateful reminiscences of heroic services of the state, were permitted to escape the devilries enacted by the factitious saints of the Puritan calendar: the frescoes perished; but better taste and better feelings have supervened, bidding fair to re-establish both the art itself, and the influential purposes to which it was anciently devoted."

The report of Mr. Barry on the proposed decorations of the interior of the new Houses of Parliament, is really a splendid programme of the association of sculpture and painting, upon an occasion too so fertile in appliances and means, that the principles of taste will, it is presumed, be developed in a manner to serve as examples for much of future time. With reference to painting, Mr. Barry says—"I would that the walls of the several halls, galleries, and corridors of approach, as well as the various public apartments throughout the building, should be decorated with paintings, having reference to events in the history of the country; and that these paintings should be placed in compartments formed by such a suitable arrangement of the architectural designs of the interior, as will best promote their effective union with the arts of sculpture and architecture. With this view, I should consider it to be of the utmost importance, that the paintings should be wholly free from gloss upon the surface, that they may be perfectly seen and fully understood from all points of view." "By paintings with surfaces free from gloss or glaze, we understand those wherein the colours employed are mixed in other mediums than oils or varnishes; and though fresco is not named, yet the magnitude of the surfaces to be covered, and the exception to those which are glazed, leads us to suppose that it is intended to revive this branch of art. Now, though the buildings to be thus adorned are progressing with considerable rapidity, much time must elapse before the interior is prepared to receive the embellishments contemplated; meanwhile, many will have their longings to share in these distinguished labours, and, generally, the revival will open a new field for talent, in which there will shortly be no want of encouragement for those who may have successfully cultivated it; so oblivious, however, has the art become, that we have repeatedly heard the question put as to its nature and mode of execution, and we think an explanation will be useful to many of our readers. Fresco is the art of painting in relievo with water-colours on fresh plaster; the amalgamation thus formed of the decorative material with the body to which it is applied, is endued with unchangeableness and permanence of a very extraordinary kind."

The appointment of "A Commission on the Fine Arts," especially directed "to inquire into the mode in which, by means of the interior decorations of the Palace of Westminster, the fine arts of this country can be most effectually improved," has no doubt led to the revival of the art of fresco-painting. The various reports of the commission contain a great deal of valuable information on the subject, and the employment of several artists to furnish specimens, has brought forward some beautiful examples of fresco-painting, and elicited talent that might, but for these circumstances, have been lost to the world. In addition to the encouragement thus afforded, the stimulus of a public competition, and the distribution of rewards to the successful candidates, Her Majesty and Prince Albert had given the advantage of their countenance to the art, by ordering the decoration of a summer-house in the gardens of Buckingham Palace with fresco paintings.

The idea of this experiment, for so it must be called, was surely a happy one; and not the less seasonable, that every one who had considered the subject (at least every one who understood it), felt that it was a method which presented peculiar difficulties to some of the ablest and most distinguished of our painters, whose habitual style of treatment of their subject and effect, had been precisely the reverse of what is required in fresco.

The application of fresco-painting, it may be observed, to the decoration of architecture demands the adaptation of parts to a whole; a preconcerted mode of treatment, in which the painting shall seem to be in union with the original design of the edifice; the harmonious combination of many minds, working under the direction of one mind, to one purpose; and with regard to the mechanical part of the process, it requires much thought and study in the preparation of the materials, and great care and precision, as well as great rapidity, in the execution.

The summer-house in question is very small, and is situated on an artificial mount in the gardens, overlooking the ornamental waters.

The entrance to the pavilion opens into the principal apartment, an octagon 15 feet 9 inches from side to side, and 14 feet 11 inches in height, to the centre of the vaulted ceiling. It is here, in eight lunettes at the foot of the vault, that the frescos from "Comus" appear, of which for the most part types have been exhibited in the rooms of the Royal Academy, by the respective artists. Over the entrance-door, is Stanfield's, illustrative of the following passage :—

"Yet some there be that by due steps aspire
To lay their just hands on that golden key,
That opes the palace of Eternity.
To such my errand is." Comus, v. 12—17.

It is admirably transparent, and exhibits more power over the material than the majority of the works. Passing round with the sun, Mr. Uwin's follows, having for motto,

"This is the place as well as I may guess,
Whence even now the tumult of loud mirth
Was rife."

Then comes Leslie: Ross follows. Eastlake's is over the mantlepiece; Maclise, Edwin Landseer, and Dyce, complete the eight. A copy of Mr. Maclise's work was in the Academy exhibition of 1845, and will be remembered by all. The lines illustrated are,

"If virtue feeble were,
Heaven itself would stoop to her."

Maclise shows the lady spell-bound in the marble chair, and displays much of his usual power. Mr. Landseer has found in the following lines an opportunity to exhibit his great skill in depicting the brute form :—

"Their human countenance
Th' express resemblance of the gods, is changed
Into some brutish form of wolf or bear,
Or ounce or tiger, hog or bearded goat."
Comus, v. 68—71.

Comus, surrounded by his crew, is terrified by the approach of the brothers, who appear behind in the act of rushing upon them. A bacchante, with a beautiful female form, and the head of a hound, has thrown herself in affright upon the arm of Comus. Other monsters, half brute, half human, in various attitudes of mad revelry—grovelling, bestial insensibility—confusion and terror—are seen round him; the pathetic, the poetical, the horrible, the grotesque, all wildly, strangely mingled. In the spandrils are two heads—a grinning ape, and a bear drinking.

Mr. Dyce winds up the illustrations with the presentation of the lady and her two brothers to their parents, who come forth to receive them, and he has produced what must be considered the best fresco, although perhaps wanting exactly the right sentiment.

The operations of the Fine Arts Commission seem tohave been highly satisfactory to the public in general, and, in respect to fresco-painting in particular, must be viewed as eminently successful. The exhibitions in Westminster Hall presented numerous paintings in this so long-disused art, of a highly artistic character; and the number of the prizes awarded, testify the great merit of the productions. The result of the preliminary competition was shown in the selection of several eminent artists to execute fresco-paintings in the new Palace of Westminster, and in the completion by those gentlemen of some of the finest pictures in this peculiar style, that have been seen since the days of the great painters of former times.

It would extend this article beyond the limit assigned to it, to give a full description of these admirable works; we must therefore confine ourselves to a list of the artists selected, and the subjects allotted to each for illustration.

The commissioners having decided that six compartments in the new House of Lords should be decorated with fresco-paintings, proceeded to allot the several works in the following manner :—

To Mr. Horsley, the subject of Religion.
To Mr. Thomas, the subject of Justice.
To Mr. Maclise, the subject of Chivalry.
To Mr. Dyce, the subject of the Baptism of Ethelbert.
To Mr. Redgrave, the subject of Prince Henry, afterwards Henry V., acknowledging the authority of Chief Justice Gascoigne.
And to Mr. Cope the subject of Edward the Black Prince receiving the Order of the Garter from Edward III.

In the Upper Waiting Hall, or, as it is to be called, the "Hall of Poets," the eight available panels which it affords, are appropriated to frescoes illustrative of Chaucer, Spenser, Milton, Shakspere, Dryden, Pope, Byron, and Scott. Such of these paintings as are finished at the time we write, are noble works, full of power and beauty, and fully justifying the commissioners in the selection they have made of the artists employed.

The principal works that have been produced in former times in fresco, are the series of biblical and evangelical historic pictures which adorn the walls and ceiling of the chapel of Sixtus V. at Rome, by M. A. Buonarotti; the chambers of the Vatican, known by the name of the Stanze of Raphael; which consist principally of religious histories interspersed with some legendary tales, relative to the popes; and the cupola of the duomo of Parma, or church of St. Giovanni in that city, by A. Correggio. It represents the Ascension of the Virgin, amidst a choir of angels, and with a number of figures of saints below regarding it. One beautiful and grand work, by Daniel Ricciarelli, commonly called Da Votterra, at the altar of the church of Trinita da Monte, the subject of which is taking Christ down from the cross, is said to have been destroyed by the French, in their endeavours to remove it to France. Dorigny has engraved a large print of the design; and the picture has been thought so well worthy of attention, that an infinite multitude of copies have been made of it.

FRET, (from the Latin, *fretum*,) a species of guillochi, made of straight grooves or channelures at right angles to each other; the section of each channel being that of a rectangle. A fret is generally one connected groove with some of its parts in the same straight line. The labyrinth fret is that which consists of many turnings or windings, but in all cases the parts are parallel and perpendicular to each other. The prominent parts or interstices are generally of the same breadth throughout. In several Grecian examples, intervals are left in regular positions throughout the length of the fret.

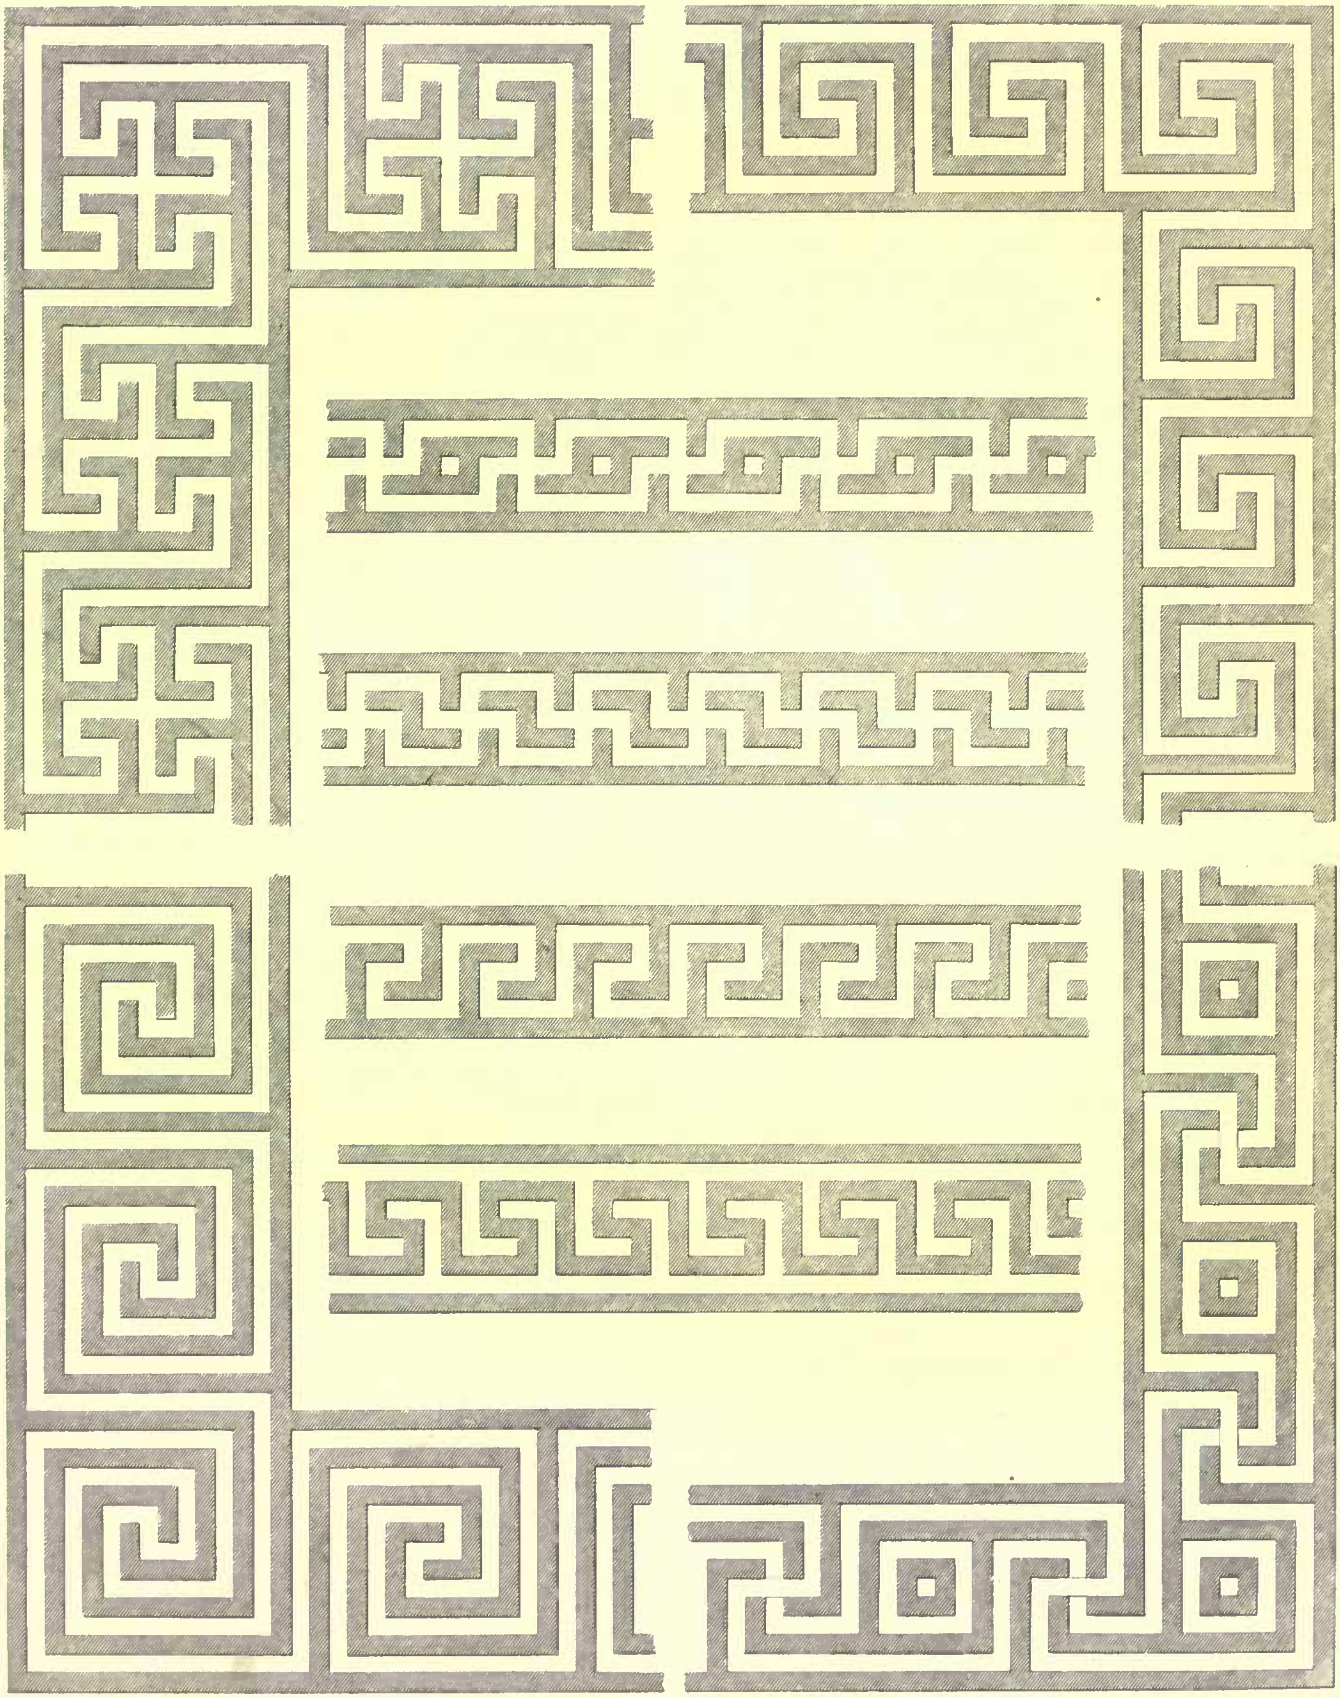
Fret is also elaborate carved-work, the same as Entail.

FRIARY, the building inhabited by a fraternity of friars.

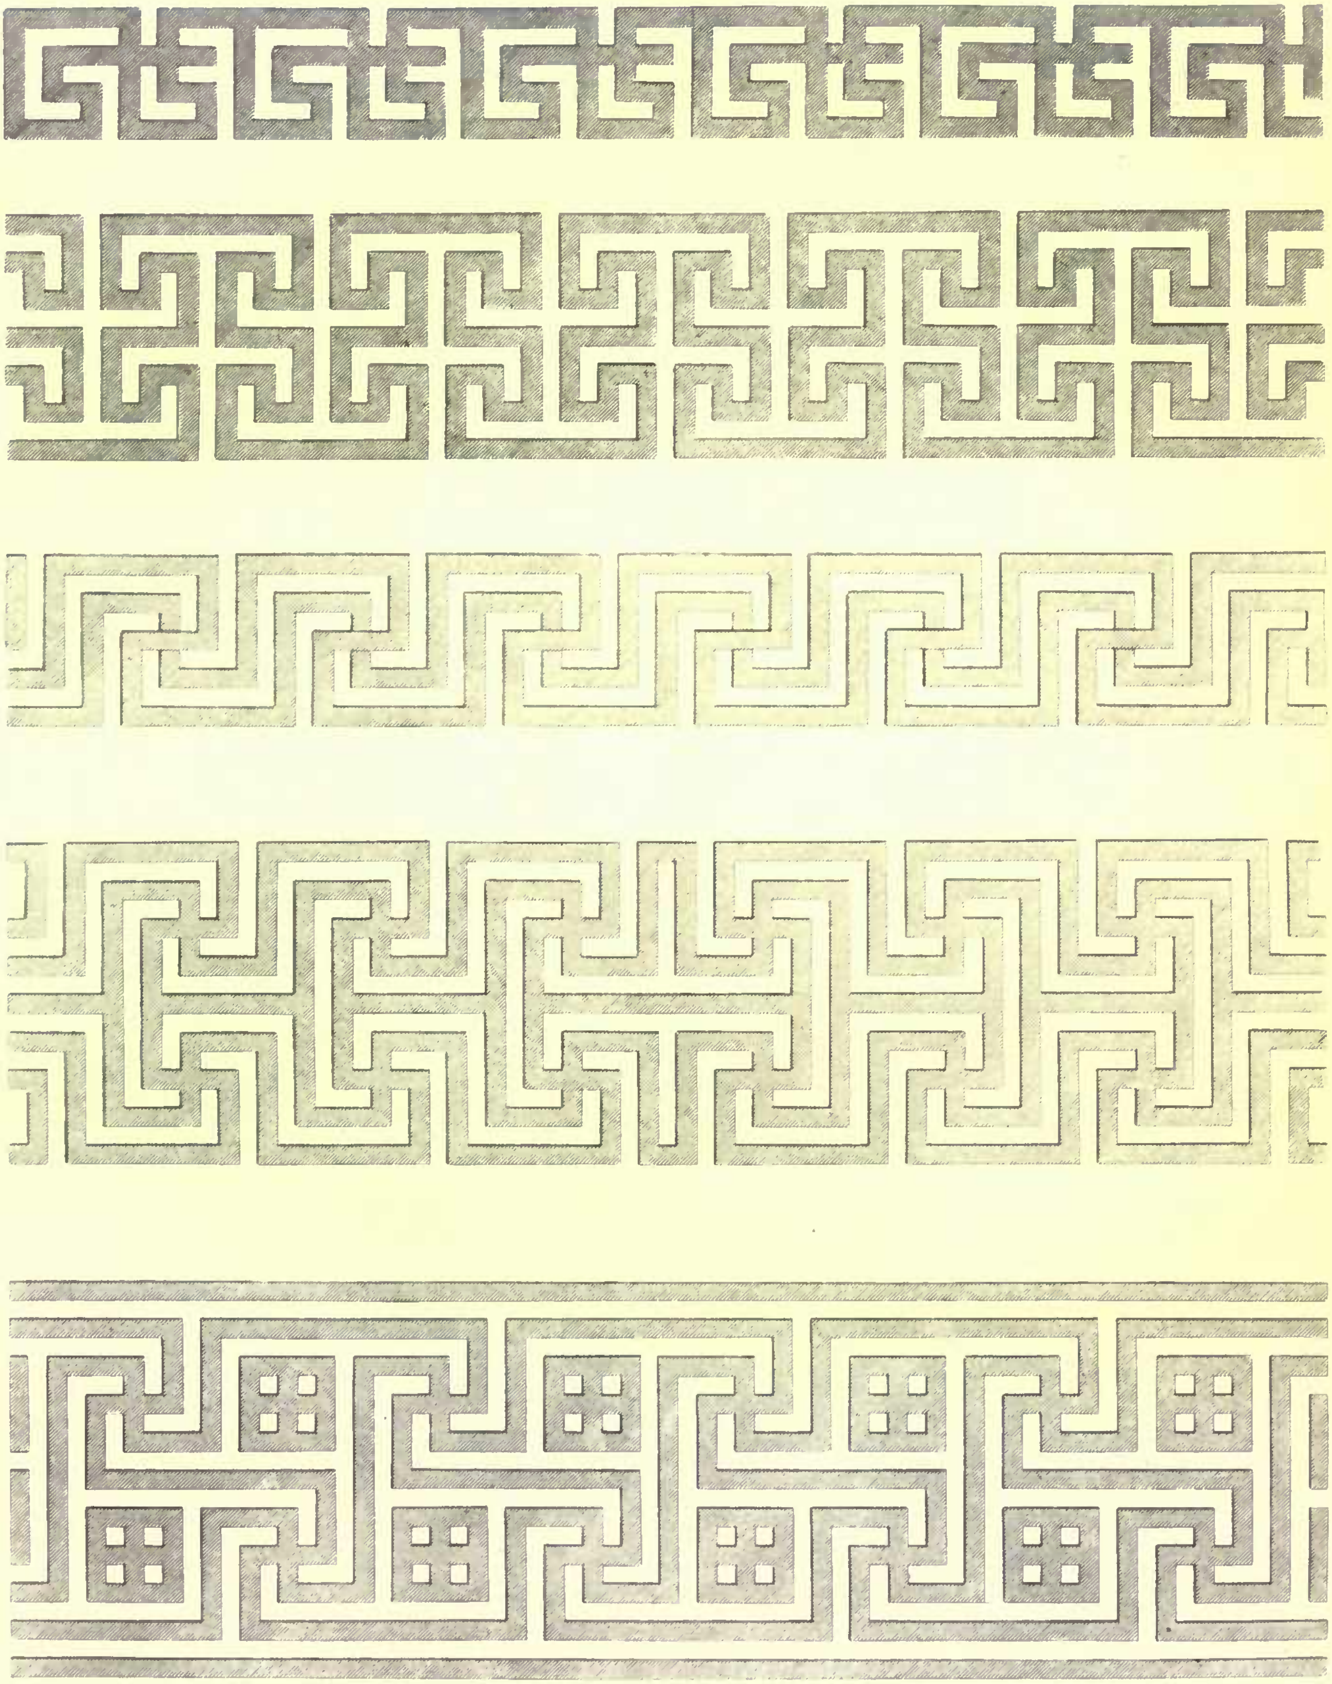
FRIEZE, or Frize, (called by the Greeks *zoophorus*) the middle principal member of the entablature which separates the cornice from the architrave.

The frieze was supposed to be originally formed by the transverse beams, which were necessary to prevent the walls or sides from spreading outwards by the pressure of the rafters of the roof.

The Doric is the only order that has an enriched frieze peculiar to the order itself. The ornaments with which the friezes of the Ionic, Corinthian, and Roman orders are frequently decorated, are only accidental, and when introduced are accommodated to the circumstances or use of the building. When the frieze is charged with ornament, it ought to be higher than when plain. Vitruvius directs the frieze



FRETS.



of the Ionic to be one-fourth part less than the epistylium, when it is plain; and one-fourth part greater when ornamented; this seems reasonable, in order to set off the decorations to greater advantage.

Ancient examples show no authority for a general proportion in all the orders. In the Grecian Doric, the frieze is very high, being equal to the altitude of the architrave, and each of these greater than the cornice; the Corinthian, on account of the numerous members of the cornice, has its frieze less than one-third of the height of the entablature.

Vitruvius makes the line of separation between the frieze and the cornice immediately under the dentils, and not at the bottom of the cymatium, as by Palladio, Perault, and others; for the frieze must have a terminating member as well as the architrave.

Friezes are either *convex* or *pulvinated:* examples of the latter are to be met with as follow: at Rome, in the Composite order of the temple of Bacchus; Corinthian order of the basilica of Antoninus; and in the Composite order of the Goldsmiths' arch: in all which the curves are circular, and not very prominent. At Spalatro, in the Corinthian order of the portico of the vestibulum of the Periostilium; in the same order, exterior and interior, of the temple of Jupiter, and of the entrance of the temple of Æsculapius: where the curves are all circular, and very prominent. In Wood's *Ruins of Balbec* (as represented in plate 31) of the Corinthian order, where the curve is elliptical. In the Corinthian order of Wood's *Ruins of Palmyra,* (plates 23 and 46), the curve is elliptical; and in plates 33 and 40, it is circular. In the *Ionian Antiquities;* (vol. ii., plates 27 and 45) the curves are of a contrary flexure, with the concave part above; and in plate 50, the curve is circular.

Swelled friezes are to be found among the examples of antiquity, particularly during the decline of the Roman empire; but these precedents ought not to influence their use, as they are unnatural, and defeat the purpose they were intended to answer, namely, to form a relief to the eye between the cornice and the architrave.

Frieze, *Panel,* the upper panel of a six-panelled door.

Frieze, *Rail,* the top rail but one of a six-panelled door.

Friezes, *Flourished,* such as are enriched with reeds or imaginary foliages, as in the Corinthian frieze of the frontispiece of Nero.

Friezes, *Historical,* those which are adorned with bas-relievos, representing histories, or sacrifices, as those of the Parthenon and the temple of Theseus at Athens, and the arch of Titus at Rome.

Friezes, *Marine,* such as represent sea-horses, tritons, and other attributes of the sea; or shells, baths, grottos, &c.

Friezes, *Rustic,* those whose courses are rusticated, as the Tuscan frieze of Palladio.

Friezes, *Symbolical,* such as are adorned with the attributes of religion, as the Corinthian of the temple behind the Capitol at Rome, whereon are represented the instruments and apparatus of sacrifice.

Frieze of the Capital, the same as Hypotrachelion, which see.

FRIGERATORY, (from the Latin, *frigidus,* to cool) a place in a house intended to keep things cool in summer.

FRIGIDARIUM, (Latin) an apartment in which to keep things cool.

It also means the cold bathing-room in the baths of the ancients, as well as the vessel in which the cold water was received. The word has been likewise applied to the reservoir of cold water in the hypocaustum or stove-room, which was termed *ahenum frigidarium.*

FRIZE. *See* Frieze.

FRONT, (from the Latin, *frons,* the face,) any side or face of a building. The principal front should be that which commands the best prospect, or may be seen to the greatest advantage; and is generally the entrance-front.

FRONTAGE, the front part of an edifice.

FRONTAL, the hanging suspended over the front of the altar. It was made of the richest material, silk, velvet, and cloth of gold, and worked in the most costly manner in embroidery. Otherwise termed *Antependium.*

FRONTON, (French) a pediment, or other ornament over doors, niches, &c.

FROSTED, a species of rustic work, imitative of ice formed by irregular drops of water.

FROWEY TIMBER, such as works freely to the plane without tearing, and consequently has the grain nearly in the same direction.

FRUSTUM, (Latin) the part of a geometrical parallelogram next to the base, after cutting away the upper part, which contains the apex. Thus we have frustums of pyramids, cones, conoids, hemispheres, &c.

To measure the frustum of a square pyramid.

To the rectangle of the sides of the two bases, add one-third of the square of their difference; their product being multiplied by the height, will give the solidity.

Example.—In the frustum of a square pyramid, one side of the base A B or B C is 3 feet 6 inches, each side of the top 2 feet 3 inches, and the perpendicular height H I, 8 feet 9 inches, the solidity is required.

By Duodecimals.

FULCRUM, in mechanics, that by which a lever is sustained.

FUMARIUM, an upper room used by the Romans for collecting the smoke from the lower ones. The Fumarium was chiefly used, however, for smoking or ripening wines.

FUNNEL, that part of a chimney which is contained between the fire-place and the summit of the shaft. *See* Chimney.

FURCATED, having a forked appearance.

FURLONG, a measure of length, the eighth part of a mile, forty poles.

FURNITURE, the fastenings of doors and windows with brass knobs, &c.

FURRING, when the edges of any number of timbers in a range are out of the surface they were intended to form, either from their gravity, or in consequence of an original deficiency of the timbers in their depth; the fixing of thin scantlings or laths upon the edges, so as to form that surface, is called *furring*. Thus the timbers of a floor, though level at first, are often obliged to be *furred:* in the reparation of old roofs, the rafters have mostly to undergo this operation: and the ceiling joists, both of new and old floors, frequently require it.

FURRINGS, the pieces of timber employed in bringing any piece of work in carpentry to a regular surface, when the work is deficient through the sagging of the timbers, or other causes.

FUR-UP. *See* Furring.

FUST, (from the French) the shaft of a column, or trunk of a pilaster.

Fust, a term used in Devonshire, and perhaps in some other counties, for the ridge of a house.

FUSTIC, sometimes called Yellow Wood. This wood, the *Morus tinctoria*, is a native of the West Indies, and affords much colouring-matter, which is very permanent. The yellow given by fustic without any mordant, is dull and brownish, but stands well. The mordants employed with weld, act upon fustic in a similar manner, and by their means the colours are rendered more bright and fixed. The wood of this tree is also used in mosaic cabinet-work and turnery.

FUSUROLE, or Fusarole, (from the Latin) a semi-circular member cut into beads, generally placed under the echinus of the Ionic and Roman capitals.

G.

GABION, a hollow cylinder of wicker-work, resembling a basket, but having no bottom. It is formed by planting slender stakes vertically in the ground, at intervals from each other, on the circumference of a circle, and interweaving with them osiers or other flexible twigs.

Such gabions are used during a siege, in executing trenches by the process of sapping: for this purpose, they are placed on end, with their sides inclining a little outwards, on that side of the line of approach which is nearest to the fortress; and, being filled with earth obtained by the excavation of the trench, they form a protection against the fire of the enemy. After the gabions are filled, the required thickness is given to the parapet of the trench by throwing the earth below the line.

GABLE, (from the British, *gravel*) the upper portion of the end of a building wall, which closes the end of the roof, in shape similar to a triangle, and answering, in some respects, to the term Pediment, applied to classic architecture. The gable forms a prominent feature in mediæval buildings, and its shape conforms to that of the roof; which is various at different periods. In Norman buildings, the angle of the roof is as nearly as possible a right angle, while in Early English edifices the gable is frequently an equilateral triangle. In the Decorated the roof is somewhat depressed, which depression increases in the Perpendicular and later buildings. The finish to Norman gables was probably a flat coping, to Early English a moulded coping, sometimes further ornamented with crockets and finials; but these were more frequently introduced in the later styles, in which also the gables were sometimes finished with a pierced parapet or battlement. In Domestic architecture, gables with overhanging roofs were ornamented with Barge-Boards.

The term is also applied to the entire wall at the gable-end of a building.

Gable-roofed, having a roof abutting against a gable wall.

Gable-window, a window in the gable end of a building.

GABLET, a small gable; an ornament in shape like a gable, frequently introduced over tabernacles, niches, buttresses, &c.

GAGE, (French) in carpentry and joinery, an instrument for drawing one or more lines on any side of a piece of stuff, parallel to one of the arrises of that side.

There are four kinds of gages: the common gage, the mortise-and-tenon gage, the internal gage, and the flooring gage. The common gage and the flooring gage are both applied to the drawing of a line parallel to an arris.

The common gage consists of two pieces of wood, one of which passes through a mortise in the other, and has an iron or steel tooth fixed near one of its extremities; so that the point may be placed at any distance from the mortised piece: then the piece which passes through the mortise is fixed by a wedge also through that piece: the piece through which the mortise passes is called *the head*, and the piece passing through the mortise, in which the iron tooth is fixed, is called *the staff.*

When a line is drawn from the arris upon one side, at a given distance, the head is a fence that always keeps the staff at right angles to the arris, and equidistant, in moving it to and fro.

The mortise-and-tenon gage is a common gage with a longitudinal slider, moveable in a dovetail groove: the slider has also a tooth fixed as near to the end next the tooth in the end of the staff as possible; so that the teeth may be brought almost to any distance from one another.

The internal gage is constructed similar to the staff of the mortise-and-tenon gage: it has a longitudinal slider, the whole length of the staff, without a head, or any other tooth than that of the slider.

The flooring gage consists of a head and staff fixed together, at a very obtuse angle: on the head are a number of equidistant furrows at right angles to the staff: the section of each furrow is an internal right angle, one side of which is in a straight line with the tooth, and the other becomes a fence in the act of gaging.

This gage is made to answer battens or deals of various widths: Each width is numbered, according to the furrow that is applied as a fence; so that a flooring board, which is not sufficiently long, may be extended, by a piece of the same breadth, to the length required.

GAIN, the bevelled shoulder of a binding-joist for the purpose of giving additional resistance to the tenon below. *See* Tusk.

GALILEE, a porch, usually built at or near the west end of the great abbey-churches, where the monks collected themselves, and drew up in returning from some of their processions; where dead bodies were deposited previous to their interment; and where, in certain monasteries, females alone were allowed to see the monks to whom they were related, or to attend divine service.

Galilees exist in England in the cathedrals of Durham, Ely, and Lincoln. In the former instance, it is a large chapel at the west end of the nave, measuring 80 feet by 50, and divided into five aisles by semi-circular arcades on clustered columns; it likewise contained three altars. The galilee at Ely is in the same position, but of much smaller dimensions, while that at Lincoln is on the west side of the south transept.

Many improbable conjectures have been formed concerning the derivation of the name. The real occasion of it seems to be this: when any female applied at the abbey-gate for leave to see her relative, who was a monk, she was directed to the western porch of the church, and told, in the terms which so frequently occur in the service of the pascal time, alluding to Matt. xxviii. 10, and Mark xvi. 7, that she should see him in Galilee. This explanation is confirmed by a passage of Gervasius the monk of Canterbury. *De Combust. et Repar. Dorob. Ecc. Twysd. X. Script.*

GALLERY, an apartment of a house, not always destined to answer the same purpose: the term is applied, in a general way, to any passage or apartment, the length of which greatly exceeds its breadth. A common passage to several rooms in one range, in any upper story of a house, is called a gallery; a long room for the reception of pictures is called a gallery; the platform raised upon pillars, or projected from the wall of a church, open in the front to the central space, for the accommodation of a greater number of people than the body of the church would admit, is called a gallery. The whispering-gallery of St. Paul's, as also that of the chapel of Greenwich Hospital, are projected, and supported by cantalivers from the wall. The whole, or a portion of the uppermost story of a theatre, is likewise called a gallery. The appellation is also frequently given to porticos formed with long ranges of columns on one side.

Savot, in his *Architecture*, derives the gallery from *Gaul*, as supposing the ancient Gauls to have been the first who used them: Nicod, from the French, *aller*, to go; q. d. *allerie:* others bring it from *galère*, galley, because it bears some resemblance thereto in respect of health.

The length of galleries is (according to Palladio) from eight to ten times their breadth.

GANG-LADDER, in canal-making, a frame answering the same purpose as a horsing block.

GANG-WAY, a temporary stair, made with planks set edge to edge of each other, having transverse pieces of wood nailed over for steps; used particularly by masons, bricklayers, and carpenters, for ascending or descending the various stories of a building, before the stairs are put up.

GAOL, (from the French, *géole*, formed of the Latin, *geola*, *gaola*, or *gayola*, a cage) a prison, or place of legal confinement; the word is now generally written Jail.

Every county has two gaols; one for debtors, which may be any house where the sheriff pleases; the other for the peace and matters of the crown, which is the county gaol.

By 22 and 23 Car. II. c. 20, the gaoler shall keep debtors and felons separate, on pain of forfeiting his office, and treble damages to the party aggrieved; and by 31 Geo. III. c. 46, transports are to be kept separate from other prisoners. As the gaol is intended, in most cases, for custody, and not for punishment, it is enacted by 14 Geo. III. c. 59, that the justices, in their several quarter-sessions, shall order the walls and ceilings of the several cells and wards, both of the debtors and felons, and of any other rooms used by the prisoners in their respective gaols, where felons are usually confined, to be scraped and whitewashed once in the year, at least, and to be regularly washed and kept clean, and constantly supplied with fresh air by hand-ventilators or otherwise; and shall order two rooms in each gaol, one for the men and another for the women, to be set apart for sick prisoners; and order a warm and cold bath, or commodious bathing-tub, to be provided in each gaol, and direct the prisoners to be washed in such warm or cold baths, or bathing-tubs, &c., and they shall appoint an experienced surgeon and apothecary, at a stated salary, to attend the gaol, and to report, at each quarter-sessions, the state of the health of the prisoners; order clothes for the prisoners when they see occasion, prevent their being kept under ground, when it can be done conveniently, and from time to time make orders for restoring or preserving the health of the prisoners; the expenses to be paid out of the county rates, or out of the public stock of any city, franchise, or place to which the gaols belong. The gaoler is subject to fine for neglect or disobedience of the orders of justices, by complaint to the judges of assize, or to the justices in their quarter-sessions. By 31 Geo. III. c. 46, visiting-justices are appointed for inspecting gaols at least three times in each quarter of a year, in order to prevent abuses, &c., and they are to report to the quarter-sessions. The justices in sessions may also appoint clergymen to officiate in gaols, and allow them a salary to be paid out of the county rates.

If a gaol be out of repair, insufficient, &c., the justices of the peace in their quarter-sessions may agree with workmen for rebuilding or repairing it; and by warrant under their hands and seals, order the sum agreed upon to be levied upon the several hundreds and divisions in the county, by a proportionate rate; and the justices in sessions may borrow, on mortgage of the said rates, any sum not less than £50 nor more than £100, and discharge the whole by yearly payments. 11 and 12 Will. III. cap. 19. 24 Geo. III. c. 54. *See* Prison.

GARD, *Pont du.* *See* Aqueduct, Bridge.

GARDEN, *Hanging*, a sort of ancient garden, which is said to have been formed in a raised manner, on arches, by Nebuchadnezzar king of Babylon, with the view of gratifying his wife Amyctis, who was the daughter of Astyages, king of Media. These gardens are supposed by Quintus Curtius to have been equal in height to the city, which is 50 feet. They contained on every side a square of 400 feet, and were carried up in several terraces, surmounting each other, to which there were ascents by different flights of stairs or steps that had 10 feet in width. The arches that sustained the whole of this pile were raised above each other, being strengthened by a wall on every side of above seven yards in thickness. The floors of the several terraces were laid first with large flat stones, of considerable lengths and breadths, over which was placed a stratum of reed mixed very fully with bitumen, then two rows of bricks closely cemented together with mortar, and the whole afterwards covered with thick sheet-lead, upon which the mould of the garden was deposited, to such a depth as to admit large trees to take root and establish themselves in it. Trees, plants, and flowers of various kinds, were introduced into these gardens. The upper terrace was likewise provided with an aqueduct or engine, by which the water was drawn up from the river, and dispersed over the whole of the gardens when necessary.

Some have condemned these gardens as unnatural, while others have considered them as deserving of a portion of praise; but whatever merit may have been allowed them, they could certainly never have had anything of the natural or rural character about them.

Garden-Sheds, erections for containing garden implements, flower-pots, hot-bed frames, and glass sashes; also for working in, during bad weather. They are best placed on the back-wall of the tool-house, by which means they may be made to hold the furnaces, fuel, and other articles.

GARGOYLE, Gargle, Gargyle, and Gurgoyle, a stone projecting from the wall of Gothic buildings, and serving for a spout to convey the water from the roof, and throw it off the wall. These stones are more frequently carved into grotesque figures or animals, through the mouth of which the water passes; sometimes, however, the water is carried through a leaden pipe above or below the figure. Their usual position is in the cornice of buildings, but they are found also in other positions, such as buttresses, &c.

GARLANDS, (from the French, *guirlande;* from the Latin, *garlanda*, or Italian, *ghirlanda*,) ornaments of flowers, fruits, and leaves, anciently used at the gates of temples, where feasts or solemn rejoicings were held. Garlands of festoons were also put on the heads of victims, in the ancient heathen sacrifices.

GARNETS, *Cross*, a species of hinge, used in the most common works, formed in the shape of the letter T, turned thus, ⊢⊣, the vertical part being fastened to the style or jamb of the door-case, and the horizontal part to the door or shutter.

GARRET, (from the French, *garite*, the tower of a citadel) the uppermost story of a house, when taken either partially or wholly from the space within the roof.

GARRETING, the insertion of small pieces of stone between the joints of rough masonry, as in rubble and flint walls.

GARRISON, a fort, castle, or fortified town, furnished with troops to defend it.

GATE, a large door for shutting the entrance of parks, fields, towns, castles, palaces, or any other considerable buildings.

The width of gates is from eight to twelve feet: the height depends upon the purpose to which they are applied. *See* Door.

Gate, in *Rural Economy*, a frame of wood constructed with a number of bars, and fixed in such a manner as to swing upon hinges, for the purpose of affording convenient passage into and out of inclosed grounds, or other places.

In the constructing of gates, of whatever kind or form they may be, the materials should constantly be well prepared by proper seasoning before they are put together; as, where this is not the case, they soon become much injured by their constant exposure to the effects of the sun and wind. They also require that the different parts be put together with considerable accuracy and correctness. In respect to durability, there can be no doubt but that oak is by much the best sort of wood to be employed; but some of the more light kinds of wood, such as those of the deal, willow, and alder sorts, answer the purpose extremely well, and are very durable, as, on account of their lightness, they do not destroy themselves so much in shutting. It is found by experience that the lighter gates can be made in their foreparts, so that they be sufficiently strong for the intended purpose, the better they answer. For this reason, in some cases, as where horses are chiefly to be confined, the top bars, by being left of more strength, may admit of the others having less substance; but if this be not done, they are apt to be broken by the horses rubbing their necks upon them, unless where they are made of great height.

The width of gates for general purposes is mostly from eight and a half to nine feet, and the height from five to six feet; the bars being five or six in number, and each four or five inches in breadth. Hence they are frequently denominated five or six-barred gates. In cases where fowls or other small animals are to be guarded against, it is better to run a smaller bar between the two lowermost ones, as by this means their passage is prevented.

Gate, in *Engineering*, is applied to the close-boarded doors of locks or sluices on canals or rivers, for penning up the water: in a lock these are distinguished by upper-gates and lower-gates, according as they are placed at the head or tail of the lock.

Gate-House, a building erected over a gate, or that through which entrance was obtained into the main building. Gate-houses were very usual in the erections of the middle ages, and were employed in all large buildings, ecclesiastical, military, and civil, also as entrances to fortified cities; thus in London we still preserve the names of several gate-ways in the old wall, as New-gate, Bishops-gate, Lyd-gate, &c., at each of which places was formerly a gate-house, through which entrance was obtained within the city. These buildings were often of an imposing character; and in military works consisted, for the most part, of a large arch-way with groined ceiling, and a portcullis at each end, flanked by two massive projecting towers, pierced with loop-holes, through which to annoy the enemy, and surmounted by a battlemented parapet. Those attached to civil and ecclesiastical buildings were generally of a more ornamental description, sometimes consisting of only a square tower with a turret at one or more angles, having a large arch-way in the centre with groined ceiling and room above, the window of which—frequently an oriel—formed a picturesque addition to the elevation. The forms of these gate-houses were, however, various, and admitted of different degrees of ornamentation. In some cases, there was a small arch-way by the side of the principal one for foot-passengers, and in others a similar one on either side; they were called posterns. Remains still exist in most of the old towns, amongst the most remarkable of which are those of Battle Abbey, Sussex, Bristol, Bury St. Edmund's, St. John's Gate, Clerkenwell, and St. Augustine's College, Canterbury.

Gate-way, the passage through which entrance is obtained into a town, building, &c.

GATHERING OF THE WINGS, in a chimney, the sloping part above the fire-place, where the funnel contracts or tapers till it reaches the tube or flue.

GAVEL, the same as Gable, which see.

GAUGE, *See* Gage.

Gauge, a term applied to signify the width between the rails on a railway.

GEMMEL, Gymmer, or Chymol, an ancient term for a hinge.

GENERATING LINE, or Plane, in geometry, is a line, or plane, moving according to a given law, either round one of its extremities, as a fixed point or axis, or parallel to itself, in order to generate a plane figure or solid, which is formed by the space it has gone over.

GENESIS, (from the Greek, *γένεσις*, *origin*, or *beginning*) in geometry, the formation of a line, plane, or solid, by the motion of a line, plane, or surface; thus, a sphere is conceived to be generated by the motion of a semicircle revolving on its diameter, which is called *the axis of circumvolution*. A triangle may be conceived to be generated by the motion of a line parallel to its base, in such a manner that the describing line must be a fourth proportional to the base, the altitude, and the distance of the line from the vertex of the triangle.

In the genesis of figures, the moving point, line, or surface, is called *the describent*, and the line round which, or according to which, the revolution is made, *the dirigent*.

GENTESE, in Early English architecture, cusps or featherings in the arch of a doorway.

GEOD'ESY, that branch of applied mathematics which determines the figures and areas of large portions of the earth's surface, the general figure of the earth, and the variations of the intensity of gravity in different regions by means of direct observation and measurement.

GEOLOGY, the science which treats of the internal structure of the earth as far as we have been able to penetrate below its surface, of the arrangement of the materials of which it is composed, and of the changes which have taken place in them.

GEOMETRICAL, something that has a relation to geometry: thus we say, geometrical method, geometrical genius, geometrical strictness, geometrical construction, geometrical demonstration, &c.

Geometrical Locus, or Place. *See* Locus.

Geometrical Pace, a measure of five feet.

Geometrical Plan. *See* Plan.

Geometrical Plane, in perspective, the same as *ground plane*, or *original plane*.

Geometrical Solution of a Problem, a solution according to the strict principles of geometry, by lines that are truly geometrical.

In this sense, we say, *a geometrical solution*, in contradistinction to *a mechanical* or *an instrumental solution*, where the problem is only solved by ruler and compasses.

Geometrical problems are distinguished into three kinds, viz., plane, solid, and linear.

Plane problems are such as may be solved by a right line and a circle.

Solid problems are derived from the consideration of a solid that is a cone.

Linear problems are derived from lines more compounded.

Geometrical Stair, such as is only supported by the wall at the one end of the steps, with a continued string at the other.

GEOMETRY, (from the Greek, *γεωμετρια*, formed of *γεα* or *γη*, *earth*, and *μετρεω, to measure*) the doctrine, or science of extension, or things extended, viz. of lines, surfaces, or solids. Geometry has also been defined in general terms as the science of space.

According to Herodotus, Strabo, and Diodorus, the Egyptians were the first inventors of geometry, and it is asserted by these ancient writers, that to the annual inundations of the Nile, we are to attribute the first steps in this science. That river, in its overflowings, bearing away all the bounds and landmarks of men's estates, and covering the whole face of the country, the people were obliged to distinguish their lands by the consideration of their figure and quantity; and thus, by experience and habit, they formed to themselves a method, or art, which was the origin of geometry. A farther contemplation of the draughts of figures of fields thus laid down, and plotted in proportion, might, naturally enough, lead them to the discovery of some of their excellent and wonderful properties; and as these speculations continually improved, so the art gradually improved also, until it attained the perfection of the present day. Josephus, however, seems to attribute the invention to the Hebrews; and others, among the ancients, make Mercury the inventor.

From Egypt, geometry passed into Greece, being carried thither, as some say, by Thales, where it was much cultivated and improved by himself, Pythagoras, Anaxagoras of Clazomene, Hippocrates of Chios, and Plato. The latter testified his conviction of the necessity and importance of geometry, in order to the successful study of philosophy, by the following inscription on the door of his academy: "*Let no one ignorant of geometry enter here.*" Plato, conceiving that geometry was too mean and restricted an appellation for this science, substituted for it the more extensive name of *mensuration;* and others have denominated it *pantometry.* Other more general and comprehensive appellations are perhaps more suitable to its extent, especially in the present advanced state of the science; and accordingly, some have defined it as *the science of inquiring, inventing, and demonstrating all the affections of the magnitude.* Proclus calls it *the knowledge of magnitudes and figures, with their limitations;* as also of their ratios, affections, positions, and motions of every kind. About fifty years after Plato, lived Euclid, who collected together all those theorems which had been invented by his predecessors in Egypt and Greece, and digested them into fifteen books, intitled the *Elements of Geometry;* and those propositions which were not satisfactorily proved, he more accurately demonstrated. The next to Euclid, of those ancient writers whose works are extant, is Apollonius Pergæus, who flourished in the time of Ptolemy Euergetes, about two hundred and thirty years before Christ, and about one hundred years after Euclid. The third ancient geometer, whose writings remain, is Archimedes of Syracuse, who was famous about the same time with Apollonius. We can only mention Eudoxus of Cnidus, Architas of Tarentum, Philolaus, Eratosthenes, Aristarchus of Samos, Dinostratus, the inventor of the quadratrix, Menechmus, his brother, and the disciple of Plato, the two Aristeuses, Conon, Thrasideus, Nicoteles, Leon, Theudius, Hermotimus, and Nicomedes, the inventor of the conchoid; besides whom there are many other ancient geometers, to whom this science is indebted.

The Greeks continued their attention to geometry, even after they were subdued by the Romans. Whereas the Romans themselves were so little acquainted with this science, even in the most flourishing time of their republic, that they gave the name of mathematicians, as Tacitus informs us, to those who pursued the chimeras of divination and judicial astrology. Nor were they more disposed to cultivate geometry, as we may reasonably imagine, during the decline, and after the fall of the Roman empire. The case was different with the Greeks; among whom we find many excellent geometers, since the commencement of the Christian era, and after the translation of the Roman empire. Ptolemy lived under Marcus Aurelius; and we have, extant, the works of Pappus of Alexandria, who lived in the time of Theodosius; the commentary of Eutocius, the Ascalonite, who lived about the year of Christ 540, on Archimedes' mensuration of a circle; and the commentary on Euclid, by Proclus, who lived under the empire of Anastasius.

The consequent inundation of ignorance and barbarism was unfavourable to geometry, as well as to the other sciences; and those few who applied themselves to this science, or indeed to any branch of learning incomprehensible by the vulgar, were calumniated as magicians. In those times of European darkness, the Arabians were distinguished as the guardians and promoters of science; and from the ninth to the fourteenth century they produced many astronomers, geometers, geographers, &c., from whom the mathematical sciences were again received into Spain, Italy, and other parts of Europe, somewhat before the beginning of the fifteenth century. Some of the earliest writers after this period, are Leonardus Pisenus, Lucas Paciolus or de Burgo, and others who flourished between 1400 and 1500. After this period appeared many editions of Euclid, or commentaries upon his *Elements; e.g.*, Orontius Fineus, in 1530, published a commentary on the six first books; as did James Peletarius in 1557; and about the same time, Nicolas Tartaglia published a commentary on the whole fifteen books. We might also mention other editions or commentaries; such as those of Commandine, Clavius, Billingsly, Scheubelius, Harlinus, Dasypodius, Ramus, Herigon, Stevinus, Saville, Barrow, Tacquet, Dechales, Furnier, Scarborough, Keill, Cann, Stone, and many others.

At the revival of letters, there were few Europeans capable of translating and commenting on the works of the ancient geometers; and geometry made consequently but little progress till the time of Des Cartes, who published his *Geometry* in 1637. However, not to mention all those who extended geometry beyond its elementary parts, such as Theodosius, in his *Spherics*, Serenus, in his *Sections of the Cone and Cylinder;* Kepler, in his *Nova Stereometria*, &c.; in 1635, Bonaventure Cavalerius, an Italian, of the order of Jesuits, published his *Geometry of Indivisibles;* Torricelli, his *Opera Geometrica;* Viviani, his *Divinationes Geometricæ*, *Exercitatio Mathematica*, *De Locis Solidis*, *De Maximis et Minimis*, &c.; Vieta, *Effectio Geometrica*, &c.; Gregory St. Vincent, in 1647, published his treatise, intitled *Quadratura Circuli et Hyperbolæ*, a work abounding with excellent theorems and paralogisms; and Pascal, about the same time, published his *Treatise of the Cycloid.* Geometry, as far as it was capable of deriving aid and improvement from the arithmetic of infinites, was indebted to the labours of Fermat, Barrow, Wallis, Mercator, Brounker, J. Gregory, Huygens, and others; to whom we may add Newton and Leibnitz. But Sir Isaac Newton contributed to the progress of pure geometry by his two treatises, *De Quadratura Curvarum*, and *Enumeratio Linearum Tertii Ordinis:* and still farther by his incomparable and immortal work, intitled, *Philosophia Naturalis Principia Mathematica*, which will always be considered as the most extensive and successful application of geometry to physics.

The modern Geometers are innumerable; and the names of Cotes, Maclaurin, R. Simpson, T. Stewart, T. Simpson, &c. not to mention living writers, will always be held in esteem and veneration by those who are devoted to the study of geometry and mathematics.

The province of geometry is almost infinite: few of our ideas but what may be represented to the imagination by lines, upon which they become of geometrical consideration: it being geometry alone that makes comparisons and finds the relations of lines.

Architecture, mechanics, astronomy, music, and in a word, all the sciences which consider things susceptible of more and less, *i. e.* all the precise and accurate sciences, may be referred to geometry; for all speculative truths consisting only in the relations of things, and in the relations between those relations, they may be all referred to lines. Consequences may be drawn from them; and these consequences, again, being rendered sensible by lines, become permanent objects, which may be constantly exposed to a rigorous attention and examination: thus affording to us infinite opportunities both of inquiring into their certainty, and pursuing them farther.

Geometrical lines and figures are not only proper to represent to the imagination the relations between magnitudes, or between things susceptible of more and less; as spaces, times, weights, motions, &c., but they may even represent things which the mind can no otherwise conceive, for example, the relations of incommensurable magnitudes.

It must be observed, that this use of geometry among the ancients was not strictly scientifical, as among us; but rather symbolical: they did not argue, or deduce things and properties unknown, from lines, but represented or delineated by them things that *were* known. In effect, they were not used as means or instruments of discovering, but as images or characters, to preserve, or communicate, the discoveries already made.

The ancient geometry was confined to very narrow bounds, compared with the modern. It only extended to right lines and curves of the first order, or conic sections; whereas in modern geometry new lines, of infinitely more and higher orders, are introduced.

Geometry is commonly divided into four parts, or branches; Altimetry, Stereometry, Planimetry, and Longimetry. See those words.

It is again distinguished into *theoretical* or *speculative*, and *practical*. The first contemplates the properties of continuity; and demonstrates the truth of general propositions, called *theorems*. The second applies those speculations and theorems to particular uses in the solution of *problems*. Speculative geometry, again, may be distinguished into *elementary* and *sublime*. The former is that employed in the consideration of right lines and plane surfaces, and solids generated from them. The *higher* or *sublime* geometry is that employed in the consideration of curve lines, conic sections, and bodies formed of them.

The science of geometry is founded on certain axioms, or self-evident truths; it is introduced by definitions of the various objects which it contemplates, and the properties of which it investigates and demonstrates, such as points, lines, angles, figures, surfaces and solids:—lines again are considered as straight or curved; and in their relation to one another, either as inclined or parallel, or as perpendicular:—angles, as right, oblique, acute, obtuse, external, vertical, &c.:—figures, with regard to their various boundaries, as triangles, which are in respect to their sides equilateral, isosceles, and scalene, and in reference to their angles, right-angled, obtuse-angled, and acute-angled; as quadrilaterals, which comprehend the parallelogram, including the rectangle and square, the rhombus and rhomboid, and the trapezium and trapezoid; as multilaterals or polygons, comprehending the pentagon, hexagon, heptagon, &c.; and as circles;—also as solids, including a prism, parallelopipedon, cube, pyramid, cylinder, cone, sphere, and the frustum of either of the latter.

For practical geometry, the fullest and most complete treatises are those of Mallet, written in French, but without the demonstrations; and of Schwenter and Cantzlerus, both in high Dutch. In this class are likewise to be ranked Clavius's, Tacquet's, and Ozanam's *Practical Geometries;* De la Hire's *Ecole des Arpenteurs;* Reinholdus's *Geodæsia;* Hartman Beyers's *Stereometria;* Voigtel's *Geometria Subterranea;* all in high Dutch: Hulsius, Galileus, Goldmannus, Scheffelt, and Ozanam, *on the Sector*, &c. &c. An excellent treatise on practical geometry, particularly with reference to the study of architecture and perspective, was published some years ago by Mr. Peter Nicholson, and still holds its ground in public estimation, notwithstanding the numerous works on the subject which have appeared from time to time. The following short essay on Practical Geometry, containing the formation of plain figures arising from straight lines and circles, will also be found exceedingly useful in the study of architectural construction. Curves of variable curvature, as those arising from the sections of a cone by a plane, will be found under their respective heads; as, Conic Sections, Ellipsis, &c.

Geometry, *Analytical*, or *Descriptive*, the method of finding the situation of a point in a plane. *See* Descriptive Geometry.

Geometry, *Practical*, the method of reducing or applying the rules of the science to practice, examples of which will be found in the following problems.

Problem I.—*In a right line,* A B, *from any given point,* C *to erect a perpendicular.*

Figure 1.—When the given point is near the middle of the line. On each side of the point C, on the line A B, take any two equal distances, as C *d*, C *e;* from *d* and *e*, with any radius greater than C *d*, or C *e*, describe arcs of equal radii, cutting each other in F; through the points F and C, draw the right line F C, and it will be the perpendicular required.

Figure 2.—When the given point is at or near the end of the line. Take any other point, as *d*, in A B; from *d*, with the distance *d* C, describe an arc, C *e f;* take the portion C *e*, of the arc, at pleasure, and make the portion *e f* equal to C *e;* draw the chord C *g f;* from C, with the radius C *e*, describe the arc *g e* H; make *e* H equal to *e g;* and through the points C and H draw the right line C H, which is the perpendicular required.

Figure 3.—Another method. Take any other point, *d*, as before: from C, with the distance C *d*, describe an arc, *d e f;* from *d*, with the same radius, describe an arc at *e;* from *e*, with the same radius, describe an arc at G; draw *d e* G, and through the points G and C draw G C, which is the perpendicular required.

Problem II.—*From a given point,* C, *to drop a perpendicular upon a given right line,* A D.

Figure 4.—In A B, take any two points, *f* and *g;* and from either point, *f*, with the radius *f* C, describe an arc, C E; from *g*, with the distance *g* C, describe arcs at C and E, of equal radii; and draw the right line C E, which is the perpendicular required.

Figure 5.—Another method. From the point C, describe an arc, *f g*, cutting A B at *f* and *g;* from the points *f* and *g*, with any equal radii greater than the half of *f g*, describe two arcs, cutting each other in D; draw C D, and C D is perpendicular to A B, and drawn from the point C, as required.

PROBLEM III.—*To draw a right line parallel to a given right line,* A B, *at a given distance,* C D.

Figure 6.—Take any points, as *e* and *f*, in the right line A B; then, with the distance C D, from the points *e* and *f*, describe arcs, G and H, of equal radii; draw the right line G H to touch the arcs at G and H; and G H will be parallel to A B, at the distance C D, as required.

PROBLEM IV.—*Through a given point,* C, *to draw a right line parallel to a given right line,* A B.

Figure 7.—In A B, take any two points, as *d* and *e*, and draw C *d;* make the angle B *e* F equal to the angle B *d* C; make *e* F equal to *d* C; and draw the right line C F, which passes through the point C, and is parallel to A B, as required.

Figure 8.—Another method. Take any point, as *e*, in A B, and from *e*, with the distance *e* C, describe an arc, C *d*, cutting A B in *d;* from C, with the same distance, C *e*, describe an arc, *e* F; make *e* F equal to *d* C; draw the right line C F, and it will pass through C, parallel to A B, as required.

PROBLEM V.—*To bisect a right line,* A B, *by a perpendicular.*

Figure 9.—Take any distance greater than the half of A B; from the points A and B, describe arcs of equal radii, cutting each other at C and D; draw C D, and it will be perpendicular to A B, and bisect A B at the point E, as required.

PROBLEM VI.—*At a given point,* E, *in a right line,* E F, *to make an angle equal to a given angle,* A B C.

Figures 10 *and* 11.—From B, with any radius, describe an arc, as *g h*, cutting B C at *g*, and B A at *h;* from E, with the same radius, describe another arc, *i k*, meeting E F at *i;* make *i k* equal to *g h;* draw the right line E *k* D; and the angle D E F is equal to the angle A B C, as required.

PROBLEM VII.—*To bisect a given angle,* A B C.

Figure 12.—From A B, cut off any part, as B *d;* take the part B *e* from B C, equal to B *d;* from the points *d* and *e*, with any distance greater than the half of *d e*, describe arcs of equal radii, cutting each other at F; draw F B, and it will bisect the angle A B C, as required.

PROBLEM VIII.—*To bisect a given arc,* A B C, *of a circle.*

Figure 13.—Draw the chord A C; bisect A C by a perpendicular, B D; and the point B will divide the arc A B C into two equal arcs, A B, B C.

PROBLEM IX.—*A circle,* A B C A, *and a tangent,* D E, *to the circumference, being given to find the point of contact.*

Figure 14.—Let the centre, F, be given; draw F A perpendicular to D E; and the point, A, where it cuts the tangent, is the point required.

Figure 15.—If the centre be not given, draw the chord F G, parallel to the tangent D E; bisect F G by a perpendicular, H A, meeting the tangent at A; then A is the point of contact required.

PROBLEM X.—*An arc,* A B C, *and a point* B, *in the circumference being given; to draw a tangent through the point,* B.

Figure 16.—From the point B, cut off two equal arcs, B D, and B E; draw the chord D E; through B, draw F G, parallel to D E; and F G is the tangent sought.

PROBLEM XI.—*Given a circle,* A B C, *and a straight line,* D E, *equal to, or less than the diameter; from a given point,* A, *in the circle, to inscribe a chord equal to* D E.

Figure 17.—From the point A, with a radius equal to D E, describe an arc, cutting the circumference at B; draw A B, which is the chord required.

PROBLEM XII.—*In a given circle,* A D C D, *to inscribe an equilateral triangle; or to divide the circle into three equal parts.*

Figure 18.—With the radius of the circle cut off the arcs A D, D B; join A B; from A, with the radius A B, describe an arc, cutting the circumference at C; join A C, C B; and A B C is the equilateral triangle required.

PROBLEM XIII.—*In a given circle,* A B C D A, *to inscribe a square; or to divide the circumference into four equal parts.*

Figure 19.—Through the centre, E, and any point, A, in the circumference, draw the diameter A C; and the diameter B E D, perpendicular to A E C; draw the chords A B, B C, C D, D A; and A B C D A will be the square required.

PROBLEM XIV.—*In a given circle,* A B C D E A, *to inscribe a pentagon; or to divide the circumference into five equal parts.*

Figure 20.—Draw the diameters A *i f* and *g i h* at right angles to each other; bisect the radius *g i* at *k;* from *k*, with the distance *k* A, describe an arc A *l*, cutting *g h* at *l;* and from A, with the distance A *l*, describe an arc cutting the circle at B; draw the chord A B; make the successive chords, A B, B C, C D, D E, each equal to A B; join E A, and A B C D E A will be the pentagon required.

PROBLEM XV.—*In a given circle,* A B C D E F A, *to inscribe a hexagon; or to divide the circle into six equal parts.*

Figure 21.—From any point, as A, draw the successive chords A B, B C, C D, D E, E F, each equal to the radius, and join the last, F A; then A B C D E F A will be the hexagon required; or the circle will be divided into six equal parts.

COROLLARY.—Hence, by the first of the three last problems, the circle may be divided into eight equal parts; by the second, it may be divided into ten equal parts; and by the third, it may be divided into twelve equal parts, only by bisecting the arcs: and if each arc be again bisected, each circle will be divided into four times the number of equal parts, as at first. The above are the only truly geometrical methods of dividing circles into equal parts, no general method having been discovered.

PROBLEM XVI.—*Upon a given straight line,* A B, *to describe an equilateral triangle.*

Figure 22.—From the points A and B, with the distance A B, describe arcs, cutting each other in C; draw C A and C B; and A B C is the equilateral triangle required.

PROBLEM XVII.—*Upon a given straight line,* A B, *required to describe a square, or tetragon.*

Figure 23.—Bisect A B by a perpendicular *e i;* make *e i* equal to the half of A B; from *i*, with the distance *i* A or *i* B, describe a circle; draw the chords B C, C D, equal to A B; join D A; and A B C D is the square or tetragon required.

PROBLEM XVIII.—*Upon a given straight line,* A B, *to describe a regular pentagon.*

Figure 24.—Draw B *f* perpendicular and equal to the half of A B; produce A *f* to *g*, making *f g* equal to *f* B; from the points A and B, with the radius B *g*, describe arcs, cutting each other at *i;* from *i*, with the radius *i* A, or *i* B, describe a circle; inscribe the successive chords B C, C D, D E, each equal to A B; join E A; and A B C D E A is the pentagon required.

PROBLEM XIX.—*Upon a given straight line,* A B, *to describe a regular hexagon.*

Figure 25.—From the points A and B, with the distance A B, describe arcs, cutting each other at *i;* from *i*, with the distance C A, or C B, describe a circle, A B C D E F A; make the successive chords B C, C D, D E, E F, each equal to A B, and join F A; and A B C D E F is the hexagon required.

PROBLEM XX.—*Upon a given straight line,* A B, *to describe an octagon, a decagon, or a dodecagon.*

Figures 26, 27, *and* 28.—Find the centre, *i*, of a circle, by such of the three last Problems as will contain a polygon of half the number of sides required; draw *i k* upwards, perpendicular to A B, equal to *i* A or *i* B; and the point *k* will

be the centre of a circle that will contain the polygon required.

EXAMPLE I. *Figure* 26.—For an octagon, find the centre, *i*, as in Problem XIII.

EXAMPLE II. *Figure* 27.—For a decagon, find the centre, *i*, as in Problem XIV.

EXAMPLE III. *Figure* 28.—For a dodecagon, find the centre, *i*, as in Problem XV.

Complete the remaining parts as above directed; and thus a circle may be found to contain any duplical multiple of these sides.

PROBLEM XXI.—*Through three given points*, A, B, C, *to describe the circumference of a circle, provided the three points be not in the same straight line.*

Figure 29.—Join A B and B C, and bisect them by perpendiculars meeting each other at D; from D, with the distance A D, of either point, describe a circle, and its circumference will pass through the other two points B and C.

PROBLEM XXII.—*To describe a circle of a given radius through two given points*, A *and* B, *provided the radius be greater than half the distance between the two given points.*

Figure 30.—From A, with the given radius, describe an arc from B; with the same radius, describe another arc, cutting the former at C; from C, with the distance C A, or C B, describe the circle A B D; and it will be the circle required.

PROBLEM XXIII.—*To describe a circle to pass through two given points*, A *and* B, *and touch a straight line*, C D; *provided the two points and the straight line be not in the same straight line.*

Figure 31.—Produce A B and D C, to meet in E; bisect the angle A E D by the straight line E F; bisect A G by the perpendicular G F; from the point of concourse, F, with the radius F G, describe a circle, G H I K, which is the circle required.

PROBLEM XXIV.—*To describe a circle to pass through a given point*, A, *and touch two straight lines*, B C *and* D E, *provided that the point be situated between the two lines.*

Figure 32.—Let the two lines, B C and D E, if not parallel, meet in F; join A F; bisect the angle B F D, by the straight line F K; in F K, take any point, as G, and draw G H, perpendicular to B C; from G, with the distance G H, describe an arc, H I, cutting A F at I; join I G, and draw A K parallel to I G and K L parallel to G H; cutting D F at L; from K, with the radius K L, describe a circle L A M, which will be the circle required.

PROBLEM XXV.—*To describe a circle that shall touch three straight lines*, A B, C D, E F, *provided all the three lines be not parallel.*

Figure 33.—Produce the lines, so that one of them, as C D, may meet the other two, A B and E F; and let the meeting of A B with C D, be at G, and of C D with E F at H; bisect the angles B G H and G H F by the straight lines G I and H I; from I, drop a perpendicular, I C, to any one of the three lines, C D; from I, with the distance I C, describe a circle, and it will touch the three straight lines A B, C D, E F, as required.

PROBLEM XXVI.—*To describe a circle that may touch a straight line*, A B, *at a given point*, C, *and pass through another given point*, D.

Figure 34.—Draw C *f* perpendicular to A B; join C D, which bisect by a perpendicular, E *f*; from *f*, with the distance *f* C, describe a circle, which will be the circle required.

PROBLEM XXVII.—*To describe a circle that shall touch a straight line*, A B, *at a given point*, E, *and another straight line*, B D, *provided that the two straight lines be not in the same straight line.*

Figure 35.—Make B *f* equal to B E; draw E G perpendicular to A B, and *f* G perpendicular to B D; from G, with the radius E G, or *f* G, describe the arc, H E *f* I, and it will touch A B at E and B D, as required.

PROBLEM XXVIII.—*To describe an arc that shall touch a given circumference*, A B C, *and a straight line*, D E, *in a given point*, F.

METHOD I.—*Figure* 36. Draw F I perpendicular to D E; from F I, produced if necessary, cut off F G, equal to the radius of the circle A B C; join K G, which bisect by a perpendicular cutting F I at I; from I, with the radius I F, describe an arc, or circumference, A F H, which is the arc required.

METHOD II.—*Figure* 37. Draw F I perpendicular to D E, and A G parallel to F I; draw A F B and B I G; from I, with the distance I F, or I B, describe an arc, F B H, which is the arc required.

PROBLEM XXIX.—*With a given radius*, G H, *to describe an arc or circumference that may touch a given arc or circumference*, C A B, *and pass through a given point*, D.

Figure 38.—From G H cut off G I, equal to the radius of the given circle; from F, with the distance I H, describe an arc; from D, with the distance G H, describe another arc, cutting the former at E; from E, with the distance E A or E D, describe an arc, G A D, and the problem is solved.

PROBLEM XXX.—*In a given sector*, A B C D, *to inscribe a circle.*

Figure 39.—Bisect the angle B A D by A G C; draw E C F tangent to the circle; produce A B to E, and A D to F; bisect the angle E A F by A G, and the angles A E F by E G; from G, with the radius G C, describe a circumference, C H I, which is the solution required.

PROBLEM XXXI.—*In a given circle to inscribe any number of equal parts.*

Divide the given circumference into as many equal parts as the number of inscribed circles: from the points of division, draw radii, and the circle will be divided into equal sectors; in any one of these sectors inscribe a circle by the last Problem; bisect the angle contained by each two radii; from the centre of the given circle, with the distance of the centre of the circle inscribed in the sector, describe a circumference, cutting the lines which bisect the sectorial angles; and the points so cut are the centres.

EXAMPLES.

Figure 40.—The given circle contains six equal inscribed circles.

Figure 41.—The given circle contains eight equal inscribed circles.

Figure 42.—The given circle contains twelve equal inscribed circles.

PROBLEM XXXII.—*Any three straight lines* A B C, *being given, to find a fourth proportional.*

Figure 43.—Make any angle, as D E F; on the straight line E D, make E G equal to A, and E D equal to B; on the straight line E F, make E H equal to C; join G H; draw D F parallel to G H; and E F is the fourth proportional sought; or E G : E D : : E H : E F; that is, A : B : : C : E F.

N.B. When the lines B and C happen to be equal, the result or fourth term is called *a third proportional;* therefore, suppose B equal to C, then A : B : : B : E F. So that finding a third proportional is the same as finding a fourth, and may be considered as only a particular case of it; and in this construction E D and E H would be equal.

PROBLEM XXXIII.—*To divide a straight line*, A G, *in the same proportion as another line*, A D, *is divided by the points* B *and* C, &c.

Figure 44.—Join D G; draw B E and C F parallel to D G, cutting A G at E and F; then will A G be divided by E and F, as A D is by B and C; or A E, E F, F G are to one another and to the whole A G, as A B, B C, C D are to one another and to the whole A D. In the same manner may any given line be divided into equal parts.

PROBLEM XXXIV.—*Between two straight lines,* A *and* B, *to find a mean proportional.*

Figure 45.—Draw the straight line C D E; make C D equal to A, and D E equal to B; bisect C E in *f*; from *f*, with the distance *f* C or *f* E, describe the semi-circle C G E; draw D G perpendicular to C E; and D G is the mean proportional required. Then C D : D G : : D G : D F; that is, A : D G : : D G : B.

PROBLEM XXXV.—*To divide a straight line,* A B C D, *harmonically in the given ratio of* I *to* K.

Figure 46.—Draw any straight line, as *e* A *g f*; make A *e* and A *f* each equal to I, and A *g* equal to K; join *f h* D; draw *g h* parallel to A D, and *h* C parallel to *e f*; join *h* B *e*; then A D : D C : : A B : B C.

PROBLEM XXXVI.—*Any three straight lines,* A B C, *being given, to describe a triangle, provided the sum of any two be greater than the third.*

Figure 47.—Draw the straight line D E equal to A; from D, with the distance B, describe an arc; and from E, with the distance C, describe another arc, cutting the former at F; draw D F and E F; and D E F is the triangle required.

PROBLEM XXXVII.—*Given the base,* A B, *of a triangle, the angle,* B A C, *and the ratio,* E *to* F, *of the other two sides, to describe the triangle, provided that* E *be to* F *in a greater ratio than the radius to the sine of the given angle* B A C.

Figure 48.—Make A *h* equal to E; from *h*, with the distance F, describe an arc, cutting A B at *i*; draw *i h*, and B C parallel to *i h*; and A B C will be the triangle required.

PROBLEM XXXVIII.—*To make a rectilinear figure equal and similar to a given rectilinear figure.*

RULE.—Divide the given rectilinear figure into triangles, by lines drawn from some one of its angles; take any one of its sides, and make a straight line in any situation equal thereto; upon the straight line thus posited, constitute a triangle, equal to the triangle on the corresponding line of the given figure; upon the side of the triangle which is to form a diagonal of the figure required, constitute another triangle, equal to the corresponding one of the given figure; proceed to form triangles on each succeeding diagonal in the same manner, till all the triangles are constructed; and the figure thus composed will be equal and similar to the given figure.

PROBLEM XXXIX.—*To make a quadrilateral equal and similar to a given one,* A B C D.

Figure 49.—Divide the given quadrilateral into two triangles, by the diagonal A C; make E F, equal to A B; and describe the triangle E F G, having its sides respectively equal to the triangle A B C; upon E G, as a base, describe another triangle, E G H, equal to A C D; and the quadrilateral E F G H is equal and similar to the given one, A B C D, as required.

PROBLEM XL.—*To make a rectilinear figure similar to a given one,* M N O P Q, &c., *upon a given straight line,* A B; *the extremity,* A, *being given, but unlimited towards* B.

Figures 50 *and* 51.—From the extremities, M, of the side of the given figure, corresponding to the given point, A, draw diagonals to every angular point; cut off a part, A *n*, equal to the corresponding side, M N, of the given figure; upon A *n* construct a figure, A *n o p q*, &c., equal and similar to the given figure, M N O P Q, &c., by the preceding problem; from A B cut off A D equal to the side of the rectilinear figure to be described; draw D E parallel to *n o*, cutting the diagonal A E at E; draw E F parallel to *o p*, cutting the diagonal A F at F; proceed in this manner to draw each successive side parallel to the corresponding side of the figure constructed; from the extremity of the last diagonal, cut the next diagonal, and from the last diagonal, in the same manner, to the other side, adjoining the given point A; and the figure A D E F G, thus constructed, will be similar to the figure M N O P Q, &c. as required.

PROBLEM XLI.—*Given two adjoining sides,* A B, B C, *of a parallelogram in position and magnitude, to describe the parallelogram.*

Figure 52.—From C, with the opposite side A B, describe an arc; from A, with the opposite side B C, describe another arc, cutting the former at D; join A D and D C, and A B C D is the parallelogram required.

N.B. If the angle C B A be given in quantity, but not in position, make it equal to the given angle by Problem VI.

PROBLEM XLII.—*Given two sides,* A *and* B, *of a rectangle, to describe the rectangle.*

Figure 53.—Draw a straight line, C D, equal to A; draw C F perpendicular to C D; and make C F equal to B; then proceed as in the last Problem, and the parallelogram C D E F will be the rectangle required.

PROBLEM XLIII.—*Given the diagonal,* A B, *of a rectangle, and one of the sides, not exceeding the diagonal, to describe the rectangle.*

Figure 54.—On the diagonal A D, describe the circumference A C B D A; make the chords A C and B D equal to the given side; join A D and B C; and A D B C A is the rectangle required.

Figure 55.—If the rectangle be a square, bisect the diameter A B by another, C D; and draw the four equal chords, which will form the square required.

PROBLEM XLIV.—*To make a triangle equal and similar to a given trapezium,* A B C D.

Figure 56.—Draw the diagonal B D, and draw C E parallel to B D, meeting the side A B produced at E; join D E, and A D E will be the triangle required.

PROBLEM XLV.—*To make a triangle equal to any given right-lined figure,* A B C D E.

Figure 57.—Produce A B on both sides of its extremities towards F and G; draw the diagonals A D and B D; through E draw E F, parallel to A D; and through C draw C G parallel to B D; join D F and D G, then D F G is the triangle required.

PROBLEM XLVI.—*To reduce a triangle,* A B C, *to a rectangle.*

Figure 58.—Bisect the altitude C G in D; through D draw E F parallel to A B, and from B draw B F perpendicular to A B; draw A E and B F perpendicular to A B; then A B F E will be the triangle required.

PROBLEM XLVII.—*To make a rectangle, having a side equal to a given straight line,* A B, *equal to a given rectangle,* C D E F.

Figure 59.—Produce the sides C F, D E, F E, and C D of the rectangle; make E G equal to A B; through G draw L H parallel to F E, cutting C F produced at L; draw L E, the diagonal, which produce to cut C D at K; draw K H parallel to E G, and E I H G will be the rectangle required.

PROBLEM XLVIII.—*To make a parallelogram with a given angle equal to a given parallelogram,* A B C D.

Figure 60.—Make the angle B A E equal to the given angle, and let A E cut C D, produced if necessary at E; draw B F parallel to A E, cutting D C at F; then will the parallelogram A B F E be equal to the given parallelogram, A B C D.

PROBLEM XLIX.—*To make a square equal to a given rectangle,* A B C D.

Figure 61.—Produce A B, the side of the rectangle, and make B E equal to B C; bisect A E in I; on I, as a centre, with the radius I E or I A, describe a semicircle, A H E; produce the other side, C B, of the rectangle, to cut the circle in H; describe a square, B H G F, upon B H; then B H G F is the square required.

PROBLEM L.—*To make a square equal to two given squares.*

Figure 62.—Let A and B be the two given squares. Construct the right-angled triangle *c a b;* let one of the sides, *c a*, containing the right angle, be equal to the side of the square, A; and let the other, *a b*, be equal to the side of the square B. On *c b*, describe the square C, which is the square required.

In the same manner may a circle be made equal to two given circles; for, if *c a*, *a b*, be considered as diameters, or radii of the two given circles, *c b* will be a diameter or radii of a circle, equal in area to them both: and also in the same manner, if two similar rectilinear figures be given, a rectilinear figure may be found similar to either, and equal to both; for, if *c a* and *a b* be considered as homologous sides, that is, those which are opposite to the equal angles, *c b* will be the homologous side of the figure required.

PROBLEM LI.—*To make a square equal to three given squares.*

Figure 63.—Let A, B, C, be three given squares. Make a right angle, *c a b;* let *a c* be equal to the side of the square A, and *a b* equal to the side of the square B; join *b c*, and it will be the side of a square equal to A and B. Draw *b d* perpendicular to *b c*, and make *b d* equal to the side of the remaining square C; join *d c*, and it will be the side of a square equal to the three given squares, A, B, C, as was required.

From this process, it is evident that a square may be found equal to any given number of squares, by first finding one equal to any two of them, and then another equal to the square found, together with one of the remaining squares; then find another equal to the square last found, together with one of the other remaining squares; and so on, till all the squares are made use of, and the last square found will be equal to all the given squares.

SCHOLIUM.—It frequently happens in the description of the segment of a circle, when the height of the segment is very small in proportion to the chord, that there is no room to find the centre; the following problems show how to describe the arc without finding the centre:

PROBLEM LII.—*Having the chord and height of the segment of a circle, to describe the segment without finding the centre.*

Figure 64.—First Method.—Let A B be the chord of the segment, and C D its height; join D A and D B; make an instrument, E F G, so that the angle E F G may be equal to the angle A D B, and the sides F E and F G at least equal to the chord A B; put a pin at A, and another at B; slide the instrument along the pins, keeping the side F E close to the pin A, and F G to the pin B; a pencil being held at the angular point F will describe the arc A F B, as was to be done.

Figure 65.—Second Method.—Join D B, and draw D H parallel to B A; make an instrument, E F G, so that the angle E F G may be equal to the angle H D B, and the sides E F and E G at least equal to the half chord D B; put pins in the points A and D, and sliding the instrument along them, a pencil at F will describe half of the arc; and by moving the pin out of A, and putting it in B, the other half will be described in the same manner.

The former of these Problems depends on *Prop.* XXI. b. iii. *Euclid*, viz., that all the angles in the same segment of a circle are equal; and the latter, on *Prop.* XXXII. b. iii. *Euclid*, viz., that if a straight line touch a circle, and from the point of contact a straight line be drawn, cutting the circle, the angles made by such line with the line touching the circle, will be equal to the angles in the alternate segments.

Either of these instruments, in the description of flat segments, may be applied occasionally; but the latter, by reason of the obtuseness of the angle, slides with less friction along the pins, takes up much less room, and can be applied in any cases where it is impossible to use the other.

N.B.—If C D is very small, the instrument may be made in one piece.

Besides the methods here shown for the description of the segment of a circle from the rules of geometry, the following arithmetical rule will be found eligible on many occasions, particularly, where there is a want of a floor to draw the lines upon, or a want of space at the ends of the curve.

RULE.—Divide the square of the half chord by the versed sine, or height of the segment; add the height of the segment to the quotient; then half the sum is the radius of the circle.

EXAMPLE.—Suppose the chord of the segment of a circle to be 24 feet, and the versed sine or rise of the segment 5 feet; the radius of the circle is required.

```
2) 24
   ——
   12 half chord.

   16.9 the radius required.
```

This is derived from *Prop.* XXXV. b. iii. *Euclid*, where it is shown, that if two straight lines in a circle cut each other, the rectangle under the segments or parts of the one, is equal to the rectangle of the segments of the other; and consequently, if the segments of one of the lines be equal to each other, the rectangle under the parts of the other line will be equal to the square of either part of the line, which is divided equally; but the contents of a rectangle, divided by one of its sides, gives the other side; or the area of the square, which is equal to the rectangle, being divided by the given side of the rectangle, gives the other side of the rectangle; and adding the versed sine, gives the diameter.

The method of dividing the circumference of a circle into any number of equal parts, or to inscribe any polygon therein, according to the approximation of Renaldinus, will be found under the article CIRCLE, Figure 5.

The various methods of describing the ellipsis upon a plane, will be found under the article ELLIPSIS; but, besides what is there shown, the following problems, concerning this curve, will also be found necessary in the art of perspective delineation.

PROBLEM LIII.—*Given the trapezium,* A B C D, *and a point,* E, *in one of the sides, to find a point in each of the other sides, so that if an ellipsis were to be inscribed, it would touch the trapezium in those points.*

Figure 66.—Produce the sides of the trapezium till they meet at K and L; then draw the diagonals A C and B D, cutting each other at F; produce B D, till it cut K L, at M. Through F, and the given point E, draw E G, cutting B C at G; and from M, through the points E and G, draw M H and M G, cutting the other two sides in the points I and H, then E, H, G, I, will be the four points required.

PROBLEM LIV.—*A trapezium*, A B C D, *being given, and a point*, E, *in one of the sides, to find the centre of an ellipsis that may be inscribed in the trapezium, and pass through the point of contact*, E, *without drawing any part of the ellipsis.*

Figure 67.—Find the points of contact H, G, I, E, as in the last Problem. Join the points G and E, by the right line G E; bisect it in M, and from K, where the opposite sides A D and B C meet, and through the point M, draw K M indefinitely; also join any other two points of contact, as H I; bisect H I and N from L, where the opposite sides B A and C D meet; draw L N, meeting K M at P; then P will be the centre of the ellipsis required.

In like manner, if the points G and H were joined, and bisected at Q, and a line being drawn from B, where the opposite sides A B and C B meet, through Q, it would also meet in P, the centre, &c.

PROBLEM LV.—*Given a trapezium*, A B C D, *and a point*, E, *in one of the sides, to find the two axes of an ellipsis that may be inscribed in the trapezium. and pass through the point*, E, *without drawing any part of the ellipsis.*

Figure 68.—Find the opposite points of contact, H, E, F, G, by Problem LIII.; from thence, find the centre, P, by the last Problem. From E, and through the centre P, draw E M, making P M equal to P E; and through H or any other point of contact, draw H K, parallel to D C, cutting E M at K; then K H is an ordinate to the diameter E M. Through P, the centre, draw P R parallel to H K; then find the extremities, R and S, of the diameter R S, by Problem 3, of ELLIPSIS. The conjugate diameters, E M and R S, being now found, then find the two axes, V W and X Y, by Problem 4, of ELLIPSIS.

GIBLEA CHEQUE, GIBLE CHECK, or JIBLET CHEEK, a recess made by cutting away the right angle formed by the front and returns of the aperture of a stone door-case, in the form of a rebate or reveal, so as to make the outside of the door, or closure, flush with the face of the wall. The term is used by stonemasons in Scotland.

GIGANTIC ORDER, a name given by Scamozzi to the Tuscan order.

GILDING, the art of applying to various substances an extremely thin coating of gold. If the substances to be gilt be metallic, this is effected by simple adhesion of the surfaces, but if not, the gold is attached by means of some adhesive medium. The use of gilding in the ornaments and decorations of an apartment, adds greatly to the richness of its appearance, but unless applied judiciously, and sparingly, it is apt to have a tawdry effect, most offensive to good taste.

GILL, a measure, the fourth part of a pint. The imperial gill now in use contains 8.6648125 cubic inches.

GIMLET, or GIMBLET, (from the French) a piece of steel of a semi-cylindrical form, hollow on one side, having a cross handle at one end, and a worm or screw below at the other: its use is to bore a small hole in a piece of wood. The screw draws the instrument forward into the wood while it is turned by the handle, and the excavated part, forming a sharp angle with the exterior, cuts the fibres across, and contains the core of wood cut out.

GINÆCONITES, (Greek) apartments in the surrounding porticos of the Greek houses, which contained the family rooms tricliniums and cubiculums. *See* HOUSE.

GIOCONDO, an architect, who flourished in the sixteenth century, was a native of Verona, where he first taught languages for a subsistence, and was also well qualified in mathematical learning. On visiting France, he was employed to build two bridges over the Seine. He very soon afterwards obtained the title of architect royal to the French king, but did not live long after; the exact period of his death is uncertain. He published several works which did him much credit as a writer, and extended his fame as an artist. Amongst others, an edition of Pliny's *Epistles*, and a correct edition of Vitruvius, illustrated with figures, the latter he dedicated to Pope Julius II. He assisted in editing many other works of the ancients, and was the first person who gave a design for Cæsar's bridge over the Rhine. In 1506, he wrote four dissertations, addressed to the magistracy of Venice, concerning the waters of that city. He was employed with Raphael and San Gallo, in superintending the erection of St. Peter's. His last work was probably the rebuilding of the stone bridge at Verona.

GIRANDOLE, (Italian) a chandelier; a large kind of branched candlestick.

GIRDER, (from the Saxon) a large beam, either of one entire piece, or consisting of several, in order to shorten the joists of a floor, which would otherwise have too great a bearing.

When girders are made double, they should be turned the contrary way to that in which they were sawn, that the stronger end may support the weaker. If it be found necessary to truss girders, the truss should be similar to that of a roof. The best form of girder for floors of moderate dimensions, consists of two braces and a straining piece, having one-third of the whole length, excepting the part at each end, which is necessary for the butment or wall-hold.

The two braces are strained by means of queen-bolts, and resisted at the other end by iron butments, which are formed to the same section as the braces, and are made to go through on each side, so as to have a bolt at either end; the braces and straining piece being let into each beam.

When girders have a very great bearing, and have only the depth of a single piece, it is well known that the strain at the joggles and abutments is prodigious: girders of long bearing should therefore be made into two flitches, one above the other, and braced as above.

By this plan, the depth allowing of an upper and lower beam, the girder will be infinitely more stiff than one of the depth of a single piece, and consequently more able to support the naked flooring and boarding.

No summers or girders should be over the heads of doors or windows.

No summer or girder should lie less than ten inches into the wall; nor joists less than eight inches.

The ceiling joists ought to be framed about half an inch below the girder, and the girder ought to be furred to the level of the ceiling joists.

Girders ought to be made of heart wood, as free from knots as possible, because they destroy the continuity of the fibres, and impair the strength of the girder.

The following rules for finding the scantlings, are given by Tredgold in his *Elementary Principles of Carpentry.*

"*Case* 1.—To find the depth of a girder when the length of bearing and breadth of the girder are given.

"*Rule.*—Divide the square of the length in feet, by the breadth in inches; and the cube root of the quotient multiplied by 4.2 for fir, or by 4.34 for oak, will give the depth required in inches.

"*Case* 2.—To find the breadth when the length of bearing and depth are given.

"*Rule.*—Divide the square of the length in feet, by the cube of the depth in inches; and the quotient multiplied by 74 for fir, or by 82 for oak, will give the breadth in inches.

"*Example to Case* 2.—Let the bearing be 20 feet, and the depth 13 inches; to find the breadth, so that the girder shall be sufficiently stiff.

Drawn by M.A. Nicholson

Eng^d by R. Thew.

The cube of the depth is 2197, and the square of the length is 400; therefore $\frac{400}{2197} \times 74 = 13.47$ inches, the breadth required.

"In these rules, the girders are supposed to be 10 feet apart, and this distance should never be exceeded; but should the distance apart be less or more than 10 feet, the breadth of the girder should be made in proportion to the distance apart.

"When the bearing exceeds about 22 feet, it is very difficult to obtain timber large enough for girders; and it is usual, in such cases, to truss them. The methods in general adopted for that purpose, have the appearance of much ingenuity; but in reality, they are of very little use. If a girder be trussed with oak, all the strength that can possibly be gained by such a truss, consists merely in the difference between the compressibility of oak and fir, which is very small indeed; and unless the truss be extremely well fitted at the abutments, it would be much stronger without trussing. All the apparent stiffness produced by trussing a beam, is procured by forcing the abutments, or, in other words, by cambering the beam. This forcing, cripples and injures the natural elasticity of the timber; and the continual spring from the motion of the floor, upon parts already crippled, it may easily be conceived, will soon so far destroy them as to render the truss a useless burden upon the beam. This is a fact that has been long known to many of our best carpenters, and which has caused them to seek for a remedy in iron trusses; but this method is quite as bad as the former, unless there be an iron tie as an abutment to the truss; for the failure of a truss is occasioned by the enormous compression applied upon a small surface of timber at the abutments. The defects of ordinary trussed girders are very apparent in old ones, as it is not simply strength that is required, but the power of resisting the unceasing concussions of a straining force, capable of producing a permanent derangement in a small surface at every impression." Girders of wrought and cast iron are now used extensively in railway and canal works, for bridges, &c.

GIRDING BEAM. *See* Girder.

GIRDLE, (from the Saxon) a circular band or fillet surrounding a part of a column.

GIRT, the same as Fillet, which see.

Girt, in timber measure, according to some, the fourth part of the circumference, and is generally taken for the side of a square, equal in area to the section of the tree cut through where the perimeter is taken in order to obtain the girt.

GIVEN DATUM, a term frequently used in mathematics, signifying a thing supposed to be known, whether in position or magnitude; which is accordingly said to be *given in position*, or *in magnitude*, or both, as one or the other, or both, are known.

GLACIS, (French) an easy slope or declivity.

GLASS, (from the Saxon, *glaes*) a hard, brittle, transparent lactitious substance, formed by the fusion of silicious matter, such as powder flint or fine sand, blended with alkaline earth, metallic oxide, and other substances. In building, glass is used in thin transparent plates for windows, which admit light, while they exclude wind and rain.

The time at which glass was invented, is very uncertain. "It was known," says Dr. Ure, "to the Phenicians, and constituted for a long time an exclusive manufacture of that people, in consequence of its ingredients, (natron, sand, and fuel,) abounding upon their coasts. It is probable that the more ancient Egyptians were unacquainted with glass, for we find no mention of it in the writings of Moses. But, according to Pliny and Strabo, the glass-works of Sidon and Alexandria were famous in their times, and produced beautiful articles, which were cut, engraved, gilt, and stained of the most brilliant colours, in imitation of precious stones. The Romans employed glass for various purposes; and have left specimens in Herculaneum, of window-glass, which must have been blown by methods analogous to the modern. The Phenician processes seem to have been learned by the Crusaders, and transferred to Venice in the 13th century, where they were long held secret, and formed a lucrative commercial monopoly. Soon after the middle of the 17th century, Colbert enriched France with the blown mirror glass manufacture."

The application of glass to the glazing of windows, is of comparatively modern introduction, at least in northern and western Europe. In 674, artists were brought to England from abroad to glaze the church windows at Wearmouth in Durham; and even in the year 1567, this mode of excluding cold from dwellings was confined to large establishments, and by no means universal even in them. An entry then made, in the minutes of a survey of Alnwick Castle, the residence of the Duke of Northumberland, informs us that the glass-casements were taken down during the absence of the family to preserve them from accident. A century after that time, the use of window-glass was so small in Scotland, that only the upper rooms in the royal palaces were furnished with it, the lower part having wooden shutters to admit or exclude the air.

At an early period of its history in this country, the glass-manufacture became an object of taxation, and duties were from time to time imposed on it, which operated most injuriously, not only on the manufacture itself, but on building generally, by preventing the more extensive use of so ornamental an article. Within the last few years, however, a more enlightened policy has prevailed; and so great a reduction of the duties on glass has been granted, that an enormous increase in the manufacture and use of it has taken place. The result is seen in the improved appearance of our dwelling-houses, in the great superiority of the quality of the glass used at present, and in the magnificent plate-glass windows now so generally adopted in shop-fronts.

Of the glass used in building, there are three qualities in common use, denominated *best*, *second*, and *third*. The best is that which is of the purest metal, and free of blemishes, as blisters, specks, streaks, &c. The second is inferior, from its not being so free of these blemishes. The third is still inferior, both in regard to quality and colour, being of a greener hue. They are all sold at the same price per crate, but the number of tables is different, according to the quality: best, 12 tables; second, 15 tables; third, 18 tables.

These tables are circular when manufactured, and about four feet in diameter; in the centre is a knot, to which, in the course of the process, the flashing rod was fixed, but, for the safety of carriage and conveniency of handling, as well as utility in practice, a segment is cut off, about four inches from the knot: the large piece with the knot, still retains the name of *table*, the smaller piece is technically termed *a slab*. From these tables being of a given size, it is reasonable to suppose that when the dimensions of squares are such as cut the glass to waste, the price should be advanced.

Crown glass is the best description of window-glass. It is made without any mixture of metallic oxide, and is both specifically lighter, and much harder, than flint glass. Broad glass is an inferior kind of window-glass, made with a cheaper kind of alakli. Plate-glass is superior in quality and in appearance to all other glass. From the quantity of metal it contains, it must be almost, if not altogether, colourless—that sort which is tinged, being of an inferior quality. It is both blown and cast. Plates which are blown are limited in dimensions, while those that are cast are made of very great size, the limit being caused by the expensiveness of the machinery required for the management of very large masses of the material. Plate-glass is necessarily costly, because of the numerous and laborious operations which it undergoes, and of the risks of fracture while subjected to them. In sashes it has a magnificence peculiar to itself; objects seen through it are not distorted; and objects seen in it, have the same fair appearance. It is now made of very large dimensions.

Glass has also been introduced as a material for the manufacture of pipes. Mr. James Hartley, of Bishopwearmouth Glass Works, has, after extensive experiments, succeeded in establishing the practicability of making glass pipes, suitable for the conveyance of gas or water, and has, it is also said, proved that pipes, stronger than the ordinary metal ones, and much cheaper, may be made of glass.

A still more novel application of this material is noticed in *The Builder*, viz., the importation from Antwerp of a small parcel of glass-tiles. These tiles are similar in form to the common clay-tile for roofing buildings, the advantage held out being their lightness, and being pervious to the rays of the sun. The latter quality is presumed to render them suitable for the roofs of green-houses, as they will not interrupt the heat and light, whilst they are sufficiently strong to resist the effects of hail-storms, which will much reduce the cost of insurance on green-houses. They have the appearance of the common green glass, they vary in price from eleven to sixteen shillings per dozen, according to their thickness and weight. *See* STAINED GLASS.

GLAZING, the business of the glazier, consisting in fitting glass in sashes, frames, and casements, and fixing it either in putty or lead.

It may be classed under the denominations following:—*Sash-work*, *lead-work*, and *fret-work*.

The tools necessary for sash-work are, a diamond, a ranging-lath, a short-lath, a square, a rule, a glazing-knife, a cutting chisel, a beading hammer, duster, and sash-tool; and in addition, for stopping-in squares, a hacking knife and hammer. The diamond is a speck of that precious stone, polished to a cutting point, and set in brass in an iron socket, to receive a wooden handle, which is so set as to be held in the hand in the cutting direction; the top of the handle goes between the root of the fore-finger and middle-finger, and the under part, between the point of the fore-finger and thumb; there is, in general, a notch in the side of the socket, which should be held next the lath. *See* DIAMOND.

Some diamonds have more cuts than one.

Plough diamonds have a square nut on the end of the socket next the glass, which on running the nut square on the side of the lath, keeps it in the cutting direction. Glass benders have these plough diamonds without long handles, as, in cutting their curious productions, they cannot apply a lath, but direct them by the point of their middle finger gliding along the edge of the glass. The ranging lath must be long enough to extend rather beyond the boundary of the table of glass. Ranging of glass, is the cutting it in breadths, as the work may require, and is best done by one uninterrupted cut from one end to the other. A short lath is applied to stripping the square to suit the rebate of a sash; as in ranging, they are generally cut full. A square is used in cutting the squares from the range, that they may be more certainly cut at right angles. The carpenter's chisel is used in paring away some of the rebate of the sash, when the glass does not lie so flat as to allow a proper breadth for front putty. The glazing knife is used for laying-in the putty in the rebates, for bedding-in the glass, and for finishing the front putty. A bradding-hammer is made with a head in the form of a small parallelopiped, with a socket for the handle, rising at an obtuse angle from the middle of one of its sides; the square edges of the head drive the brads in a horizontal position, and is less liable to accident than if performed by another tool: some use the basil of the chisel.

Brass points are esteemed the best; small cut brads are also used. All new work should be bradded, to prevent the glass being moved out of its bed.

The duster is used in brushing up the front pulleys, and taking off the oil from the glass. The sash-tool is used in taking off the oil from the inside, after the back pulleys are cleaned off, and is generally used wet. The hacking-knife is for cleaning out the old putty from rebates, where squares are to be stopped in. The use of the rule needs no explanation.

N.B.—Glaziers' rules are two feet long, in four different pieces. Lead-work is used in inferior offices, and is in general practice throughout the country.

Frames are made to receive these lights, with bars across, to which the lights are fastened by leaden bars: these bars are called *saddle bars*, and where openings are wanted, a casement is introduced, either of wood or iron. Sometimes a sliding frame answers the same purpose. Church windows are in general made in this manner, in quarries or in squares. The tools which this work, in addition to the former, require, are these: a vice, with different cheeks; and cutters, to turn out the different kinds of lead, as the magnitude of the window or the squares may require.

In common there is broad and narrow lead. The German vices are esteemed the best, and turn out a variety of lead in different sizes.

There are moulds belonging to these vices, in which bars of lead are cast; in which form the mill receives them, and turns them out with two sides parallel to each other, and about three-eighths of an inch broad, with a partition connecting the two sides together, about an eighth of an inch wide, forming, on each side, a groove nearly $\frac{3}{16}$ by $\frac{1}{8}$ of an inch, and about six feet long.

The remainder of the tools, besides a vice and moulds, are, a setting-board, a latterkin, setting-knife, rosin-box, tin, glazing-irons, and clips.

The setting-board is that on which the ridge of the light is marked and divided into squares, and struck out with a chalk line, or drawn with a lath, which serve to guide the workman. One side and end are squared, with a projecting bead or fillet.

The latterkin is a piece of hard wood, pointed, and so formed as to clear the groove of the lead, and widen it for the more readily receiving the glass.

The setting-knife is a blade with a round point, loaded with lead at the bottom of the blade, with a long square handle. The square end of the handle serves to force the squares home tight in the lead; being loaded with lead, it is of greater weight, and also cuts off the ends of the lead with greater ease, as, in the course of working these lights, the lead is always longer than necessary, till trimmed.

The rosin-box contains powdered rosin, which is put on all the joints previous to soldering.

Tin is for preparing the glazing before soldering.

The clips are for holding the irons.

All the intersections are soldered on both sides, except the outside joints of the outer side, *i. e.* where they come to the outer edge. These lights should be cemented, which is done by thin paint being run along the lead bars, and the chasm filled with dry whiting, and after it has stood a short time, till the oil is secreted a little, a small quantity of dry red or white lead is dusted over it again; it then dries hard, and will resist the weather well.

Fret-work is the ornamental part, and consists of working ground and stained glass, in fine lead, into different patterns. In many cases, family arms and other devices are worked in it. It is a branch capable of great improvement, but at present neglected.

Old pieces are very much esteemed, and valued high. The same expense would, doubtless, were it not for prejudice, furnish elegant modern productions. They are placed in halls, and stair-case windows, or in some particular church windows; in many instances, they are introduced where there is an offensive aspect in a place of particular or general resort.

Glaziers clean windows; and in London it is a great part of their work.

GLOBE, (French) a spherical body, more usually called a sphere. *See* SPHERE.

GLUE, (from the French) a tenacious viscid matter, made of the skins of animals, for cementing two bodies together.

Glue is bought in cakes; and is better, as the skin of the animal from which it is made is older: that which swells much when steeped in water, without dissolving in it, is of the best quality.

To prepare glue; break the cakes into small fragments of convenient size: soak them in as much water as will just cover them; after it has remained about twelve hours, boil the whole in a copper or leaden vessel, over a gentle fire, till the glue is dissolved in the water, stirring it constantly with a wooden stick: it should then be poured through a sieve, to separate it from the scum and other filth: and lastly, it should be boiled over a smart fire, and put into a wooden vessel, in which it is to remain for use.

To make good glue for external work: grind as much white lead with linseed oil as will just make the liquid of a whitish colour, and strong but not thick; and it will then be fit for use.

The following is given by Mr. Clennel as a good method of making glue. The materials above enumerated are "first digested in lime-water, to cleanse them from grease or dirt; they are then steeped in clean water with frequent stirring, and afterwards laid in a heap, and the water pressed out. They are then boiled in a large brass cauldron with clean water, scumming off the dirt as it rises, and it is farther cleansed, by putting in, after the whole is dissolved, a little melted alum, or lime, finely powdered. The scumming is continued for some time, after which the mass is strained through baskets, and suffered to settle, that the remaining impurities may subside. It is then poured gradually into the kettle again, and farther evaporated by boiling and scumming, till it becomes of a clear dark-brownish colour. When it is thought to be strong enough, it is poured into frames or moulds about six feet long, one broad, and two deep, where it gradually hardens as it cools, and is cut out when cold by a spade into square cakes. Each of these is placed in a sort of wooden box, open in three divisions to the back; in this, the glue, while yet soft, is cut into three slices, by an instrument like a bow, with a brass wire for its string. The slices are then taken out into the open air, and dried on a kind of coarse net-work, fastened in moveable sheds, four feet square, which are placed in rows in the glue-maker's field. When perfectly dry and hard, it is fit for sale."

Mr. Austin, of Hatton Garden, some time since, took out a patent for "*a new method of glueing or cementing certain materials for building and other purposes.*" The mode of manufacture and applying it, is thus described in the specification:—

"The cement used by the patentee is made by mixing India-rubber with cold naphtha, in the proportion of eight ounces of India-rubber cut into small pieces, to each gallon of naphtha, stirring it from time to time, until the India-rubber is dissolved; then, to one part, by weight, of this mixture two parts of lac are added, and the whole is thoroughly blended together by the application of heat, accompanied with occasional stirring. When greater elasticity is required, a larger proportion of the India-rubber solution is used; if greater hardness is necessary, a larger proportion of lac is employed; and where the India-rubber would be liable to injury from great exposure and pressure, a much less proportion is used, and it is sometimes dispensed with altogether; asphalte, pitch, or resin, or other materials of that nature, may in some instances be substituted for the lac.

The materials for building-purposes to which this cement is applied are, slate, tiles, stone, glass, and metal-plates. When being used, the cement is kept in a heated state in a dish or vessel containing a narrow trough, termed a stamper, which slides up and down therein between guides; the slate or other material is brought to the heat of 150 degrees Fahrenheit, and placed upon the dish, and the stamper being then raised, imprints or stamps a margin of cement thereon. The requisite margins of cement for forming overlapping joints being thus applied to the slate or other material, the cemented portions or margins are laid in contact with each other, and in a short time become firmly united, forming water-tight surfaces. Sometimes, to expedite the process, a coating of naphtha, or other spirit that will act upon the cement, or a solution made by dissolving the cement in naphtha or other spirit, is applied to the cemented portions, or margins. The cement may also be used for securing the above materials to the building, as well as to each other."

"The patentee connects pieces of glass together with the above cement when making skylights, conservatories, frames for horticultural purposes, &c.; he also cements slate, stone, metal, and manufactured clays and cements, together, or to wood, or to woven and other fabrics, to wood for building or other purposes; he likewise cements pieces of leather for making boots and shoes, and hose or pipes for fire-engines; also leather and cork together, or to wood, metal, or woven or other fabrics, and woven and other fabrics to wood, for the manufacture of trunks, portmanteaus, packing cases, and other purposes. When joining these materials, the parts must be dry and free from dust, and should be warmed previous to receiving a coat of the cement, in order that it may not be chilled at the moment of application. If the joint is to be made at once, the parts must be expeditiously put together and pressed, as the cement rapidly loses its heat, and becomes solidified, but the junction may be effected at any subsequent period by the application of heat, or the spirit or solution before described."

GLYPH, any canal or cavity used as an ornament; hence the tablets in the frieze of the Doric order are called *triglyphs*, from their having three vertical channels; that is, two whole ones and a half one at each edge of the triglyph.

GNEISS, is the name of one of the great mountain formations, being reckoned the oldest of the stratified rocks. It is composed of the same substances as granite, viz.: quartz, mica, and feltspar. In gneiss, however, they are not in granular crystals, but in scales, so as to give the mass a slaty structure. It abounds in metallic treasures.

GOBELIN, the term applied to the celebrated tapestry, introduced into France by the brothers Gobelin. In the year 1677, Colbert purchased the dye-houses from the Gobelin family, in virtue of an edict of Louis XIV., styled it the *Hotel Royal des Gobelins*, and established on the ground a great manufactory of tapestry, similar to that of Flanders. The celebrated painter Le Brun was appointed director-in-chief of the weaving and dying patterns. Under his administration were produced many magnificent pieces of tapestry, which have ever since been the admiration of the world; such as Alexander's battles, the four seasons, the four elements, and the history of the principal events in the reign of Louis XIV. There is an academy within the Gobelins for the instruction of youth in the various branches of the fine arts, in physical science, and mechanics, subservient to the improvement of the manufacture.

GNOMONIC COLUMN, *See* Column.

Gnomonic Projection of the Sphere, that in which the eye is situated in the centre of the sphere, and projects all the circles upon a plane touching its surface.

It is evident, that in this projection, all the great circles of the sphere are projected into straight lines, since they all pass through the centre of the sphere. Every lesser circle parallel to the plane of projection is projected into a circle, and any lesser circle not parallel to the plane of projection, is projected into one of the conic sections.

A very excellent tract upon the projection of the sphere, by Mr. Emerson, contains the full theory of the gnomonical projection.

GOCCIOLATOIO, *See* Corona.

GOLA, Gola-Diretta, Gola-Rovescia, *See* Cymatium.

GOLDMAN, an architectural writer, as also a mathematician, born at Breslaw, in Silesia, in the year 1623, and died at Leyden, 1665. He published his *Elementa Architectura Militaris*, 1643: another treatise of his, on the same subject, was published in 1696, accompanied with numerous engravings, and a life of the author.

GONIOMETER, (from γωνια, *an angle*, and μετρω, I *measure*) an instrument for measuring solid angles. A most convenient instrument for this purpose was invented by Dr. Wollaston.

GONIOMETRICAL LINES, lines used in order to determine the quantity of an angle. Such are the lines of sines, tangents, and secants, commonly placed upon plane scales, the sector, Gunter's scale, &c.

GORGE, (French) a concave moulding, much less recessed than a scotia, used chiefly on frames, chambranles, &c.

Gorge is sometimes used for the cyma recta. It is used for the neck of a column; but it is more properly called *collarino*, *gorgerin*, or *gorge*.

GORGERIN or Gorge, in architecture the little frieze in tne Doric capital, between the astragal at the top of the shaft of the column, and the annulets. Some call it *collarino*. Vitruvius gives it the name of hypotrachelium.

GOTHIC ARCHITECTURE, a title generally understood in the present day to apply to that style of building in which the Pointed arch is the most prominent, though not the only characteristic. The term has been variously applied at different times, and by different writers, whether contemporaneous or otherwise; indeed, so great is the confusion on the subject, that it is not always easy to define the class of buildings alluded to under this title. Some authors include under the term all styles of building which differ from those adopted by the Greeks and Romans, embracing all modes of building which were in vogue from the decline of Classical architecture to its revival in the sixteenth century. Others limit the phrase to those modes which prevailed from the decline of Roman art to the introduction of the Pointed arch, including the Romanesque, Lombardic, Saxon, and Norman styles, in all of which the semi-circular arch was employed. A third class of writers apply the name solely to the Pointed style, under which restriction the term is for the most part employed in the present day, though some would still farther limit the application by adopting it solely for that division of Pointed architecture which is by most writers designated Pure or Decorated Gothic.

The term Gothic seems to have been first brought into use by the Italians, who applied it to all styles of building then prevalent which deviated from the Classic. Vasari, an Italian architect who lived at the commencement of the sixteenth century, after speaking of Greek orders, says, "there is another kind called Gothic (Tedesca) which differs materially both as to ornament and proportion from that of ancient and modern date. So deficient is it in systematic rules, that it may be deemed the order of confusion and inconsistency. The portals of this description of buildings, which has so much infested the world, are adorned with slender columns entwined like vine-branches, and unequal to sustain the weight, however light, which is placed above them. Indeed, the whole exterior, with its other decorations, its profusion of canopied niches raised above one another, with so many pyramids, leaves, and points, renders it apparently impossible, not only that they should be durable, but that it should support itself—giving the whole an air of being made of pasteboard rather than of stone and marble. This style was invented by the Goths, who spread the contagion through Italy. May God deliver every country in future from the adoption of plans, that substituting deformity for beauty, are unworthy of further attention."

From the description which he gives in this passage, it will be very reasonably inferred, that he refers to the Pointed style of architecture, but it is evident that he also includes the modes adopted on the decline of Roman art, for he cites, as examples, the palace of Theodoric at Ravenna, and the churches of St. John the Evangelist, and of St. Vitalis, in the same city, as also other buildings of Lombardic and Byzantine architecture. Amongst the first writers who introduced the term into England was, we believe, Evelyn, and he gives the following description:—"Gothic architecture," says he, "is a congestion of heavy, dark, melancholy, monkish piles, without any just proportion, art, or beauty;" and elsewhere he describes it as "a fantastical light species of building." Sir Christopher Wren confirms the use of this term, for, after describing edifices erected after this mode of building as "mountains of stone, vast gigantic buildings, but not worthy the name of architecture," he says, "This we now call the Gothic manner; so the Italians called what was not after the Roman style." In another place our author applies the term *Saracenic* to buildings in the Pointed style, supposing that form of arch to have been brought from the East by the Crusaders. But to show what vague notions he held upon the subject, we must add, that he attributes the cathedral of Winchester, and the church of St. Cross, to a period preceding the Norman conquest. Warton's ideas upon this head must have been also very indefinite, for he makes his earliest division of the style to commence about A. D. 1200, which he calls *Gothic Saxon*, as distinguished from the true Gothic, of which he makes tracery in the window-heads the chief characteristic. He even denies the title of Gothic to Salisbury cathedral, which he includes under the term Gothic Saxon. Bishop Warburton gives the name of *Norman* to Pointed architecture, reserving that of *Saxon* for those styles in which the semi-circular arch prevailed.

Captain Grose, a few years later, adverting to the use of the title in question, says, "Most of the writers who mention our ancient buildings, particularly the religious ones, notwithstanding the striking difference in the styles of their construction, class them all under the common denomination of Gothic; a general appellation, by them applied to all buildings not exactly conformable to some one of the five orders of architecture. Our modern antiquaries more accurately divide them into Saxon, Norman, and Saracenic; or that species vulgarly, though improperly, called Gothic."

Mr. Bentham, a cotemporary, remarks upon the same subject as follows:—"The term Gothic, applied to architecture, was much used by our ancestors in the last century, when they were endeavouring to recover the ancient Grecian or Roman manner; whether they had then a retrospect to those particular times when the Goths ruled in the empire, or only used it as a term of reproach to stigmatize the productions of ignorant or barbarous times, is not certain; but I think they meant it of Roman Architecture: not such certainly as had been in the age of Augustus, but such as prevailed in more degenerate times, when the art itself was almost lost, and particularly after the invasion of the Goths: in which state it continued many ages without much alteration. Of this kind was our Saxon and earliest Norman manner of building, with circular arches and strong massive pillars, but really Roman architecture, and so was called by our Saxon ancestors themselves. Some writers call all our ancient architecture, without distinction of round and pointed arches, Gothic; though I find of late the fashion is to apply the term solely to the latter, the reason for which is not very apparent. The word Gothic, no doubt, implies a relation some way or other to the Goths; and if so, then the old Roman way of building with round arches above described, seems to have the clearest title to that appellation; not that I imagine the Goths invented or brought it with them; but that it had its rise in the Gothic age, or about the time the Goths invaded Italy. The style of building with pointed arches is modern, and seems not to have been known in the world till the Goths ceased to make a figure in it. Sir Christopher Wren thought this should rather be called the Saracen way of building; the first appearance of it here was certainly in the time of the Crusades; and that might induce him to think the archetype was brought hither by some who had been engaged in those expeditions, when they returned from the Holy Land."

After these remarks, no one will wonder at Dr. Milner complaining of the confusion and difficulty with which the study of Gothic architecture had been surrounded by the vague and unsettled manner in which terms had been employed by his predecessors and cotemporaries who had written upon the subject.

The employment of the term and its application seems to have arisen from an idea entertained by the Italians, that the style of building to which they applied it was introduced by the Goths after their incursion into Italy; this is evident from the expressions of Vasari, above quoted. Now, if the use of the title were restricted to those buildings with round arches which were prevalent after the fall of the Roman empire, there might be apparently some grounds for its assumption, but this does not seem to be the case even with the Italians, and certainly not with our own countrymen, although some of them doubtless thought that the Pointed arch was an invention of the Goths, in illustration of which we quote a passage on the subject from Sir Henry Wotton. He says:—"As for those arches which our artisans call of the third and fourth point, and the Tuscan writers *de tergo* and *de quarto acuto*; because they always concur in an acute angle, and do spring from a division of the diameter into three, four, or more parts at pleasure. I say, such as these, both for their natural imbecility of the sharp angles themselves, and likewise for their very uncomeliness, ought to be exiled from judicious eyes, and left to their first inventors the Goths or Lombards, amongst other reliques of that barbarous age.

Whether the Pointed style, or that previously existing, be considered as invented by the Goths, the notion in either case is false and without foundation. The Goths had no architecture of their own; and not only are they innocent of introducing any new style into Italy, but more than that, they do not seem to have caused any alteration in the old. What changes did take place arose very naturally from the gradual decline of art. It is not our intention in this place to enter into any discussion on the origin of Gothic Architecture; we defer that for a future paper on POINTED ARCHITECTURE; all we desire to state at present, is that neither the Pointed style nor that preceding, in which the semi-circular arch continued to be employed, were introduced by the Goths; and that, therefore, the term *Gothic* could not justly be applied to them on that score.

By many writers the term is doubtless used as a term of reproach, and is intended as equivalent to the words—uncivilized, barbarous; on which account, many persons of the present day have objected to its continued use. At the time of the revival of classical architecture, or rather of the adaptation of classic orders and details to modern architecture, the excellencies of Pointed architecture were but little understood or appreciated; and hence the desire to stigmatize it as barbarous. Since then, however, the prejudice for the orders has ceased, and Gothic art is viewed with a more favourable, and, we may add, more experienced eye, and men are desirous of rescuing it from any stigma, even though it be but a nominal one.

From this cause, many names have been suggested in lieu of the contemptuous *Gothic*, amongst which we may enumerate the following—*Christian*, *Catholic*, *English*, and *Pointed*—as being the most usual. It is true the word *Gothic* is ill-devised, insignificant, and entirely inapplicable, yet we cannot think that any of the terms proposed are sufficiently expressive to explode a title of so long standing and such universal acceptation. The term was originally, without doubt, employed as a mark of reproach, but now-a-days no such meaning is implied by it, and no one is misled by its use. In applying the term now, no one ever thinks of its original intention, but considers it solely as a phrase descriptive of a certain class of buildings, of which each man forms his opinion, quite independently of its appellation. Even supposing we were to explode this expression, what could be substituted in its place: no one term has been universally agreed upon; and we should have a general scramble, each partisan seeking to adopt his own peculiar title, and probably maintaining it to the utmost of his power; so that instead of one, we should have several titles, each striving for, but none obtaining universal adoption.

We submit, that it is better to have one term well established, even though it be confessedly a very incorrect one, than several exceptionable ones of only partial use.

Sir James Hall speaks to the point when he says: "In the present unsettled state of public opinion, both with respect to the origin and the history of this style, I have judged it best to attempt no innovation in this matter, and have made use of the name of *Gothic Architecture;* which, though certainly no less objectionable than many of those that have been offered to the public, has the advantage of being universally known and understood amongst us."

The two first names which we have mentioned as proposed substitutes for the word *Gothic*, namely, *Christian* and *Catholic*, are objectionable, on the grounds that this is not the only style which is entitled to such designations. Both Lombardic and Byzantine were styles adopted by the Christian church; nay more, in a certain sense they may be said to have been of Christian growth. Mr. Pugin contends, that although other styles have been employed in early ages, they were rather of Pagan origin, or arose from unsuccessful imitations of Pagan buildings; in fact, that they were mere make-shifts, used only for a temporary purpose, until a more perfect system, and one more thoroughly Christian, should arise. We are most willing to admit that Gothic architecture is the perfection of Christian art, but, at the same time, cannot in justice allow its exclusive title to that term. The third term can only be of partial application, and only then correctly employed when applied to the style as practised in our own country: the theory that Gothic architecture originated in this country, has, we believe, been long since exploded. The term *Pointed*, though on many accounts a very correct one, is still open to similar objections to those urged against the two first, inasmuch as it would naturally include other styles besides the one to which it is intended to be applied.

In the quotations which we have above introduced from writers of the last two centuries, we have been necessitated to admit some contemptuous and opprobrious observations on the merits of Gothic buildings, when compared with those of Greece and Rome; but we cannot permit such remarks to pass by unheeded. At the period of what is called the revival of classic art, such unworthy opinions as those we have alluded to were far from uncommon; indeed, it was fashionable in those days to stigmatize everything belonging to the middle ages as dark and barbarous, and no one could give better proof of his admiration of classic antiquity than by reviling and sneering at every other kind of art, more especially at that which threatened a most dangerous rivalry. The quotations which we have already given on this head have been taken from Vasari, Wotton, Evelyn, and Wren; we will now give some more extracts of the same tendency, taken, for the most part, from the writings of the last-named architect. In his *Parentalia*, he says: "It was after the irruptions of swarms of those truculent people from the north, the Moors and Arabs from the south and east, overrunning the civilised world, that wherever they fixed themselves, they began to debauch this noble and useful art, when instead of those beautiful orders so majestical and proper for their stations, becoming variety, and other ornamental accessories, they set up those slender and misshapen pillars—or, rather bundles of staves and other incongruous props—to support incumbent weights and ponderous arched roofs, without entablature; and though not without great industry, not altogether naked of gaudy sculpture, trite and busy carvings; it is such as gluts the eye, rather than gratifies and pleases with any reasonable satisfaction. For proof of this, without travelling far abroad, I dare report myself to any man of judgment, and that has the least taste for order and magnificence, if, after he has looked a while upon King Henry VII.'s chapel at Westminster—gazed upon its sharp angles, jetties, narrow lights, lame statues, lace, and other out-work and crinkle-crankle, and shall then turn his eyes on the Banqueting House, built at Whitehall by Inigo Jones, after the ancient manner; or on what his majesty's surveyor has done at St. Paul's, and consider what a glorious object the cupola, porticoes, colonnades, and other parts present to the beholder; let him well consider and compare them judicially, without partiality and prejudice, and then pronounce which of the two manners strikes the understanding, as well as the eye, with more majestic and solemn greatness, though they, in so much plainer and more simple dress, conform to the respective orders and entablature, and, accordingly, determine to whom the preference is due. Not, as we have said, there is not something solid, and oddly artificial, too, after a sort; but the universal and unreasonable thickness of the walls, clumsy buttresses, towers, sharp-pointed arches, doors, and other apertures, without proportion; nonsensical insertions of various kinds of marbles impertinently placed; turrets and pinnacles, thick set with monkeys and chimeras, and abundance of busy-work and other incongruities, dissipate and break the angles of the sight, and so confound it that one cannot consider it with any steadiness where to begin or end; taking off that noble air and grandeur, bold and graceful manner, which the ancients had so well and judiciously established." "Nothing was thought magnificent that was not high beyond measure, with the flutter of arch-buttresses —so we call the sloping arches that poise the higher vaulting of the nave. The Romans always concealed their butments; whereas the Normans thought them ornamental. These, I have observed, are the first things that occasion the ruin of cathedrals; being so much exposed to the air and weather, the coping, which cannot defend them, first failing, and, if they give way, the vault must spread. Pinnacles are of no use, and of little ornament. The pride of a very high roof raised above a reasonable pitch is not for duration." Elsewhere speaking of their construction, he says: "Few stones were used but what a man might carry up a ladder on his back from scaffold to scaffold, though they had pulleys and spoked wheels upon occasion; but having rejected cornices, they had no need of great engines. Stone upon stone was easily piled up to great heights, therefore the pride of their work was in pinnacles and steeples." "The Gothic way carried all their mouldings perpendicular, so that they had nothing else to do but spire up all they could." "They affected steeples, though the Saracens themselves used cupolas."

We do not feel so much surprised at such expressions escaping men unattached to the profession, or even Vasari, for he was an Italian, and therefore naturally biassed in favour of classic art; but to hear such opinions from a man like Sir Christopher, must ever be a subject for wonder and regret. Wren was, without controversy, a man of great talents and high attainments; of considerable taste, and of unusual scientific knowledge; nor was he ignorant either of the nature of Gothic architecture—for he had made a special professional examination of its finest examples—or of its principles; for, as we believe, he learned much from them, and applied them in his own buildings. That prejudice should have extorted from such a man such unhappy tirades in condemnation of Mediæval art, is, we repeat, at once a matter for wonder and regret. It is pitiable to hear such a man challenging his predecessors with so great self-satisfaction, and inviting a comparison between his own works and theirs; complaining, too, of their faulty construction and useless ornaments, when he himself received no little scientific information at their hands; and as regards the useless ornaments —if, indeed, we do not give him too much credit for constructive skill—was not only aware of their practical utility, but even adopted their principle, though in a less skilful manner, in his own vaunted Cathedral. But we will not rest satisfied with our own authority. Since Wren's time, Mediæval art has met with less prejudiced judges; and many writers of high standing, and architects of well known ability, have given ample testimony in its favour. It is now more fully understood, and its beauties better appreciated; in short, Gothic art is now what Classic was in Wren's days— the "fashion." But ere we proceed to bring forward any more favourable witnesses, let us do Wren justice, and give another extract from his works, which tends in some measure to qualify his previous language.

Even he recognizes, in some few buildings of this style, "a discernment of no contemptible art, ingenuity, and geometrical skill, in their design and execution." Also—"Thus the work required fewer materials, and the workmanship was, for the most part, performed by flat moulds, in which the wardens could easily instruct hundreds of artificers. It must be confessed, this was an ingenious compendium of work suited to these northern climates; and, I must also own, that works of the same height and magnificence in the Roman way, would be very much more expensive than in the other Gothic manner, managed with judgment."

But to pass on to later writers—Rev. J. Milner, alluding to Evelyn and Wren's remarks, says—"Every man who has an eye to see, and a soul to feel, on entering into York Minster and Chapter-House, or into King's College or Windsor Chapel, or into the cathedrals of Lincoln or Winchester, is irresistibly struck with mingled impressions of awe and pleasure which no other buildings are capable of producing; and however he may approve of the Grecian architecture for the purposes of civil and social life, yet he instinctively experiences in the former a frame of mind that fits him for prayer and contemplation, which all the boasted regularity and magnificence of Sir Christopher's and the nation's pride, I mean St. Paul's Cathedral, cannot communicate, at least, in the same degree."

Bishop Warburton says—"Our Gothic ancestors had juster and manlier notions of magnificence on Greek and Roman ideas, than those mimics of taste who profess to study only classic elegance; and because the thing does honour to the genius of those barbarians, I will endeavour to explain it."

Mr. Dallaway says—"Certain it is, that the Gothic churches, whatever be the peculiar manner of their era, present their beauties to every eye. We cannot contemplate them without discovering a majestic air well worthy of their destination, with a knowledge of what is profound in the science and practice of building, and a boldness of construction, of which classic antiquity furnishes no examples."

The following words of Coleridge are remarkable: in comparing the Classic and Gothic modes of architecture, he says,—"The Greek art is beautiful. When I enter a Greek church, my eye is charmed and my mind elated; I feel exalted, and proud that I am a man. But the Gothic art is sublime. On entering a cathedral, I am filled with devotion and with awe; I am lost to the actualities that surround me, and my whole being expands into the infinite; earth and air, nature and art, all sweep up into eternity, and the only sensible impression left is, that I am nothing."

Whewell, referring to the use of the word Gothic as a term of reproach, says—"If we would employ the term barbarous with any significance, it is not to be applied to one style of art merely because it differs from another. A Gothic building is no more barbarous than a Grecian one, if the ideas which govern its forms be fully understood and executed: but those attempts rather are to be called barbarous, which imitate the features of good models, and which, not catching the principle of the art, exhibit such parts incongruously composed and imperfectly developed. In writing Greek, an Anglicism is a barbarism; but we shall not be willing to allow English to be barbarous, because it is not Greek; and a mixture of the two is equally barbarous, whether it pretends to be one or the other."

Mr. Poole, a recent writer on the subject, is very warm in his admiration: he says—"But there arose in the west in the middle ages a style of architecture growing in all its parts and characters out of the wants of the church; and adapting itself to the expression of the very things which she desires to express in all her methods of embodying herself to the eyes of the world, and to the hearts of her sons. And so entirely did this style arise out of the strivings of the church to give a bodily form to her teaching, that it seems to have clothed her spirit, almost as if the invisible things had put forth their unseen, but powerful and plastic energies, and gathered around them on all sides the very forms and figures which might best serve to embody them to the eye of sense. A Gothic church in its perfection is an exposition of the distinctive doctrines of Christianity, clothed upon with a material form; and is, as Coleridge has more forcibly expressed, 'the petrifaction of our religion,' or, as it has been expressed by a mind essentially differing from Coleridge's, which makes the coincidence the more remarkable, 'the divine order and economy of the one seems to be emblematically set forth by the just, plain, and majestic architecture of the other; and as the one consists of a great variety of parts united in the same regular design according to the truest art and most exact proportion, so the other contains a decent subordination, various sacred institutions, sublime doctrines, and solid precepts of morality, digested into the same design, and with an admirable concurrence tending to one view,—the happiness and exaltation of human nature.'

"Much has been said about the proper designation of this style. The term Gothic has use on its side to so great a degree, that it will never be superseded, and though it has no truth in it at all, and was at first given in ignorant derision, one would scarce wish it altered; the style which it designates is exclusively Christian, and it is nothing new or displeasing to that which is distinctively Christian, to take a name from a scorner, and to convert the opprobrium into a glory.

"Such then is Gothic architecture:—theological, ecclesiastical, and mystical, in all its parts and characters. It grew to its perfection both in general design, and in more minute details of ornament and execution, during many successive generations; and although we have few churches entire and unmixed of its earliest forms, we have remains more or less perfect in almost every variation in its style, from the Norman of the twelfth century, to the elaborate perpendicular of the Tudor."

We conclude with the following remonstrance from Mr. Pugin, a gentleman to whom we are pre-eminently indebted for his perseverance in the study and defence of Mediæval art, and to whose "Contrasts," although somewhat overdrawn, we would beg to refer the reader, as apropos to the question before us.

Mr. Pugin says—"Before true taste and Christian feelings can be revived, all the present and popular ideas on the subject must be utterly changed. Men must learn, that the period hitherto called dark and ignorant, far excelled our age in wisdom, that art ceased when it is said to have been revived, that superstition was piety, and bigotry faith. The most celebrated names and characters must give place to others at present scarcely known, and the *famous edifices* of modern Europe sink into masses of deformity by the side of the neglected and mouldering piles of Catholic antiquity. If the renunciation of preconceived opinions on this subject, and the consequent loss of the present enjoyment derived from them, be considered as a great sacrifice, does not the new and glorious field that is opened offer far more than an equivalent? What delight, to trace a race of native artists hitherto unknown, in whose despised and neglected productions the most mystical feeling and chaste execution is to be found, and in whose beautiful compositions the originals of many of the most celebrated pictures of more modern schools are to be traced! what exquisite remains of the sculptor's skill lie buried under the green mounds that mark the site of once noble churches! what originality of conception and masterly execution do not the details of many rural and parochial churches exhibit! There is no need of visiting the distant shores of Greece and Egypt, to make discoveries in art. England alone abounds in hidden and unknown antiquities, of surpassing interest."

Of the peculiar effect produced upon the mind by Gothic edifices, and of the principles upon which its excellencies depend, Milner gives us the following explanation:—"The eye is quickly satiated by any object, however great and magnificent, which it can take in all at once, as the mind is with what it can completely comprehend; but when the former, having wandered through the intricate and interminable length of a pointed vault in an ancient cathedral, discovers two parallel lines of equal length and richness with it; thence proceeding discovers the transepts, the side chapels, the choir, the sanctuary, and the ladye chapel, all equally interesting for their design and execution, and all of them calculated for different purposes; the eye, I say, in these circumstances is certainly much more entertained, and the mind more dilated and gratified, than can possibly be effected by any single view, even though our modern architects should succeed in their attempts to make one entire sweep of the contents of a cathedral, in order to show it all at a single view, and to make one vast empty room of the whole."

Mr. Poole adds—"But surely some part of the effect of a Gothic cathedral resides in that very excess of length over breadth, affording a long perspective, directing the eye towards the altar, through an avenue of oft-repeated similar parts, and creating, as it were, an artificial infinite. The roof as well as the walls of a Gothic building is so composed as to help this effect to the utmost. Groin beyond groin, boss beyond boss, pendant beyond pendant, is seen,—first of all each distinct and clear, but by degrees approaching and touching one another in the perspective, and at last, lost in the complexity—not confusion, but complexity—of the whole. The plain becomes obscure, the defined indefinite, in the long-drawn distance.

"Even irregularity of structure lends its aid to produce this effect, and irregularity is a beauty purely Gothic. The eye that wanders in an oblique direction, travels through the nearer arches to some unexpected aisle or chapel, and seems lost in an undefined distance. It is scarcely possible to exaggerate the effect of this combination of elevation, length, and irregularity, so averse from the Grecian concinnity and uniformity; especially when they are helped by the dim religious light poured through the painted windows.

"Fancy yourself for a moment standing just within the great western entrance of one of our cathedrals, and you will feel what is meant by breadth in architectural effect. The eye is of course directed eastward, and there it has its point of repose; and the great east window limits its view, at a distance, which, with all the accessories before mentioned, seems indefinite. But the aisles at either hand have absolutely no termination to the mind's eye. For a while you see through the intervening arches; but you see less and less at each interval, and long before the actual termination of the aisle, the piers, approaching one another in the perspective, close upon the unfinished view. The mind's eye goes forward, while the eye of sense is arrested. The limit is as effectual as if it had been abrupt; but it is so gradual that you scarce feel where it occurred. There is a perfect consciousness of the length beyond, notwithstanding the absolute impossibility of discerning it."

Thus much for the impugners and apologists of Gothic architecture;—it will appear somewhat incredible that so great a difference of opinion should exist amongst men all eminent for taste and judgment, but such is the case; what in Wren's time was considered barbarous, is now upheld as scientific and beautiful. We follow the taste of our age, which we believe to be correct, and maintain the superiority of Gothic over Classical art, not only as regards its general effect, but also in scientific construction, correct and tasteful ornamentation, accommodation, and general convenience. In our previous extracts we have alluded more especially to the general effect of the two styles, we will now touch upon each of the other qualities seriatim, and, in doing so, we shall give, as before, greater prominence to the opinions of those who have arrived at a high standing in their profession, and principally of those who have devoted their time specially to this subject, than to any observations of our own; as we deem their authority will carry more weight with it than anything we can say. We need only mention the names of Pugin and Bartholomew, Willis, and Whewell, to obtain an attentive perusal, and would refer our readers for more extensive information on the subject than our space will allow of, to the standard works of those gentlemen.

In some of the extracts from the *Parentalia*, previously given, we hear Wren inveighing against the Mediæval builders on account of their rude and unskilful construction; we contrast their remarks with some others on the same subject by the late Mr. Bartholomew, than whom we could scarcely have a more impartial judge, for while on the one hand he is a great admirer of the Mediæval architects, he is no less predisposed in favour of Wren, on whose scientific skill in construction, he is continually pouring forth the most warm—we had almost said the most extravagant—encomiums. Let us hear what are his opinions in this controversy; they are expressed as follows:—

"During the middle ages, geometrical science was applied to architecture in the loveliest manner; the general plan, the columns, the arches, the doors, the windows, the galleries, the vaulting, the flying buttresses, every panel, every compartment, the most minute ornament, exhibited an intimate acquaintance with that profound and masterly science, without which building becomes vicious, cumbrous, expensive, mean, fragile, absurd and disgusting.

"After the decline of Gothic architecture, a foolish notion went abroad in the world, that cumbrousness and extravagance of material were characteristics of Gothic architecture; even that great and talented man, John Evelyn, who possessed a very superior knowledge of architecture, entertained the then current opinion: but of late, mankind have become strangely undeceived on this point; and the plans and sections of ancient and modern buildings, brought together in parallel, now fill the mind with astonishment, that so comparatively small a quantity of materials, and those frequently of minor quality, could have been piled up to exist, with little failure or decay, such a long course of time. It is not that Gothic buildings are always perfect in construction, but in general they are nearly so; in fact, so light are some of them, that they need more substance, as well as harder materials, to resist the mere operation of time upon their surfaces. The Gothic architects always built with the greatest economy: when square stone was easily procurable, they formed their walls very thin; but when, from the length of the carriage of it, it became costly, they used for their walls the most ordinary rubble-stone of the country, and they then gave to their walls thickness sufficient to prevent them from rending and rolling apart from the fluent nature of their materials."

Elsewhere he says—"Now the Mediæval Christian builders arrived to such a delicate and intimate acquaintance with architectural dynamics, that, by the discovery of the way in which all the particles of their materials are affected by gravity, they were enabled, by merely subjecting them to frangibility caused by compression, so to economize them and reduce their quantity, that many members of Gothic edifices after five hundred years' devastation by time, are more sound than corresponding members of our modern buildings which have not subsisted fifty years, and which contain five times their proportion of materials.

"It was this scientific economy which enabled those real magicians to rear up securely their works so high towards heaven in the beauty of architectural holiness; it was this scientific economy which left them money enough to cover their sweet fabrics within and without with the richest intaglio, and the goldsmith's work of heaven, while their patrons grumbled not, nor grudged the rich profusion, but joined heart and soul in the goodly work, and the wise and noble fabricator needed none of that kind of over-persuasion, or cajolery, or intentional misunderstanding, or tasteful out-witting, by which alone the modern architect is frequently enabled to wring from his employer other than bare walls; this scientific economy rendered unnecessary the rabble of cement-makers and sand-concreters—those spendthrift empirics, which suck out the brains of architecture, rifle her pockets, violate her chastity, bruise her face to a mummy, and then cover it with oil-plasters and cosmetics of white-wash and iron oxide.

"So admirable in general is the skill displayed in the dynamic disposition of the material of a Gothic cathedral; so shrewdly are the forces of its gravitation reduced to simple compression, that the whole is like a wonderful piece of shoring, sublimely and permanently imitated in stone. He who compares its flying-buttresses to a piece of wood-scaffolding, at once confesses that it is raised with that art which emanates from the workman's most delicate and anxious caution."

In truth, the erections of this style are but the embodiments of constructive science, not only does the main form and general outline depend thereon, but even those peculiarities which an unpractised eye would be tempted to esteem mere decoration: but those who have made themselves acquainted with the subject, are well aware that the Mediæval architects never constructed decoration, but decorated construction; they made their building perfect, and then applied their ornament with most correct judgment and refined taste. A Gothic building is a practical illustration of the principle of the arch, and of its application in the most perfect form. We had almost termed it the extension and perfection of Roman architecture, for they were the first to apply the principle, but only in a partial and imperfect manner; the idea was new to them, and they did not fully comprehend it, they did not understand its universal applicability, and therefore only partially adopted it. In their buildings many of the forms of Grecian architecture still remained; they were fettered by its rules, by its influence, and thereby prevented from bringing their new theory to perfection. They had been used to the forms, they knew of no others, and hence arises their inconsistency. Roman architecture was, so to speak, a transition, and, so far, imperfect style; in it we see the new and old principles struggling for the mastery, yet each maintaining a certain influence; we have indeed the arch, but there still remains the entablature, which was in this place totally useless and inconsistent, they were each the exponent and characteristic of its own theory, and as the two systems were repugnant the one to the other, so was their introduction into the same building liable to the charge of inconsistency. The entablature in the one case answered the same purpose as the arch in the other, and therefore, where the one prevailed, the other should have disappeared; but this we know was not at first the case, it was left to the Mediæval architects to bring the new system to perfection. Roman architecture is but the germ, Gothic its complete development.

We cannot forbear offering one or two instances of the scientific skill of the Gothic architects, as exemplified in their mode of construction. It is a matter which has been frequently alluded to in other works, but one, we think, without which any treatise on Gothic architecture would be imperfect. It was their custom, as we all know, to cover their large buildings with vaults of masonry, a method of roofing in which they greatly excelled their predecessors. The Romans were acquainted with this method, and applied it in many instances, yet their specimens of vaulting, when compared with the Mediæval, appear but clumsy expedients; they were confined to the use of the common cylindrical and quadripatrite vaulting, or that of which each compartment consisted of four cells only, the latter kind being caused by the intersection of two cylindrical vaults at right angles to each other. But even in this simple kind of groining they found a difficulty, for when the intersecting vaults were of different span, and of the same elevation, their arches being confined to the semi-circular form, they were at a loss how to proceed. In Gothic architecture, the difficulty is entirely obviated by the employment of the Pointed arch, and by its application the Mediæval builders were enabled to construct vaults of so elaborate and varied a character, such as the Romans, with their forms, dared never to have dreamed of. But this is not the only improvement our ancestors effected in vaulting; the Roman vaulting consisted entirely of large stones, and was therefore of very great weight, a circumstance which was very detrimental to its application, for as the wall had to bear the entire burden, it was absolutely requisite that they should be of extraordinary strength. Now, our Gothic builders obviated this difficulty likewise in a most scientific manner; they made their vaults equally secure with a much smaller consumption of material, by which means they not only saved the walls an undue pressure, but also considerably reduced their expenditure throughout the building. This they managed in the following manner. In their large works, such as cathedrals, in which vaulting was more frequently applied, it was their custom to carry up a pier or bearing shaft on the face of the nave-shafts, either springing directly from the ground, or supported on a corbel at some point immediately above the piers. From the top of these shafts, as points of bearing, were extended ribs or arches across the nave from the bearing-shafts on the one side to those on the other, in three or more directions; in the more simple forms, each compartment of the vaulting consisted of six entire arches, enclosing four cells or spaces between the ribs, which were arranged in this manner;—from each of the four bearing-shafts sprang three arches; one, the longitudinal, extending to the next shaft on the same side of the nave, that is, in the direction of the length of the building; another, the transverse, stretching at right angles to the longitudinal to the shaft immediately opposite on the other side of the nave; and a third, the diagonal, extending between the most distant shafts from one angle of the bay to the opposite. These diagonal ribs intersect each other, and at the point of intersection butt against a key-stone, which generally extends below the level of the vault, and is sculptured in the form of foliage or some other ornament; this key-stone locks the system together securely. The ribs formed the constructive portion of the vault; they were the skeleton, as it were, on which the covering or cuticle was stretched: they were the only portions of the vault in which large stones were used, the cells being filled up with much smaller stones, and they of less ponderous material, by which means the whole vaulting was rendered lighter and more secure. In this way did they gain an incalculable advantage over the Romans; nor did their skill cease here; having so far reduced the forces of the enemy, they prepared to carry the remaining thrust of the vault away from the walls of the clere-story, and conduct it safely to the foundations, and this they accomplished with equal or even greater skill. From that point of the clere-story wall, where the thrust of the vaulting was collected, the force was carried over the aisles by means of an arch termed a flying-buttress, which rested at its lower extremity on the pillar buttresses attached to the aisle-walls. But here it is necessary to notice one or two peculiarities which might be likely to escape the observation of a transient observer. Having collected the active force of the vaulting to one spot by means of the ribs, they there spread out the flying-buttress in the same manner as now-a-days we place a board against a wall in cases of temporary shoring, and sometimes placed one arch below another, the two being separated at the wall, but uniting ere they reach the wall-buttress, by which method the force was concentrated at that point, while the whole of the clere-story wall was equally supported. Having conducted the drift to this point, it remained to bring it safely to the ground; and how could this be effected? The method, which would at once naturally have suggested itself, would have been to extend the buttresses from the wall to such an extent as to receive the thrust within its mass until it reached the earth; but this would necessitate a very great projection, and therefore a large consumption of space and materials. This difficulty they met and nullified in the most skilful manner, and by a most simple contrivance. It was by merely superadding a pinnacle to the wall-buttress above the point at which the force was collected. We have now another force in operation, that of the downward pressure or gravity of the materials composing the pinnacle, and this combining with the thrust of the vault, changes the direction of that force so as to make it more nearly perpendicular, and bring it within a buttress of moderate projection, which, be it remembered, served a further purpose of strengthening the aisle-walls and diminishing their thickness, for it is well known, that a wall with buttresses at intervals, is as strong, or stronger, than a mere wall of the combined thickness of the wall and buttress. In this manner did they press everything, whether friendly or inimical, into their active service, and succeeded in rearing edifices of the most skilful construction, most rigid economy, and chaste and delicate decoration.

How Wren could have inveighed against the construction of our Gothic buildings we cannot understand, especially as he seems to have imitated them in several particulars, though not certainly with equal taste or skill. He has used very similar means to those above described, in resisting the thrust of his vaulting, in his vaulted Cathedral; buttresses are carried over the aisle to the outer wall, and are concealed by a screen running round the building, and having the appearance of an additional story, which certainly gives the building a more imposing appearance on the exterior, but at the expense of truth, and, like the dome, creates a feeling of disappointment when you enter the interior. To this circumstance Mr. Pugin alludes in a passage which we shall have occasion hereafter to quote. As regards Wren's objection respecting the size of the stones used in Gothic edifices, we need say nothing, it refutes itself, for surely if a building can be raised with equal security by the use of small stones which a man can carry on his back, it is much superior, at least in point of economy, to one raised with large blocks which require ponderous machinery to move them to their destined positions.

We leave Sir James Hall to answer objections made on the score of false proportions; he deals with them in a way no less summary than it is decisive. After speaking of the principles of Gothic architecture, he says:—"This view furnishes a complete answer to the common objection made to the Gothic style, of wanting proportions, for that accusation has always been the consequence of judging the Gothic by Grecian rules, in which case it could not fail to appear absurd and disproportioned; whereas when tried by its own laws, it will be found completely consistent and harmonious in all its parts;" of course, if persons commence by assuming Grecian proportions to be the acme of perfection, and all that differs from them to be false and barbarous, we may at once yield the argument, for the question is decided ere we commence.

Mr. Pugin alluding to the same subject says:—"Under the head of architectural propriety, we have also to consider the scale and proportions of buildings. Without vastness of dimensions it is impossible to produce a grand and imposing effect in architecture; still, unless these be regulated on true principles, they may destroy their effect by their very size; and here I wish to draw your attention to a point which will prove the great superiority of the Christian architecture of the middle ages, over that of classic antiquity, or of the revived pagan style. In Pointed architecture the different details of the edifice are multiplied with the increased scale of the building; in classic architecture they are only magnified." This principle of multiplying parts with the increased size of the building, is a characteristic of the style, and is one in our opinion in which it greatly excels its rival.

It now only remains to touch upon two subjects of comparison; the first as regards the application of ornament, and the last as to convenience and accommodation. The writers of Wren's time were too apt to consider Gothic architecture as a system of decoration, gaudy and puerile; a system in which useless ornament was the chief aim and object, and in which it was introduced without reason or moderation, and hence they termed it meretricious and barbarous. Investigation has taught us differently; and where they saw naught but confusion and redundancy, we detect order and sound judgment. Ornamentation was seldom introduced by our old church-architects without a cause or without a meaning: we do not mean to go so far as to assert that such was never the case, but we do say that there was, for the most part, a nice adaptation, a propriety, in their decoration; the parts to be enriched were not introduced without a specific object, and their manner of enrichment was made subservient to that object; for instance, look at the projecting string-course, the weather-mouldings of the heads of windows, to conduct the moisture from the enriched and delicate part of their work, so as to preserve it from injury, and the terminating dripstone to throw it off the walls. Each part was decorated so as at once to delight the eye, and answer an useful end; each moulding was beautiful and appropriate to its own peculiar duty; their contours varied, not from any wild fancy or exuberant imagination, but simply to make it efficient to the purpose for which it was employed. Look again at their buttresses, to which we have already alluded, and the gorgeous pinnacles, not a mere decoration, as our forefathers would have it, but a most useful and indispensable addition. But we can almost forgive them for seeing only the beauty, at least where they acknowledge so much, for the graceful finish given to the buttress thereby, is sufficient to justify such an addition, even supposing it served no other purpose than mere ornament, and we need not wonder at their resting satisfied with it as a means of decoration without looking to any further purpose. The buttresses themselves likewise were equally agreeable to the eye, as they were useful and essential to the construction; by them we obtain a bold and pleasing variety in the main outline of the building, and that play of light and shade which adds so greatly to the appearance of a Gothic edifice. Looking once more at the smaller members, we find niches, corbels, bosses, vaulting ribs, each answering two ends, one useful, the other ornamental. What objects can be more beautiful than some of the Gothic niches, especially of the later styles, and yet what more necessary in a climate like ours; on the exterior of buildings, more especially, they serve to protect the higher branches of carving from the inclemency of the weather, and in the interior from accident or injury; but it was probably their unusual elegance rather than their usefulness, which caused their introduction as a means of internal decoration. In short, the Mediæval artists did not construct ornament, but ornamented construction. On this subject we add the following remarks from Pugin's Principles of Pointed Architecture:—

"The two great rules for design are these:—1st. That there should be no features about a building which are not necessary for convenience, construction, or propriety; 2nd. That all ornament should consist of enrichment of the essential construction of the building." "In pure architecture the smallest detail should have a meaning, or serve a purpose; and even the construction itself should vary with the material in which they are executed." "Strange as it may appear at first sight, it is in Pointed architecture alone that these great principles have been carried out; and I shall be able to illustrate them, from the vast cathedral to the simplest erection. Moreover, the architects of the middle ages were the first who turned the natural properties of the various materials to their full account, and made their mechanism a vehicle for their art."

Pointed architecture does not conceal her construction, but beautifies it: classic architecture seeks to conceal, instead of decorating it.

"The clumsy vaults of St. Paul's, London, mere coffered semi-arches without ribs or intersections, have their flying buttresses: but as this style of architecture does not admit of the great principle of decorating utility, these buttresses, instead of being made ornamental, are concealed by an enormous screen, going round the building: so that in fact one-half of the edifice is built to conceal the other. Miserable expedient! worthy only of the debased style in which it has been resorted to."

"An architect should exhibit his skill by turning the difficulties which occur in raising an elevation, from a convenient plan, into so many picturesque beauties; and this constitutes the great difference between the principles of Classic and Pointed domestic architecture. In the former he would be compelled to devise expedients to conceal these irregularities; in the latter he has only to beautify them But I am quite assured that all the irregularities that are so beautiful in ancient architecture, are the result of certain necessary difficulties, and were never purposely designed; for to make a building inconvenient for the sake of obtaining irregularity, would be scarcely less ridiculous, than preparing working-drawings for a new ruin. But all these inconsistencies have arisen from this great error;—the plans of buildings are designed to suit the elevation, instead of the elevation being made subservient to the plan."

The last observation of Mr. Pugin's leads us very naturally to the consideration of the next subject. The Greeks were confined to one plan in their edifices, the parallelogram; and in their application of this form they had but little choice, the main variation consisting in the arrangement of the external colonnade. It was a form well enough adapted to their religious observances, and restricted to buildings of that nature. Their edifices were chaste and grand, but chargeable at the same time with sameness and monotony; the one idea was universally resorted to, and probably because they had no occasion for any other. The Romans, however, did not restrict themselves to this form, their wants were more extensive than those of the Greeks, from whom they borrowed the main idea of their architecture; they wanted something more than temples; in short, they were a more secular people than the Greeks, and thought their secular buildings worthy of as costly magnificence as the temples of their gods. To this circumstance we owe the introduction of the practice of grouping, as it is termed, and the adaptation of the plans of the buildings to the various purposes of life; the Romans broke through the ancient rules of uniformity, and struck out into a wider and bolder path, which led by many directions to a great variety of results. But even the Romans were but tyros in this new system, which they left to after-ages to bring to perfection. The old Greek style was but little adapted to this altered state of things; and as much as the Romans gained in convenience, by so much they lost in appearance; the old principles could but ill brook their forced adaptation to new rules, and in process of time they died, (if we may be allowed the expression,) a natural death. The principles of Gothic architecture took their rise from the wants of the times, and gave completeness to that of which the Romans had originated the idea; and the style has this superiority over every previous one, that it can easily adapt itself to any purpose. No matter what shape you require your plan, nay, it matters not, though it be of no acknowledged or describable shape at all, you may rear upon it an elevation in accordance with the principles of the style, and one which only requires a skilful hand and practised eye to make it at once tasteful and convenient. Sir James Hall has the following trite remarks, which are very much to the point; he says:—

"In order therefore to apply Grecian architecture to our purposes, it has been found necessary very much to alter the old Greek plan; but this having but little variety, could not easily admit of any change. And a Grecian colonnade being of itself a most perfect form, we cannot well conceive how anything should be taken from it or added to it without injury; at least, to do so would require a hand no less dexterous than that by which it was originally designed. It is not, therefore, wonderful, that our artists, employing Grecian architecture for new purposes, and introducing without ceremony forms unknown to the Greeks, should produce works devoid of those beauties for which theirs are so highly distinguished.

"The greatest detriment seems to have been occasioned by the introduction of windows, for which the old Greek masters had made no regular provision, but which are indispensable in most of our buildings. For by thus obtruding a new form upon the old style, its unity of design must be violated. The more so, that a set of windows partake, by their form and arrangement, of the regularity of a colonnade, and consequently occasion more disturbance of the general effect, than if there had been no resemblance between them.

"The necessity among the moderns of forming edifices spacious within, has been a source of great confusion; for the old Greek masters not having need of room, have left us no good examples of the kind, and our own artists, in pursuit of that object, have piled order upon order, and have joined together various parts in the same building, which, though each may be beautiful in itself, have no connection together, and can only deserve the name of more or less elegant pieces of patch-work.

Thus Grecian architecture, though rich in ornamental details, was susceptible of little variety in the general plan.

It has therefore failed when applied to our purposes, though in the hands of the old Greek masters, and employed in the construction of works suited to the wants of that people, it has far surpassed any other style. Gothic architecture, on the other hand, with great variety of ornamental details, admitting of the greatest latitude in the general plan and distribution of the parts, and being susceptible of almost any shape, is applicable to every purpose, and might be suited to the manners of every nation.

"A Gothic edifice receives and accommodates an immense multitude of people, and furnishes an unbounded supply of light in a manner which constitutes one of its principal ornaments. And this advantage seems to belong to the Gothic exclusively; for it does not appear, that in any other style of architecture, a provision has been made for the provision of light in an ornamental manner. It possesses, in the highest degree, several different and seemingly incompatible qualities. When entire in all its parts, everywhere clean and fresh, and enlightened by a bright sunshine, we admire its airy lightness and lively elegance; but when clothed in a majestic veil of obscurity, or reduced to ruins and overgrown with moss and ivy, we are struck with awe by its solemn grandeur.

"It results from this comparison, that the Grecian style excels in all those qualities of elegance and grace which depend upon the nice adjustment and masterly execution of details. Whereas the Gothic style, which with great truth has been compared to the genius of Shakspeare, is lively, picturesque, and sublime, qualities which are derived from the bold variety, and often from the wild irregularity, of its forms."

With this passage we naturally close our comparison; we have stated our own opinions on the subject, and produced authorities on both sides—the reader must form his own decision.

We now proceed to a description and arrangement of the style, but, before doing so, it will be needful to take some notice of those styles which immediately preceded it. Soon after the disruption of the Roman empire, we find architecture, lapsing into barbarism, still retaining strong characteristics of the previous style, but exhibiting only a clumsy imitation. The buildings of this age were but heaps of discordant parts, put together without reference to unity of design or arrangement. Out of this medley arose a style, which, however barbarous it may be deemed, can still boast some title to consistency, for, by this time, architects had broken through the trammels of the old methods which had hitherto fettered them. The style, known by some under the general title of Romanesque, and by others divided according to some marked peculiarity, or to the countries in which it was adopted, into Byzantine, Lombardic, and Norman, was the immediate precursor of the Gothic or Pointed style. It differs essentially from the Roman method in many respects, and presents us with several new principles, amongst which may be enumerated the entire disuse of the entablature, the arches springing directly from the capital of the pier or column; the total disregard of classic proportions, and an unusual variety and license in this respect, some columns being of the average height of the Classic orders, others much stunted, and others again exceedingly extended, more especially those attached to walls or piers, which become little better than vertical mouldings; the practice of including two or more arched openings under one common arch; and some few other particulars, which it is not necessary to mention. We give the following description of the buildings of the period to which we allude, as laid down by one of the writers already quoted. It will be seen to differ, in some respects, from our own account, but this may arise from his more especially alluding to some particular class of buildings, or because he was desirous of making a marked distinction between the erections of this style, and of that which followed it, the Gothic. He gives notice of some particulars which we have omitted.

"The arches," he says, "are round; one supported on pillars retaining traces of the Classical proportions; the pilasters, cornices, and entablatures have a correspondence and similarity with those of Classical architecture; there is a prevalence of rectangular faces and square-edged projections; the openings in walls are small, and subordinate to the surfaces in which they appear, the members of the architecture are massive and heavy; very limited in kind and repetition; the enrichments being introduced rather by sculpturing surfaces, than by multiplying and extending the component parts. There is in this style a predominance of horizontal lines, or at least no predominance and elongation of vertical ones. For instance, the pillars are not prolonged in corresponding mouldings along the arches; the walls have no prominent buttresses, and are generally terminated by a strong horizontal tablet or cornice."

The style, although an approach in that direction, differs in many material points from the later Gothic; but as we have occasion to notice the main features of distinction between the Roman and Gothic modes of building, and have also noticed the differences between the former and the Romanesque styles, we do not deem it necessary to institute a detailed comparison between the intermediate and Gothic systems.

Sir Christopher Wren takes notice of the variations of the two extreme styles, and although his deductions as to questions of merit cannot justly be assented to, his comparison as to principles is, for the most part, correct. He says:

"In this they essentially differed from the Roman way, who laid all their mouldings horizontally, which made the best perspective; the Gothic way, on the contrary, carried all their mouldings perpendicularly; so that the ground-work being settled, they had nothing else to do but to spire all up as they could. Thus they made their pillars a bundle of little tori, which they divided into more when they came to the roof, and these tori split into many small ones, and, traversing one another, gave occasion to the tracery work, as they call it. They used the sharp-headed arch, which would rise with little centering, required lighter key-stones and less butment, and yet would bear another row of doubled arches, rising from the key-stone, by the diversifying of which they erected eminent structures, such as the steeples of Vienna, Strasburg, and many others."

Mr. Rickman, to whom we are so much indebted for his researches on this subject, gives the following more detailed comparison in a tabular form:—

Grecian.	*English.*
The general running lines are horizontal	The general running lines are vertical.
Arches not necessary.	Arches a really fundamental principle, and no pure English building or ornament can be composed without them.
An entablature absolutely necessary, consisting always of two, and mostly of three, distinct parts, having a close relation to, and its character and ornaments determined by, the columns.	No such thing as an entablature composed of parts; and what is called a cornice bears no real relation to the shafts which may be in the same building.

Grecian.	*English.*
The columns can support nothing but an entablature, and no arch can spring directly from a column.	The shafts can only support an arched moulding, and in no case an horizontal line.
A flat column may be called a pilaster, which may be used as a column.	Nothing analogous to a pilaster; every flat ornamented projected surface is either a series of panels or a buttress.
The arch must spring from a horizontal line.	No horizontal line necessary, and never any but the small cap of a shaft.
Columns the supporters of the entablature.	Shaft bears nothing, and is only ornamental, and the round pier still a pier.
No projections like buttresses, and all projections stopped by horizontal lines.	Buttresses essential parts, and stop horizontal lines.
Arrangement of pediment fixed.	Pediment only an ornamented end-wall, and may be of almost any pitch.
Openings limited by the proportions of the column.	Openings almost unlimited.
Regularity of composition on each side of a centre necessary.	Regularity of composition seldom found, and variety of ornament universal.
Cannot form good steeples, because they must resemble unconnected buildings piled on each other.	From its vertical, lines may be carried to any practicable height, with almost increasing beauty.

Mr. Willis, in the annexed table, treats the subject in a somewhat different form, referring rather to rules of principles, than details of practice:—

Classical styles.	*Middle-Age styles.*
Different planes of decoration avoided, and never exceeding two in an entire composition.	Different planes of decoration placed behind each other to any number, and in every possible degree of variety, even in a single member, as in an arch.
Superincumbent weights united as far as possible, by resting on the horizontal cornice, which combines them into one mass.	Superincumbent weights divided into as many parts as possible, and then given to independent props.
Arch, foreign to this style, and when introduced its diagonal pressure excluded from the decoration.	Arch, the essential feature; its diagonal pressures studiously manifested, and the rest of the composition harmonized with them by other inclined lines.
Artifices of construction concealed, as impairing the simplicity of effect.	Every artifice of construction displayed.
Chamfered surfaces inadmissible, and mouldings can only stop against a surface perpendicular to their course.	Chamfered surfaces universal; mouldings are applied to them, and may die against them or any other surface at any angle.
Panels mere superficial ornaments.	Panels are apertures between the parts of the decorative frame of the building.

Elsewhere he adds:—

"These decorative features differ in many respects from the Classical, but the leading principle is to be found in the increased multiplicity of parts, and in a system which affected to support them all independently, arranging them in groups, in opposition to the Classical scheme, in which the parts are simple, and bound together by the dominant cornice."

"It is suggested to me by a friend," says the Rev. W. Whewell, author of Architectural Notes on German Churches, "that this distinctive principle of construction in the Gothic architecture, appears to be the admission of oblique pressures and inclined lines of support; in Greek architecture, the whole edifice consists of horizontal masses reposing on vertical props. In Gothic buildings, on the contrary, the pointed arch is always to be considered as formed by two sides, leaning against each other at the top, and pressing outward at their lower ends. The eye recognizes this statical condition in the leading lines of the edifice, and requires the details to conform to it. We have thus in the Grecian buildings nothing but rectangular forms and spaces, horizontal lines with vertical ones subordinate to them. The pediment is one mass with its horizontal cornice, and does not violate this rule. Arches, when they occur, are either subordinate parts, or mark the transition style, in which the integrity of the principle is no longer preserved. In Gothic works, on the other hand, the arch is an indispensable and governing feature; it has pillars to support its vertical, and buttresses to resist its lateral pressure; its summit may be carried upwards indefinitely, by the joint thrust of its two sides. All the parts agree in this character of infinite upward extension, with an inclination or flexure to allow of their meeting at top; and they obviously require, and depend on pressures acting obliquely."

He adds the following particulars in a more tangible and systematic form.

"1. The arch is essential, the entablature is not, and the columns support arches instead of entablatures.

"2. There are any number of planes of decoration one behind the other. When we have in this way several arches under one, we are led, as Mr. Willis has shown, to tracery; when we have arches of different forms one under another, we are led to foliation.

"3. The weights are divided into as many parts as possible, and these are given to independent props; whence we have, among other results, clustered piers and pillars.

"4. The diagonal pressures of the arch are displayed, whence we have buttresses and pinnacles.

"5. And, generally, the running and dominant lines are vertical in this style, as they were horizontal in the ancient styles: the characteristic forms of the one being horizontal, reposing, definite; of the other, vertical, aspiring, indefinite."

We do not feel it incumbent upon us to add anything to the above, the subject having been fully treated of by each writer, the difference of treatment which may have been noticed, arising from the fact, that some of the writers have looked at the grand principles of the two styles, while the others have confined themselves to a comparison of the results of such principles, as applied in practice.

Having thus given a general description of the Gothic style, and its main characteristics, as distinguished from the Classical and succeeding modes of building, we will now proceed, in order to give a more detailed account of it as a distinct style, without any reference to other systems. In order to do this, it will be requisite to adopt some systematic arrangement in connecting and subdividing the various examples, so as to arrive at some clear notion of the rules which guided the Mediæval architects in the erection of their buildings; and in doing this we shall confine ourselves to the methods usually employed, not only because they are well established, but further, because they have been determined upon with great judgment.

Amongst the earlier writers, there does not seem to have been much attention given to this part of the subject; Warton, however, in his tract, attempts a classification, in which he thus distributes the different varieties:—In the first division, which he denominates *Gothic Saxon*, as not fully entitled to the name of Gothic, but having a decided tendency to that style, he places Salisbury Cathedral, and gives the thirteenth century as the epoch of that division. The next division, which he terms *Absolute Gothic*, he extends over the fourteenth and first half of the fifteenth century; he lays down as the characteristic feature, the ramification of the decoration in the window-heads, and gives as an example, the body of Winchester Cathedral. To the third division he gives a duration of only forty years, from A. D. 1441, to 1480, at which latter period he places the commencement of the *Florid Gothic*, the third division having the title of *Ornamental Gothic*; of the latter he gives King's College Chapel, as a specimen; and of the former, the chapels of St. George, Windsor, and of Henry VII., Westminster.

Mr. Dallaway arranges the styles as follows:—

	A. D.	During the reigns of
Semi or Mixed Norman..	1170—1220..	Henry II., Richard I., & John
Lancet-arch Gothic.....	1220—1300..	Henry III., & Edward I.
Transition or Pure Gothic	1300—1400..	Edward I., II., & III., & Richard II.
Decorated Gothic......	1400—1460..	Henry IV., V., & VI.
Tudor or Florid Gothic.	1460—1540..	Edward IV., to Henry VIII.

But the arrangement which most modern writers have followed, is that of Rickman, which is more simple, consisting of only three divisions, viz.:—

	A. D.
Early English............	1189—1307
Decorated English........	1307—1377
Perpendicular English.....	1377—1630

Mr. Bloxam subdivides the Early English into two distinct styles, and in this he agrees with Mr. Dallaway, but he names the earliest division Semi- or Mixed Norman, and the later Early English. He also subdivides the period allotted by Rickman to the Perpendicular style, restricting that title to those examples erected before A. D. 1540, and to the later buildings applying the term Debased.

Others again have retained the tripartite division of Rickman, but have used other titles, denominating the first division First Pointed, the second Middle Pointed, and the last Third Pointed.

The difficulty in classifying the examples of this style arises mainly from the gradual development of each particular division, the one merging into the other by such imperceptible degrees, that it is difficult to determine where the one commences and the other ends, although when each style is seen in its matured and perfect form, it is readily distinguishable from its neighbour. The most prominent characteristics of each style are to be seen in the windows, where the distinction is usually very manifest; the shape of the arches also, forms another principal feature by which the date of a building may be to a certain degree determined, although not very accurately, for the same shaped arches are used in different styles. Perhaps the most certain distinctive marks are to be observed in the mouldings and matters of detail; and these, taken together with the more prominent features, will in general lead to a tolerably accurate decision. We shall consider the peculiarities of each style in a systematic and detailed form, dividing a building into its several component parts, and comparing them, as it were, analytically. Before entering on this task, however, we deem it advisable to refer to the nomenclature and system of classification in the description of particular buildings, recommended by Mr. Willis; so that should any of his terms occur in the following pages, they may be correctly understood. We must recommend them for adoption, as affording, for the most part, a simple, intelligible, and systematic mode of arrangement.

In the description of a building, he advises that one bay of the interior should be taken as an example; divided into its several parts, and each of these treated fully and systematically. This, with a specification of the number of bays, will form a description, generally speaking, of the main portion of the building, unless any differences occur in the other bays, and in such case it will be requisite of course to note the variation. The same course is to be pursued on the exterior of the building, but here it will be requisite to note, in a more especial manner, the arrangement and decoration of the principal façades, as also of the towers and spires, if there be any, and of any other similar addition.

The following are some of the principal terms employed by him in his nomenclature.

Impost, the line or surface of common section between the arch and the support upon which it rests; not, as heretofore explained, the mouldings or capital from which the arch springs, but the plane upon which the arch and pier meet.

Continuous imposts, those in which the mouldings of the arch are continued, without interruption, to the ground.

Discontinuous imposts, where the mouldings of the arch die into the pier without any band of mouldings.

Corbelled imposts, where the mouldings of the arch spring from a corbel without being continued to the ground.

Arches he divides into *simple* and *compound*, the latter term being applied to such as consist of several different surfaces projecting one beyond another, or such as may be resolved into a number of concentric archways successively placed within and behind each other.

Shafted archways are those in which the horizontal section of the shaft differs from that of the arch.

Banded archways, those in which the horizontal sections of the pier and those of the arch coincide, but which have impost mouldings or capitals.

Shafts are divided as follows:—

Vaulting shafts, those which sustain the ribs of vaulting.

Bearing shafts, those which sustain the whole superincumbent weight.

Sub shafts, such as sustain arches of which the upper side is united to the soffit of the next arch or wall.

Face shafts, such as sustain arches of which the back only is united to the wall, and which appear as though placed upon the face of the wall.

Edge shafts, those which support arches united by their sides and back to the nearest wall or arch, so as to appear to support the edge only.

Nook shafts, are similar in plan to edge shafts, but the rib differs from an edge-rib in not being united to the contiguous wall, but, like the shaft, nestled into the re-entering angle formed by the side and face of the contiguous arches.

The same terms are applied to the arches which are sustained respectively by the above-named piers; thus we have *sub-arches*, *face arches*, &c. Shafts which sustain vaulting ribs are termed by Mr. Whewell *Building pillars;* and compound piers, *pilaster masses*.

When an arch is indented with foils or cusps, it is said to be *foiled*, but when it has another foiled arch below the simple one, it is said to be *foliated*.

Thus, in describing an archway, it is first designated as simple or compound, and, if compound, it is described as consisting of so many orders, according to the number of arches it consists of, or, in other words, according to the number of the different soffits or projections, and thereupon each order is described separately in reference to the nature of the impost, whether continuous or discontinuous, as to the position of the shafts and arches, as sub-shafts, face shafts, &c., and so on, in accordance with the nomenclature above given.

Mr. Whewell describes the arches of a vault as *longitudinal*, *transverse*, and *diagonal*, the first term being applied to those running in the direction of the length of the building; the second, those carried at right angles to the longitudinal; and the last, to those carried diagonally, intersecting each other at the centre, and connecting the extreme angles of the severy.

Vaulting is also described as *quadripartite*, *sexpartite*, *octopartite*, &c., according to the number of cells contained in each bay.

Mr. Willis divides the intersections of vaults into *groins* and *ridges*, the former term being applied to those forming an external angle or *edge*, and the latter to those forming an internal angle or *nook*. Hence we have *groin ribs*, *ridge ribs*, and *surface ribs*, the last expression applying to those spread over the surfaces of the vaulting cells.

It will be further necessary ere proceeding to the particular description of the styles, to give some account of the various kinds of arches employed in Gothic buildings. This is especially necessary, as the arch forms a very strong characteristic of the style, and is of very great assistance in deciding, by its shape and formation, the period to which any particular example may belong.

The arches in use in Mediæval buildings, are the triangular, circular, and pointed. Of these, the first, composed of two straight lines inclined towards each other, and forming two sides of a triangle, are almost peculiar to the Saxon style, but are occasionally, though rarely, found at a later period; the second, the outline of which consists of a curve of constant curvature, or some portion of a circle, may be divided into three different kinds, according to the proportion of the circle which it includes.

The most simple of these three kinds, and that which is the more frequently used, is the semi-circular, comprising one half of the circle, the centre of which is in the springing line of the arch. This form was in general use from the time of its introduction by the Romans, until the establishment of the Gothic style, from which it was almost discarded; some few instances are, however, still to be found, in examples posterior to that period.

The horse-shoe arch, as it is called, containing a larger portion than the half of the circumference, and having the centre of the circle above the spring-line, is of very rare occurrence at any period. The segmental, on the contrary, which contains a portion of a circle only, and which springs above its centre, is of occasional employment at every period, more especially as an arch of construction, but also in apertures, as doors and windows. There is yet another method of using the semi-circular arch, by stilting it on uprights, so that the curve of the arch is continued downwards in a straight line below the springing of the course; this is found more especially in the pre-Gothic styles.

Of the Pointed arch, which is characteristic of the style, there are many varieties. In the first place, they divide themselves into two-centred and four-centred arches, of the former of which there are at least three descriptions; the Lancet, the Equilateral, and the Obtuse.

The Lancet consists of two segments, the centres of which fall outside the arch, the radius being of greater length than the span: it may be described about an acute-angled triangle. The equilateral has the centres of the segments on the opposite extremities of the span, the radii of the circles therefore being equal to the span of the arch; it may be described about an equilateral triangle. In the obtuse arch, the centres of the segments fall within the arch, and has therefore the radii less than the span of the arch; it may be described about an obtuse-angled triangle.

The four-centred arch, which is also named the Tudor arch, from the dynasty during which it was in use, is described from two centres on either side, the one being on a level with the springing, and the other at a considerable distance below it, the curves of lesser curvature, or those described with the longer radius, meeting at a point, and thus leaving the arch still pointed.

There is another kind of arch termed the ogee, each side of which consists of a curve of double curvature, the lower curve being concave on its under side, and having its centre on a level with the spring, and the upper convex, with the centre on a level with the apex.

There yet remains to be noticed a more ornamental kind of arch, which is by no means uncommon, and is what is termed a foiled—or, to designate it still more closely—a trefoiled arch. The appellation arises from the shape or outline, which is that of a trefoil, or rather of a semi-quatrefoil. There are two kinds of these; the round-headed trefoil, in which the curve between the cusps is a semi-circle, and the pointed trefoil, in which the same curve is composed of segments less than a semi-circle. There are also what are termed square-headed trefoil arches, in which the centre compartment, instead of being circular, is square or rectangular, leaving the side-ones still circular.

Such are the arches most frequently applied in Gothic buildings; there are some few other varieties, but they are of so rare occurrence, that it is scarcely worth while taking notice of them.

But to return to the classification and description of the various styles; the first of which, the Early English, dates from A. D. 1180 to 1300, including the reigns of Henry II., Richard I., John, Henry III., and Edward I., may be called, in general terms, the style of the thirteenth century. The architecture of this period is exceedingly beautiful and chaste, simple and elegant in design, and excellent and delicate in execution, equally applicable to the modest village church, and the noble abbey or cathedral, remarkable in the one for its unobtrusive simplicity, and, in the other, for its solemn and majestic grandeur.

In describing this and the succeeding styles, we shall follow the method commenced by Rickman, and adopted by most of the later writers, of considering them in detail; that is to say, we shall select the most important of the component parts of a building, and describe them separately as to their character and treatment in each style. We shall arrange these parts and their descriptions in the following manner: *Arches;* next their supports, *Piers*, which we subdivide into *Shaft Capital*, and *Base;* then *Windows*, *Doorways*, *Buttresses*, *Parapets*, *Roofs*, and so forth, including *Towers*, *Spires*, and decorative features, such as *mouldings*, *pateræ*, *foliage*, and other sculpture.

Arches. The arches principally in vogue at this period, were acutely pointed, either lancet or equilateral, the former being most prevalent in the larger structures; in which, however, the latter was not unfrequent, as may be seen at Salisbury cathedral, where it is more frequent than any other shape. It is, however, a rule that the arches are comparatively more acutely pointed in larger churches and cathedrals, and accordingly we find the obtuse-pointed arch most extensively used in small parish churches. The semi-circular arch was not entirely out of use at this period, as we find it frequently combined with the pointed, two or more of which are sometimes included under one of the former shape, as at Whitby Abbey, and in other examples. There are also not a few instances in which the semi-circular form is used alone, and sometimes treated in a similar manner as regards decoration, to those of a later date. Segmental arches were likewise in use, not only as constructive arches, but also as coverings for apertures, and more especially doorways.

The soffits of the arches were, in the more magnificent examples, richly moulded with a series of projecting rolls with deep hollows intervening, but in smaller churches they were for the most part merely cut in recession, so as to present two or more surfaces, having the angles of each projection plainly and broadly chamfered.

Piers. In large edifices the *shafts* of the piers were often composed of a series of pillars clustered together in various forms, to the number of four and upwards. Sometimes these shafts were attached to each other, but they were frequently detached, consisting of a massive central pier, usually circular, but sometimes octagonal or square, and surrounded by four or more slender pillars, entirely detached from each other and the central shaft, except at the base and capital, and occasionally at one or two points in the height of the shaft, where they were connected by narrow bands or annulets of moulding. These annulets are used also in the other kinds of shafts, and are characteristic of the style. The smaller pillars, when detached, are often constructed of a more costly material than the other parts of the shaft, being sometimes of Purbeck marble and polished. The same arrangement of central shaft, with four surrounding pillars, is to be found with the pillars attached to the main pier; specimens of both kind exist at Westminster Abbey. The pillars are usually simple rounds, but sometimes they have a narrow vertical fillet.

In smaller churches the shafts were a simple circle or octagon in plan; more frequently the former, and are distinguishable from those of a later date only by the details of base and capital. It frequently happens that the shafts of piers in the same edifice differ in form, and they are frequently so arranged as to have circular and octagonal forms alternately in the same arcade.

The *capitals* of this period are usually bell-shaped, and are often, especially in the smaller examples, quite plain, with the exception of a necking, and one or two mouldings beneath the abacus. In such cases, they are distinguished from the capitals of later styles only by their mouldings, which consist of rounds and deep hollows; the bell is generally very deeply undercut, which is a strong characteristic of the style. The mouldings are generally plain and few, but sometimes the nail-head or dog-tooth ornament is inserted between them. In the larger and richer specimens, the bell is covered with foliage, which springing from the necking, is curled over with a graceful curve beneath the upper mouldings. The foliage is somewhat stiff in appearance, but of a bold and striking character, and is sometimes undercut to such an extent as to be partially detached from the bell; it consists for the most part of a variety of adaptations of the trefoil leaf, and we rarely meet figures of any kind. In clustered piers, the capitals follow the form of the pier; as also in the single shaft they adopt the same form, with the exception that the multangular shaft has not unfrequently a circular capital. The abacus is either circular or octagonal, and sometimes square in plan, and consists of mouldings varying in number, and made up of deep hollows with overhanging rounds, which are either plain or filleted.

The base consists of a series of mouldings, frequently of a deep hollow and fillet between two rounds, of which the lower one projects beyond the other; it is also often similar to the Attic base, with the exception that the proportions differ, the upper torus being greatly reduced, and the concave mouldings deeply undercut. The base most frequently stands upon a single or double plinth, which in the earlier examples is square, having the angle covered with a leaf which springs from the mouldings of the base, and falls over the plinth. In later specimens, the plinth assumes the form of the base, and is either circular or polygonal; it is sometimes of great height, having a second series of mouldings below the base.

The *windows* of this style are for the most part long and narrow, with acutely-pointed heads. The earliest and simplest form is that of a long narrow single light, with arched head, and without moulding of any kind either internally or externally, the exterior angle being merely chamfered, and the interior widely splayed. Such windows were sometimes without any weather-moulding, but occasionally a string-course was carried from one window to another, at a level with the springing of the head, and then lifted over it, adopting its form, and carried on to the next aperture. In later times such windows appear in groups of two, three, or more, the first being commonly found in the side-walls of churches, and the latter being almost confined to the east end, except in very large buildings, where it is found in all positions. The separate lights of these groups are generally placed at some distance apart on the exterior, so as scarcely to appear as belonging to the same window; but in the interior, owing to the great splay given to each light, the distance between them appears inconsiderable, giving them the appearance of a single compound window. This idea is sometimes manifested on the outside by the two or more lights being contained under one drip-stone. The glass is inserted near the outer face of the wall, which circumstance, taken in connection with the great thickness of the walls, accounts for the difference of the size of the aperture on the two faces of the wall. This arrangement was in all probability adopted for the purpose of obtaining a larger proportion of light, or rather spreading what they obtained over a larger portion of the interior.

The arches of the splay on the interior, seldom follow the form of the window heads on the exterior, but spring from a lower level, and are almost always chamfered or moulded at their angles or edges; the mouldings projecting below the soffit, and either dying into the jamb, or resting upon corbels at the spring of the arch.

In windows of three lights, the centre one is almost always of a greater length than those at the side, its head rising considerably above theirs, so as to preserve the arched form in the entire window. We occasionally meet with windows of four lights, the two centre ones rising above the others, but more frequently with others of five or seven lights rising in gradation to the centre one, which is higher than the rest. These large windows have a very beautiful effect, occupying as they do nearly the whole of the east wall. In all the above cases the jambs are sometimes plain, being merely chamfered and splayed as before described; but at other times we find them decorated with small detached pillars, with moulded arches. This is most frequent in the interior, where the shafts are not unusually of polished marble, but such decoration is also to be met with on the exterior, especially in large buildings. In windows of a late date, the arched heads are sometimes foiled.

Before the termination of this style, windows of a somewhat different appearance were introduced, which originated thus:—In cases where windows of more than one light were employed, it was, as has been mentioned, a not unusual practice to include them under one arch, the head of which was left plain; but in the course of time this space began to be pierced with another small light in the form of a circle or trefoil, which at once relieved the blank space beneath the arch, and admitted a greater amount of light. At Brownsover church, Warwickshire, there is a very simple arrangement of this kind, in which the third light is somewhat in the shape of a diamond placed between the arched heads of the principal lights, to which two sides of the figure are parallel, the two remaining sides being parallel to the curved sides of the larger connecting arch. In the earlier specimens of this class, the openings are still chamfered only, with shafts sometimes on the inside; but at a later period the lights were brought closer together, and were divided by slender shafts, and the arches and ornamental lights in the head moulded and foliated. We have many beautiful examples of windows of three lights, with three foliated circles in the head, and sometimes of five or more lights similarly decorated. The windows of the Chapter-house, York, are most beautiful specimens of five lights, which are arranged in two pairs of two lights each, connected under one arched head containing a foliated circle: the central light being also surmounted by an arch containing a trefoil. The whole of these are enclosed under the principal arch, which contains above the lights, three large foliated circles. The effect of this design is grand in the extreme. The east window of Lincoln Cathedral is another magnificent example: it contains eight lights in all, which are divided into two compartments containing four lights each, with arched heads filled with foliated circles, whilst the principal head is filled with one large circle containing seven of a smaller size. This is probably the largest window of the kind we possess.

Circular or rose-windows are not unfrequent in this style, and are divided into compartments by slender shafts with capitals, &c., radiating from the centre, and sustaining at the circumference small arches, which are usually trefoiled. Smaller windows of this form are either left plain, foiled, or filled with quatrefoils, &c. Windows of triangular shape are also found, as well as a peculiar sort of window in the form of what is called the Vesica Piscis; but these are always small, and placed in subordinate situations, such as the gables or the clere-stories of parish churches. Small square-headed windows are sometimes employed, but only in towers and similar situations.

The *dripstones* follow the form of the arch, and usually terminate on a projecting head or knob of foliage, but are sometimes returned horizontally along the wall; the moulding has a deep hollow on the under side to prevent the rain running over it. A string-course is generally carried along the external and internal walls, immediately below the windows.

The *doorways* of this period are most frequently furnished with nook-shafts in the jambs, which are, for the most part, detached from the walls, except at the capitals and bases. The more simple doorways have only one shaft on either side, supporting an archivolt of a few bold mouldings, the whole surmounted by a simple hood-moulding conforming to the shape of an arch, and terminating in a head or bunch of foliage, or returned in a horizontal direction along the walls. More elaborate specimens have two or more shafts on either side, and a greater number of mouldings in the arch. The jamb is cut in recession to receive the shafts, and the spaces between the mouldings or shafts are frequently filled up with the dog-tooth ornament or a running pattern of foliage. The arched heads of doorways are most frequently pointed, but not rarely round-pointed or square-headed trefoil.

The doorways of the larger structures are mostly divided into two arched apertures by a simple or clustered shaft, which is often of polished marble, and furnished with a richly moulded or foliaged capital. The arches are also foiled or foliated, and enclosed under one main arch, the space between being perforated in circles, trefoils, &c., and sometimes filled with groups of sculpture.

The *doors* are either plain or covered with iron scroll-work, sometimes proceeding from the hinges, which are often of a very ornamental character, but at other times nearly plain. In some cases this scroll-work is very elegant, and completely covers the door.

The *buttresses* of this period are, for the most part, of a simple character, consisting, in smaller churches, of two or more stages, the lowermost projecting beyond the other, each set-off being sloped at the top so as to carry off the rain. The buttress finishes at the top under the parapet, or eaves, with a simple slope similar to that of the other projections. In larger buildings, the buttress is frequently finished with a triangular head or gablet, but is seldom carried above the parapet, except where stone vaulting is employed, and, in such cases, it is covered with a pinnacle which is either plain or enriched with blank arcades. Sometimes each set-off is finished with a triangular head, and, at others, the water-table is continued round three sides of the buttress. The edges of such buttresses are often chamfered, or the angles ornamented with slender shafts; occasionally, too, the face is formed into a niche to contain a statue.

There is a peculiarity about the position of buttresses of this period, which is often the only means of distinguishing them from those of later date; at the angles of buildings they are not placed diagonally, but at right angles to the wall, so that whereas in this style we require two buttresses at each angle, placed at right angles to each other and to the adjoining walls, in the following styles we need but one.

Flying-buttresses, which are arches springing from the wall-buttresses over the roof to the clere-story, were now first introduced, and are common in all large buildings with vaulted roofs. They are of simple design, with a plain capping and archivolt.

Parapets are not frequent in small buildings, the roof being carried over the walls with dripping eaves; but when they occur, they are of a simple character, finished at the top with a moulded capping, and supported underneath by a corbel-table, which consists of a series of blocks moulded or sculptured in the form of heads or masks, and sometimes of foliage; these are often connected together by trefoiled, or other arches. The projection of the parapet above the corbel-table is often merely chamfered, but in the richer specimens moulded, and sometimes decorated with the dog-tooth ornament. In cathedrals, we occasionally see the parapet relieved by panelling, as at Salisbury, where the panels are of the form of trefoiled arches, and sometimes pierced with trefoils, &c. Battlements are not often found in this style.

Pinnacles, which rise above the general level of the buildings, are often mere continuations of the rectangular buttress capped with simple pyramids of square or polygonal bases, without any ornamentation, but in more costly examples the latter form is chiefly employed for the entire pinnacle, and is enriched with one or more series of blank arcades, which give them a light and elegant appearance; in some instances, the arcades are perforated.

The *Roofs* are of a high pitch, the angle at the apex coinciding mostly with that of an equialateral triangle, but sometimes they are more depressed. In small buildings, as we have above stated, they not unfrequently overhang the walls, but in larger ones they are stopped by the parapet. In the interior of large churches and cathedrals the roof is generally vaulted, the vaulting being of the simplest kind, or that which has been described as quadripartite, that is, consisting of four cells in each bay, and being divided only by transverse and diagonal ribs, not having a longitudinal one along the apex, as in later examples. The mouldings of the ribs consist generally of rounds plain or filleted, and deep hollows, and are covered at their intersection by bosses of sculptured foliage.

The wooden roofs of the period were like all Gothic roofs, except those of a very late date, open to the ridge, and unceiled, so as to afford a view of the timbers from the body of the building. In recent times, however, most of these open roofs have been excluded from view by the intervention of a modern ceiling, and it is seldom they are brought to light, except on the occasion of an extensive repair or restoration of the entire fabric. This fact will account for the paucity of information respecting this portion of a building, a want which is more particularly felt in respect of the early styles; so much so, indeed, that we scarcely know for certainty how to distinguish the early English from the Decorated examples, and it is probable that there is no very marked difference between them, although it is usual to make a distinction in treatises of this nature.

The most simple roofs, which we may attribute as more particularly belonging to this period, consist only of common rafters placed at short distances apart, without the intervention of trussed principles, and have a very good effect, owing to the lengthened perspective produced by the frequent repetition of the same parts. The rafters are very often secured by means of collar beams and braces, or by intersecting braces springing from purlins about half-way up the rafters, and rising to a higher purlin on the opposite side of the roof. These two systems are very common and simple, but not unfrequently the two were united, so as to have a collar beam with cross braces intersecting a point usually above it; and sometimes, in addition to these, we have a strut below, all resting upon the wall-plate, so that the entire outline of the under side presents the appearance of a polygonal arch. In some instances, the braces are curved in the form of a pointed arch. Where the roof is carried over both nave and aisles, the portion over the nave is of a similar description to those above mentioned, and in that over the aisles, the side next the nave is supported by short beams or struts abutting against the nave walls; this is also common in lean-to roofs. Although the practice of adopting only common rafters may be more usual, the introduction of principals is not unfrequently resorted to, which, in such instances, follow the same constructive form as the common rafters before referred to, the common rafters, however, are of a more simple character than the principals.

Tie-beams do not seem to have been of frequent occurrence, and king-posts are still less usual, their absence being very readily accounted for by their necessary weight in roofs of a high pitch; when tie-beams are employed, they are sometimes supported underneath by sloping braces abutting against the wall, and this method removes, in a great degree, the objection made against ties, of destroying the vertical tendency of the general design.

The timbers of the roof are often plain or chamfered on the edges, but in the richer specimens they are moulded, or at least the main beams, such as principals, purlins, wall plates, and such like, but the common rafters are mostly plain.

The *Towers* of the period are of various proportions, but generally bear a substantial, massive appearance; they are almost always square on plan, but sometimes octagonal, and in a few instances square below and octagonal above. They are strengthened at the angles by buttresses, two at each corner, projecting at right angles to the walls, which generally terminate a stage or more below the top; projecting stair-turrets are not uncommon, but are sometimes concealed by the buttresses.

The tower is divided into stages by set-offs or otherwise, of which the upper ones are frequently decorated with blank arcades, a few being perforated, to serve as windows; sometimes the faces are perfectly plain, with the exception of the apertures for windows, which consist of one or more light, the most important being placed in the upper stories. Here, in smaller churches, we generally have a window of two lights divided by a shaft, and having a foiled aperture under the arched head, but in larger churches we find windows of three lights, or triplets, but of equal height; in the lower stories we usually find single lancets.

These towers are occasionally covered by a low pyramidal or a gable roof, but more frequently by a lofty spire of stone or wood, although for the most part less acutely pointed than those of a later style. The spires are almost invariably broach-spires, that is to say, such as spring directly from the roof, without the intervention of a parapet; their plan is almost always octagonal, four of the sides sloping down to the eaves, but the four corner ones leaving a triangular space at each angle of the tower uncovered, which is occupied either by a pinnacle, or more frequently by a triangular pyramid, which connects the angles of the tower with the angular faces of the spire. Towards the lower part of the spire, the cardinal sides are furnished with windows, which rise perpendicularly, so as to give a projection at the top which is covered with a gable-head, and sometimes we have two or more tiers of such windows placed often on alternate sides of the spire. The whole is surmounted by a finial and vane. The cornice below the eaves is frequently ornamented with the dog-tooth moulding, or a running pattern, and is often supported upon a bold corbel-table.

A very elegant substitute for tower and spire, is employed in small churches, in the shape of a bell-gable, with one or more openings to contain the bells.

The *Mouldings* of the style have no great variety of form, but consist almost universally of bold rounds with deep undercut hollows intervening, so as to produce a great amount of shadow. The rounds are sometimes filleted with one or more fillets, but this is not usually the case with the smaller mouldings. Where several mouldings are connected together, there is considerable difference of size, the entire series being generally divided into a few distinct portions by mouldings of a large size, which are often filleted, and the intermediate spaces filled up by smaller plain mouldings. In such cases, it will be generally found that the mouldings are so arranged,

SEMI-NORMAN AND EARLY ENGLISH EXAMPLES.

that if a line be drawn to touch the most prominent points, it will form a succession of rectangular recesses. The large rounds are sometimes brought to a pointed edge in the middle, and the smaller ones very deeply undercut on one side: in some cases, a fillet intervenes at the junction of the round and hollows, but they mostly unite in a continuous line without any interruption. String-courses often consist of a plain round-moulding, or of a roll-moulding of two different curves, so as to cause the upper half to overlap the lower; sometimes they are mere slopes with hollow underneath. Hood-mouldings consist for the most part of an overlapping round with deep hollow underneath. The base-mouldings are composed of a series of slopes, with sometimes a string-course moulding along the top, but in more elaborate works they comprise a series of mouldings consisting of projecting and overhanging rounds deeply undercut.

The hollows of the mouldings are often filled with ornaments peculiar to the style, of which the most usual and characteristic is that termed the *dog-tooth* ornament. It is a kind of pyramidal flower of four leaves, the division between the leaves being placed in the centre of each side of the pyramid; the flower is placed in an inverted position, the base of the pyramid being placed against the hollow, with the apex projecting. This ornament varies to some extent in different examples, but always preserves the same general appearance; it is very effective on account of the deep shadow produced at the division of the leaves. They are placed in a hollow moulding, or in the edge of a jamb, either singly, with a space intervening between each two, but more frequently in close proximity to each other. Single leaves and flowers of a different character are sometimes inserted in a similar way, and sometimes a running pattern of leaves or foliage.

Sculptured foliage is much used in the more costly buildings, forming capitals, corbels, crockets, and bosses, and is usually of a stiff character, that is to say, the leaves have a crisp appearance not observable in other styles. It is very beautiful, however, and worked with much taste and freedom; although it does not present an appearance so natural or flowing as that employed during the next period. Amongst other varieties of foliage, the trefoil is predominant, the two lower lobes of which, and sometimes all three, are worked with a bulb or swelling in the centre, the middle lobe being frequently of larger size than the others.

The crockets likewise are usually in the form of a trefoil-leaf, curled back like the head of a pastoral staff.

The *walls* of large buildings are frequently ornamented by a series of blank arches supported on pillars. These are common, running round the base of the walls on the interior, and are employed in many other situations, both externally and internally, so much so as to become a characteristic of the style. Another method of ornamenting blank walls is by diapering, or carving them in low recession after some small and recurring pattern, frequently in the form of square leaves, as in the triforia, Westminster Abbey.

Niches were in use at this period, but of a less elaborate character than those of succeeding styles. The figures were frequently set on small pedestals, and surmounted by a canopy consisting oftentimes of a three or five-foiled arch with plain pedimental head; in many cases, the canopies project or bow forwards. Niches are often placed in ranges of two or more, under one common arch, and in such cases are generally separated by single shafts.

Mr. Bloxam has subdivided this style into two, the earliest of which he names the *Semi-Norman* style. It is the same as that styled by others the *Transition* style, and embraces that class of buildings in which the round and pointed arches seem to be struggling for pre-eminence, and which bear evident marks of their near affinity to both systems: remarkable examples of the kind are the Church of S. Cross, and Malmesbury Abbey.

The general characteristics of this division consist in the use and combination of round and pointed arches in the same building; in some instances, pointed arches are surmounted by others of the semi-circular form, in others semi-circular arches are made to intersect, and thus form pointed arches. Another characteristic is the existence of pointed arches on massive piers of Norman design. The piers are mostly Norman in character and proportion, but have their capitals often ornamented with a simple description of foliage. In other respects, the details of such buildings are for the most part Norman.

Sometimes the piers are of more slender proportions, and attached to a large central pier, which is either square or round; and a still closer approximation to the Early English examples is shown in the horizontal bands surrounding the piers about midway.

The soffits of arches are frequently recessed, which shows an advance upon previous examples, but the chamfer common to Early English buildings is omitted, the edges being left square.

The Decorated style.

Otherwise termed, in architecture, the *Middle-pointed*, stands next in respect of time and decoration. It had its commencement in the reign of Edward the First, and arrived at maturity during the reigns of the two succeeding Edwards, from which circumstance the name of *Edwardian* has sometimes been applied to it. It dates from 1307 to 1377, or a little later, and may be named generally the style of the fourteenth century. This period of architecture is of all others the most beautiful; it rivals the preceding in chasteness, while it surpasses it in richness; and at the same time is free from the extravagant and redundant ornamentation of the succeeding styles.

The *arches* of this period are described from equilateral or obtuse-angled triangles, and in many instances are not easily distinguishable by their shape from those of the previous style; and in smaller buildings, where the soffits are merely recessed and chamfered without mouldings, it is a difficult matter to distinguish them at all; the date, however, may usually be determined by the mouldings of the caps and bases of the piers. In larger or more costly buildings, the arches are moulded, and the distinction marked by their contour. The mouldings consist of rounds projecting to the extent of from one to three-quarters of the circumference, and are frequently filleted, alternating with plain soffits and faces. As arches of decoration, the trefoiled was not uncommon. Hood-moulds frequently occur, and are terminated on heads or foliage.

The *shafts* of *piers* in small parish-churches are mostly of a simple circular or octagonal plan, similar to those of the preceding period, and, like the arches, are only distinguished by their capitals and bases. The alternate arrangement of the circular and octagonal piers is still adhered to. In larger buildings the piers are clustered, and consist of four or more shafts, which are in contour, either half or three-quarter cylinders. They differ from Early English examples in being attached to each other, whereas the latter are detached from each other, and frequently from the central shaft. The plan of these clustered piers is often that of a lozenge, or of a square placed diagonally; another shape is that of a quatrefoil, but many other forms are found which we cannot stop to mention. In many instances, we see four or more main shafts with smaller shafts introduced between them, and sometimes mere mouldings in the place of the secondary shafts; in late examples, small shafts occur, separated by a deep hollow and two fillets, a form which prevails in the succeeding style, but in perpendicular examples the hollow is very shallow in comparison. In all the above cases vertical fillets are employed to a very large extent both upon the shafts and mouldings. In very large structures the piers are made up of a very great number of shafts.

The *capitals* are either bell-shaped or octagonal, and in clustered pillars usually follow the general form of the pier, but sometimes are continued in one sweep all round without any regard to the contour of the shafts. They are frequently only moulded, the prevailing mouldings being rounds, plain or filleted, ogees and hollows, in which some ornament, such as the ball-flower, is often introduced. The mouldings are not so deeply cut as in the Early English examples. In most of the clustered, and many of the single pillars, the vase is covered with rich and beautiful foliage placed horizontally, and consisting of very perfect and natural imitations of the oak, ivy, vine, &c., very freely and delicately executed. Some capitals are ornamented with sculptures of heads, figures, and such like. The *abacus* is either circular or polygonal in plan, and its mouldings are composed of rounds, frequently with an overlap, of ogees, and hollows. We have instances of continuous imposts in this style, where the mouldings of the pier are carried round the arch without the intervention of a capital.

There is great variety in the *bases* of this period. In plan they usually agree with the shaft, but are sometimes octagonal where the piers are circular, the mouldings following the contour of the pier, and overhanging the plinth; in some few instances the mouldings are raised on a square plinth. The plinths are frequently double, and of considerable height, the lower one projecting beyond the upper with a simple splay, reversed ogee, or hollow, with sometimes one or two small mouldings above. The base mouldings vary, but consist, for the most part, of reversed ogees or quarter-rounds, with the occasional insertion of one or two small rounds. In clustered columns the bases follow the general outline of the pier.

The *doorways* have one or more shafts in the jambs, which differ from the Early English examples in being constantly engaged. These have moulded or sculptured capitals, but the jambs are filled up with mouldings, which are continued round the arch without interruption. Many doorways are without pillars, being entirely composed of mouldings, which are continuous with those of the architrave, and are composed of a series of quarter-round and semi-cylindrical mouldings, the former being often filleted up the face. The hollows are frequently filled up with sculptured foliage, such as the ball-flower, or a square ornament placed at intervals, and sometimes with a running pattern of ivy or vine leaves, &c.; occasionally we find a series of niches carried up the jamb. The doorways are not usually so much recessed as those of the previous style, and the shafts are more slender, approximating more nearly to mouldings. In large buildings the arch is mostly pointed, but in smaller examples the ogee arch is not unfrequent, and the square-headed trefoil occasional: the architrave is usually moulded. The hood-moulds are seldom returned, but terminate in a head or knop of foliage. The arches are frequently surmounted by a triangular, or ogee canopy, which is finished with crockets and finials, and the spandrels filled with sculpture of various kinds. The doors themselves are often hung with ornamental hinges, as in the previous style, but the iron-work is of somewhat different design. In other respects the doors are mostly plain, though sometimes panelled and with tracery in the heads. The nails are often of an ornamental description, being of an hexagonal form, or made in the shape of a leaf or flower.

The *windows* of this period are usually of a large size, and of several lights, but there are also windows of a single light which are of a less elongated form than the Early English, and their heads are frequently trefoiled. Larger windows are divided into two or more lights by vertical mullions, but are seldom divided horizontally except in tall spire-lights, or in domestic edifices. These vertical mullions are carried up as far as the springing of the arch, and from that point branch out in various directions, interlacing and forming patterns of varied and beautiful design, known under the name of tracery. The variation from Early English practice is here distinctly marked, first in the employment of mullions in the place of shafts with capitals and bases, but more prominently in the method of filling the head or arch, of the origin of which we have taken notice above. In the earlier specimens the tracery is composed of circles, trefoils, quatrefoils, triangles, and other simple and complicated geometrical forms, arranged in various patterns, and is hence termed, geometrical tracery; but at a later period the lines assumed a more wavy or flowing appearance, and were disposed with greater freedom, such description of work being distinguished as flowing tracery. A very simple kind of window is that in which the mullions merely cross in the heads; and another of two lights with a simple trefoil in the head. This last approximates very closely to some Early English examples, but there is another kind which bears a close resemblance to the earlier specimens or triplets, and consists merely of three lights comprised under one arch, the centre one of which is higher than the two side ones, and separated from them by mullions. The subordinate arches formed by the intersections of the mullions, are generally foiled, as are also the principal compartments of the tracery; but there are some few exceptions.

The heads of the windows are principally two-centred pointed arches of various proportions; but segmental arches both simple and pointed, not unfrequently occur, as also does the ogee. Square-headed windows are by no means uncommon, especially in subordinate parts of the building, and have their heads filled with tracery, as in the other cases; some few, however, are entirely devoid of tracery. Common hood-mouldings resting on masks, heads, &c., are most frequent, but sometimes in rich examples we find pedimental and ogee canopies introduced, and ornamented with crockets and finials.

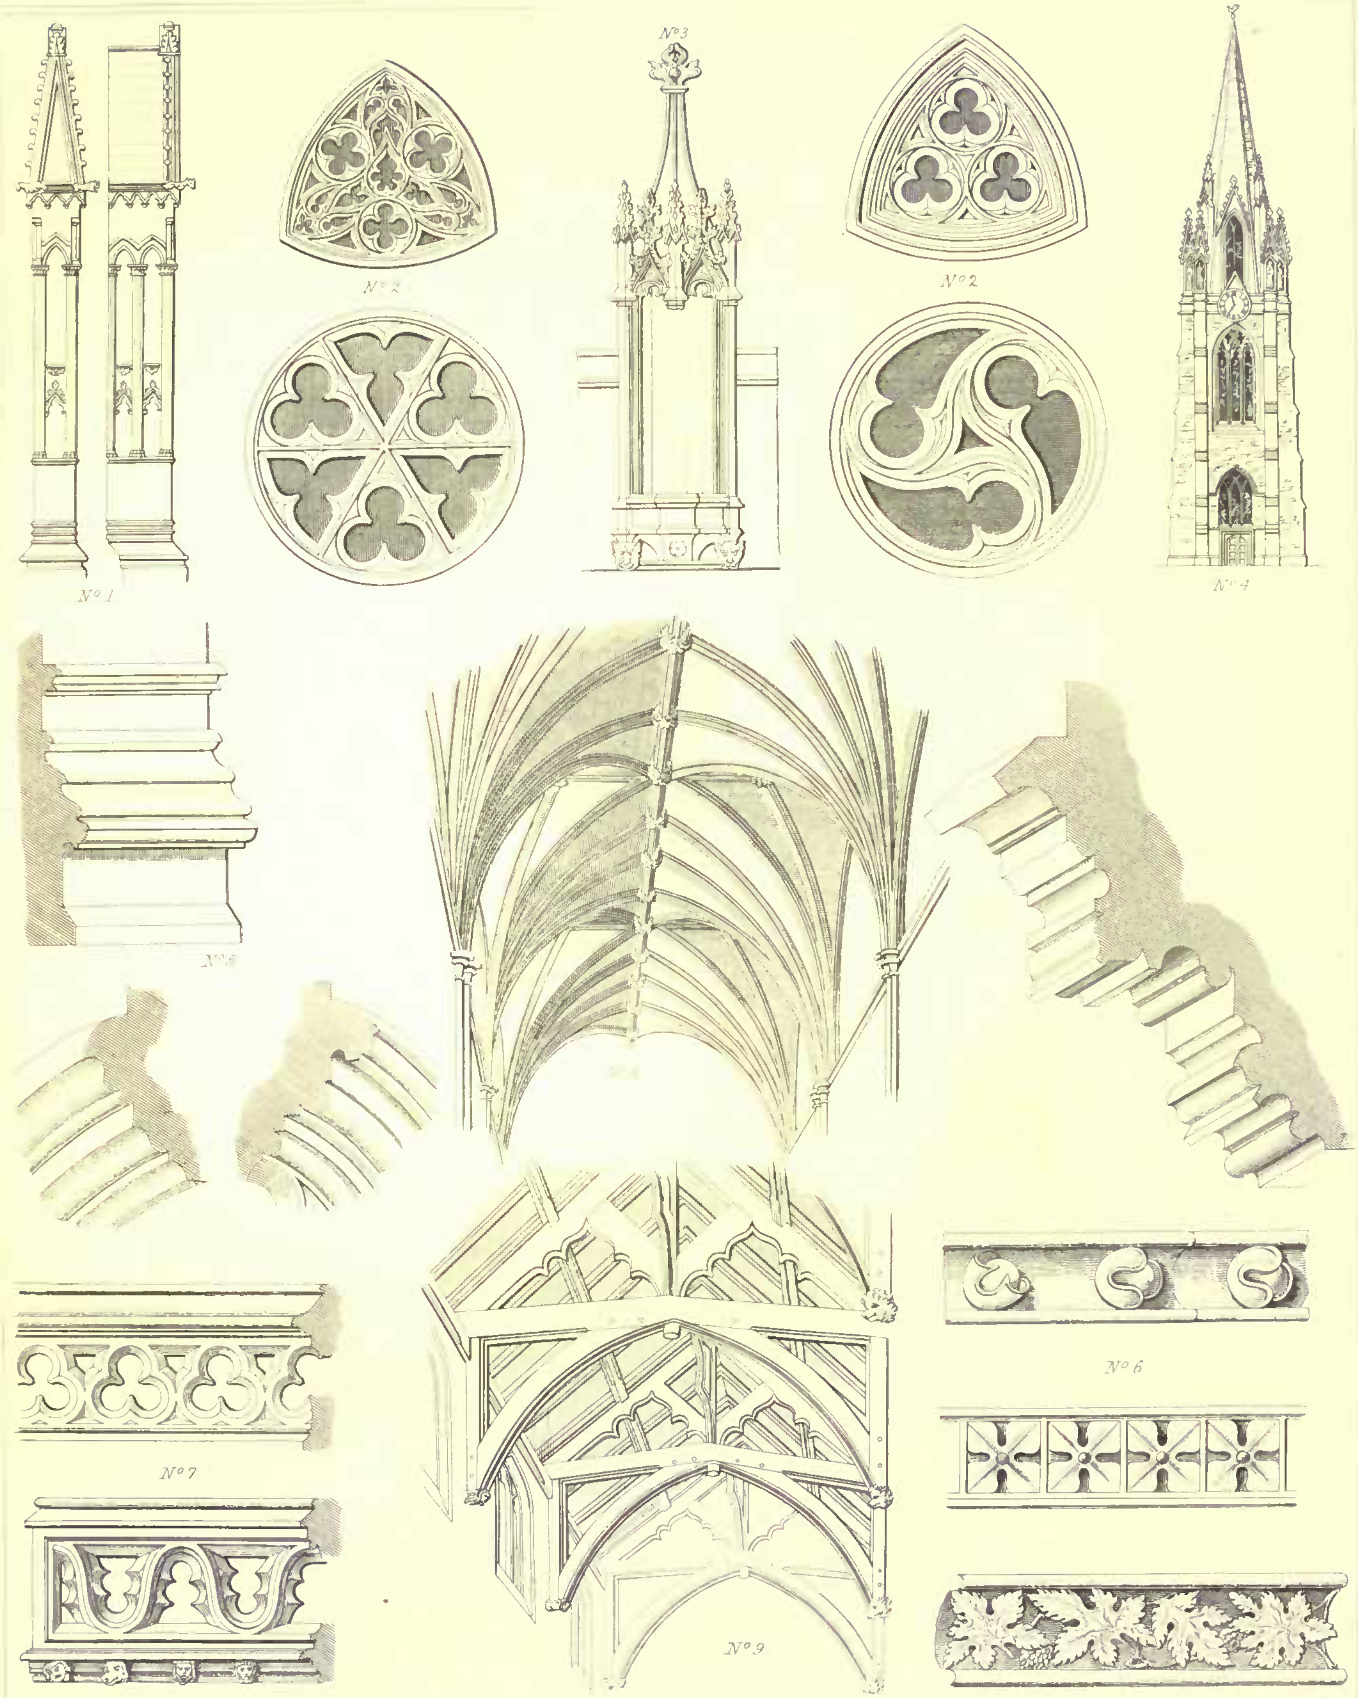
The mullions are most frequently simply chamfered, or in later examples slightly hollowed, but in more costly buildings each mullion is composed of a series of mouldings, set diamond-wise, and sometimes the hollows are filled up at intervals with some ornament peculiar to the style. In some cases we find shafts with capitals and bases still introduced, more especially against the jambs. String-courses are seldom omitted on the exterior beneath the windows. The windows are splayed on the interior, and the inner arch is frequently of a different form to that on the exterior, its edge being moulded or chamfered, similar to the practice followed in Early English examples.

Very beautiful windows of this style are to be seen at Exeter cathedral, almost every one of them being of a different pattern; the most elaborate, however, and the largest, is over the west entrance.

Circular windows filled with tracery are not uncommon in large structures, and are sometimes of excellent design. Windows in the shape of squares, trefoils, quatrefoils, spherical triangles, and sex-foiled circles, are common, but are of small size, and are usually seen in subordinate situations, such as clere-stories, gables, &c.

GOTHIC ARCHITECTURE — DECORATED EXAMPLES.

GOTHIC ARCHITECTURE — DECORATED EXAMPLES



R. Thew.

The more simple *buttresses* are not easily to be distinguished from those of other styles, consisting, as they do, of plain piers, with one or more slopes or set-offs without any further decoration; but in some cases they may be known from those of the Early English, by their position at the angles of buildings, where they are set diagonally. This, however, is not a very sure criterion, for some Decorated buttresses stand in the same position as those of the preceding style. In many instances the set-offs are finished with a pedimental head or gablet, which is sometimes plain, but more frequently foliated, and decorated with crockets and finials. In rich examples, the faces are often recessed for niches, which are surmounted by rich canopies, small buttresses, pinnacles, &c. The buttress seldom reaches above the parapet unless surmounted by a *pinnacle*, which is mostly of an elaborate description, being finished on all sides by a pedimental head similar to that above described, and the whole surmounted by an acute pyramidal top with crockets and finials.

The *parapet* is frequently embattled with plain or moulded capping, but very often consists of a plain horizontal cap. Some horizontale xamples are pierced or sunk in trefoils, &c., and very often with trefoils inserted in the spaces left on either side of an undulating moulding. *Corbel-tables* are of rare occurrence, but the parapet is usually finished on the under side by a cornice consisting of a roll-moulding, overlapping a deep hollow, in which are sometimes inserted ball-flowers, masks, and other ornaments.

The *roof* still continues of a lofty pitch, but somewhat more depressed than in the previous style. The larger churches are vaulted as before, but there is some difference in the arrangement of the ribs, which are greatly increased in number. Each bay or compartment of the vaulting is intersected, not only by longitudinal, transverse, and diagonal ribs, but these again are intersected by others in a variety of ways, so as to divide the vault into a greater number of cells, a practice which gives the roof a more complicated and richer appearance. Bosses of elegant design, and excellent workmanship, cover the intersections of the ribs, which are moulded, and the hollows frequently filled with the ball-flower ornament.

The same remarks apply to the wooden roofs of this period as to those of the preceding: we have but few examples now remaining, roofs of a later period having frequently been substituted in buildings of this style. The early roofs are doubtless of much the same character as the Early English, but in later examples there are some distinctions, although it is a somewhat difficult task to decide the exact date of any. In some examples the beams are merely chamfered as before, but in many they are moulded or have their edges foiled or cusped in such a manner that the spaces between the timbers present the appearance of some description of polyfoil. Tie-beams seem to have been of frequent occurrence in this style, and are often suspended by king-posts, which are sometimes but plain timbers, but at others assume the form of an octagonal shaft with moulded base and capital. Polygonal roofs having the timbers so disposed as to present to view a number of canted surfaces, are not unusual, they are mostly of six sides, but sometimes in later examples heptagonal. The principles of high-pitched roofs are frequently disposed in the form of an arch, and where tie-beams are employed, the same outline is preserved, by supporting them on curved braces, fixed to a wall-piece and resting on corbels. Longitudinal braces are frequently carried from the king-post of one principal to that of the next, and are often of an arched form resting at each end on tie-beams, and reaching to the ridge-piece at the apex, such arches being frequently foiled. A somewhat similar arrangement is adopted on the sloping sides of the roof, the purlins resting on arched purlin-braces, which stand upon the wall-plates, and are carried up under the common rafters. In some instances both king-posts and collars are employed, in others, king-posts with struts on either side, and occasionally queen-posts and straining pieces are introduced.

A curious roof of this date is thus described by Mr. Bloxam :—" In the little desecrated church of Horton, near Canterbury, is an open wooden roof, of a construction different to those which have been described. It is divided into bays by horizontal tie-beams, with the under parts moulded, resting on the wall-plates and on vertical wall-pieces supported on corbels, with a curved brace between each wall-piece and the tie-beam. From the centre of each tie-beam rises an antagonal-shaped king-post up to about two-thirds in height of the valley of the roof, where it supports a longitudinal rib or beam. From the principals of the roof, at about two-fifths in height, spring plain braces, which cross diagonally just above the longitudinal rib, and rest on the opposite principal. Above these there is neither collar-beam nor apparent ridge-piece. From four sides of the king-post spring curved braces, both longitudinal and lateral; the former support the longitudinal rib, the latter the braces which cross above it. The roof is high-pitched." Other examples of this or a similar description occur, and the arrangement of curved braces springing from the four sides of the king-post are not uncommon.

In the richer class of roofs the spandrels formed by the intersection of the timbers are frequently filled with tracery.

The general arrangement of the *towers* is similar to that of the previous style, the greatest differences appearing in the apertures and decorations. The windows of the lower stories are many of them of small dimensions, and of single lights with ogee or foliated heads, and label or square hood-mould. The belfry-windows are the most important features, and are arranged singly or in pairs; they are of a large size, frequently filling up the entire story. The largest window, however, frequently occurs on the west face of the lower story, or that above the entrance, and forms one of the general range in the interior of the church; it is often of very large dimensions and elaborate design, standing in this respect next to that in the east wall of the chancel. Blank arcades are not so much in vogue as in Early English examples, and when used are of a form and decoration common to the period.

The *spires* are very acutely pointed, but in some cases are very low, forming merely a low pyramidal roof to the tower: the latter is mostly constructed of wood, a material frequently employed in the construction of the loftier kinds, which in larger structures, however, are almost universally of stone. The large spires boast a larger number of spire-lights than those of earlier date; and not only so, but they are of a more elaborate description, being capped by lofty pediments enriched with crockets and finials. They are also sometimes divided into a number of compartments by horizontal bands of panelling, and the angles of the spire enriched with crockets running all the way up, and terminating in a large finial. The tower is mostly finished with a parapet, which is either plain or embattled, and sometimes pierced in quatrefoils, &c., and is supported on a moulded cornice, the hollows of which are often filled with the ball-flower or some other ornament. At the angles we frequently find projecting gurgoyles in the form of animals, &c. Pinnacles of a prominent and elaborate character are of constant occurrence, and sometimes behind them rise ornamented flying-buttresses to support the lower portion of the spire. Parapets and gutters, however, are not universal, for we not unfrequently meet with broach-spires of this period.

The *mouldings* consist for the most part of a greater number and variety of members than those of the Early English style. Rounds and hollows still prevail, but the latter are not so much undercut as before; in the earlier examples they are still deep, but grow more shallow towards the termination of the style. Quarter, half, and three-quarter rounds are most prevalent, and are often filleted and separated by small hollows; ogees, too, are of frequent occurrence, as are also ovolos and cavettos. Another undulating moulding, similar to that in use in the next period, but of somewhat different projection, is also used, and is in appearance somewhat like a double cyma, consisting of a convexity in the centre between two hollows. The roll-moulding, in which the upper half overlaps the lower, is in constant use. Rounds and hollows are sometimes separated by fillets, but frequently run into each other without any interruption.

For string-courses, the overlapping roll-moulding is very common, but sometimes a simple roll or a roll filleted, or what is termed keeled, is used in its place; the latter term being applied when the roll comes to a sharp edge in the centre. These mouldings are used either separately, or with other subordinate ones; a hollow is not unfrequently carried underneath. Hood-moulds are formed of quarter-rounds or ogees with a hollow or plain chamfer beneath, and are seldom returned. The base-moulds consist of one or more slopes with or without a projecting edge, the whole being surmounted by a filleted or keeled round. In all the above cases the ball-flower and other ornaments are often inserted in the hollows and carettos.

The leaves selected for imitation in the *foliage* of this period, are those of the oak, vine, ivy, fern, white-thorn, &c., which are copied with a boldness and freedom not common in previous examples. They are also more naturally disposed, and have a less stiff and formal appearance than those of any other style; there are not so many sudden projections, and the outline is of a more gently undulating form than in the Early English specimens: in capitals, the stems are twined about in various directions, instead of rising vertically from the neck.

The most usual and characteristic of the ornaments is the ball-flower, which consists of a round ball enclosed within a flower of three or four petals, the ball appearing beneath the slight opening of the petals; it is supposed by some to represent a rose-bud. It is used in almost every situation, but more especially in the hollow mouldings of jambs, arches, cornices, &c., in which it is inserted at intervals. Another ornament consists of an open square flower of four leaves, with a small ornament in the centre, which is employed in the same manner as the preceding; but a series of them is sometimes used, the flowers being placed in contact with each other, in which manner it is frequently applied as a diaper. They are sometimes introduced alternately with the ball-flower. A representation of a very beautiful ornament which occurs at Adderbury, is given by Mr. Bloxam in his manual. It bears some affinity in form to the dog-tooth moulding, and consists of four ivy leaves placed in the angles of a square, with their upper sides to the wall, the stems projecting outwards, and meeting in one point, which gives the ornament a pyramidal form. Leaves, masks, heads, &c., are often used in similar positions.

The crockets of finials are of various descriptions, but are readily distinguished from the Early English by their natural and flowing outline, and by the crumpled leaves, so different from the crisp appearance of the latter.

The *niches* are of a very elaborate description, and are usually of a considerable depth, having the roof covered with minute ribs and bosses. They are almost always surmounted by pedimental or ogee canopies, which are sometimes bowed forward in the form of an ogee, and are almost always decorated with crockets and finials. The arches are foliated, as are also frequently the spandrels above them. Some niches have conical coverings like spires crocketed at the angles, and surrounded with a series of canopies one on each face of the spire. The sides, too, are often enriched with small ornamental buttresses. Some again have flat tops.

The *Perpendicular* style dates its rise towards the close of the fourteenth century, at the latter portion of the reign of Edward III., and prevailed until the disuse of Gothic architecture. It is characterized by the exuberance and redundancy of its ornaments, and is wanting in the simplicity of the Decorated style. In the earlier examples, this enrichment is not carried beyond bounds, but in later times it becomes excessive, and the chief aim of the architects seems to have been to employ as much labour as possible on decoration. This practice proved injurious, and at last fatal, and Gothic architecture may date its decline from the commencement of the fifteenth century.

This style is called by some *Third-pointed*, and by others *Florid*. The term *Perpendicular* was given to it on account of the peculiar arrangement of the tracery in window-heads, which forms a very marked characteristic of the style; but some have objected to the name, as of only partial application, and suggest the term *Horizontal*, as being much more appropriate and significant of the general tendency of the style; and in this they are certainly correct, as witness the depressed arch, low-pitched roof, square-headed windows and door-ways, square hood-moulds, and the horizontal transoms. But on this subject we shall not here enter; the term is well established, and could not readily be laid aside, supposing such a course to be desirable.

Pointed *arches* of all descriptions are to be met with in this style, nor do they differ materially from those of the preceding period, but drop arches are perhaps more prevalent. An arch of a peculiar kind, however, began to be used some time ere the close of the style, which is not to be found in any other; it is described from four centres, two of which are on the springing line, and describe arcs of very small radii, and the other two at some distance below it. Such arches have a very depressed appearance, the rise above the springing line being inconsiderable when compared with that of the two-centred arches; the rise, however, varies to some extent in different examples. This arch is termed the Tudor arch, and was introduced about the middle of the fifteenth century. Ogee arches are of constant and universal occurrence, and foiled arches are very frequent in decorative work.

Arches are very frequently moulded, but in the plainer examples are only recessed and chamfered. The mouldings consist of much the same members as before, but they are of a less prominent character; the hollows are more shallow, and the projecting mouldings less prominent: the contour is of an undulating appearance, the junctions of the different members being but indistinctly marked. A large but shallow cavetto is of frequent occurrence, and is sometimes ornamented by the insertion of a square flower at intervals. The soffits of some arches are ornamented with panelled work.

The *shafts of piers* are sometimes simple octagons in plain, as in the preceding styles, but are not of such frequent occurrence as before, and sometimes differ in contour, having the sides of the octagon slightly concave; they may be distinguished from earlier examples by their capitals and bases. Clustered piers are very frequent, and their general

GOTHIC ARCHITECTURE.—PERPENDICULAR EXAMPLES.

plan is that of a square set diagonally, but the breadth of the pier between the aisles is frequently greater than the depth between the arches. They are composed of four or more slender shafts, engaged, with hollows, ogees, and fillets intervening. A very common arrangement presents a section of the form of a square, having its angles cut in a broad but shallow concavity, and the four sides or flat faces ornamented with a half or three-quarter round shaft attached, and projecting beyond the face. This shaft does not occupy the entire face, but leaves a flat surface on either side ; it is finished with distinct cap and base, but the surface and concave angles of the parallelogram are frequently continued round the arch without interruption. When piers are placed diagonally, the angles are often ornamented with slender pillars with caps and bases, while the intermediate spaces, which constitute the main body of the pier, are moulded and continued uninterruptedly to the apex of the arch. The sub-shafts are sometimes the only ones furnished with capitals, the face-shafts being carried up to the whole height of the building to the wall-plate without caps, but sometimes the shaft is continued above the capital. Three or more shafts clustered together are not unfrequently found at the angles in the place of the single one above alluded to.

The plan of such small shafts is commonly circular and plain, but they are sometimes filleted, and occasionally polygonal, with concave sides. The piers are not unfrequently composed of mouldings only, and these carried up continuously, without capital or any other projection, to the apex of the arch; and where arches are neither moulded or recessed, the sides of the pier and soffits of the arch are usually enriched with panel-work.

Capitals are either circular or octagonal, but the necking is usually of the former, and the upper members of the abacus almost invariably of the latter form, whether the capital and its mouldings be circular or octagonal. The vases are mostly plain, but sometimes enriched with foliage, which is of a more conventional form than in the previous style. The mouldings consist of ogees, rounds, beads, and hollows, the second and fourth of which are frequently combined without forming edges, and have a bead underneath. The top of the abacus is often splayed, and sometimes ornamented with a crest of small battlements : the sides are occasionally hollowed out. In clustered piers, the capital is sometimes carried all round without interruption, and the vase covered with foliage, but more frequently the capital of each shaft forms a separate and distinct member.

The *base* mouldings are usually set upon a lofty polygonal plinth, which is sometimes double ; the lower one projecting, and the projection moulded with a hollow or reversed ogee. The upper members of the base-mouldings follow the form of the shaft, but the lower ones are often polygonal, like the plinth which they overhang. In clustered piers, the bases are mostly treated separately, as is the case with the capitals, but sometimes the mouldings are continued all round, as are the plinths almost invariably.

The earlier *doorways* of this style have two-centered pointed arches, but the most common and characteristic form is the four-centered : for smaller doorways, the ogee is sometimes used. The two centered arch is often surmounted by an ogee-shaped hood-mould, enriched with crockets and finials, but some of them, and nearly all the four-centered, are enclosed within a square head formed by the outer mouldings, with hood-mould of the same form, the spandrels being filled with quatrefoils, flambeaux, roses, shields, &c. Sometimes, however, the hood-mould follows the form of the arch, even in the four-centered examples. The hood-mouldings are often returned horizontally, and when not so, terminate at the springing of the arch, on heads, shields, &c., or have the mouldings twisted round in the form of a lozenge, or circle, with some little ornament in the centre. The hood is usually placed immediately above the apex of the arch, but in some specimens it is considerably elevated, the intermediate space above the spandrels being filled with quatrefoils, or other panelled work ; the upper members of the hood sometimes coincide with the lower portion of a string course. Double doorways are of very rare occurrence.

The jambs are not unfrequently ornamented with shafts with caps and bases, but they are mostly small, and often not well defined, except by the capitals and bases ; in many instances all the mouldings are continued round the arch, without apparent impost. Large hollows are very frequent amongst the mouldings of doorways, and are occasionally filled with foliage or other decoration.

The doors themselves are often covered with panel-work of a rich description, and sometimes with tracery in the head. The smaller doors are often weather-boarded, without any ornament; the iron scroll-work being rarely employed at this period.

The *windows* of this style are easily distinguished from all others, by the vertical disposition of the tracery in the heads ; the mullions of the lights, instead of branching out at the springing into flowing lines, are continued vertically to the intrados, and secondary mouldings are continued in the same direction from the centre of each light, and converge once or twice ere they reach the arch. The principal and subordinate lights are all arched and foliated, the principal being frequently divided horizontally by transoms, which are a further characteristic of the style. Windows which consist of several lights are divided into two or more compartments, containing each two or more lights, and these are frequently arched over in the heads. The transoms are often finished at top with a small ornamental battlement ; and the mullions present a concave outline. The heads of windows offer a great variety of form, some being two-centre-pointed of various degrees of acuteness, others four-centred, others again segmental, triangular, and square-headed. Windows of the last class are very common, having perpendicular tracery in the heads ; they are frequent in clere-stories, where we also find circles and quatrefoils used for the same purpose.

The plainer *buttresses*, are similar to those of the preceding styles, consisting of one or more projections, with plain faces and set-offs, frequently terminating in a slope under the parapet, but sometimes finished with a crocketed pinnacle. In the richer examples the faces are covered with panel-work, and are finished with square pinnacles, sometimes set diagonally and terminated with a crocketed spire, or finished with an animal or such like ornament.

The *parapets* are often embattled, and have usually the coping carried all round the embrasures ; the plain surface down as far as the cornice, is not unfrequently panelled or pierced in quatrefoils, foiled-arches, &c. The top of the parapet is as often horizontal, and either plain or covered with sunk or pierced ornaments, consisting of trefoils and other polyfoils inserted within square, circular, or triangular compartments. The cornice consists of a few mouldings, the most prominent of which is frequently a large shallow cavetto, which is often enriched with flowers placed at intervals.

The early *roofs* of this style are of a moderate height, but later examples are of very low pitch. The vaulting is still more complicated than in the preceding style ; the number of ribs is increased, and they are frequently disposed so as to form geometrical patterns, as in the choir of Oxford cathedral, and in many other examples. A kind of vaulting peculiar to the later period of this style, is termed fan-tracery vaulting. In it several ribs diverge at equal angles, and in all directions, from one bearing-post, and spread on the roof in the form of a circle, the entire figure having somewhat the appearance of a semi-cone: all the ribs preserve the same curvature. These spring from either side of the roof, and often meet in the centre, or the space left between, as also the spandrels are filled with ribs, forming geometrical tracery; when, however, a large space intervenes, it is frequently occupied with pendent figures of the same description, forming a kind of inverted cones suspended from the roof, the surface of which, like those at the sides, is covered with divergent ribs, and richly panelled. Roofs of this kind are more frequent in small structures, such as chantries and the like, but we have magnificent specimens of a grander description in Henry VII.'s chapel, Westminster, St. George's, Windsor, Peterborough cathedral, and some few other churches.

The wooden roofs of this period are more numerous, and more readily defined, than those of any previous era. Their increased number arises probably from a practice common at the time, of substituting more enriched roofs in the place of plainer examples of earlier date, a practice which is often evinced by the form of a more highly-pitched roof than that existing, being still visible on the tower, against which it abutted. The majority of examples of this style are of a very low pitch, so much so as sometimes to be entirely hid on the exterior of the building by the parapet; but roofs of a lofty pitch are by no means uncommon.

In the loftier examples tie beams are not used, but the principals are usually connected by a collar beam immediately below the ridge, or by a block-collar completely filling up the angle of the ridge; where the collars are in a lower position, a king-post is sometimes carried from them to the ridge-beam. The collars are often ornamented with mouldings or small battlements, which have a very good effect. A simple form of roof consists of principals of stout planking resting on corbels, and cut in the form of an arch, with block collars underneath the ridge, as at Stourbridge church. Sometimes arched planking of this kind is supported on projecting hammer-beams, with curved braces underneath resting on corbels, which method gives the outline of the entire roof the form of a trefoiled arch either round or pointed. A similar form is often constructed of the usual timbers, and springs from the level of the wall-plate, without curved braces, as at Athelhampton Hall, Dorset.

Tie-beams are sometimes used in roofs of this kind, supported by braces resting against wall-pieces, and these again, on corbels or shafts, the spandrels being often filled with tracery. The principal rafters above the tie-beam frequently consist of planking of arched outline, pierced with quatrefoils, &c., as at Malvern Abbey. Some roofs again are constructed without principals, the common rafters being tied at the top with a collar-beam resting upon timbers disposed so as to form a circular arch, the lower extremities of which rest upon hammer-beams.

The hammer-beam is peculiar to this style, and is found employed to a very great extent in the large hall-roofs of the period. A very common form for these roofs consists of two principal rafters tied at the upper part with a collar-beam, under the extremities of which are two queen-posts resting on hammer-beams, and these again on curved braces. The latter are fixed to wall-pieces, which stand on corbels at some distance down the walls. Arched braces are frequently carried from the end of the hammer-beam to the centre of the collar, which is sometimes suspended by a king-post. Some examples have two sets of hammer-beams, one above the other, as at Hampton Court, where the roof is a sort of curb; it is very strong, but composed of many timbers, which are somewhat complicated in their disposition. We must not pass over unnoticed, the roof of Westminster Hall, which is one of the most magnificent in existence. Its principal feature is an arched rib composed of three thicknesses of timber, which completely spans the building, and is carried down below the top of the walls to the corbels. Immediately above the apex of this arch is a collar-beam, having in the centre a king-post reaching to the ridge, and at the sides two queen-posts with a straining piece. The hammer-beams are carried out beyond the line of the arch, and are supported at the extremities on curved braces resting on the corbels, a similar curve being also carried upwards to touch the large arch so as to form by their combined outline a trefoiled arch. Above the ends of the hammer-beams rises an upright or queen-post, which is carried up to the end of the collar, and supports the principal rafters at about midway. This, as also most roofs of the kind, is moulded and enriched with perforated panel-work, and other ornaments; the hammer-beams are often carved into representations of angels bearing shields, musical instruments, &c.

The obtuse low-pitched roofs peculiar to this period, are often framed with tie-beams and king-posts, with curved bracing-ribs underneath, resting against an upright wall-piece supported on a corbel; the braces being mostly curved in the form of an obtuse arch. The spandrels are often filled with open tracery, as are also the spaces above the tie-beams. Sometimes roofs of an exceedingly low pitch, or even perfectly flat, are formed without any truss whatever, consisting only of principal and common rafters, and purlins, without either tie or collar beams. In such cases the principals are often supported at the end by upright wall-pieces resting upon corbels at a considerable distance below the wall-plates, and from the foot of the wall-pieces curved braces are carried up to the centre of the principals. These braces are often solid, constructed out of a piece of stout planking and entirely filling up the spandrels.

The sloping bays of low-pitched roofs are often divided into square compartments by purlins and common rafters, the former being increased in number, and the latter placed at a greater distance apart than usual. The intersections of the timbers are almost always covered with ornamental bosses, and the timbers themselves richly moulded. Sometimes these compartments are subdivided by other secondary mouldings, with bosses likewise at the intersections. The larger beams in almost all these examples are moulded, and the horizontal timbers, such as wall-plates, ties, and collars, are often enriched with small battlements, or have the mouldings ornamented with some decoration peculiar to the period.

The *towers* are frequently constructed on a very grand scale, and are very often devoid of spires, being occasionally surmounted by octagonal lanterns, as at Boston, Lincolnshire, where the tower is of great height and magnificence. Another very beautiful and lofty example occurs at Dundry, near Bristol, but in this case it is finished at the top by four little square turrets, placed one at each angle; the turrets, as also the lofty battlemented parapet, being pierced in panel-work, a practice very common in parapets of this period. At Magdalen College, Oxford, is another very beautiful example, the corners of which are finished above the battlements with octagonal turrets or pinnacles, carried up from the ground in the shape of buttresses; another buttress is carried up the centre of each face, and is finished above the parapet with a pinnacle of smaller dimensions. Another ornament in this example is of common occurrence, and consists of bands of sunk quatrefoils or other ornaments. In smaller churches the tower is often finished with a plain parapet or simple battlement, but it is a very prevalent practice of the period to carry up a polygonal stair-turret at one angle, which rises some feet above the general level of the tower, and forms a very picturesque object. The windows and general arrangement of the towers are much the same as in the last style, differing only in matter of detail; square-headed windows are of frequent occurrence, and often appear in the belfries, especially in that class of towers just alluded to.

Spires are not so frequent as in other styles, and are never what are termed broach-spires, the tower being invariably crowned by a parapet. Where spires occur, they are of the same form and general description as before. They are often supported at their angles by flying-buttresses, springing from the corners of the tower. The angles are also frequently crocketed.

The *mouldings* of this period are in general flatter, or of less projection, and therefore less effectiveness, than those of previous styles. There is also a greater prevalence of angles or corners. Round and hollow mouldings are often connected without any apparent line of separation; but members of a different description are separated by either quirks or fillets. A large shallow concave moulding is very prevalent, and forms a characteristic mark of the style. It appears very often in archivolts and cornices, and is often enriched by the insertion of flowers, leaves, and other ornaments. Ogees are perhaps more frequently used than any other kind of mouldings, but rounds, beads, and cavettos are of very common occurrence. An arrangement of ogees in close contact, with the convex sides next each other, is of constant occurrence, and is characteristic of the style. A moulding of an undulating contour, being convex in the middle, and concave on either side, is common in abaci and dripstones, as is also the reverse of this, the hollow being in the middle, and the convexity on either side. Fillets are used, but are not often applied to larger mouldings. In general, it may be observed, that in all cases the mouldings of this style are more flat, the hollows and projections approaching more nearly to a straight line.

The *ornaments* used, consist mainly of detached flowers or leaves usually of a square outline, of running patterns and bunches of foliage, of grotesque heads and figures of animals; of shields, and various kinds of heraldic devices. The rose, the badge of the houses of York and Lancaster, is a characteristic ornament, as is also a lozenge-shaped leaf, supposed to represent the strawberry-leaf, and generally known under the name of the Tudor flower. The foliage is very elaborately and delicately carved, but does not exhibit the same amount of freedom of design or execution, which is manifest in the earlier styles.

The *walls* are often covered internally, and sometimes externally, with panel-work tracery, which is a characteristic feature of the style.

The *niches* of the period are somewhat similar to those of the Decorated style, but sometimes consist of mere recessed panels. They are usually, however, either octagonal or sexagonal in plan, with vaulted covering. Of canopies, some are flat, and others projecting; the latter being either semi-circular, or polygonal in plan, and either finished horizontally, or capped with a small spire or bell-shaped roof. The angles are occupied with buttresses and pinnacles, the latter being sometimes suspended from the overhanging covering, which is enriched with crockets and finials, and other ornaments in profusion.

With the commencement of the Reformation, the practice of Gothic architecture may almost be said to have ceased, as did all ecclesiastical building to a very great extent. The sacrilegious plunder of Henry VIII., his destruction of the monasteries and religious houses, and the wholesale spoliation and destruction of the works of antiquity which was carried on under his orders, tended to discourage persons from the erection of churches or religious edifices, and the art was soon entirely lost. The introduction of the Italian style assisted greatly in the overthrow of a mode of building which had been in vogue some three or four hundred years. Pure Gothic architecture may be said to have ceased about the middle of the sixteenth century, but it still retained some influence for a few years later. The method of building adopted during this interval, has been fitly denominated the *Debased.*

The characteristics of this style, if it may be so termed, may be briefly enumerated as follows:—The windows are square-headed, divided into bays by perpendicular mullions, the heads of each bay being frequently left square, but sometimes obtusely-arched, and occasionally foiled. The mullions are plain and unfinished, without mouldings of any kind, and all the workmanship is of a very inferior kind. Hood-moulds are often, but not always, used.

The *doorways* are either obtusely-pointed, or round-headed with prominent key-stones. In late specimens, many of the features of Italian architecture are introduced in details and construction. Examples of the Debased style exhibit a poverty of design and clumsiness of execution, in comparison with those of previous styles, which will at once decide their date and position.

In the above sketch, we have made no allusion to Continental Gothic; our remarks and descriptions having been entirely confined to the style as developed in our own country; nor have we space here to treat of the former separately. We can only refer to those writers who have treated this subject specifically, amongst whom the following names stand pre-eminent. Whewell's Architectural Notes on German Churches; Willis on the Architecture of the Middle Ages in Italy; and Moller's Memorials of German Gothic Architecture.

From this article, we refer to the words Church, Cathedral, Ecclesiastical Architecture, and to various articles of the same nature.

GOUFING FOUNDATIONS, a term used in Scotland, and particularly at Glasgow, for the under-pinning of a wall when found insecure.

GOUGE, a concave and convex chisel, the section of which is the frustum of the sector of a circle, serving to cut a concave excavation in wood or stone. The basil is made from either the concave or convex side.

GOWT, or Go-out, in engineering, a sluice used in embankments against the sea, for letting out the land-waters when the tide is out, and preventing the ingress of salt water.

GRACES, Gratiæ, or Charities, in the heathen mythology, were fabulous deities, and represented as three young and handsome sisters, attendant on Venus.

Their names are Aglaïa or Ægle, Thalia, and Euphrosyne; *i. e. shining*, *flourishing*, and *gay*. They were supposed by some to be the daughters of Jupiter and Eurynome, the daughter of Oceanus, and by others to be the daughters of Bacchus and Venus. Vossius *de Idol.* lib. xiii. cap. 15. Homer (*Iliad*, lib. xiv.,) changes the name of one of the Graces, and calls her Pasithea; and he is followed by Statius. (*Theb.* lib. ii.) Some will have the Graces to have been four, and make them the same with the *Horæ*, *Hours*, or rather with the four seasons of the year.

The Lacedæmonians admitted only two of them, whom they worshipped under the names of Klyta, Kleta, or Clita, and Phænne. The Athenians allowed the same number, but denominated them Auxo and Hegemone.

A marble in the king of Prussia's cabinet represents the three Graces in the usual manner, with a fourth seated, and covered with a large veil, with the words underneath, AD SORORES IIII. Yet Mons. Beger will by no means allow the Graces to have been four: the company there present, he understands to be the three Graces, and Venus, who was their sister, as being daughter of Jupiter and Dione.

They are always supposed to have hold of each other's hands, and never parted. Thus Horace, (lib. iii. od. 21.) describes them:

"Segnesque nodum solvere gratiæ."

They were also represented in the attitude of persons dancing; whence Horace says (lib. i. od. 4):

"Alterno terram quatiunt pede."

They were commonly thought to be young virgins. In the earlier ages they were represented only by mere stones, that were not cut; but they were then represented under human figures, at first clad in gauze. The custom of giving them drapery was afterwards laid aside; and they were painted naked, to show that the Graces borrow nothing from art, and that they have no other beauties than what are natural.

Yet, in the first ages, they were not represented naked, as appears from Pausanias, lib. vi. and ix., who describes their temple and statues. They were of wood, all but their head, feet, and hands, which were white marble. Their robes or gowns were gilt; one of them held in her hand a rose, another a die, and the third a sprig of myrtle.

They had temples, as we learn from Pausanias, at Elis, Delphos, Perga, Perinthus, Byzantium, and in several other places of Greece and Thrace. The temples consecrated to Cupid were likewise consecrated to the Graces: and it was also customary to give them a place in those of Mercury, in order to teach men, that even the god of eloquence needed their assistance. Indeed, some authors reckoned the goddess of Persuasion in the number of the Graces, thus intimating, that the great secret of persuasion is to please. The Muses and the Graces had commonly but one temple; and Pindar invokes the Graces almost as often as he does the Muses. Festivals were appropriated to their honour through the whole course of the year, but the spring was chiefly consecrated to them as well as to Venus. Greece abounded with monuments sacred to these goddesses; and their figures were to be seen in most cities, done by the greatest masters. They were also represented on many medals. The favours which these goddesses were thought to dispense to mankind, were not only a good grace, gaiety, and equality of temper, but also liberality, eloquence, and wisdom, as Pindar informs us; but the most noble of all the prerogatives of the Graces was, that they presided over all kindnesses and gratitude; insomuch that, in almost all languages, their names are used to express both gratitude and favours.

GRADATION, (from the Latin, *gradus*, a degree,) in architecture, an artful disposition of parts, rising as it were by steps or degrees, after the manner of an amphitheatre; so that those placed before do not obstruct the view from those behind.

The painters also use the word *gradation* for an insensible change of colour by the diminution of the tints and shades.

GRADATION, in painting, relates both to chiaro-oscuro and to colour: that is, all the different degrees in which light and dark, and colour, may be modified, are comprehended in it.

An object receding from the light, and gradually losing it, becomes at its farthest extremity obscurely defined. A coloured body, pure or bright in tint, under the same circumstances, gradually diminishes in clearness of hue throughout its receding parts, and becomes dull and dark. By fixing the scale of gradation in both these particulars, effects of great force or great simplicity may be produced. The scale of descent being made rapid, great force will ensue, from the strong oppositions it promotes; and the reverse will take place when the degrees of descent are prolonged, and less contrast thereby effected. The nature of the subject, and the situation of the figures with regard to light, must be the artist's guide in this matter.

The gradation of colour includes not only the different degrees of purity, or brilliancy of the same colour, but also the approximations of each colour to its neighbour, necessary to produce harmony; and also the art of gradually losing the local colour in obscurity, and yet maintaining its character in the object; which is extremely difficult, and of great importance, in the art of painting.

GRADETTO, GRADETTI, or ANNULI. *See* ANNULETS.

GRADIENT, in engineering, a term indicative of the proportionate ascent or descent of the several planes upon a railway, thus: an inclined plane four miles long, with a total fall of 36 feet, is described as having a fall of 1 in 586⅔, or 9 feet per mile. Mr. Macneill suggested the word CLIVITY, as a more appropriate term than gradient; and its compounds, *acclivity* and *declivity*, are very comprehensive and significant.

GRAFTING TOOL, in engineering, a kind of spade, used by *navigators* in railway and canal works; it is made very strong and curving; often called only a *tool*.

GRAIN, the plates of wood or stone, in the direction of which it may be split into various thicknesses.

GRAIN, in mining, is applied by quarry-men and masons to the minute figures in most blocks of stone, by which they are disposed to split more easily in some certain direction, than in any other, as wood is disposed to split in the direction of its grain. *Beat*, *sheet*, *lamella*, and *stratula*, are other terms of almost similar import. Experienced masons can generally discover the grain of the most homogeneous or perfect freestone blocks, or such as will cut with equal ease in any direction. This they often do, by observing the directions of the very minute plates of mica, or silver, as they call it, which are frequently found arranged in the stone, in the direction of the grain, or beat of the stone; which, it must be observed, is not always that of the beds or stratification, many rocks having stratula which cross their beds obliquely, often at an angle of from 30 to 45 degrees with the bed or plane of the stratum; and such stratula not uncommonly dispose the stone to split into flags, or paviers, or even tile-stones, or slates for houses, and into the most thin and perfect lamina. Sometimes these oblique stratula cross stone beds of very great thickness, and have been frequently mistaken, by inattentive observers, for the stratification itself.

GRANARY, a building contrived for laying up and storing corn, in order to preserve it for a length of time.

The construction of this class of buildings has not, we believe, received that attention which the importance of it deserves, and we consider therefore that some account of the proper mode of designing and erecting granaries on scientific principles will be both interesting and useful.

It must be evident to all, that, owing to the uncertainty of harvests, the produce of a year may be either abundance or dearth, the frequent recurrence of the latter, in the earlier ages, obliged most of the ancient nations to seek means of preserving the superabundant produce of plentiful years, in order to be prepared against the privations of less fortunate ones. This necessity was more imperative, when the means of conveyance by land and water were less perfect than at present. In modern times a higher state of civilization has taught mankind to feel the advantages of a free circulation of produce, famine is not now therefore so fearful an evil as formerly. The improvements in the mode of culture have also much increased the produce of the earth; but the probabilities of famine, though decreased, still remain to a certain extent, and the construction of proper repositories for storing up grain must be always important, as a means of lessening its evils.

In some countries public granaries are established upon a very large scale, and in them is preserved the grain collected from the whole of the surrounding districts. The French have given great attention to the subject, and the following plan for a public granary, by an eminent French engineer, is well worth imitation. M. Bruyere observes, that in the calculations necessary to fix the dimensions of a granary destined to contain a determinate quantity of grain, the following considerations must be attended to.

A granary of reserve, as it is termed in France, contains wheat of different ages, and the duration of their preservation is three years, the grain being supplied by thirds every year. The disposition to ferment being caused by the degree of moisture, and by the quantity, and the oldest corn being the dryest, it follows that the mean depth of the heap should vary with the age of the corn. From these data, and by the help of experience, the depths of the heaps of corn may be fixed as follows:—

Corn of one year	19½	inches.
" " two years	24	"
" " three years	27	"

A distance of about a yard should be left between the foot of the heaps and the wall, and an empty space of thirteen to sixteen feet between the heaps, for the operation of turning. To these spaces must be added also those occupied by the staircases, rollers, trap-doors, working-rooms, &c., and the whole must be deducted from the superficial content of each floor. The remainder, multiplied by the number of stages, and the mean height of the heaps, will give the solid content of wheat that the granary can contain.

The situation of a public granary is important; if possible it should be placed near a canal or navigable river, in order to receive or send out the grain by water, or by any other easy method of transport, as the expense is thereby much diminished.

For the same reason, granaries should be near a sufficient quantity of mills, whose motive power can, in certain cases, be applied to the different machines used in the manipulation of the corn. These mills should not, however, be placed in the same building with the granaries, or be too near to them on account of the danger of fire, and because the two operations are hurtful to each other; the dust of the wheat injuring the flour, and the motion of the water rendering the grain too moist.

The aspect of granaries should be south, as the change of temperature will then be sufficient to keep a current of air between the opposite openings, and it is most important to use the driest winds for ventilating and drying the grain.

In order to diminish the extent of granaries, it is necessary to add to their height, by multiplying the number of floors; and, as it is easy to raise the grain by the help of machines, we thus gain the advantage of being able to make it descend from sieve to sieve, which cleans and sorts them in the least expensive manner.

The lowest floor, should be sufficiently elevated above the earth to prevent damp, and to facilitate carting. Experience has proved that a height of 8 feet is sufficient for the curve that is described by the wheat when thrown up by a shovel. Each floor should therefore have a height of 10 feet.

The walls of the granary should be thick, not only on account of strength, but also to keep out damp and heat. The windows should descend to the level of the floor, so that the air may circulate through the lowest part, and strike the foot of the heap of grain. The entrance of the air is facilitated by widening the openings from the interior to the exterior. They should be grated with iron wire to prevent the entrance of birds, and furnished with shutters which, when open, fall back on the thickness of the wall.

When the granary is of considerable size, it appears natural to place the entrance in the middle of its length. This entrance should be large enough to permit vehicles to cross the building, so as to load or unload under cover. To prevent the division of the lowest floor, this passage is sometimes made by a projecting porch, under which the vehicles can be ranged, though in a less convenient manner. The staircases should be placed, near the passage, for the carts, but, to prevent interruption of the heaps of corn, some place them in a projection opposite the porch, or in one of the angles of the building.

It is desirable that granaries should not be of too great an extent, in order that the grain may more readily dry by the currents of air. On the other hand, as it is always necessary to reserve the passages along the walls, the size of the interior should not be less than 40 feet, or exceed 65 feet. In all cases, they are divided by pillars of stone, wood, or cast iron. (*Bruyère Etudes Relatives à l'árt des Constructions.*)

The following may be taken as a guide for the erection of a granary in this country. The building should be rectangular in plan, the height about twice the distance between the opposite walls, that is, 20 feet high by 10 feet in width on each side, and provided with numerous air-holes, declining outwards, to prevent the entrance of rain or snow. From each air-hole to a corresponding one on the opposite side, should be fixed an inverted angular spout or gutter, to permit the air to pass through unimpeded by the corn lying about; as many of these gutters should be fixed, as there are holes to receive the ends after crossing the building; and the extremities of the holes should be covered with wire gauze, to defend them from vermin.

The first floor of the granary should be divided into a series of hoppers, these hoppers to empty themselves into one large hopper underneath, provided with a sliding door to regulate the passage of the grain into a sack or other receptacle. At the top of the building a loft should be erected, to which the corn may be first hoisted by a tackle or crane, and be discharged over a cross-bar into the body of the building, which operation may be continued until it is filled to the top. Upon drawing off any corn at the bottom, the whole of it will be put in motion, and the airing of every part promoted; the process of airing should, however, be continually going forward through the numerous passages under the inverted gutters, the angles of which do not fill up by the lateral pressure of the grain.

GRAND STAIRCASE, the principal staircase of a large edifice, for the use of the family and visitors. *See Staircase.*

GRANGE, the ancient name of a barn; sometimes applied to the farmhouse itself. The term grange was also used in former times to designate the farming establishments attached to religious institutions.

GRANITE, an aggregate rock, the essential ingredients of which are feldspar, quartz, and mica, being the same as those of gneiss, from which granite differs chiefly in the arrangement of the three component parts. In granite these are mingled without order or regularity, which produces a granular structure, while that of gneiss is generally slaty.

"GRANITE is one of the most abundant rocks at or near the surface of the earth, it is likewise considered as the foundation rock of the globe, or that upon which all secondary rocks repose. In alpine situations it presents the appearance of having broken through the more superficial strata of the earth; the beds of other rocks in the vicinity rising towards it, at increasing angles of elevation as they approach it. It forms some of the most lofty of the mountain-chains of the eastern continent; and the central parts of the principal mountain-ranges of Scandinavia, the Alps, the Pyrenees, and the Carpathian mountains, are of this rock. No organic fossil remains have ever been found in granite, although it is sometimes found overlying strata containing such remains." (*Imperial Dictionary.*)

Of all materials for building, granite is the most durable, as shown by many of the ancient Egyptian monuments. By the Egyptians and other very ancient nations it was more particularly applied, together with sienite, for the purposes of architecture and statuary, and many very interesting monuments of their skill and patience are still existing in the collections of antiquities. As instances of the extreme durability of granite, we may mention, that the obelisk in the place of Saint Jean de Lateran at Rome, which was quarried at Syene, under the reign of Zetus, king of Thebes, 1300 years before the Christian era; and the one in the place of Saint Pierre, also at Rome, consecrated to the sun by a son of Sesostris, have resisted the weather for full 3000 years.

The use of granite for architectural and economical purposes is perhaps nowhere more amply displayed than at St. Petersburg, where not only the imperial and other palaces, but even ordinary dwelling-houses, have their lower parts lined with slabs of granite. The left bank of the great Neva, from the Foundry to the Gulf of Cronstadt, and both banks of the Fontanka and of the Catharine canal, are lined by high walls constructed of such slabs of granite; as are many bridges over the Neva, balustrades, &c. The pillars, stairs, balconies, &c. in the palace of Cronstadt, are almost all of the finest kinds of granite. Those employed for ornamental architecture are cut and polished by lapidaries; but those intended for less delicate purposes, such as common slabs, steps, cylinders, troughs, &c. are worked by peasants, particularly by those of Olonesk. The government-towns, however, Moscow not excepted, are too distant from the chief granite mountains, to be enabled to make frequent use of that rock for the above purposes.

Mr. Brand has divided the different granites used in the arts after their predominant colours; the following are the principal varieties, in which, however, the black-and-white kind is not included, one of its ingredients being hornblende, which assigns it a place among the sienites.

GRANITE, *Gray, of Chessi*, in the department of the Rhine, consists of white quartz and black mica, with large crystals of rose-coloured feldspar. The columns of the Eglise d'Enée (ancient temple of Augustus) at Lyons, are of this kind of granite, which has also been worked by the Romans.

GRANITE, *Gray, of Thain*, consists of gray quartz, black mica, and white feldspar crystals, which are sometimes from two to three inches long. The quarries of this granite are on the road from Lyons to Valence, on the right bank of the Rhône. It is very well adapted for the construction of large monuments. The granite of St. Peray, not far from Thain, is exactly like this, except that its feldspar crystals are of a rose-colour.

GRANITE, *Gray, of Lavezzi*, a small island near Bonifacio, south of Corsica, in the straits which separate that island from Sardinia, is composed chiefly of small irregular crystals of feldspar, mixed with a little black mica, besides which it contains also feldspar crystals, of a milk-white colour. In the quarry of that island a large unfinished column is to be seen, which had been relinquished by the Roman workmen.

GRANITE, *Gray, of Elba.*—Its grain is pretty uniform; its colour sometimes approaches to light violet. There are four columns of this variety to be seen in the Musée Napoleon: they were taken out of the church which contained the tomb of Charlemagne, at Aix-la-Chapelle.

They gray granites are much more common than the green or greenish, of which the following deserve to be mentioned.

GRANITE, *Antique green.*—Its predominant ingredient is white quartz, with here and there some light green feldspar. There is a column of it in the Villa Pamfili, near Rome.

GRANITE, *fine-grained antique.*—(Basalte verd oriental.) The component parts of this sort are so minute and intimately blended, that they can scarcely be distinguished by the naked eye. Its colour approaches to deep olive. It is very hard and takes a fine polish. The Egyptians have much employed it for the construction of monuments; and several statues of it may be seen in the Capitol and the Villa Albani. There is another variety with white spots, known at Rome under the name of *Basalto Orientale pidochioso;* but it is very rare, for there are but two columns of it in existence, namely, in the church of St. Pudentiana at Rome. Some varieties bearing that name are silenite.

GRANITE *of St. Christophe:* composed of violet quartz, white feldspar, and green mica. This magnificent rock is found at Oisans, in the department of the Isère.

GRANITE, *Corsican, orbicular.*—This beautiful rock (which probably belongs to the sienite formation) was discovered by M. Barral, in the island from which it derives its name. Its composition is very extraordinary; it has a basis of ordinary gray granite, which, however, in most parts exhibits a considerable portion of hornblende. But what more particularly characterizes it, is a number of balls, of from one to two inches in diameter, each composed of several concentric and perfectly parallel layers, the outermost of which, generally white, opaque, and two or three lines thick, is composed of quartz and feldspar, blended in various proportions, and exhibiting a radiated appearance, rather converging towards the centre of the ball. The second layer, which is of a greenish black colour, and about one line thick, is composed of fine laminar hornblende; and this is succeeded by a white and usually translucid quartz layer, of about four or five lines in thickness, inclusive of two or three very thin layers of hornblende, that are commonly seen within the substance of this third principal layer. Each of these layers is generally of equal thickness in the whole of its circumference. These three parts may be considered as the coating: the interior of each ball is less defined than the surrounding layers, and consists of a blackish and a whitish substance, the former surrounded by, and passing into the latter, the centre of which is usually a dark gray spot.

The quarry of this rock is unknown, a single block only having been found in the gulf of Valinco, in Corsica: its weight was about 80lb., but it was soon broken into small fragments, which are now distributed among collectors. There is a beautiful vase of it, one foot six inches high, in the cabinet of M. Dedrée. The granite of Corsica is figured by M. Faujas de St. Fond, in his *Essai de Géologie*, and in Mr. Sowerby's *Exotic Mineralogy.*

Among the red granites, we have what is called *red oriental granite*, which usually contains hornblende, often in large separate patches.

Granite, *Red, of Ingria.*—"This granite," says M. Patrin, "is distinguished from others in this, that the feldspar, instead of being in grains, or parallelopiped crystals, as in most other granites, constantly appears in the shape of round or oval pieces, of from half an inch to two inches in diameter. This granite takes a very fine polish, and in this state exhibits the feldspar in the shape of white, round, or oval (*chatoyant*) spots, in a reddish ground. The rock which serves as a pedestal of the equestrian statue of Peter the Great, at St. Petersburg, is of this granite: the block was originally 32 feet long, 21 feet thick, and 17 feet wide; but, in order to give it its present shape, imitative of a picturesque natural rock, it has been much diminished in size. This block was disengaged from a swamp, about forty versts from Petersburg: its weight was calculated to be above three millions of pounds." We have seen several fragments that were detached from the very block forming the pedestal of the statue; but in none of them did we observe the form ascribed by Patrin to the feldspar.

The public summer promenade-garden at Petersburg is decorated with a superb colonnade of this granite: the columns, which are sixty in number, are of the Tuscan order; their shafts, made of one piece, are about 20 feet high, and three feet in diameter. The island, called Kotlin-Ostrow, on which is the fortress of Cronstadt, is covered with blocks of this granite, the feldspar of which is sometimes of the kind called Labrador-stone.

Granite, *Red, of the Vosges Mountains.*—This granite is composed of large laminæ of rose-coloured feldspar, gray grains of quartz, and small scales of mica. It has so strong a resemblance to the Egyptian red granite, that it is difficult to distinguish them. Its quarries are on the heights of Montaujeu, near the Papean mountains, in the Vosges.

Granite, *Violet, of Elba.*—The feldspar of this variety is in large violet crystals. The pedestal of the equestrian statue, in the Piazza della Santissima Annonziata at Florence, is made of it, as are also the *sodes* in the chapel of St. Laurence in the same town.

Granite, *Rose-coloured of Beveno.*—This beautiful granite consists of flesh-coloured feldspar, white quartz, and some grains of black mica. Considerable quarries of it are found on the borders of the Lago Maggiore, which are worked without intermission, for supplying Milan, and the whole of the neighbouring country, with this granite. It takes a very fine polish: here and there it exhibits ribands, or zones, of a gray colour, which are composed of the same ingredients as the rest of the mass, but reduced into very minute particles. Many columns, porticos, &c. are seen of it at Milan.

The name of *Graphic granite* is given to those kinds in which the feldspar forms large concretions, intermixed with gray quartz crystals, exhibiting, when cut transversely, angular figures, mostly shaped like a 7; while others are less regular, and bear a distant resemblance to rude alphabetical writing. They are not considered to be genuine granite by some mineralogists.

Granite, *Graphic, of Portsoy.*—The feldspar is of various tints of pale flesh-red; the quartz dark, but transparent, with now and then some small particles of mica. This rock is minutely described by Dr. Hutton.

Granite, *Graphic, of Siberia.*—Its feldspar is of a yellowish white, or reddish colour; the quartz, exhibiting figures similar to those of the quartz in the preceding sort, is of the variety called *smoky topaz.* Mica occurs in it in small nests, and black shorl in acicular crystals.

Granite, *Graphic, of Autun.*—Of a pale rose-colour; quartz crystals gray, very numerous; found in the neighbourhood of Autun, department of Saône and Loire, particularly at Marmagne. This, in Mr. Brand's opinion, is the most beautiful of all granites. Another variety of this stone is found at the same place: its feldspar is white; the quartz gray, in small crystals; it is susceptible of a very fine polish.

Granite, *Graphic, of Corsica.*—Likewise of a rose-colour; but generally paler than that of Autun, from which it is also distinguishable by its quartz crystals being larger, and at greater distance from each other. It contains some thinly disseminated bronze-coloured mica, and takes a fine polish.

GRATICULATION, a term used by some writers for dividing a drawing into compartments of squares, in order to be reduced.

GRAVITY, *Table of Specific, See* Specific Gravity.

GREAT CIRCLE OF A SPHERE, a circle passing through the centre, which is one of the greatest.

GREAT STAIRCASE, *See* Grand Staircase.

GREEK ARCHITECTURE, such as was practised by the Greeks. For information on this general subject we must refer to the description of each order given under their several titles, where will also be found some account of their origin and progress. *See* below, Greek Orders; also Architecture, Roman Architecture, &c.

Greek Cross. *See* Cross.

Greek Masonry, the manner of bonding walls, as used by the Greeks. *See* Masonry.

Greek Mouldings, *See* Mouldings.

Greek Orders, are the Doric, Ionic, and Corinthian orders. *See* Doric, Ionic, and Corinthian; also Orders, and Architecture.

Greek Ornaments. *See* Ornaments.

GREENING, in plumbery, the rubbing of a new sheet of lead with any green vegetable, where it is to be soldered, in order to prevent the solder from adhering except at the places where it is scraped off.

GREENHOUSE, a house of shelter in a garden, contrived for preserving the more tender and curious exotic plants.

Structures of this kind were formerly erected with slated roofs, like dwelling-houses, and with large upright windows in front, divided and supported by pillars; examples of which may yet be seen in several of the royal gardens about London, and also in different parts of the country. It was soon found that handsome specimens of plants could not be grown in houses of this description; and the only purpose to which they are now applied, is the growing of orange or lemon-trees, and protecting other plants in winter.

Greenhouses, as now built, serve not only as conservatories, but likewise as ornaments of gardens; being usually large and beautiful structures, sometimes in the form of galleries, wherein the plants are handsomely ranged in cases. *See* Conservatory.

The greenhouse is a sort of building designed for the purpose of preserving various kinds of exotic shrubs, &c., through the winter season, and for growing and protecting those kinds of plants which are too tender to live in the open air. It is fronted and covered with glazed frames, but the aid of artificial heat is not necessary except in intensely cold weather. It is advisable, however, in constructing such houses, to erect flues to use occasionally, which may prove serviceable, not only in severe frosts, but also in moist, foggy weather, when a moderate fire will now and then dry up the damps, which would otherwise prove pernicious to many of the tender kinds of plants.

It differs from the conservatory chiefly in this circumstance, that the plants, trees, or shrubs, are in pots or tubs, and placed upon stands, frames, or stages, during the winter, to be removed to proper situations in the open air, during the hot summer season; while in that, there are beds, borders, and clumps, laid out in the ground-plan, and made up with the best earthy materials, to the depth of three or four feet, in which the shrubs, trees, &c. are regularly planted; the whole of the roof being removed during the summer to admit fresh air, and replaced on the approach of the autumn, to remain until the following summer.

Greenhouses should stand in the pleasure-ground, near the house, if possible, upon a somewhat elevated spot, full to the south, and where the sun has access from its rising to its setting. These buildings are generally of brick or stone, having the fronts and tops almost wholly of glass-work; and ranging lengthwise east and west. They are generally constructed upon some ornamental plan. As to the general dimensions, in respect to length, width, and height, they may be from 10 to 50 feet, or more, in length, according to the number of plants to be contained; and in width, from 10 or 15 feet to 20 feet; but, for middling houses, 15 or 18 feet is a sufficient width; and in height in the clear, nearly in proportion to the width.

The walls on the backs and ends, particularly the former, should be carried up two bricks thick; and if more than 15 feet high, two bricks and a half thick; at one end of the back wall, on the outside, a furnace may be erected for burning fires occasionally, communicating with flues within, ranging in two or three returns along the back wall, having one flue running along the front and end walls, raised wholly above the floor of the house.

The fronts of the buildings should have as much glass as possible, and wide glass doors should be made in the middle, both for ornament and entrance, and for moving in and out the plants. It would also be convenient to have a smaller entrance door at one end; the width of the windows for the glass sashes may be five or six feet: and the piers between the sashes may be either of timber, six, eight, or ten inches wide, according to their height, or if of brick or stone work, two feet wide at least, sloping both sides of each pier inward, that by taking off the angles, a free admission may be given to the rays of the sun. For the same reason, the bottoms of the sashes should reach within a foot of the floor of the house, and their tops almost as high as the roof; and if brick or stone piers two feet wide, shutters may be hung on the inside, to fall back against each pier. The roof may be either wholly or only half glass-work, next the front; the other half slated, especially if the upright or front piers are of timber; and the shutters to cover the top glasses may be so contrived as to slide under the slated roof: where the piers are of brick or stone, it is common to have the roof entirely slated or tiled; but slating is the most ornamental for a half or whole roof; and the ceiling within should be white; which, as well as the whole inside wall, must be well plastered and white-washed, so as to render it clean and neat.

But in greenhouses of modern construction, in order to have as much glass as possible in front, the piers between the sashes are commonly of timber only, from six to eight or ten inches thick, according to the height, so as to admit as great a portion of light and heat of the sun as possible, and the roofs are wholly of glazed frame-work.

The greenhouses for large collections of plants have sometimes two wings of smaller dimensions, added to the main building, at each end, in a right line, separated sometimes from it by a glass partition, with sliding sashes for communication, and the front almost wholly of glass-work, and half or whole glass roofs. Thus, by these additional wings, the houses consist of three divisions, whereby the different qualities and temperatures of the various plants can be more eligibly suited. The middle, or main division, may be for all the principal and more hardy, woody, or shrubby kinds, which require protection only from frost; one of the wings appropriated for the succulent tribe, and the other to the more tender kinds, that require occasionally heat in winter, but which can live without the heat of a stove or hot-house.

On whatever plans greenhouses are constructed, the whole of the inside walls should be neatly finished off with plaster and whitewash, and the wood-work painted white; the bottom being paved with large square paving tiles, or some similar material.

In the greenhouse there should be stands, frames, or tressels, which may be moved in and out, upon which rows of planks may be fixed, so as to place the pots or tubs of plants in regular rows, one above another; by which their heads may be so situated as not to interfere with each other. The lowest rows of plants next the windows should be placed about four feet from them, that there may be a convenient breadth left to walk in front; and the rows of plants should rise gradually from the first, in such a manner, that the heads of the second row may be entirely advanced above the first, the stems only being hid; and at the back of the house a space allowed of at least five feet, for the conveniency of watering the plants, and to admit a current of air round them, that the damps occasioned by their perspiration may be the better dissipated; when this is not done, the damps, pent in too closely, often occasion a mouldiness upon the tender shoots and leaves, and, when the house is close shut up, this stagnating rancid vapour is often very destructive; for which reason the plants should never be crowded too close to each other, nor should succulent plants ever be placed among them.

GRIFFIN, or Griffon, (from the Greek γρυψ,) a fabulous creature, usually supposed to have the head and wings of an eagle, with the body, legs, and tail of a lion; but sometimes with the head of the latter, and the horns and beard of a goat, as in the Ionian antiquities. The ancients adorned the statues and temples of their gods with symbols of their supposed influence. The griffin, which was particularly sacred to Apollo, and in fabulous antiquity believed to be ever watching the golden mines on the Scythian and Hyperborean mountains, is introduced as a guardian of the lyre, which belonged to him, as inventor of music. It has a lion's head, because Apollo, or the sun, is most powerful when in that sign of the zodiac. The Persians also had a statue of him, with the head of that animal.

GRILLAGE, in engineering, a term applied to a kind of frame-work, made something like a grating, of heavy pieces of timber laid lengthwise, and crossed by other pieces, notched down upon them. It is used to sustain foundations, and prevent their irregular settling, in soils of unequal firmness or solidity. This frame-work is firmly bedded, and the earth packed into the interstices between the timbers; a flooring of thick planks, termed a platform, is then laid on it, and on this the foundation-courses rest.

GRINDSTONE, a cylindrical stone, mounted on a spindle through the axis, and turned by a winch-handle, for grinding edge-tools.

GRINDING, the act of wearing off the redundant parts of a body, and forming it according to its destined surface.

GRIT-STONE, a stone consisting of particles of sand agglutinated together. Of this kind of stone there are many varieties, differing in the size of the particles of sand that compose them, the several properties of these sands, and their various degrees of compactness and agglutination.

Some of them are used for building, others for grinding, others for whetting sharp steel instruments, and others for filtering water. *See* Stone, and Whetstone.

Grit-Stone, in mining, a hard granular or gritty stone, composed of grains of silex or quartz, cemented together, generally either by a silicious, an argillaceous, or a ferruginous cement. The first of these, or the silicious grit-stones, are alone fit to be used in repairing roads. The other sorts, in wet weather, soon become a heavy sandy mire upon the road; when the argillaceous parts are dissolved and washed away by the winter rains, this mire changes in summer to loose sand, rendering the roads almost intolerable. Most travellers will have observed this in the argillaceous grit-stone district about Ashby de la Zouch, in Leicestershire, and numerous other coal countries, and the ferruginous grit-stone district about Woburn, in Bedfordshire, and other places. The greater part of the numerous grit-stone rocks and beds of such stone in the coal-mines, are argillaceous, of a fine grit, with minute plates of mica, and are unfit for roads, until hardened by the action of fire; being still, however, very weak and improper materials for road-making, if better can be produced.

A large portion of the argillaceous grit-stones have but a slight disposition to perish or moulder when exposed, and can be used in walls and ordinary buildings; others will perish in a few years; and a large portion of what appears, when first dug, at proper distances below the surface, to be very hard grit-stone, will, after a very short time of exposure, fall to a loamy or clayey sand; such very perishable grit-stone strata are called, by the colliers, *stone-binds*, *gray-beds*, &c., except about Newcastle, where they are denominated *sand-stones.*

In some places, crystallized granular lime-stones occur, as in the yellow or magnesian lime-stone range, near Mansfield in Nottinghamshire, and such are sometimes, though improperly, called *grit-stones*, or *gritty lime-stones. See* Sand-stone.

GROIN, in architecture, the hollow formed by the intersection of two or more simple vaults, crossing each other at the same height.

In the geometrical point of view, the centre of a groin is formed by the entire meeting of the surfaces of two or more cylindrits; that is, such, that every straight line around the whole circumference, on the surface of the one cylindrit, will meet every straight line around the circumference of the one adjoining.

Hence the sections parallel to the axes of all the cylindrits which form the groin are in the plane of their springing; otherwise the surfaces could not meet each other entirely.

Hence, also, the axes of all the cylindrits are also in the same plane, and cut each other in the same point.

In the above definition of a groin, it must, however, be observed, that its surface is no portion of that of the solid which would be contained by the surfaces of the cylindrits and a plane passing through their axes, but only that part of the whole which is formed on the outside of the space which would be thus enclosed in the centre of the groin and form a polygonal dome. The surface of the groin is therefore equal to the whole of the cylindritic surfaces, deducting that of the dome.

The surface of any cylindrit is either that of a cylinder or cylindroid.

When the cylindrits which form the groin are all cylinders, the two vaults are of equal breadth.

In any simple vault of a groin, the planes which are tangents to the surfaces at the springing, have equal inclinations with each respective wall. When all the openings of a groin are equal, the groin is termed an *equilateral.*

The branches of a groin are each of the two opposite parts of each simple vault.

The invention of groins must have been subsequent to that of simple vaulting, and probably originated from arched passages, when it was necessary to occupy the whole height. At what time they were first introduced in architecture, is uncertain; the remains of antiquity show that they are of very remote date, which, however, cannot be traced beyond the times of Roman power and grandeur. Use or necessity was, without doubt, the occasion of their invention, but in process of time they were used as ornaments, and became fashionable at the decline of the Roman empire; they are to be found in the amphitheatre at Rome, formed at the intersections of the radiating and elliptic passages. In the temple of Peace, and baths of Diolcetian, at the same place, instead of massive piers, they are supported upon columns, the most feeble of all supports, and which would be incapable of resisting the lateral pressure of the arches, were it not for the auxiliary support of the walls immediately behind them, at the sides and angles of the building, which act as buttresses.

Groins continued to be used after the dissolution of the Roman empire, in ecclesiastical structures; and wherever grandeur or decoration was required, they were never omitted; they became the most principal ornament of the time, and formed the most conspicuous features in the edifices in which they were employed: at first they were used in the same manner as by the Romans, but in after-times the groins were supported upon ribs, which sprung from cylindrical or polygonal pillars, with capitals of the same form; this produced a necessary change in the figure of the vaulting, as the bottoms of the ribs rose from the circumference of a circle, instead of the angles of a square, with its sides parallel to the walls; and as the spaces between and over the ribs were vaulted in a twisted or winding surface, so as to coincide in every part with a straight line level between the ribs, the angles of the groined surface were thus very obtuse at the bottom, but diminished continually upwards, and ended in a right angle at the summit of the ceiling. Afterwards, when the pillars were formed upon a square plan, the sides of which were obliquely disposed with regard to the sides of the building, and decorated with vertical mouldings, or small attached columns, and the number of ribs increased, the first idea of fan-work would be presented at the springing of the ribs; but in this the architects would soon perceive an incongruity of form in the surface, as it approached the summit of the vaulting; the ribs would be formed all of equal radii, and disposed around, to support a concavity, which might be generated by revolving a curve round an axis which was in the centre of the pillars; and being accustomed to groins meeting in lines crossing each other, it was natural to suppose they would at first permit the ribs to run out and meet each other, which would then be of unequal lengths. If the difference between the openings was not very great, the intersection thus formed by the meeting of the opposite sides of the vaulting would not differ materially from straight lines, but would not be parallel to the horizon, as they would run upwards towards the centre of the groin; but this would depend on the angle formed by two opposite ribs in the same plane. Thus, if the tangents formed at the vertex of the opposite curves contained an angle of 120 degrees, the apex line on the ceiling would form a curve in receding from the vertical angle of the said ribs, of a very decided convexity; but in going progressively forward, the curvature would change into a concavity, and then would begin again to descend. The idea of intersecting the ribs thus disposed in vertical planes around a common axis, by circular horizontal ribs, was natural; and thus again would generate another idea of supporting the upper ends of the ribs, by a circular ring concentric with the axis of the pillar, and this being done from four pillars, would leave a space enclosed by four convex arcs of circles: nothing farther was required to complete this system of vaulting than to fill up the space, and the whole would be keyed together. In this manner, by slow and imperceptible changes, a species of vaulting was invented, very different from that of the Greeks and Romans. Instead of closing the space, if we suppose another ring, forming a complete circumference, to be built interiorly to touch the former arcs, and the four triangular curved spaces closed and wedged together with masonry, the whole will stand equally firm as if the middle had been solid, and thus an aperture for light will be formed the same as in dome-vaulting. This species of vaulting has also another property, that it can be carried up from a square plan with less hazard than the common mode of groining.

In warehouses which are loaded with the greatest weights, and where the walls are placed at a remote distance, it becomes necessary to introduce many supports to the floors: these, if constructed of timber, being liable to accidents from fire, and to rot, are consequently exposed to sudden danger; to prevent which, every precaution should be taken, at least as far as may appear to be warrantable from the profits to arise from the articles to be deposited. This will be fully accomplished by the introduction of groins, which not only answer the same purpose as the flooring of timber-work with its wooden supporters, but are more durable, and proof against fire and rot. Though groins are only employed in the lower stories of buildings, on account of the great expense and loss of space which would be occasioned by the requisite thickness of the walling; yet they may at all times be used in cellars and ground stories, without much additional labour or expenditure of materials.

It having been found that brick groins, rising from rectangular piers, are inadequate to the weight they have to support, and are incommodious to the turning of goods round the corners of the piers, it will be found convenient to employ octagonal piers, and to cut off the square angles of the groin, equal to the breadth of the side of the piers. This mode of construction is decidedly preferable to that in which square piers are used; for the angles of the groins, built in the common way, as they form a right angle, are hardly capable of sustaining themselves, much less the load required to be supported, owing to the bricks being so much cut away at the angles, in order to fit them thereto and to each other, so that they have little or no lap. This scheme should certainly be carried into practice, wherever groins are applied to such uses.

In the construction of edifices for dwelling, they ought always to be employed in cellars, and other damp situations, particularly where there are paved apartments above.

Groins for use only, may be indifferently constructed of brick or stone, as one or other material may be most easily procured.

If employed by way of proportion or decoration, their beauty depends on the generating figures of the sides, the regularity of the surface, and the acuteness or sharpness of the angles, which should not therefore be obtunded. In the best buildings, where durability and elegance are equally required, they may be constructed of wrought stone; and where elegance is wanted at a small expense, of plaster, supported by timber-work.

Groins are consequently constructed in two different ways, according as they are built of stone or brick, or formed of timber-work, lathed and plastered. In the former case, a timber centering is made to form the concavity, and to support the groin during its erection. The centering consists of several ribs, disposed at three or four feet distance, made to the size of the vault which has the greatest opening: The extremities of these ribs rest on beams supported by standards, and are boarded over without any regard to the transverse openings, which are afterwards formed by another set of ribs adapted thereto, and then boarded so as to meet the boarding of the first vault, which if of considerable breadth, must have short ribs fixed upon its surface, in order to shorten the bearing of the boarding of the transverse openings; and thus the centering will be completed. It is obvious, that in forming the ribs for each vault, the outer curve must be the arc of a circle or ellipsis within the curve of the vault, and distanced from it towards the axis equal to the thickness of the boarding. In making the groined centre, it will be necessary to find the place of the angles on the boarding of the large vault, in order to ascertain the place of the ribs and boarding of the transverse vault; this may be done by three different methods. First, let two straight edges be placed vertically at the angles, and a third straight edge, or an extended line, be made to touch the surface of the boarding, and marked at all the points of contact, keeping the latter straight edge or line always upon the edges of the two vertical straight edges.

The defect of this method is, that the place of the angles at the bottom can never be found, since it would require the cross straight edge or line to be of infinite length, and the vertical ones of infinite height. A more eligible method, therefore, where there is room, is, secondly, to fix two ribs in the transverse part, and direct a level straight edge upon their edges, so that the end may come in contact with the boards, and mark the boarding in this place; find a sufficient number of points for the purpose, in the same manner, and draw curves through the points, which will give the curves for fixing the end of the filling-in ribs, otherwise called *jack ribs.*

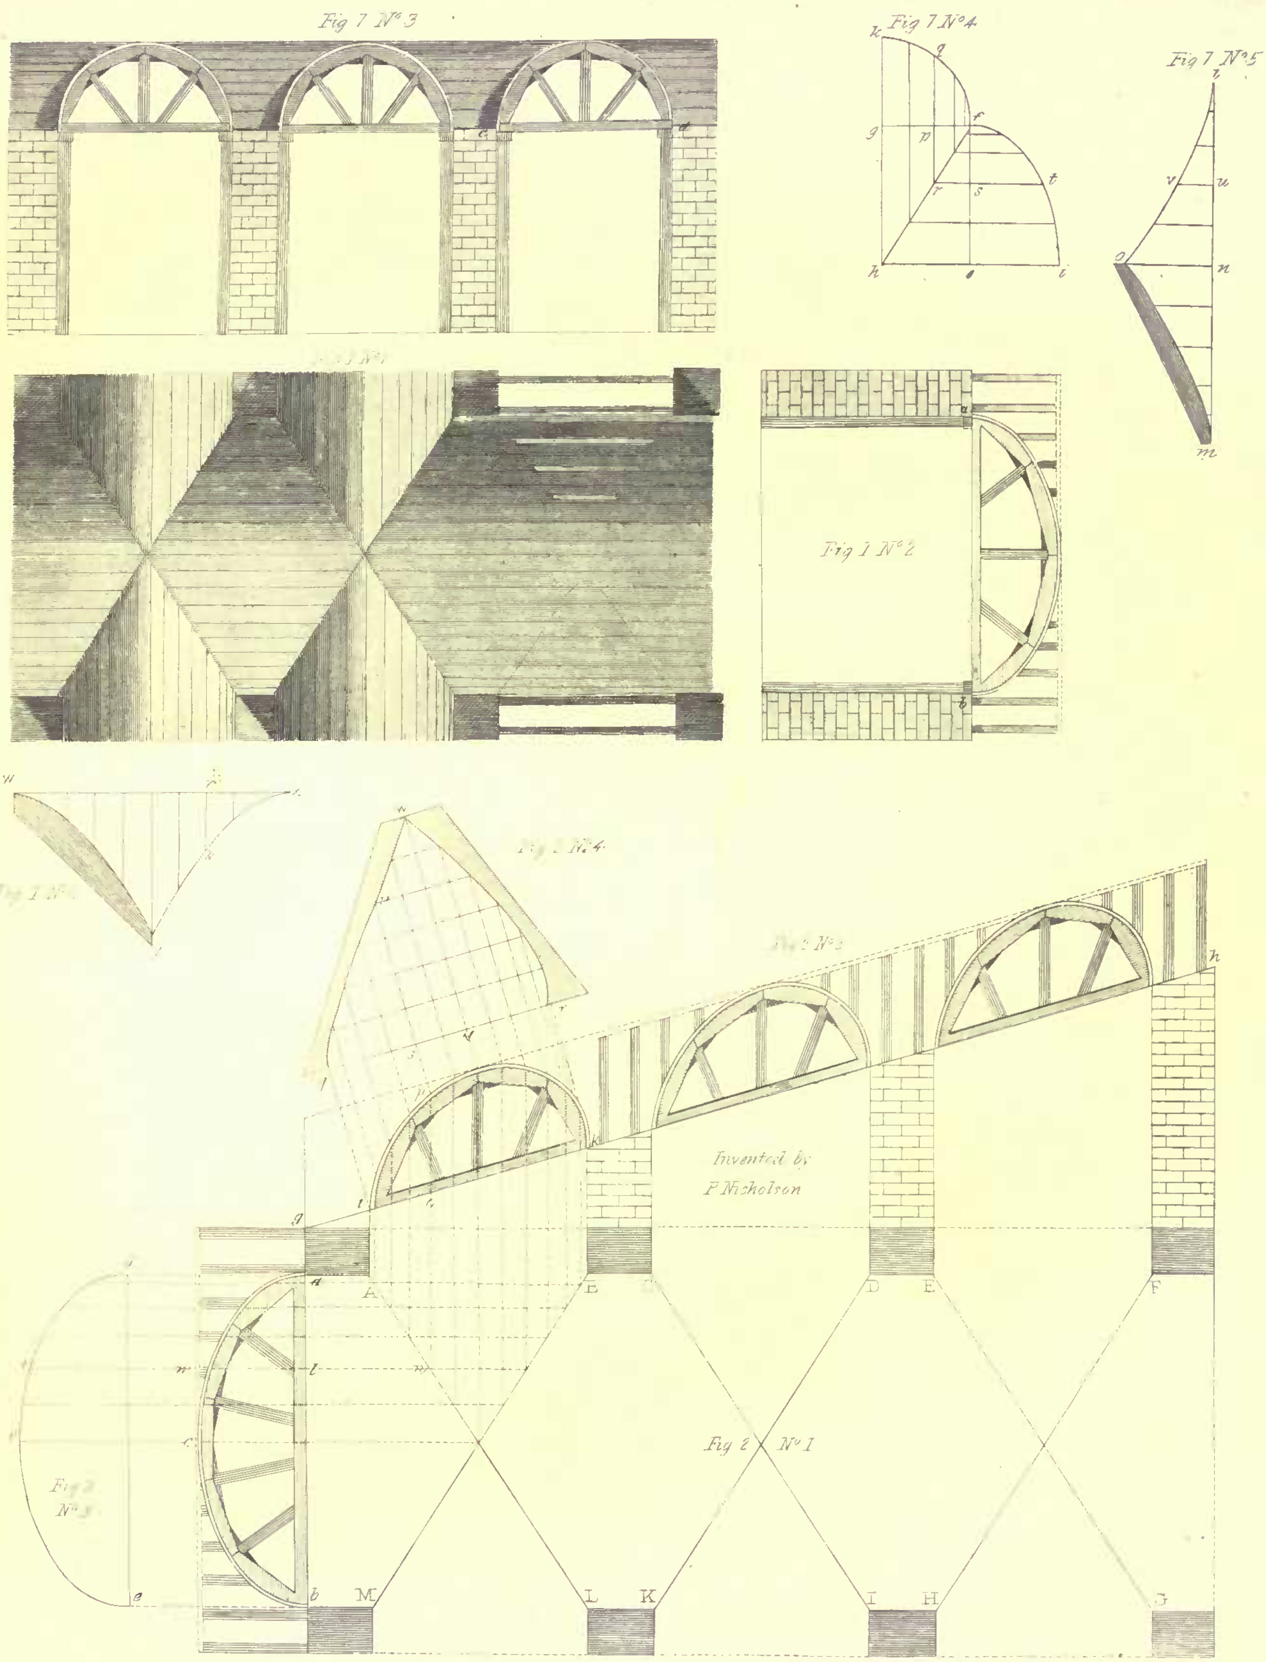
In constructing groins to be finished with plaster, the angle-ribs must be first fixed, then straight longitudinal pieces parallel to the axis of the groin fixed, either flush with the under sides of the angle-ribs, or their under sides a little below those of the angle-ribs, so as to admit of their being nailed together; this is the most eligible method of constructing plaster groins.

There is another mode, by forming curved ribs, in planes perpendicular to the axis of each simple vault: but here, as the curve of these ribs must be the same as that of the cylindrit of each simple vault, the waste of timber will be very great; though not if the ribs are constructed in straight pieces. Whatever mode is adopted in the formation of plaster groins, the under sides of the ribs must always range in the intended surface of each simple vault. These constructions will be more clearly understood in the following explanations.

Plate 1. (Centering for Groins,) *Figure* 1, No. 1. A plan of the widest opening of the groin, first boarded the whole length without interruption; then the cross vaults are boarded; the two cross openings upon the left hand appear as finished, ready to receive the masonry or brickwork, while that on the right exhibits the ribs without the boarding.

No. 2. The elevation of the widest aperture, showing the edges of the ribs of the transverse openings fixed upon the surface of the boarding of the longitudinal opening; this also shows the height of the jack-ribs, which will give their length also.

No. 3. Shows the elevation of the transverse apertures, as completely finished.



Drawn by P Nicholson.

Problem I.—*Given one of the ribs of the transverse ranges, to find the body-range.*

Suppose the given rib to be a semi-circle, or a semi-ellipsis, describe a semi-ellipsis, the length of which is that of the body-range, and the semi-conjugate axis the height of the given rib, which is that of the groin; and the semi-ellipsis thus described will be the contour of the ribs which are to form the body-range.

In the same manner, if a rib of the body-range be given, that of the transverse openings may be found.

But if the given rib be any other curve than that of a semi-circle or semi-ellipsis, lay down the curve of half the given rib upon any straight line, as a base; from the point where the curve intersects the base, draw another straight line at a right angle therewith: upon this line set the extent of half the width of the range from the angular point: complete the rectangle, of which these two straight lines are adjoining sides; draw that diagonal of the rectangle which meets the curve given; take any number of points in the given curve, draw ordinates perpendicular to the base to intersect them; from these points draw lines parallel to the other two sides of the rectangle, to meet the diagonal; from the points of division, draw straight lines parallel to the base of the given rib, to meet the side of the rectangle, which joins the curve of the given rib; from these points raise perpendiculars; transfer the ordinates of the given rib upon the perpendiculars; and the curve drawn through the extremities of these perpendiculars will be that of the rib required.

Figure 1, No. 4, *f q k g f* is the given rib, *g f* its base, equal to half the width, *c d*, No. 3, of the transverse openings; *f t i e f* is the rib found from the given rib *f q k g f*, and *f e* its base, equal to half the width, *a b*, of the body-range.

Figure 1, No. 5. Shows the method of finding the mould for drawing the angles for placing the jack-ribs. The operation is thus performed:

Figure 1, No. 5. Upon any straight line, *m l*, transfer the arc *f t i*, No. 4, stretched out with all its parts from *l* to *m*; from the points thus transferred, erect perpendiculars, and transfer *e h*, No. 4, to the middle perpendicular, *n o*, No. 5; then the remaining parallels of *e h* of the triangle *e h f*, No. 4, respectively to the parallels of *n o*, No. 5, on each side of it; and through the remote extremities of these perpendiculars, draw a curve each way from the point *o*; and thus two equal curves will be formed. But lest the reader should not be able to follow a general description, the following shows not only how any particular point may be found in the required rib, but also how any point may be found in the covering.

First: *To find a point in the required rib.*

Figure 1, No. 4. Take any point, *q*, in the given rib; draw *q p* perpendicular to *g f* the base; draw *p r* parallel to *f e*, cutting *f h* at *r*; draw *r s* parallel to *g f*, cutting *f e* at *s*; draw *s t* perpendicular to *f e*; make *s t* equal to *p q*, and *t* is a point in the curve. In like manner, as many points may be found as required.

Now let it be required to find the point *u*, No. 5. Transfer the arc *i t*, No. 4, upon the straight line *m l*, No. 5, from *n* to *u*; draw *u v* perpendicular to *m l*; make *u v* equal to *s r*, and *v* is a point in the curve. The trilinear area *m o l* is the envelope of the portion of the groined surface represented by either of the two triangles of the plan of the groin, which have the width of the body-range for the base; *m o* is the edge of a mould by which the angle of the groin, or the cylindritic lines, are found; the point *m* is laid to the bottom, and the mould bent upon the surface, so that the point *o* may be in the summit, and the convex side of the mould towards a vertical section passing through the point from which the bottom of the mould rises.

Figure 1, No. 6. Shows the envelope corresponding to either of the two triangular parts of the plan of the transverse parts, and is found in the same manner as No. 5. This shows the mould for cutting the boarding, by laying it out to the full breadth upon a plane, and drawing the ends of the boards by the curved edge of the mould, so as to fit against the boarding of the body-range.

Figure 2. Shows the construction of a groin upon an inclined plane, the widest opening, or body-range, having its ascent or descent in the direction of the inclination of the plane; the transverse ranges are therefore level. The ribs in both directions are set in vertical planes. The rib for the body-range is a semi-ellipsis; those of the sides will also be semi-ellipses, but will not have their axes in a vertical and horizontal position. The elevation of the transverse openings is shown at No. 2, and that of the body-range at the lower end. Each elevation exhibits the construction of the centre, a section of the boarding, and the manner of placing the jack-ribs.

No. 3. Is a section of the body-range at right angles to the plane of its inclination.

No. 4. Shows the form of the moulds for drawing the angles, in order to place the jack-ribs. The construction is thus: Divide the half, *d f*, of the curve *d e*, No. 3, into any number of equal parts; from the points of division draw lines parallel to the axis of the body-range, cutting the diagonal A L; from the points of intersection draw lines parallel to the sides of the transverse opening, and continue them on the other side of the inclination, *g h*, of the elevation of the said openings; from *g h*, as a base, make the heights of the several lines thus continued equal to the corresponding heights of the elevation of the body-range, and a curve drawn through all the extremities will give the form of the ribs, *i p k*, for the transverse openings. From the summit of the centre thus constructed, draw the line *v w* at right angles to the inclination *g h*; extend the arc *d f*, No. 3, with its divisions, to *v w*, No. 4; through all the points of division in *v w* draw lines at right angles thereto; from all the points found in the curve of the rib *i p k*, No. 2, draw lines parallel to *i h*, cutting the respective lines perpendicular to *v w*; and a curve drawn on each side of *v w* will give the angle of the groin.

Groin Ceiling, a cradling constructed of ribs, lathed and plastered. It differs in its construction from groin centering, as the former requires angle-ribs. There are two different methods of constructing groin-ceilings; one by ribs fixed vertically and perpendicularly to the sides of each branch; the other by angle-ribs and ceiling-joists, or straight pieces of timber, running parallel to the axis of each branch, fixed to the angle-ribs, and to other intermediate ribs, in vertical planes, at right angles to the sides of each of the branches, and placed upon opposite piers, to shorten the bearing, in order to make less scantlings for the ceiling-joists, and thereby save timber. But in whatever mode the groined-ceiling is constructed, the surface must finish in the same manner. It is evident, however, that the latter method by ceiling-joists will require much less timber and workmanship than the former, where so much stuff is cut to waste, and so much time employed in making the angle-ribs.

Figure 1. The cradling of a groin ceiling, constructed with ceiling-joists. Stout ribs are thrown across the angles and between the opposite piers; the ceiling-joist being put on below and spiked upwards. In this, the rib, *a l b c*, of a transverse range is given, to find the others. Take any number of points in the half arc *a l b*; draw lines parallel to *g i*, the base of the rib of the body-range, to cut the diagonal *d f*; from the points thus obtained in *d f*, draw lines at right angles to *d f*, and make the corresponding perpendiculars equal to those of the given arc *a l b*; then construct the other half by reversion, and it will form the whole angle-rib.

To obtain the rib of the body-range from the points of section in the base line *d f*, draw lines parallel to *a c*, to cut *g i*, and produce them on the other side of *g i;* from the points thus obtained in *g i*, transfer the corresponding heights of the ordinates of the given rib upon the perpendiculars as ordinates, then construct the ordinates of the other half by reversion, which will give the curve of the ribs of the larger branch.

Figure 2. The cradling of a groin-ceiling, constructed entirely of ribs. The section of the ceiling of the transverse ranges is that of a semi-circle; consequently, the angle-ribs, and those of the body-range, are semi-ellipses, the width of the body-range being greater than those of the transverse branches. The description of the curves of the ribs will be found under the article Ellipsis, *Method* III. *Figure* 3.

The ribs must be bevelled each way, so as to range with either branch of the groin. This is best done by getting them in two thicknesses, then each half of each thickness must range the contrary way, one half with the ceiling of the largest branch, and the other half with the ceiling of the lesser branch, in the same groin; the branches being supposed on the same side of the diagonal: so that when the two parts are put together to form the rib completely, the bevelling of the one half of one thickness and that of half of the other, will range with the surface of the ceiling of one branch, and the contrary edges with the surface of the ceiling of the other branch. In ranging the ribs, each thickness is cut out by the mould: then, in order to range the half of each thickness, the mould must be shifted, so that the upper point of the curved edge will slide in a line parallel to the base, while its lower point will slide upon the base line to the distance required at the bottom: this is represented on the lower end of the principal branch.

Figure 3. A groin in which the principal branch is inclined: *i k l* is the given curve of the rib; *a b* the line of elevation of the spring of the arches. Draw the diagonal *p o*, and *o s* perpendicular to it; join *o n*, which produce to cut *a b* at *r;* make *o s* equal *q r;* produce *o p* to meet *i l* at *a*, and join *s a* (*the reader must however observe, that the engraver has joined* s p *instead of* s a, *and has not produced* o p, *as here stated, and as it was in the drawing*). Bisect *i l* at *y*; through *y* draw *k v* parallel to *m o* or *p n*, meeting the curve in *k*, and *op* at *v;* draw *v u* perpendicular to *o p*, cutting *s a* at *t;* make *t u* equal to *y k;* draw *v* x parallel to *i l*, cutting *a b* at *w;* make *w* x equal to *y k;* then *p s* will be a diameter, and *t u* the semi-conjugate of the ellipsis, which forms the curve of the angle-rib: also *w r* and *w* x are the semi-conjugate diameters of the curve of the ribs for the transverse branches, and the curves may be described as in *Method* V. *Problem* I. of the article Ellipsis. Or, the two axes may be found as in *Problem* II. of the same article, and the curves described according to *Method* III. *Problem* I.; or the curve may be drawn by ordinates as here exhibited. The cradling is shown at the lower end.

Figure 4. Shows the construction of ribs for the arches of apertures cut under the pitch of a large vault at right angles to the wall. Apertures of this description are called *lunettes.*

Let A *z e m p* D be the curve of the section of the principal vault; it is required to construct the ribs of a lunette of a given height.

Produce the base A D to *k*, and the side *g* D to *l;* let *f g* be the breadth of the aperture; bisect *f g* in *i;* draw *i h* perpendicular to *f g*, which assume equal to the intended height of the lunette; draw *h k* parallel to *g* D, cutting D *k* at *k;* make D *l* equal to D *k;* draw *l m* parallel to D A, cutting the curve of the principal vault in *m;* draw M *o* parallel to D *g*, cutting *h i* produced to *o;* join *o f* and *o g;* assume any number of points in the part *m d* of the curve D *m e* A; from the assumed points draw lines parallel to *m o*, cutting *o g;* from the points of division draw lines perpendicular to *o g;* make the lengths of the several perpendiculars from the base equal to the corresponding ordinates contained between the base *n* D and the arc *m* D; then a curve being drawn through the remote extremities of the perpendiculars not in *o g*, will give the curve of the angle-rib. Again, from the intersections in *o f* and *o g*, draw lines perpendicular to *f g*, and produce them on the other side of *f g;* make the heights of the perpendiculars equal to the corresponding heights of the ordinates belonging to the curve D *m*, of the given rib on each side of the middle line *i h;* then a curve being drawn through all the extremities of the perpendiculars not in *f g*, will give the curve of the ribs of the lunette.

On the left-hand side is shown another metnod of tracing the curves of the angular rib, and of ribs forming the sides of the lunette. The cradling is shown below the lower end of the plan.

Groin, sometimes spelt Groyne, a kind of jetty built across the beach at right angles to the line of the shore from high to low-water mark. Groins are used particularly on the southern and south-western coast of England, to retain the shingle already accumulated, to recover it when lost, or to accumulate more at any particular point; also to break and check the action of the waves. The following description of a groin is taken from Mr. Weale's very useful little work, 'A Dictionary of Terms of Art:'—

"The component parts of a groin are piles, planking, land-ties, land-tie bars, blocks, tail-piles, and keys and screw-bolts. The length of a groin depends on the extent, and the requisite strength of its component parts on the nature of the beach on which it is to be constructed.

"Those at Eastbourne, on the coast of Sussex, of which the following is more particularly a description, are from 150 to 250 feet in length, and the beach at that place being very rough, consisting of coarse heavy shingle and large boulders, they require to be composed of proportionably strong materials to resist its force.

"The piles are from 12 to 25 feet long, and 8 by 6½ inches scantling, shod with iron. The planking is in length of 8, 12, and 16 feet, 2½ inches thick, and with parallel edges. The land-ties are of rough timber from 20 to 25 feet long, and large enough at the butt-end to receive the bars. The land-tie bars are 13 feet 6 inches long, and 12 by 5 inches scantling. The land-tie-bar blocks are about 2 feet long, and of the same scantling as the piles. The land-tie tail-keys are about 2 feet 6 inches long, and 6 by 2½ inches scantling. The above materials are of oak or beech. The screw-bolts are of inch round iron, 2 feet 9½ inches, and 2 feet 1½ inch long, in equal proportions.

"The relative proportions of the component parts are, four piles, one land-tie with tail-piles and keys, one land-tie bar with two blocks, two long and two short bolts, about 180 square feet of planking, and about 140 six-inch spikes for every 16 feet in length; and the expense of a groin, constructed with materials of the above dimensions, may be calculated at about £30 for the same length.

"General rules observed in the construction.

"When the object, in constructing a groin, is to recover shingle, or accumulate more, the first pile is driven at the high-water mark of neap-tides, leaving its top level with that of spring-tides. The next is driven at the point on the sands, beyond the bottom of the shingle, to which the groin is to

RIBBING FOR GROINS, CEILINGS &c.

extend, leaving about four feet of it out of the beach. The tops of these two piles may be taken for the general slope of the groin, unless the beach should be very steep, and much curved, in which case it becomes necessary to follow its curvature in some degree. From the high-water mark of neap-tides, the piles are carried back nearly level to that of spring-tides, and as much further as may be considered necessary. The piles are driven four feet asunder from centre to centre, and so as to admit the planking between them alternately, and they should be sunk about two-thirds of their length. The longest piles are placed between the high-water mark of neap-tides and the bottom of the shingle, particularly from 20 to 40 feet below the former point. The planking is, if possible, carried down to about two-thirds from the tops of the piles, and kept parallel with them. The land-ties are placed about one-third from the top of the planking (supposing the latter to commence from the tops of the piles,) and their tails are sunk to the level of the bottom of the planking or as nearly so as possible."

GROOVE, a channel cut in a piece of wood by taking away a rectangular prism, one of the sides of which is a portion of the side of the wood in which the excavation is made. A groove therefore forms two external, and two internal angles. It differs from the rebate thus: the rebate is formed by taking away a rectangular prism at the angle, and consequently the part taken away has two of its sides common to those of the piece, with one internal, and two external angles.

A groove is made in joinery by a plough, which is moveable so as to admit of the excavation being run at any distance from the arris.

Grooves are frequently used in order to insert a tongue in the joint of two pieces of wood, intended to be united. They are also used for inserting the panels in framed work, as in doors, shutters, partitions, &c.

In the present day, grooves are among the most fashionable ornaments; but there are few or no instances of their decorative use among the ancient Greeks and Romans.

GROTESQUE, that beautiful light style of ornament used by the ancient Romans, in the decoration of their palaces, baths, and villas. It is also to be seen in some of their amphitheatres, temples, and tombs, the greatest part of which being vaulted, and covered with ruins, have been dug up and cleared by the modern Italians, who for these reasons gave them the name of *grotte*, which is perhaps a corruption of the Latin *cryptæ*, a word borrowed from the Greeks, as the Romans did most of their terms in architecture: and hence the modern word *grotesque*, and the English word *grotto*, signifying a *cave*.

In the time of Raphael, Michael Angelo, Julio, Romano, Polidore, Giovanni d'Udine, Vasaro, Zuchero, and Algerdi, there is no doubt but there were much greater remains of the grotte than what are now to be seen, and in imitation of them were decorated the loggias of the Vatican, the villas of Madonna, Pamfili, Capraola, the old palace at Florence, and indeed whatever else is elegant or admirable in the finishing of modern Italy.

This classical style of ornament, by far the most perfect that has ever appeared for inside decorations, and which has stood the test for so many ages, like other works of genius, requires not only fancy and imagination in the composition, but taste and judgment in the application, and when these are happily combined, this gay and elegant mode is capable of inimitable beauties.

Vitruvius, with great reason, condemns an over licentiousness of this kind and blames the painters of his time for introducing monstrous extravagances. We do not mean to vindicate any thing that deserves such appellations; but surely in light and gay compositions, designed merely to amuse, it is not altogether necessary to exclude the whimsical.

Its origin is discernible in the Egyptian hieroglyphic writing, where the heads and limbs of men and beasts are attached to blocks of stone, to vases, or to foliage, &c., thereby characterizing the inclinations and the powers of the deity or person whose history they record, or whose peculiar transactions they are intended to preserve in the remembrance of future ages.

With the Egyptians it remained rude and unpolished; but when the Greeks adopted it, they made an ornamental use of it, and it became a medium to exhibit their general knowledge of nature. The taste with which they united in one form, not only parts of various animals, but objects so totally diverse in their nature and appearance, as the productions of the animal and vegetable kingdoms, is in the highest degree delightful to contemplate. The formation of chimerical beings, as the dragon, the sphinx, the griffin, &c., owe their origin to this taste; which received much of its force and interest in heathen days, from the mythological enigmas couched under these compound forms. Such is the character of that ornament so common on Egyptian structures, the winged serpent surrounding an egg. Now that these mysterious emblematic meanings are disregarded, and no longer treated with reverence, grotesque painting and sculpture are continued in use merely because the forms they produce are pleasing to the eye; and although the understanding is insulted by them, such is the power of the beauty of form, that we are gratified by it, in spite of our reason.

Those who wish to make themselves acquainted with it, will find the best exemplars on ancient Greek sarcophagi, altars, vases, friezes, &c., of which Piranesi and Rocchegiani have given an ample store to the public in their valuable works. Mr. C. H. Tatham has given likewise a tasteful and judicious series of examples of this kind, in his *Collection of Etchings of Ornamental Architecture, from the Antique at Rome*. Le Roy's, Le Pôtre's, and many other works of the like kind, may also be consulted with advantage.

GROTTO (from the French, *grotte*) is used for a little artificial edifice made in a garden, in imitation of a natural grotto.

The outsides of these grottos are usually adorned with rustic architecture, and their inside with shell-work, fossils, &c. finished likewise with *jets d'eau*, or fountains, &c.

A cement for artificial grottos may be made thus; take two parts of white rosin, melt it clear, and add to it four parts of bees' wax; when melted together, add two or three parts of the powder of the stone you design to cement, or so much as will give the cement the colour of the stone; to this add one part of flour of sulphur; incorporate all together over a gentle fire, and afterwards knead them with the hands in warm water. With this cement, the stones, shells, &c., after being well dried before the fire, may be cemented.

Artificial red coral branches, for the embellishment of grottos, may be made in the following manner: take clear rosin, dissolve it in a brass pan; to every ounce of which add two drams of the finest vermilion; when you have stirred them well together, and have chosen your twigs and branches, peeled and dried, take a pencil, and paint the branches all over whilst the composition is warm: afterwards shape them in imitation of natural coral. This done, hold the branches over a gentle coal fire, till all is smooth and even as if polished.

In the same manner white coral may be prepared with white lead, and black coral with lamp-black. A grotto may be built, with little expense, of glass, cinders, pebbles, pieces of large flint, shells, moss, stones, counterfeit coral, pieces of chalk, &c., all bound or cemented together with the above-described cement.

The grotto at Versailles is an excellent piece of building. Solomon de Caux has an express treatise of grottos and fountains.

GROUND CILL. *See* GROUND SILL.

GROUND JOISTS, the joists which rest upon sleepers laid upon the ground, or on bricks, prop-stones, or dwarf walls; they are consequently only used in basements and ground-floors.

GROUND LINE, in perspective, the intersection of the picture with the ground plane. *See* GROUND PLANE.

GROUND NICHE, a niche whose bottom is on a level with the floor.

GROUND PLAN, the plan of the story of a house on the same level with the surface of the ground, or elevated only a few steps before the door. The ground floor is not always the lowest floor, the basement being frequently beneath it.

GROUND PLANE, in perspective, the situation of the original plane in the supposed level of our horizon. It differs from the horizontal plane thus: the horizontal plane is any plane parallel to the horizon; whereas the ground plane is a tangent plane to the surface of the earth on which we walk, and is supposed to contain the objects to be represented, the earth itself being considered as a spherical body.

The term *ground plane* is used in a more confined sense than that of *original plane*, which may be any plane, whether horizontal or inclined.

GROUND PLATE. *See* GROUND SILL.

GROUND PLOT, the plan of the walls of a building, where they first commence above the foundation; though it is more properly the piece of ground selected for building upon. For dwellings, its chief properties are a healthy situation, a convenient supply of water and other necessaries of life, and an agreeable aspect. If for trade or manufacture, it must be convenient for receiving the raw materials, and for exporting the articles manufactured.

GROUND RENT. Rent paid for the privilege of building on another man's land. In the neighbourhood of London it is very difficult to obtain freehold-land, and most of the building-ground, therefore, is let on long leases, subject of course to the payment of ground-rent.

GROUND SILL, or GROUND PLATE, the lowest horizontal timber on which the exterior walls of a building are erected. It chiefly occurs in timber buildings; or in buildings whose outside walls are formed of brick panels with timber framings.

GROUND TABLE. The top of the plinth.

GROUND WORK. *See* FOUNDATION.

GROUNDS, in joinery, certain pieces of wood concealed in a wall, to which the facings or finishings are attached, having their surfaces flush with the plaster. Narrow grounds are those to which the bases and surbases of rooms are fastened. Grounds are used over apertures, not only to secure the architraves, but also to strengthen the plaster. In order to keep the plaster firm, should the materials happen to shrink, a groove is sometimes run on the edge of the ground next to the plaster, or the edge of the ground is rebated on the side next to the wall; so that in the act of plastering, the stuff is forced into the groove or rebate, which prevents it from shifting when it becomes dry.

GROUP, in painting or sculpture, an assemblage of two or more figures of men, beasts, or other things which have some relation to each other.

GROUPED COLUMNS, or PILASTERS, those which consist of more than two. Nothing of this description is to be found among the ruins of the ancients; nor are they conformable to the strict rules of architecture, though some few examples exist in modern buildings.

GROUT, a thin semi-liquid mortar, composed of quicklime with a portion of fine sand, which is prepared and poured into the internal joints of masonry. It is particularly used where the work consists of large masses of stone. The process is called *grouting*.

Grouting is also now generally used in street-paving.

GRY (Greek) a measure containing one-tenth of a line.

A line is one-tenth of a digit, a digit one-tenth of a foot, and a philosophical foot one-tenth of a pendulum, whose diodromes or vibrations, in the latitude of 45 degrees, are each equal to a second of time, or one-sixtieth of a minute.

GUARDS (from the French *garde*, a defence) in engineering, upright pieces of wood, nailed to the lock-gates of a canal, to prevent the barges from striking the planks of the gates.

GUERITE (French) in fortification, a sentry-box; being a small tower of wood or stone, placed usually on the point of a bastion, or on the angles of the shoulders, to hold a sentinel who is to take care of the ditch, and watch against a surprise.

GUILD-HALL, or GILD-HALL, the great court of judicature for the city of London, and other cities; where are kept the lord-mayor's court, the sheriff's court, the court of hustings, court of conscience, court of common-council, chamberlain's court, &c.

GUILLOCHI (Italian) an ornament in the form of two or more bands or strings twisting over each other, so as to repeat the same figure in a continued series by the spiral returnings of the bands. The term is also applied to the ornaments, consisting of bands turning at right angles, commonly called *frets*.

GULA, or GUEULE. *See* CYMATIUM.

GULBE, the same as GORGE, which *see*.

GULLIES, in engineering, a name applied in some places to the iron tram-plates or rails laid for the use of tram-waggons.

GULOICK, the same as IMPOST, which *see*.

GUNTER'S CHAIN, so called from the inventor, the chain commonly used by surveyors in measuring land. It is 66 feet long, or 22 yards, or 4 poles of $5\frac{1}{2}$ yards each; and is divided into 100 links of 7.92 inches each; 100,000 square links make one acre.

GURGOYLE, the same as GARGOYLE.

GUTTÆ (Latin) ornaments formed like the frustum of a cone, depending from the soffits of the mutules and regula under the band of the architraves of the Doric order. In several of the Grecian Dorics, the guttæ are cylindrical instead of being conical: their number on the soffits of the mutules is eighteen, disposed in three rows, each row parallel to the front.

They are sometimes also called *lachrymæ*, tears; and *campanæ*, or *campanulæ*, bells. Leon Baptista Alberti calls them *nails*. *See* DROPS, and DORIC ORDER.

GUTTER, in building, a channel for collecting and conveying the water from the roof, situated between the parapet and the inclined side of the covering, or between the inclined sides of a double roof, the intersection of the vertical plane of the wall and the inclined plane of the roof, or the two inclined planes forming horizontal lines. When two inclined sides of a roof meet each other at an internal angle, and form an inclined intersection to the horizon, the angle thus formed is called a *valley*. The external angles formed by two inclined planes are called *hips;* and hence hips are exactly the reverse of valleys, and thus we have the difference between gutters, hips, and valleys. The intersections of the planes which form the sides of gutters are horizontal, but the intersections of the planes which form hips and valleys are inclined. Gutters for lead are formed partly by a boarding perpendicular to the plane of the walls, and partly by the inclined sides of the roof and the vertical planes of the walls, and are supported by horizontal bearers from the walls to the sides of the rafters, against which they are nailed at one end; the other end is supported close to the wall upon small posts or puncheons, which are notched and nailed to the bearers. The boarding, which is supported by the bearers, and which stands perpendicular to the planes of the walls, forms the bottom of the gutter, and is laid with a declivity in the parallel direction of the plane of the wall, of about an inch in 10 feet, and with steps, called *drips*, at every 12 or 18 feet. The drips are formed in planes perpendicular to the horizon and to the walls, rising about two, or two inches and a half, so as to add to the descent of the gutters, and at such distances from each other as are equal to the length of the sheets. Gutters are laid with lead of such weight, that the superficial foot contains from seven to twelve pounds, according to the stress that is supposed to be on the surface. The sheets are laid from 12 to 18 feet in length, as the descent for the water may permit. When there is a sufficient current for the water, shorter sheets of 12 feet in length are to be recommended in preference to longer ones, on account of the latter sometimes cracking by expansion, as all metals are liable to do. Cast lead is preferable to milled lead, as being more solid in its texture, and on this account is more to be depended upon when it expands, so as to keep from tearing asunder; but milled lead is equally thick throughout, and has its surface regularly smooth, properties which are not to be found in cast lead; therefore, wherever beauty and neatness of workmanship are required, milled lead must be employed. The goodness of cast lead depends upon the equality of its thickness, which cannot at all times be depended upon; and it should be observed, that plumbers themselves are divided in their opinion whether cast or milled lead ought to have the preference.

In London, parapet walls and leaden gutters are indispensable on account of the Building Act, as the numerous inhabitants are less liable to accidents from the falling of broken slates or tiles; and in cases of fire in the lower part of the building, they are convenient for making an escape from the danger, and also for assisting in extinguishing the flames. Several attempts have been made to substitute copper, but this material has not been found to have the desired effect, though zinc has been extensively used of late years instead of lead. The water is conveyed from the gutters by leaden pipes. In the country, dripping eaves are much used, and are to be preferred in elevated situations, as in the winter season the gutters and pipes are frequently stopped by snow or frost, so as to bring down the ceilings and plastering, injure the walls, and rot the timber; and thus not only render the building unfit for living in, but reduce it to ruin in the course of a few years. On this account, many of the first-rate houses suffer much by the overflowing of the water, unless the gutters are so constructed, that the water may escape before it finds its way into the building. Gutters should never be soldered where it can be avoided, particularly when the soldering would make the sheets of unusual length, as in this case it would be impossible to ensure it from cracking; the expenses of repairing would be frequent, and the ultimate effect ruinous. The thickest lead is used in gutters and flats, each generally of the same weight, while the hips and ridges are from five to six pounds to the foot, and most generally of milled lead.

The following are the regulations in the Metropolitan Building Act relating to parapets and gutters. "If an external wall adjoin a gutter, then such external wall must be carried up, and remain one foot at the least above the highest part of such gutter. And the thickness of an external wall so carried up above the level of the under side of the gutter-plate, and forming a parapet, must be at the least.

"In every such wall of the extra first-rate of the first class, and in every such wall of the first-rate of the second class, 13 inches thick; and

"In every other external wall, of whatever rate, or whichever class, 8½ inches thick."

GUTTERING. *See* GUTTER.

GUTTUS (Latin) a term among antiquaries for a sort of vase, used in the Roman sacrifices, to receive the wine and sprinkle it *guttalim*, drop by drop, upon the victim.

Vigenere on T. Livy, gives the figures of the guttus as represented on divers medals and other ancient monuments.

GYMNASIUM, a place fitted for performing exercises of the body.

The word is *γυμνασιον*, formed of *γυμνος*, *naked;* because they anciently put off their clothes, to practise with the more freedom.

Among the ancients, the gymnasium was a public edifice destined for exercise, and where people were taught, and regularly disciplined, under proper masters.

According to Solon, in Lucian's *Anacharsis*, and Cicero, *De Orat.* lib. ii. the Greeks were the first who had gymnasia; and among the Greeks, the Lacedæmonians; after them the Athenians, from whom the Romans borrowed them.

There were three principal gymnasia at Athens: the Academy, where Plato taught; the Lyceum, famed for Aristotle's lectures; and the Cynosargus, allotted to the populace.

Vitruvius describes the structure and form of the ancient gymnasia, lib. v. cap. 2. They were called *gymnasia*, because the champions performed *naked;* and *palæstræ*, from wrestling; which was one of the most usual exercises there: the Romans sometimes also called them *Thermæ*, because the baths and bagnios made a principal part of the building.

It appears, that so early as the time of Homer, they did not perform their exercises quite naked, but always in drawers; these they did not lay aside before the thirty-second Olympiad. One Orsippus is said to have been the first who introduced the practice: for having been worsted, by means of his drawers undoing and entangling him, he threw them quite aside, and the rest afterwards imitated him.

The gymnasia consisted of seven members, or apartments. M. Burette, after Vitruvius, recites no less than twelve. viz. 1. The exterior *portico*, where the philosophers, rhetoricians, mathematicians, physicians, and other virtuosi, read public lectures, and where they also disputed, and rehearsed their performances. 2. The *ephebeum*, where the youth assembled very early, to learn their exercises in private, without any spectators. 3. The *coryceum*, *apodyterion*, or *gymnasterion*, a kind of wardrobe, where they stripped, either to bathe or exercise. 4. The *elæothesium*, *alipterion*, or *unctuarium*, appointed for the unctions, which either preceded or followed the use of the bath, wrestling, pancratia, &c. 5. The *conisterium*, or *conistra*, in which they covered themselves with sand, or dust, to dry up the oil, or sweat. 6. The *palæstra*, properly so called, where they practised wrestling, the pugillate, pancratia, and divers other exercises. 7. The *sphæristerium*, or tennis-court, reserved for exercises wherein they used balls. 8. Large unpaved alleys, which comprehended the space between the porticos and the walls wherewith the edifice was surrounded. 9. The *xysti*, which were porticos for the wrestlers in winter, or bad weather. 10. Other *xysti*, or open alleys, allotted for summer and fine weather, some of which were quite open, and others planted with trees. 11. The baths, consisting of several different apartments. 12. The *stadium*, a large space of a semicircular form, covered with sand, and surrounded with seats for the spectators. For the administration of the gymnasia, there were divers officers: the principal were, 1. The *gymnasiarch*, who was the director and superintendent of the whole. 2. The *xystarch*, who presided in the xystus or stadium. 3. The *gymnasta*, or master of the exercises, who understood their different effects, and could accommodate them to the different complexions of the athletæ. 4. The *pædotriba*, whose business was mechanically to teach the exercises, without understanding their theory or use. Under these four officers were a number of subalterns, whose names distinguished their different functions.

As to the kinds of exercises practised in the gymnasia, they may be reduced to two general classes, as they depend either on the action of the body alone, or as they require external agents or instruments. The former are chiefly of two kinds, *orchestice* and *palæstrice.*

The *orchestice* comprehended, 1. *Dancing*, 2. *Cubistice*, or the art of tumbling. 3. *Sphæristice*, or tennis, including all the exercises with pilæ, or balls.

The *palæstrice* comprised all exercises under the denomination of *palæstra;* as *wrestling*, *boxing*, *pancratia hoplomachia*, *running*, *leaping*, *throwing the discus*, the *exercise of the javelin*, and that of the *hoop*, denominated by the Greeks τροχος, which consisted in rolling an iron hoop five or six feet in diameter, beset with iron rings, the noise of which apprising the people to give way, afforded them also an amusement. Both strength and skill were requisite in directing this hoop, which was to be driven with an iron rod.

To these must also be added the exercises belonging to the medicinal gymnastics, as 1. *Walking.* 2. *Vociferation*, or shouting. 3. *Holding one's breath.*

The bodily exercises, which depended on external agents, may be reduced to *mounting* the horse; *riding* in a chaise, or other wheeled vehicle; *rocking* in beds or cradles, and sometimes *swinging:* to which may be added, the art of *swimming.* Hoffman enumerates no less than fifty-five sorts of gymnastic exercises.

The term *gymnasium* has descended to modern times. In Germany, the higher schools, intended especially as immediately preparatory to the universities, are termed gymnasia. Schools for the improvement of bodily strength, grace, or agility, are also called gymnasia. Within the last few years small portions of the newly-formed parks in the neighbourhood of London have been set aside for this purpose, and provided with the proper appurtenances for gymnastic exercises. To these the ancient word gymnasium is still applied.

GYNÆCEUM, (from the Greek γυνη, *a woman*, and οικος, *a house*,) among the ancients, the apartment of the women; or a separate place, in the inner part of the house, where the women kept themselves retired, employed in their spinning, out of the sight of the men.

Under the Roman emperors there was a particular establishment of gynæcea, being a kind of manufactories managed chiefly by women, for the making of clothes, furniture, &c., for the emperor's household. Mention is made of these gynæcea, in the Theodosian and Justinian code, and by divers other authors.

In imitation of these, divers of the modern manufactories, particularly those of silk, where a number of women and maids are associated and formed into a body, are called *gynæcea.*

GYPSOGRAPHY, a new method of engraving on plaster, to which this term has been given by the inventors. Gypsography, or metallic relief-engraving, is performed in the following manner. The surface of a copper-plate is prepared with a thin coating, or layer of plaster-of-paris, of uniform depth, through which the draughtsman etches with a point to the surface of the copper: he is enabled, as he proceeds, to observe the effect of every touch of the etching point. When the drawing or etching is completed, it forms a complete matrix or mould, and is cast in type-metal, in a similar manner to the process of stereotype-casting, and at once forms a block or plate, which must in every minute feature produce a perfect fac-simile of the original design of the artist, and from which, at the type-press or steam-machine, thousands of impressions can be worked in a few hours.

GYPSUM, a substance formed by the combination of sulphuric acid with calcareous earth.

Gypsum is found in a compact and crystallized state, as alabaster and selenite, or in the form of a soft chalky stone which in a very moderate heat gives out its water of crystallization, and becomes a very fine white powder, extensively used under the name of plaster-of-paris. This last is the most common, and is found in great masses near Paris, where it forms the hill Montmartre, near Aix in Provence, and near Burgos in Spain. It is found in smaller portions in various parts of Europe.

Of the different kinds of plaster the coarser sorts are employed, with the admixture of common lime-stone, for cements. The gypsum, which naturally contains carbonate of lime, makes very good cement; but that which has an admixture of clay and sand, affords a cement of an inferior quality.

The kilns in which the plaster-stones are burnt, are generally of a very simple construction; often they are built of gypsum itself. The fragments to be calcined are loosely put together, in such a manner as to form a parallelopiped heap, below which are vaulted pipes or flues, for the application of a moderate heat. The calcination must not be carried to excess, since in this case the plaster will be deprived of its quality of forming a solid mass when mixed with a certain portion of water. During the process of calcination, the water of crystallization rises as a white vapour, which, if the atmosphere be dry, is quickly dissolved in air.

On the river Wolga, in Russia, the burning of gypsum constitutes one of the chief occupations of the peasantry. They calcine all kinds of gypsum promiscuously, on grates made of wood, they then reduce the plaster to powder, pass it through a sieve, and form it into small round cakes, which they sell at from one, to one and a half rouble, per thousand.

In order to make use of the plaster, water is added to the powder, which is produced by pounding the calcined fragments; an operation performed either in mills constructed for the purpose, or by the hands of men. This work is exceedingly prejudicial to the persons employed in it, whose health is soon impaired by the pernicious effects which the dust of this substance has upon the lungs.

The less the gypsum intended for plaster is mixed with other substances, the better it is qualified for the purpose of making casts, stucco, &c.; the sparry gypsum, or selenite, which of course is the purest of all, is employed for taking impressions from coins and medals; and for those beautiful imitations of marble, granite, and porphyry, that are known by the name of *scagliola*, derived from the Italian word, *scagli*, or laminæ of selenite; the latter is vulgarly called *talc* in Italy and France, and also in England.

The *compact gypsum* of Kirwan (*alabastrite*, La Meth.; *albâtre gypseux*, de Lisle; *dichter gypstein*, Werner) when of a white, or yellowish, or greenish colour, semi-transparent, and capable of receiving a polish, is known among statuaries by the name of *alabaster*, which term is also retained as a secondary appellation in most books of mineralogy, and is certainly the *alabastrites* of Pliny, which is characterized by that author as a stone resembling gypsum. When its colours are disposed in bands or clouds, it is called, in the first case, *onyx alabaster*, and in the latter, *agate alabaster*. It not unfrequently contains a sufficient portion of carbonated lime to produce a brisk effervescence with nitrous acid; and hence has originated the confusion of authors, who make the circumstance of effervescence an essential distinctive character between the gypseous and calcareous alabasters. Its specific gravity seldom exceeds 1.9. Its fracture is compact, splintery, sometimes verging on the fine-grained foliated. In transparency, it is considerably superior to white wax, allowing light to pass readily through it, but not transmitting the forms of objects.

Gypseous alabaster is very easily worked, but it is not susceptible of a polish equal to marble. It is made into vases, columns, tables, and other ornamental articles of furniture; thin slabs of it have been used in one of the churches of Florence instead of window-glass. Its brittleness, however, and want of lustre, have caused it to be almost wholly superseded by more durable materials. Among the ancients, the most esteemed came from Caramania, Upper Egypt, and Syria: of the variety called *onyx*, the boxes for holding perfumes were mostly fabricated; thus, in Horace, we meet with "*Nardi parvus onyx.*"

The *calcareous alabaster*, or sinter, (*albâtre calcaire*,) is a stone of the same family as stalactite, consisting chiefly of carbonate of lime, and exhibiting a considerable variety of colours; such as pure white, yellowish, greenish, reddish, and bluish gray: its fracture is striated or fibrous, the striæ sometimes parallel and sometimes divergent: its hardness is somewhat inferior to that of marble, which nevertheless does not prevent it from receiving a good polish: its specific gravity from 2.4 to 2.8: its transparency is nearly equal to that of white wax: it effervesces with acids, and burns to lime. Two sorts of alabaster are distinguished by statuaries, the *common* and *oriental;* under the latter of these are ranked the hardest, the finest, and the best coloured pieces; a number of sub-varieties are also produced by the colours being in veins, or dentritic, or in concentric undulating zones. Italy and Spain yield the most beautiful specimens: the inferior kinds are found in Germany and France. It is manufactured, like the gypseous alabaster, into tables, vases, statues, chimney-pieces, &c.

Many of the hot sulphureous waters rise out of the ground of a turbid wheyish colour, on account of a large quantity of gypsum and chalk, which they hold suspended, and in a state of half solution; as these grow cool, and lose their carbonic acid, the earthy particles are for the most part deposited, lining the bottom and sides of the channels in which they flow with a compact alabaster. Advantage has been occasionally taken of this circumstance to obtain very beautiful impressions of bas-reliefs, by exposing the moulds to a current of such water till they have become filled with the earthy deposit. The most remarkable of these springs in Europe, is that which supplies the baths of St. Philip in Tuscany: it is situated on a mountain near Radicofani, and forms the source of the little river Paglia. The water as it issues forth is very hot, springs out with great impetuosity, has a strong sulphureous odour, and holds in solution a large quantity of calcareous matter. From its very source it flows in deep channels, covered with a thick crust of stalactite, of a dazzling white, especially when the sun shines upon it; and which is harder or softer in proportion to the rapidity of the stream, and the obliquity of its fall. This circumstance suggested to Dr. Vegni, the idea of establishing on this mountain, a manufacture of artificial alabaster. For this purpose, he first collected a number of plaster-models, of the best bas-reliefs, in Rome and other places of Italy. These models serve to form the hollow moulds which are made of sulphur, according to the following process. The plaster model is rubbed over with boiled linseed oil, and surrounded with an edging of plaster, of the same height as the intended thickness of the subsequent bas-relief. Then sulphur, melted with just sufficient heat to make it flow, is poured on the plaster-model, and fills it to the height of the edging. The sulphur mould thus made, is placed in a kind of wooden tub, roughly put together, open at top and bottom, and of less diameter below than above. This tub has on the inside a false bottom, made of slips of wood laid cross-wise, in order to detain, for a short time, the water which dashes on them. Just above this is a row of wooden pegs, fastened to the tub, around its whole inner circumference, on which the sulphur mould is let down, and thus supported. The whole is then placed under the boiling spring, and inclosed with walls, to prevent it from being displaced by the wind. The water, which dashing on the moulds, deposits its earth both within and without them, giving the impression of bas-relief within, and disposing itself in an undulated surface on the outside. The hardness of the alabaster depends on the degree of obliquity at which the mould is placed in order to receive the dashing of the water. The more vertical its position, the harder is the alabaster. However, as the hardest models are not so white as the softer, the water is in some cases caused to make a circuitous course, in order to deposit all its grosser particles before it arrives at the mould. Even the softer ones, however, are as hard as Carrara marble, and surpass it in whiteness. The time required for these productions varies, according to the thickness, from one month to four. When the sulphur mould is sufficiently filled, and the ground of the model has acquired a thickness capable of supporting the figures, the whole is removed from the water; the wooden supports are broken by gentle strokes of the hammer, and the incrustation on the outside of the mould is chipped off by repeated strokes. Then the tub is struck with a smart blow of a hammer, which separates the model from the mould; generally, however, cracking the latter. The brilliancy of the models is completed by brushing them with a stiff hair-brush, and rubbing with the palm of the hand.

The composition of this alabaster is gypsum, mixed with a small proportion of carbonated lime. Dr. Vegni, after many attempts, succeeded in giving a fine black, or flesh colour, to the figures thus formed, by putting a vessel half full of colouring matter into the water, before it arrives at the mould. The colouring may be also varied, by protecting particular parts of the mould, while the water continues charged with colouring matter.

A spring of the same kind as that just described, and applied to similar purposes, is that of Guancavelica in Peru. The water rises from the ground into a large bason, boiling hot, and of a muddy yellowish-white colour. At a little distance from the bason, the water becoming cool, deposits calcareous matter in such vast abundance, as to fill large moulds with a compact stone, of which some of the houses of the town are constructed. The moulds of statuaries, in like manner, being exposed to the water, are filled with hard, confusedly crystallized alabaster, and the bas-reliefs thus produced, by polishing, become semi-transparent, and very beautiful. The images made use of by the Catholics of Lima, in their religious ceremonies, are said to be formed in this manner

Gypsum, pulverized by grinding or burning, has been used as a manure in France and America; and its fertilizing properties highly extolled. The use of it in this country, however, does not seem to have been attended with similar successful results.

H.

HACKING, in walling, the interruption of a course of stone, by introducing another course upon a different level, in consequence of the want of stones to complete the whole thickness; and thus frequently making two courses at one end of the wall or pier, of the same height with one course at the other end. The last stone laid in one height is frequently notched, to receive the first stone of the other, where the two heights commence. Hacking is never employed in good workmanship, and ought always to be guarded against by the superintendent, in case of work performed by contract where the contractor furnishes the stones. The term is used in Scotland, and particularly in Glasgow.

HALF-MOON, in fortification, the same as RASELIN; which see.

HALF ROUND, a semicircular moulding, which may be either a *bead* or *torus*.

HALF SPACE, or PACE, as it is sometimes called, a resting place in a double parallel-flighted stair, where the higher riser of the lower flight is in the same vertical plane with the lowest riser of the higher flight. Also any raised platform such as the dais at the upper end of the halls of the middle ages.

HALF-TEINT, now more generally written Half-Tint, in painting, is, precisely speaking, the teint which lies exactly midway between the extreme light and the extreme dark which any colour is capable of receiving and reflecting. But painters use it in a far more general sense, viz., as inclusive of almost all the intermediate gradations between these two points; and therefore regard all objects, in what relates to colour and chiaro-oscuro, as composed of these three—*light*, *dark*, and *middle-tint*, or *half-tint*.

How much of the vision of objects is included within the sphere of half-tint, may be illustrated by imagining a ball of ivory placed opposite the sun, and viewed in nearly the same direction. In this situation, a small portion of it will reflect an image of the sun to the eye of the observer, which image, in the language of artists, will be termed its *high-light*. Towards its lower part a very small portion will be lost in shade. The far greater part of the ball, not reflecting light enough to come under the former of these denominations, nor being sufficiently deprived of it to receive the latter, is recognized under the term we are now discussing.

When pictures therefore represent the ordinary effect of day-light, where the illumination produces breadth of light, as the sun does, and still more in that kind of light produced by an illumined atmosphere when the sun is not clearly seen, it is evident that half-tint must be the reigning portion of tone and colour in them. Add to this that as objects recede in the plane of the picture from the source of light, they fall into comparative half-tint, their high-lights and shadows participating of the hue with which the intervening atmosphere envelopes them. From both these causes it may fairly be reckoned that nine-tenths at least, and a greater proportion occasionally, in subjects of this nature, will be half-tint, unless artificial shadows are introduced.

This being the case, too much attention cannot be given to the management of the half-tint, as it produces the prevailing tone of colour in the picture. The difficulty lies in giving each colour introduced a gradation participating of the same hue, but at the same time preserving the true characters of the original colours in the whole. The reason of blending this one hue with all colours is made evident by considering the mode of operation adopted by nature, in which all gradations of shade are the effect of privation of light, and consequently of colour, which depends upon it, till at last every colour is lost in one dark hue, by the total lack of illumination; and that hue is alike with all. It is that hue, therefore, in different degrees, which produces the gradation from extreme light to dark, and which, acting equally on all, produces harmony in the effects by breaking each with a participation of itself.

This is the simplest mode of producing the half-tint, and maintaining it with an harmonious effect throughout the various parts of a picture. It will of course allow of intermixtures of reflections, either from parts of the same body, as in the folds of draperies, or from different coloured objects acting upon each other; and thus with its simplicity, richness and variety may be combined. What the hue of the dark shade with which it is produced, may be, depends entirely upon the taste of the painter, and the nature of the illumination. One only rule can be given. It ought, in its mixture with the light, or local colour, to produce a tint more cool than that in its hue.

HALF-TIMBERED HOUSES, such as were in use during the reign of Elizabeth, and the period immediately preceding. They consisted of wooden framing, filled in with plaster, and had a very picturesque appearance.

HALL, (Saxon) a word anciently used for a mansion-house or habitation.

HALL, (French, *salle*) in architecture, a large room at the entrance of a fine house, palace, or the like.

Vitruvius mentions three sorts of halls: the *tetrastyle* which has four columns supporting the plafond or ceiling; the *Corinthian*, which has columns all round, let into the wall, and is vaulted over; and the *Egyptian*, which had a peristyle of insulated Corinthian columns, bearing a second order with a ceiling: these are called *œci*. The hall is properly the first and finest partition or member of an apartment; and in houses of ministers of state, public magistrates, &c., is that wherein they dispatch business, and give audience. In very magnificent buildings, where the hall is larger and loftier than ordinary, and placed in the middle of the house, it is called a *saloon*.

The length of the hall should be at least twice and a quarter its breadth; and in great buildings three times its breadth. As to the height, it may be two-thirds of the breadth; and if made with an arched ceiling, it will be rendered much handsomer, and less subject to accidents from fire. In this case, its height is found by dividing its breadth into six parts, five of which will be the height from the floor to the under side of the key of the arch.

A royal apartment is said to consist of a hall, or chamber, of guards, *aula prætoriana;* an ante-chamber, *procamera;* a chamber, *camera;* a cabinet, *conclave;* and a gallery, *porticus.*

Hall, also the principal apartment in the castles and mansions of the middle ages. These were usually of great length and size, having the chief entrance at one end, where was a screen surmounted with a minstrel's gallery. At the farther end was a raised platform or dais, with frequently an oriel window on one or both sides, where the principal guests dined. The fire-place was sometimes in the middle of the hall, with an aperture in the roof for the escape of the smoke; but at others at the side, with a chimney carried up in the walls. The aperture in the roof was often covered by an open lantern.

Amongst the larger halls in England, may be reckoned those of Westminster, and Crosby Hall, London; Eltham, and Penshurst, Kent; and that of Hampton-Court.

Hall, a public building erected for the administration of the police and justice of a city or corporation.

In this sense we say the *town-hall*, a *company's hall*, &c.

A stately building in the city of London, and the great court of judicature for that city, is called *Guild-hall;* and many of the City companies have very fine buildings, called their Halls, as the Goldsmiths' Hall, Fishmongers' Hall, &c.

Hall is also particularly used for a court of justice; or an edifice wherein there is one or more tribunals.

In Westminster-hall are held the great courts of this kingdom, viz., the Chancery, Exchequer, Queen's Bench, and Common-Pleas.

In adjoining apartments is likewise held the high court of parliament. Westminster-hall was the royal palace, or place of residence, of our ancient kings; who ordinarily held their parliaments and courts of judicature in their dwelling-houses, and frequently sat in person in the courts of judicature, as they still do in parliament.

The great hall, wherein the courts of Queen's Bench, &c. are kept, is said to have been built by William Rufus; others say by Richard I. or II. It is reckoned superior, in point of dimensions, to any hall in Europe; being 238 feet long, and 68 broad.

HALVING, a method of joining timbers by letting them into each other: it is preferable to mortising, even where the timbers do not pass each other, as they are less liable to be displaced by shrinking.

HAM, a Saxon word, signifying a house.

Ham, is also used to denote a street or village; whence it is, that the names of many of our towns end in *ham*, as Nottingham, Buckingham, &c.

HAMMER, an instrument used by carpenters, for driving nails, spikes, &c.; and by masons, for reducing stone, by breaking it in chips.

HAMMER-BEAM, a transverse beam at the foot of the rafter, in the usual place of a tie. Hammer-beams are constructed in pairs, having each a beam disposed on opposite sides of the roof. They are chiefly used in roofs constructed after the Gothic style; the end which hangs over, being frequently supported by a concave rib, springing from the wall as a tangent to the curve, and in its turn supporting another rib forming a Gothic arch with the counter-part. The ends of hammer-beams are decorated with various devices.

HANCES, or Haunches, the arcs of circles forming the ends of arches described with compasses, in imitation of elliptic arches. The figure representing the whole ellipsis is generally described with four circular segments, of which those that are opposite are equal to each other, and are bisected by each extremity of each axis; the two arcs which terminate the greater axis are called the *hances*, and those which terminate the shorter, the *schemes.*

HAND, a measure of four inches.

Hand-Irons. *See* End-Irons.

Hand-Rail, of a stair, a rail raised upon slender posts, called *balusters*, intended to assist persons in ascending and descending, and to protect them from falling down the well-hole.

Hand-Railing, the art of making hand-rails by moulds, according to geometrical principles.

The art of forming hand-rails was never, before the publication of the *Carpenter's Guide*, subjected to any certain geometrical principle. The best method then known, was that of tracing it, like an angle-bracket, from the rise and tread of as many steps as the rail was supposed to occupy in winders, and making the face-mould of a parallel breadth, after obtaining the middle of the concave side. This is manifestly false; and the magnitude of the error will be greater as the circumference of the arc at the plan of the rail is greater than its chord. A rail, or any portion of a rail, formed upon this principle, could never stand vertically over its plan. The method here shown is founded upon the following principles: that if a cylinder be cut in any direction except parallel to the axis or base, the section will be an ellipsis; if cut parallel to the axis, its section is a rectangle; and if parallel to the base, its section is a circle.

Let us suppose a hollow cylinder made to a given plan, the interior will be concave, and the exterior convex; and let this cylinder be cut by any inclined or oblique plane, the section formed will be bounded by two concentric similar ellipses; consequently, the section will be at its greatest bread that each extremity of the greater axis, and at its least breadth at each extremity of the lesser axis. Therefore, in any quarter of the ellipsis, there will be a continued increase of breadth from the extremity of the lesser axis to that of the greater. Now a cylinder can be cut by a plane through any three points; therefore suppose we have the height of the rail at any three points in the cylinder, and cut the cylinder through these points, the section will be a figure equal and similar to the face-mould of the rail; and if the cylinder be cut by another plane, parallel to the section, at such a distance from it as to contain the thickness of the rail, this portion of the cylinder will represent a part of the rail with its vertical surfaces already wrought; and if the back and lower surface of this cylindric portion be squared to vertical lines, either on the convex or concave side, through two certain parallel lines, drawn by a thin piece of wood bent upon that side; the portion of the cylinder thus formed will represent the part of the rail intended to be made.

The principles upon which this art depends are those of cutting a right prism through any three given points in space, and of forming a development of any portion of the surface of the prism.

Thus, let the interior surface of the surrounding wall be that of an entire cylinder, the breadth of the steps divided into the frustums of equal and similar sectors, and the heights all equal, as is universally the case; then, if an interior cylinder surface be erected concentric with the wall, and the ends of the steps or surfaces to be trodden upon, and the planes of the risers tending to the axis be supposed to meet the interior cylindric surface, it is evident that if the portion of the intercepted surface contained between the indented line formed by the ends of the steps, and the circumferent line at the base be developed, or stretched out, all the points of the indented line formed by the outward or salient angles, will be in the same straight line, and all the points formed by the inward or re-entrant angles will be in another straight line. It is equally evident, that this will not only be the case with cylinders, but with cylindroids, and every other description of prisms: that is, the points of the development of the indented line will always have such a position, that two straight lines parallel to each other may be drawn through the whole number of them.

The points of concourse of the salient angles, are called *the nosings of the steps.*

The line drawn through all the nosings of the steps, is called *the line of the nosings.*

Now let the portion of the cylinder before uncovered, be again enveloped, the development in this state becomes an envelope, and the line of nosings becomes a uniform helix, which would be the form of the rail for such a stair.

In this case, it would be easy to execute the rail to any length, in equal portions succeeding each other; for as the curvature of the helical line is everywhere the same, the same moulds which are used in the formation of one piece, would serve for every succeeding piece.

The steps around the circular part are termed *winders;* in these the risers tend to the axis of the cylinder.

Steps with their treads of the same breadth, are termed *flyers;* in these the risers are all parallel.

Very few staircases are entirely circular; but those of the semi-circular form, with winders in the semicircle, and flyers below and above, are very numerous; in such, the line of nosings would be crooked, and would form an angle at the junction of the flyers and the winders, and that round the semicircle would be an helix, consisting of half a revolution.

In the development of the steps, the line of nosings would consist of three straight lines; the two straight lines through the nosings of the flyers, would be parallel to each other, and each extremity of the middle one would join one extremity of each of the other two; but the angles are commonly taken away, by introducing a curve in their places.

A hand-rail, however, is not a mere helical line, but a solid, which may be contained between two concentric cylindric surfaces, or concentric prismatic surfaces. The principles are the same, whatever be the form of the plan. A solid erected upon any plan, is called *a prism;* a cylinder is therefore a round prism, and a cylindroid an elliptic prism. A hand-rail may stand upon a circular base, or partly circular and partly straight, or upon an entire elliptic base. In the construction of hand-rails, all prisms are excluded, which consist of plain surfaces; or, which is the same thing, where the sides of the plan consist entirely of straight lines; as in such cases, the rails themselves are either straight, or partly curved and partly straight upon the top and lower sides only, the sides being in vertical planes.

Let us therefore confine ourselves to prisms upon a circular or an elliptic base, or upon a base partly circular and partly straight; or lastly, upon a base partly elliptical and partly straight. The two last may be said to have compound bases or plans, and the two former simple bases or plans. Such a prism may be denominated *a curved prism.* The plan of any curved prism is understood to be of the same breadth, and consequently the solid erected thereon will be everywhere of the same thickness. The prism may therefore be a hollow cylinder, or a hollow clyindroid, or a concave body, partly cylindric and partly straight; the latter may be open on one side, and may have the four planes which join the curved surfaces parallel to each other, and tangent to each of the cylindric surfaces.

Let us therefore suppose such a prism as that last mentioned, to be cut entirely through its vertical surfaces, in such a manner that any point in the surface of division may coincide with a straight line everywhere perpendicular to the external prismatic surface, then, every such line will be parallel to the plane of its base, and those lines in the cylindrical part of the prism will tend to the axis. Now it is evident, that the cut, or dividing surface, will not be a plane, but will wind or twist between the cylindric surfaces. It is also evident, that the cut may pass through a line drawn in any manner we please, in one of the prismatic surfaces; or, that the development of this line may have any degree of curvature in the whole length, or in any portion of the length, or may even be a straight line. One of these being supposed to be the case, let the upper part of the prism be taken away, then the upper surface of its remaining part will be brought to view; let a line be drawn on the exterior surface parallel to the arris, and another on the concave side parallel to its arris; and let another cut or dividing surface be made to pass through the two lines thus drawn, and let the upper part be removed by this division; then the part thus removed will form a solid helix, or kind of half screw, which may be either uniform in its upper and lower surfaces, or have any degree of curvature in any part that may be required, according to the development before mentioned. This is the form of the rail for such a stair; but to form the solid helix, without cutting it from a hollow curved prism, is what is required in hand-railing.

Now, as two of its sides are actually cylindrical, and would be vertical if placed in position, and the other two winding surfaces may be formed to any development desired; take any determinate portion of the helical solid, as a quarter of a revolution, or perhaps something more, as occasion may require, and endeavour to form such a portion, or wreath, out of a thin plank, instead of cutting it from a solid curved prism. Before this can be done, it is necessary to understand the principle of cutting a prism through any three fixed points in space, by a plane passing through those points; the points may be in the surface of the prism itself, and may be either all in the concave side, or all in the convex side; or partly in the concave side, and partly in the convex side;—that such a supposition is possible will readily appear, since any three points are always in the same plane; and, therefore, the plane may cut the prism through any three given points.

The three points through which the section is cut, are said to be given, when the seats are given on the plane of the base of the prism, which plane is understood to be at right angles to the axis of the prism, and when the distances or heights from the seats to the points themselves are given.

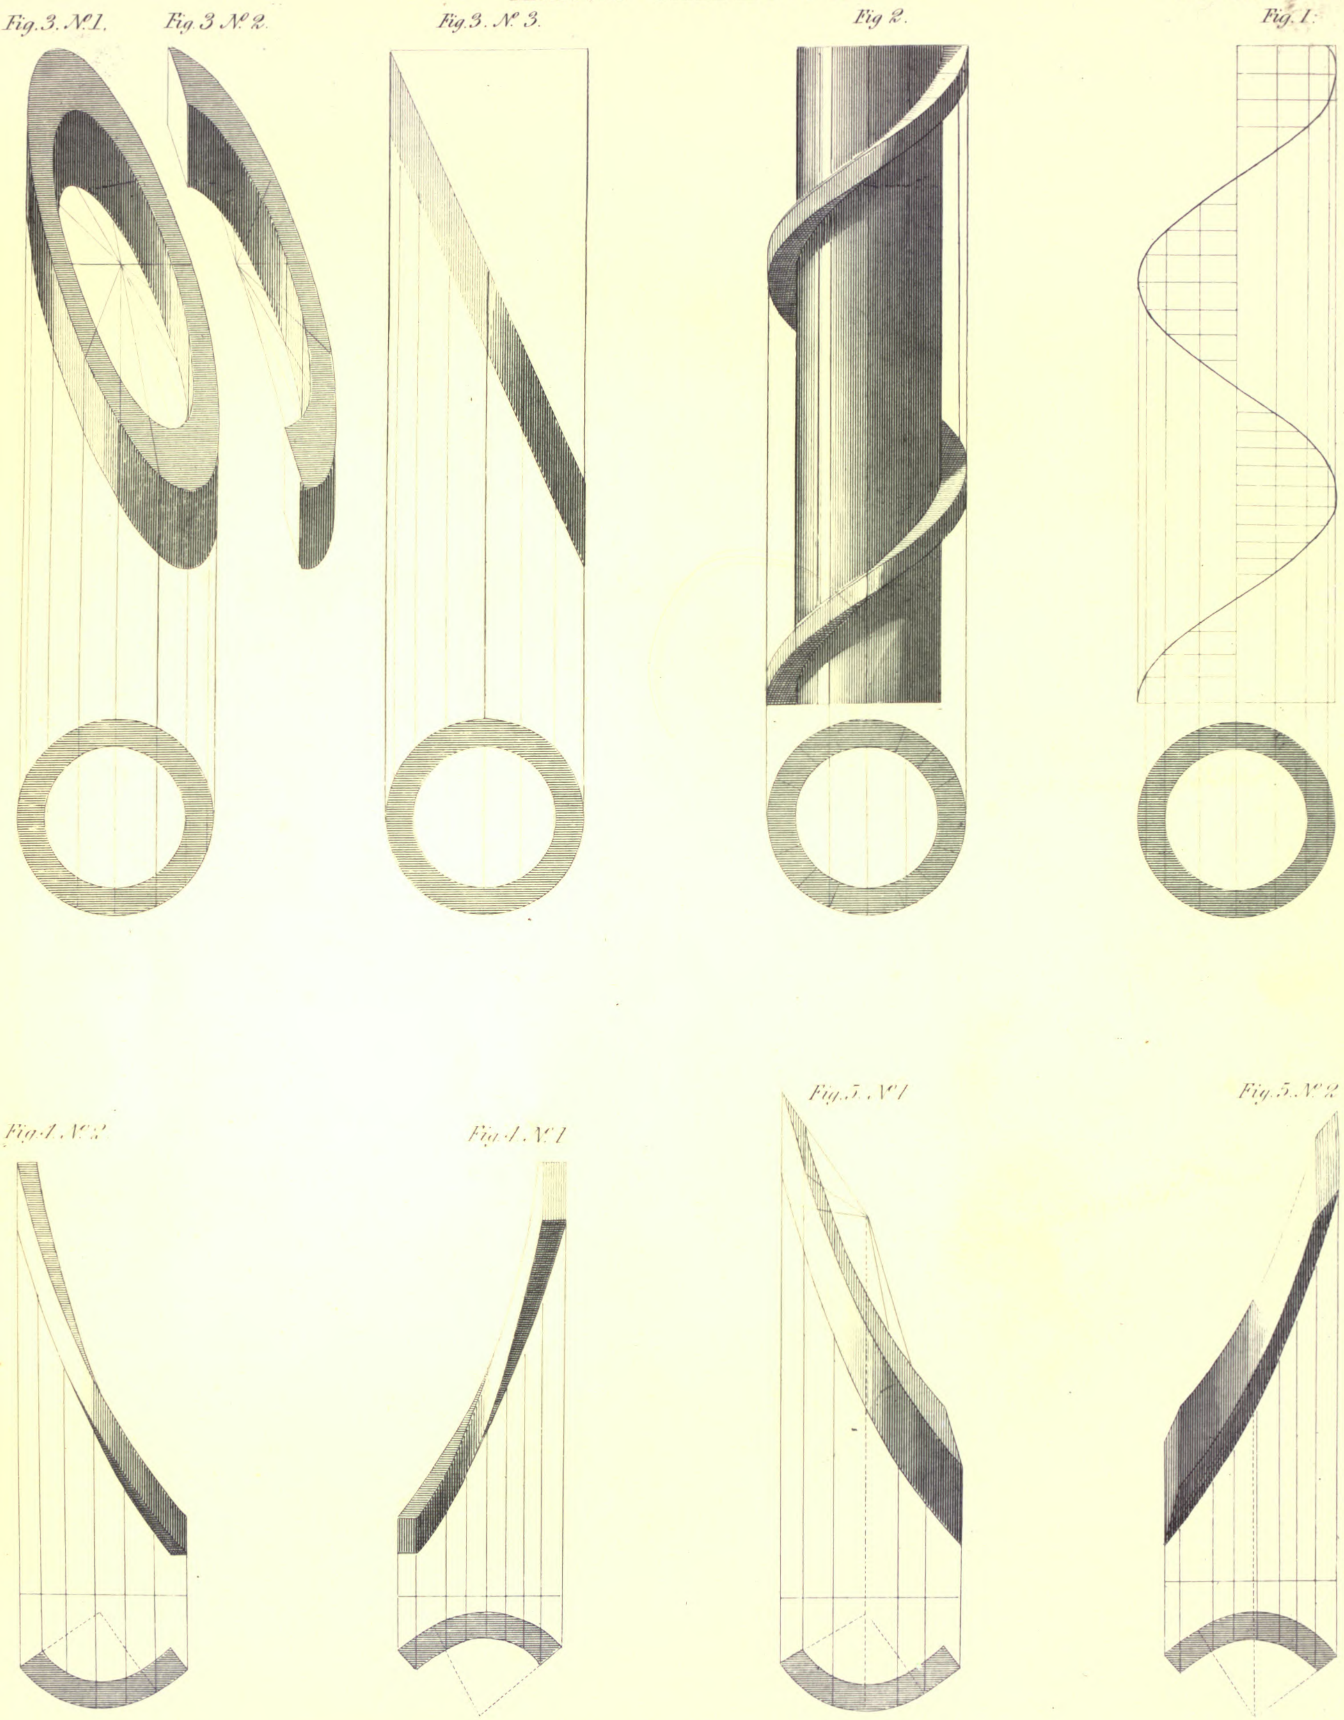
It is always to be understood, that the three seats are not in a straight line, and consequently the three points themselves not a straight line.

The seat of a point in space on any plane, is that point in the plane where a perpendicular drawn through the point in space cuts the plane.

In the helical solid, the winding surface connecting the two prismatic surfaces, has been defined to be of such a property as to coincide with a straight line perpendicular to the exterior prismatic surface, and, consequently, if the axis of the curved prism be perpendicular to the horizon, every such line will be parallel to the base; now, let the seats of three such lines be given on the plan, viz., let each extreme boundary be one, and let another be taken in the convex side passing through the point, which would give the middle of the development of the said side of the plan; the three seats would be terminated by the convex and concave sides of the plan, and will always be perpendicular to the convex side, and equal in length to each other. Call the three level lines,

HAND RAILING.

PLATE. VIII.



A. Nicholson, del.

of which their seats are given, *the lines of support;* let a plane be laid on the three lines of support, and it will rest either upon three points, or upon one of the said lines and two points; hence the points which come in contact with the plane, will be at one extremity of each line of support; let each of the points, which come in contact with the plane thus posited, be called *a resting point.* The three resting points are the three points in space, through which the plane is supposed to pass that cuts the curved prism.

Now because each line of support has two extremities, there will be six extreme points in all, but as only three can be resting points, unless the plane coincides with one of the lines of support, it will be proper to show, which three of the six are the resting points. Let the plane, thus laid upon some three extremities of the lines of support, be continued to intersect the base of the curved prism, then the nearest extremity of the seat of any line of support, to the intersecting line, is the seat of the resting point of that line. For this purpose, let a development of the convex side of the rail be made according to the plan and rise of the steps. The part of this development that is made to bend round the concave or convex cylindric surface of the helical portion or wreath, is called a *falling-mould,* which is supposed to be brought to an equal breadth throughout its length. Only one falling-mould is used in the construction of hand rails. Let therefore the falling-mould for the convex side be constructed, and let two straight lines be drawn from the ends of the upper edge of that part of the falling-mould corresponding to the ends of the wreath perpendicular to the base of the whole development; also let another intermediate line be drawn parallel to the other two, so as to bisect the part of the base intercepted by the said two parallels, the three parallels will give us the heights of the three resting points, the shortest height is at one extreme, and the longest at the other. Suppose now the shortest of these three heights taken from each of the three, and the remainders taken as heights, instead of the whole, then the height of the first resting point will be nothing and will therefore coincide with its seat; and if the middle height be less than half the length of the remaining height, the seats of the resting points will be the first and second extremities of the first and second lines of support taken on the convex side, and the extremity of the third on the concave side. The first resting point is a point in the intersection of the plane of the base with the inclined plane.

The process is now completely reduced to that of finding the section of a prism through three given points, which suppose to be done, and the plane of section will touch the supposed wreath at the resting points of each line of support without cutting the wreath at any such line; then the three lines of support will be on the same side of the plane, viz., on the under side. Suppose now another section taken below, and parallel to the former, so that the wreath may be just contained between these parallel sections or planes, and the distance between the two sections will represent the thickness of the plank. The section of the prism through its vertical surfaces is called *the rake* or *the rake of the plan;* and a mould being cut to the rake is called *the face-mould.*

The manner of forming a helical line or screw is as follows:—

Plate VIII. *Figure* 1. Divide the circumference of the outer circle of the base into equal parts; draw a line through the centre to represent the axis of the cylinder, parallel to the axis, and through the points of division in the outer circumference draw lines; divide the line of heights or the line representing the axis, into as many equal parts as the circumference of the base is divided into, and through the points of division draw lines at right angles to the axis, intersecting, as in the figure; through the points of intersection, draw a curve which will represent the helix, or one of the arris lines of the rail.

Figure 2.—The projection of the solid helix coiling round the cylinder; which helix represents the hand-rail before it is moulded.

Figure 3.—No. 1.—A solid section of a cylinder contained between two parallel planes, a part of the side of this solid contained between two planes passing through the axis is the form of a piece from which the rail is made after it is cut out of the plank. No. 2, half the solid section, No. 3, the inclination of the cutting planes.

Such large portions as these, however, are by no means proper to be employed in hand-railing, as the size would necessarily occasion the fibres of the wood to run in a transverse direction to the length of the rail, and consequently weaken it, but they are useful in this place to convey clear ideas of the principle upon which the art is founded.

Figure 5.—No. 1.—The proper form of a part from which a portion of the rail is to be made after it has been cut out of the blank; exhibiting the convex side of the same, and the upper plain surface, which is that of the plank. No. 2. The concave side of the same, with the joints and lower surface of the plank.

Figure 4.—A portion of the rail completely squared with the concave side, the joints, the bottom part of the upper winding surface, and the upper part of the lower winding surface, brought into view. No. 3. The convex side of the same, showing the upper part of the upper surface, and the lower part of the lower surface.

The business of hand-railing is to find the mould for cutting a rail out of planks.

Though hand railing is only treated of here, as connected with cylindrical well-holes: it is equally applicable to rails erected upon any seat whatever.

The mould, which applies to the two faces of the plank, regulated by a line drawn on its edge, so as to be vertical when the plank is elevated to its natural position, is called the *face-mould*; or sometimes the *raking-mould.*

A parallel mould, applied and bent to the side of the rail-piece, for the purpose of drawing the back and lower surface (which are to be so formed that every level straight line, directed to the axis of the well-hole, from every point of the side of the rail formed by the edges of the falling-mould, shall coincide with the surface) is called a *falling-mould.*

When the upper surface of the plank is not at right angles to a vertical plane passing through the chord of the plan, in order to cut the corresponding portion of the rail out of the least thickness of wood, the plank is said to be *sprung.*

A right-angled triangular board, made to the rise and tread of a step, is called the *pitch-board.*

In a stair-case, where there are both winders and flyers, two pitch-boards will be concerned, of different treads, but of the same heights, as the height of the steps must be equal.

The bevel by which the edge of the plank is reduced from the right angle, when the plank is sprung, in order to apply the face-mould, is called *the spring of the plank;* and the edge or narrow side thus reduced, is called the *sprung edge.*

The bevel by which the face-mould is regulated to each side of the plank, is called the *pitch.*

The formation of the upper and lower surface of a rail is called the *falling of the rail.*

The upper surface of the rail is called *the back.*

The first thing in the practice is to spring the plank, then to cut away the superfluous wood, as directed by the draughts formed by the face-mould. This may be cut so very exactly with a saw, by an experienced hand, as to require no further reduction; and when set in its place, the surface on both sides will be vertical in all parts, and in a surface perpendicular to the plan. In order to form the back and lower surface, the falling-mould is applied to one side, which is generally the convex side, in such a manner, that the upper edge of the falling-mould at one end may coincide with the face of the plank, the same in the middle, and to leave so much wood at the other end to be taken away, as not to reduce the plank on the concave side. The piece of wood to be thus formed into the wreath or twist, being agreeable to three given heights. This description is general, in order to comprehend the following construction of the moulds themselves, which when explained, we shall then enter into a more particular detail of their application.

To construct the falling and face-moulds of a rail to a level landing, supposing the plane of the plank to rest upon the middle point of the section, which separates the upper and lower circular parts, and to rest upon the line parallel to, and in the middle of the straight part, so as to have the grain of the wood parallel.

Plate I. *Figure* 1.—The falling-mould of the hand-rail: B C the extension of the semicircular part; B A and C D the treads of the adjoining flyers.

To find the extension of the semicircular part, from the middle point, I, of B C, draw I K L perpendicular to B C; divide the radius I K into four equal parts, and repeat one of these parts from K to L seven times; draw the diameter M N parallel to B C; join L M and L N, and produce each of these lines to B and C; then B C is the rectification of the semi-circumference M I N. Draw B T and D H perpendicular to A D; make B E equal to the height of a step; I O on the straight line I L, one step and a half; C F equal to the height of two steps; and D H equal to the height of three steps; join A E and H F, and through O draw P Q parallel to B C; produce A E and H F to meet P Q at P and Q; then cut off the angles at P and Q by equal touching curves, one at each; then A E O F is the middle of the falling-mould; and as the rail is generally made two inches deep, draw two parallel lines each an inch distant from this central line, and S U & will be the upper edge of the falling-mould, and δ Y J the lower edge.

To find the face-mould of the hand-rail.

Figure 2.—At any convenient place lay down the half plan, *a b c d e f a*, of the hand-rail; *a b c f* being the straight part of the rail, and *c d e f* the plan of the circular part; draw *g e d* parallel to *a f* or *b c*; bisect *d e* at *h*, and draw *h i* perpendicular to *g d*; make *h i* equal to I U, *Figure* 1, and the angle *h i k* equal to the angle G H F; let *h* represent the middle point of the section between the two circular parts; and suppose *n* to represent the resting point in the middle of the section, which separates the straight and circular parts; make B R, *Figure* 1, equal to *c b* or *f a*, *Figure* 2, and draw R S, *Figure* 1, perpendicular to A B, cutting the upper edge of the falling-mould at S; make *h r*, *Figure* 2, equal to B T, *Figure* 1, and draw *r s*, *Figure* 2, parallel to *g d*, cutting *i k* at *s*; make *h m* equal to *r s*, and join *m n*, which is the directing ordinate; from *k* draw *k l* parallel to *m n*, and *k l* is the intersection of the plane of the plank; find the countersection *k t*, as in the SECTIONS OF CYLINDERS, or as in the subsequent part of this Work, under SOLID ANGLES.

To find any point in the curve of the face-mould.—Draw *u v w* parallel to *k l*, cutting *k d* at *u*, and the concave side of the plan at *v*, and the convex side at *w*; draw *u x* parallel to *h i*, cutting *k i* at *x*; draw *x y z* parallel to *k t*; make *x y* equal to *u v*, and *x z* equal to *u w*; then *y* is a point in the concave side of the face-mould, and *z* is a point in the convex side. The pitch-bevel shown by the dark lines, is found by drawing a vertical line to the pitch-line, and the angle formed by these lines is the pitch-bevel.

In this manner as many points may be found as will be necessary to complete the concave and convex sides of the falling-mould; or rule each system of lines at the same line, thus; take as many points in the convex side of the plan as will be found requisite; through all these points draw lines parallel to *k l*, to cut *g d*; from all the points of division in *g d* draw lines parallel to *h i*, cutting *k i*; through all the points of division in *k i* draw lines parallel to *k t*; terminate each line from the point of intersection equal to the corresponding outer and inner ordinates of the plan, and through the points found by its concave side draw a line; also through the points found by the convex side of the plan draw another curve: then the corresponding points found for each extremity of the plan will complete the face-mould. It is evident that the parts 3-4, 5-6 of the face-mould corresponding to *a b*, *c f* on the plan, is a parallelogram, therefore if the point 6, where the concave side and the straight parts meet, and the point 5, where the convex and straight parts meet, are found and joined by the line 5-6; and if 5-4 and 6-3 be drawn parallel to *k i*, and the point *q* corresponding to *o*, be found, by drawing 4-3 through *q*, the straight part of the face-mould will be completed.

The line of separation 5-6 will be more exactly determined as follows: Through *n* draw *n* 7 parallel to *h i*, cutting *k i* at 7; then find only one of the points 5 or 6, say 5; draw 5-7; then 5-6, which is a part of 5-7, is the line of separation.

This face-mould will answer for the upper, as well as the lower half.

The angle *l* 2-1 is the spring of the plank, and is found in the same manner as in solid angles, and having the intersection and cointersection, the face-mould is found as in the sections of a cylinder. The face-mould might have been found as in *Figure* 3, by taking the heights from a line drawn over the face-mould parallel to A D, *Figure* 1, and laying the plan upwards, as in *Figure* 3, then proceeding with the operation downwards, as directed in *Figure* 2 upwards. Or, if the drawing is inverted, the line V H, *Figure* 1, will become the base of the heights, and everything else will be in the same position as in *Figure* 2.

In the application of the moulds, imagine the plank set up to the pitch, and in the same way spring the edge from the under side for the lower piece, and from the upper side for the upper piece. To apply the moulds to the plank, now supposed to be sprung or beveled, take the pitch and draw the vertical line, the stock of the bevel being applied to the acute edge of the plank, upwards or downwards, as the case may require: then draw a line equal to the distance of 3-6 from *k i*, upon each plane of the plank parallel to the side; then the point 8 being kept to the end of the vertical line, and the side 3-6 upon the parallel line, draw round all the edges of the mould; turn the mould to the other side, apply the point 8 to the other end of the vertical line, and the part 3-6 upon the line drawn parallel to the face, and draw round all the edges as before; then cut away the superfluous stuff. The sides of the piece intended to form the twist must be perfectly cylindrical, and all the parts so formed, that a straight line or edge may apply to any point, at the same time that it coincides with the surface, and is parallel to the vertical line drawn on the edge of the plank.

The falling-mould is thus applied: Draw a line upon the ends of the solid piece, at right angles to the vertical sides, from *zero* at each end, next to the upper side; then apply the upper edge of the face-mould next to the top of the plank, and each end to the corresponding end of the piece, bending it so that all parts may be in contact with the stuff; then

draw a line round all the edges, and it will show the superfluous wood to be cut off.

To construct the face-mould of a hand-rail to a stair upon a level landing, in two parts, round a semicircular newel; so that when the two pieces are united or fixed in their places, the grain or fibres of the wood will mitre at the joint.

Plate II.—Let *Figure* 1 be the rail stretched out, as in the preceding example: draw the chord of the rail, *i k*, *Figure* 2, No. 1; bisect the end *k u* at *a*, and the other end *i w* at *c*; draw *j z b c* perpendicular to the chord *k i*, cutting the concave and convex sides at *z* and C; make *z b* equal to *i c*, and E C, *Figure* 1, equal to *w* C, *Figure* 2, No. 1, extended: draw C D, *Figure* 1, perpendicular to A E, cutting the upper edge of the falling-mould at D, and the lower edge at H. In *Figure* 2, No. 1, draw *a d* perpendicular to *k i*, and *c e* parallel to *a d*; make *a d* equal to A B, *Figure* 1; *c e*, *Figure* 2, No. 1, equal to E F, *Figure* 1; and *c f*, *Figure* 2, No. 1, equal to C D, *Figure* 1; join *a c* and *d e*, *Figure* 2, No. 1; draw *f g* parallel to *a c*, cutting *d e* in *g*; draw *g t* parallel to *e c*, cutting *a c* in *t*; join *t b*; draw *c y* parallel to *t b*, cutting the convex side of the plan at *y*; produce *y c* to cut the chord *k i* at 2; draw 2 *h* parallel to *c e*; make 2 *h* equal to *c e*; draw *k* K parallel to *a d*; make *k* K equal to *a d*; join *h* K; produce *h* K and *i k* to meet each other in *l*; draw *l m* parallel to *t b*: from any point, *m*, in *l m*, draw *m* 3 perpendicular to *l i*; produce *i l* to *p*, cutting *m* 3 at 3; through 3 draw 4 *n* perpendicular to *h l*; produce *h l* to 4; make 3 *o* on *p l* equal to 3-4; join *o m*; make 4 *n* equal to *o m*, and join *n l*: then draw ordinates on the plan parallel to *l m*, to cut both sides of it, and also the chord *k i*; from the intersections in *k i*, draw lines parallel to *c e*, to cut *h l*; from the points of section in *h l*, draw lines parallel to *l n*; make the lines thus drawn parallel to *l n*, equal to the corresponding lines on the plan; and a curve drawn through these respective points will give the face-mould.

In drawing ordinates upon the plan, care should be taken that an ordinate be drawn through the points upon each side of the plan at the line of separation of the straight and circular parts, and also through each extremity of the ends; or, by finding M N, the line of separation, and the point K, the point L will be found by drawing K L parallel to N M, and M L parallel to N K; and thus the portion M N K L, corresponding to *v x k u* on the plan, will be obtained.

The angle *p o m* gives the spring-bevel, *Figure* 2, No. 3; and the angle *s r q* gives the pitch-bevel, *Figure* 2, No. 2. The face-mould is applied to the plank by laying the points P and K close to the edge that is sprung; then drawing the pitch-bevel, No. 2, from either point P or K; for it is not necessary to draw them from both, as the corresponding point will be found upon the other side of the plank; then proceed with the remaining parts as before directed.

To spring the plank for a level landing through two given points, so as to parallel the grain.

Plate III.—Let No. 3 be the falling-mould, as before: draw any line, C A, for the base of the heights of the face-mould; then C D is the lower height, where the two wreathed pieces meet, and A B is the upper height, making allowance for the squaring of the joint. Lay down the plan A *k* C, No. 1; draw C *n* parallel to A *k*; draw A B perpendicular to A *k*; make A B equal to A B, No. 3, and the angle A B E, No. 1, equal to the angle V W S, No. 3; produce A *k* to E; draw C D parallel to A B; make C D equal to C D, No. 3, and the angle C D F equal to the angle A B E, that is, equal to the angle V W S, No. 3: produce *n* C to F; join F E; in F E take any point, E, and draw E I perpendicular to F C, meeting it in I; from I draw I K perpendicular to F O, cutting it in L; make I H equal to I L, and join H E; make L K equal to H E, and join F K; then F E is the director of the ordinates of the base, and F K that of the face-mould. Proceed with the rest as in *Plate* I. *Figure* 1.

No. 2 shows the other mould; but it must be observed, that one mould is sufficient for both wreaths.

Plate IV. shows the falling and face-moulds of a rail with winders. As to the method of laying down the moulds from three given heights, the principle is the same as described in *Plate* I. for a level landing. It therefore only remains to speak of the manner of forming the butt-joints. Draw a line at right angles to the sides of the falling-mould, through the middle of the vertical line, where otherwise would have been the splice joint; from the end of this line draw another at the upper edge, and also one from the under edge, perpendicular to the base line; then the middle height being taken as usual, the remote line is the height of the face-mould.

Thus, H I, No. 1, is the height of *h i*, No. 2; K L, No. 1, the height of *k l*, No. 2; and M N, No. 1, the height of *m n*, No. 2; the remaining part of the construction is as usual. No. 3 is the upper face-mould, taken from inverted heights: or the falling-mould may be considered as inverted. The same letters are put upon both constructions, to show the similar parts. Here are eight winders, all drawn to a scale, to show the proportion of the parts in practice. This hand-rail requires two moulds, on account of the middle of the falling-mould being much higher than the hypothenuse of the winders.

Plate V. shows the falling and face-moulds for a rail constructed as in *Plate* IV. The only difference is, that in this Plate the middle of the falling-mould is the hypothenuse of the wreath. This situation of the falling-moulds will cause both the face-moulds to be identical: that is, their figures will be equal and similar, so that considerable time will be saved in the preparation. This position, and the identification of the moulds, may always be adopted when the distance between the opposite parts of the string is more than ten inches. The mode of making the height of the rail in the middle of the winders the same as that of the flyers, is practised by several celebrated staircase hands, though it is nothing more than a mere matter of opinion, and may be adopted or not, at the option of the architect, or of the workman, if left to him.

It is worthy of notice, that the springing of the plank is of the utmost consequence in the saving of stuff, where the well-hole is wide; but where it is narrow, very little will be gained by it.

To draw the scroll of a hand-rail, and to find the mould for executing the twist.

Plate VI. Figure 1, No. 1, represents the plan of the rail. The scroll is drawn by centres, in the following manner: Make a circle in the centre, 3½ inches in diameter; divide the diameter into three equal parts; one of which subdivide into six equal parts; set one part from the centre upwards, draw a line from the end of that part, at right angles, towards the left hand, and limit this perpendicular to two parts; from the end of the last perpendicular draw a third downward, limiting it to three equal parts; proceed in this manner till six perpendiculars have been drawn, each differing in length by one from the preceding, and the form of a spiral fret will be obtained. The points of concourse of every two lines will give the centres, which are six in number, besides the centre of the circle, and are numbered in order from such centre: draw a straight line downward from the first centre, by continuing the line already drawn till it cuts the circle: continue the second perpendicular to the right hand, and the third upwards to the left hand; these will form the limiting lines for the four arcs, which will complete one revolution.

Continue the lines in the same order for the next revolution, or for the portion of it required. Begin with the centre next to that of the circle for the first centre, and describe a quarter arc from the point of contact of the circle to the next limiting line; then around the second centre, with the distance to the intersection of the preceding arc, on the preceding limiting line, describe another arc; proceed in this manner till the whole spiral is completed. Set the breadth of the rail from *o* to *a*, and describe another spiral by the same centres, by turning the arcs the contrary way, till the last arc of the spiral cuts the first; which will complete the scroll of the rail; then the addition of a part of the straight of the rail will complete the whole.

The outer spiral consists of one revolution and a half, and the inner of only about half a revolution, which also makes the scroll itself appear only half a revolution; but if more is required, every additional centre will add a quarter of a revolution to the scroll.

To find the face-mould for the shank of the scroll.

Figure 1, No. 1. Lay the base of the pitch-board upon the outside of the shank of the scroll, with the acute angle turned to the outside, or largest convexity: draw a line parallel to the base of the pitch-board, to touch the convex side of the scroll next to the straight part; let this line cut the outside of the rail at 6: between 0 and 6 take any number of intermediate points, 1, 2, 3, 4, 5, and draw lines perpendicular to the base of the pitch-board, to cut the hypothenuse of the said pitch-board; from the points of section draw lines at right angles to the hypothenuse; let the perpendiculars parallel to the base line of the pitch-board be continued downwards, to cut the concave side of the shank; and let one of the perpendiculars be drawn from the concave, and another from the convex side of the rail, where it is intersected by the line parallel to the base line; make all the lines at right angles to the hypothenuse equal to the respective ordinates of the shank taken from both concave and convex sides of it: then curves being traced, and the straight parts joined to the angular points, will be the face-mould.

To find the falling-mould.

Divide the distance between 0 and 6, *Figure* 1, No. 1, into six equal parts, and run the chord on the convex side as far as the rail is required to fall: upon any convenient line, A D, No. 2, run the chord of the part from 0 to 13; place the angular point, C, of the pitch-board at 4; with the base A C, upon A D, tange the angle B C D made by the hypothenuse of the pitch-board and the line A D, with a curve to touch at B and D, as shown at No. 3; then draw another curvilinear parallel, containing the depth of the rail between the two curves; and the falling-mould, No. 2, will be completed as far as the rail has a descent, which ends at 13. The block of the scroll, which is the remaining part after the shank is taken away, is wrought out of a solid piece of wood, the height of the perpendicular upon 0. The shank is squared in the same manner as shown in *Plate* II.

No. 4. The falling-mould for the concave side of the rail is exhibited here, in order to show, that if the ramp and the curve of the scroll do not begin together, and if the rail be made absolutely square, that is, having all its plumb sections rectangles, and the convex side made agreeable to its falling-mould, with an easy curve, it will be impossible to form the back with a regular curve on the concave side, and a hump will always be formed. Therefore, in reducing the hump to an agreeable curve, the rail will be thrown out of the square; but the degree by which it deflects from the truth is so small as not to be perceived.

The inside of the falling-mould is formed by taking the stretch out of *a b*, *b e*, *c d*, &c., of the corresponding parts 0 1, 1 2, 2 3, &c., in No. 1, and applying them from *a* to *b*, from *b* to *c*, from *c* to *d*, &c., No. 4; then drawing the perpendiculars from the points *a*, *b*, *c*, &c., and transferring thereto the corresponding perpendiculars insisting upon 0, 1, 2, &c., No. 2, and then tracing the curves. According to the principles of hand-railing, a vertical or plumb section of the rail at right angles to the cylindric sides, or tending to the axis of the cylinder, is level on the back; therefore, as the concave and convex sides of the plan of the scroll are concentric circles, the arc on the concave side, so far as relates to the same quadrant, will be divided equally, as well as the outside; and therefore drawing lines to the centres from the points of section on the convex side will divide each quadrant equally, and the lines thus radiating will be perpendicular to the curve on both sides of the plan; all the parts throughout the same quadrant will be equal on the concave side as well as on the convex side; and on the convex side the parts will be equal throughout all the quadrants; but on the concave side the parts of each succeeding quadrant, in turning towards the centre, will be quicker than those in the preceding quadrant. In the part of the rail which is straight upon the plan, the sections at right angles to the sides divide each side into equal parts, and the parts on the one side equal to those of the other: hence the reason why the hump takes place at the junction of the ramp and twist.

If a scroll is made agreeable to the form of the plan as struck round centres with compasses, it will always appear to the eye as if crippled at the separating section of the straight and twisted parts. To remedy this defect, the curve of the vertical sides, or that which relates to the plan, ought to be extended with an easy curve into the straight part.

No. 5. An elevation of the shank of the scroll. The portion of the plan is taken from No. 1, and the heights which give the curves are taken from the falling-mould, No. 2; its use is to show the thickness of stuff which is contained between two parallel lines; the lower line comes in contact with the projection at two points, the upper one comes in contact with the projection in one point only.

To show the method of forming the curtail of the first step.

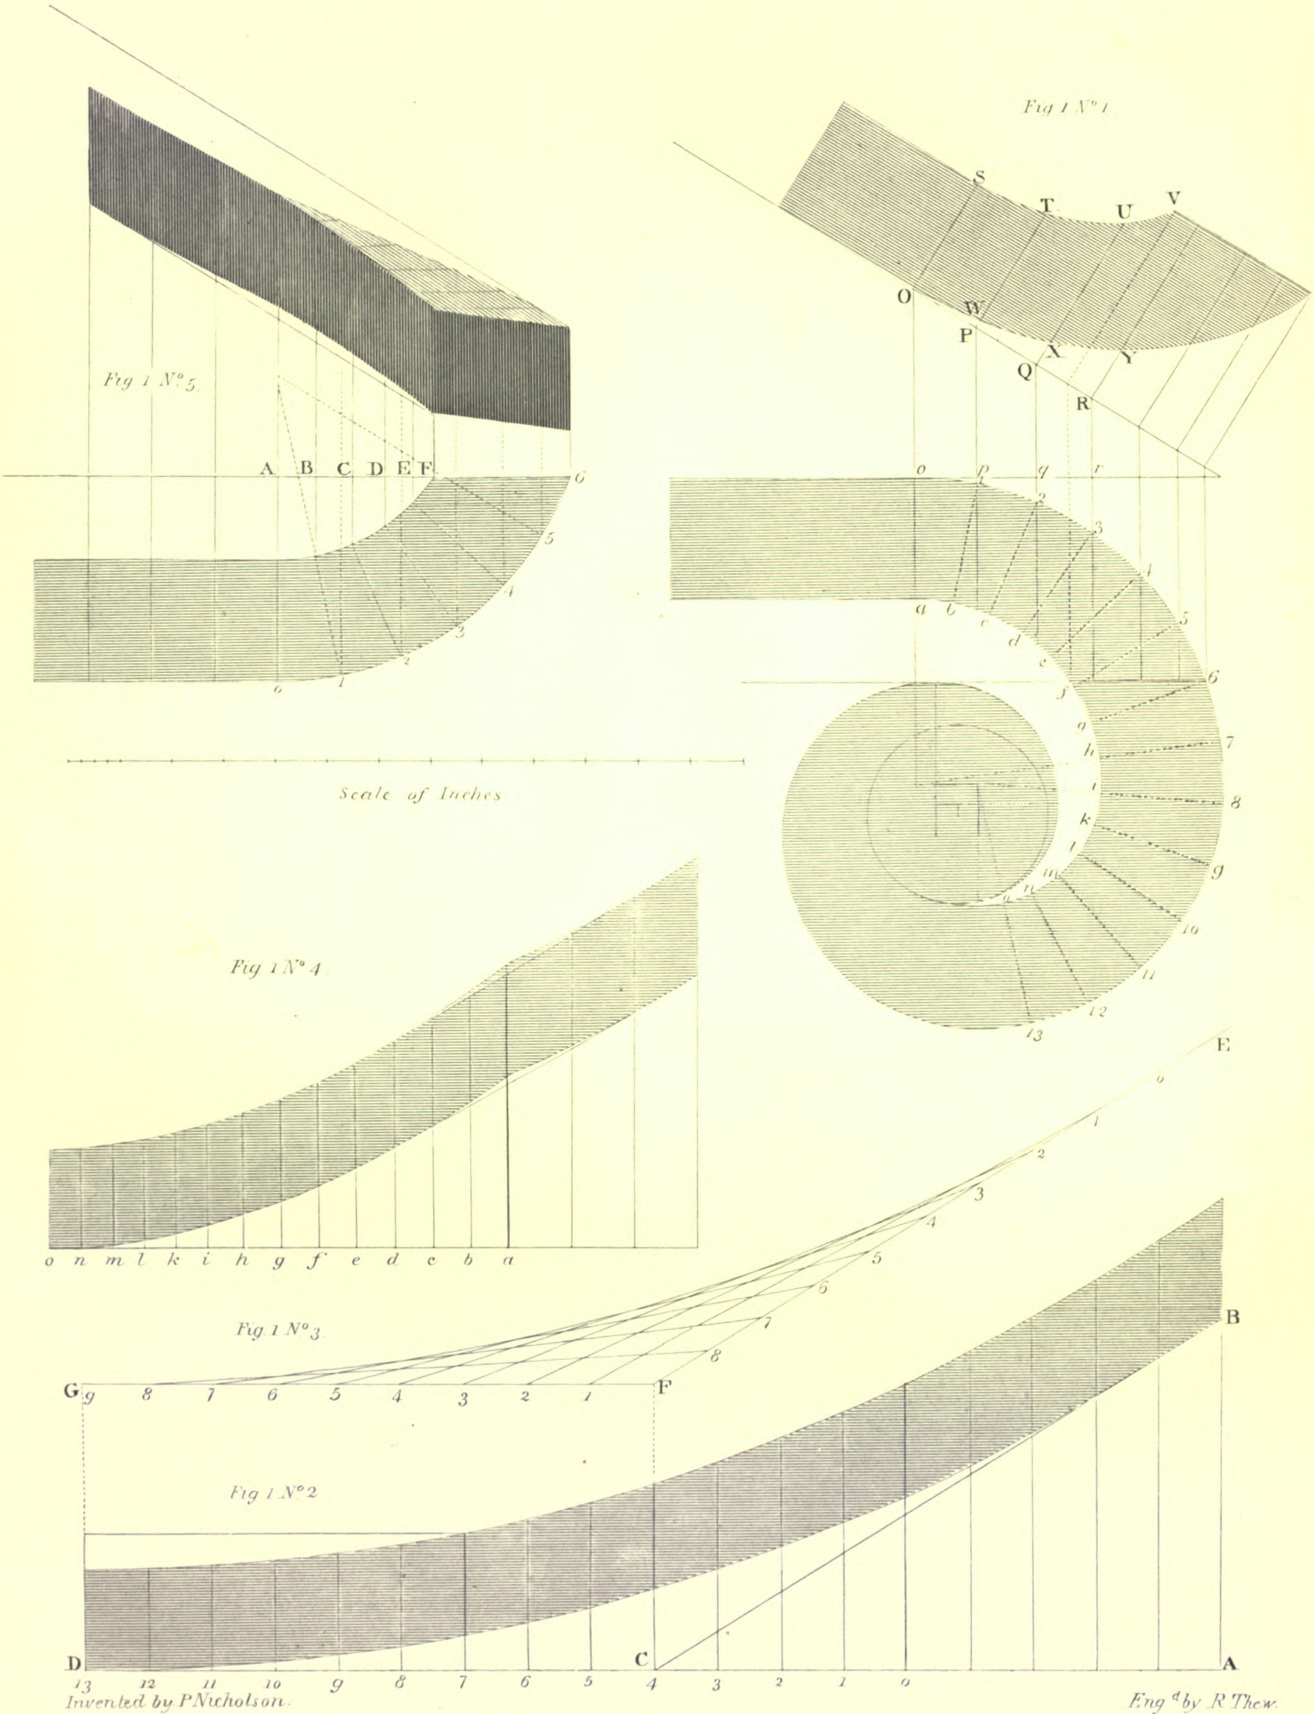
Plate VII. *Figure* 1, No. 1.—Draw the scroll as in the preceding Plate; set the balusters in the middle of the breadth, putting one at the beginning of every quarter; then the front of the balusters is in the plane of the face of the riser, and the opposite side in the plane of the string-board: set the projection of the nosing before the baluster on both sides, and draw two spiral lines parallel to the sides of the scroll, till the curves intersect each other, and they will then form the curtail end of the step, as required, F G H I K represent the convex side of the scroll; L M N, the convex side of the curtail; and A, B, C, D, E, the centre points of the balusters.

No. 2 shows the profile of the curtail, the end of the second step, and part of the end of the third.

Figure 1, No. 3, shows the centres for drawing the curtail, which are the same as for drawing the scroll.

To describe a section of the rail, supposing it to be two inches deep, and two and a quarter inches broad, the usual dimensions.

Figure 2.—Let A B C D be a section of the rail, as squared. On A B describe an equilateral triangle, A B *g;* from *g*, as a centre, describe an arc to touch A B, and to meet *g* A and *g* B: take the distance between the point of section in *g* A and the point A, and transfer it from the point of section to *k*, upon the same line *g* A; join D *k;* from *k*, with the distance between *k* and the end of the arc, describe another arc, to



Invented by P.Nicholson.

B. Thew Sc.

meet D *k;* with the same distance describe a third arc, of contrary curvature, and draw a vertical line to touch it; thus will one side of the section of the rail be formed. The counter-part is formed by a similar operation.

Figure 3 is the most simple form for the section of a rail, being that of a circle.

To describe the mitre-cap of a rail.

Figure 4.—Describe a circle, *a e b d*, to the intended size (the proportion here between the rail and the cap is as 2 to 3); draw the diameters *a b* and *e d* at right angles; produce *e d*, and place the middle of the section of the rail upon *e d;* draw B Q to touch the section of the rail, and to cut the circle *a e b d* in Q; draw the side P Q of the mitre; draw A B to meet the points of contact, A and B, of the lines parallel to *e d*, which are tangents to the section. Then to find any point in the curve of the section of the mitre-cap: let G be a point in the section of the rail; draw G *k*, meeting P Q in *k;* from the centre of the circle *a e b d*, describe an arc, *k f*, meeting *a b* in *f;* from the point of section, *f*, draw *f g*, perpendicular to *a b;* and make *f g* equal to F G.

All other points are found in the same manner; or a series of lines may be drawn from any number of assumed points in the section, and lines parallel to *e d*, drawn from them to cut P Q; arcs may then be described from each point of section to meet *a b*, and perpendiculars drawn from the points of section in *a b;* all these perpendiculars should be made equal to the respective ordinates of the section, and a curve drawn through their extremities will form the curve of the mitre-cap.

HANGING, of doors, or shutters, the act of placing them upon centres or hinges, for the convenience of opening and shutting. *See* HINGING.

HANGING STYLE, the style of a door or shutter, to which the hinge is fastened.

The term is also applied to a narrow style fixed on the jamb, on which the door or shutter is sometimes hung. In this case the hanging style is used with the view of making the shutter or door revolve more than a right angle, in order to turn it into a given position; as to bring a door close to a partition, to keep it out of the way.

HANGINGS, linings for rooms, made of arris, tapestry, or the like.

HANGS OVER, an expression used in speaking of a wall, when the top projects beyond the bottom.

HARD BODIES, such bodies as are absolutely inflexible to any shock or collision whatever.

This is the common meaning of the term; but Huygens, by hard bodies (*corpora dura*) meant what others call perfectly elastic bodies: for he thus expresses himself: "Quæcunque sit causa, corporibus duris, a mutuo contactu resiliendi cum se invicem impinguntur: ponimus, cum corpora duo inter se æqualia, æquali celeritate, ex adverso ac directe sibi mutuo occurrent, resilire utrumque eadem qua advenit celeritate." Huyg. *De Motu Corp. ex Percuss. Hypoth.* 2. But this hypothesis is consistent only with perfect elasticity, and not with the common supposition of hardness or inflexibility, which produces no resilition. The laws of motion for hard bodies are the same as for soft bodies, and these two sorts of bodies might be comprised under the common name of *unelastic.*

Some who follow Leibnitz's doctrine, concerning the measure of the moving force of bodies, deny the existence of hard or inflexible bodies. And it is so far true, that no experience ever taught us that there are any such. The hardest bodies to appearance do not preserve their figures in collision, such bodies being only elastic, yielding to the shock, and then restoring themselves.

M. Bernoulli goes so far as to say, that hardness, in the vulgar sense, is absolutely impossible, being contrary to the law of continuity. For supposing two such hard bodies of equal masses, and with equal velocities, to meet directly, they must either stop or return after the collision. The first supposition is commonly admitted; but then it follows, that these bodies must instantaneously pass from motion to rest, without going through successive diminutions of their velocities till they stop: but this is thought to be contrary to the fundamental laws of nature. Hence this author rejects perfectly solid and inflexible atoms, which others think a consequence of the impenetrability of matter.

HARD, a name given to a ford or passable place in a river, particularly in and near the Fens, where many of these formerly occurred, composed of gravel, probably brought thither for the purpose. These HARDS proved very detrimental to navigation in dry seasons, and obstructed and augmented the floods in wet ones, until they were removed. Frequent mention is made of them by Mr. Smeaton, and by other writers on the navigation and drainage of those districts.

HARD FINISHING. *See* PLASTERING.

HARDENING OF TIMBER. *See* TIMBER.

HARMONIC or HARMONICAL PROPORTION, is when, in a series of quantities, any three adjoining terms being taken, the difference between the first and second is to the difference between the second and third as the first is to the third. The reciprocals of a series of numbers in arithmetical progression are in harmonical proportion: thus the reciprocals $\frac{1}{1}$, $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$, &c. of 1, 2, 3, 4, &c.. are in harmonical proportion; also, the reciprocals $\frac{1}{1}$, $\frac{1}{3}$, $\frac{1}{5}$, $\frac{1}{7}$, &c., of 1, 3, 5, 7, &c. are harmonicals.

HARMONY, an agreement between all the parts of a building; the word is of similar import with SYMMETRY, which *see.*

HARNESS ROOM, a small apartment for keeping the harness in, that it may be preserved from mouldiness. The harness-room should be perfectly dry, and placed as near the stable as possible.

HASP, a fastening; it is in form a small clasp that passes over a staple to be fastened by a padlock.

HATCH-WAY, an aperture through the ceiling, to afford a passage to the roof.

HATCHET (from the French *hachette*) a small axe, used by joiners for reducing the edges of boards.

HAUNCH. That part of an arch between the vertex and the springing.

HEAD (from the Saxon) an ornament of sculpture of carved work, frequently serving as the key of an arch or platband.

These heads usually represent some of the heathen deities, virtues, seasons, or ages, with their attributes. The heads of beasts are also used in suitable places; as a bullock's or sheep's head, for a shambles or market-house; a dog's, for a kennel; a deer's or boar's, for a park or forest; or a horse's, for a stable.

In the metopes for the friezes and other antique Doric temples, we meet with representations of bullocks' or rams' heads flayed, as a symbol of the sacrifices offered there.

HEAD, *Jerkin, See* JERKIN HEAD.

HEADER. *See* HEADING COURSE.

HEADING COURSE, in masonry, a course of stones in which their length is inserted in the thickness of the wall; those with their length in the face of the wall are called *stretchers.* The same is also to be understood of brickwork.

HEADING JOINT, in joinery, the joint of two or more boards at right angles to the fibres; or, in hand-railing, at right angles to the back; this is done with a view to continue the length of the board when too short. The heading-joints in good work are always ploughed and tongued, as in flooring, dado, &c. In dado, the heading-joints, besides being ploughed and tongued, are also glued.

Head-Way of a Stair, the clear distance, measured perpendicular to the horizon, from the tread of any step, resting-place, or landing, to the ceiling immediately above, in one revolution, making allowance for the thickness of the steps.

HEARSE or Herse, a metal frame sometimes set over effigies on tombs.

HEART-BOND, in masonry, the lapping of one stone over two others, which together make the breadth of the wall. This is practised when thorough-stones cannot be procured. *See* Masonry.

HEARTH. *See* Chimney.

HEATHER-ROOF, that kind of roof employed in building which is thatched over or covered with heather or heath, instead of some other material. It is recommended, as well adapted to buildings of the farm description, by the writer of the *Survey of the County of Argyle, in Scotland*, on the principle that it does well with timber of the ordinary sort, is capable of being procured for a trifle, lasts nearly as long as slates, and gives less trouble in the repair. It is asserted that a roof of this material, when well put on, will last one hundred years, provided the timber continues good that length of time. And it is stated, that formerly, most of the churches in the above county were covered with this sort of roof; likewise that heather-roofs are frequently met with in the district of Cowal, and that there are a few of them in Kintyre.

This sort of material may certainly be employed with advantage as a covering for small houses and other buildings, where other kinds of substances cannot be procured, except at a great expense; but at the same time it is very inferior to slate, and other similar matters, in forming the coverings of such erections.

HECATOMPEDON (from ἑκατον, a *hundred*, and πες *a foot*) a name given to the Parthenon, or temple of Minerva, at Athens.

HECATONSTYLON (ἑκατονςυλον) in ancient architecture, a portico with a hundred columns. This name was peculiar to the great Portico of Pompey's theatre at Rome.

HECK, a rack.

HEEL, in mouldings, the same as the sima-inversa.

Heel of a Rafter, the foot of the rafter, as it is formed to rest upon the wall-plate.

HEIGHT, the perpendicular distance of the most remote part of a body from the plane on which it rests.

HELICOID PARABOLA, or the Parabolic Spiral, a curve arising upon the supposition of the axis of the common Apollonian parabola being bent round into the periphery of a circle. The helicoid parabola, therefore, is a line passing through the extremities of the ordinates, which converge towards the centre of the said circle.

HELIOPOLIS, or The City of the Sun, in ancient geography, a city of Egypt, placed by geographers not far from Helle, at some distance from the eastern point of the Delta. It was built, according to Strabo, on a long artificial mount of earth, so as to be out of the reach of the inundation. This causeway, covered with rubbish, is still visible two leagues to the north-east of Grand Cairo, and three from the separation of the Nile. This city had a temple to the sun, where a particular place was set apart for the feeding of the sacred ox, which was there adored under the name of Menevis, as he was at Memphis under that of Apis. There was also in this city another magnificent temple, in the ancient Egyptian taste, with avenues of sphinxes and superb obelisks, before the principal entry. These temples were fallen into decay under the reign of Augustus; as the city had been laid waste with fire and sword by the fury of Cambyses. Of the four obelisks built by Sochis in that town, two were removed to Rome; another has been destroyed by the Arabs; and the last of them is still standing on its pedestal. It is composed of a block of Thebaic stone, perfectly polished, and is, without including its base, 68 feet high, and about 6½ feet wide on each aspect. It is covered with hieroglyphics. This beautiful monument, and a sphinx of yellowish marble, overset in the mud, are the only remains of Heliopolis. *See* Egyptian Architecture.

HELIX, a term applied to the little scrolls in the Corinthian capital, called also *urillæ;* they are sixteen in number, viz. two at every angle, and two in the middle of the abacus, branching out of the caulicoli or stalks which rise between the leaves.

HELMET, a warlike ornament, in imitation of the helmet worn by the cavaliers, both in war and in tournaments, as a cover and defence of the head; the helmet is known by divers other names, as the *head-piece*, *steel-cap*, &c. The Germans call it *helen* or *hellem;* the Italians *elmo;* the French *casque*, as did also the ancient English.

The helmet covered the head and face, only leaving an aperture about the eyes, secured by bars, which served as a visor.

HEM, the protuberant part of the Ionic capital, formed by spirals.

HEMI, a word used in the composition of divers terms. It signifies the same with *semi* or *demi*, viz., *half;* being an abbreviation of ἡμισυς, *hemisys*, which signifies the same. The Greeks retrenched the last syllable of the word ἡμισυς in the composition of words; and, after their example, we have done so too, in most of the compounds borrowed from them.

HEMICYCLE, (Latin, *hemicyclium*, compounded of ἡμισυς, *half*, and κυκλος, *circle*) a semicircle. This word is particularly applied, in architecture, to vaults in the cradle form; and arches, or sweeps of vaults, constituting a perfect semicircle. To construct an arch of hewn stone, they divide the hemicycle into so many voussoirs; taking care to make them an uneven number. that there be no joint in the middle, where the key-stone should be.

HEMICYCLIUM, a part of the orchestra in the ancient theatre. Scaliger, however, observes, it was no standing part of the orchestra; being only used in dramatic pieces, where some person was supposed to be arrived from sea, as in Plautius's *Rudens*.

HEMISPHERE, (Latin, *hemispherium*, compounded of ἡμισυς, *half*, and σφαιρα, *sphere*) in geometry, one half of a globe, or sphere, when divided into two by a plane passing through its centre.

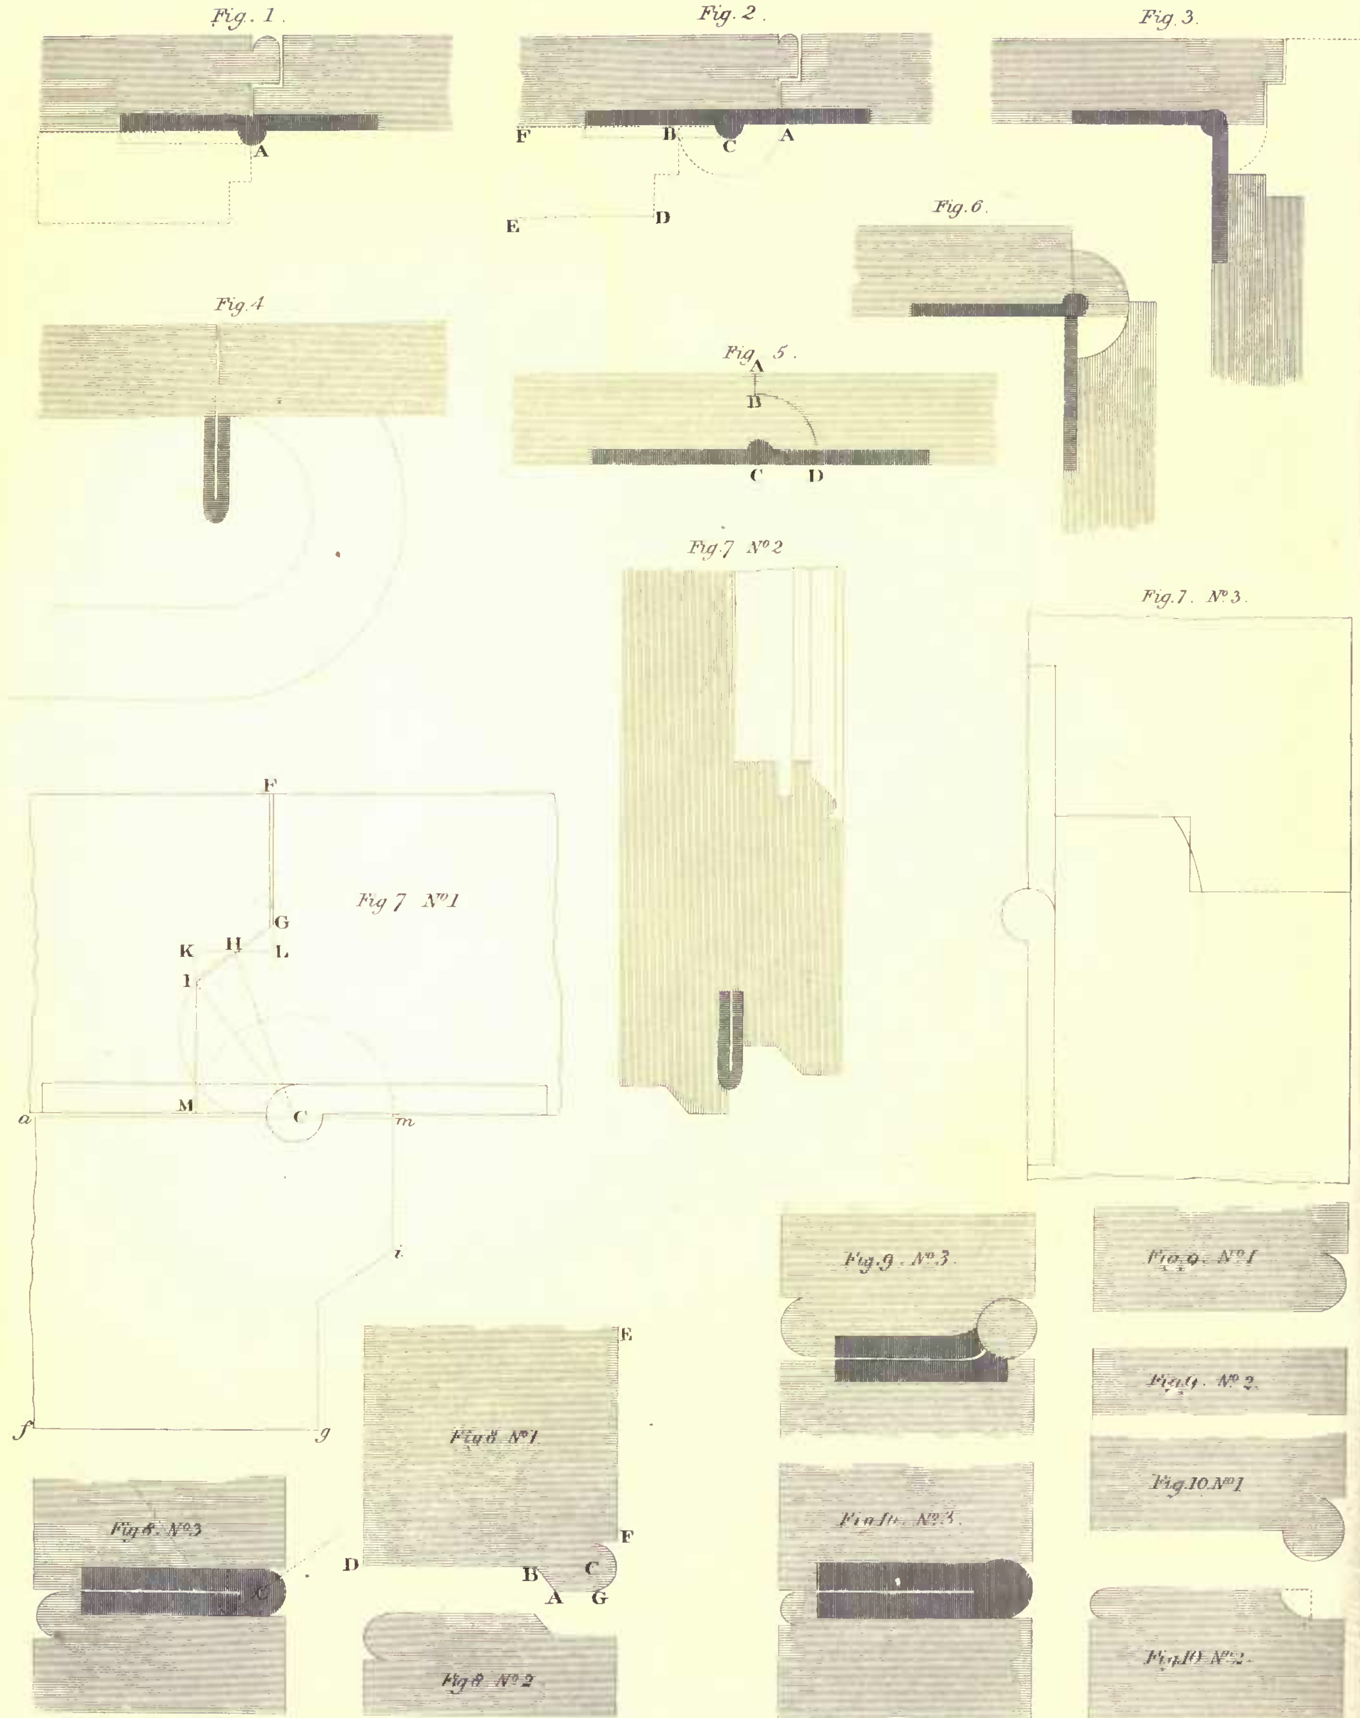
HEMISPHEROIDAL, a body approaching to the figure of a hemisphere, but not exactly so; of this description are what may be termed *elliptical domes*, upon either axis.

HEMITRIGLYPH, the half triglyph.

HENDECAGON, Endecagon, or Undecagon, (compounded of ἑνδεκα, *eleven*, and γωνια, *angle*) in geometry, a figure which has eleven sides, and as many angles. If each side of this figure be 1, its area will be equal to 9.3656399 $=\frac{11}{4}$ tangent $73\frac{7}{11}$°, radius being 1.

HEPTAGON, (of ἑπτα, *septem*, *seven*, and γωνια, *angle*) in geometry, a figure consisting of seven sides and seven angles. If the sides and angles be all equal, it is called *a regular heptagon*. The area of a regular heptagon is equal to the square of one of its sides multiplied by 3.6339126.

HINGING



Invented. by P. Nicholson.

Engd. by R. Thew.

HEPTAGONAL, consisting of seven angles, and therefore also of seven sides.

HERBOSUM MARMOR, a species of marble, much esteemed and used by the ancient architects and statuaries. It was of a beautiful green colour, but had always with it some cast of yellow. It was dug in the quarries of Taygetum, but was esteemed by the workmen the same in all respects, except colour, with the black marble dug at Tænarus in Lacædemonia, and thence called *Tænarian marble.*

HERRING-BONE, a term applied to a particular kind of masonry, in which the stones are laid aslant, inclining alternately right and left. Such work was common in Roman and Saxon structures.

HERMOGENES, the inventor of the eustyle intercolumniation; also of the octostyle pseudodipteros. He is mentioned by Vitruvius, chap. 2. book iii.

HEWN STONE, any stone when reduced to a given form by means of the mallet and chisel.

HEXAEDRON, or HEXAHEDRON (formed of ἑξ, *six*, and ἡδρα, *seat*) in geometry, one of the five regular bodies, popularly called *a cube*. *See* CUBE.

The square of the side of a hexaedron is in a subtriple ratio to the square of the diameter of the circumscribed sphere. Hence, the side of the hexaedron is to the diameter of the sphere in which it is inscribed, as one to the $\sqrt{3}$: and consequently it is incommensurable to it.

HEXAGON, (from ἑξ, *six*, and γωνια, *angle*) a figure of six angles, and consequently of six sides. If the angles and sides are equal, the figure is called a *regular hexagon*. If the side of a hexagon be denoted by *s*, its area will be 2.5980762 *s*.

HEXASTYLE, (from ἑξ, *six*, and ϛυλος, *column*) a building with six columns in front.

HINDOO ARCHITECTURE. *See* INDIAN ARCHITECTURE.

HINGES, metal ligaments, upon which doors, shutters, folds, lids, &c., turn in the act of opening and shutting.

There are many species of hinges, viz., butts, rising-hinges, pew-hinges, casement-hinges, casting-hinges, chest-hinges, coach-hinges, desk-hinges, dovetail-hinges, esses, folding-hinges, garnets, weighty side, side-hinges with rising joints, side-hinges with squares, screw-hinges, scuttle-hinges, shutter-hinges, trunk-hinges, of various descriptions, hook-and-eye-hinges, and centre-pin-hinges.

HINGING, a branch of joinery, which shows the art of hanging a board to the side of an aperture, so as to permit or exclude entrance at pleasure. The board which performs this office is called *a closure*. The placing of hinges depends entirely on the form of the joint, and as the motion of the closure is angular, and performed round a fixed line as an axis, the hinge must be so fixed that the motion may not be interrupted; thus if the joint contain the surfaces of two cylinders, the convex one in motion upon the edge of the closure, sliding upon the concave one at rest on the fixed body, the motion of the closure must be performed on the axis of the cylinder, which axis must be the centre of the hinges; in this case the joint will be close, whether the aperture be shut or open. But if the joint be a plane surface, it must be considered upon what side of the aperture the motion is to be performed, as the hinge must be placed on the side of the closure where it revolves.

The hinge is made in two parts, movable in any angular direction, one upon the other.

The knuckle of the hinge is a portion contained under a cylindric surface, and is common to both the moving part and the other part at rest; the cylinders are indented into each other, and made hollow to receive a concentric cylindric pin which passes through the hollow, and connects the moving parts together.

The axis of the cylindrical pin is called the *axis of the hinge.*

When two or more hinges are placed upon a closure, the axes of the hinges must be in the same straight line.

The straight line in which the axes of the hinges are placed is called the *line of hinges.*

The following are examples of the different cases.

The principle of hanging doors, shutters, or flaps, with hinges.

The centre of the hinge is generally put in the middle of the joint, as at A, *Figure* 1; but in many cases there is a necessity for throwing back the flap to a certain distance from the joint; in order to effect this, suppose the flap, when folded back, were required to be at a certain distance, as A B in *Figure* 2, from the joint; divide A B in two equal parts at the point C, which will give the centre of the hinge; the dotted lines B D E F, show the position when folded back.

Note.—The centre of the hinge must be placed a small degree beyond the surface of the closure, otherwise it will not fall freely back on the jamb or partition.

It must also be observed, that the centre of the hinge must be on that side that the rebate is on, otherwise it will not open without the joint being constructed in a particular form, as will be afterwards shown.

Figure 3 shows the same thing opened to a right angle.

To hang two flaps, so that when folded back, they shall be at a certain distance from each other.

This is easily accomplished by means of hinges having knees projecting to half that distance, as appears from *Figure* 4; this sort of hinges is used in hanging the doors of pews, in order to clear the moulding of the coping.

To make a rule joint for a window-shutter, or other folding-flaps.

Figure 5.—Let A be the place of the joint; draw A C at right angles to the flap, shutter, or door; take C, in the line A C, for the centre of the hinge; and the plain part A B, as may be thought necessary; on C, with a radius, C B, describe the arc B D; then will A B D be the true joint.

Note.—The knuckle of the hinge is always placed in the wood, because the farther it is inserted the more of the joint will be covered, when it is opened out to a right angle, as in *Figure* 6; but if the centre of the hinge were placed the least without the thickness of the wood, it would show an open space, which would be a defect in workmanship.

To form the joints of styles, to be hung together, when the knuckle of the hinge is placed on the contrary side of the rebate.

Figure 7.—Let C be the centre of the hinge, M I the joint on the same side of the hinge; K L the depth of the rebate in the middle of the thickness of the styles, perpendicular to K M, and L F the joint on the other side, parallel to K M; bisect K L at H, join H C; on H C describe a semicircle, C I H, cutting K M at I: through the points I and H, draw I H G, cutting F L at G; then will F G I M be the true joint; but if the rebate were made in the form of M K L F, neither of the styles could move round the joint or hinge.

To form the edges or joint of door-styles, to be hung to each other, so that the door may open to a right angle, and show a bead to correspond exactly to the knuckle of the hinge. Also the manner of constructing the hinges for the various forms of joints, so as to be let in equally upon each side.

Figure 8, No. 1, shows the edge of a style, or it may in some cases be a jamb, on which a bead is constructed exactly to the size of the knuckle of the hinge, and rebated backwards, equal to half the thickness of the bead: the manner of constructing the rebate will be shown as follows:

Through C, the centre of the bead, which must also be the centre of the hinge, draw C B D perpendicular to E F; draw A G parallel to it, touching the bead at G; make G A equal to G C, the radius of the bead; join C A; make A B perpendicular to A C, cutting C D at B; then will G A B D be the joint required.

No. 2, shows a part of the hanging style constructed so as to receive the edge of No. 1.

No. 3, shows the above hinged together with common butt-hinges.

Note.—It must be observed in this, and all the following examples of hinges, that the joints are not made to fit exactly close, as sufficient space for the paint must be allowed.

Figure 9, No. 1 and 2. The manner of constructing these being only a plain joint at right angles to the face of the style, no farther description is necessary.

No. 3 shows No. 1 and 2 hinged together, and the particular construction of the hinge, so as to be seen as a part of the bead, and the strap of the hinge to be let equally into each style: this construction will admit of a bead of the same size exactly opposite to it.

Figure 10, No. 1 and 2. The manner of constructing the edges of styles to be hinged together with common butts, to be let equally into each style: the manner of constructing this joint is so plain, by the figure, that it would be useless to give any other description of it. No. 3, the two pieces hinged together.

Methods of jointing styles together so as to prevent seeing through the joints, each side of the styles to finish with beads of the same size, exactly opposite to each other, and for the strap of the hinges to be let equally into both parts or styles.

Figure 11, No. 1 and 2, the manner of constructing the joint before hinged together.

No. 3 shows No. 1 and 2 hinged together with common butts.

Figure 12, No. 1 and 2, shows another method of constructing the joints, before hinged together.

No. 3, shows No. 1 and 2 hinged, and the particular form of the hinges for the joint.

The principle of concealing hinges, showing the manner of making them, and of forming the joint of the hanging style, with the other style connected to it by the hinges, either for doors or windows.

Figure 13, for a window:

X, inside bead of the sash-frame.

Y, inside lining.

Z, style of the shutter.

Let A be the intersection of the face of the shutter, or door, with that of the inside lining of the sash-frame.

A R, the face of the inside lining.

Bisect the angle P A R by the right line A A; now the centre C being determined in A A at C, so that the knuckle of the hinge may be at a given distance from the face P A of the shutter; through C draw the line D D, at right angles to A A; then one side of the hinge must come to the line C D, the hinge being made as is shown by the figure.

To construct the jamb to be clear of the shutter.—

On C, as a centre, with a radius C A, describe an arc A M, and it will be the joint required.

Note.—When these sort of hinges are used in shutters, the strap of the hinge may be made longer on the inside lining, than that which is connected with the shutter.

Figure 14, is the manner of hanging a door on the same principle: the shadowed part must be cut out, so that the other strap of the hinge may revolve; the edge, C D, of the hinge, will come into the position of the line A A, when the window is shut in.

Here the strap part of the hinge may be of equal lengths.

Figure 15, the common method of hanging shutters together, the hinge being let the whole of its thickness into the shutter, and not into the sash-frame.

By this mode it is not so firmly hung, as when half is let into the shutter and half into the sash-frame, but the lining may be of thinner stuff.

Note.—It is proper to notice, that the centre of the hinge must be in the same plane with the face of the shutter, or beyond it, but not within the thickness.

Figure 16, the method of hanging a door with centres. Let A D be the thickness of the door and bisect it in B; draw B C perpendicular to A B; make B C equal to B A or B D; on C (the centre of the hinge) with a radius C A or C D, describe an arc, A E D, which will give the true joint for the edge of the door to revolve in.

HIP, in architecture, a piece of timber placed between every two adjacent inclined sides of a hip-roof, for the purpose of fixing the jack rafters. For the manner of finding the length and backing of the hips, *see* HIP-ROOF.

HIP-KNOB, a pinnacle, finial, or other ornament placed on the top of the hips of a roof, or on the apex of a gable, especially where barge-boards are employed.

HIP-MOULD, a mould by which the back of the hip-rafter is formed: it ought to be so constructed as to apply to the side of the hip, otherwise there will be no guide for its application.

HIP-ROOF, a roof whose ends rise immediately from the wall-plate, with the same inclination to the horizon as the other two sides of the roof have.

The backing of a hip is the angle made on its upper edge, to range with the two sides or planes of the roof between which it is placed.

Jack-rafters are those short rafters fixed to hips equidistantly disposed in the planes of the sides and ends of the roof, and parallel to the common rafters, to fill up the triangular spaces, each of which is contained by a hip-rafter, the adjoining common rafter, and the wall-plate, between them. The seat or base of the rafter is its ichnographic projection on the plane of the wall-head, or on any other horizontal plane.

The principal angles concerned in hip-roofing are, the angle which a common rafter makes with its seat on the plane of the wall-head; the vertical angle of the roof; the angle which a hip makes with the adjoining common rafter; the angles which a hip makes with the wall-plate on both sides of it; the angle which a hip-rafter makes with its seat; and the acute angle which a hip-rafter makes with a vertical line. The principal lengths concerned are, the height of the roof; the length of the common rafters and their seats; the length of the hips and their seats; and, lastly, the length of the wall-plate contained between the lower end of a hip and the lower end of the adjacent common rafter.

The sides and angles may be found by geometrical construction or trigonometrical calculation. It is evident, that if the hipped end of a roof be cut off by a vertical plane parallel to the wall, through the upper extremity of the hips, it will form a rectangular pyramid, or one whose base is a rectangle. The base of this pyramid is bounded by the wall-plate between the two hips on one side, and on the opposite side by the seat of the two adjoining common rafters; on the other two opposite sides, by that part of the wall-plate on each side contained by the lower end of the hip and the next common rafter adjoining. One of the sides is the isosceles triangle contained by the two adjoining common rafters with their seat; the opposite side is the hipped end of the roof, forming

HINGING.

PLATE II.

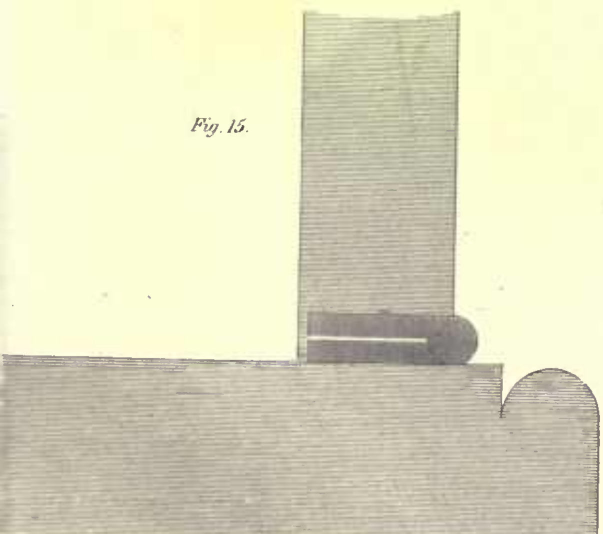

Fig. 16.

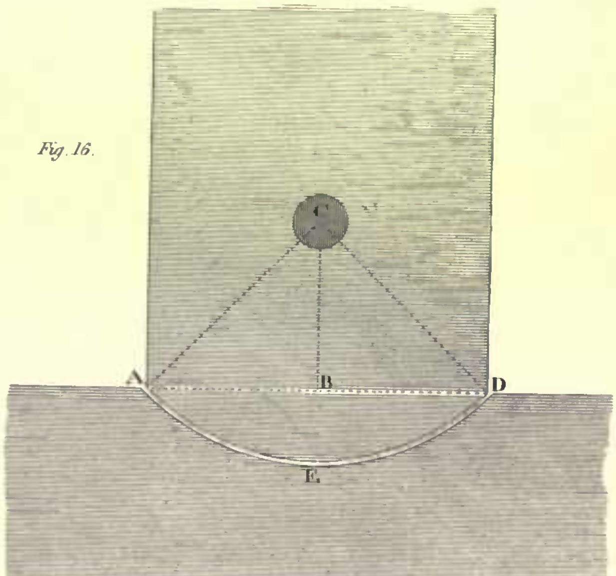

Drawn by P. Nicholson.

Eng'd by R. Thew.

also an isosceles triangle; the other two opposite sides are the right-angled triangles contained by the two hips and the two adjoining rafters on the side of the roof. This rectangular pyramid may be divided into three triangular pyramids by the two vertical triangular planes, formed by the hip-rafters, their seats, and the common perpendicular from their vertex.

Two of these pyramids, when the plan of the building is a rectangle, are equal and opposite. In each of these equal and opposite pyramids the base is a right-angled triangle, contained by the seat of the hip-rafter, the seat of the adjoining common rafter, and the part of the wall-plate between the hip and the adjoining common rafter. One of the sides is a right-angled triangle contained by the adjoining common rafter, its seat, and perpendicular: a second side is a right-angled triangle contained by the common rafter, the hip-rafters, and the wall-plate, between them; and the remaining third side is the triangle contained by the hip-rafter, its seat, and perpendicular. With regard to the remaining pyramid, its base is a right-angled triangle contained by the seats of the two hips and the wall-plate between them, the right angle being that contained by the seats of the two hips; two of its sides are the triangular planes passing the hip-rafter, which are also common to the other two pyramids; its third side is the hipped end of the roof.

Given the plan of a building, or the form of a wall-plate of a hip-roof, and the pitch of the roof, to find the various lengths and angles concerned, whether the roof is square or bevel.

EXAMPLE I.—*To find the length of the rafters, the backing of the hips, and the shoulders of jack-rafters and purlins, geometrically.*

Plate I.—*Figure* I.—Let A B C D be the plan. Draw E F parallel to the sides, A D and B C, in the middle of the distance between them. On D C, as a diameter, describe the semicircle D F C: draw F D and F C, then the angle D F C is a right angle. Draw G F H perpendicular to E F, cutting the sides A D and B C in G and H; from F E cut off F I equal to the height or pitch of the roof, and join G I; from F C cut off F K equal to F I, and join K D; then G I is the length of a common rafter, and D K that of the hip; for if the triangles G F I and D F K be turned round their seats, G F and D F, until their planes become perpendicular to the triangle G F D, the perpendicular F I will coincide with F K, and the point I will coincide with the point K; the lines G I and D K, representing the rafters, will then be in their true position.

The same by calculation. $GI^2 = GF_2 + FI^2$ (Euclid i. 47.) therefore, $GI = (GF^2 + FI^2)\frac{1}{2}$ the length of the common rafter, $DF^2 = GF^2 + GD^2$ the square of the seat of the hip. $DK^2 = DF^2 + FK^2 = GF^2 + GD^2 + FI^2$, therefore $DK = \overline{GF^2 + GD^2 + FI^2}^{\frac{1}{2}}$.

In the same manner the other hip-rafter C L is found, as also the hip-rafters A M and B N.

Let it be required to find the backing of the hip-rafter whose seat is C F.

Geometrically.—Imagine the triangle C F L to be raised upon its seat C F, until its plane becomes perpendicular to the plane of the wall-plate A B C D, then there will be two right-angled solid angles; the three sides of the one are the plane angles of F C D, F C L, and the hypothenusal plane angle D C L. In each of these solid angles the two sides, containing the right angle, viz., the plane angles F C H, F C D, and the perpendicular plane angle C F L, which is common to both, being given to find the two opposite inclinations to the sides F C H and F C D, and the remaining third sides.

Now the angles G D C and H C D are besected by the seats F D and F C of the hip-rafters; for if E F is produced to meet D C in U, U will be the centre of the circle D F C; and U C, U F, U D, are equal to each other; and because U F is equal to U C, the angle C F U is equal to F C U; but C F U is equal to the alternate angle F C H; therefore, the angle F C U is equal to F C H; that is, the angle U C H is besected by the seat F C of the hip-rafter. In the same manner may be shown that U D G is besected by the seat D F of the other hip-rafter. From any point, O, in F C, draw O V perpendicular to L C, cutting it in P, and O W perpendicular to F C, cutting D C in W; from O C cut off O Q equal to O P. Join Q W, then O Q W will be the inclination opposite the plane angle F C U, and this is the angle which the end of the roof makes with the vertical triangle contained by the hip-rafter, its seat, and perpendicular. Produce W O to meet D C in X, and join Q X, then W Q X is the inclination of the two planes of a side and end of the roof, whose intersections are B C and C D, on the plane of the wall-head. Now, the angle W Q X, which is double the angle W Q O, is the backing of the hip. Make P V equal to Q W, and join C V, then will P C V be the angle contained by the two sides L C, C D, or that of the hypothenusal plane angle contained by the intersection B C, and the hip-rafter L C. This angle may be otherwise found thus:—Produce G H to R; make C R equal to C L, then the angle H C R is equal to P C V. Now the angle H C R, or P C V, is the angle which the purlins (when one of their faces is in the side of the roof) make with the hip-rafter L C; and the angle C V P, or C R H, is the angle which a jack-rafter makes with the same hip; in the same manner may the backings of the other hips be found. The other bevel of the jack-rafters is the angle H I F. To find the other bevel for cutting the shoulder of the purlin, proceed thus: on F, as a centre, with the distance F O, describe the arc G Y; draw F Y perpendicular to G I, Y Z parallel to E F, cutting F D in Z, and Z & parallel to G H, cutting A D in &. Join & F, then G & F is the angle which the other side of the shoulder makes with the length of the purlin.

At the other end of this diagram is shown the manner of finding the two bevels for cutting the shoulder of the purlin against the hip-rafter when the side of the purlin is not in the plane of the side of the roof.

To find the same things by calculation.—The backing of the hip-rafter and hypothenusal side is obtained as follows:—It has been shown that the three plane angles, and the three inclinations of solid angles, consisting of three plane angles, are found exactly as the sides and angles of spheric triangles, any three parts being given; the degrees of the plane angles being exactly the same as the sides of the spheric triangles, and the inclinations the proper measures of the spheric angles; therefore, if two of the plane angles should be perpendicular to each other, the spheric triangle representing this solid angle will have also two of its sides perpendicular to each other. Now, in this, there are given the two sides containing the right angle to find the hypothenuse and angles.

It is shown, by writers on spherical trigonometry, that in any right-angled spherical triangle, radius is to the cosine of either of the sides, as the cosine of the other side to the cosine of the hypothenuse. Suppose the plane angle F C L to be 27°, and the angle F C H 52°, to find the hypothenuse and angles of a right-angled spherical triangle, one of whose legs is 27° and the other 52°, it will therefore be—

As radius, sine of 90°	=	10.00000
Is to the cosine of F C L, 27°	=	9.94988
So is the cosine of F C H 52°	=	9.78934
		19,73922
		10.00000
To the cosine of the hypothenusal side 56° 44′		9.73922

This ascertains the angle which the jack-rafter makes with the hip. Since all the sides are now given, we shall have, by another well-known property, of the sines of the sides being as the sides of the opposite angles, the following proportion :—

As the sine of the hypothenuse 56° 44′	=	9.92227
Is to the sine of a right angle, or 90°	=	10.00000
So is the sine of the side F C H, 52°	=	9.89653
		10.89753
		9.92227
To the sine of the opposite angle 70° 28′	=	9.97426
Therefore the backing is twice 70° 28′	=	140° 56′

In finding the angle opposite the side F C H, it was not necessary that the hypothenusal side should have first been found. It might have been found independently thus :—The sine of either of the sides about the right angle is to radius, as the tangent of the remaining side is to the tangent of the angle opposite to that side ; therefore,

As the sine of the side F C L, 27°	=	9.65705
Is to the tangent of the side F C H 52°	=	10.10719
So is radius, sine of 90°	=	10.00000
		20.10719
		9.65705
To the tangent of the angle opposite the side F C H, 70° 28′	=	10.45014

In the same manner may other bevels be found by trigonometrical calculations; but as such extreme exactness is not necessary, the geometrical constructions ought to be well understood.

EXAMPLE II.—*The figure* A B C D (*Figure* 2) *of the wall plate of a hip span-roof, and the height of the roof being given; to find the backing of the hips, the angles made upon the sides of the purlins by their longitudinal arrises, and the angles made upon the sides of the jack-rafters; the roof being equally inclined to the different sides of the building, except at the oblique end*, A B.

Figure 2.—Let the two sides, A B, A D, and D C of the wall-plate be at right angles to each other, and the end C B at oblique angles to A B and C D; draw the seat, E F, of the ridge in the middle of the breadth, parallel to A B and D C ; make A G and D H equal to half the breadth of the building ; join G H, which will be the seat of the common rafters adjoining the hips ; make E I equal to the height of the roof; and draw I G and I H, which are the length of the common rafters. Draw E D and E A, the seats of the hips ; make E K equal to E I ; and draw K A, which gives the length of each hip. Through any point, L, in the seat of the hip A E, draw M N perpendicular to A E, cutting the adjacent sides of the wall-plate at M and N ; take the nearest distance from L to the rafter A K, and make L O equal to it ; and draw O M and O N ; and M O N is the backing of the hips, represented by their seats A E and D E.

This operation is the same as having the two legs of a right-angled solid angle to find the angle opposite to one of the legs; the angle M O N being exactly the double of the angle so found; for the hip angle of the roof consists of two equal solid angles.

Suppose the bevel end at C B to be inclined at a different angle to the other sides, and let F C and F B be the seats of the hips; draw F Q perpendicular to F C, and F P perpendicular to F B, each equal to the height of the roof; then draw Q C and P B, which are the lengths of the hip-rafters.

The backings S U T and V W X, are found in the same manner as above, and may be described in the same words.

From A, with the distance A K, describe an arc cutting G H at J, and join A J; then G J A will be the side bevel, which the jack-rafters make with the hips; and if a right angle be added to G J A, it will form an obtuse angle, which is that made by the upper arris of the side of a purlin placed in the inclined side of the roof with the hip-rafter.

Let *a* be the position of a purlin in the rafter H I ; in G H take any point, *b*, and draw *b c* parallel to the inward direction of the purlin *a;* from *b*, with any distance, *b c*, describe an arc *c d*, cutting G H at *d;* draw *b e*, *c f*, and *d g*, parallel to E F; the former two cutting E D at *e* and *f;* draw *f g* parallel to G H, and join *e g;* produce *b e* to *h;* and *h e g*, or *b e g* will be the angle required, according to which side it is applied: this will be found synonymous to one of the legs, and the adjacent angle of a right-angled solid angle being given, to find the hypothenuse. In the same manner, if neither side of the purlin should be parallel to the inclined side of the roof, as at *k* in the rafter G I, the bevel or angle upon each side may be found, as shown.

Plate II.—*Figure* 3, shows half the angle of the backing of the hips, the length of the common and hip-rafters, the bevel of the jack-rafters on their upper sides in an equal inclined roof, without laying down or drawing any more than the necessary seats; and this is all that is necessary when each side of the roof is alike; A B being the wall-plate between the hip and the rafter which joins the top of the hip, A C the seat of the rafter which joins the top of the hip, B C that of the hip, A F the length of the rafter which joins the hip, B E the length of the hips, C H G half the backing, A D B the angle which the jack-rafters form with the upper sides of the hips, and, consequently, with the addition of a right-angle, the side bevel of the purlin.

Figure 4, shows the same bevels, except that the side joint of the purlin is found by a different process, thus: from B, with the distance B A, describe an arc at D; from O, with the distance A C, describe another arc, cutting the former at D; join B D, and the angle G B D will be the angle in the plane of the roof, made by the lower arris of the purlin and the joint against the hip-rafter.

Besides the angles already mentioned, A F C *Figure* 3, shows the angle formed by the upper side of the rafter and the ridge-piece, and the angle B E C, the angle which the top side of the hips makes with a vertical or plumb-line; also the angle F A C shows the form of the heel of the common rafters, and E B C that of the hips.

Figure 5, is a diagram showing the length of the parts and angles concerned in the roof, in the same manner as above; but the plan of the building, or form of the wall-plate, is a quadrilateral, which has neither part of its opposite sides parallel; the method of executing the roof in this case is to form a level on the top, from the top of the hips at the narrow end to the other extremity, as otherwise the roof must either wind, or be brought to a ridge forming a line inclined to the horizon; and either of the two last cases is very unsightly. But, that nothing should be wanting, the construction is given in the next figure.

Plate III.—*Figure* 6.—*To lay out an irregular roof in ledgment, with all its beams bevel upon the plan, so that the ridge may be level when finished ; the plan and height of the roof being given.*

The length of the common and hip-rafters are found as usual. From each side in the broadest end of the roof, through C and D, draw two lines parallel to the ridge-line

draw lines from the centres and ends of the beams, perpendicular to the ridge-line, and lay out the two sides of the roof 2 and 3, by making E D at 3 equal to X N in 1, the length of the longest common rafter, and *c a* in 3 equal to *u &* at A, and so on with all the other rafters.

To find the winding of this roof.—Take *y &*, half the base of the shortest rafter, and apply this to the base of the longest rafter from *z* to 1; then the distance from 1 to 2 shows the quantity of winding.

To lay the sides in winding.—Lay a straight beam along the top ends of the rafters at E, that is, from *c* to E, and lay another beam along the line A B, parallel to it, to take the ends of the hip-rafters at M and L, and the beams to be made out of winding at first. Raise the beam that lies from *a* to B, at the point B, to the distance 1 2 above the level; which beam, being thus raised, will elevate all the ends of the rafters gradually, the same as they would be when in their places.

The same is to be understood of the other side D; the ends are laid down in the same manner as in making a triangle of any three dimensions.

In this example, the purlins are supposed to be framed into the sides of the rafters flush, so that the top of the purlins may be flush with the back of the rafters. The manner of framing the dragon beams and diagonal ties, is shown at the angles.

Plate IV.—*Figure* 7, shows the manner of framing a roof when the sides are square. The purlins are prepared to bridge over the rafters, which are notched out of the sides next to the back, in order to receive them.

HIPPIUM, in antiquity, that part of the hippodrome which was beaten by the horses' feet.

HIPPODROME, (from the Latin, *hippodromus*, composed of ἱππος, *horse*, and δρομος, *course*, of the verb δρεμω, *curro*, *I run*,) in antiquity, a list, or course, wherein chariot and horse-races were performed, and horses exercised.

The Olympian hippodrome, or horse-course, was a space of ground 600 paces long, surrounded with a wall, near the city Elis, and on the banks of the river Alpheus. It was uneven and in some degree irregular, on account of the situation; in one part was a hill of moderate height, and the circuit was adorned with temples, altars, and other embellishments. Pausanias has given us the following account of this hippodrome, or horse-course:—"As you pass out of the stadium, by the seat of the Hellanodics, into the place appointed for the horse-races, you come to the barrier (αφεςις) where the horses and chariots rendezvous before they enter into the course. This barrier, in its figure, resembles the prow of a ship, with the rostrum or beak turned towards the course. The other end, which joins on to the portico of Agaptus, (so called from him who built it) is very broad. At the extremity of the rostrum or beak, over a bar that runs across the entrance (επι κανονος,) is placed a figure of a dolphin in brass. (This dolphin is a symbol of Neptune, surnamed Hippian or Equestrian, for his having produced a horse by striking the earth with his trident, according to the fable; without the recollection of this circumstance, the reader might be surprised to meet with the figure of a dolphin in a horse-course.) On the two sides of the barrier, each of which is above 400 feet in length, are built stands or lodges, as well for the riding-horses as the chariots, which are distributed by lot among the competitors in those races; and before all these lodges is stretched a cable, from one end to the other, to serve the purpose of a barrier. About the middle of the prow is erected an altar, built of unburnt brick, which, every Olympiad, is plastered over with fresh mortar; and upon the altar stands a brazen eagle, which spreads out its wings to a great length. This eagle, by means of a machine, which is put in motion by the president of the horse-races, is made to mount up at once to such a height in the air, as to become visible to all the spectators; and, at the same time, the brazen dolphin before mentioned sinks to the ground. Upon that signal, the cables stretched before the lodges, on either side of the portico of Agaptus, are first let loose, and the horses there stationed move out and advance, till they come over against the lodges of those who drew the second lot, which are then likewise opened. The same order is observed by all the rest, and in this manner they proceed through the beak or rostrum; before which they are drawn up in one line, or front, ready to begin the race, and make trial of the skill of the charioteers and fleetness of the horses. On that side of the course, which is formed by a terrace raised with earth, and which is the largest of the two sides, near to the passage that leads out of the course across the terrace, stands an altar, of a round figure, dedicated to Taraxippus, the terror of the horses, as his name imports. The other side of the course is formed, not by a terrace of earth, but a hill of moderate height, at the end of which is erected a temple, consecrated to Ceres Chamyne, whose priestess has the privilege of seeing the Olympic games."

There is a very famous hippodrome at Constantinople, which was begun by Alexander Severus, and finished by Constantine. This circus, called by the Turks *Atmeidan*, is 400 paces long, and above 100 paces wide, *i. e.* geometrical paces of five feet each. Wheeler says, it was in length about 550 ordinary paces, and in breadth about 120; or, allowing each pace to be five feet, 2,750 feet long and 600 broad. At the entrance of the hippodrome there is a pyramidal obelisk of granite, in one piece, about 50 feet high, terminating in a point, and charged with hieroglyphics, erected on a pedestal of eight or ten feet above the ground. The Greek and Latin inscriptions on its base show that it was erected by Theodosius; the machines that were employed to raise it were represented upon it in basso-relievo.

The beauty of the hippodrome at Constantinople has been long since defaced by the rude hands of the Turkish conquerors; but, under the similar appellation of *Atmeidan*, it still serves as a place of exercise for their horses. Whether the Olympic hippodrome was so long or so wide as this of Constantinople, it is not now easy to determine; but it must evidently have been considerably longer than an ordinary stadium, in order to allow for the turnings of the chariots and horses round the pillars which served as metas or goals, without running against them, or against one another. The length of the course, or the distances between the two metas or goals, is not easily ascertained. It is probable, however, that the two pillars, *viz.*, that from which the horses started, and that round which they turned, which divided the course into two equal lengths, were two stadia distant from each other; consequently, the whole length of the race, for a chariot drawn by full-aged horses, consisting of 12 rounds, amounted to 48 stadia, or six Grecian miles; and that of the chariot drawn by colts consisted of eight rounds, or 32 stadia, or four Grecian miles—a Grecian mile, according to Arbuthnot's computation, being somewhat more than 800 paces, whereas an English mile is equal to 1,056. Pausanias informs us, that in the Olympic hippodrome, near that pillar called Nyssé, probably that which was erected at the lower end of the course, stood a brazen statue of Hippodamia, holding in her hand a sacred fillet or diadem, prepared to bind the head of Pelops for his victory over Œnomaus; and it is probable that the whole space between the pillars was filled with statues or altars, as that in the hippodrome at Constantinople seems to have been. Here, however, stood the tripod, or table, on which were placed the olive-crowns and the branches of palm destined for the victors. Besides the hippodromes at Olympia and Constantinople, there were courses of a similar kind at Carthage, Alexandria in Egypt, and other places.

We have some vestiges in England of the hippodrome, in which the ancient inhabitants of this country performed their races. The most remarkable is that near Stonehenge, which is a long tract of ground, about 350 feet, or 200 druid cubits wide, and more than a mile and three-quarters, or 6,000 druid cubits in length, enclosed quite round with a bank of earth, extending directly east and west. The goal and career are at the east end. The goal is a high bank of earth, raised with a slope inwards, on which the judges are supposed to have sat. The metæ are two tumuli, or small barrows, at the west end of the course. These hippodromes were called, in the language of the country, *rhedagua*, the racer *rhedagwr*, and the carriage *rheda*, from the British word *rhedeg, to run.* One of these hippodromes, about half a mile to the southward of Leicester, retains evident traces of the old name *rhedagua*, in the corrupted one of *rawdikes.* There is another of these, says Dr. Stukely, near Dorchester, another on the banks of the river Lowther, near Penryth, in Cumberland, and another in the valley just without the town of Royston.

HISTORICAL COLUMNS. *See* Column.

HOARDING, (from the Saxon,) an enclosure about a building, while erecting or under repair.

HOIST, an apparatus, or lift, for raising bodies from a lower to an upper story in a building.

HOLLOW, (from *hole*,) a concave moulding, whose section is about the quadrant of a circle. It is, by some writers, called *easement.*

Hollow Bricks, a kind of brick recently invented, moulded of various sizes and shapes, but usually of larger size than those commonly in use. They are mere shells, as it were, the heart of the brick being removed. The advantages claimed for such bricks are their superior strength when considered with reference to the quantity of material; and as a consequence, their comparative lightness, a quality which tells in very many ways. In the manufacture, they are more evenly baked and dried, the heat being equally distributed over every part; and hence their texture and hardness are more to be depended upon than in solid bricks. When used for houses, there is much less fear of damp than in new work as at present constructed; and an equability of temperature is ensured in the interior. Sound also is much less easily communicated by them than by common bricks. It has been proposed to construct them with grooves and ledges, or with some similar contrivance, so that they may be fitted compactly together in a short space of time, for temporary or other purposes. Floors also are proposed to be constructed of the same materials, so as to render buildings entirely fire-proof.

Hollow Newel, an opening in the middle of a staircase. The term is used in contradistinction to *solid newel*, into which the ends of the steps are built. In the hollow newel, or well-hole, the steps are only supported at one end by the surrounding wall of the staircase, the ends next the hollow being unsupported.

Hollow Wall, a wall built in two thicknesses, having a cavity between, either for the purpose of saving materials, or to preserve a uniform temperature in the apartments.

Hollow Quoins, in engineering, piers of stone or large bricks, made behind each lock-gate of a canal, which are formed into a hollow from top to bottom, to receive the rounded head of the lock-gates. In some instances the hollow quoin is formed of one piece of oak, cut to the proper shape, and fixed vertically against the wall. Cast-iron is also now frequently used for forming the hollow quoin or hinge for the lock-gates of large canals, or the entrance-basons to docks.

HOMESTALL, or HOMESTEAD, the place of a mansion-house; the word is used in some countries to signify the original house or dwelling attached to an estate.

HOMOLOGOUS, (from ὁμνος, *similar*, λογος, *reason*,) in geometry, the correspondent sides of similar figures.

HOOD-MOULD, a band or string carried over any aperture, such as a door or window; more particularly employed in Pointed architecture: the term is synonymous with Label and Weather Moulding.

HOOK PINS, in carpentry, iron pins made tapering towards one end, for the purpose of drawing the pieces of a frame together, as in floors, roofs, &c. In joinery, the pins which answer a similar purpose are called Draw-Bore Pins.

HOOKS, (Saxon) bent pieces of iron, used to fasten bodies together, or to hang articles on, out of the way. They are of various kinds, some of iron and some of brass; as casement-hooks, chimney-hooks, which are made of both brass and iron; curtain-hooks, hooks for doors and gates, double-line-hooks, tenter-hooks, armour-hooks, &c.

HORDING. *See* Hoarding.

HORIZONTAL CORNICE, of a pediment, the level part under the two inclined cornices.

Horizontal Line, in perspective, the vanishing lines of planes parallel to the horizon.

Horizontal Plane, a plane passing through the eye, parallel to the horizon, and producing the vanishing line of all level planes.

Horizontal Projection, the projection made on a plane parallel to the horizon. This may be understood either perspectively or orthographically, according as the projecting rays are directed to a given point, or are perpendicular to the horizon.

HORN, (Saxon) a name sometimes applied to the Ionic volute.

HORSE PATH, in engineering, a name sometimes applied to the towing-path by the side of canals, and narrow navigable rivers, for the use of the towing or track horses.

Horse Run, in engineering, a simple and useful modern contrivance, for drawing up loaded wheel-barrows of soil from the deep cuttings of canals, docks, &c. by the help of a horse which goes backwards and forwards, instead of round, as in a horse-gin.

HORSING BLOCK, a square frame of strong boards, used by navvigators or canal diggers for elevating the ends of their wheeling planks.

HOSPITAL. According to present usage, the term is applied to buildings endowed by public or private charity, as infirmaries, in which invalids are lodged and attended; but in olden times the term was used to signify any building erected for charitable purposes, as for the relief of the indigent, the entertainment of travellers, &c.

HOSTEL, or Hotel, a French term, anciently signifying a house, but now more commonly used for the palaces or houses of the king, princes, dukes, and great lords. The word is also applied to large inns, taverns, or places of public entertainment.

HOT-HOUSE, in horticulture, is a structure in which exotic plants are cultivated, under circumstances approximating, as closely as possible, to those under which they naturally exist; or it is used for accelerating the production of flowers and fruits of either indigenous or exotic plants. Hot-houses appropriated to the latter purposes are very frequently termed *forcing-houses.*

In the beginning of the seventeenth century, that description of hot-house generally termed the *green-house* began to be constructed in Germany; and one in the Apothecaries' Garden at Chelsea is mentioned by Ray in 1684. These, like many others of a later construction, had glass only in the front, which was perpendicular; and the mode of applying artificial heat exhibited little more knowledge of means for the end, than the remains of flues found in the ruins of the dwelling-houses and baths of the Romans.

In 1724, when Switzer published his treatise entitled "The Practical Fruit Gardener," the principles of managing hot-houses were still very imperfectly understood; for he observes, p. 305, that "peaches, nectarines, and apricots don't love to be forced; at least, the fruit is very seldom good: there being much occasion to keep the glasses close, the fruit is always rendered flat and insipid. This is not pure speculation, but the result of the practice that I have observed in the glass-houses at Brompton Park."

Considerable alterations, particularly in houses for grapes, were made towards the end of the last century. The most material improvement was the substitution of a slanting glass roof for a perpendicular glass front; but the advantages of this were much diminished by the heaviness of the sashes, and the large quantity of opaque matter which it was thought necessary to employ in order to ensure the durability of such structures.

In the present century great advances have been made in hot-house building, and more particularly since 1815. The application of heat by steam or hot water through iron pipes, and the admission of a greater quantity of light by glazing on metallic bars, instead of wooden sashes, are the principal features of these improvements. The employment of hollow bricks, too, will probably prove of great advantage, although we are not aware of their adoption in any building at present erected. *See* CONSERVATORY.

Those houses which are intended for the peach, nectarine, cherry, fig, &c. should in cold situations, be constructed against walls, and made with glass on one side. But in climates less severe, houses formed of glass on all the sides, having the trees so planted as to grow irregularly in the standard method, will be more beneficial as well as more ornamental.

For the forcing of vines, they may be of any kind of form, either small or large, according to the season at which the trees are to be brought into fruit. But a double-roofed house, with an inner roofing, is recommended as the most proper for general crops, as well as the cheapest in cost of erecting.

In the general construction of these houses, a wall of eight or ten feet in height, or more, is raised behind, with a low wall in front and both ends, on which is placed upright glass-work, four, five, or six feet in height, and a sloping glass roof, extending from the top of the front to the back wall. Internal flues for fire-heat, in winter, are also contrived, and a capacious oblong or square pit in the bottom space, in which to have a constant bark-bed, to furnish a continual regular heat at all seasons; so as in the whole to warm the enclosed internal air always to a certain temperature. Houses thus formed are generally used in raising pines.

Hot-houses are mostly ranged lengthwise, nearly east and west, that the glasses of the front and roof may have the full influence of the sun. This is the most convenient situation for common houses, either for pines or exotic plants. But some houses of the sort, instead of being placed in this direction, are ranged directly south and north, having a sloped roof to each side, like the roof of a house; as also to the front or south end; both sides and the south-end front being of glass. These houses are made from ten or twelve to fifteen or twenty feet wide, the length at pleasure; and from ten to twelve feet high in the middle, both sides fully head-height; being formed by a brick wall all round, raised only two or three feet on both sides, and south end; but carried up at the north end like the gable of a house. Upon the top of the side and south-end walling is erected the framing for the glass-work, which is sometimes formed two or three feet upright, immediately on the top of the wall, having the sloped glass-work above; and sometimes wholly of a continued slope on both sides, rising immediately from the top of the side-walls to that of the middle ridge. They are furnished either with one or two bark-pits; but if of any considerable width, generally with two, ranging parallel, one under each slope of the top glass, and separated by a two-foot path running along the middle of the house, and sometimes continued all round each pit, with flues ranged along against the inside walls; the whole terminating in an upright funnel, or chimney, at the north end of the building. There are other hot-houses which are formed entirely on the square, having a ten or twelve feet brick wall behind; that of the front, and both sides, being only two or three feet high, for the support of the glass-work, which is placed nearly upright almost the same height, and sloped above on both sides and front, which are wholly of glass. These are furnished within with bark-pits and flues, as in the previous instances.

In particular cases they are made semicircular, or entirely circular, being formed with a two or three feet brick wall supporting the glass-framing, which is continued quite round. The bark-pit is also circular, and the flues, after being carried all round the inside of the walling, terminate in a chimney on the northern side of the house. However, the first forms are probably the best for general purposes.

Hothouses on these plans are made of different dimensions, according to the size of the plants they are designed to contain. For common purposes they should be only of a moderate height, not exceeding ten or twelve to fourteen feet behind, and five or six in front; some are, however, built much more lofty behind, to give sufficient height for the taller-growing exotics, placed toward the back part. Those of the first-described size are, however, best adapted to the culture of pines, and other moderate-growing plants, as well as for forcing in. Very lofty houses require a greater force of heat, and by the glasses being so high, the plants naturally tending towards the glasses, receive less benefit from the sun and are apt to draw up too fast into long slender leaves and stems. Where the top-glasses are at a moderate distance from the plants, they receive the benefit of the sun's heat more fully, which is essential in winter, become more stalky at bottom, assume (particularly the pine-apple) a more robust and firm growth, and are rendered more capable of producing large fruit in the season.

After having determined on the dimensions of the house as to length and width, the foundations of brick-work should be set out accordingly, allowing due width at the bottom to support the flues a foot wide, wholly on the brick basis; detached an inch or two from the main walls; then setting off the back or north-wall, a brick and a half or two bricks thick, and the front and end walls nine inches, carry up the back wall from ten to fourteen feet high; those of the front and ends to be only from about two feet to a yard. Take care in carrying up the walls to allot a proper space for a door-way, at one or both ends, towards the back part; setting out also the furnace or fire-place of the flues in the bottom foundation towards one end of the back wall behind, formed also of brick-work, made to communicate with the lowermost flue within. When the house is of great length, as forty feet or more, a fire-place at each end may be necessary; or, if more convenient, both may be in the back part of the end walls, or in the middle way of the back wall; each must communicate with a separate range of flues. In either case they should be formed wholly on the outside of the walls, about twelve or fourteen inches wide in the clear, but more in lengthwise inward; the inner end terminating in a funnel to communicate internally with the flues. An iron-barred grate should be fixed at bottom to support the fuel, and calculated for coal, wood, peat, turf, &c. An ash-hole should be made underneath. The mouth or fuel-door should be about ten or twelve inches square, having an iron frame and door fixed to shut with an iron latch, as close as possible. The whole furnace should be raised sixteen or eighteen inches in the clear, finishing the top archwise. Then continue carrying up the walls of the building regularly, and on the inside erect the flues close along the walls.

It is sometimes advantageous to have the flues a little detached from the walls, one, two, or three inches, that, by being thus distinct, the heat may arise from both sides, which will be an advantage in more effectually diffusing the whole heat internally in the house; as, when they are attached close to the walls, a very considerable portion of the heat is lost in the part of the wall behind. In contriving the flues, they should be continued along the front and both ends, in one range at least, in this order. But it is better if they are raised as high as the outward front and end walls, in one or two ranges, one over the other. On the tops of these may be placed pots of many small plants, both of the exotic and forcing kinds, with much convenience.

In the construction of the flues, make them generally about a foot wide in the whole, including six or eight inches in the clear, formed with a brick-work on edge; the first lower flue should communicate with the furnace or fire-place without, and be raised a little above it, to promote the draught of heat more freely. Continue it along above the internal level of the floor of the back alley or walk of the house the above width, and three bricks on edge deep, returning it in two or three ranges over one another, next the back wall, and in one or two along the ends and front wall, as the height may admit; each return two bricks on edge deep, and tiled or bricked over. In the beginning of the first bottom-flue a sliding iron regulator may be fixed, to use occasionally, in admitting more or less heat, being careful that the brick-work of each flue is closely jointed with the best sort of mortar for that purpose, and well pointed within, that no smoke may break out. Have each return closely covered with broad square paving tiles on the brick-work; covering the uppermost flues also with broad thick flat tiles, the whole width, all very closely laid, and joined in mortar. The uppermost, or last range of flues, should terminate in an upright vent or chimney, at one end of the back wall; and where there are two separate sets of flues, there should be a chimney at each end. An iron slider in the termination of the last flue next the chimney may also be provided, to confine the heat more or less on particular occasions, as may be found necessary.

Sometimes, in very wide houses, in erecting the flues, spare ones, for occasional use, are continued round the bark-pit, carried up against the surrounding wall, but detached an inch or two, to form a vacancy for the heat to come up more beneficially, and that, by having vent, it may not dry the tan of the bark-bed too much. In the beginning a sliding iron regulator may be fixed, either to admit or exclude the heat, as expedient; so that the smoke, by running through a larger extent, may expend its heat wholly in the flues; before it be discharged at the chimney. Great care should be taken that neither the fire-place nor flues be carried too near any of the wood-work of the buildings.

After this work is done, proceed to set out the cavity for the bark-pit, first allowing a space next the flues for an alley or walk, eighteen inches or two feet all round, and then in the middle space form the pit for the bark-bed, six or seven feet wide, the length in proportion to that of the house, and a yard or more deep; enclosing it by a surrounding wall. It may either be sunk at bottom a little in the ground, raising the rest above by means of the parapet wall; or, if there is danger of wet below, it should be raised a little above the general surface. The surrounding wall should be nine inches, but a half-brick wall is often made to do, especially for that part which forms the parapet above ground. It should be coped all round with a timber plate or kirb, framed and mortised together, which effectually secures the brick-work in its proper situation.

The bottom of the pit should be levelled and well rammed, and, if paved with any coarse material, it is of advantage in preserving the bark. The path or alley round the pit should also be neatly paved with brick or stone, as may be most convenient.

The glass part for enclosing the whole, should consist of a close continued range of glass sashes all along the front, both ends and roof, quite up to the back wall; each sash being three feet or three feet six inches wide; and for the support of these, framings of timber must be erected in the brick walling, conformable to the width and length of the sashes, the whole being neatly fixed.

For the reception of the perpendicular glasses in the front and ends, a substantial timber plate must be placed along the top of the front and end walls, upon which should be erected uprights, at proper distances, framed to a plate or crown-piece above, of sufficient height to raise the whole front head-high, both ends corresponding with the front and back. To receive the sloping bars from the frame-work in front, a plate of timber must be framed to the back wall above, proper grooves being formed in the front plate below and above, to receive the ends of the perpendicular sashes, sliding close against the outside of the uprights all the way along the front. Or they may be contrived for only every other sash, to slide one on the side of the other, but the former is the better method.

From the top of the upright framing in front should be carried substantial cross-bars or bearers, sloping to the back wall, where they are framed at both ends to the wood-work or plates, at regular distances, to receive and support the sloping glass sashes of the roof. These are placed close together upon the cross-bars or rafters, and generally range in two or more tiers, sliding one over the other, of sufficient length together to reach quite from the top of the upright framing in front to the top of the back wall. The cross-bars should be grooved lengthwise above, to carry off wet falling between the frames of the sloping lights; and the upper end of the tier of glasses should shut close up to the plate in the wall behind, running under a proper coping of wood or lead which must be fixed along above close to the wall, and lapped down, of due width to cover, and shoot off the wet sufficiently from the upper termination of the top sashes. Some wide houses have, exclusive of the sliding glass sashes of the main slope, a shorter upper tier of glass fixed; the upper ends being secured under a coping as above, and the lower ends lapping over the top ends of the upper sliding tier, and this over that below in the same manner, so as to shoot the wet clear over each upper end or termination. Likewise, along the under outer edge of the top plate or crown-piece in front may be a small channel to receive the water from the sloping glass sashes, and convey it to one or both ends without running down upon the upright sashes, being careful that the top part behind be well framed and secured water-tight, and the top of the back wall finished a little higher than the glass with a neat coping the whole length of the building.

The bars of wood which support the glasses should be neatly formed, and made neither very broad nor thick, to intercept the rays of the sun. Those, however, at top, should be made strong enough to supp rt the glasses without bending under them. In wide houses, uprights are arranged within, at proper distances to support the cross rafters more perfectly than could otherwise be the case.

But in respect to the glass-work in the sloping sashes, the panes of glass should be laid in putty, with the ends lapping over each other about half an inch, the vacancies of which are, in some, closed up at bottom with putty; others leave each lapping of the panes open, for the admission of air, and that the rancid vapours arising from the fermentation of the bark-bed, &c., within, may thereby be kept in constant motion, to diminish condensation, and also, that such as condense against the glasses may discharge themselves at those places without dropping upon the plants. The upright sashes in front may either be glazed as above, or the panes laid in lead-work; being very careful to have the glazing well performed, and proof against any wet that may happen to beat against them. The doors should have the upper parts sashed and glazed to correspond with the other glass-work of the house.

On the inside, the walls should be plastered, pargeted, and white-washed: and all the wood-work, within and without, painted white in oil-colour. Some, however, have the back wall painted or coloured rather dark.

Ranges of narrow shelves, for pots of small plants, may be erected where most convenient, some behind over the flues, a single range near the top glasses towards the back part, supported either by brackets suspended from the cross-bars above, or by uprights erected on the parapet wall of the bark-pit. A range or two of narrow ones may also be placed occasionally along both ends above the flues, where there is a necessity for a very great number.

In wide houses, where the cross-bars or bearers of the sloping or top glass sashes appear to want support, some neat uprights, either of wood or iron, may be erected upon the bark-bed walling, at convenient distances, and high enough to reach the bearers above. This is a neat mode of affording them support.

On the outside, behind, should be erected a close shed, the whole length, or at least a small covered shed over each fire-place, with a door to shut, for the convenience of attending the fires. The former is much the best, as it will serve to defend the back of the house from the outward air, and to stow fuel; also for garden tools when not in use; as well as to lay portions of earth in occasionally, to have it dry for particular purposes in winter and early spring, as in forcing-frames, &c.

Sometimes hot-houses are furnished with top-covers, to draw over the glass sashes occasionally, in time of severe frosts and storms; and sometimes by slight sliding shutters, fitted to the width of the separate sashes; but these are inconvenient, and require considerable time and trouble in their application. At other times they are formed of painted canvass, on long poles or rollers, fixed lengthwise along the tops of the houses, just above the upper ends of the top sashes, which, by means of lines and pulleys, are readily let down and rolled up, as there may be occasion.

HOVEL (Saxon), a low building, with some part of the lower side open, to afford shelter to young animals during stormy weather.

HOVELING, the carrying up of the sides of a chimney, that when the wind rushes over the mouth, the smoke may escape below the current, or against any one side of it. The working up of the sides is covered at the top with tiles or bricks in a pyramidal form, in order to get rid of the inconvenience occasioned by adjoining buildings being higher than the chimney, or by its being in the eddy of any very lofty buildings, or in the vicinity of high trees; in which cases the covered side must be towards the building.

HOUSE, a habitation, or a building constructed for sheltering a man's person and goods from the inclemencies of the weather, and the injuries of ill-disposed persons. Houses differ in magnitude, being of two or three, and four stories; in the materials of which they consist, as wood, brick, or stone; and in the purposes for which they are designed, as a manor-house, farm-house, cottage, &c.

A pleasure-house, or country-house, is one built for occasional residence, and for the pleasure and benefit of retirement, air, &c. This is the *villa* of the ancient Romans; and what in Spain and Portugal they call *quinta;* in Provence, *cassino;* in some other parts of France, *closerie;* in Italy, *vigna.*

The citizens of Paris have also their *maisons de bouteilles* (bottle-houses) to retire to, and entertain their friends; which, in Latin, might be called *micæ;* the emperor Domitian having a house built for the like purpose, mentioned under this name by Martial.

It is a thing principally to be aimed at, in the site or situation of a country-house, or seat, that it have wood and water near it.

It is far better to have a house defended by trees than hills: for trees yield a cooling, refreshing, sweet, and healthy air and shade during the heat of the summer, and very much break the cold winds and tempests from every point in the winter. The hills, according to their situation, defend only from certain winds; and, if they are on the north side of the house, as they defend from the cold air in the winter, so they also deprive you of the cool refreshing breezes which are commonly blown from thence in the summer; and if the hills are situate on the south side, they then prove also very inconvenient.

A house should not be too low-seated, since this precludes the convenience of cellars. If you cannot avoid building on low grounds, set the first floor above the ground the higher, to supply what you want to sink in your cellar in the ground; for in such low and moist grounds, it conduces much to the dryness and healthiness of the air to have cellars under the house, so that the floors be good, and ceiled underneath. Houses built too high, in places obvious to the winds, and not well defended by hills or trees, require more materials to build them, and more also of reparations to maintain them; and they are not so commodious to the inhabitants as the lower-built houses, which may be built at a much easier rate, and also as complete and beautiful as the other.

In houses not above two stories with the ground-room, and not exceeding twenty feet to the wall-plate, and upon a good foundation, the length of two bricks, or eighteen inches for the heading course, will be sufficient for the ground-work of any common structure, and six or seven courses above the earth to a water-table, where the thickness of the walls is abated or taken in on either side the thickness of brick, namely, two inches and a quarter.

For large and high houses, or buildings of three, four, or five stories, with the garrets, the walls of such edifices ought to be from the foundation to the first water-table three heading courses of brick, or 28 inches at least; and at every story a water-table, or taking in on the inside for the girders and joists to rest upon, laid into the middle, or one quarter of the wall at least, for the better bond. But as for the innermost or partition wall, a half brick will be sufficiently thick;

and for the upper stories, nine inches or a brick length will suffice.

The general principles of the construction of edifices and private houses will be found under the article Building. We shall under this head give a description of the private houses of the ancients: —

Of the private dwellings of the ancients, we have but little or no account, and it is probable that they possessed but small pretensions to architectural grandeur. We hear of temples, palaces, and such like public buildings, and of these we have careful and detailed descriptions, but of the habitations of the mass of the people, we have only a cursory notice. This fact would lead us to believe that but little attention was paid to domestic buildings of the earlier periods of history, and such indeed seems to have been the case; all the care of the people being confined to the temples of their gods, and the palaces of their governors. With a proper though misplaced zeal, the taste of their architects was exhausted in erecting and adorning the habitations of their deities; and indeed in all ages and countries, the art seems to be principally indebted for its progress to the religious feelings of mankind.

In his description of Babylon, Herodotus speaks of houses being ranged on either side of the various streets into which the city was divided, and of others of a smaller character, on either side of the outer wall, so placed as to allow of a wide passage or roadway between the two ranges. The former are described as consisting of three or four stories, and the latter of only one story.

If we may form a judgment from the paintings of the ancient Egyptians, their domestic buildings were of very uniform character. Some houses were two or three stories in height, and these seem to have belonged to the more common sort, but the larger mansions were only of one story, but of considerable extent in plan. They consisted of one or more rectangular courts surrounded by chambers similar to the existing specimens of Roman construction; or sometimes a group of building was placed in the centre of such a court. The roofs, as in all Eastern buildings, were flat, and probably covered with an awning, as a protection from the heat.

According to Pliny, the Greeks originally dwelt in caves, and were taught the art of house-building by two brothers, Euryalus and Hyperbius, who were Tyrrhenians, from which nation buildings of all kinds are said to have been introduced into Greece. During their early history, up to the time of Aristides and Pericles, their dwellings were of a very simple description, nor did they arrive at any magnificence until the time of Alexander, when they had given themselves over to a luxurious mode of living. At this period their dwellings became of great extent, and were very highly embellished, being similar in form and arrangement to those of the Romans,—of which in all probability they afforded the idea—but far inferior to them in extent and magnificence. Ere, however, the Romans had become thus extravagant in the adornment of their villas, they had passed through the same stages as their predecessors, and it was not until by their conquests they had become acquainted with the luxury of Asia and Greece, that they began to erect such splendid mansions. The villa of Marcus Cato, we are told, was so rude, that the walls were not even plastered; nor did that of Scipio Africanus, or the Villa Publica, greatly excel in richness of decoration. The first houses of the Romans were nothing better than simple cottages thatched with straw; and when the city was rebuilt after it was burned by the Gauls, the houses were mostly constructed of wood and covered with shingles, although of so great a height as to become dangerous. This was the case, even in the reign of Augustus. The greater part of the city was again destroyed by fire in the time of Nero, and was rebuilt in a more substantial and elegant manner; but we can form only a remote idea of the houses, having no examples remaining.

The country seats or villas were the dwellings on which the higher classes expended the greatest care, and a full description of these will be found in Pliny's Letters, which we proceed to give, but, before doing so, insert some remarks and directions on the subject by Vitruvius.

Of the private and public Apartments of Houses, and of their Construction according to the different Ranks of People; (from Vitruvius.)

"These buildings being disposed to the proper aspects of the heavens, then the distribution of such places in private houses as are appropriated to the use of the master of the house, and those which are common for strangers, must be also considered: for into those that are thus appropriated, no one can enter unless invited; such as the cubiculum, the triclinium, the bath, and others of similar use. The common are those which the people unasked may legally enter; such are the vestibulum, cavædium, peristylium, and those that may answer the same purposes: but to persons of the common rank, the magnificent vestibulum, tablinum, or atrium, are not necessary, because such persons pay their court to those who are courted by others.

"People who deal in the produce of the country must have stalls and shops in their vestibules, and cryptæ, horreæ, and apothecæ, in their houses, which should be constructed in such a manner as may best preserve their goods rather than be elegant. The houses of bankers, and public offices, should be more commodious and handsome, and made secure from robbers; those of advocates and the learned, elegant and spacious, for the reception of company; but those of the nobles, who bear the honours of magistracy, and decide the affairs of the citizens, should have a princely vestibulum, lofty atrium, and ample peristylium, with groves and extensive ambulatories, erected in a majestic style; besides libraries, pinacotheeas, and basilicas, decorated in a manner similar to the magnificence of public buildings; for in these places, both public affairs and private causes are oftentimes determined. Houses therefore being thus adapted to the various degrees of people, according to the rules of decor, explained in the first book, will not be liable to censure, and will be convenient and suitable to all purposes. These rules also are applicable, not only to city houses, but likewise to those of the country; except that in those of the city the atrium is usually near the gate, whereas in the country pseudo-urbana, the peristylium is the first, and then the atrium; having a paved porticus around, looking to the palestra and ambulatories.

"I have, as well as I have been able, briefly written the rules relative to city houses, as I proposed. I shall now treat of those in the country, how they may be made convenient, and in what manner they should be disposed.

"*Of Country Houses, with the description and use of their several Parts.*

"In the first place, the country should be examined with regard to its salubrity, as written in the first book concerning the founding of a city, for in like manner villas are to be established. Their magnitude must be according to the quantity of land and its produce. The courts and their size must be determined by the number of cattle and yokes of oxen to be there employed. In the warmest part of the court, the kitchen is to be situated, and adjoining thereto the ox-house, with the stalls turned towards the fire and the eastern sky; for the cattle seeing the light and fire, are thereby rendered smooth-coated; even husbandmen, although ignorant of the nature of aspects, think that cattle should look to no other part of the heavens than to that where the sun rises. The breadth of the ox-house should not be less than ten feet, nor more than fifteen: the length should be so much as to allow no less than seventeen feet to each yoke.

"The bath also is to be adjoined to the kitchen, for thus the place of bathing will not be far from those of the husbandry occupations. The press-room should be near the kitchen, that it may be convenient for the olive business; and adjoining thereto the wine-cellar, having windows to the north; for, should they be toward any part which may be heated by the sun, the wine in that cellar would be disturbed by the heat, and become vapid. The oil-room is to be so situated as to have its light from the southern and hot aspects; for oil ought not to be congealed, but be attenuated by a gentle heat. The dimensions of these rooms are to be regulated by the quantity of fruit, and the number of the vessels; which, if they be cullearin, should in the middle occupy four feet. Also, if the press be not worked by screws, but by levers, the press room should not be less than forty feet long, that the pressers may have sufficient space; the breadth should not be less than sixteen feet, by which means there will be free room to turn, and to dispatch the work; but if there be two presses in the place, it ought to be twenty-four feet broad. The sheep and goat-houses should be so large, that not less than four feet and a half, nor more than six feet, may be allowed to each animal. The granary should be elevated from the ground, and look to the north or east, for thus the grain will not so soon be heated, but, being cooled by the air, will endure the longer; the other aspects generate worms and such vermin as usually destroy the grain.

"The stable, above all in the villa, should be built in the warmest place, and not look toward the fire, for if these cattle be stalled near the fire, they become rough-coated; nor are those stalls unuseful which are placed out of the kitchen, in the open air, toward the east; for in the winter time, when the weather is serene, the beasts, being led thither in the morning, may be cleaned while they are taking their food.

"The barn, hay-room, meal-room, and mill, are placed without the villa, that it may be more secure from the danger of fire.

"If the villa is to be built more elegantly, it must be constructed according to the symmetry of city houses, before described: but so as not to impede its use as a villa.

"Great care ought to be taken, that all buildings have sufficient light, which in villas is easily obtained; because there are no walls near to obstruct it. But in the city, either the height of the party-walls, or the narrowness of the streets, may occasion obscurity. It may, however, be thus tried: on the side where the light is to be received, let a line be extended from the top of the wall that seems to cause the obscurity, to that place to which the light is required; and if, when looking up along that line, an ample space of the clear sky may be seen, the light to that place will not be obstructed; but if beams, lintels, or floors, interfere, the upper parts must be opened, and thus the light be admitted. The upper rooms are thus to be managed; on whatsoever part of the heavens the prospect may lie, on that side the places of the windows are to be left, for thus the edifice will be best enlightened. As in tricliniums and such apartments, the light is highly necessary, so also is it in passages, ascents, and staircases, where people carrying burdens frequently meet each other.

"I have explained, as well as I have been able, the distribution of our buildings, that they may not be unknown to those who build; I shall now also briefly explain the distribution of houses, according to the custom of the Greeks, that they also may not be unknown.

"*Of the Disposition of the Houses of the Greeks.*

"The Greeks use no atrium, nor do they build in our manner; but from the gate of entrance they make a passage of no great breadth; on one side of which is the stable, on the other, the porters' rooms, and these are directly terminated by the inner gates. This place between the two gates is called by the Greeks *thyroreion.* After that, in entering, is the peristylium, which peristylium has porticos on three sides. On that side which looks to the south, are two antæ, at an ample distance from each other, supporting beams, and so much as is equal to the distance between the antæ, wanting a third part, is given to the space inwardly; this place is called by some *prostas*, by others *parastas.* From this place, more inwardly, the great œci are situated, in which the mistress of the family, with the workwomen, resides. On the right and left of the prostas, are cubiculæ, of which one is called *thalamus*, and the other *amphithalamus;* and in the surrounding porticos, the common tricliniums, cubiculums, and family rooms are erected. This part of the edifice is called *gynæconitis.*

"Adjoining to this is a larger house, having a more ample peristylium, in which are four porticos of equal height, or sometimes the one which looks towards the south has higher columns; and this peristylium, which has one portico higher than the rest, is termed *rhodian.* In these houses they have elegant vestibulums, magnificent gates, and the porticos of the peristyliums are ornamented with stucco, plaster, and lucunariæ, of inside work (wood.) In the porticos which look to the north, are the Cyzicene triclinium, and pinacothecæ: to the east are the libraries, to the west the exedræ, and in those looking to the south are the square œci, so large that they may easily contain four sets of dining couches, with the attendants, and a spacious place for the use of the games. In these œci are made the men's dining couches, for it is not their custom for the mothers of families to lie down to dine. This peristylium and part of the house is called *andronitides*, because here the men only are invited without being accompanied by the women.

"On the right and left also, small houses are erected, having proper gates, triclinæ, and convenient cubiculæ, that when strangers arrive, they may not enter the peristylium, but be received in this hospitalium; for when the Greeks were more refined and opulent, they prepared tricliniæ, cubiculæ, and provisions, for strangers; the first day inviting them to dinner, afterwards sending them poultry, eggs, herbs, fruits, and other productions of the country. Hence the pictures representing the sending of gifts to strangers, are by the painters called *zenia.* Masters of families, therefore, while they abode in the hospitium, seemed not to be from home, having the full retirement in these hospitaliums. Between the peristylium and hospitalium are passages, which are called *mesaulæ;* because they are situated between two *aulæ*; these are by us called *andronas;* but it is remarkable that the Greeks and Latins do not in this agree; for the Greeks give the name of *andronas* to the œcus where the men usually dine, and which the women do not enter.

"It is the same also with some other words, as *xystos*, *prothyrum*, *telamones*, and others; for *xystos* is the Greek appellation of those broad porticos, in which the athletæ exercise in winter time; whereas, we call the uncovered ambulatories *xystos;* and which the Greeks call *peridromidas.* The *vestibula*, which are before the gates, are by the Greeks called *prothyra;* whereas, we call *prothyra* that which the Greeks call *diathyra.* The statues of men bearing mutules or cornices we call *telamones*, for what reason is not to be found in history; but the Greeks call them *atlantes;* Atlas being in history represented as supporting the world; for he was the first who, by his ingenuity and diligence, discovered and taught mankind the course of the sun and moon, the rising and setting of all the planets, and the revolutions of the heavens; for which benefit the painters and statuaries represented him bearing the whole earth; and the Atlantides, his children, which we call *Vergilius*, and the Greeks *Pheïades*, are placed among the stars in the heavens. I have not, however, mentioned this in order to change the customary names or manner of discoursing, but only to explain them, that these things might not be unknown to the lovers of knowledge."

Extracts from Pliny's Letters.

Description of the villa at Laurentinum.

"You are surprised, it seems, that I am so fond of my Laurentinum, or (if you like the appellation better) my Laurens; but you will cease to wonder, when I acquaint you with the beauty of the villa, the advantages of its situation, and the extensive prospect of the sea-coast. It is but seventeen miles distant from Rome; so that, having finished my affairs in town, I can pass my evenings here, without breaking in upon the business of the day. There are two different roads to it: if you go by that of Laurentum, you must turn off at the fourteenth mile-stone; if by Ostia, at the eleventh. Both of them are, in some parts, sandy, which makes it somewhat heavy and tedious, if you travel in a carriage, but easy and pleasant to those who ride on horseback. The landscape, on all sides, is extremely diversified, the prospect, in some places, being confined by woods, in others extending over large and beautiful meadows, where numberless flocks of sheep and herds of cattle, which the severity of the winter has driven from the mountains, fatten in the vernal warmth of this rich pasturage. My villa is large enough to afford all desirable accommodations, without being extensive. The porch before it is plain, but not mean, through which you enter into a portico in the form of the letter D, which includes a small but agreeable area. This affords a very commodious retreat in bad weather, not only as it is enclosed with windows, but particularly as it is sheltered by an extraordinary projection of the roof. From the middle of this portico you pass into an inward court, extremely pleasant, and from thence into a handsome hall, which runs out towards the sea; so that when there is a south-west wind, it is gently washed with the waves, which spend themselves at the foot of it. On every side of this hall, there are either folding-doors, or windows equally large, by which means you have a view from the front and the two sides, as it were, of three different seas: from the back part, you see the middle court, the portico, and the area; and, by another view, you look through the portico, into the porch, from whence the prospect is terminated by the woods and mountains which are seen at a distance. On the left-hand of this hall, somewhat farther from the sea, lies a large drawing-room, and beyond that, a second of a smaller size, which has one window to the rising, and another to the setting sun: this has, likewise, a prospect of the sea, but being at a greater distance, is less incommoded by it. The angle which the projection of the hall forms with this drawing-room, retains and increases the warmth of the sun; and hither my family retreat in winter to perform their exercises: it is sheltered from all winds, except those which are generally attended with clouds, so that nothing can render this place useless, but what, at the same time, destroys the fair weather. Contiguous to this, is a room forming the segment of a circle, the windows of which are so placed, as to receive the sun the whole day: in the walls are contrived a sort of cases, which contain a collection of such authors whose works can never be read too often. From hence you pass into a bed-chamber through a passage, which, being boarded, and suspended, as it were, over a stove which runs underneath, tempers the heat which it receives, and conveys it to all parts of this room. The remainder of this side of the house is appropriated to the use of my slaves and freed-men: but most of the apartments, however, are neat enough to receive any of my friends. In the opposite wing, is a room ornamented in a very elegant taste; next to which lies another room, which, though large for a parlour, makes but a moderate dining-room; it is exceedingly warmed and enlightened, not only by the direct rays of the sun, but by their reflection from the sea. Beyond, is a bed-chamber, together with its ante-chamber, the height of which renders it cool in summer; as its being sheltered on all sides from the winds makes it warm in winter. To this apartment another of the same sort is joined by one common wall. From thence you enter into the grand and spacious cooling-room, belonging to the bath, from the opposite walls of which, two round basons project, sufficiently large to swim in. Contiguous to this is the perfuming-room, then the sweating-room, and next to that, the furnace which conveys the heat to the baths: adjoining, are two other little bathing-rooms, fitted up in an elegant rather than costly manner: annexed to this, is a warm bath of extraordinary workmanship, wherein one may swim, and have a prospect, at the same time, of the sea. Not far from hence, stands the tennis court, which lies open to the warmth of the afternoon sun. From thence you ascend a sort of turret, containing two entire apartments below; as there are the same number above, besides a dining-room which commands a very extensive prospect of the sea, together with the beautiful villas that stand interspersed upon the coast. At the other end, is a second turret, in which is a room that receives the rising and setting sun. Behind this is a large repository, near to which is a gallery of curiosities, and underneath a spacious dining-room, where the roaring of the sea, even in a storm, is heard but faintly: it looks upon the garden, and the *gestatio* which surrounds the garden. The gestatio is encompassed with a box-tree hedge, and where that is decayed, with rosemary; for the box, in those parts which are sheltered by the buildings, preserves its verdure perfectly well; but where, by an open situation, it lies exposed to the spray of the sea, though at a great distance, it entirely withers. Between the garden and this gestatio runs a shady plantation of vines, the alley of which is so soft, that you may walk bare-foot upon it without any injury. The garden is chiefly planted with fig and mulberry trees, to which this soil is as favourable, as it is averse from all others. In this place is a banqueting-room, which, though it stands remote from the sea, enjoys a prospect nothing inferior to that view: two apartments run round the back part of it, the windows whereof look upon the entrance of the villa, and into a very pleasant kitchen-ground. From hence an enclosed portico extends, which, by its great length, you might suppose erected for the use of the public. It has a range of windows on each side, but on that which looks towards the sea, they are double the number of those next the garden. When the weather is fair and serene, these are all thrown open; but if it blows, those on the side the wind sets are shut, while the others remain unclosed without any inconvenience. Before this portico lies a terrace, perfumed with violets, and warmed by the reflection of the sun from the portico, which, as it retains the rays, so it keeps off the north-east wind: and it is as warm on this side as it is cool on the opposite: in the same manner it proves a defence against the south-west; and thus, in short, by means of its several sides, breaks the force of the winds from what point soever they blow. These are some of its winter advantages: they are still more considerable in summer; for at that season it throws a shade upon the terrace during all the forenoon, as it defends the gestatio, and that part of the garden which lies contiguous to it, from the afternoon sun, and casts a greater or less shade, as the day either increases or decreases; but the portico itself is then coolest, when the sun is most scorching, that is, when its rays fall directly upon the roof. To these its benefits I must not forgot to add, that, by setting open the windows, the western breezes have a free draught, and, by that means, the enclosed air is prevented from stagnating. On the upper end of the terrace and portico stands a detached building in the garden, which I call my favourite; and indeed it is particularly so, having erected it myself. It contains a very warm winter-room, one side of which looks upon the terrace, the other has a view of the sea, and both lie exposed to the sun. Through the folding-doors you see the opposite chamber, and from the window is a prospect of the enclosed portico. On that side next the sea, and opposite to the middle wall, stands a little elegant recess, which, by means of glass-doors and a curtain, is either laid into the adjoining room, or separated from it. It contains a couch and two chairs. As you lie upon this couch, from the feet you have a prospect of the sea; if you look behind, you see the neighbouring villas; and from the head you have a view of the woods; these three views may be seen either distinctly from so many different windows in the room, or blended together in one confused prospect. Adjoining to this is a bed-chamber, which neither the voice of the servants, the murmuring of the sea, nor even the roaring of a tempest, can reach; not lightning nor the day itself can penetrate it, unless you open the windows. This profound tranquillity is occasioned by a passage, which separates the wall of this chamber from that of the garden; and thus, by means of that intervening space, every noise is precluded. Annexed to this is a small stove-room, which, by opening a little window, warms the bed-chamber to the degree of heat required. Beyond this lies a chamber and anti-chamber, which enjoys the sun, though obliquely indeed, from the time it rises, till the afternoon. When I retire to this garden-apartment, I fancy myself a hundred miles from my own house, and take particular pleasure in it at the feast of the Saturnalia, when, by the license of that season of festivity, every other part of my villa resounds with the mirth of my domestics: thus I neither interrupt their diversions, nor they my studies. Among the pleasures and conveniences of this situation, there is one disadvantage, and that is the want of a running stream; but this defect is, in a great measure, supplied by wells, or rather I should call them fountains, for they rise very near the surface. And, indeed, the quality of this coast is remarkable; for in what part soever you dig, you meet, upon the first turning up of the ground, with a spring of pure water, not in the least salt, though so near the sea. The neighbouring forests afford an abundant supply of fuel; as every other accommodation of life may be had from Ostia: to a moderate man, indeed, even the next village (between which and my house there is only one villa) would furnish all common necessaries. In that little place there are no less than three public baths; which is a great conveniency, if it happen that my friends come in unexpectedly, or make too short a stay to allow time for preparing my own. The whole coast is beautifully diversified by the contiguous or detached villas that are spread upon it, which, whether you view them from the sea or the shore, have the appearance of so many different cities. The strand is sometimes, after a long calm, perfectly smooth, though, in general, by the storms driving the waves upon it, it is rough and uneven. I cannot boast that our sea produces any very extraordinary fish; however, it supplies us with exceeding fine soles and prawns; but as to provisions of other kinds, my villa pretends to excel even inland countries, particularly in milk; for hither the cattle come from the meadows in great numbers, in pursuit of shade and water.

"Tell me now, have I not just cause to bestow my time and my affection upon this delightful retreat? Surely you are too fondly attached to the pleasures of the town, if you do not feel an inclination to take a view of this my favourite villa. I much wish, at least, you were so disposed, that to the many charms with which it abounds, it might have the very considerable addition of your company to recommend it. Farewell."

The following observations may tend to illustrate several of the obscure parts, in the foregoing description of Pliny's villa at Laurentinum.

Pliny had no estate round his seat at Laurentinum; his whole possessions there being included (as he informs us, n. 4. let. 3.) in the house and garden. It was merely a winter villa, in which he used to spend some of the cold months, whenever his business admitted of his absence from Rome; and, for this reason it is, that we find warmth is so much considered in the disposition of the several apartments, &c. And, indeed, he seems to have a principal view to its advantages as a winter house, throughout the whole description of it.

Scamozzi, in his *Architect. Univers.* lib. 3. 12. has given a plan and elevation of this villa. Mons. Felibien has also annexed a plan to his translation of this letter; as our own countryman, the ingenious Mr. Castel, has done in his *Villas of the Ancients illustrated.* But they differ extremely among themselves as to the disposition of the several parts of this building, and, perhaps, have rather pursued the idea of modern architecture, than that which is traced out in their original; at least, if the supposition advanced by one of the commentators upon this epistle be true; who contends that the villas of the ancients were not one uniform pile of building contained under the same roof, but that each apartment formed a distinct and separate member from the rest. The ruins of this villa are said to have been discovered some time about the year 1714, but whether any plan was ever taken of so valuable a remain of antiquity, or the reality of it ascertained, the translator has not been able to learn.

The Roman magnificence seems to have particularly displayed itself in the article of their baths. Seneca, dating one of his epistles from a villa which once belonged to Scipio Africanus, takes occasion, from thence, to draw a parallel between the simplicity of the earlier ages, and the luxury of his own times in that instance. By the idea he gives of the latter, they were works of the highest splendour and expense. The walls were composed of Alexandrine marble, the veins whereof were so artfully managed, as to have the appearance of a regular picture: the edges of the basons were set round with a most valuable kind of stone, found in Thasius, one of the Greek islands, variegated with veins of different colours, interspersed with streaks of gold; the water was conveyed through silver pipes, and fell, by several descents, in beautiful cascades. The floors were inlaid with precious gems, and an intermixture of statues and colonnades contributed to throw an air of elegance and grandeur upon the whole. *Vide* Sen. *Ep.* 86.

"The custom of bathing in hot water was become so habitual to the Romans, in Pliny's time, that they every day practised it before they lay down to eat, for which reason, in the city, the public baths were extremely numerous; in which Vitruvius gives us to understand, there were, for each sex, three rooms for bathing, one of cold water, one of warm, and one still warmer; and there were cells of three degrees of heat, for sweating: to the fore-mentioned members, were added others for anointing and bodily exercises. The last thing they did before they entered into the dining-room was to bathe; what preceded their washing was their exercise in the spheristerium, prior to which it was their custom to anoint themselves. As for their sweating-rooms, though they were, doubtless, in all their baths, we do not find them used but upon particular occasions." Castel's *Villas of the Ancients*, p. 31.

"The enclosed porticos in Pliny's description differed no otherwise from our present galleries, than that they had pillars in them: the use of this room was for walking." Castel's *Villas*, p. 44.

Mr. Castel observes, that though Pliny calls his house *Villula;* it appears that, after having described but part of it, yet, if every diæta or entire apartment may be supposed to contain three rooms, he has taken notice of no less than forty-six, besides all which, there remains near half the house undescribed, which was, as he says, allotted to the use of the servants; and it is very probable this part was made uniform with that he has already described. But it must be remembered, that diminutives in Latin do not always imply smallness of size, but are frequently used as words of endearment and approbation; and in this sense it seems most probable that Pliny here uses the word *Villula.*

The following is Pliny's description of his summer villa in Tuscany, book v. letter vi., addressed to Apollinaris.

"The kind concern you expressed when you heard of my design to pass the summer at my villa in Tuscany, and your obliging endeavours to dissuade me from going to a place which you think unhealthy, are extremely pleasing to me. I confess, the atmosphere of that part of Tuscany, which lies towards the coast, is thick and unwholesome: but my house is situated at a great distance from the sea, under one of the Apennine mountains, which, of all others, is most esteemed for the clearness of its air. But that you may be relieved from all apprehensions on my account, I will give you a description of the temperature of the climate, the situation of the country, and the beauty of my villa, which I am persuaded you will read with as much pleasure as I shall relate. The winters are severe and cold, so that myrtles, olives, and trees of that kind, which delight in constant warmth, will not flourish here: but it produces bay-trees in great perfection; yet, sometimes, though indeed not oftener than in the neighbourhood of Rome, they are killed by the severity of the seasons. The summers are exceedingly temperate, and continually attended with refreshing breezes, which are seldom interrupted by high winds. If you were to come here, and see the numbers of old men who have lived to be grandfathers and great-grandfathers, and hear the stories they can entertain you with of their ancestors, you would fancy yourself born in some former age. The disposition of the country is the most beautiful that can be imagined; figure to yourself an immense amphitheatre; but such as the hand of nature only could form. Before you lies a vast extended plain, bounded by a range of mountains, whose summits are covered with lofty and venerable woods, which supply variety of game: from thence, as the mountains decline, they are adorned with underwoods. Intermixed with these are little hills of so strong and fat a soil, that it would be difficult to find a single stone upon them; their fertility is nothing inferior to the lowest grounds; and though their harvest, indeed, is somewhat later, their crops are as well matured. At the foot of these hills the eye is presented, wherever it turns, with one unbroken view of numberless vineyards, terminated by a border, as it were, of shrubs. From thence you have a prospect of the adjoining fields and meadows below. The soil of the former is so extremely stiff, and, upon the first ploughing, turns up in such vast clods, that it is necessary to go over it nine several times, with the largest oxen and the strongest ploughs, before they can be thoroughly broken; whilst the enamelled meadows produce trefoil, and other kinds of herbage, as fine and tender as if it were but just sprung up, being continually refreshed by never failing rills. But though the country abounds with great plenty of water, there are no marshes; for, as it lies upon a rising ground, whatever water it receives without absorbing, runs off into the Tiber. This river, which winds through the middle of the meadows, is navigable only in the winter and spring, at which seasons it transports the produce of the lands to Rome; but its channel is so extremely low in summer, that it scarcely deserves the name of a river; towards the autumn, however, it begins again to renew its claim to that title.—You could not be more agreeably entertained, than by taking a view of the face of this country from the top of one of our neighbouring mountains: you would suppose that not a real, but some imaginary landscape, painted by the most exquisite pencil, lay before you: such an harmonious variety of beautiful objects meets the eye, which way soever it turns. My villa is so advantageously situated, that it commands a full view of all the country round; yet you approach it by so insensible a rise, that you find yourself upon an eminence, without perceiving you ascended. Behind, but at a great distance, stands the Apennine mountains. In the calmest day we are refreshed by the winds that blow from thence, but so spent, as it were, by the long tract of land they travel over, that they are entirely divested of all their strength and violence before they reach us. The exposition of the principal front of the house is full south, and seems to invite the afternoon sun in summer (but somewhat earlier in winter) into a spacious and well-proportioned portico, consisting of several members, particularly a porch built in the ancient manner. In the front of the portico is a sort of terrace, embellished with various figures, and bounded with a box-hedge, from whence you descend by an easy slope, adorned with the representation of divers animals, in box, answering alternately to each other, into a lawn overspread with the soft, I had almost said the liquid, acanthus: this is surrounded by a walk enclosed with tonsile evergreens, shaped into a variety of forms. Beyond it is the gestatio, laid out in the form of a circus, ornamented in the middle with box cut in numberless different figures, together with a plantation of shrubs, prevented by the shears from shooting up too high: the whole is fenced in with a wall covered by box, rising by different ranges to the top. On the outside of the wall lies a meadow that owes as many beauties to nature, as all I have been describing *within* does to art; at the end of which are several other meadows and fields interspersed with thickets. At the extremity of this portico stands a grand dining-room, which opens upon one end of the terrace; as from the windows there is a very extensive prospect over the meadows up into the country, from whence you also have a view of the terrace, and such parts of the house which project forward, together with the woods enclosing the adjacent hippodrome. Opposite almost to the centre of the portico, stands a square edifice, which encompasses a small area, shaded by four plane-trees, in the midst of which a fountain rises, from whence the water, running over the edges of a marble bason, gently refreshes the surrounding plane-trees, and the verdure underneath them. This apartment consists of a bed-chamber, secured from every kind of noise, and which the light itself cannot penetrate; together with a common dining-room, which I use when I have none but intimate friends with me. A second portico looks upon this little area, and has the same prospect with the former I just now described. There is, besides, another room, which, being situated close to the nearest plane-tree, enjoys a constant shade and verdure: its sides are incrusted half-way with carved marble; and from thence to the ceiling a foliage is painted with birds intermixed among the branches, which has an effect altogether as agreeable as that of the carving: at the basis a little fountain, playing through several small pipes into a vase, produces a most pleasing murmur. From a corner of this portico you enter into a very spacious chamber, opposite to the grand dining-room, which, from some of its windows, has a view of the terrace, and from others, of the meadow; as those in the front look upon a cascade, which entertains at once both the eye and the ear; for the water, dashing from a great height, foams over the marble bason that receives it below. This room is extremely warm in winter, being much exposed to the sun; and in a cloudy day, the heat of an adjoining stove very well supplies his absence. From hence you pass through a spacious and pleasant undressing-room into the cold-bath-room, in which is a large gloomy bath: but if you are disposed to swim more at large, or in warmer water, in the middle of the area is a wide bason for that purpose, and near it a reservoir from whence you may be supplied with cold water to brace yourself again, if you should perceive you are too much relaxed by the warm. Contiguous to the cold-bath is another of a moderate degree of heat, which enjoys the kindly warmth of the sun, but not so intensely as that of the hot-bath, which projects farther. This last consists of three divisions, each of different degrees of heat: the two former lie entirely open to the sun; the latter, though not so much exposed to its rays, receives an equal share of its light. Over the undressing-room is built the tennis-court, which, by means of particular circles, admits of different kinds of games. Not far from the baths, is the staircase leading to the enclosed portico, after you have first passed through three apartments: one of these looks upon the little area with the four plane-trees round it; the other has a sight of the meadows; and from the third you have a view of several vineyards: so that they have as many different prospects as expositions. At one end of the enclosed portico, and, indeed, taken off from it, is a chamber that looks upon the hippodrome, the vineyards, and the mountains; adjoining is a room which has a full exposure to the sun, especially in winter; and from whence runs an apartment that connects the hippodrome with the house: such is the form and aspect of the front. On the side, rises an enclosed summer portico, which has not only a prospect of the vineyards, but seems almost contiguous to them. From the middle of this portico you enter a dining-room, cooled by the salutary breezes from the Apennine valleys; from the windows in the back front, which are extremely large, there is a prospect of the vineyards; as you have also another view of them from the folding-doors, through the summer portico. Along that side of this dining-room, where there are no windows, runs a private staircase for the greater conveniency of serving at entertainments: at the farther end is a chamber from whence the eye is pleased with a view of the vineyards, and (what is not less agreeable) of the portico. Underneath this room is an enclosed portico, somewhat resembling a grotto, which, enjoying, in the midst of the summer heats, its own natural coolness, neither admits nor wants the refreshment of external breezes. After you have passed both these porticos, at the end of the dining-room stands a third, which, as the day is more or less advanced, serves either for winter or summer use. It leads to two different apartments, one containing four chambers, the other three; each enjoying, by turns, both sun and shade. In the front of these agreeable buildings, lies a very spacious hippodrome, entirely open in the middle, by which means the eye, upon your first entrance, takes in its whole extent at one glance. It is encompassed on every side with plane-trees, covered with ivy, so that while their heads flourish with their own foliage, their bodies enjoy a borrowed verdure; and thus, the ivy twining round the trunk and branches, spreads from tree to tree, and connects them together. Between each plane-tree are planted box-trees, and behind these, bay-trees, which blend their shade with that of the planes. This plantation, forming a straight boundary on both sides of the hippodrome, bends at the farther end into a semi-circle, which being set round and sheltered with cypress-trees, varies the prospect, and casts a deeper gloom; while the inward circular walks, (for there are several) enjoying an open exposure, are perfumed with roses, and connect, by a very pleasing contrast, the coolness of the shade with the warmth of the sun. Having passed through these several winding alleys, you enter a straight walk, which breaks out into a variety of others, divided by box edges. In one place you have a little meadow; in another, the box is cut into a thousand different forms; sometimes into letters, expressing the name of the master; sometimes that of the artificer; whilst here and there little obelisks rise intermixed alternately with fruit-trees: when, on a sudden, in the midst of this elegant regularity, you are surprised with an imitation of the negligent beauties of rural nature: in the centre of which lies a spot surrounded with a knot of dwarf plane-trees. Beyond these is a walk planted with the smooth and twining acanthus, where the trees are also cut into a variety of names and shapes. At the upper end is an alcove of white marble, shaded with vines, supported by four small Carystian pillars. From this bench, the water, gushing through several little pipes, as if it were pressed out by the weight of the persons who repose themselves upon it, falls into a stone cistern underneath, from whence it is received into a finely polished marble bason, so artfully contrived, that it is always full without ever overflowing. When I sup here, this bason serves for a table, the larger sort of dishes being placed round the margin, while the smaller ones swim about in the form of little vessels and water-fowl. Corresponding to this, is a fountain which is incessantly emptying and filling; for the water which it throws up a great height, falling back into it, is, by means of two openings, returned as fast as it is received. Fronting the alcove (and which reflects as great an ornament to it as it borrows from it) stands a summer-house of exquisite marble, the doors whereof project and open into a green enclosure; as from its upper and lower windows, the eye is presented with a variety of different verdures. Next to this is a little private recess (which, though it seems distinct, may be laid into the same room) furnished with a couch; and, notwithstanding it has windows on every side, yet it enjoys a very agreeable gloominess, by means of a spreading vine which climbs to the top, and entirely overshades it. Here you may recline and fancy yourself in a wood; with this difference only, that you are not exposed to the weather. In this place a fountain also rises, and instantly disappears: in different quarters are disposed several marble seats, which serve, no less than the summer-house, as so many reliefs after one is wearied with walking. Near each seat is a little fountain; and, throughout the whole hippodrome, several small rills run murmuring along, wheresoever the hand of art thought proper to conduct them, watering here and there different spots of verdure, and, in their progress, refreshing the whole.

"And now, I should not have hazarded the imputation of being too minute in this detail, if I had not proposed to lead you into every corner of my house and gardens. You will hardly, I imagine, think it a trouble to read the description of a place which, I am persuaded, would please you were you to see it; especially as you have it in your power to stop, and, by throwing aside my letter, sit down, as it were, and rest yourself as often as you think proper. I had, at the same time, a view to my own gratification; as, I confess, I have a very great affection for this villa, which was chiefly built or finished by myself. In a word (for why should I conceal from my friend my sentiments, whether right or wrong?) I look upon it as the first duty of every writer frequently to throw his eyes upon his title-page, and to consider well the subject he has proposed to himself; and he may be assured, if he precisely pursues his plan, he cannot justly be thought tedious; whereas, on the contrary, if he suffers himself to wander from it, he will most certainly incur that censure. Homer, you know, has employed many verses in the description of the arms of Achilles, as Virgil also has in those of Æneas; yet neither of them are prolix, because they each keep within the limits of their original design. Aratus, you see, is not deemed too circumstantial, though he traces and enumerates the minutest stars; for he does not go out of his way for that purpose, he only follows where his subject leads him. In the same manner (to compare small things with great) if endeavouring to give you an idea of my house, I have not deviated into any article foreign to the purpose, it is not my letter which describes, but my villa which is described, that is to be considered as large. But not to dwell any longer upon this digression, lest I should myself be condemned by the maxim I have just laid down; I have now informed you why I prefer my Tuscan villa to those which I possess at Tusculum, Tiber, and Præneste. Besides the advantages already mentioned, I here enjoy a more profound retirement, as I am at a further distance from the business of the town, and the interruption of troublesome avocations. All is calm and composed; circumstances which contribute, no less than its clear air and unclouded sky, to that health of body and cheerfulness of mind which I particularly enjoy in this place; both which I preserve by the exercise of study and hunting. Indeed, there is no place which agrees better with all my family in general; I am sure, at least, I have not yet lost one (and I speak it with the sentiments I ought) of all those I brought with me hither: may the gods continue that happiness to me, and that honour to my villa! Farewell!"

This villa in Tuscany was Pliny's principal seat, lying about 150 miles from Rome, and in which he usually resided during the summer season. The reader will observe, therefore, that he considers it in a very different manner from that of Laurentinum (his winter villa,) both with respect to the situation and the house itself. Cluver, in his geography, has placed this villa a little above *Tifernum Tiberium*, now called *Citta di Castello*, where our author built a temple at his own expense. This has given room to imagine that possibly there may be yet some remaining traces of this house to be discovered in Tuscany, near a town which the Italians call *Stintignano*, in the neighbourhood of *Ponte di San Stefano*, about ten miles north of an episcopal city now called *Borgo di San Sepulchro*.

Amongst the Jews, Greeks, and Romans, houses were flat at top, so that persons might walk upon them; and usually had stairs on the outside, by which they might ascend and descend without coming into the house. Each house, in fact, was so laid out that it enclosed a quadrangular area or court. This court was exposed to the weather, and being open to the sky, gave light to the house. This was the place where company was received, and for that purpose it was strewed with mats or carpets for their better accommodation. It was paved with marble or other materials, according to the owner's ability, and provided with an umbrella of vellum, to shelter them from the heat and inclemencies of the weather. This part of their houses, called by the Romans *impluvium* or *cava ædium*, was provided with channels to carry off the water into the common sewers. The top of the house was level, and covered with a strong plaster, by way of terrace. Hither, especially amongst the Jews, it was customary to retire for meditation, private converse, devotion, or the enjoyment of the evening breezes.

Some examples of the domestic buildings of the Romans still exist at Herculaneum and Pompeii, but they by no means equal those above described. At the former place the houses are small, and only one story in height; but at the latter we have a few on a somewhat grander scale. There are about 80 houses standing in this town, of which those of Diomedes, Sallust, and Pansa, are the finest; the second standing upon a plot of ground about 40 yards square; and the latter occupying, with its court and garden, a space of about 100 yards by 40.

Towards the close of the last, and commencement of the present century, some few examples have also been discovered in our own country. The most important is that at Woodchester, in Gloucestershire, which was discovered by Mr. Lysons in 1795, and consists of a large open court or atrium, an inner court, and a smaller one in the wing—the whole being surrounded with offices and apartments about sixty in number. The length of the apartments is about 25 feet. Another example in the same county was discovered in 1818, at Great Witcombe. Another example is that at Bignor, Sussex, discovered by Mr. Lysons in 1811, of which we give the following description, extracted from the original account, and partially from Stuart's Dictionary:—

"The first discovery of this villa occurred in 1811. A farmer who occupied the land, in removing the earth, discovered a fine mosaic pavement, which was afterwards found to have formed a part of the floor to one of the rooms. In the centre of this apartment was an hexagonal *piscina*, or cistern, formed of a hard white sort of stone, 4 feet in diameter and 1 foot 7¾ inches in depth, with a border of stone round it 9¼ inches wide, and a step within it, at nearly half its depth, 5½ inches wide; at the bottom is a round hole, 3 inches in diameter, from which a leaden pipe for carrying off the water was afterwards discovered on the outside of the south wall, running in a southern direction. The room appeared to have been heated by an hypocaust, and, in clearing away the earth, part of a small Doric column was found. In the next room discovered, the walls remained to the height of more than two feet at the north-east corner, where was a funnel above the pavement, communicating with the hypocaust below. The pavement was in good preservation; and the dimensions of the room were 40 feet 4 inches by 17 feet. The first room, 31 feet 11 inches by 19 feet. The walls on the east, west, and north sides, were 2 feet 6 inches thick; that on the south, 3 feet. This is conjectured to have been the *triclinium*, or grand banqueting room. Another pavement was found in a third room, at the end of which, opposite from the room last mentioned, was a doorway 3 feet 3½ inches wide, leading into another room, 22 feet by 10 feet 4 inches—the pavement formed of coarse red tesseræ. On the south side of the great pavement, the foundations of a cryptoporticus were discovered, which appears to have been of much larger dimensions than any one hitherto discovered in this island; it was 10 feet wide, and 157 feet 6 inches long. Its tessellated pavement was destroyed, except at the west end; on the north side of this gallery the foundation-walls of a range of rooms was discovered, running eastward, in a line with the great room first discovered. The one which adjoined that room on the east side was 19 feet 2 inches by 18 feet 9 inches, and had a floor of terras of a light red colour. The next room to the eastward was nearly of the same dimensions, and had a coarse tessellated pavement. Adjoining the two last-mentioned rooms on the north side, were the foundations of one 16 feet square, containing a mosaic pavement. The *præfurnium* of the hypocaust, by which the great room and others had been heated, was discovered on the north side of the north wall of the third-mentioned room, and consisted of two walls 18 inches thick and 18 inches asunder, projecting 16 inches from the wall of the building; between them was a kind of arch formed by bricks projecting beyond each other, and communicating with the flues under the different pavements; about 30 feet north of the room, marked 5, in Mr. Lysons' plan, a very fine mosaic pavement was discovered, and a magnificent apartment, marked 3, was traced, to which 5 was found to have served as an ante-room. The wall on the north side of this room was found to continue 32 feet towards the west, where it terminated with a projection or buttress of two feet, forming two sides of what appeared to have been a kind of court, enclosing an area of 30 feet, filled with great quantities of stones, bricks, and tiles. At a small distance from the west wall of the great room, last described, the base and part of the shaft of a small column were discovered. At the west end of the ante-room, 5, was a very small room, 4, (9 feet by 12 feet,) having two doorways, one on the east, opening into 5, and the other on the north, communicating with the square area marked 1. The continuation of the east wall of the room 11, at the west end, or rather the continuation of the cryptoporticus, was next explored to the southward, and traces of it were found to the extent of 100 feet. The room 27, adjoining 26, had its walls still remaining on the east, north, and south sides, to about two feet high, which were covered with stucco two inches thick, painted red, with a skirting of plaster at two inches high, projecting two inches and a half from the wall. On the east side was found, in good preservation, a fireplace 21½ inches wide in front, 17 at the back, and 8 deep, with a hearth formed of 8 bricks, each about 7 inches square. The fireplace was formed by two brick tiles on each side, which had been cramped together with iron, and were placed on the sides of the stove introduced by Count Rumford. I am not aware, Mr. Lysons observes, of any open fireplace of this kind having been discovered elsewhere in the remains of a Roman building, though it is certain, from various passages in the Roman writers, that other means were employed by the ancients for warming their apartments, besides hypocausts. The *caminus* is mentioned by Cicero, Horace, Vitruvius, and others; but the learned commentators on these authors are by no means agreed as to its form or situation, and it has been much questioned by some of them, on the authority of several passages in ancient writers, and from none having been discovered in Roman buildings, whether there was any chimney, or other means of conveying away the smoke, though it is hardly to be conceived that a room could have been habitable under such circumstances at times, when it was necessary to close the doors and windows.

This room was 14½ by 17; the room 29 was 16 feet 5 inches by 15 feet 6 inches, and against the wall was another fireplace resembling the one described. The range of rooms running eastward from the great triclinium, were found to extend the whole length of the cryptoporticus 10.11. On the south side of the building, another cryptoporticus was discovered, marked 45; which communicated with a range of 12 rooms, containing nothing remarkable except those at the east end, which furnished many interesting remains of baths. The room 56 is nearly a square of 25 feet, and contained a finely preserved mosaic pavement. Beyond this mosaic pavement were three rows of black and red tiles, 6 inches square, laid chequer-wise; and next to the wall a row of bricks, each 11 inches by 15½. Great part of a small stone column was found on the pavement, in the same style as the fragment first discovered, being a sort of irregular Doric, the tori of the base being both of the same size. The adjoining room 55 was 30 feet by 25; the floor formed of black and white stones, and next to the wall a row of bricks. Nearly in the middle, was a cold bath 18 feet from east to west, and 3 feet 2 inches deep; it had 3 steps on the east, north, and west sides. On the west side of this room appeared the remains of an extensive hypocaust marked 53 54; and from the frequency of the brick piers, it appeared that the apartment over it must have been a sudatory, probably divided into several smaller rooms. The præfurnium was on the outside of the wall, on the south end; the piers were 2 feet 9 inches high, and 7½ inches square, and consisted of 18 layers of bricks, with a larger one 10½ inches square, laid at the top and bottom. In room 52 adjoining, was another hypocaust, communicating with a larger one by an arch of brick. The area No. 1 was in another examination found to be surrounded by an inner wall, which appeared to have formed a kind of portico; and an entire column was found resembling the fragments found before, which showed that it had been surrounded by a colonnade. A cold bath was also found in the apartment marked 21. Mr. Lysons thinks the villas to have been the residence of a *proprætor*, or at least of the legate or governor of the province. At the time Mr. Lysons first communicated an account of this villa to the Archæologia, the discovery was confined to the rooms marked No. 1 to 26. During the years 1816 and 1817, by tracing the foundations of the walls on the east and west sides of the great court, it was discovered that the cryptoporticus extended all round. The western cryptoporticus 46, was 8 feet wide and 108 long, including a small room 45, at the north end, which had a mosaic pavement. Several rooms, No. 27, 51, 52, 53, 54, 55, 56 and 57. besides the cryptoporticus and passages, were discovered on the western side of the great court, most of them extending into an arable field belonging to the rector of Bignor. No remains of pavements were discovered in this division of the building, except those in the cryptoporticus above mentioned, and some fragments of the coarser kind in the rooms No. 28 and 29. Many large tesseræ were found among the rubbish in the passage No. 50. By digging further to the eastward of the single wall mentioned in the former account, that wall was ascertained to be part of an Eastern cryptoporticus. Nos. 60 and 61, which completed the enclosure of the great court, and the foundations of the buildings, were discovered in a field called the Loure-field, extending 181 feet eastward. Nos. 62 to 71.; several of these buildings were of large dimensions, and they were enclosed within a boundary wall of considerable thickness, not built at right angles with the eastern side of the principal court, but in a very irregular manner, the following being the dimensions of the several sides of this court, viz.: the eastern side 277 feet 4 inches; the west side 385 feet 5 inches; the north side 286 feet; and the south side 322 feet 8 inches.

It would appear reasonable to suppose that the Britons must have advanced considerably in the civilized arts of life, by such examples of Roman luxury as were afforded in their larger residences, such as that above described, for although not equal to those in Rome, it is evident that they were of considerable dimensions, and decorated with taste and skill, in proof of which we have only to refer to the mosaics and paintings. Whether, however, the Britons did not profit by such examples; or whether they were prevented by external circumstances from turning their increased skill and knowledge to practical account, it is tolerably certain that they did not improve so much in these matters as they might reasonably be expected to have done.

It is true, that after the departure of the Romans, they were fully employed in resisting the attacks of their rougher neighbours, and probably had but little time for cultivating the arts of peace. They cannot have made much progress in house-building before the arrival and successful invasion of the Saxons; for had they, we should certainly look for some proof of it in the erections of their invaders, and this we do not find. Most of their churches and cathedrals, or at least of the earlier ones, seem to have been constructed of timber, and we cannot therefore suppose that their domestic buildings were erected in a more durable or costly manner. William of Malmsbury speaks of them as "low and mean dwellings;" they were probably constructed of wood, and roofed with reeds and straw. But even in Norman times, and for some period after the Conquest, there seems to have been but little progress made in this respect. The principal buildings erected for habitation immediately after the conquest of the Normans, consisted of small round towers raised on a mound, and designed with an eye to security rather than convenience. Located in an enemy's country, and in the midst of men who, although conquered in battle, were nevertheless impatient of their victors' control, and unsubdued in courage, it became a matter of necessity to secure themselves against the contingency of a sudden attack, and William found it a matter of policy to promote the erection of fortified residences by his followers. The earliest buildings of this kind were simple towers, either round, rectangular, or polygonal in plan, and of small size, but of considerable strength, the walls being sometimes as much as 12 feet in thickness, while the external diameter of the entire building did not measure more than from 40 to 50 feet. The windows and apertures were very narrow, and the entrance raised several feet above the ground, and approached by a steep flight of steps. Such a building is the keep at Conisborough, erected about this time. It is circular in plan, about 90 feet in height, which is divided into three stories, the lowermost, which is lighted only from the interior, being used probably as a dungeon; the next, in which is the entrance, as a storeroom; and the upper ones, for residence. The interior diameter, in this instance, is about 23 feet, and the thickness of the walls from 10 to 13 feet. At a somewhat later period, such towers or keeps were surrounded by a court enclosed within a strong wall and ditch, the former being strengthened by towers at intervals, and the latter crossed at the entrance by a drawbridge, which was defended by an advanced outwork or watch-tower, termed the barbacan. In such castles the keep was not used as a place of residence, except in cases of danger or emergency, more convenient and roomy apartments being provided in the towers or court-yard.

We next arrive at the Edwardian castles, which present an improved appearance. The keep was now dispensed with, the castle being still strongly fortified by an outer wall, with towers at intervals; but greater attention seems to have been paid to convenience and domestic comfort; and the buildings begin to assume the character of a fortified residence rather than of a mere stronghold: strength is evidently not the only property considered, although still a necessary qualification. Caernarvon castle is a good example of this date.

During the fourteenth century, the sterner features of castles were considerably modified, and assumed a lighter and more peaceful appearance. The apartments were enlarged, and rendered at once more commodious and agreeable. The apertures of the windows also were considerably enlarged, and, late in the period, filled with tracery in the heads. Examples exist at Windsor, Warwick, and Kenilworth.

It must not be forgotten, however, that during all this time there was in existence a different class of dwellings of a less imposing character, but perhaps more strictly entitled to the appellation of domestic buildings. They are included under the general term of *manor houses.*

Previous to the thirteenth century, houses were built of timber, and at first only of one story, being somewhat in the form of the inverted hull of a ship, formed of timber frame-work, the intervals being filled in with horizontal planks. Afterwards, this hull was raised on walls, likewise of timber frame-work filled up with clay, stones, and plaster. Stowe says that the houses in London of this period were not more than 16 feet in height; built of wood, and covered with reeds and straw. The general plan seems to have been that of a parallelogram, and where there were two stories, the approach to the upper was by an external staircase. The lower story was vaulted, and lighted by small windows; but there does not appear to have been any convenience for warming, except in the upper floor, where there is a hearth in the middle of the floor with smoke-hole above: the windows also of the upper floor were larger than those below. In some instances, the building was surrounded by a moat. An example of this kind exists at Boothby Pagnel, Lincolnshire. In some houses of the same date, the principal feature was the hall, which extends the whole height of the building, and is sometimes divided into aisles similar to those of a church, as in the palace of the bishop of Hereford.

In the thirteenth century the same general plan was preserved; but at its close, some little differences occur, as at Little Wenham Hall, Suffolk, where, above the general range of building, which is two-storied, one portion is carried up an additional story, so as to present externally the appearance of a tower. In this example, the lower portion of the building is constructed of flint and stone, and the upper part of brick—a material not found in any previous example, and not generally used for a considerable time afterwards. Square towers were common additions to the houses of the next century, the plans of which were more varied than those of preceding periods. The Mote, Ightam, Kent, is an example of this date; it is square on plan, and surrounded by a moat. Timber houses of this date exist at York and Salisbury, with ornamental barge-boards, which appear to have been introduced about this time, as were also dormer windows and chimney-shafts.

In the fifteenth century, the erection of castles, as distinguished from manor-houses, may be said to have ceased; the two were merged together, as it were; for although the dwellings were still fortified, they were incapable of a regular siege, as comfort was no less considered than security. Houses were erected of all shapes and materials, and often considerably oramented. The square plan, amongst others, was still in use, as was also the surrounding moat, although the latter was not so frequent as formerly. Chimneys became common at this period, and several shafts were often connected into one stack. Panelled ceilings were now introduced, both of wood and plaster; and the windows became large, and highly ornamented; bay and oriel windows were common. The internal walls of large mansions were often painted, or hung with tapestry, and, towards the close of the century, lined with wainscot. Examples of this date are

Eton College, Eltham and Hampton-Court palaces, and Crosby-Hall. Timber houses, which have the spaces between the timbers filled with ornamented plaster, are also of this date. Brick came into very general use during this century.

During the commencement of the next century, the houses retained much the same character, although perhaps somewhat more enriched, and occasionally with some introduction of Italian work. Ere the close, however, the Italian style had become predominant, which gives a vast difference in the buildings of the sixteenth century. The ceilings of this last style were entirely of plaster, which is often highly enriched with carving. Ornamental staircases and galleries were first introduced at this period, but open balusters were not common at the first, the space below the hand-rail being filled up with plaster. Timber houses are still common, and often of good design, the intervals between the quartering being filled with bricks or plaster. Examples of this date are Wollaston-Hall, Nottinghamshire; Longleat, Wiltshire; the Quarries, Rochester; and Little Charlton House, Kent.

During the next century, the Italian style of building continued to prevail, the Gothic features gradually disappearing until they were entirely lost in the works of Inigo Jones, Vanbrugh, &c. Amongst the earlier works may be mentioned Audley End, Essex; Hatfield House, Herts; and Holland House, near London; and amongst the latter, the spacious mansions of Blenheim and Castle Howard.

In the earlier Domestic buildings of this country but little attention was given to comfort. For a very long period the houses were constructed of a timber framing, either covered with planks, or having the intervals between the parts of the framing filled in with clay. Such materials of course rendered the houses subject to frequent conflagrations; and in cities where the houses were closely packed together in narrow streets, such accidents were most destructive. A law was enacted by Richard I., that all houses in the city should be built to a certain height of stone, and covered with slate or tiles; and after the fire, which consumed the greater part of Oxford in 1190, the same precaution was adopted in that city; and in cases where the people were too poor to effect this, a high stone wall, built up between every fourth or fifth house, was deemed sufficient. In these cases, however, the stonework was only rough rubble-work. Brick was introduced from Flanders, and we do not find any instance of its employment in this country until the close of the thirteenth century at Wenham-Hall, where the lower part is of stone, and the upper story of brick. This material did not come into general use until the reign of Henry VI., at the early part of the fifteenth century, but before its close it was very much employed.

In the interiors, the walls were, in most cases, left bare, or sometimes painted or hung with arras or tapestry suspended on hooks three or four inches from the wall. This ornamentation, however, was seldom introduced but in regal mansions, or such as vied with them in splendour; they were by no means of frequent or common use, nor were probably employed at all till the fourteenth century. There was a splendid specimen of tapestry in Warwick Castle in 1344, and Chaucer, who lived a few years later, in describing his chamber, says—

> "All the walls with colours fine,
> Were paint both text and glose;"

The floors were either of earth or stone, but at a later period were rough-cast with plaster and pebbles, and the dais, or upper end of the hall, planked. They were strewed with straw, or leaves, even in royal residences, for we hear of parties holding lands of Edward I., on condition of providing straw for strewing the king's chamber in winter, and herbs in summer; and Fitzstephen tells us, that Thomas à Becket, when chancellor to Henry II., "had his hall strewed every day in the winter, with fresh straw or hay, and in the summer with rushes and green leaves fresh gathered, that such knights as the benches could not contain, might not dirty their fine clothes when they sat on the floor." From this we learn that such litter served for a seat even in great houses; it also served for a bed amongst a lower class of persons.

The fireplace was in the centre of the hall, where logs of wood were supported on dogs, the smoke being allowed to find its way as best it could, through an opening in the roof, which was usually covered with a small turret or lantern, the sides being left open, or filled with louvre-boards. There does not seem to have been any means of warming the smaller chambers, except by pans of charcoal. It is true, we find chimneys in Winwall House, which is supposed to belong to the twelfth century, but this is an unique specimen, and it is certain that they were not in use for a considerable period after that. At Rochester and Hedingham Castles also, we have examples, but the flues are carried up only a very short distance in the wall, and then turned out. Early examples of chimneys are found at Conway Castle, built by Edward I. in the middle of the thirteenth century, and at Kenilworth of about the same date. These, however, are but exceptions; chimney flues were not common in the fourteenth century.

Glass for windows does not seem to have been in use in any other than ecclesiastical buildings, until the time of Edward I., and then it was of very rare occurrence, to be found only in the halls of princes. The common practice adopted for the admission of light consisted in the insertion of louvre-boards in apertures at the upper part of the apartment, but these, although effectual to exclude the rain, were but little adapted to exclude the wind also. To this end another expedient was resorted to—oiled canvas or linen was stretched over the apertures, which was to a certain extent effectual for all requirements, and certainly a great improvement upon louvre-boarding. Glass did not come into general use for gentlemen's houses before the reign of Henry VIII., and we find Sir Thomas More, in his "Utopia," alluding to this circumstance, when he says, that they keep the wind off their houses with glass, for it is there much used, and some also with very fine linen dipped in oil or amber. That it was occasionally in use some time previous to this period, is evident from Chaucer's description of his chamber, for he says:—

> "With glas
> Were all the windowes well yglazed;
> Full clere, with not a hole ycrased;"

They were also beautifully painted, for he goes on—

> "That to behold it was great joy;
> For holly all the story of Troy
> Was in the glaising wrought."

Such were the comforts of our ancestors; we should scarcely call them by that name now-a-days, when the regal luxuries of former times are looked upon as necessaries even by our poorer classes. From the time of the Reformation, however, domestic convenience and comfort made rapid progress; we fear we might say too rapid, for the real happiness and welfare of the people. Belonging to the olden times, we find ecclesiastical structures, which, even in their present state of neglect and decay, rival the resources of modern taste and skill, while their domestic buildings were mean and cheerless: we have lived to see the tables turned—churches mean, cold, and neglected; nay, even our old structures, the bequests of our ancestors, allowed to fall to ruin and decay, while our own dwellings are loaded with luxuries, and over-crowded with ornament. But this scandal is passing away, and we are glad to see some slight return to the principles of our forefathers.

For a further elucidation of this subject, as regards the Domestic buildings of Old England, we refer to the article on Tudor Architecture.

The dwelling-houses of the metropolis are divided by act of parliament into three classes, each of which is subject to certain regulations as regards the building, as is shown in the following table:—

If in height	If in area	If containing	The Raters.	The thickness of external walls must be		The thickness of party-walls must be		
more than 70 ft., and not more than 85 ft.	more than 10 sqrs., and not more than 14 sqrs.	7 stories	1st class	21½ in. from top of footing to underside of floor next but 3 below topmost floor,	and 13 in. thence to top of wall.	21½ in. from top of footing to underside of floor next but three below topmost floor,	and 17½ in. thence to underside of floor next below topmost floor,	and 13 in. thence to top of wall.
more than 85 ft.	more than 14 sqrs.	more than 7 stories.	extra 1st.	21½ in. from top of footing to underside of floor next but 2 below topmost floor,	and 17½ in. thence to top of wall.	21½ in. from top of footing to underside of floor next but three below topmost floor.	and 17½ in. thence to underside of topmost floor,	and 13 in. thence to top of wall.
more than 52 ft., and not more than 70 ft.	more than 6 sqrs., and not more than 10 sqrs.	6 stories.	2nd.	17½ in. from top of footing to underside of floor next but 1 below topmost floor,	and 13 in. thence to top of wall.	17½ in. from top of footing to underside of floor next but one below topmost floor:	13 in. thence to top of wall.	
more than 38 ft., and not more than 52 feet.	more than 4 sqrs., and not more than 6 sqrs.	5 stories.	3rd.	17½ in. from top of footing to underside of floor next but 2 below topmost floor,	and 13 in. thence to top of wall.	17½ in. from top of footing to underside of floor next but two below topmost floor:	13 in. thence to underside of topmost floor,	and 8½ in. thence to top of wall.
not more than 38 feet.	not more than 4 sqrs.	not more than 4 stories.	4th.	13 in. from top of footing to underside of floor next below topmost floor,	and 8½ in. thence to top of wall.	13 in. from top of footing to underside of floor next but one below topmost floor.	and 8½ thence to top of wall.	

HOUSING, the space excavated out of a body, for the insertion of some part of the extremity of another, in order to fasten the two together: thus the string-board of a stair is most frequently excavated, or notched-out for the reception of the steps. The term is also applied to a niche for containing a statue.

HOVELLING, a method adopted for the prevention of smoky chimneys by carrying up the two sides which are the most obnoxious to currents of air, above the others; or by leaving apertures on all sides for the escape of the smoke.

HUE (from the Saxon) in painting, any degree of strength or vividness of colour, from its greatest or deepest, to its weakest tint.

HUMERI, the angles of a temple formed by the longitudinal and transverse walls of the cella.

HUNDRED OF LIME, a denomination of measure, in some places denoting 35, and in others 25 heaped bushels or bags.

Hundred, *Great* or *Standard*, = 112lb. avoirdupoise = 4 quarters = 7 stone (of 16lb.) = 14 cloves (8lb.) = 16 cloves (7lb.) = 1,792 ounces = 20,972 drachms avoirdupoise = .93333 long cwt. (120lb.) = 103lb. 2½ oz. Dutch, or Scottish weight. This is the legal hundred-weight of the custom-house of London, and in all the southern parts of England.

Hundred, *Long*, or *Northern*, = 120lb. = $8\frac{4}{7}$ stones (14lb.) = 12 rationes (10lb.) = 1.0714286 great cwt. (112lb.) This weight is legalized on all or most of the canals and navigable rivers in the north of England and of the midland counties, by their acts for collecting tolls, &c.

Hundred is also used as a measure to express a certain quantity or number of things.

Deal boards are sold at six score to the hundred, called *the long hundred*. Pales and laths are counted at five score to the hundred if five feet long, and six score if three feet long.

HUNG, *Double*, see Double Hung.

HUNTING TOWERS, ancient buildings erected, as is supposed, for the purpose of giving ladies an opportunity of viewing the progress of the chase. Examples remain at Chatsworth, and at Tibbermuir near Perth, in Scotland.

HURLERS, a name given to a rude erection of stones existing near St. Clare, Cornwall. They are of Druidical origin. *See* Celtic Architecture.

HURRIES, in engineering, is sometimes applied, at Newcastle and other places, to the strong stages of wood erected on the sides of navigable rivers and harbours, to which the railways are conducted from the coal pits; by which means the load is emptied at once, by the help of a spout, from the railway waggons into the holds of ships.

HUT (from the Saxon *hutte*) a small cottage or hovel. It is also used for the soldiers' lodges in the field, otherwise called *barracks* or *caserns*.

HUT, in rural economy, a low sort of building, of the cottage kind, generally constructed of earthy materials, as strong loamy clay, &c. A number of huts of this description have been built on the borders of the South Esk, in Scotland, which have a very neat and rural appearance, affording the idea at a distance of their being formed of a kind of brown brick-work. The materials employed consist of a sort of muddy clay, blended with the roots of aquatic plants, which are dug beyond the flood-mark of the river, in such sizes and shapes as are suitable for the intended purpose. The pieces, or peats, as they are called, are generally cut out in the form of bricks, but somewhat larger, being prepared in every respect in the manner of peat-fuel. It is useful in some cases to build huts with lime-mortar, but more commonly with clay only.

These huts are generally preferred by the cottagers to such as are built of stone, being warmer, and nearly as durable.

It seems not improbable but that a similar sort of material for building this kind of cottages may be met with in many situations where it has not yet been discovered, and be made use of in this way, as well as for various fences of the wall kind.

HYPÆTHRAL TEMPLE, see the following article.

HYPÆTHRON, or Hypæthros (from the Greek, *open above*) a temple with ten columns on the pronaos and posticus, in external appearance similar to the dipteral; but within, it had a double tier of columns on each side, detached from the wall, and the middle area was open to the sky. The cell was approached from both front and rear. From the description given by Vitruvius, it appears, that Rome did not afford any example of this species; and he points out the temple of Jupiter Olympus at Athens as one.

HYPERBOLA (from ὑπερ and βάλλω) one of the conic sections, being that which is made by a plane cutting the opposite side of the cone produced above the vertex, or, by a plane which makes a greater angle with the base than the opposite side of the cone makes. In this figure the squares of the ordinates are greater than, or exceed, the rectangles under the parameters and abscissas, whence the name *hyperbola.*

A few useful properties of the hyperbola.—1. The squares of the ordinates of any diameter are to each other, as the rectangles of their abscissas.

2. As the square of any diameter is to the square of its conjugate, so is the rectangle of two abscissas to the square of their ordinate.

3. The distance between the centre and the focus, is equal to the distance between the extremities of the transverse and conjugate axes.

4. The difference of two lines drawn from the foci to meet in any point of the curve, is equal to the transverse axis.

5. All the parallelograms inscribed between the four conjugate hyperbolas, are equal to each other, and each is equal to the rectangle of the two axes.

6. The rectangles of the parts of two parallel lines, terminated by the curve, are to each other as the rectangles of the parts of any other two parallel lines, anywhere cutting the former. Or, the rectangles of the parts of two intersecting lines are as the squares of their parallel diameters, or squares of their parallel tangents.

7. All the parallelograms are equal which are formed between the asymptotes and curve, by lines parallel to the asymptotes.

For other properties, see the articles CONE, and CONIC SECTION.

HYPERBOLA, *Acute*, one whose asymptotes make an acute angle.

HYPERBOLA, *Ambigenal*, that which has one of its infinite legs falling within an angle formed by the asymptotes, and the other falling without that angle.

HYPERBOLA, *Apollonian*, the common hyperbola, as derived from the cone. See HYPERBOLA.

HYPERBOLA, *Deficient*, a curve having only one asymptote, though two hyperbolic legs running out infinitely by the side of the asymptote, but contrary ways.

HYPERBOLA, *Equilateral*, has its asymptotes equal to each other.

HYPERBOLAS, *Infinite*, or HYPERBOLAS OF THE HIGHER KINDS, are expressed or defined by general equations similar to that of the conic or common hyperbola, only having general exponents, instead of the particular numeral ones, but so that the sum of those on one side of the question is equal to the sum of those on the other side. Such as $a\, y^{m+n} = b\, x^m (d + x)^n$, where x and y are the abscissa and ordinate to the axis or diameter of the curve; or $x^m y^n = a^{m+n}$, where the abscissa x is taken on one asymptote, and the ordinate y parallel to the other.

HYPERBOLIC CONOID, a solid formed by the revolution of an hyperbola about its axis; it is otherwise called HYPERBOLOID, which see.

HYPERBOLIC CURVE, the same as the hyperbola. To draw a tangent to any point in the hyperbolic curve, draw a semi-diameter to the given point, and find its conjugate; then through the given point, draw a straight line, parallel to the conjugate diameter; which line will be a tangent to the curve.

To find the focus of the hyperbolic curve, take the distance between the extremities of the transverse and conjugate axes, and apply it from the centre upon the axis, and the remote extremity of the distance gives the focus.

HYPERBOLIC CYLINDROID, a solid formed by the revolution of an hyperbola about its conjugate axis, or line through the centre perpendicular to the transverse axis.

HYPERBOLOID, a conoid formed by the revolution of an hyperbola about its axis. It is otherwise called an *hyperbolic conoid.*

To find the solidity of an hyperboloid, or the frustum of an hyperboloid.—To the areas of the two ends, add four times the area of the middle section parallel thereto, and multiply the sum by one-sixth part of the axis or height, and the product is the solidity. In the complete hyperboloid, the area of the end at the apex being nothing, the rule will be similar to what is laid down under the article CONOID.

An hyperboloid is to a paraboloid of the same base and altitude as $t + \frac{2x}{3}$ is to $t + x$.

Let $t =$ the transverse, $c =$ the congugate } axes of the generating hyperbola.
$x =$ the abscissa or altitude of the solid.
$y =$ the ordinate or radius of the base.
$p = 3.1416$.

Then $y^2 = c^2 \times \frac{tx + x^2}{t^2}$, by the property of the solid;

and $p\, y^2 \dot{x} = p\, c^2 \dot{x} \times \frac{tx + x^2}{t^2}$, the fluxion of the solid;

$p\, y^2 x = p\, c^2 x^2 \times \frac{\frac{1}{2} t + \frac{2}{3} x}{t^2}$, the fluent of the solid;

but because $y^2 = c^2 \times \frac{tx + x^2}{t^2}$, we obtain $c^2 = \frac{y^2 t^2}{tx + x^2}$

Therefore, substituting $\frac{y^2 t^2}{tx + x^2}$ for c^2 in the fluent $p\, c^2 x^2 \times \frac{\frac{1}{2} t + \frac{2}{3} x}{t^2}$ we obtain $\frac{p\, y^2 x}{2} \times \frac{t + \frac{2}{3} x}{t + x} =$ half the area of the base multiplied into the altitude, $\times \frac{t + \frac{2}{3} x}{t + x}$, for the solidity of the solid. But the paraboloidal area is half the area of the base multiplied into the altitude; that is, $\frac{p\, y^2 x}{2}$; now $\frac{p\, y^2 x}{2} \times \frac{t + \frac{2}{3} x}{t + x} : \frac{p\, y^2 x}{2} : : t + \frac{2}{3} x : t + x$; and hence the proposition is manifest.

HYPERTHYRUM, the lintel of a doorway, or that part of the frame which stands over the supercilium. In Grecian buildings it consisted of a frieze and cornice, the latter supported by a console at each extremity.

HYPOCAUSTUM, (from ὑπο *under*, and καυςον *to burn*,) among the Greeks and Romans, a subterraneous place, in which was a furnace for heating the baths. Another kind of hypocaustum was a sort of kiln to heat their winter parlours.

Several hypocausts have been found amongst the Roman remains still existing in Britain. About three years since, the remains of a portion of a Roman villa were laid open in Lower Thames-street, London, and beneath the floor of one of the rooms was discovered a hypocaust formed of columns about two feet in height, each consisting of fourteen tiles about twelve inches square. These were connected at the top by larger tiles, which formed the superstructure of the floor. Flue-tiles, with varied patterns incised on their surfaces, were likewise found amongst the ruins, which originally conveyed warm air up the sides of the building.

More recently, a hypocaust was discovered at Cirencester, and in a most perfect condition, the furnace, which was in existence, still containing some portion of the fuel. In this case, the columns were of two kinds, square and circular, the former being composed of tiles laid one upon the other to the number of ten, and the latter being formed of blocks of stone. Resting upon these pillars were large square tiles, as in the preceding example, and above these a layer of concrete six inches in thickness, on which the pavement was laid. The room above the hypocaust measured twenty-five feet square, and it is remarkable that the hypocaust extended only half-way underneath, the remaining half of the pavement being laid solid.

Still more recently, the remains of some apartments have been found within a Roman camp at Lymne, Kent. An extensive hypocaust was discovered under the floor of these apartments, formed entirely of layers of large tiles placed at regular intervals, but the pavement had been totally destroyed. Several hollow flue-tiles were also discovered of a similar description to those above alluded to. These, in all probability, were connected with the hypocaust, and served to convey the hot air from the furnace through the principal apartments of the villa, the hypocausts being used not only for baths, as is by some supposed, but also in the place of fires, and answered an exactly similar purpose to our modern hot-air pipes.

In a hypocaust discovered at Lincoln some few years since, the piers supporting the pavement were all of the circular form.

HYPODROMUS, (Greek ὑπὸ, *under*, and δρομος, *from* τρεχέιν, *to run*,) amongst the Romans, a shady or covered walk or ambulatory.

HYPOGÆUM, (from ὑπο, *under*, and γῆ *the earth*,) in ancient architecture, a name given to all parts of a building that were underground.

The term was more particularly applied to the common sort of sepulchres used by the Romans; they were built underground, whence their name, and are now known under the name of catacombs. The urns containing the ashes of the deceased were placed round the chamber in niches cut out in the walls, which, from their resemblance to the niches of a pigeon-house, were called columbaria.

Montfaucon has given descriptions and illustrations of several such hypogæa in his *Antiquitè Expliquée.* In many examples, especially in those of later date, the chambers are highly ornamented.

HYPOPODIUM, (from ὑπο, *under*, and πȣς, *foot*,) a piece of furniture in the ancient baths, on which the feet rested.

HYPOSCENIUM, (from ὑπο, *under*, and σκηνῆ, *a scene*,) a partition under the logium appointed for the music.

HYPOTRACHELIUM, (from ὑπο, *under*, and τραχήλιον, *the neck*,) the lower part of the Tuscan and Doric capitals, comprehended between the astragal at the top of the shaft, and the fillet or annulets under the ovolo. This description applies only to the Roman Doric; for the Grecian, instead of an astragal, had from one to three horizontal grooves circumscribing the column.

ARCHITECTURAL DICTIONARY.

ICE-HOUSE, a repository for the preservation of ice during the summer months.

The aspect of an ice-house ought to be towards the south-east, on account of the advantage of the morning sun in expelling the damp air, which is far more prejudicial to it than warmth. The best soil on which such a house can be erected is a chalk-hill, or declivity, as it will conduct the waste water without the aid of any artificial drain; but where such land cannot be procured, a loose stony earth, or gravelly soil on a descent, is preferable to any other.

For the construction of an ice-house, a spot should be selected at a convenient distance from the dwelling-house. A cavity is then to be dug in the form of an inverted cone, the bottom being concave, so as to form a reservoir for the reception of waste water. Should the soil render it necessary to construct a drain, it will be advisable to extend it to a considerable length, or, at least, so far as to open at the side of the hill or declivity, or into a well. An air-trap should likewise be formed in the drain, by sinking the latter so much lower in that opening as it is high, and by fixing a partition from the top, for the depth of an inch or two into the water of the drain, by which means the air will be completely excluded from the well. A sufficient number of brick-piers must now be formed in the sides of the ice-house, for the support of a cart-wheel, which should be laid with its convex side upwards, for the purpose of receiving the ice; and which ought to be covered with hurdles and straw, to afford a drain for the melted ice.

The sides and dome of the cone should be about nine inches thick, the former being constructed of brick-work, without mortar, and with the bricks placed at right angles to the face of the work. The vacant space behind ought to be filled with gravel, or loose stones, in order that the water oozing through the sides may the more easily be conducted into the well. The doors of the ice-house should likewise be made to shut closely; and bundles of straw put before them, more effectually to exclude the air.

The ice to be put in should be collected during the frost, broken into small pieces, and rammed down hard in strata of not more than a foot, in order to make it one complete body; the care in putting it in, and well ramming it, tends much to its preservation. In a season when ice is not to be had in sufficient quantities, snow may be substituted.

ICHNOGRAPHY, (from ιχνος, *footstep*, and γραφω, *to describe*,) an orthographical projection of an object on a horizontal plane, or the description of an object on a plane representing the horizon, by straight lines from all points of the object perpendicular to the plane. This term is used only in reference to a projection of the same nature with another, on which it is made perpendicular to the former, by lines from all points of the object falling perpendicular to such plane, and consequently parallel, to that of the ichnography.

ICOSAHEDRON, (from the Greek, εἰκοσαεδρον,) in geometry, a regular solid, consisting of twenty triangular pyramids, whose vertices meet in the centre of a sphere, supposed to circumscribe it; and therefore have their height and bases equal; wherefore the solidity of one of those pyramids multiplied by twenty, the number of bases, gives the solid content of the icosahedron.

To form or make the icosahedron.—Describe upon a card paper, or some other such like substance, twenty equilateral triangles; cut it out by the extreme edges, and cut all the other lines half through, then fold the sides up by these edges half cut through, and the solid will be formed.

The linear edge or side of the icosahedron being A, then will the surface be

$$5\,A^2\sqrt{3} = 8.6602540A^2,$$

and the solidity $= \frac{5}{6}\,A^3\sqrt{\frac{7 + 3\sqrt{5}}{2}} = 2.1816950A^3.$

IMAGE, (from the Latin, *imago*,) the scenographic or perspective representation of an object. See PERSPECTIVE.

IMAGERY, painted or carved work.

IMBOW, (from *bow*,) to arch over, to vault.

IMBOWMENT, an arch, or vault.

IMPAGES, (Latin,) in ancient joinery, is supposed to mean the rails of a door, as appears from Vitruvius, book iv. chap 6. "The doors are so framed, that the cardinal scapi may be the twelfth part of the whole height of the aperture. Out of twelve parts between the two scapi, the tympans have three parts. The impages are so distributed, that the height being divided into five parts, two superior and three inferior are disposed. Upon the middle, the middle impages are placed; of the rest some are framed at top, and some at bottom; the breadth of the impage is a third part of the tympan; the cymatium is a sixth part of the impage; the breadth of the scapi is the half of the impage; the replum is the half and a sixth part of the impage."

IMPETUS (Latin) the span of a building, roof, or arch.

IMPLUVIUM, the cistern in the centre of the atria of Roman houses, to receive the rain, the atria being uncovered.

IMPOST (French) the upper part of a pier or pillar, which sustains an arch; or the collection of mouldings under an arch, forming a cornice of small projection as a finishing to the pier.

INBAND JAMBSTONE, a stone laid in the jamb of an aperture for the purpose of bond: its length being inserted in the thickness of the wall, and showing only its end in the face of it.

INCERTAIN WALL. *See* WALL.

INCH (*ince*, Saxon, *uncia*, Latin) a measure of length, supposed equal to three grains of barley laid end to end; the twelfth part of a foot.

INCLINATION (from the Latin) a word frequently used by mathematicians to signify the mutual approach of a line and a plane, or of two planes, to each other, so as to constitute an angle. In this sense we speak of the inclination of the meridians, the inclination of the sun's rays, &c.

The inclination of a line to a plane, is measured on a second plane, by supposing the second to pass along or through a line perpendicular to the first, and forming an intersection with it: then the angle comprehended on the second plane, between the line and the intersection, is called *the inclination of the line to the plane.*

The inclination of one plane to another, is measured on a third plane drawn perpendicular to the common intersection of the two first, till it intersect them: then the angle contained between the lines of section is *the inclination of the planes.*

INCLINED PLANE, in mechanics, a plane forming an oblique angle with the horizon, or placed at a given angle to another: so that when an inclined plane is spoken of absolutely, another is always to be understood, which is the primitive or first plane, from which the inclined plane rises. When a force, in a given direction, supports a weight upon an inclined plane, such force is to the weight as the sine of the angle made by the line in which the force acts with the line perpendicular to the plane.

Given, the heights of any three points in an inclined plane, and their seats in position upon the primitive plane, to determine the inclination of the planes.—Join the seat of the greatest height to that of the least height, and take the least height from the other two: then say, As the greatest difference is to the least difference, so is the whole length of the line joining the two seats to the portion of it between the seat of the least height and that of the greatest; join the intermediate point to the seat of the mean height by a straight line, which call A B; draw a straight line, C D, perpendicular to A B; through the seats of the greatest and least heights draw two lines, C E and D F, parallel to A B; make C E equal to the greatest height, and D F equal to the least; join E F, and produce C D and E F to meet in O; then the angle C O E is the inclination of the planes.

INCRUSTATION (French) an adherent covering. This term is frequently applied to plaster, or other tenacious materials employed in building.

INDEFINITE (from the Latin *indefinitus*, not limited) is sometimes used to express something that has but one extreme; as a line drawn from any given point, while the other extremity is extended infinitely, or to any given distance, without affecting its use.

INDENTED (from the Latin *in*, and *dens*, a tooth) in architecture, toothed together.

INDIAN ARCHITECTURE, the style which was practised by the inhabitants of India. Although what relates to India was anciently but very imperfectly known to the western world, yet such is the change in human affairs, and the eagerness with which every matter relating to India has of late been investigated, that we are now furnished with accounts fully as ample as those relating to Egypt or Persia. In the following brief relations we shall be guided by some excellent papers, by Sir William Jones and others, in the *Asiatic Researches;* Robertson's *Disquisitions respecting Ancient India;* the learned and laborious work of Maurice on *Indian Antiquities;* and several other authorities quoted for particular descriptions.

In India, the cities and palaces were on a scale with its great wealth and population. They were generally indebted for their origin to the favour of powerful princes, and successively became the centre of the riches and traffic of the East. In the historical poem, called the *Mahabbarit* (or History of the Great War) translated by Abul Fazel, the secretary or minister of the great Akbar, it is said, that Oude, the capital of a province of that name, to the north-east of Bengal, was the first regular imperial city of Hindoostan, and that it was built in the reign of Krishen, one of the most ancient rajahs. The *Ayeen Akbery* (vol. ii. p. 41) represents Oude to have anciently been 148 coss (or about 259 miles) in length, and 36 coss (or about 53 miles) in breadth; but this bears more resemblance to a province than a city. "This city," says Sir W. Jones, "extended, if we may believe the brahmins, over a line of ten yojans (or 40 miles.) It is supposed to have been the birth-place of Rama." According to the *Mahabbarit*, Oude continued the imperial city 1,500 years, until about the year 1,000 before the Christian era, when a prince of the dynasty of the Surajas, who boasted their descent from the sun, erected Canouge upon the banks of the Ganges, and made the circumference of its walls 50 coss, or about 87 miles. Strabo, from Megasthenes, who had seen Canouge, says it was situated at the confluence of another stream with the Ganges; that its form was quadrangular, the length 80 stadia, breadth 15, or, taking the mean stadium of the ancients, about 8 miles by 1½; that it had wooden fortifications, with turrets for archers to shoot from, and was surrounded by a vast ditch.—Strabo, lib. xv. p. 667. Arrian calls it the greatest city amongst the Indians; he says that it was situated at the junction of the Erannaboa with the Ganges: he gives the same dimensions as Strabo; and says, that there were 570 towers on the walls, and 65 gates. Diodorus Siculus, lib. xvii. says, that when Alexander passed the Hyphasis, he was informed, that on the banks of the Ganges he would meet the most formidable sovereign of India, called Xambranes, king of the Gangarides, at the head of 20,000 horse, 200,000 foot, 2,000 war-chariots, and 4,000 fighting elephants. The *Mahabbarit* states that Sinkol, a native of Canouge, brought into the field, against Affrasiah, king of Persia, 4,000 elephants, 100,000 horse, and 400,000 foot. But that after Delu had founded Delhi, and established his court there, Canouge declined, and was involved in civil discord;—still we learn from the same authority, that Sinsarchand, or Sandrocottus, the successor of Porus, restored Canouge to its ancient splendour; and that here, about the year 300 before Christ, he entertained the ambassadors from Seleucus, the successor of Alexander, and that Megasthenes was amongst the number. In the beginning of the fifth century, Ramdeo Rhator (or the Mahratta) entered Canouge in triumph, and reigned there 54 years. The last king under whom this city may be considered as the metropolis of a great empire, was Maldeo, who, about the beginning of the sixth century, added Delhi to his dominions. At this time, Canouge was said to contain 30,000 shops in which areca was sold. Although not the metropolis, it long after continued of great consequence. About the year 1,000, when Sultan Mahmed invested it, it is represented as a city which, in strength, has no equal. It became an appendage to the empire established by Mahmed.—*Ferishta*, vol. i. p. 27.

Major Rennell is of opinion that Canouge and Palibrothra were the same. Others endeavour to prove the contrary; and that both may have existed at the same time capitals of the Prasii, as Delhi and Agra have done in later times.

The precise period of the origin of Delhi is not correctly ascertained: according to the *Ferishta*, it was founded by Delu, who usurped the throne about 300 years before Christ. The *Ayeen Akbery* fixes it about the commencement of this æra, and informs us, that twenty princes of the name of Bal, or Paul, followed in regular succession for 437 years; that the last of its native princes was Pithoura, when it was conquered by the Mahomedan slave Cattub, named by Herbelot, Cathbaddin Ibek, who made Delhi the capital of the vast empire he established in Hindoostan; and that each successive monarch of the Mahomedan dynasty adorned it with splendid edifices, appropriated to the purposes of religion and commerce. At the invasion of Timur Beck, it had arrived at the highest distinction for commerce and wealth, being then the centre of the traffic carried on between Persia, Arabia, and China. Timur entered it on the 4th July, 1399; and on the 13th of the same month, this celebrated city was destroyed. Sherifedden, the Persian historian, says, that old Delhi was celebrated for a mosque and palace, built by an ancient Indian king, in which were a thousand marble columns. Under the dynasty which succeeded Timur, it recovered its original splendour, and was again ornamented with mosques, baths, caravanseras, and sepulchres.

The great Akbar, the glory of the Timur house, having fixed his residence at Agra, Delhi, of course, experienced a partial eclipse; but in 1647, according to Fraser, Ischaim Shah, the grandson of Akbar, restored Delhi under the name of Ischaimbad, where he built a magnificent palace, formed extensive gardens, and constructed a throne in the shape of a peacock, whose expanded tail was entirely composed of diamonds, and other precious stones. It continued the capital of Hindoostan till 1738, when it was sacked by Nadir; and afterwards repeatedly by Ahmed Abdallah, from 1756 to 1760, when it was totally destroyed. During the reign of Aurungzebe, it was said to contain two millions of inhabitants.

Lahore is situated to the north-west of Delhi, on the banks of the Rauvee, the ancient Hydraotes: it appears to have been the Bucephalus of Alexander. Jeipal, the rajah of Lahore, during the incursions of Subuitagi, and his son Mahmud, defended his possessions with great bravery, and so great were his riches, that, when taken prisoner, around his neck alone were suspended sixteen strings of jewels, each of which was valued at 180,000 rupees, and the whole at £320,000. Lahore continued to flourish under the sultan of Cosro, and was the imperial seat of Cuttub before he removed it to Delhi; even afterwards it remained the general storehouse for the traffic of Persia, Arabia, India, and China. It was restored by Homaion, who amongst other magnificent buildings, erected a palace, which was completed by Ischaim Geer, the son of Akbar. This palace, according to Mr. Finch, who visited it in 1609, had twelve gates, nine towards the land side and three towards the river. He says, the rarities were too numerous and glorious to be represented in a description; that the mahls, courts, galleries, and rooms of state, were almost endless; and that, in the king's lodgings, the walls and ceilings were overlaid with plates of gold. M. Bernier, who was in this city in the suite of Aurungzebe, speaks of this place as a high and magnificent building, but then hastening to ruin.

Agra, the Agara of Ptolemy, situated in 27° 15′ north latitude on the banks of the Jumna, we have already observed, was raised to splendour by the great Akbar. He caused the earthen wall, by which the city had been enclosed by the Patan monarchs, to be taken away and replaced by one of hewn stone, brought from the quarries of Fettipore. He collected the most skilful artificers from every part of his dominions; and the palace alone employed above 1,000 workmen for twelve years. The castle was built in the form of a crescent, upon the banks of the Jumna; and in a line with it were ranged the palaces of the princes and great rajahs, intersected with canals and beautiful gardens. Akbar also erected many caravanseras and mosques. He invited foreigners of all nations; he built them factories; and permitted to all the free use of their religion. It was soon crowded with Persian, Arabian, and Chinese merchants, besides those immediately from European settlements. But when Ischaim removed the imperial insignia and treasures to Delhi, and made it the residence of his court, Agra sunk rapidly to decay.

These five imperial cities seem, with regard to extent, splendour, and wealth, to have exceeded the greatest cities of the western world; and, besides these, many others were almost of equal magnificence; for Chundery is said to have contained 384 markets, and 360 caravanseras; and Ahmedabad was once so large as to require to be divided into 360 quarters.—Maurice, *Ind. Antiq.* vol. i. p. 118–124.

These extensive and proud cities were evidently the symbols of temporary policy and power, and have passed away, like so many splendid scenes on the great theatre of the East. But as the religion of India has been more permanent than their political relations, it is from the sacred edifices we are to trace most distinctly the characters of Indian architecture, and be enabled to judge how far they have any affinity with those of other nations. Of their large temples, (pagodas) we find accounts of five different forms.

1. Simple pyramids constructed of large stones, and diminished by regular recesses or steps, as at Deogur and Tanjore; the exterior rude, and the interior having only light from without by a small entrance door; illuminated by a profusion of lamps, with the exception of a chamber in the middle, which has only a single lamp. Aquetil says, that to him one of the mountains of Canara seemed hewn to a point by human art.

2. The second kind were formed by excavations in the sides of rocky mountains. Abul Fazul (*Ayeen Akbery*, vol. ii. p. 208) says, that in the soobah of Cashmere, in the middle of the mountains, 12,000 recesses were cut out of the solid rock. From Captain Wilford's paper on Caucasus, inserted in the sixth volume of the *Asiatic Researches*, we learn that an extensive branch of the Caucasus was called by the Greeks Parapamis, obviously derived from Para Vami, the pure and excellent city of Vami, commonly called Bamiyan. It is situated on the road between Balkh and Cabul, and like Thebes in Egypt, consists of vast numbers of apartments and recesses cut out of the rock; some of which, on account of their extraordinary dimensions, are supposed to be temples. There are also, at that place, two colossal statues, one of a man eighty ells high, and another of a woman fifty ells high, erect and adhering to the mountain from which they are cut. At Salsette, Elephanta, and Vellore or Ellora, the excavations were not only extensive, but were divided into separate apartments, with regular ranges of sculptured pillars and

entablatures, and the walls and ceilings covered with multitudes of figures of their genii, deutah, men, and women; and various animals, such as elephants, horses, lions, &c. all of the most excellent workmanship. See *Plates* I. and II.

3. A third set was composed of square or oblong courts of vast extent. The circumference of the outward wall of that in the island of Seringham, adjacent to Trichinopoly, is said to extend nearly four miles. The whole edifice consists of seven square enclosures, the walls being 350 feet distant from each other. In the innermost spacious square are the chapels. In the middle of each side of each enclosure-wall there is a gateway under a lofty tower: that in the outward wall, which faces the south, is ornamented with pillars of single stones, thirty-three feet long, and five in diameter.—*Voyages de M. Sonnerat*, tom. i. p. 217; and Robertson's *India*, p. 268. Tavernier describes the pagoda of Santidos, in the Guzerat, as consisting of three courts paved with marble, and surrounded with a portico supported by marble columns; the inside of the roof and walls formed of mosaic work and agates, and all the portico covered with female figures cast in marble. Aurungzebe profaned this temple by killing a cow within its precincts, and converting it into a Turkish mosque. At Chittambrum, on the coast of Coromandel, there is only one court, 1,332 feet in one direction, and 936 in another, with an entrance gateway under a pyramid 120 feet high, and the ornamental parts finished with great delicacy.—John Call, *Phil. Trans.* vol. lxii. p. 354. Orme's *Hist.* vol. i. p. 178.

4. A fourth sort, as Benares pagoda, in the city of Casi, which from the earliest times was devoted to Indian religion and science. The temple is in the form of a cross, with a cupola terminated by a pyramid in the centre, and having also a tower at each extremity of the cross. From the gate of the pagoda to the Ganges, there is a flight of steps.—*Tavernier*, tom. iv. p. 149. Rouen edit.

5. A fifth are made in a circular form, as the celebrated pagoda of Juggernaut, which Hamilton compares to an immense butt set on end. Juggernaut is only another name of the god Mahadeo, who is represented by the vast bull which juts out of the eastern aspect of the building. It is the seat of the arch-brahmin of all India, and its sacred domains are said to afford pasturage for 20,000 cows.

Besides these general terms, if our limits permitted us to trace those interesting structures through the various districts of this extensive country, many different arrangements might be described; but, for the present, we must be satisfied with mentioning the pagoda of Bezoara, (or Buswara of Major Rennell,) now a fort upon the Kistna river: it was not enclosed with walls, but erected upon 52 lofty columns with statues of Indian deities standing between the columns. It was situated in the midst of an oblong court, around which there was a gallery raised on sixty-six pillars, like a cloister.—*Voy. des. Ind.* tom. iii. p. 226. Rouen Ed. 1713. Near this, on a hill ascended by one hundred and ninety-three steps, was another pagoda of a quadrangular form, terminated by a cupola.

These temples were generally erected on the banks of the Ganges, Kistna, and other sacred rivers, for ablution. Where there was no river, a tank or reservoir of a quadrangular form was constructed, and lined with free-stone or marble, with steps descending into them. Crawford observed many 300 or 400 feet in breadth.—Crawford's *Sketches*, vol. i. p. 106. At the entrance of the principal pagodas, there is a portico supported by rows of lofty columns, and ascended, as in the case of Tripetty, by more than one hundred steps; under these porticos, and in the courts which generally enclose the buildings, multitudes attend at the rising of the sun, and having bathed, and left their sandals at the border of the tank, impatiently await the unfolding of the gates by the ministering brahmin.—*Thevenot.*

We must reserve, until we come to treat of the detail of Indian architecture, many particulars relative to those splendid edifices, which, with the plates accompanying them, will afford a more distinct view of the nature of their arrangements and appropriations; but it will be proper in this place to notice some leading circumstances respecting the Indian sculptures, with a view to ascertain what affinity they had to those in Egypt. From the *Ayeen Akbery*, and Captain Wilson's paper on Caucasus, we find, that in the Soubah of Cashmere, between Balkh and Cabul, in the numerous excavations, there were 700 places where the figure of a serpent was carved; and that near these excavations, there were sculptured in rock, on the side of the mountain, figures of 15, 50, and 80 ells high; that in the great temple of the sun, which was near Juggernaut, and said, by the *Ayeen Akbery*, to have consumed, in the expense of building, the whole revenue of the Orissa for twelve years; that in front of the gate, there was a pillar of black stone, of an octagon form, 50 cubits high; that at the eastern gate, there were two elephants, each with a man on his trunk; at the western gate were figures of horsemen, completely armed; and at the northern gate two tigers, who had killed two elephants, and were sitting upon them. That in one extensive apartment, there was a large dome constructed of stone, upon which was carved the sun and stars, and around them a border of human figures. In the pagoda at Juggernaut, Hamilton describes the idol as a huge black stone, of a pyramidal form; and there was a bull, representing the god Mahadeo, jutting from the wall of the eastern aspect. Tavernier observed a conspicuous idol of black stone in the temple of Benares; and that the statue of Creeshna, in his celebrated temple of Mathura, was of black marble. In the great pagoda at Elephanta, the bust of the triple-headed deity measures 15 feet from the base to the top of the cap, the face is five feet long, and it is 20 feet across the shoulders. Along the sides of the cavern are colossal statues, to the number of forty or fifty, from 12 to 15 feet high; some have a sort of helmet of a pyramidal form; others a crown with devices; others display bushy ringlets, some with curled, and others with flowing hair; many have four hands, some six; with sceptres, shields, weapons of war, and symbols of peace. At the west end of the pagoda, there is a great dark recess, 20 feet square, totally destitute of ornaments, except the altar in the centre, and the gigantic figures which guard the several doors which lead into it. Niebuhr says these figures are eight in number; they are naked, and 13½ feet high; their heads, decorated like the other statues, have rich collars round their necks, and jewels of great size in their ears. In the before-mentioned recess, the Lingam divinity is represented. The pagoda at Salsette exceeds that at Elephanta; the two colossal statues immediately before the entrance of the grand temple are 27 feet high; they have caps and ear-rings. There are here two hundred figures of idols; ninety of which are in and about the great pagoda. In the interior spaces, which recede from the apartments, the Lingam is represented. Many of the sculptures in these grand temples have reference to the astronomical, as well as mythological notions prevalent in India.

At Vellore, Ellore, or Ellora, (*Plates* I. and II.) the sculptures, &c. are still more extraordinary; and all are dedicated to the Lingam or Mahdew. The height of the grand pyramid is here 90 feet; the smaller ones 50 feet; the obelisk 38 feet. The elephants on each side of the court are larger than life; and there is an apartment for the bull Nundee. See Sir C. W. Mallet's paper. *Asiatic Researches*, vol. vi. p. 383.

Sir W. Jones (*As. Res.* vol. i. p. 253) is of opinion, that the Eswara and Isi of the Hindoos are the Osiris and Isis of Egypt. He says, that the word Misr, the native appellation of Egypt, is familiar in India; that Tirhoot was the country, asserted by a learned brahmin to be that in which an Egyptian colony of priests have come from the Nile to the Ganges and Yamma (Jumna). And again, in his third annual discourse, the remains of architecture and sculpture in India, prove an early connection between this country and Africa; the pyramids of Egypt, the colossal statues of the Sphinx, and the Hermis Canis, which last bears a great resemblance to the Varahavatu, or the incarnation of Vishnu, indicate the style and mythology of the same indefatigable workmen, who formed the vast excavations of Canarah, the various temples and images of Buddha, and the idols which are continually dug up at Gaya.

Kempfer asserts, that the great Indian saint, Buddha, was a priest of Memphis, and having fled to India, introduced the worship of Apis.—Kempfer's *Hist. Japan.* vol. i. p. 38, ed. 1738.

Athanasius Kircher is of opinion, that after Cambyses had murdered Apis, the most revered of the Egyptian deities, he committed wanton cruelties on the priests, and destroyed their magnificent temples, as related by Herodotus, and that the priests flying into the neighbouring countries of Asia, there propagated the superstitions of Egypt.

The lotus was anciently in Egypt, and is still in India, held sacred. Herodotus calls it the lily of the Nile. The Egyptian priests had a sacred language; so have the brahmins. The Egyptians, according to Diodorus Siculus, were divided into five tribes, of which the first was sacerdotal; the Indians are separated into four tribes, besides an inferior one, named Buzzer Sunker.

Father Loubere, who went ambassador from the king of France to the king of Siam, in 1687, thinks the superstition of Boodh no other than the Sommonacodom, or stone deity of the Siamese, originally from Egypt. He says, that their astronomers have fixed the death of Sommonacodom to the year B.C. 545, and that it was then their first grand astronomical epocha commenced. Now, according to Usher, Cambyses invaded Egypt in 525 B.C. Loubere adds, that the Siamese priests live in convents, which consist of many cells ranged within a large enclosure; that in the middle of the enclosure stands the temple; that pyramids stand near to, and quite round the temple, all within four walls.—See Loubere's *Hist. of Siam*, in Harris's *Coll. of Voy.* vol. ii. p. 482.

Sir W. Jones thinks that the great statue of Narrayen, or the Spirit of God, who at the beginning floated on the waters, as that statue is now to be seen in the great reservoir of Catmander, the capital of Nepaul, is the same as the Cneph of Egypt, under a different appellation; both statues are made of blue marble.—See *Asiatic Researches*, vol. i. p. 261.

Mr. Call has published a drawing of the signs of the zodiac, which he found in the ceiling of a choultry at Verdapettah, in the Medurah country, viz., Brahma, painted in pagodas, in the act of creation, floating over the watery abyss, reclining upon the expanded leaf of lotus; and Osiris is found in the same attitude, recumbent on the same plant, in the Egyptian monuments.—Mauriee, vol. ii. p. 394.

In the Hindoostan edifices, although many parts of the general arrangement and principal features resemble those of Egypt, yet simplicity has been more departed from, and circular outlines similar to those of pagodas have been introduced. The most splendid of the Indian edifices being wholly formed by excavation, may most properly be denominated sculptures; but even for this mode, abundance of originals exist in Egypt. The numerous sculptured tombs adjacent to the principal cities in the Thebaïd, are perfect examples, as far as regards excavations within the natural rock; and the gigantic colossal statues are equally so as to isolated forms.

Detail of Indian Architecture.—The city of Agra was built in the form of a crescent along the banks of the Jumna; its walls were constructed with stones of great size, hard, and of a reddish colour resembling jasper. It was four miles in extent, and consisted of three courts, with many stately porticoes, galleries, and turrets, all richly painted and gilt, and some overlaid with plates of gold. The first court was built round with arches, which afforded shade; the second was for the great omrahs and ministers of state, who had here their apartments for transacting public business; and the third court, within which was the seraglio, consisted entirely of state apartments of the emperor, hung round with the richest silks of Persia. Behind these were the royal gardens. In front of the palace, towards the river, a large area was left for the exercise of the royal elephants, and for battles of the wild beasts; and in a square which separated the palace from the city, a numerous army lay constantly encamped. Mandesto, who visited Agra in 1638, then in the zenith of its glory, says, it was surrounded by a wall of freestone and a broad ditch, with a drawbridge at each of its gates. He states, that at the farther end of the third court, under a piazza, were a row of silver pillars; that beyond this was the presence-chamber, with golden pillars; that within a balustrade was the royal throne of massy gold, almost incrusted with diamonds, pearls, and other precious stones; that above this throne was a gallery, where the Mogul appeared every day at a certain hour, to hear and redress the complaints of his subjects; and that no person but the king's sons were admitted behind these golden pillars. He mentions also an apartment remarkable for its tower, which was covered with massy gold, and for the treasure it contained, having eight large vaults filled with gold, silver, and precious stones. Tavernier, who visited the Agra near the end of the 17th century, and in the absence of the court had permission to examine the inside, describes a gallery, the ceiling of which was decorated with branched work of gold and azure, and the walls hung with rich tapestry. The gallery which fronted the river, the monarch had proposed to cover over with a sort of lattice-work of emeralds and rubies to represent grapes with their leaves when they are green, and when they begin to grow red; but this design then remained imperfect, there being only three stocks of a vine in gold, with their leaves enamelled with emeralds, and rubies representing grapes; being a specimen of what was intended for the whole.

We have been thus minute in the description of the palace of Agra, because, having been built by one of the most enlightened princes of the East, it affords a perfect specimen of the scale upon which the monarchs of those extensive and rich countries acted. And it will be allowed, that the establishments of Akbar and his great rajahs, occupying four miles along the banks of the Jumna, and connected with a handsome and prosperous city, must have produced a picture sufficiently splendid, and emblematic of the wealth and power of the prince who erected it.

At Cuttek, or Cuttack, the capital of Orissa, there is a fine palace. It consists of nine distinct buildings:—1. for elephants, camels, and horses; 2. for artillery, military stores, and quarters for the guards; 3. for porters and watchmen; 4. for artificers; 5. for kitchens; 6. for the rajah's public apartments; 7. for the transaction of private business; 8. where the women reside; 9. the rajah's sleeping apartments.

The specimens here selected being the most noted, will, we trust, convey an idea of the nature of the Indian cities and palaces; and we shall therefore proceed to consider their sacred edifices.

We have already stated, that these were of five different sorts; that is, 1. pyramids; 2. excavations; 3. square or oblong courts; 4. in the form of a cross; and 5. perfectly circular.

1. We are here at a loss to determine whether or not the construction of Indian pyramids preceded that of their excavations. To construct a pyramid of rude stones, is certainly a much simpler operation than forming a cavern ornamented with sculpture; so that although it may be conceived that mankind might, for the purposes of worship, make use of the simple plain cavern, either natural or artificial, previous to the construction of buildings of great magnitude on the surface: yet it is not very probable that the splendid excavations of Elephanta and Vellore, in which were rich sculptures, and even pyramids cut out of the solid rock, could have preceded a rude pyramid on the surface. But as the purposes to which the pyramids of Deogur and Tanjore are appropriated partake very much of the nature of the cavern, their entrance-doors being very small, their interior being lighted by means of lamps, and the middle chamber by one lamp only; there is some reason for supposing, that in places where rocky eminences were not conveniently situated, or from motives now unknown, some change of ideas taking place, these pyramids might be constructed for purposes similar to the original cavern or grotto, in the same manner as the Egyptian pyramids are considered to have been done with regard to the tombs of the Thebaïd. The external faces of the pyramids of Deogur and Tanjore are very rude.

2. In regard to excavations, they are numerous and extensive. In some instances, they are very simple and plain; in others, highly ornamented with architectural forms and sculptures. From Captain Wilson's paper in the 6th volume of the *Asiatic Researches*, we learn, that an extensive branch of the Caucasus was named by the Greeks, Parapamis, from *Para Vami*, the pure and excellent city of Vami, commonly called Bamaiya. It is situated on the road between Balkh and Cabul, where vast numbers of apartments are cut out of the rocks, some of them so large that they are supposed to have been temples. And Abul Fazel says, that in the soubah of Cashmere, in the middle of the mountains, 12,000 apartments were cut in the solid rock. At this place there were 700 places where the figure of a serpent was sculptured.

Although neither the precise form nor dimensions are given, yet from the great number of excavations, and the place being noticed by the Greeks, it must, in former ages, have been of importance, at least, for its sanctity; and its situation between India and Persia renders it still an interesting subject of inquiry.

In other parts of India, the excavated temples have fallen more frequently under the observation of well-informed scientific persons, who have, with laudable industry, furnished the public with exact representations, and full details respecting them. The three principal ones, and which our limits will only enable us to notice, are Elephanta, Salsette, and Vellore or Ellora.

Elephanta is situated near Bombay, in an island so named from the figure of an elephant being cut upon the rocks on the south shore. The grand temple is 120 feet square, and supported by four rows of pillars; along the side of the cavern are from forty to fifty colossal statues, from 12 to 15 feet high, of good symmetry, and, though not quite detached from the rock, boldly relieved; some have a helmet of pyramidal form, others a crown, decorated with jewels and devices, and others have only bushy ringlets of flowing hair; many of them have four hands, some six, holding sceptres, shields, symbols of justice and religion, warlike weapons and trophies of peace, some inspire horror, others have aspects of benignity. The face of the great bust is 5 feet long, and the breadth across the shoulders 20 feet. At the west end of this great pagoda is a dark recess, 20 feet square, totally destitute of ornament; the altar is in the centre, and there are two gigantic statues at each of the four doors by which it is entered. Niebuhr represents these statues as naked, 13½ feet high, and the sculpture good; their heads are dressed like the other statues, and they have each rich collars round their necks, and jewels in their ears. Hunter states, that, on entering Elephanta, there is a veranda or piazza, which extends from east to west 60 feet, that its breadth is 16 feet, and that the body of the cavern is on every side surrounded by similar verandas.—*Archæologia*, vol. vii. p. 287.

Canara, in the island of Salsette, which is also situated near Bombay, is represented by Linshotten, who visited it in 1759, as being like a town. He describes the front as hewn out of the rock, in four stories or galleries, in which there are 300 apartments: these apartments have generally an interior recess, or sanctuary, and a small tank for ablution. In these recesses, as at Elephanta, are representations of the Lingan deity. The grand pagoda is 40 feet high to the soffit of the arch or dome; it is 84 feet long, and 46 broad. The portico has fine columns, decorated with bases and capitals: immediately before the entrance to the grand temple are two colossal statues, 27 feet high, which have mitre caps and ear-rings. Thirty-five pillars, of an octagonal form, about 5 feet diameter, support the arched roof of the temple; their bases and capitals are composed of elephants, horses, and tigers, carved with great exactness. Round the walls, two rows of cavities are placed with great regularity, for receiving lamps. At the farther end is an altar of a convex shape, 27 feet high, and 20 in diameter; round this are also recesses for lamps, and directly over it is a large concave dome cut out of the rock. Immediately about this grand pagoda, there are said to be 90 figures of idols, and not less than 600 within the precincts of the excavations.

Mr. Grose, who visited India in 1750, seems to be of opinion, that the labour required to construct Elephanta and Salsette, must have been equal to that of erecting the pyramids of Egypt; and though it is not mentioned which of the many pyramids he refers to, the remark sufficiently expresses his admiration of the greatness of these Indian works. He observes (p. 92) that the roof of Elephanta was flat; that of Salsette of an arch-form, supported by rows of pillars, of great thickness, arranged with much regularity; that the walls are crowded with figures of men and women, engaged in various actions, in different attitudes; that along the cornice there are figures of elephants, horses, and lions, in bold relief; and above, as in a sky, genii and dewtah are seen floating in multitudes.

But magnificent as the excavations at Elephanta and Salsette must appear, they are still surpassed by those near Vellore, Ellore, or Ellora, which is situated 18 miles from Aurungabad, capital of the province of Balagate, N. lat. 19° 20′, E. long. 75° 30′.

Sir C. Mallet, in a paper he transmitted to the president of the Asiatic Society, and published in the sixth volume of their *Researches*, gives a detailed account of sixteen of them:—

1. Jagnath Subba.
2. Adnaut Subba.
3. Indur Subba.
4. Pursuram Subba.
5. Doomar Lyna.
6. Jun Wassa.
7. Comar Wana.
8. Chana, or Oil Shop.
9. Neelkunt Mahdew.
10. Ramish Wur.
11. Kylas, or Paradise.
12. Dus Outar.
13. Tee Tal.
14. Bhurt Chutturghun.
15. Biskurma, or Carpenter's Hovel.
16. Dehr Wanar, or Hallulcore's quarters.

Of these we must, of course, confine ourselves to such parts as are calculated to convey a general idea of their architecture; with this view, we have selected for engravings (*see Plates* I. and II.) the ground-plan of Kylas, the entrance and section of Bĭskurma, the elegant entrance to the cave of Jugnath Subba, the temple of Indur Subba, and a singularly-beautiful piece of sculpture at the door of Jun Wassa. We shall also give the description and dimensions of the Kylas and the Biskurma.

Kylas, alias *Paradise*, (aspect, west.)—This wonderful place is approached more handsomely than any of the foregoing, and exhibits a very fine front in an area cut through the rock. On the right-hand side of the entrance is a cistern of very fine water. On each side of the gateway there is a projection reaching to the first story, with much sculpture and handsome battlements, which, however, have suffered much from the corroding hand of time. The gateway is very spacious and fine, furnished with apartments on each side, that are now usually added to the dewries of the eastern palaces. Over the gate is a balcony, which seems intended for the Nobut Khanneh. On the outside of the upper story of the gateway, are pillars that have much the appearance of a Grecian order. The passage through the gateway below is richly adorned with sculpture, in which appear Bouannee Ushtbooza on the right, and Gunnes on the left. From the gateway you enter a vast area, cut down through the solid rock of the mountain, to make room for an immense temple of the complex pyramidal form, whose wonderful structure, variety, profusion, and minuteness of ornament, are too elaborate for description. This temple, which is excavated from the upper region of the rocks, and appears like a grand building, is connected with a gateway by a bridge left out of the rock as the mass of the mountain was excavated. Beneath this bridge, at the end opposite the entrance, there is a figure of Bouannee sitting on a lotus, and two elephants with their trunks joined as though fighting, over her head. On each side of the passage under the bridge, is an elephant marked (*a*) in the plan, one of which has lost its head, the other its trunk, and both are much shortened of their height by earth. There are likewise ranges of apartments on each side behind the elephants, of which those on the left are much the finest, being handsomely decorated with figures. Advanced in the area, beyond the elephants, are two obelisks (*b*) of a square form, handsomely graduated to the commencement of the capitals, which seem to have been crowned with ornaments, but they are not extant, though, from the remains of the left-hand one, I judge them to have been a single lion on each.

To preserve some order, and thereby render easier the description of this great and complex work, we shall, after mentioning, that on each side of the gateway within there is an abundance of sculpture, all damaged by time, proceed to describe the parts of the centre structure; and then, returning to the right side, enumerate its parts; when, taking the left hand, we shall terminate the whole in a description of the end of the area opposite the gateway, and behind the grand temple, exemplifying the whole by reference to the annexed plan.

Centre below.—Passing through the gateway (1) below, you enter the area (2), and, proceeding under a small bridge, pass a solid square mass (3), which supports the bull Nundee stationed above; the sides of this recess are profusely sculptured with pillars and figures of various forms. Having passed it, you come to the passage under another small bridge, beneath which there is, on one side, a gigantic figure of the Rajah Bhoj, surrounded by a group of other figures, opposite to which is a gigantic figure Guttordhuj, with his ten hands. At each end of this short passage commences the body of the grand temple (4), the excavation of which is in the upper story, that is here ascended by flights of steps on each side (5).

Right and left-hand sides of the temple below.—The right-hand side is adorned with a very full and complex sculpture of the battle of Ram and Rouon, in which Hunomaun makes a very conspicuous figure. Proceeding from this field of battle, the heads of elephants, lions, and some imaginary animals, are projected, as though supporting the temple, till you come to a projection (6), in the side of which, sunk in the rock, is a large group of figures, but much mutilated. This projection was connected with the apartments on the right-hand side of the area by a bridge (7), which has given way, and the ruins of it now fill up the sides of the area. It is said to be upwards of a hundred years since it fell.

Passing the projection of the main body of the temple, it lessens for a few paces, then again projects (8); and after a very small space on a line of the body of the temple, the length of this wonderful structure, if what is fabricated downwards out of a solid mass can be so called, terminates in a smaller degree of projection than the former. The whole length is supported in the manner above mentioned, by figures of elephants, lions, &c., projecting from the bases, to give, it should seem, the whole vast mass the appearance of movability by those mighty animals. The hindmost, or eastern extremity of the temple, is composed of three distinct temples, elaborately adorned with sculpture, and supported, like the sides, by elephants, &c., many of which are mutilated. The left-hand side (from the entrance) differs so little from the right, that it is unnecessary to be particular in mentioning anything, except, that, opposite the description of the battle of Ram and Rouon, is that of Keyso Pando, in which the warriors consist of footmen, and others mounted on elephants, and cars drawn by horses, though none are mounted on horses. The principal weapon seems the bow, though maces and straight swords are discoverable.

Centre above.—The gateway consists of three centre rooms (9), and one on each side (9). From the centre rooms, crossing the bridge (10), the ascent is by seven steps (11) into a square room (12), in which is the bull Nundee. This room has two doors and two windows. Opposite the windows are the obelisks (*b*) before mentioned.

From the station of Nundee we cross over the second bridge (13), and ascend by three steps (14) into a handsome open portico (15), supported by two pillars (above each of which, on the outside, is the figure of a lion, that, though mutilated, has the remains of great beauty; and, on the inside, two figures resembling sphinxes) towards the bridge, and two pilasters that join it to the body of the temple, the grand apartments of which (16) are entered from the portico by four handsome steps and a doorway, on each side of which are gigantic figures. Advancing a few paces into the temple, which is supported by two rows of pillars, besides the walls that are decorated with pilasters, there is an intermission of one pillar on each side, leading to the right and left to an open portico (17), projecting from the body of the temple; from the right-hand one of which, the bridge, already mentioned as broken, connected the main temple with the side apartments, to which there is now no visible access but by putting a ladder for the purpose; though I was told there is a hole in the mountain above, that leads to it, which I had not time nor strength to explore. The access from the opposite is by stairs from below. The recess (18) of the Ling (19) of Mahdew, to which there is an ascent of five steps, forms the termination of this fine saloon, on each side of the door of which is a profusion of sculpture. The whole of the ceiling has been chunamed and painted, great part of which is in good preservation.

A door (20) of each side of this recess of the Ling of Mahdew leads to an open platform (21), having, on each side of the grand centre pyramid that is over the recess of the Ling, two other recesses (22), one on each side, formed also pyramidically, but containing no image. Three other pyramidical recesses (23), having no images within them, terminate the platform, all of them elaborately ornamented with numerous figures of the Hindoo mythology. Many of the outer, as well as the inner parts of this grand temple, are chunamed and painted. The people here attribute the smoky blackness of the painting within to Aurungzebe having caused the different apartments to be filled with straw and set on fire, which can be reconciled on no other ground than that he meant to efface obscenities, as there are many in the sculptures. Upon the whole, this temple has the appearance of a magnificent fabric, the pyramidal parts of which seem to be exactly in the same style as that of the modern Hindoo temples.

Right-hand side of the area.—This side of the rock has a continuance of excavations, as marked in the plan; but all those below, except the veranda, which I shall quit for the present, are of little note; and those above of three stories, called Lunka (24), which appear much more worthy of attention, are inaccessible but by a ladder, from the fall of the bridge. We shall, therefore, proceed to the

Left-hand side of the area.—In this side there are excavations of some consideration below, from which we ascend to an upper story, called Par Lunka, by an indifferent staircase, into a fine temple (25); at the extremity of which is a recess, containing the Ling of Mahdew; and opposite thereto, near the entrance from the staircase, is the bull Nundee, with two large fine figures, resting on maces, on each side of the recess in which he sits. The ceiling of this temple is, I think, lower than any of the foregoing. The whole of this temple is in fine preservation, strongly supported by very massy pillars, and richly ornamented with mythological figures, the sculpture of which is very fine. The ceiling, like the others, has the remains of painting visible through the dusky appearance of smoke with which it is obscured. Descending from Par Lunka, we pass through a considerable ensculptured excavation (26), to a veranda (27), which seems allotted to the personages of the Hindoo mythology (a kind of pantheon) in open compartments. These figures commence on the left hand with, 1. The Ling of Mahdew, surrounded by nine heads, and supported by Rouon. 2. Goura Parwuttee, and beneath Rouon, writing. 3. Mahdew, Parwuttee, and beneath Nundee. 4. Ditto, ditto. 5. Vishnu. 6. Goura and Parwuttee. 7. A Bukta (votary) of Vishnu, with his legs chained. 8. Goura and Parwuttee. 9. Ditto. These representations of Goura and Parwuttee all differ from each other. 10. Ditto. 11. Vishnu and Luchmee. 12. Bal Budder issuing from the Pind, or Ling of Mahdew. Here ends the left-hand side, and commences the east extremity, or end of the area (28), in which the figures are continued, *viz.*, 13. Goura and Parwuttee. 14. Behroo, with Govin Raj transfixed on his spear. 15. Dytasere on a chariot, drawing a bow. 16. Goura and Parwuttee. 17. Kal Behroo. 18. Nursing Outar, issuing from the pillar. 19. Kal Behroo. 20. Bal Behroo. 21. Vishnu. 22. Govin. 23. Brimha. 24. Luchmedass. 25. Mahmund. 26. Nunain. 27. Behroo. 28. Govin. 29. Bal Behroo. 30. Govin Raj and Luchmee. 31. Kissundass. Here ends the veranda of the eastern extremity: and we now proceed with that on the right hand (29), having in our description of that side, stopped at the commencement of this extraordinary veranda, for the purpose of preserving the enumeration of the figures uninterrupted, *viz.*, 32. Mahdew. 33. Ittuldass. 34. Dhurm Raj embracing Uggar Kaum. 35. Nursing destroying Hurn Kushb. 36. Vishnu sleeping on Seys Naug, the kummul (lotus) issuing from his navel, and Brimha sitting on the flower. 37. Goverdhun. 38. Mahdew Bullee, with six hands. 39. Krishna sitting on Gunoor. 40. Bharra Outar. 41. Krishna Chitterbooz trampling on Callea Naug. 42. Ballaju. 43. Anna Pooma. It is to be observed, that almost all the principal figures are accompanied in their respective panels by others, explanatory of the history of the idol in which it is represented.

Dimensions of the Kylas.

	Ft.	In.
Outer area, broad	138	0
Ditto, deep	88	0
Greatest height of the rock, through which the outer area is cut	47	0
Gateway, height	14	0
Ditto, breadth, without the modern building	14	4
Passage of the gateway, having on each side rooms, 15 feet by 9	42	0
Inner area or court, length from gateway to the opposite scarp	247	0
Ditto, breadth	150	0
Greatest height of the rock, out of which the court is excavated	100	0
Left Side of the Court, lower Story, viz.		
A small cave, in front two pillars, and a pilaster at each end, with three female figures buried up to the knees with rubbish, length	22	6
Ditto, breadth	8	0
Ditto, height	9	8
Another excavation, in front five pillars, two pilasters, length	57	9
Ditto, breadth, within the benches that are round this cave	6	0
Ditto, height, at the end of this is a staircase to the upper story	10	4
Interval unexcavated	20	0
Another excavation, having two large plain square pillars, and two pilasters in front, with a bench round the inside, the rock projecting beyond the pillars, length	54	6
Ditto, breadth	12	6
Ditto, height	16	0
Doorway, leading to a gallery, or veranda, 5 feet 11 inches high, by 2 feet 9 inches wide. Gallery containing figures. Length from doorway to the extreme depth of the whole excavation	117	8
Ditto, breadth	13	0
N.B. In this length are eleven pillars, each 2 feet 8 inches square.		
Ditto, height within the pillars (the projecting rock is about 3 feet lower, extending irregularly in the course of the length, from 7 to 13 feet beyond the pillars)	14	8
End of the Area, opposite the Gateway, behind the Temple.		
Whole breadth from side to side, measuring from the inner wall of the gallery on each side	186	6
Breadth of the gallery, including the pillars, there being 17 in this range	13	4
N.B. The rock projects beyond the pillars along this range, and the right hand one irregularly, from 15 to 22 feet, and is lower than the ceiling.		

Right-hand of the Court, lower Story, viz.

	Ft.	In.
Figure gallery, or veranda, of the same dimensions as the preceding parts of the same gallery, for the space of ten pillars, the angle of one being included in the foregoing; three of which were broken, it is said, to make trial of the power of the deity of the place; and when it was found that the superincumbent rock did not sink, the tempter, said to be Aurungzebe, forbore farther trial.		
Doorway, 2 feet 4 inches broad, by 5 feet high, leads to a veranda; within this veranda is a room of 60 feet by 22, and 11 feet 4 inches high. Right end unfinished: length	60	0
Ditto, breadth	17	0
Ditto, height	13	0
A small projecting room, 15 feet by 13, and 6 feet high, being choked with several finely-sculptured figures. An excavation raised 12 feet from the surface of the court, length	36	10
Ditto, depth	14	9
Ditto, height	12	0
There is a multiplicity of figures in this apartment, detached from the wall. Amongst the rest, a large skeleton figure, with a smaller one on each side. The principal is sitting, with each foot on a prostrate naked figure.		
An excavation, which has a small recess, opposite the entrance, of 6 feet by 7, and 8 high, length	24	0
Ditto, breadth	18	0
Ditto, height	10	0
An excavation terminating the lower story on the side, length	24	0
Ditto, depth	10	0
Ditto, height	11	6

Except between the two pillars, where the roof is arched, and is there 14 feet 8 inches high. This is the first instance I have seen of the arch.

Left hand Side, upper Story, viz.

	Ft.	In.
A small unfinished excavation, the dimensions of which were not worthy taking.		
Par Lunka is a fine large excavation, ascended by a flight of 25 steps, and a doorway of 3 feet 8 inches broad, by 7 feet 7 inches high; length, exclusive of the recess, in which is the temple of Mahdew	70	7
Ditto, breadth	61	9
Ditto, height	14	6
Recess, in which stands the temple of Mahdew, depth	26	0
Ditto, breadth, (the temple on the outside is 26 by 20 feet)	39	0

N.B. The whole of this apartment is full of figures, some very finely sculptured; and the centre floor is raised one foot, and the ceiling in proportion.

Right-hand Side, first Story.

	Ft.	In.
A large room, formerly connected with the grand temple by a bridge, now broken down	60	0
Ditto, depth	18	0
Ditto, height	16	0
Another room within the foregoing, entered by a door from it, having a bench all round. This inner room is very dark, having no light but from the doorway; length	36	0
Ditto, depth	29	0
Ditto, height	11	0

Right-hand Side, second Story.

	Ft.	In.
Entered by a staircase from the right side of the foregoing, of 24 steps. A large room, of the same dimensions as a correspondent one below, except two feet less in the height.		
Another room within the foregoing, depth	35	0
Ditto, length	37	0
Ditto, height	14	0
The rock seems to have given way in the centre of this room, and the rubbish has fallen in.		

Centre.

Balcony over the gateway, 14 feet by 8, and 8 high. A room within it 9 feet square, and about 9 feet high. Another within it, same dimensions. One on each side from the centre, 22 × 15 each. Bridge 20 feet × 18, with a parapet 3 feet 6 inches high. Ascent by nine steps from the bridge into a distinct room, in which is the bull Nundee, 16 feet 3 inches square. Another bridge, 21 feet × 23 broad, leading to the upper portico of the temple. This portico, with the parapet wall, is 18 feet × 15 feet 2 inches, and 17 high; within a bench that is rounded, of 4 feet high, by 3 feet 7 inches broad. This portico may be entered from the gateway, by a passage that the filling up of the rubbish has afforded; but the proper passage is by flights of steps on each side, of 36 steps each, leading up on each side the body of the temple.

Grand Temple.

	Ft.	In.
Door of the portico 12 feet high × 6 feet broad; length from the door of the portico entering the temple to the back wall of the temple	103	6
Length from the same place to the end of the raised platform behind the temple	142	6
Greatest breadth of the inner part of the temple	61	0
Height of the ceiling	17	10
Two porches on each side, measured without, 34 feet 10 inches × 15 feet 4 inches.		

The particulars of the intricate measurement of this fine temple will be best understood from the plan formed on the spot.

Height of the grand steeple or pyramid computed about 90 feet from the floor of the court, and of the smaller ones about 50; height of the obelisks about 38 feet; base 11 feet square, being 11 feet distant from each side of the room in which is the bull Nundee. The shaft above the pedestal is 7 feet square. The two elephants on each side the court or entry are larger than life." *Bishurma or Viswakurma ka Joompree.—The Carpenter's Hovel.* (Front W. 5 S.)—According to the legend, Bishurma (creator of the world, but allegorically artificer of Ram) was the artist who fabricated the whole of these wonderful works in a night of six months; but the cock crowing before they were finished, they remained imperfect, and he retired, having wounded his finger, to this hovel, in which state, the figure in front (1) of the entrance of this beautiful excavation, is said to be a representation of him holding the wounded finger; but it is more probable, that the figure is in the act of devout meditation, as many figures, with similar positions of the hands, occur. But, quitting the fable for the fact, this excavation is, in beauty, inferior to none. In form it is unique, and in design elegant. The portico is light, and striking to the beholder. On the right hand of the entrance is a fine cistern of water Above the gateway, II, which is richly sculptured on the outside, is a balcony, which seems well suited, if not intended, for a music-gallery to the interior temple, I, which has the appearance of an elegant chapel, with an arched roof, and is exactly in the style of a similar excavation at Canara, on the island of Salsette, and another at Ekvera, near the top of Bhore Ghaut, first explored by Mr. Wales the painter. At the upper end is the figure (I) above mentioned. From the ceiling are projected stone ribs, following the curvature of the arch to the capitals of the pillars on each side, through the whole length of the excavation. Beside the grand aisle, or body of the excavation, there is a small passage formed by the row of pillars on each side round the altar; but it is dark and narrow. This singular form of a cave, wherever it has been met with, has conveyed the same impression of its being a place of congregation and adoration, rather than of residence or habitation, and has given rise to an idea, from the orbicular ceiling, and the name and attitude of its inhabitant, that it may be meant to represent the Almighty, meditating the creation of the world, under the arch or canopy of unlimited space. It is necessary, however, to accompany this idea with an acknowledgment, that the similar caves of Ekvera and Canara are not inhabited by Bishurma, they having only a very high altar, the top of which is circular, and situated, as represented in the annexed drawing, at the back of Bishurma.

Dimensions.

	Ft.	In.
Area, square	49	0
Veranda below, in front, and each side, having 12 pillars, and two pilasters, breadth	14	0
Ditto roof, height	10	4
Doorway, 4 feet broad × 8 feet four inches high; gallery above the door, square	14	0
Length of the temple from the entrance to the opposite wall behind the altar	79	0
Breadth of ditto from wall to wall	43	5
Height of ditto from the centre of the arch to the floor	35	0
N.B. The height between the pillars and wall where the ceiling is flat, is	14	10
Breadth between the pillars and wall	7	8
Circumference of pillars (two square, and 28 octagon ones)	8	1
Altar at the end, about 24 feet high.		

3. The third kind of temples are those composed of square enclosures; the largest is that of Seringham, situated near Trichinopoli. The pagoda is composed of seven square enclosures, one within another; each side of the outermost is a mile in length, making the whole four miles in circumference. The walls of each enclosure are 350 feet from those of the others; they are 25 feet high, and four feet thick. Each enclosure has four gateways, that is, one in the middle of each side, opposite the cardinal points. In the outward wall, the gateway which fronts the south is ornamented with pillars, several of the single stones 33 feet long, and five feet diameter; those of which the roof is composed are still larger. All the gateways are covered with figures emblematical of their divinities. In the innermost enclosures are the chapels. Into the last, which is 1,024 feet square, and contains the sanctuary of Vishnu, no European is willingly admitted; but during the wars between the English and French, it was alternately occupied by each of the belligerents. The pagoda of Chittambrum, which consists of one square only, 1,332 feet by 396, entered by a pyramid 122 feet high, has already been described.

The pagoda Ahmed-Abad, in Guzerat, or pagoda of Santidus, consists of three courts surrounded with marble columns, and paved with marble. No person is admitted into the innermost court with sandals on. All the porticos are covered with female figures, of excellent workmanship; the inside of the roof and walls are decorated with mosaic and precious stones.—*See Tavernier* and *Thevenot's Travels.* This pagoda was converted into a Turkish mosque by Aurungzebe.

The Jumna Mesgid is quadrangular, 140 paces by 120; round the inside of the enclosing wall runs a gallery, having its roof supported by 34 pillars. The temple itself stands upon 44 pillars, ranged in couples; the pavement is marble; in the middle of the front are three large gateways. On the sides are two gateways; each gate has a sort of pilasters; the minarets are Mahometan.

The pagoda of Baswara, or Bezora, now a fort, on the Vistnu river, is not enclosed by walls, but stands upon 52 lofty columns, with statues of Indian deities standing between them; it was placed in the midst of an oblong court, and surrounded by a gallery, supported by 66 pillars.—*See Tavernier.*

4. The fourth kind are in the form of a cross. The most noted is that of Benares, in the city of Casi, on the banks of the Ganges, down to which there is a flight of steps. This, from the earliest period of history, has been devoted to Hindoo religion and science. The form of the temple is that of a great cross, with a cupola in the centre, which, towards the top, takes a pyramidal form. At the extremity of each branch of the cross, which are of equal length, there is a tower with balconies, to which the access is on the outside. Within the temple, immediately under the central cupola, there is an altar, eight feet in length, and six in breadth, covered sometimes with tapestry, sometimes with cloth of gold and silver. Tavernier saw several idols, one, in particular, six feet high, having its neck decorated with a chain of precious stones; the head and neck only were visible; the body was covered with a robe. On the right of the altar was a golden figure, composed of an elephant, a horse, and a mule; upon this the deity journeyed on his guardian care of mankind. In this pagoda was also an idol of black stone, or Sammenacodom. Aurungzebe polluted this temple.

Mattra, the Methora of Pliny, eighteen miles from Agra, on the road to Delhi, is the birth-place of the beneficent god, Chreeshna. The pagoda is constructed of the same stone as Delhi, and stands upon a very extensive octagonal platform of hewn stone. This platform is ascended by two flights of stone steps, which lead to the grand portal, composed of pillars with the usual sculptures. The pagoda is in the form of a cross with a lofty cupola in the centre, and two others nearly similar on each side. The sanctuary is separated by a balustrade, behind which only priests are admitted. In the sanctuary is a square altar, 16 feet in height, covered with gold and silver brocade, and here stands the god Ram Ram; the head only is visible, and appears of black marble, with two large rubies for eyes; the body is covered with a robe of purple velvet.

5. Of those which are of a circular form, Sonnerat thinks that Juggernaut is the most ancient in India, and says that the brahmins attribute it to the first king on the coast of Orissa, 4,800 years. Its plan is a perfect circle, of immense size. Juggernaut is said to be only another name for the god Mahadeo, who is represented by the figure of a large bull, which projects out of the eastern side of the edifice; the image of Juggernaut stands in the centre of the building,

upon an elevated altar, surrounded by an iron railing. Mr. Hamilton describes the idol as being an irregular pyramidal black stone, and the temple deriving light only from one hundred lamps. He compares the edifice to a great butt set on end. This place is the residence of the arch-brahmin of all India, and the sacred dominions are said to yield pasturage for 20,000 cows.—See Buchanan's *Christian Researches.*

Besides these, which are offered as specimens of the different forms of Hindoo temples, there is one more which our general views of the matter require to be noticed. The *Ayeen Akbery* relates, that near to Juggernaut is the temple of the sun, in constructing which, the whole revenue of the Orissa was, for twelve years, wholly expended; that the wall which surrounds the whole is 150 cubits high, and 19 cubits thick; that there are three entrances: at the eastern gate are two elephants, each with a man on his trunk; on the west, are two figures of horsemen, completely armed; and over the northern gate, are two tigers sitting upon two dead elephants. In front of the gate is a pillar of black stone, of an octagonal form, 50 cubits high. After ascending nine flights of steps, there is an extensive enclosure with a large cupola, constructed of stone, and decorated with sculptures of the sun and stars, surrounded by a border, composed of a variety of human figures, some kneeling, some prostrate with their faces on the earth, and some representing minstrels, also a number of imaginary animals. But of this splendid temple, so minutely described in the *Ayeen Akbery*, not a vestige is now to be found.

It may be observed generally, that these temples, for the sake of ablution, are usually placed on the banks of the Ganges, Vistnu, or some sacred river; or where that is not the case, artificial tanks or reservoirs are constructed, generally of a quadrangular form, lined with free-stone or marble, and having steps to descend into them. Crawford mentions several tanks from 300 to 400 feet in breadth.—Crawford's *Sketches*, vol. i. p. 106. Some of these tanks cover eight or ten acres, have steps of masonry 50 or 60 feet long, are faced with brickwork, and plastered substantially and neatly. The corners of the tank are generally ornamented with round or octagonal pavilions.—*Oriental Sports*, vol. ii. page 116.

In the Birman empire, which, for situation and various circumstances connected with its history, is one of the most interesting districts of the East, the temples of Godama are of a pyramidal form, of solid brick-work, placed upon an elevated terrace; and the base of the great pyramid is frequently encompassed by a double row of small ones, having its summit terminated by an umbrella made of iron bars into a sort of filligree work, and adorned with bells; many of these pyramids are from 300 to 500 feet high. In the larger temples, the umbrella, with at least the upper part, sometimes the whole, of the pyramid, is entirely gilt. Other temples, of similar shape, are hollow, and have images of Godama within them; but the images are more frequently placed in chapels, which encompass the pyramid. Dr. Buchanan saw at Ava an image made of one block of pure alabaster, of so large a size, that one of its fingers appeared about the length and thickness of a large man's thigh and leg. The whole statue must therefore have been about fifty feet high.

At one village, Colonel Symes saw 30 or 40 yards full of statuaries, all employed in making images of the god Godama, and all in the same position, that is, sitting crossed-legged upon a pedestal: the smallest exceeded the human stature. The price of this size was 100 tackals, or 12 or 13 pounds sterling. They work the marble with a chisel and mallet, and polish with three stones of different fineness; and, lastly, by rubbing with the hand, which gives a great degree of brightness and smoothness.

At Ummapoora were spires, turrets, and lofty obelisks. The fort is an exact square, with public granaries and store-rooms, and a gilded temple at each angle, upwards of 100 feet high. In the centre of the front stands the royal palace, with a wide court in the front, beyond which is the council-hall, supported by eighty pillars, on eleven roods. The royal library is a brick building, raised on a terrace, and covered with a roof of very compound structure; it consists of one square room, with an enclosed veranda or gallery round it.—See Colonel Symes's *Embassy to Ava*, 1795.

With regard to the present practice of Hindoo architecture, we learn that in Benares, their holy city, situated on the north bank of the Ganges, 460 miles N. W. of Calcutta, the streets are so narrow as not to admit of two carriages to pass one another. The houses are built with large stones, accurately joined. Some of them are six stories high, with terraces on the summits; a band or string-course, decorated with sculpture tolerably well executed, serves to mark externally the division of each story. The windows are very small. The houses on the opposite side of the streets sometimes communicate by galleries. The number of houses built of stone and brick are reckoned at 12,000; those with mud walls 16,000. In this city there is an observatory of immense magnitude, a great number of Hindoo temples, and a spacious mosque, built by Aurungzebe, from the minarets of which, the whole city may be seen.

By the kindness of a gentleman, whose opportunities and disposition for accurate observation have qualified him to afford the most authentic information, we are enabled to give the following account of the modes pursued by the Hindoos in the construction of their dwelling-houses: "The houses of the opulent are substantially built of stone and brick, with lime mortar, generally terraced with small bricks, about four inches square, and one inch in thickness; the beams are laid about 12 feet apart, and the joints 10 inches. The masons begin to form the terrace at one angle of the building, sitting upon a plank, which is supported on the brickwork as they proceed, until they finish at the angle opposite to that at which they commenced. They have no planks upon the beams or joists to support the work below; but as the middle of the terrace (generally about 18 feet wide) is from five to six inches higher than the sides, an arch is thereby formed and supported by the surrounding walls, which are 20 inches in thickness, and have a parapet placed upon them, both for ornament and adding to the security. Over this brick arch is laid a coat or layer of jelly or gravel, or broken bricks, about the size of a large pea, mixed with quick-lime and Jaggury water; this is beat down hard with small hand mallets. Over this first coat is laid a second, composed of rough lime-mortar, which is scored across. The third and last coat is a fine chunars; and this, altogether, forms so strong and firm a body, that a whole terrace sometimes falls down entire and unbroken. Many houses are built with pointed roofs, covered with flat tiles, four inches square, and three-quarters of an inch in thickness; others have a slight coat of lime, with pantiles, which are seldom above seven inches by four; they are semicircular nearly. The houses of the middling class are usually built in a square, and covered with tiles, with a seat round the inside of the square, about three feet high, and three feet in width, protected by a veranda; it is here the inhabitants sit to receive their guests. There are no windows in the external walls, but to each house there is a small door, and frequently a window; the latter placed as high as the veranda will admit. In the open square there is generally a well, with a water-course below the house, for domestic purposes. The houses of the poor are miserable: a few bamboos stuck in the ground, in a circular form, are collected, bent, and tied at the top, so as to represent an egg with the end cut off. They are seldom 10 feet in diameter, with a hole about three feet high to creep in at; this is shut with a leaf, tied on a simple wicker frame. The towns are generally a long street, with others at right angles, but seldom built with much regularity: some are large, some small; some are thatched, and others tiled. Those in the interior parts of the country are inferior to those near the sea-coast towns, where Europeans are settled."

From the account of Colonel Symes's embassy to Ava, we learn, that in the Birman empire, in private houses, the use of brick and stone is prohibited, and they are therefore all constructed of wood. They are raised from the ground by wooden posts or bamboos, according to the size of the building, and made tolerably convenient. The roofs are slightly covered, and at every door stands a long bamboo, with an iron hook at the end, to pull off the thatch, and another with an iron grating, to stifle the flame by pressure. Firemen constantly patrol the streets at night.

INDIAN INK, a black pigment brought principally from China, and much used in architectural drawing for lining, as well as colouring. Indian Ink should be free from grit, and readily fixed, so that when used for outlines, it may not be disturbed, or run, when washed over with any other colour. A good test of the former quality is afforded by cutting the cake, or rubbing it over the teeth; but the latter can only be discovered by use.

INDIAN RED, a pigment introduced from India, composed of peroxide of iron. It is of a russet hue, and forms a good colour for representation of brickwork.

INDIAN YELLOW, another Indian colour, produced from the urine of the camel. It is an excellent tint, and has the property of resisting the action of light to a greater extent than other similar colours.

INDIAN RUBBER, the substance known by the names Indian rubber, elastic gum, Cayenne resin, cautchoc, and by the French *caoutchouc*, is prepared from the milky juice which occurs in several plants, such as the *siphonia cahuca*, *jatropha elastica*, &c. It is, however, extracted chiefly from the first plant, which grows in South America and Java. The manner of obtaining this juice, is by making incisions through the bark of the lower part of the trunk of the tree, from which the fluid resin issues in great abundance, appearing of a milky whiteness as it flows into the vessel placed to receive it, and into which it is conducted by means of a tube or leaf, fixed in the incision, and supported with clay. On exposure to the air, this milky juice gradually inspissates into a soft, reddish, elastic resin. It is moulded by the Indians in South America into various figures, but is commonly brought to Europe in that of sphere-shaped bottles, which are said to be formed by spreading the juice of the siphonia over a proper mould of clay; as soon as one layer is dry, another is added, until the bottle is of the thickness desired. It is then exposed to a thick dense smoke, or to a fire, until it becomes so dry as not to stick to the fingers, when, by means of certain instruments of iron or wood, it is ornamented on the outside with various figures. This being done, it remains only to pick out the mould, which is easily effected by softening it with water. Indian rubber may be subjected to the action of some of the most powerful menstrua, without suffering the least change, while its pliability and elasticity are eminently peculiar to itself.

INDURATING, (from the Latin *induro*, to harden) a term applied to such things as give a harder or firmer consistence to others, either by the greater solidity of their particles, or by dissipating the thinner parts of their matter, so as to leave the remainder harder.

INFIRMARY, a hospital, or house for the reception and cure of invalids.

INLAYING. *See* MARQUETRY, MOSAIC, and VENEERING.

INN, a public tavern, or lodging-house, for the entertainment of travellers, &c.

INNER PLATE, the wall-plate in a double-plated roof, which lies nearest the centre of the roof, the side of the other wall-plate, called the *outer plate*, being laid in the inner surface of the wall.

INNER SQUARE, the edges forming the internal right angle of the implement called a *square*.

INSCRIBED, (from the Latin *inscribo*, to write) in geometry, is said of a figure when all its angles touch either the angles, sides, or planes of another figure within which it is contained.

INSCRIBED FIGURE, a figure placed within another figure or solid, so that all its angles may touch either the angles or sides of it, or both.

INSERTED COLUMN, one that is let into a wall.

INSTRUMENTS, *Mathematical*, a set of implements for describing mathematical diagrams and drawings of every description, when the figures or elementary parts are composed of straight lines, circles, or arcs of circles. The most useful drawing instruments are the following:

A drawing-pen—a pair of plain compasses, commonly called *dividers*—a pair of drawing compasses, with a pen and pencil foot—a pair of bow-compasses—a pair of triangular compasses—a pair of proportional compasses—a set of spring-bows for small work, consisting of spring-dividers, spring-bow pen and bow-pencil—a protractor, in the form of a semicircle, or of a rectangle—a plain scale—a sector—and a parallel rule.

Figure 1. *Plate* I.—The *drawing-pen*. No. 1, the steel pen. No. 2, the same with a pointer, which is screwed into the upper end of the drawing-pen, and has its point enclosed in it, as in a case. The end which contains the ink consists of two thin plates, adjusted by a screw; one of the plates is movable on a joint, for the purpose of being cleaned.

Figure 12. *Plate* II.—The *dividers*. The common sort.

Figure 9, No. 2, hair dividers, in which, by means of a screw, at *a*, the slighest alteration may be made in the extent, by turning it, one way or the other, as the distance requires to be shortened or extended.

Figure 12.—The *drawing compasses*. No. 1, the crayon foot. No. 2, the ink foot. Both these feet are movable upon a joint, so that when fitted in for use, they may be brought perpendicular to the surface of the paper, and thereby perform with greater accuracy. One leg of these compasses has a cylindrical socket, with a parallel slit on the outer side, into which the upper end of each foot is closely fitted: the slit permits the leg of the compass to expand at the socket, and thereby retains the foot with the greater force, in consequence of the spring acquired by the surrounding parts of the socket in forcing in the foot.

Bow-Compasses, one of small dimensions, and were so called from the handling point in the original construction being made in the form of a bow; but which being found inconvenient for the fingers, has been altered to the present shape.

Figure 11.—A pair of *triangular compasses;* consisting of three legs, two of which are movable at the head, in the same manner as the dividers or the drawing-compasses; the third leg, which is made of steel, is fitted into a socket, through a knob projected from the side of the head, by which means

INSTRUMENTS

INSTRUMENTS.

PLAT

Drawn by M. A. Nicholson. Engd. by R. Thew.

it is movable in almost any direction, while the other two remain stationary. Sometimes there is a joint in one of the legs, which permits its being lengthened or shortened at pleasure, so as to answer the expansion of the other two.

The *plain proportionol compasses* are made in the form of a cross, having a parallel slit cut down the middle of each part, and a centre piece fitted to each, so as to be movable round a pin, and to slide from one end of the slit to the other, or to any intermediate distance, to admit of the two points at one end being set in any ratio to the two points at the other. The centre piece is fastened by means of a nut and screw.

Figure 10.—The *improved proportional compasses.* In these, the method of construction is in all respects the same as in the plain proportional compasses; but the adjusting screw is an addition, which admits of its being set with greater accuracy. The parts of the proportional compasses, when shut, mutually cover each other. Scales of different gradations are engraved on the margin of each part, and on both sides of the compasses, for certain uses, which will be afterwards shown.

The common *protractor* is in a semicircular form, with a scale upon one side;

Figure 11, *Plate* I.—The best kind of *protractor*, in the form of a rectangle.

Figure 12.—A *plain scale;* consisting of lines divided into equal parts, of various proportions.

Figure 13.—A *sector*, in the form of a joint rule. The figure represented is of the best kind, having a French joint.

Figure 14.—The common *parallel rule.*

Figure 15.—The rolling *parallel rule.*

The *drawing pen* is used in making ink lines by the edge of a ruler; the cavity between the plates receives the ink, which is supplied from a common quill-pen, or a camel-hair pencil; or, what is perhaps better than either, by wetting the inside of the nibs, and taking up the ink or colour with the point of the pen, by which means the ink will rise without difficulty, and free from sediment. In performing this operation, the plane of the inside of the plate should be parallel to the edge of the rule, and in a plane perpendicular to the surface of the paper.

The use of *the dividers* is to take the extent of any line or surface from one point to another, in order to transfer it to some other line; to repeat any extension upon a straight line in an equimultiple; to divide a straight line, or the circumference of a circle, or any arc thereof, into equal parts; to proportion the parts of a drawing by a scale, in any desired ratio to each other; to construct a drawing similar to one already drawn, either greater or less, by an appropriate scale to each; to construct an angle of any number of degrees; to measure the quantity of any given angle in degrees.

The *drawing compasses* are used either in describing temporary arcs, or whole circumferences, with black-lead pencil, or permanently in ink. If the diagram or drawing consist of many circles, and is to be finished in ink, the circumferences must be first drawn with a pencil, and when afterwards inked must be cleaned with Indian rubber.

The *bow compasses* are used in the description of small circles, in which the legs of the larger kind would be apt to vibrate, and thereby make the arc or circumference ragged.

The *triangular compasses* are used in transferring a given angle from one place to another; or in taking the three points of a triangle at once, and transferring them to any required place, where the figure may be completed by joining the points. These compasses, though exceedingly useful, are but little known: they are serviceable in copying all kinds of drawings, as from two fixed points the position of a third may always be ascertained.

The *proportional compasses* are used in making one drawing similar to another, without the use of scales or triangular lines; in graduating the radii of spirals; in dividing circles into any number of parts between two limits, generally from six to twenty; in dividing a straight line into any number of equal parts, from two to a certain other limit, which is generally about ten.

Some general uses of the proportional compasses may be obtained from the following examples, which, though made to particular numbers in the cases of the planes and solids, will show the application of the principle to any other number contained in the margin of the instrument.

To divide a straight line into any number of equal parts. —Set the index marked upon the centre to the number on the line of lines; then take the extent of the given line with the longer points of the instrument, and the shorter points will divide the line as required. Thus, let it be required to divide three inches, or any distance within the reach of the compasses, into five equal parts: set the index to five on the line of lines: then take three inches, or the distance required by the longer points of the compass, and the shorter points will divide the line into five equal parts.

To divide a circle into any number of equal parts, from six to twenty, that the length of the compasses will admit of. —Set the index upon the number in the line of circles, and with the longer points take the radius of the circle; then the distance between the shorter ends being repeated as chords round the circumference, the circle will be divided as required. Should it be required to divide the circle into ten parts, set the index to ten on the scale of circles, and with the longer points of the compasses take the radius of the circle, and the shorter points will divide the circumference into ten equal parts. And thus any regular polygon, from six to twenty sides, may be inscribed in a circle.

Line of Lines exemplified.

To divide a line of 5 *inches into three equal parts.*—Set the index to three on the scale of lines, then from any scale of equal parts take the extent of 5 between the longer legs, and the distance between the shorter will be one-third of that between the longer.

Line of Circles exemplified.

To inscribe an enneagon, or regular polygon of nine sides, in a circle.—Let the radius of a circle be 3 inches, it is required to inscribe therein an enneagon. Set the index to the ninth division, open the compasses and take the extent of the radius, 3 inches, between the longer legs; then will the distance between the shorter be a side of the required polygon. And thus for any other number marked on these compasses.

Line of Planes exemplified.

To find the square root of a given number by the proportional compasses; say, that of four.—Shut the compasses and unscrew the nut, slide the centre along the groove till the index points to the number 4 upon the line of planes. Open the compasses, and from any scale of equal parts on the plane scale, or elsewhere, take 4 between the points of the longer legs; apply the points of the shorter legs upon the same scale, and the distance between them will be equal to the square root of the distance between the points of the longer legs, which in this case is 2, the square root of the given number 4.

Likewise, if the index be set to 9, the root of 9 will be 3.

To find a mean proportion between two given numbers.— Required the mean proportion between 2 and 4½. The way to find a mean proportion between two numbers is, to multiply them together, and extract the square root of the product. Therefore open the compasses with the index set against 9, the product of the two given numbers, till the distance of the longer legs be equal to 9, taken from some scale of equal parts; then the distance between the points of the shorter legs will be equal to 3 of those parts, which is the mean proportion to 2 and $4\frac{1}{2}$. For as $2 : 3 :: 3 : 4\frac{1}{2}$.

The use of the Line of Solids exemplified.

To extract the cube root of a given number.—To find the cube root of 8 by the line of solids, shut the compasses, unscrew the nut, move the centre along the groove till the index points to 8 on the line of solids; open the compasses, and take 8 between the long points from any scale of equal parts; then the distance between the shorter legs will be the cube root of the given number, which in this example is 2.

Again, by reversion, if the index is set to 2 on the line of lines, take 2 by the shorter legs of the compass, then apply the longer legs to the scale, and it will be found that they extend to 4. Then suppose the square of 3 to be wanted; fix the index to 3 on the line of lines, take 3 by the shorter points, and by applying the longer points to the scale, it will be found that 9 parts will be contained between them, which is the square of 3.

The same may be also pointed out by the index itself, without referring to any scale, not only with respect to the squares, but also of the cubes. Thus let it be required to find the square of 3: set the index to 3 on the line of lines, and turn the other side of the compasses, where the index will be found, against 9. Again, if the index be set to 2 on the line of lines, it will stand against 4 on the line of planes, and against 8 on the line of solids. This is the foundation of the construction of the line of planes and the line of solids: the line of lines being first constructed, the others will easily follow; since the planes are only the squares, and the solids the cubes, of the distances or numbers on the line of lines. The proportional compasses might therefore be made a very useful arithmetical instrument, provided each of the distances were graduated, and the compasses sufficiently long to give the operation correctness.

The use of the *protractor* is to lay down an angle of any number of degrees. Thus, let it be required to lay down an angle of 25 degrees on the line A B, *Figure* 16: supposing the angular point to commence at A, lay the centre of the semicircle, which is shown by a short line, to the point A, and bring the diameter or edge upon the line; then mark the paper at 25 in the circumference, at C; then a line drawn from A to C will form an angle C A B, or B A C, of 25 degrees, generally marked thus 25°. Again, let it be required to make an angle with A B, *Figure* 17, equal to 90°, or to constitute a right angle at the point B: bring the diameter or straight edge of the instrument upon the line A B, and the centre upon the point A; then at the point 90, in the middle of the semi-circumference, make a mark upon the paper at C, and join C B; then will A B C be the right angle required. Lastly, let it be required to find the quantity of any given angle: lay the centre of the instrument upon the angular point, and the straight edge upon one of the lines, and the number against the other line will show the degrees contained in both.

The *rectangular protractor* is used in the same manner; the edge which is not graduated answers to the straight edge, and the other three sides to the graduated semi-circumference, and are numbered round in the same order; the only advantage which this form can have over the semicircular, is, that when fitted into a case, the points at the extremities of the gradations, being more removed from the centre, gives the position of the line to be drawn more accurately, for a small error in any distance will be repeated proportionally to such distance: for example, supposing the line to be continued two, three, or four times as long, the error will be two, three, or four times as great as at first; whereas, if the instrument were four times as long, the error would be the same on the circumference of a circle four times the radius, as it would on the circumference of a circle once that radius, and consequently bear a greater proportion to the circumference of the latter circle than to that of the former.

The *parallel rule*, as its name implies, is an instrument by which straight lines are drawn parallel to each other. Of the two kinds in use, we should prefer the rolling one, as it moves more easily and steadily upon a surface which is not exactly a plane. When the common parallel rule is used upon a round board, it is very apt to revolve; and if the board be hollow, it moves very heavily. With respect to the rolling parallel rule in drawing lines in pencil, it performs its office with the greatest rapidity; but in drawing a series of lines in ink, as the friction is less than in the parallelogramic rule, it is apt to roll away. To remedy this inconvenience, the author would suggest the following alterations: instead of the axle and wheels being in the middle of the rule, it would be much better to place them as nearly as possible to the remote edge from that by which the lines are drawn, as it would give a greater command of leverage from the force exerted upon the drawing edge, and thereby require much less pressure, and consequently would make it much easier for the fingers. Another improvement would be, to insert a convex piece of brass, made exactly as a portion of the wheel on the lower side, as near to the drawing edge as possible, exactly opposite to each wheel; this addition would increase the friction, and keep the edge from the paper at the same time, which would be rather a convenience. These two pieces of brass should be notched the same as the wheel, otherwise no advantage would accrue from them. The rolling parallel rule has also this convenience; that any point in the drawing edge, when the rule is in motion, describes a line perpendicular to the edge of the rule, from which property it becomes easy to raise a perpendicular.

To draw a straight line parallel to a given line through any given point.—Place the edge of the rule upon the line, and then roll it to the point given, where a new line drawn will be parallel to the one given, and will also pass through the point, as required.

To draw a straight line perpendicular to a given line, from a given point.—Let a small line be made on the edge of the rule as an index; place the edge of the rule upon the line, so that the index may be brought to the given point; then move the rule to any parallel distance required, and mark the paper at the index with a point, from which draw a line to the given point, and it will be perpendicular to the given line, as required. Or, instead of a fixed index, the edge of the rule may be marked with a pencil, or the perpendicular may be drawn by the end of the rule.

From a given point out of a straight line, to draw a perpendicular to the straight line.—Place the edge of the rule upon the line, and move it forward to the point; then mark a short line, as nearly perpendicular from the point as the eye can judge, upon the bevel edge of the rule, with a pencil, and roll the rule backwards till the edge comes to the line, where mark the paper at the pencil line on the edge of the rule, and draw a straight line between this mark and the given point, which will be perpendicular to the line given, and pass through the given point.

From the perpendicular motion of the rolling parallel rule, its place can be depended upon at any distance. Whereas, in the parallelogramic rule, as it is opened by so many steps, and the motion at each point is in the arc of a circle, and made towards the same end of the rule, the line drawn from any point in the first line of the parallel, to the same point in the edge of the rule at the remote parallel, will be exceedingly oblique, and frequently so much so, as not to reach the place where the line is intended to be drawn : consequently the rule must be brought back towards the side which it is intended to reach; an operation not only troublesome, but also attended with much uncertainty.

From a given point to make an angle equal to, and in the same position as a given one.—Place the edge of the parallel rule upon one of the legs of the given angle, roll it to the given point, and draw a straight line ; then bring the edge of the rule to the other leg, roll it to the given point and draw another line, which will complete the angle required.

This operation might also be performed by the common parallel rule, though not so handily.

In lieu of the parallel rule, some use a T-square, which consists of a thin parallelogramic blade mortised into a rectangular prismatic piece, at right angles to one of its narrow sides or planes, in the form of the letter T, and a set-square, drawing both parallel and perpendicular lines by means of a thin board, and the straight edge of the T-square; the board is made up in the form of a right-angled triangle, and is termed a set-square. Any straight edge may be used with the set-square, but in most instances the T-square is most convenient, as, when moved along the side of a drawing board, it will give any horizontal line, and the set-square any perpendicular. To use this with any straight edge, place one of the legs of the triangle, which forms the right angle, upon the line; place the straight edge upon the hypothenuse of the triangle, and if it be required to draw another line parallel, slide the triangle along the edge of the rule till the edge that was upon the line comes to the given point, then draw a line by this edge, and it will be the co-parallel of the given line, but if the line be required to be perpendicular to the given line, place the triangle as before, then slide it along, till the other edge, (that is, the one at right angles, that was placed to the line,) comes to the point required, and draw a line by it, which will be perpendicular to the given line.

From the hypothenuse being placed upon the straight edge, the triangle is not liable to turn, as the pressure exerted in drawing the lines is everywhere perpendicular to the hypothenuse ; but in drawing any parallel or perpendicular lines at a great distance, the same inconvenience would occur which attends the common parallel ruler ; that is, the lines could not be drawn within a rectangle to the full length of the first line, which is a side thereof.

In this case, to draw one line parallel to another, place one of the perpendicular edges of the triangle upon the line, as before, but instead of applying the straight edge to the hypothenuse, apply it to the other leg of the right angle, and the motion of the drawing edge will be the same as in the rolling parallel rule.

If, however, the difference be considerable between the two sides of the right angle, and if the shorter side be that which is applied to the straight edge, the pressure of the hand at the extremity will be liable to turn round the triangle ; this inconvenience may be remedied to a great degree by making the two sides of the triangle which contain the right angle equal to each other, and the angle made by either side, which forms the right angle, and the hypothenuse, will be 45° or half a right angle. Though this equality of the legs makes the triangle more clumsy, it has its advantages not only in the case here described, but also in bisecting a right angle, which is an operation frequently wanted.

The *plain scale*, in common cases of instruments, has the following lines or scales upon it, viz., a line of 6 inches ; a line of 50 equal parts ; a diagonal scale : these are put on one side. On the other side are, a line of chords, marked C ; and seven particular scales of equal parts, or decimal scales, of different sizes ; the numbers at the beginning of each denote how many of the small divisions at the beginning are contained in one inch, viz., 10, 15, 20, 25, 30, 35, 40.

The use of the line of inches is the same in this as in all other rules, viz., to take the length or dimensions of bodies in inches and tenths of an inch, in order to compute their contents.

The line of 50 equal parts, being equal to 6 inches, shows the foot to be divided into 100 of the same equal parts, and the divisions of this line are placed by those of the inches, that it may be easily seen what number in one is equal to a given number of the other ; thus 3 inches is equal to 25 parts of the 100 ; and 30 of these latter are equal to 3 inches and 6 tenths. This line is therefore often useful in practical mathematics.

The *diagonal scale* is probably a *centesimal scale*, because by it an unit may be divided into 100 equal parts; and therefore any number, to the 100th part of an unit, may be expressed, which is an exactness generally sufficient in practical business. How this is done will be easy to understand, as follows: let A B, *Figure* 18, *Plate* III., be 1, or an unit, and divide it into 10 equal parts at 1, 2, 3, 4, &c. At a proper distance, B C, draw the line C D, equal and parallel to A B, and divide it also into 10 equal parts at *a*, *b*, *c*, *d*, &c : then join the points A *a*, 1 *b*, 2 *c*, 3 *d*, &c., and these will be the ten diagonal lines. Lastly, divide B C into ten equal parts also, and number them 1, 2, 3, 4, &c., to 10 at C ; then, through each of these divisions, draw lines parallel to A B, through the length of the scale, and the construction is completed.

In this diagonal scale, A B is one inch ; then if it be required to take off $1\frac{73}{100}$ inches, or 1.73, set one foot of the compasses in the third parallel under 1, at *e*, and extend the other foot or point to the seventh diagonal in that parallel, at *g* ; and the distance *e g* is that required ; for *e f* is one inch, and *f g* is 73 parts of 100.

Again, suppose it required to set off upon any line 2.37 inches ; then place one point of the compasses on the seventh parallel under 2, at *h*, and extend the other to the third diagonal in the same parallel at *i* ; and the distance *h i* is that required. Or, if A B be 10, the distance *e g* is 17.3, and *h i* is 23.7. Also, if A B be 100, then *e g* is 173, *h i* is 237 ; and so on.

This diagonal scale has the centesimal division at each end, and the unit in one is just the double of that of the other : thus, if A B be one inch at one end, it is half an inch at the other ; or if it be half an inch in the larger, it is one quarter in the lesser divisions, as is the case upon most of the common plain scales.

This unit, A B, may also be one foot, one yard, one rod, one mile, &c. So that every unit in every kind of measure is hereby estimated in hundredth parts of the whole, which shows the diagonal scale to be a most useful invention.

On the other side of the plain scale are the seven decimal lines, which are usually called *plotting scales*, because, their divisions of an unit into ten parts being different in the proportion of 4 to 1, the surveyor may vary the scale of his plot or plan of an estate, &c., in that ratio, in seven different drawings ; and the superficies or sizes of the greatest and least plans, will be as 16 to 1. Or, that drawn by scale No. 10, will be sixteen times larger than the plan laid down from scale No. 40.

The same variety is also to be had in the construction of all other geometrical figures, whether superficies or solids ; and with respect to the latter, the greatest will be the least as 64 to 1; that is, the architect can vary the size of his structure in the ratio of 64 to 1, in seven different elevations.

The last line on the common plain scale is that of chords; and is much more used than the protractor for laying off or measuring any proposed angle. Thus, let it be required to draw the line B C, *Figure* 19, to make an angle of 35° with the line A C. To do this, set one point of the compasses in the beginning of the line of chords, and extend the other to 60; with that extent, as a radius, place one foot in C, and with the other describe the arc A B; then take from the chords 35° in the compasses, and set them on the arc from A B; then through C and D draw C B, and it is done.

Again.—If it be required to measure any angle, as A B C, *Figure* 20, produce B A, if necessary; take 60° from the chords in the compasses, and with one foot in B describe the arc A C, cutting the leg B A at A, and B C at C; then take the arc A C in the compasses, and applying it upon the beginning of the line of chords it will reach to 30°, the quantity of the angle required. But the line of chords is more useful on the sector, to which we now proceed.

N.B.—The construction of this line is shown in the next article.

The *sector* is a most useful instrument, as forming a universal plane scale.

The lines commonly laid down upon the sector, are—a line of equal parts, marked L at the end; a line of chords to 60°, marked C; a line of sines, to 90°, marked S; a line of tangents, to 45°, marked T; another line of tangents from 45 to 75 or upwards, marked *t a*; a line of secants, marked *s e*; a line of polygons marked P O L.

Besides these, when the sector is quite opened, there are placed on one side—a Gunter's line of artificial numbers, *n*; a line of artificial sines, *s*; and a line of artificial tangents, *t*. Likewise a line of 12 inches, and another of the foot divided into 1000 equal parts, placed by it, for the purposes already mentioned.

Before a proper idea can be formed of these sectoral lines, and their uses, their construction must be shown from the circle. Therefore, let A C D, *Figure* 21, be a quarter of a circle, divided into 90°, described with the radius C A, on the centre C; let A E and C F be perpendicular to A C, at A and C; then if the radius A C be divided into 10, 100, 1000, &c., equal parts, it will be the line so called upon the sector.

If from A, a line be drawn to any part or division of the quadrant, as G, at 60°, then that line A G is the chord of that arc, or of 60°. And if the line A B be drawn, it will be the chord of 90°; and by setting one foot of the compasses in A, and extending the other to the several divisions, 10, 20, 30, 40, &c., they may be transferred from the circle to the line A B, which will then be properly divided into a line of chords in 10, 20, 30, 40, &c., to 90 as on the plane scale.

If from any point, G, in the quadrant, you let fall a perpendicular, G I, to the radius A C, or G H to the radius C B, then the line G I is called the sine of the arc A G; and the line G H is the sine of the arc G B, the complement of A G to 90°. And if all the divisions of the quadrant were transferred to C B by lines parallel to A B; then the line C B will be divided as a line of sines in the points, 10, 20, 30, 40, &c., to 90°.

By laying a rule from the centre, C, to the several divisions of the quadrant, 10, 20, 30, &c., it will cut the line A E in the points 10, 20, 30, &c., which will be thereby divided into a line of tangents; and here it must be observed, that the line of tangents, T, on the sector, extends but to 45°, equal to C A or C B radius; and that the line of lesser tangents, *t*, are projected from a lesser radius, and begin from 45° at the distance of its radius from the centre of the sector.

By drawing the line C L through the division 60° to the line A E, it makes A L the tangent of 60°, and C L the secant of 60°, or of the angle A C L. And if one foot of the compasses in C, the other is extended to the several divisions in the line A E, and transfer them to the line C F, then will the part B F be thus divided into a line of secants; being placed at the distance of the radius C B, from the centre of the sector, and beginning at E, where the radius ends.

It may be of use in many cases to observe, that the chord 60°, A G, is equal to the radius C A or C G; that the sine 60°, G I, besects the radius A C in I, and therefore the sine G H of 30° is equal to half the radius, or C I. Therefore the secant, C L, of 60° is equal to twice the radius, A C; for C I is to C G as C A to C L, and consequently the cosine is to radius as radius to the secant. Also, the tangent A L is to radius A C as radius B C is to the co-tangent B K.

From what has been said, the reason appears why the line of lines (or equal parts L) terminates upon the sector at 10; the line of chords, C, at 60°; the line of sines, S, at 90°; the larger tangents, T, at 45°; and that the lesser tangents, and also the secants are, of indefinite lengths.

From the nature of the sector, consisting of two pairs, or legs, movable upon a central joint, it is requisite that the lines should be laid on the sector by pairs, *viz.*, one of a sort on each leg, and all of them issuing from the centre—all of the same length, and every two containing the same angle. We shall now illustrate the nature of working problems by the sector, as follows, by the lines of lines, or equal parts L L.

Figure 22.—Let C L, C L, be the two lines of lines upon the sector, opened to an angle, L C L; join the divisions 4 and 4, 7 and 7, 10 and 10, by the dotted lines *a b*, *c d*, L L. Then by the nature of similar triangles, C L is to C *b* as L L to *a b*; and C L is to C *d* as L L to *c d*; therefore *a b* is the same part of L L as C *b* is of C L. Consequently, if L L be 10, then *a b* will be 4, and *c d* will be 7, of the same parts.

And hence, though the lateral scale C L be fixed, yet a parallel scale, L L, is obtainable at pleasure; and therefore, though the lateral radius is of a determined length in the lines of chords, sines, tangents, and secants, yet the parallel radius may be had of any size required, by means of the sector, as far as its length will admit; and all the parallel sines, &c. peculiar to it; as will be evident by the following examples in each pair of lines.

Example I.—*In the lines of equal parts. Figure* 22. Having three numbers given, 4, 7, 16, to find out a fourth proportional. To do this, take the lateral extent of 16 in the line C L, and apply it parallel-wise, from 4 to 4, by a proper opening of the sector; then take the parallel distance from 7 to 7 in the compasses; and applying one foot in C, the other will fall on 28 in the line of lines, C L, and is the number required; for as 4 is to 7 so is 16 to 28.

Example II.—*In the line of chords. Figure* 23. Suppose it required to lay off an angle, A C B, equal to 35°; then with any convenient opening of the sector, take the extent from 60 to 60 and with it, as radius, on the point C describe the arc A D indefinitely; then in the same opening of the sector take the parallel distance from 35° to 35°, and set it from A to B in the arc A D, and draw A B, which will make the angle at C as required.

Example III.—*In the lines of sines. Figure* 24. The lines of sines, tangents, and secants, are used in conjunction with the lines of lines in the solution of all the cases of plain trigonometry; thus let there be given in the triangle A B C, the side A B = 230, and the angle A B C = 36° 30′, to find the side A C. Here the angle at C is 35° 30′; then take the lateral distance 230 from the line of lines, and make it a parallel from 53° 30′ to 53° 30′ in the line of sines; then the

Drawn by P. Nicholson

Engd. by R. Thew.

parallel distance between 36° 30′ in the same lines, will reach laterally from the centre to 170.19 in the line of lines for the side A C required.

Example IV.—*In the lines of tangents.* If, instead of making the side B C radius, as before, A B be made radius; then A C, which before was a sine, will be the tangent of the angle B; and, therefore, to find it, the lines of tangents must be used thus:—Take the lateral distance, 230, from the line of lines, and make it a parallel distance on the tangent radius, *viz.*, from 45° to 45°; then the parallel tangent from 36° 30′ to 36° 30′, will measure laterally on the line of lines, 170.19, as before, for the side A C.

Example V.—*In the lines of secants.* In the same triangle, in the base A B, and the angles at B and C given, as before, to find the side or hypothenuse B C. Here B C is the secant of the angle B. Take the lateral distance 230 on the line of lines, make it a parallel distance at the radius, or beginning of the lines of secants; then the parallel secant of 60° 30′ will measure laterally on the line of lines 287.12, for the length of B C, as required.

Example VI.—*In the lines of sines and tangents conjointly. Figure* 25. In the solution of spherical triangles, use the line of sines and tangents only, as in the following example. In the spherical triangle A B C, right-angled at A, there is given the side A B = 36° 15′ and the adjacent angle B = 42° 34′ to find the side A C. The analogy is, as radius is to sine of A B, so is tangent of B to tangent of A C; therefore make the lateral sign of 36° 15′ a parallel at radius, or between 90 and 90; then the parallel tangent of 42° 34′ will give the lateral tangent of 28° 30′ for the side A C.

Example VII.—*In the lines of polygons. Figure* 24. It has been observed, that the chord of 60° is equal to radius, and 60° is the sixth part of 360°; therefore, such a chord is the side of a hexagon, inscribed in a circle. So that in the line of polygons, if the parallel distance between 6 and 6 be made the radius of a circle, as A C, and the parallel distance between 5 and 5 be taken and placed from A to B, the line A B will be the side of a pentagon A B D E F, inscribed in the circle. In the same manner may any other polygon, from 4 to 12 sides, be inscribed in a circle, or upon any given line A B.

Of Gunter's lines.—Having thus shown the use of all that are properly called *sectoral lines*, or that are to be used sectorwise, it only remains to describe another set of lines usually put upon the sector, which will in a more ready and simple manner give the answers to the questions in the above examples; these are called *artificial lines* of numbers, sines, and tangents, because they are only the logarithms of the natural numbers, sines, and tangents, laid upon lines of scales; this method was first invented by Mr. Edmund Gunter, and the lines are called *Gunter's lines*, or *the Gunter*. Logarithms are a set of numbers, so contrived, that, by addition and subtraction, the answers to all questions in multiplication, division, proportion, and the analogies of plain and spherical trigonometry, are found. Therefore, in the compasses, the extent, or ratio, between the first and second terms will always be equal to the extent, or ratio, between the third and fourth terms; consequently, if with the extent between the first and second terms, one foot of the compasses be placed on the third term, the other foot, on turning the compasses about, will fall on the fourth term sought.

Thus, in *Example* I., of the three given numbers 4, 7, and 16, take the extent from 4 to 7 in the compasses, then place one foot in 16, and the other will fall on 28, the answer, in the line of numbers, marked *n*.

Again, the artificial line of numbers and sines are used together in plain trigonometry, as in *Example* III., where the two angles B and C, and the side A B, are given; for here, if the extent of the two angles 53° 30′ and 36° 30′ be taken in the line of sines, marked *s*, and one foot be placed upon 230 in the line of numbers, *n*, the other will reach to 170.19, the answer.

Also, the line of numbers and tangents are used conjointly, as in *Example* IV.; thus, take in the line of tangents, *t*, the extent from 45°, radius, to 36° 30′, and it will reach from 230 to 170.19, the answer, as before.

Lastly, the artificial lines of sines and tangents are used together in the solution of spherical triangles.

Thus, *Example* VI. is solved by taking in the line of sines, *s*, the extent from 90°, radius, to 36° 15′, and in the line of tangents, *t*, it will reach from 42° 34′ to 28° 30′, the answer required.

It may be farther observed, that each pair of sectoral lines contains the same angle, viz., six degrees in the common six-inch sector; therefore, to open these lines to any given angle, as 35°, for instance, take 35° laterally from the line of chords, and apply it parallel-wise from 60° to 60° in the same lines, and they will all be opened to the given angle 35°.

If to the angle 35° be added the angle 6°, which they contain, the sum is 41°; then take 41° laterally from the line of chords, and apply it parallel from 60 to 60, then will the sides or edges of the sector contain the same angle, 35°. In this case, the sector becomes a general *recipe-angle*, which is an instrument for taking the quantity of any angle contained between two inclining planes.

INSULAR, or Insulated Buildings, such as stand alone.

INSULATED COLUMN, or Detached Column, a column that stands quite clear of a wall, and may be seen all round.

INTAGLIOS, (Italian.) the carved work of an order, or of any part of an edifice.

INTAVOLATA. *See* Cymatium.

INTERCEPTED AXIS, the same as Abscissa.

INTERCOLUMN, (from the Latin *inter*, between, and *columna*, a column.) the open area between two columns.

INTERCOLUMNIATION, the distance between columns, measured by their lower diameters. Under the article Colonnade will be found the several names given to certain distances measured by the diameter. The general distance used by the Greeks in the Doric order was that of the monotriglyph, though in the Doric portico or temple of Augustus, and the portico of Philip, king of Macedon, in the island of Delos, they are ditriglyphs. Also, on account of the triglyphs being placed in the angles of the Grecian-Doric, the extreme intercolumniation will be something less than those of the intermediate columns: as otherwise, if all the intercolumns were equal, each extreme intertriglyph would be broader than the intermediate ones.

INTERDENTILS, the space between dentils. It appears, not only from a comparison of the most celebrated examples in the Ionian antiquities, with that of Jupiter Stator at Rome, but upon the average, that the Romans set their dentils nearer together than the Greeks, and that the dentils themselves, among the former, are of a more trifling character. In the temple of Bacchus at Teos, the space between the dentils is two-thirds of the breadth of the dentil. In the temple of Minerva Polias, at Priene, the space is nearly three-fourths of the breadth. In the temple of Jupiter Stator, which has the boldest entablature of all the Roman examples, the space is about half the breadth of the dentil; and in most other examples in which dentils are to be found, generally less.

INTERDUCES. *See* Inter-Ties.

INTER-FENESTRATION, (from the Latin, *inter*, between, and *fenestra*, a window,) the space between windows.

INTER-JOIST, the space between joists, which may be a foot between centre and centre in good buildings, and in slight houses from 18 to 22 inches.
