are sentences of $L(D1-D7)$, though not of L . We shall call the new language $L(D1-D7)$ a *definitional enrichment* of L (reserving the more familiar label ‘definitional extension’ for theories, or logics, formulated in L).

REMARK 3. A description of the first sentence above, which is agreeable to fans of use and mention, is this: the result of writing the prefix ‘it is not the case that’ immediately in front of the proposition letter in Prop that is denoted by ‘ p ’. In this work we mostly stick to the familiar convention of using logical connectives *autonomously*, i.e. as names of themselves.

(II) Usually, one conceives of a definition as something added to a *theory* rather than to a ‘bare’ language (see e.g. Suppes [1957, p. 152 f.]). Suppose, then, that we add the series D1–D7 to any of the Smiley–Hanson systems below, e.g. to the logic **OK** as described in Section 10.2. How are we to understand D1–D7 within **OK**, then? In particular, what does the symbol ‘=df’ mean? We suggest here that ‘=df’ can throughout be replaced by the sign \Leftrightarrow for material *equivalence* or ‘biconditionality’, and that every resulting sentence is to be regarded as a *new axiom* which is added to those of the logic **OK**. (We assume then that the outermost pair of parentheses has been dropped from D1–D7, complying with the customary convention.) From the standpoint of the logic **OK**, D1–D7 differ from its ‘proper’ axiom schemata A0–A2 chiefly in respect of introducing into it *new* symbols that are not already in its language L , viz. the seven English connectives defined by D1–D7 (they also differ from A0–A2 in other respects not commented upon here). Thus, the logic **OK** *supplemented with* D1–D7 *as here understood*, call it **OK(D1–D7)**, will be a certain subset of the larger sentence-set $\Sigma(D1-D7)$, *not* of Σ , and is determined not only by A0–A2 and the rules of inference R1 and R2, but by the ‘definitional axiom schemata’ D1–D7 as well. Finally, just as $L(D1-D7)$ was said above to be a definitional enrichment of the language L , we now say that the logic **OK(D1–D7)** is a *definitional extension* of the logic **OK**; the same thing goes for any theory over, i.e. formulated in, L , to which D1–D7 are added.

(III) We observed a moment ago that such strings as

$$(3) \quad \begin{array}{l} \text{it is not the case that } p \\ \text{it is obligatory that } q \end{array} \quad (\text{with } p, q \text{ in Prop})$$

count as sentences in the enrichment $L(D1-D7)$ of L . Now, these strings are hardly acceptable as sentences of *English*, although they surely involve nice English components, viz. the *definienda* of D1 and D6, respectively. At best, they could count as sentences of pseudo-English or quasi-English. The reason for this being so is that, as such, p and q fail to make any sense in English; as one often says, they are just empty place-holders for genuine English sentences. But couldn't we begin to assign English readings to these letters, just as we did to the logical connectives in L by means of D1–D7? If this were possible, we might be able to *generate* some genuinely English sentences within some definitional enrichment of L . Let us try. Consider the English sentence figuring in the Alf Ross paradox, viz.

(0) You post the letter.

Again, let p be the first proposition letter in an assumed enumeration, or ordering, of the set Prop. We now lay down the definition:

(D8) You post the letter =df p

which, in accordance with the decisions taken under (II) above, is to be understood as a *single axiom*:

You post the letter $\Leftrightarrow p$

(or, perhaps, as a degenerate axiom schema having that single axiom as its only instance).

We must now raise a vitally important question: is D8, thus understood, acceptable from a standpoint of the theory of definitions? Well, its answer depends on which of the following alternatives applies:

- (A) In D8, p is, a propositional *variable*, and any theory T formulated in the language L enriched by D8, call it $L(D8)$, is closed under a *rule of substitution* for propositional variables.
- (B) In D8, p is, and indeed has to be, a propositional *constant*, which is syntactically and grammatically on a par with the logical 0-place connectives \top and \perp of L . Otherwise, D8 is altogether unacceptable from the point of view of definition theory.

Let us explore these two alternatives in turn.

Alternative A. What does it mean to say that any theory over $L(D8)$ is closed under substitution for propositional variables? At least the following, I suggest:

- (1) For each sentence A of $L(D8)$:

You post the letter $\Leftrightarrow A$

is *provable* (as a 'thesis' or 'theorem') in any such theory.

More leisurely expressed: D8 is an axiom of any theory T over $L(D8)$. Hence, D8 is provable in T . And so is any result of substituting a sentence A of $L(D8)$ for the variable p in D8.

Now, an obvious consequence of adding D8 to L is this:

(2) The strings:

You post the letter

\neg You post the letter

are sentences of $L(D8)$.

Therefore, by (1) and (2), we conclude that the string

(£) You post the letter $\Leftrightarrow \neg$ You post the letter

is not only a sentence of $L(D8)$ but also *provable* in any theory over $L(D8)$, since (£) is the result of substituting the $L(D8)$ -sentence

\neg You post the letter

for p in D8. But (£) is obviously a contradiction in any such theory (of any interest), hence, any such theory is inconsistent.

Hence, alternative A must be rejected.

Another way of explaining its failure is as follows. On alternative A , D8 violates a basic definition-theoretic principle according to which no proper definition of a sentence-forming connective is allowed to use any *free* (i.e. not bound to any quantifier) variable in the *definiens* which does not occur already in the *definiendum*. Well, in D8, on this alternative, p is a free propositional variable which obviously does not occur in the English sentence (or sentence-forming connective of degree 0) ‘You post the letter’ (although, for sure, the 16th letter ‘ p ’ of the English alphabet does). For a statement of the definition-theoretic principle in a somewhat different context, see Suppes [1957, p. 156 f.]; for its motivation in the present context, recall that we just proved every theory over $L(D8)$ to be inconsistent. Note also that the principle is a consequence of more general criteria in definition theory known as those of non-creativity and relative consistency (Suppes [1957, pp. 154–5]).

Alternative B. Having rejected A , this is the alternative we must accept in order to protect D8. Let us pay attention to two consequences of regarding p in D8 as a *constant*, and indeed a *logical* one. (Note that in the context we disregard any subdivision of constants into logical vs. non-logical (descriptive) ones; this is a deliberate, but remediable oversimplification.)

(i) The disastrous sentence (£) will not be provable in any *consistent* theory over $L(D8)$, or over $L(D1–D7, D8)$, because D8 is now

a proper definition which conforms to the rules and criteria of definition theory. In particular, there is nothing like a ‘rule of substitution’ for logical constants.

- (ii) Let us continue to think of the set Prop of ‘proposition letters’ as a set of *free* propositional *variables*, which form the stock of *non-logical* symbols of L and its enrichments. But then, obviously, the first letter p , used in D8 as now understood, is wrongly classified, being a constant symbol. So in any enrichment of L containing D8, p has to be *re-classified* as a logical constant, i.e. *moved from Prop into* the set LogCon of the enrichment. Similarly, the English sentence ‘You post the letter’, defined by D8, should be classified as a constant symbol and placed in the set LogCon of such enrichments.

EXERCISE 4. Consider the language $L(D1-D7, D8)$ and think of it as a structure $L(D1-D7, D8) = \langle \text{Bas}, \text{LogCon}, \text{Aux}, \text{Sent} \rangle$. Specify the components of that structure, observing the instructions just given under (ii) above!

REMARK 5. One might object to our argument concerning the status of p in D8 that we have overlooked a third alternative: p is a propositional *parameter*. Here is my answer: either a parameter is a free variable and the present alternative amounts to Alternative A and is ‘out’; or a parameter is a constant, so the present alternative amounts to Alternative B and we gladly accept it. Is the objection thereby met?

5.1 *On the fragment of normative English constructible in $L(D1-D7, D8)$.*

Consider the language $L(D1-D7, D8)$. The following are sentences of $L(D1-D7, D8)$:

It is obligatory that you post the letter.

Either it is not the case that you post the letter or it is permitted that you post the letter.

If it is obligatory that you post the letter then it is permitted that you post the letter.

which are also, indeed, reasonably good *sentences of English*. (We don’t deny that they can be improved from the standpoint of *stylistic elegance*, using devices like better punctuation, inversion of word order, pronominalization, attaching some negation- or obligation-expressing phrase to the main verb in the infinitive, and so on.) Now, is it possible somehow to characterize rigorously the set of those *English* sentences which we can *generate*

in the language $L(D1-D7, D8)$? Yes, easily, as follows: it is the smallest set containing (i) the English sentence (0) (= ‘You post the letter’), defined in D8, and which (ii) is closed under the seven English connectives defined in the series D1–D7. We now propose the following, somewhat more comprehensive notion:

DEFINITION 6 (FNE(D1–D7, D8)). Let $L(D1-D7, D8)$ be the *definitional enrichment* of L that arises from adding D1–D7, D8 to L . Think of it as a structure whose components are specified as in the Exercise above! Then, by the *fragment of normative English constructible in $L(D1-D7, D8)$* we shall mean the structure

$$\text{FNE}(D1-D7, D8) = \langle \text{Bas}, \text{LogCon}, \text{Aux}, \text{Sent} \rangle$$

where:

- (i) Bas = {You post the letter}.
- (ii) LogCon = {it is not the case that, both ____ and..., either ____ or..., if ____ then..., if and only if ____ then..., it is obligatory that, it is permitted that}.
- (iii) Aux = \emptyset (i.e. the empty set).
- (iv) Sent = (as usual) the smallest set which contains every basic sentence in Bas as an element and is closed under every logical connective in LogCon.

REMARK 7.

- (a) The basic sentence as well as the logical connectives are used autonomously in this description, i.e. as names of themselves. Hence, no quotation marks are needed.
- (b) Note that, although the English sentence ‘You post the letter’ was classified as a logical connective (of degree 0) in $L(D1-D7, D8)$, it is not so classified in the fragment $\text{FNE}(D1-D7, D8)$ but as a basic sentence. The reason for this decision is that we want Sent to be definable as the result of closing a *non-empty* set Bas under certain connectives.
- (c) There is no need for parentheses in the fragment. This is due to the ‘smart’ reading in English of the *binary* connectives that is codified by the definitions D2–D5; the point being that every English sentence in the fragment, which has any of the *definienda* of D2–D5 as its *principal sign* or *main connective*, begins with that very connective.

Thus, no ambiguities of grouping are forthcoming in the fragment, and its notation is Polish or Łukasiewiczian.

5.2 *The translation induced by D1–D7, D8; An extension of that translation*

Let us quickly rehearse what has been done so far. We started out by considering the purely *symbolic*, or *formal* language L common to the Smiley–Hanson systems of monadic deontic logic and its set Σ of purely symbolic sentences. Then, we added to L eight definitions D1–D7, D8, thereby obtaining a richer language $L(D1–D7, D8)$, whose set LogCon contained eight fresh *English* connectives, viz. the *definienda* of D1–D8; also, the first proposition letter in an assumed ordering of Prop , i.e. p , was moved into that set LogCon . The set of sentences of that richer language, call it $\text{Sent}_{L(D1–D7, D8)}$, was then seen not only to be larger than that of L , but indeed to contain as a subset a certain class of ‘reasonably good’ *sentences of English*, viz. the set of sentences of the *fragment* $\text{FNE}(D1–D7, D8)$ of *Normative English constructible in* $L(D1–D7, D8)$, as defined above. Call that class either by the fancy name of

$$\text{Sent}_{\text{FNE}(D1–D7, D8)} \quad (= \text{Sent}, \text{ as defined by clause (iv)})$$

or call it simply Φ .

Now, can we say anything informative about the relation of the original sentence-set Σ to that of the fragment FNE , i.e. Φ , apart from the claim that the fragment and its sentences were somehow *generated* by the addition of D1–D7, D8 to the original language L ? (Assume, for safety, that the letter p is reclassified and moved into LogCon already in L , so that we are free to add D8 to L .) Well, we can obviously assert the following:

There exists a *translation* (formalization, symbolization) of the fragment *into* the original formal language L in the sense of a *function* t which *maps* Φ *one-to-one into* Σ , where t is defined by the following recursive conditions:

- (i) $t(\text{‘You post the letter’}) = p$; cf. D8.

Again, assume that t has been defined for any English sentences A, B in Φ . Then:

- (ii) $t(\text{it is not the case that } A) = \neg t(A)$; cf. D1.
 (iii) $t(\text{both } A \text{ and } B) = (t(A) \wedge t(B))$; cf. D2.
 (iv) $t(\text{either } A \text{ or } B) = (t(A) \vee t(B))$; cf. D3.

- (v) $t(\text{if } A \text{ then } B) = (t(A) \rightarrow t(B))$; cf. D4.
- (vi) $t(\text{if and only if } A \text{ then } B) = (t(A) \Leftrightarrow t(B))$; cf. D5.
- (vii) $t(\text{it is obligatory that } A) = (Ot(A))$; cf. D6.
- (viii) $t(\text{it is permitted that } A) = (Pt(A))$; cf. D7.

It is obvious that, as defined, t is a function *from* Φ *into* Σ . It is almost just as obvious that t is *one-one* in the sense that for any two distinct sentences A, B in Φ we have that $t(A)$ and $t(B)$ are distinct sentences in Σ ; the inductive proof of this fact is rather tedious, although basically easy to grasp.

We see that each clause in the definition of t corresponds to exactly one member in the series D1–D8. Hence, it is appropriate to speak of the translation t as being *induced by* that series. Again, in the present case of Φ and Σ , we speak alternatively of t as a *formalization* or a *symbolization*, because Φ is the set of sentences of a fragment of a *natural* language, viz. English, and Σ is the set of sentences of a *purely symbolic* language, viz. L, and t translates the former into the latter. Not every translation function has this special character, of course.

Suppose now that we add further definitions in the style of D8 to the language L(D1–D7, D8), of the general form:

- (D9) $\underline{\hspace{1cm}}$ =df p_1 .
- (D10) $\underline{\hspace{1cm}}$ =df p_2 .
- \cdot
- \cdot
- \cdot
- (D8+k.) $\underline{\hspace{1cm}}$ =df p_k .

where:

- (i) k is a positive integer ≥ 1 .
- (ii) p_1, \dots, p_k are distinct proposition letters that have been reclassified already in the original language L and moved into its set LogCon, where we also find p which is distinct from all of them.
- (iii) The blanks are filled by distinct English sentences considered as *un-analyzed wholes* ('ungetrenntes Ganzes' in the terminology of Hilbert and Ackermann [1928]), and all distinct from 'You post the letter'.

Then, the *fragment of normative English constructible in* the enrichment L(D1–D7, D8–D8+k) is easy to identify: its set Bas of basic sentences contains exactly $k + 1$ English members and, as usual, its total set Sent of sentences is the result of closing Bas under the by now familiar seven

English connectives. Now, let Φ be that total set, this time, and let Σ still be the set of purely symbolic sentences of L (with p, p_1, \dots, p_k reclassified as indicated above). How are we to define the extended translation, let us still call it t , which is induced by the series D1–D7, D8–D8+k? Very easy: just add to our earlier definition of t the following k clauses in the recursion (or induction) basis:

- $$\begin{aligned} (i_1) \quad t(\text{definiendum of D9}) &= p_1; \quad \text{cf. D9.} \\ (i_2) \quad t(\text{definiendum of D10}) &= p_2; \quad \text{cf. D10.} \\ &\vdots \\ &\vdots \\ (i_k) \quad t(\text{definiendum of D8+k}) &= p_k; \quad \text{cf. D8+k.} \end{aligned}$$

EXERCISE 8. Verify that, as just defined, the extended translation t remains a one-one mapping of Φ , as presently understood, into Σ !

5.3 On the natural deontic logic over $FNE(D1-D7, D8-D8+k)$

Let $FNE(D1-D7, D8-D8+k)$, or FNE_k for short, be the fragment of normative English constructible in the enrichment $L(D1-D7, D8-D8+k)$ of L , as described above. Let Φ still be the set of sentences of FNE_k ; thus, all members of Φ are English sentences (some of them, though, less than fully elegant from the stylistic point of view). Then, by the *Natural Deontic Logic over FNE_k* we shall mean a certain subset NDL of Φ , which is vaguely characterized as follows:

NDL = the set of sentences of FNE_k which are *logically valid* or *logically correct* (or, if you have no qualms about applying that notion to normative sentences: *logically true*).

Suppose, at least for the time being and for the sake of argument, that this admittedly vague characterization of NDL makes ‘some reasonable’ sense to you and to me. Let A be any sentence in English. We then have the following immediate result:

$A \in NDL$ iff A belongs to Φ and A is logically valid.

Writing ‘ $\Vdash A$ ’ for ‘ A is logically valid’, we may alternatively express the result as a set-theoretical identity:

$$NDL = \{A \in \Phi : \Vdash A\}$$

Some further notions can now be defined:

DEFINITION 9 (Logical consequence, inconsistency and consistency in NDL). Let Γ be a *set* of sentences in Φ , and let A be a *sentence* in Φ . Then we say:

- (i) A is a *logical consequence in NDL of Γ* (in symbols: $\Gamma \Vdash_{NDL} A$) iff there are sentences B_1, B_2, \dots, B_n in Γ , with $n \geq 0$, such that

\Vdash If both B_1 and both B_2 and ... and both B_{n-1} and B_n , then A

(i.e. that sentence is to be logically valid).

- (ii) Γ is *inconsistent in NDL* iff there is a sentence B in Φ such that the sentence

Both B and it is not the case that B

is a logical consequence in NDL of Γ .

- (iii) Γ is *consistent in NDL* iff Γ is not inconsistent in NDL.

The three notions just introduced should be compared with the *proof-theoretical* concepts of derivability, inconsistency and consistency in certain formal deontic logics \mathcal{L} (see Section 10.2.1 below). Also, we observe that the usefulness of the definition above rests on our having recourse to a viable notion of *logical validity*, which is *applicable to English sentences* in Φ and, hopefully, even to larger sets of English sentences. We now face the difficulty that such an intuitive, natural-language-oriented conception is vague, imprecise and the source of endless disputes and disagreement; in this respect it differs unfavorably from the well-defined notions of *provability* and *validity* in a specified *formal system* of deontic logic. The difficulty is interestingly illustrated by the so-called ‘paradoxes of deontic logic’ in the following way.

Let \mathcal{L} be some formal system of deontic logic over our language L , to which definitions D1–D7, D8–D8+ k are added, so that the fragment FNE $_k$ and its sentence-set Φ are available as well as the natural deontic logic NDL over that fragment. Consider the set Δ of all sentences in Φ whose t -translations are provable in \mathcal{L} ; thus

$$\Delta = \{A \in \Phi : t(A) \text{ is provable in } \mathcal{L}\}.$$

Now, suppose we start to compare NDL and Δ . If we find that they are identical, then the notion of provability in \mathcal{L} ‘matches perfectly’ the intuitive conception of logical validity determining NDL and everything is fine; there is no clash between the well-defined formal notion and the intuitive conception. This possibility is not very likely to arise. It is much more likely that we face one of the following possibilities:

- (I) We find a sentence in Φ which is such that (a) it is *not* in NDL because we feel that it is *not* logically valid, but (b) its t -translation is indeed provable in \mathcal{L} (which is usually easy to verify); so the sentence is in Δ . Then we have a clash between the formal notion of provability in \mathcal{L} and the intuitive concept of validity of a kind I call below failure of *right-to-left adequacy*. Roughly speaking, the clash is due to the fact that \mathcal{L} sanctions *more* English sentences as valid than our ‘logical intuition’ is willing to accept as members of NDL. Most deontic paradoxes will be seen to be of this kind in subsequent sections.
- (II) We find a sentence in Φ which is such that (a) it is logically valid from an intuitive viewpoint and hence is in NDL, but (b) its t -translation fails to be provable in \mathcal{L} (as is usually easy to verify); so the sentence is *not* in Δ . This situation illustrates an opposite sort of clash which I call below failure of *left-to-right adequacy*. The import of such a clash is then that there are intuitive validities in NDL, which fail to be representable in the formal system \mathcal{L} . In Section 9.2.2 below I argue that the Good Samaritan paradox illustrates this failure with respect to the Smiley–Hanson systems of monadic deontic logic; admittedly, it is usually cited as an instance of the former kind of failure, just as the majority of paradoxes are.

These considerations were designed to show how the vagueness and impreciseness of an intuitive, natural-language-oriented notion of logical validity leads to ‘clashes’ when confronted with formal systems of deontic logic. In order to eliminate to some extent the vagueness from which our characterization of NDL thus suffers we propose below (Section 5.5) a criterion of validity known as the Bolzano Criterion, which will be seen ‘at work’ in Section 7. Other criteria are possible, however, as will be seen in Section 6.

Since the concepts of (failure of) *adequacy* met with in (I) and (II) above are, we suggest, highly important to any orderly discussion and even presentation of the deontic paradoxes, we shall now introduce them in a rigorous way.

5.4 *Some notions of adequate translation and faithful representation*

DEFINITION 10 (Three concepts of adequacy). Let \mathcal{L} , to begin with, be any of the ten Smiley–Hanson systems of monadic deontic logic, characterized in Section 10.2 below in proof-theoretical terms. We write ‘ $\vdash_{\mathcal{L}} A$ ’ to indicate that the formal sentence A (in Σ) is *provable* in \mathcal{L} . Consider the Natural Deontic Logic NDL ($\subseteq \Phi$) over the English fragment FNE_k as well as the extended translation t from Φ into Σ . We then say the following:

- (i) t is *left-to-right adequate* with respect to NDL and \mathcal{L} , iff, for each A in Φ , if $A \in \text{NDL}$ then $\vdash_{\mathcal{L}} t(A)$.
- (ii) t is *right-to-left adequate* with respect to NDL and \mathcal{L} , iff, for each A in Φ , if $A \notin \text{NDL}$ then $\not\vdash_{\mathcal{L}} t(A)$; where ' $\not\vdash_{\mathcal{L}}$ ' means 'not provable in \mathcal{L} '.
- (iii) t is *fully adequate* with respect to NDL and \mathcal{L} , iff, for each A in Φ , $A \in \text{NDL}$ if and only if $\vdash_{\mathcal{L}} t(A)$.

REMARK 11.

- (a) Clearly, t is fully adequate w.r.t. NDL and \mathcal{L} , just in case t is both left-to-right and right-to-left adequate w.r.t. NDL and \mathcal{L} . Again, in order to show that t is not fully adequate w.r.t. NDL and \mathcal{L} , it is enough to show that *either* t fails to be left-to-right adequate *or* t fails to be right-to-left adequate w.r.t. NDL and \mathcal{L} .
- (b) We may use clauses(i)–(iii) in the present definition as a basis for introducing the following notions of *faithful representation*, applicable to \mathcal{L} :
 - (i') \mathcal{L} is a *left-to-right faithful representation* of NDL *under* t , iff, t is left-to-right adequate w.r.t. NDL and \mathcal{L} .
 - (ii') \mathcal{L} is a *right-to-left faithful representation* of NDL *under* t , iff, t is right-to-left adequate w.r.t. NDL and \mathcal{L} .
 - (iii') \mathcal{L} is a *faithful representation* of NDL *under* t , iff, t is fully adequate w.r.t. NDL and \mathcal{L} .

5.5 On the Bolzano criterion of logical validity for sentences in natural languages

Consider the fragment FNE_k and its sentence-set Φ . As applied to members of Φ , what I shall call the Bolzano criterion of logical validity asserts the following:

- BCLV. Let $A \in \Phi$. Then, A is *logically valid* ($\Vdash A$) iff (i) A is true, and (ii) every result of uniformly substituting a sentence in Φ for any *basic* sentence in A is true as well.

For examples of this criterion 'in use', see Section 7 below.

The present version of the Bolzano criterion is, of course, a bit restrictive, since it only applies to members of Φ . Inspired by Quine [1963], Føllesdal and Hilpinen [1971, p. 1] suggest a less restrictive version:

A deontic sentence is a truth of deontic logic if it is true and remains true for all variations of its non-logical and non-deontic words (that is, expressions which are not logical or deontic words).

Again, Kanger [1957, p. 50] gives the following version of the Bolzano criterion:

By a logically true statement we understand a statement A such that the result of generalizing all extralogical constants in A is true.

If we assume all deontic words in the sense of Føllesdal and Hilpinen to be logical constants in the sense of Kanger, we could perhaps prove their respective versions of the Bolzano criterion to be equivalent.

For our purposes in the following Sections, however, the version BCLV given above should hopefully turn out to be sufficient.

6 ALF ROSS'S PARADOX

Consider the English sentences:

- (0) You post the letter.
- (1) You burn the letter.

Consider also the enrichment $L(D1-D7, D8, D9)$ of L , where $D8$ and $D9$ are as follows:

- (D8) You post the letter = df p .
- (D9) You burn the letter = df p_1 .

Again, let FNE_1 be the fragment of normative English constructible in that enrichment, where, specifically, $Bas = \{(0), (1)\}$ and Φ = the smallest superset of Bas closed under our seven English connectives defined in $D1-D7$. The translation t induced by the series $D1-D9$ is then defined as in Section 5.2 above, where, in particular, we have the following clauses in the recursion basis:

- (i) $t(\text{'You post the letter'}) = t((0)) = p$.
- (i₁) $t(\text{'You burn the letter'}) = t((1)) = p_1$.

The Alf Ross paradox, first presented in Ross [1944], is to be taken, we suggest, as an argument against t being fully adequate with respect to the natural deontic logic NDL over FNE_k and *any* Smiley–Hanson system \mathcal{L} of monadic deontic logic. In order to state the argument let us first consider the sentence

(1.1) It is obligatory that either you post the letter or you burn the letter which is in Φ ; a nicer *stylistic variant* of (1.1) in the sense of Kalish and Montague [1964, pp. 10f.] is perhaps the following:

(1.2) You ought to post the letter or burn it

Furthermore, we consider the sentences:

(0.1) It is obligatory that you post the letter,

(0.2) If it is obligatory that you post the letter then it is obligatory that either you post the letter or you burn the letter,

which are both in Φ . Note that (0.2) is the conditional having (0.1) as its antecedent and (1.1) as its consequent.

Now, the ‘paradox’ starts out with the following claim, which we shall treat as an *hypothesis* in the proof-theoretical sense by so indicating its status to the right:

1. The sentence (1.1) is not a logical ‘claim’ or hypothesis consequence in NDL of the unit set of (0.1).

In symbols: $\{(0.1)\} \not\|_{NDL} (1.1)$

By our definition of logical consequence in NDL and the fact that (0.1) is in Φ and is the only sentence in $\{(0.1)\}$, we then obtain from the hypothesis 1:

2. (0.2) is not logically valid. from 1 by the definition of $\|_{NDL}$ and the fact etc.

In symbols: $\not\vdash (0.2)$.

where we indicate to the right how this line 2 is obtained. Hence:

3. (0.2) \notin NDL from 2 by the definition of NDL.

Again, let \mathcal{L} be *any* of the Smiley–Hanson systems of monadic deontic logic. The following is a demonstration that the L-sentence $Op \rightarrow O(p \vee p_1)$ is provable in \mathcal{L} ; where we write ‘ $\vdash_{\mathcal{L}}$ ’ for ‘provable in \mathcal{L} ’:

4. $\vdash_{\mathcal{L}} p \rightarrow (p \vee p_1)$ since all tautologies over L are provable in \mathcal{L} by virtue of axiom schema A0.

5. $\vdash_{\mathcal{L}} Op \rightarrow O(p \vee p_1)$ from 4 by the fact that the set of \mathcal{L} -provable L-sentences is closed under the rule of inference

$$\frac{A \rightarrow B}{OA \rightarrow OB}$$

Here, to say that the set of \mathcal{L} -provable L-sentences is closed under that rule of inference means that for all L-sentences A, B : if $\vdash_{\mathcal{L}} A \rightarrow B$, then $\vdash_{\mathcal{L}} OA \rightarrow OB$.

We continue the argument by making the following straightforward observation:

6. $t((0.2)) = Op \rightarrow O(p \vee p_1)$ by the definition of t , clauses (i),(i₁),(iv),(vii) and (v).

Therefore:

7. $\vdash_{\mathcal{L}} t((0.2))$ from 5 and 6 by the logic of =.
8. There is a sentence A in Φ , viz. from 3 and 7 by adjunction and (0.2), such that $A \notin \text{NDL}$ but existential generalization.
 $\vdash_{\mathcal{L}} t(A)$
9. t is not right-to-left adequate with respect to NDL and \mathcal{L} from 8 by the definition of right-to-left adequacy.
10. t is not fully adequate w.r.t. NDL and \mathcal{L} from 9 by the definition of full adequacy.

Thus, on the basis of the hypothesis 1, we have used the conditional sentence (0.2) to show that t fails to be right-to-left, and hence fully, adequate w.r.t. NDL and any Smiley–Hanson system \mathcal{L} of monadic deontic logic. In other words, no such system is a faithful representation of NDL under t . Before embarking on a discussion of this argument, we stick in a little exercise:

EXERCISE 12.

- (i) Prove that the set of \mathcal{L} -provable L-sentences is closed under the rule $A \rightarrow B/OA \rightarrow OB$, for any of the ten Smiley–Hanson systems \mathcal{L} , as described in Section 10 below!
- (ii) Give a rigorous proof in full detail of line 6 above!

Let us now try to assess the above argument. Clearly, the proof of lines 9 and 10 rests, or is conditional, on the hypothesis 1, which is to the effect that (1.1) is not a logical consequence (in NDL) of (the unit set of) (0.1). What motivation or reason could then be given for this claim? The following line of thought is indicated and discussed by Wedberg [1969, p. 217], and by Hansson [1969, p. 383].

A way for the addressee of (1.1) to *obey* the command expressed by it is surely that he burns the letter. By so doing, however, he does not obey the

command expressed by (0.1), which he even positively *disobeys*. So there is a way of obeying (1.1), which is at the same time a way of disobeying (0.1) and, hence, a way of *not* obeying it. Therefore, (1.1) cannot be a logical consequence of (0.1). (The following terminological replacements are all right with me: ‘norm’ for ‘command’, ‘satisfy’ or ‘fulfil’ for ‘obey’, ‘dissatisfy’ or ‘violate’ for ‘disobey’.)

As is clearly enough indicated by the aforementioned authors, this argument is rather confused. I would like to add the following point to their valuable discussion. The criterion of logical consequence to which the argument tacitly appeals appears to be this:

LC0. Let A, B be any command-expressing sentences in English. Then, B is a logical consequence of A iff every way of obeying B is a way of obeying A .

Putting (1.1) = B and (0.1) = A in LC0, we indeed arrive at the strange result under debate. But hasn’t LC0 got things turned upside down? According to criteria in terms of obedience or satisfaction (suggested, e.g. by Von Wright [1955] and Rescher [1966]), we should rather have something like:

LC1. B is a logical consequence of A iff every way of obeying A (= the *implicans*) is a way of obeying B (= the *implicatum*).

Using LC1 in the place of LC0, we cannot derive hypothesis 1 any longer. On the contrary, using LC1, we have that (1.1) is indeed a logical consequence of (0.1), since every way of posting the letter is a way of either-posting-or-burning it.

Are we then entitled to dismiss the Ross Paradox on the basis of having removed one basic confusion that seems to underlie it? I don’t think so, nor does, e.g. Von Wright [1968, pp. 21 ff], where an interesting argument in favor of hypothesis 1 is indicated, having the form of a *reductio ad absurdum* of its negation, which is to the effect that (1.1) *is* a logical consequence of (0.1). Von Wright’s *reductio* is presented and discussed in some detail in Åqvist [1987, Section 5]. Here we just call the reader’s attention to some main conclusions emerging from that discussion.

- (i) The argument of Von Wright [1968, pp. 21 ff], is seen to depend crucially on a so-called principle of free choice permission, the status and acceptability of which has since been the object of a still lively and intensive debate. We mention the following contributions from the literature: Von Wright [1971], Føllesdal and Hilpinen [1971], Kamp [1973; 1979], Lewis [1978], Hilpinen [1979; 1981] as well as Nute [1981].
- (ii) Although the principle of free choice permission fails to be valid for the weak notion of permission reflected by the ‘standard’ P-operator

in normal monadic Von-Wright-type deontic logics (Section 4 above), there remains the possibility of defining notions of *strong* permission for which that principle is indeed valid — after all, permissive phrases are well known to be ambiguous in ordinary discourse. An interesting attempt to define such a notion of strong permission was made by Von Wright [1971]; the idea is based on the Andersonian reduction of deontic logic to alethic modal logic with a propositional constant. We also mention that Anderson [1968] uses the very same idea to develop what he calls *eubouliatic logic*, in the sense of a logic of *prudence*, *safety*, *risk* and related concepts of a decision-theoretic brand.

- (iii) Contrary to the view of its originator, the Alf Ross paradox does not seem to be a serious threat to the very possibility of constructing a viable deontic logic. But it usefully directs our attention to the ambiguity of normative phrases in natural language as a possible source of error and confusion — in viable deontic logics we should be able to express, to do justice to, and to pinpoint such ambiguities. For this reason I agree with Von Wright in claiming that the puzzle deserves serious consideration.

7 ARTHUR N. PRIOR'S PARADOXES OF DERIVED OBLIGATION (‘COMMITMENT’)

Consider the English sentences:

- (2) John Doe impregnates Suzy Mae.
(3) John Doe marries Suzy Mae.

as well as the enrichment $L(D1-D11)$ of L , where D10 and D11 as follows:

- (D10) John Doe impregnates Suzy Mae =df p_2 .
(D11) John Doe marries Suzy Mae =df p_3 .

We let FNE_3 be the fragment of normative English constructible in $L(D1-D11)$, where Bas contains (2) and (3) as new members and where Φ is defined as usual. Fresh clauses in the basis of the recursive definition of the translation t :

- (i₂) $t(\text{‘John Doe impregnates Suzy Mae’}) = p_2$.
(i₃) $t(\text{‘John Doe marries Suzy Mae’}) = p_3$.

The paradoxes of commitment, or derived obligation, go back at least to Prior [1954] and can be viewed as arguments against t being fully adequate with respect to NDL and any Smiley–Hanson system \mathcal{L} of monadic deontic logic. Consider the sentences:

- (2.1) If it is not the case that John Doe impregnates Suzy Mae then if John Doe impregnates Suzy Mae then it is obligatory that John Doe marries Suzy Mae.
- (2.2) If it is obligatory that John Doe marries Suzy Mae then if John Doe impregnates Suzy Mae then it is obligatory that John Doe marries Suzy Mae.
- (2.3) If it is obligatory that it is not the case that John Doe impregnates Suzy Mae then it is obligatory that if John Doe impregnates Suzy Mae then John Doe marries Suzy Mae.
- (2.4) If it is obligatory that John Doe marries Suzy Mae then it is obligatory that if John Doe impregnates Suzy Mae then John Doe marries Suzy Mae.

Although they are all in Φ , the sentences (2.1)–(2.4) give a somewhat queer impression and may be difficult to understand. So here are their t -translations into L:

$$t((2.1)) \neg p_2 \rightarrow (p_2 \rightarrow Op_3).$$

$$t((2.2)) Op_3 \rightarrow (p_2 \rightarrow Op_3).$$

$$t((2.3)) O\neg p_2 \rightarrow O(p_2 \rightarrow p_3).$$

$$t((2.4)) Op_3 \rightarrow O(p_2 \rightarrow p_3).$$

We now state four paradoxes of commitment in ‘one fell swoop’:

1. None of the sentences (2.*i*), for ‘claim’ or hypothesis $i = 1, 2, 3, 4$ are logically valid.
In symbols: $\not\vdash(2.i)$.

Now, let \mathcal{L} be any of the Smiley–Hanson systems of Monadic Deontic Logic. Then:

- | | | |
|----|---|--|
| 2. | $\vdash_{\mathcal{L}} t((2.i))$, for all $i = 1, \dots, 4$ | exercise |
| 3. | There are sentences A_i (with $i = 1, \dots, 4$) in Φ , viz. (2.i), such that $A_i \notin \text{NDL}$ but $\vdash_{\mathcal{L}} t(A_i)$ | from 1 and 2 by the definition of NDL, adjunction and existential generalization |
| 4. | t is not right-to-left adequate with respect to NDL and \mathcal{L} | from 3 by the definition of right-to-left adequacy |
| 5. | t is not fully adequate w.r.t. NDL and \mathcal{L} | from 4 by the definition of full adequacy |

Before trying to assess this argument, we stick in a little exercise:

EXERCISE 13.

- (i) Prove assertion 2 in the above argument!
- (ii) Find more idiomatic stylistic variants of the English (?) sentences (2.i), for $i = 1, 2, 3, 4$!

What motivation could reasonably be given for the claim 1 in this argument? I suggest the following: the common consequent of (2.1) and (2.2) as well as that of (2.3) and (2.4) may both be said to involve the notion of *commitment* or *conditional* ('derived') *obligation* in such a way that

(2.5) Impregnating Suzy Mae commits John to marrying her

is a stylistic variant (in the sense of Kalish and Montague [1964]) of both these common consequents. Let us now consider four cases in turn, with a view to illustrate the Bolzano criterion of logical validity (see above Section 5.5).

Case I. Suppose that (2.1) is logically valid. Then, by the Bolzano criterion, not only is (2.1) itself true, but so is every result of uniformly substituting a sentence of the fragment FNE_3 for any *basic* sentence in (2.1). Therefore, the following sentence in Φ must be true:

- (2.1.1) If it is not the case that John Doe impregnates Suzy Mae, then if John Doe impregnates Suzy Mae then it is obligatory that *it is not the case that* John Doe marries Suzy Mae

the t -translation of which is

$$t((2.1.1)) = \neg p_2 \rightarrow (p_2 \rightarrow O\neg p_3).$$

But this result is unpalatable for the following reason: on the basis of it we may infer from the mere fact that John does not impregnate Suzy that impregnating her commits John both to the act of marrying her as well as to the act of not marrying her. There are certainly legal systems where such an inference is rejected as absurd. Hence, (2.1) cannot be logically valid.

Case II. Here we consider an extended fragment FNE_4 , whose set Bas contains the new sentence

(4) John Doe kills Suzy Mae

which is introduced by a definition D12 in the obvious way so as to yield the fresh clause for t :

(i₄) $t(\text{'John Doe kills Suzy Mae'}) = p_4$.

Now, suppose that (2.2) is logically valid. Then, by the Bolzano criterion, not only is (2.2) true itself, but so is the result of substituting (4) for (2) in (2.2). Call this result (2.2.1) and observe that

$$t((2.2.1)) = Op_3 \rightarrow (p_4 \rightarrow Op_3)$$

Again, (2.2.1) being true is a strange result, because it seemingly entitles us to say that *if* John has a duty to marry Suzy, *then*, by logic alone, he has such a duty (even) if he kills her. But, we are told by some plain man in the street, when she is dead, John cannot marry her and so is not obliged or committed to marry her. For, as the saying goes, *ought* implies *can*. Hence, to sum up, if (2.2) is logically valid, then (2.2.1) is true. But (2.2.1) is not true (for the reasons just given); therefore, by *modus tollens*, (2.2) is not logically valid.

Case III. Suppose that (2.3) is logically valid. Then, by the Bolzano criterion, not only is (2.3) true itself, but so is the result of inserting the word 'it is not the case that' immediately in front of (3) in (2.3). Call that result (2.3.1) and note that

$$t((2.3.1)) = O\neg p_2 \rightarrow O(p_2 \rightarrow \neg p_3).$$

The argument against (2.3.1) being true is similar to the one used in Case I: on the basis of it we may infer from the mere fact that it is forbidden for John to impregnate Suzy that impregnating her commits John both to the act of marrying her and to that of not marrying her. But this is absurd for the same reason as in Case I.

Case IV. The point of departure here is the assumption that (2.4) is logically valid. The refutation of that assumption proceeds (rightly or wrongly) along

the lines followed in Case II. The result analogous to (2.2.1) is called (2.4.1) where

$$t((2.4.1)) = Op_3 \rightarrow O(p_4 \rightarrow p_3).$$

We have now got an idea about what kind of counterexamples people are apt to give against the alleged logical validity of the sentences (2.i). We may then try to pin down certain patterns of ‘intuitive reaction’ to these paradoxes of commitment, which are fairly well discernible or recognizable in the vast literature on the subject. (Incidentally, they will also be seen to apply to the Alf Ross paradox.) Let me distinguish the following two tendencies: (i) the deprivation-of-counterintuitive-force tendency, and (ii) the improved-formalization tendency, and briefly comment on them in turn.

7.1 *The deprivation-of-counterintuitive-force tendency*

One argues as follows. Admittedly, formulations like (2.i) are ambiguous in ordinary English, so there are different ways of understanding or interpreting (2.i). Now, each of the Smiley–Hanson systems \mathcal{L} is based on a clearcut model-theoretic semantics, which provides a mathematically precise interpretation of its logical constants in terms of *truth conditions* stated relatively to certain set-theoretical structures called *models* (see Section 10.3 below). Via our definitions D1–D7 etc. generating fragments of normative English, this precise interpretation is automatically transferred to every sentence of such an English fragment. So, if we just stick to *that* interpretation of (2.i) and, most importantly, do not ‘read into’ them anything ‘beyond’ it, their counterintuitive appearance will simply vanish.

To illustrate a bit: since every ‘if ... then _____’-connective in any of (2.i) is intended to mean the same as the arrow \rightarrow of material implication, as ordinarily understood in the classical propositional calculus (on which all the Smiley–Hanson systems are based), we have the following results on the *t*-translations of (2.i):

$$\vdash_{\mathcal{L}} t((2.1)) \Leftrightarrow (\neg p_2 \rightarrow (\neg p_2 \vee Op_3))$$

$$\vdash_{\mathcal{L}} t((2.2)) \Leftrightarrow (Op_3 \rightarrow (\neg p_2 \vee Op_3))$$

$$\vdash_{\mathcal{L}} t((2.3)) \Leftrightarrow (O\neg p_2 \rightarrow O(\neg p_2 \vee p_3))$$

$$\vdash_{\mathcal{L}} t((2.4)) \Leftrightarrow (Op_3 \rightarrow O(\neg p_2 \vee p_3))$$

According to the strategy of interpretation just outlined, we are to understand the sentences (2.i) to mean *exactly* what is meant by the corresponding

right members in these equivalences according to the semantics for \mathcal{L} ; most importantly, we are *not* to read anything *more* into them. We then observe the following:

- (i) Sentences (2.1) and (2.2) as well as their *t*-translations are instances of familiar tautologies, which cannot fail to be true by virtue of the usual truth-table test. Hence, their counterintuitive force disappears as soon as this fact is grasped and strictly adhered to.
- (ii) Sentences (2.3) and (2.4) as well as their *t*-translations are not instances of any truth-table tautologies. Instead, their validity in \mathcal{L} depends on and is due to the model-theoretic truth condition for the *O*-operator (in terms of ‘possible worlds’, the relation of ‘deontic accessibility’ etc. ; see Section 10.3 below). Once this fact is grasped and strictly adhered to, their counter-intuitive force will vanish. Note here that, on the basis of the last two of the equivalences above, the paradoxical conditionals (2.3) and (2.4) both reduce to *Ross-paradoxical* sentences, with which we have already dealt.

Let us also note, finally, that the present Deprivation-of-Counterintuitive-Force Tendency is nicely illustrated, e.g. by Von Wright [1956, p. 508] and by Anderson [1956, p.185], as well as by Prior [1955, p. 224]. This tendency, however, is not the only one emerging from their valuable discussion, as we shall now see.

7.2 *The improved-formalization tendency*

Even if the argument just reported is successful in ‘explaining away’ the counterintuitiveness of the sentences (2.*i*), it is difficult to remain satisfied with it ‘as giving the full story of the matter’. As we said above, formulations like (2.*i*) are admittedly ambiguous in ordinary language, so the possibility of understanding their consequents as expressing some notion of *commitment* (as illustrated by (2.5)) remains an interesting fact of linguistic usage. But then the problem arises how to formalize the notion adequately, which is surely a problem in view of the difficulties pinpointed in Cases I–IV above. Let us now quickly find out what attitudes Von Wright and Anderson took on this issue.

In the second part of Von Wright [1956] we are warned against interpreting the form

$$O(A \rightarrow B)$$

to mean ‘doing *A* *commits* us (morally) to do *B*’ (p. 508). Von Wright says that if we do so

... then a ‘paradox’ instantly arises. For then we should have to say that a forbidden act commits us to any other act (whether obligatory, permitted, or forbidden). And this, obviously, conflicts with our ‘intuitions’ in the matter.

Perhaps we can say that Von Wright’s reason for his *caveat* amounts essentially to Case III. Again, Anderson [1956, p. 185], expresses a similar warning: “... we should be wary in interpreting $OCpq$ as meaning ‘ p commits us to q ’.”

Being thus dissatisfied with $O(A \rightarrow B)$ (and with $A \rightarrow OB$, we may add in the case of Anderson) as adequately reflecting the everyday notion of commitment, our authors are naturally led to look for *new ways of formalizing* that notion. They tried different approaches, though, which we are now going to describe.

Von Wright [1956] introduces a new *primitive* symbol $P(p/c)$, to be read as: p is permitted under conditions c . He then defines $O(p/c)$ as $\neg P(\neg p/c)$, for which he suggests the reading: p is obligatory under conditions c , or: c commits us to (do) p . Furthermore, he gives two axioms for the new primitive operator, on the basis of which, to the best of my knowledge, the first known system of dyadic deontic logic was developed. Further additions to and refinements of the system were suggested in Von Wright [1964] and [1965]. This idea of using *binary* (i.e. two-place) *primitives*, expressing conditional or ‘relative’ permission, prohibition and obligation, initiated a very fruitful line of research in the history of modern deontic logic. In effect, dyadic deontic logic as originating with Von Wright [1956], can be said to have dominated recent work in the field up to this date. For the moment, we just remind the reader of the following contributions: Rescher [1958; 1962], Powers [1967], Danielsson [1968], Hansson [1969], Segerberg [1971], Føllesdal and Hilpinen [1971], Van Fraassen [1972], Von Kutschera [1973; 1974], Lewis [1974], Chellas [1974] and Spohn [1975].

Let us now turn to Anderson. He was able to make a different suggestion, because he had at his disposal a more powerful logical apparatus on which he wished to base the theory of deontic notions, including commitment: that of alethic modal logic with a propositional constant S symbolizing some penalty or sanction. So already in Anderson [1956] we find him suggesting (p. 185) that an alternative (to $OCpq$) candidate for the formal analogue of commitment is $C'pOq$: ‘ p entails that q is obligatory’. Here ‘ C' ’ denotes *strict* implication; using the symbolism adopted in the present essay, we write in the place of $C'pOq$:

$$\Box(A \rightarrow OB).$$

In Anderson [1959], written as a reaction to the Rescher [1958] attempt to elaborate further the Von Wright [1956] proposal about dyadic deontic

logic, Anderson repeats his suggestion and, highly importantly in my opinion, proceeds to lay down a number of *adequacy criteria* for a theory of commitment (or a viable analysis of that notion).

Let us pause for a while to consider the import of the Anderson proposal. To start with, let us replace the Von Wright [1956] dyadic notation $O(p/c)$ with the one adopted in the present essay, viz. $O_B A$ to be read: ‘if B then it is obligatory that A ’ or: ‘ B commits us to A ’. For this notation, see Section 15 below. The Anderson proposal is then to the following effect: consider the following

DEFINITION 14.

$$\text{Def}^{\text{com}}. O_B A = \text{df } \Box(B \rightarrow OA).$$

Then, add Def^{com} to any suitable system \mathcal{K} of alethic modal logic with the constant S (or with Kanger’s Q), which already has definitions of ‘standard monadic’ obligation and permission (see below Sections 12 and 13).

Suppose that \mathcal{K} is well determined: we are then able to investigate the logic of commitment (i.e. the laws governing locutions of the form $O_B A$) within \mathcal{K} supplemented with Def^{com} .

Having now broadly outlined the respective approaches of Von Wright and Anderson to the problem of formalizing a ‘reasonable’ concept of commitment or conditional obligation, we have to face the obvious questions: What expectations are to guide us in this enterprise? What properties do we expect that concept to have (and not to have)? I call this the problem of *adequacy criteria* and will devote a special section to it.

7.3 Adequacy criteria for a theory of commitment or conditional obligation

Consider the language of Dyadic Deontic Logic as described in Section 17 below. Its set of sentences is called $\Sigma_{0,N}^2$ and is such that, for any A, B in $\Sigma_{0,N}^2$, $O_B A$ and $P_B A$ are in $\Sigma_{0,N}^2$ as well. We now adhere to the just adopted reading of $O_B A$ as ‘ B commits us to A ’. We are looking for a theory \mathcal{L} over this language in the sense of a proper subset of $\Sigma_{0,N}^2$ (why *proper?*), which is to serve as a viable and plausible logic of commitment. Let provability and unprovability in \mathcal{L} be denoted by $\vdash_{\mathcal{L}}$ and $\not\vdash_{\mathcal{L}}$, respectively.

Adequacy criteria for \mathcal{L} may now be divided into (i) those to the effect that certain sentence schemata are to be *unprovable* in \mathcal{L} , and (ii) those to the effect that certain schemata are to be *provable* in \mathcal{L} . Let us begin by giving some examples of the first category.

In the light of our discussion of the sentences (2.i) ($i = 1, \dots, 4$) we consider certain generalized sentence schemata arising from the translations $t((2.i))$ as follows. First, generalize p_2 to an arbitrary formal sentence A

and p_3 to an arbitrary formal sentence B . We then obtain, e.g. from $t((2.1))$ the schema

$$\neg A \rightarrow (A \rightarrow OB)$$

Secondly, replace the consequent in this schema by the appropriate formal analogue of commitment available in our language of dyadic deontic logic, viz. $O_A B$. We thus obtain in our present example:

$$\neg A \rightarrow O_A B$$

Performing the same operations with all the $t(2.i)$, we obtain three schemata which, in the light of the difficult Cases I–IV, we expect all to be unprovable in \mathcal{L} . In other words, we expect \mathcal{L} to satisfy the following three adequacy criteria belonging to the unprovability category:

- (C1) $\not\vdash_{\mathcal{L}} \neg A \rightarrow O_A B$.
- (C2) $\not\vdash_{\mathcal{L}} OB \rightarrow O_A B$.
- (C3) $\not\vdash_{\mathcal{L}} O\neg A \rightarrow O_A B$.

where the monadic, i.e. without subscript, O -operator is defined by

$$OB = \text{df } O_{\top} B$$

where the constant \top , known as *verum*, denotes some arbitrary tautologous condition. This proposal for handling monadic or ‘absolute’ obligations in dyadic deontic logic was made already by Von Wright [1956, p. 509].

I shall now make two observations.

- (i) All systems of Dyadic Deontic Logic dealt with in Sections 17–23 satisfy the criteria C1–C3. In particular, this is true of the strongly normal “core” system **G**. (see Section 23 below).
- (ii) Von Wright [1956] claims that his new deontic logic satisfies C2 and C3. And Anderson [1959] explicitly adopts C3 (writing Fp for $O\neg p$, where F means ‘it is forbidden that’).

EXERCISE 15.

- (1) Prove assertion (i) just made above!
- (2) Suppose Von Wright were to *prove* the claim reported in (ii) above; how should he go about doing so?

As a further adequacy criterion for \mathcal{L} , we consider

$$(C4) \quad \not\vdash_{\mathcal{L}} O_B A \rightarrow O_{B \wedge C} A.$$

A classical intuitive counterexample to the validity of the schema in C4 is provided by the following instance of it:

$$O_{p_2 p_3} \rightarrow O_{p_2 \wedge p_4 p_3}$$

which is read: if impregnating Suzy Mae commits John Doe to marrying her, then both-impregnating-and-killing-her commits John to marrying her. This is absurd, though, since the antecedent may be accepted as true while the consequent is rejected as false. This counterexample, or argument for C4, apparently originated with Powers [1967] and is elaborated by various subsequent writers, notably Danielsson [1968, p. 66 f], Hansson [1969, p. 392], Van Fraassen [1972, p. 418 f] and Van Eck [1981, p. 8]. The objectionable schema in C4 is pertinently called a *principle of augmentation* by Chellas [1974, p. 31].

EXERCISE 16. (after Danielsson [1968, p.67]).

- (1) Suppose that our desired theory \mathcal{L} satisfies one of the following adequacy criteria belonging to the provability category:

$$(C5) \quad \vdash_{\mathcal{L}} O_B A \Leftrightarrow O(B \rightarrow A).$$

$$(C6) \quad \vdash_{\mathcal{L}} O_B A \Leftrightarrow (B \rightarrow OA).$$

Show that in each case \mathcal{L} will violate C4! Show also that in each case \mathcal{L} violates at least one of C1–C3!

- (2) Let \mathcal{K} be a system of alethic modal logic with the constant S (or Q) to which Def^{com} is added so that \mathcal{K} satisfies the following criterion:

$$(C7) \quad \vdash_{\mathcal{K}} O_B A \Leftrightarrow \Box(B \rightarrow OA).$$

Then, show that \mathcal{K} or, strictly speaking, its deontic fragment, violates C4!

- (3) What assumptions concerning deducibility in $\mathcal{L}(\mathcal{K})$ have *minimally* to be made in order for your proofs to work?
- (4) Suppose that C1–C4 are accepted as reasonable adequacy criteria for \mathcal{L} . What conclusion as to the status of C5–C7 are we to draw in the light of the above results?

EXERCISE 17. Show that all systems of dyadic deontic logic considered in Sections 17–23 satisfies the criterion C4! Hint: it is enough to prove that our strongly normal system \mathbf{G} (Section 23 below) has this property.

In Anderson [1959] it is suggested that our desired theory \mathcal{L} of commitment is to meet the following six adequacy criteria, which are all to the effect that certain schemata should be *provable* in \mathcal{L} (and thus belong to our second category):

$$(C8) \quad \vdash_{\mathcal{L}}(A \wedge O_A B) \rightarrow OB.$$

$$(C9) \quad \vdash_{\mathcal{L}}(OA \wedge O_A B) \rightarrow OB.$$

$$(C10) \quad \vdash_{\mathcal{L}}(PA \wedge O_A B) \rightarrow PB.$$

$$(C11) \quad \vdash_{\mathcal{L}}(O_A B \wedge O_B C) \rightarrow O_A C.$$

$$(C12) \quad \vdash_{\mathcal{L}}O_A B \rightarrow O(A \rightarrow B).$$

$$(C13) \quad \vdash_{\mathcal{L}}O_{\neg A} A \rightarrow OA.$$

EXERCISE 18.

- (1) Show that the system \mathbf{G} , as described in Section 23 below, satisfies the criteria C9, C10, C12 (which is a weakened version of C5) and C13!
- (2) Consider any system of dyadic deontic logic which is an axiomatic extension of $\mathbf{O}_{dy}\mathbf{S5}^N$ (see Section 18 below) and is dealt with in Part VI. Determine, for each of the four criteria just mentioned, which is the *weakest* system satisfying that criterion!
- (3) Consider again our strongly normal system \mathbf{G} (Section 23). Show that it neither satisfies C8 nor C11!

In Åqvist [1963] the following criticism was levelled against the Andersonian set C8–C13 of criteria. (On page 25, note 2 of that paper, the gist of the argument was credited to T. Dahlquist.) Suppose that \mathcal{L} satisfies both C8 and C9. Then, provided only that \mathcal{L} possesses a certain minimal deductive power, \mathcal{L} will satisfy the following condition C14:

$$(C14) \quad \vdash_{\mathcal{L}}(O_A B \wedge O_{\neg A} \neg B \wedge OA \wedge \neg A) \rightarrow (OB \wedge O\neg B).$$

Suppose further that \mathcal{L} meets this condition:

$$(C15) \quad \vdash_{\mathcal{L}}\neg(OB \wedge O\neg B).$$

Then, as we easily show using *modus tollens*, \mathcal{L} will also meet this condition:

$$(C16) \quad \vdash_{\mathcal{L}}\neg(O_A B \wedge O_{\neg A} \neg B \wedge OA \wedge \neg A).$$

The refutability in \mathcal{L} of the schema inside the negation-sign in C16 now amounts to this: whatever be meant by A and B here, the following conjunction (or set) of assumptions is logically impossible or provably false

in \mathcal{L} :

A commits us to B
(not: A) commits us to (not B)

and

it is obligatory that A
it is not the case that A .

But, the argument goes on, this result is counterintuitive, because we can find A and B , as well as English readings of them, for which that conjunction (or set) appears to be perfectly possible or consistent logically. A famous case in point is the so-called Chisholm contrary-to-duty imperative paradox, first stated in Chisholm [1963] and later discussed by a number of authors, e.g. Von Wright [1964; 1965], Sellars [1967], Åqvist [1966; 1967], Powers [1967], Hansson [1969], Føllesdal and Hilpinen [1971], Mott [1973], al-Hibri [1978], Tomberlin [1981], Van Eck [1981], and presumably several others. We now address ourselves to that puzzle.

8 RODERICK M. CHISHOLM'S CONTRARY-TO-DUTY IMPERATIVE PARADOX

Several versions of the puzzle are known in the literature. Following Van Eck [1981] I shall consider a Suzy Mae version of it, which explicitly involves the notion of commitment:

- I. It ought to be that John does not impregnate Suzy Mae.
- II. Not-impregnating Suzy Mae commits John to not marrying her.
- III. Impregnating Suzy Mae commits John to marrying her.
- IV. John impregnates Suzy Mae.

Let $\mathcal{C} = \{I, II, III, IV\}$. We note that the set \mathcal{C} is, from an intuitive standpoint, both *consistent* in the sense that no contradiction follows from it and *non-redundant* in the sense that none of its members follows from the remainder of the set. We then expect any adequate formalization of I–IV to *preserve both these properties*. Let us call this adequacy criterion our *requirement of consistency and non-redundancy*.

We now consider three attempts to formalize the sentences I–IV, using only the resources of Monadic Deontic Logic.

First attempt:

Ia. $O\neg p_2$.

IIa. $O(\neg p_2 \rightarrow \neg p_3)$.

IIIa. $O(p_2 \rightarrow p_3)$.

IVa. p_2 .

Objection: Let \mathcal{L} be any of the ten Smiley–Hanson systems. We have that IIIa is \mathcal{L} -derivable (\mathcal{L} -deducible) from Ia, although III does not follow logically from I. Hence, the non-redundancy part of our requirement is violated by this proposal.

Second attempt:

Ib(=Ia). $O\neg p_2$.

IIb. $\neg p_2 \rightarrow O\neg p_3$.

IIIb. $p_2 \rightarrow Op_3$.

IVb(=IVa). p_2 .

Objection: IIb is \mathcal{L} -derivable from IVb, although II is not a logical consequence of IV. Therefore, non-redundancy is not preserved by this formalization either, contrary to our requirement.

Third attempt:

Ic(=Ia). $O\neg p_2$.

IIc(=IIa). $O(\neg p_2 \rightarrow \neg p_3)$.

IIIc(=IIIb). $p_2 \rightarrow Op_3$.

IVc(=IVa). p_2 .

Objection: Let \mathcal{L} be any of the Smiley–Hanson +-systems, having the characteristic axiom schema A3: $OA \rightarrow PA$, which, by A1, is equivalent to

$$OA \rightarrow \neg O\neg A \quad (\text{see Section 10.2 below}).$$

We then observe that $\{Ic, IIc\} \vdash_{\mathcal{L}} O\neg p_3$ and that $\{IIIc, IVc\} \vdash_{\mathcal{L}} Op_3$. Hence $\{Ic, IIc, IIIc, IVc\} \vdash_{\mathcal{L}} \perp$, so the present formalization fails to preserve the consistency of \mathcal{C} , contrary to our requirement.

EXERCISE 19.

- (i) The objections to the three attempts just considered rest on claims about derivability in all, or certain, Smiley–Hanson systems \mathcal{L} . Give *careful* proofs (in full detail) of these claims!

- (ii) What happens to the objection to the third attempt, if the restriction to the Smiley–Hanson +-systems is dropped?
- (iii) Consider the formal sentences Ia–IVa, IIb, IIIb, which are all in Σ . Which English sentences in Φ , i.e. the set of sentences of the fragment FNE_3 (see Section 7 above), are such that these formal sentences are the t -translations of the latter English sentences, respectively? What relation do those English sentences bear to I–IV above?

Let us now pass to consideration of certain attempts to formalize the sentences I–IV, using the stronger resources of dyadic deontic logic, i.e. the language described in Section 17 below and its set of sentences $\Sigma_{0,N}^2$.

Fourth attempt:

$$\begin{aligned} \text{Id}(=\text{Ia}). & \quad O\neg p_2. \\ \text{IId}(=\text{IIa}). & \quad O(\neg p_2 \rightarrow \neg p_3). \\ \text{IIIId}. & \quad O_{p_2} p_3. \\ \text{IVd}(=\text{IVa}). & \quad p_2. \end{aligned}$$

Fifth attempt:

$$\begin{aligned} \text{Ie}(=\text{Ia}). & \quad O\neg p_2. \\ \text{IIe}. & \quad O_{\neg p_2} \neg p_3. \\ \text{IIIe}(=\text{IIIId}). & \quad O_{p_2} p_3. \\ \text{IVe}(=\text{IVa}). & \quad p_2. \end{aligned}$$

The fourth and fifth attempts to deal with Chisholm’s puzzle give rise to the following result:

THEOREM 20 (Contrary-to-duty imperative paradox). *Let \mathcal{L} be any of the systems of dyadic deontic logic presented in Sections 15–23. Let*

$$\mathcal{C}d = \{\text{Id}, \text{IId}, \text{IIIId}, \text{IVd}\}$$

$$\mathcal{C}e = \{\text{Ie}, \text{IIe}, \text{IIIe}, \text{IVe}\}.$$

Then:

- (i) $\mathcal{C}d$ is \mathcal{L} -consistent in the sense that \perp (falsum) is not \mathcal{L} -derivable from $\mathcal{C}d$. In symbols: $\mathcal{C}d \not\vdash_{\mathcal{L}} \perp$.
- (ii) $\mathcal{C}e$ is \mathcal{L} -consistent in the same sense, i.e. $\mathcal{C}e \not\vdash_{\mathcal{L}} \perp$.

- (iii) Cd is \mathcal{L} -non-redundant in the sense that none of its members is \mathcal{L} -derivable from the remainder of Cd .
- (iv) Ce is \mathcal{L} -non-redundant in the same sense.

In short, the intuitive content of the theorem is to the effect that the fourth and fifth attempts both satisfy our requirement of consistency and non-redundancy with respect to any dyadic system \mathcal{L} of a certain kind.

Proof.[Sketch] It is enough to prove the points (i)–(iv) for the case where \mathcal{L} = our strongly normal system \mathbf{G} (why?). To begin with, let us have a look at the diagram shown in Figure 1. The meaning of this is that it represents a set W of *possible worlds* (or *situations*), consisting of four distinct members x, y, z, u , which are ranked by a binary relation of *strict preference* or *strict betterness*. That relation is represented by \succ , and the ranking order is from left to right, so that u is the *best* member of W , x the *second best* etc. Moreover, the proposition letters p_2, p_3 (read in accordance with D10 and D11, Section 7 above) are taken to be true/false at different worlds as shown by the diagram:

p_2 is true at x and y , but false at z and u
 p_3 is true at x and z , but false at y and u .

Figure 1.

Molecular Boolean compounds of these ‘atoms’ receive truth-values according to the familiar tables. But how do we handle sentences of the forms OA and O_BA (expressing ‘absolute’ and ‘conditional’ obligations, respectively)? The main suggestion embodied in the dyadic approach to deontic logic (and perhaps most clearly stated by Hansson [1969]) comes down to this. Letting $B(A)$ be any sentence in $\Sigma_{0,N}^2$, we mean by a $B(A)$ -world any world in W at which $B(A)$ is true; then, we propose the following *truth condition* for any sentences of the form O_BA , relatively to any world w in W :

TC. O_BA is true at w iff all the best B -worlds are A -worlds.

Consider now the point y in W , i.e. the ‘*worst*’ of all possible worlds in W ’ according to the ranking \succ . For each member of $\mathcal{C}d$ we want to figure out whether it is true at y or not:

Id? Remembering the Von Wright [1956] type definition of the monadic O -operator (Section 7.3 above)

$$OB = \text{df } O_{\top}B$$

we obtain by TC that $O_{\top}\neg p_2$ is true at y iff all the best \top -worlds are $\neg p_2$ -worlds. But the set of \top -worlds = W (why?) and the set of *best* \top -worlds, according to \succ , = $\{u\}$, i.e. the unit set of u . Now, $\neg p_2$ is true at u , so all the best \top -worlds are $\neg p_2$ -worlds. Hence, by TC, Id is true at y .

IId? The same kind of argument is helpful in establishing the truth at y of IId.

IIId? By TC we have that $O_{p_2}p_3$ is true at y iff all the best p_2 -worlds are p_3 -worlds as well. Now the set of p_2 -worlds = $\{x, y\}$ and the set of *best* p_2 -worlds = $\{x\}$. p_3 is true at x , so all the best p_2 -worlds are p_3 -worlds. Hence, by TC, IIId is true at y .

IVd? By our diagram, p_2 (=IVd) is true at y .

Upshot so far: every sentence in the set $\mathcal{C}d$ is true at y .

We can now proceed to establish point (i) of our theorem. First of all, we claim that the ‘model’ pictured in Figure 1 can be used to define a *strong deontic H_3 -model* \mathcal{U} , in the strict sense introduced in Section 22 below, which is such that all members of $\mathcal{C}d$ are true at y in \mathcal{U} . (The construction, or definition of \mathcal{U} is left as an exercise to the reader.) Suppose then, contrary to (i), that $\mathcal{C}d$ is not \mathbf{G} -consistent. By the definition of the latter notion (see already Section 10.2.1) we obtain:

$$\vdash_{\overline{\mathbf{G}}}(\text{Id} \wedge \text{IId} \wedge \text{IIId} \wedge \text{IVd}) \rightarrow \perp$$

or simply:

$$\vdash_{\overline{\mathbf{G}}}\neg(\text{Id} \wedge \text{IId} \wedge \text{IIId} \wedge \text{IVd})$$

which is to the effect that the *negation* of the conjunction of the members of $\mathcal{C}d$ is provable in \mathbf{G} .

However, since that negation is provable in \mathbf{G} , then, by the Soundness Theorem for \mathbf{G} (Theorem 72 below), it is strongly deontically H_3 -valid, which means in particular that it is true at y in our model \mathcal{U} just constructed. But, as all members of $\mathcal{C}d$ are true at y in \mathcal{U} , their conjunction must be true at y as well. Contradiction. This proves point (i) of the theorem.

To deal with (ii) we only have to show that the sentence IIe in $\mathcal{C}e$ is true at y in the intuitive model picture in Figure 1. Well, $O_{\neg p_2} \neg p_3$ is, by TC, true at y iff all the best $\neg p_2$ -worlds are $\neg p_3$ -worlds as well. Now, the set of $\neg p_2$ -worlds $= \{u, z\}$ and the set of *best* $\neg p_2$ -worlds $= \{u\}$. $\neg p_3$ is true at u (by our diagram), so all the best $\neg p_2$ -worlds are $\neg p_3$ -worlds. Hence, by TC, IIe is true at y . The remainder of the proof of point (ii) parallels that of (i).

Our strategy in dealing with the non-redundancy points (iii) and (iv) is the following. Suppose we want to show that in $\mathbf{G} \text{IVd}(=p_2)$ is *independent in* $\mathcal{C}d$ in the sense that $\{\text{Id}, \text{IID}, \text{IIId}\} \not\vdash_G \text{IVd}$. Suppose that we find, i.e. are able to construct, a strong deontic H_3 -model \mathcal{U} and a world w in \mathcal{U} such that $\text{Id}, \text{IID}, \text{IIId}$ as well as the *negation* of IVd are all true at w in \mathcal{U} . We then use the Soundness Theorem for \mathbf{G} to conclude (exactly how?) that IVd is not \mathbf{G} -derivable from $\{\text{Id}, \text{IID}, \text{IIId}\}$.

Following this strategy, the proof of (iii) and (iv) is almost routine and can be left to the reader. Just a few hints:

The case of the independence of $\text{IVd}(=\text{IVe})$ in $\mathcal{C}d$ and $\mathcal{C}e$ is particularly easy: use the same model as above, but consider the point z , at which p_2 is false, instead of y .

For the case of $\text{Id}(=\text{Ie})$: stick to y as the ‘point of evaluation’ in the above model, but change \succ in such a way that x is ranked above u .

For the cases of IID and IIe : stick to y in the original model, but assume p_3 to be true at u .

And so on.

This completes the outline of a proof of the Theorem on the contrary-to-duty imperative paradox. ■

8.1 On the choice between the fourth and the fifth attempt

Suppose we grant that the formalizations of I–IV codified in the fourth and fifth attempts are superior to their predecessors, because they preserve *both* the intuitive consistency *and* the intuitive non-redundancy of the set \mathcal{C} . Which of $\mathcal{C}d$ and $\mathcal{C}e$ are we then to choose? I shall now offer an argument for taking a neutral position on this issue: it does not matter which one we choose, we may leave the choice open.

Let us ask, to begin with: as $\mathcal{C}d$ and $\mathcal{C}e$ differ only with respect to their second member, what is the logical relation of IID to IIe ? In answer to that question we state and prove the following result:

LEMMA 21 (IID and IIe). *Let \mathcal{L} be any of the dyadic systems dealt with in Part VI below. Then:*

- (i) *If \mathcal{L} contains the system \mathbf{E} (see Section 22 at the end), then*

$$\vdash_{\mathcal{L}} O_{\neg p_2} \neg p_3 \rightarrow O(\neg p_2 \rightarrow \neg p_3).$$

(ii) If \mathcal{L} contains the system \mathbf{G} (Section 22 at the end), then

$$\vdash_{\mathcal{L}} P_{\top} \neg p_2 \rightarrow O(\neg p_2 \rightarrow \neg p_3) \Leftrightarrow O_{\neg p_2} \neg p_3.$$

Proof.

Ad (i):

- | | |
|--|---|
| 1. $O_{\neg p_2} \neg p_3$ | hypothesis |
| 2. $N(\neg p_2 \Leftrightarrow (\top \wedge \neg p_2))$ | \mathbf{E} contains S5 for N |
| 3. $O_{\neg p_2} \neg p_3 \Leftrightarrow O_{\top \wedge \neg p_2} \neg p_3$ | from 2 by $\alpha 0$ (Section 18), which is an axiom schema in \mathbf{E} , using <i>modus ponens</i> |
| 4. $O_{\top \wedge \neg p_2} \neg p_3$ | from 1 and 3 by propositional logic |
| 5. $O_{\top \wedge \neg p_2} \neg p_3 \rightarrow O_{\top}(\neg p_2 \rightarrow \neg p_3)$ | instance of $\alpha 2$ (Section 18), which is an axiom schema in \mathbf{E} |
| 6. $O_{\top}(\neg p_2 \rightarrow \neg p_3)$ | from 4,5 by <i>modus ponens</i> |

The sequence 1–6 is a deduction in \mathbf{E} and hence in any \mathcal{L} of the sort under consideration. Rewriting O_{\top} as O in 6, we obtain the desired result (i) by the rule of conditional proof (or, if you like, the Deduction Theorem), which is valid in (for) \mathbf{E} , of course.

Ad (ii):

- | | |
|--|--|
| 1. $P_{\top} \neg p_2 \rightarrow (O_{\neg p_2} \neg p_3 \rightarrow O_{\top}(\neg p_2 \rightarrow \neg p_3))$ | from (i) by propositional logic, since \mathbf{G} contains \mathbf{E} |
| 2. $P_{\top} \neg p_2 \rightarrow (O_{\top}(\neg p_2 \rightarrow \neg p_3) \rightarrow O_{\top \wedge \neg p_2} \neg p_3)$ | instance of $\alpha 4$ (Section 18), which is one of the characteristic axiom schemata in \mathbf{G} |
| 3. $P_{\top} \neg p_2 \rightarrow (O_{\top}(\neg p_2 \rightarrow \neg p_3) \rightarrow O_{\neg p_2} \neg p_3)$ | from 2 and line 3 in the proof of (i) above, using propositional logic |
| 4. $P_{\top} \neg p_2 \rightarrow (O_{\top}(\neg p_2 \rightarrow \neg p_3) \Leftrightarrow O_{\neg p_2} \neg p_3)$ | from 1 and 3 by propositional logic |

The present sequence 1–4 is a rather fragmentary proof in \mathbf{G} of its last line, 4. Rewriting O_{\top} as O in 4, we obtain the desired result (ii). ■

COROLLARY 22. *Suppose that \mathcal{L} contains the system \mathbf{G} . Then:*

(iii) $Ce \vdash_{\mathcal{L}} \text{IIId}$

(iv) $Cd \vdash_{\mathcal{L}} \text{IIe}$

Proof. Here, (iii) follows from (i) and the fact that \mathbf{G} contains \mathbf{E} . Again, (iv) is obtained from (ii) as follows: using $\alpha 3$ (Section 18), which is a somewhat controversial schema of \mathbf{G} , together with the fact that $\vdash_{\mathbf{G}} M\top$ (\mathbf{G} contains $\mathbf{S5}$ for M), we see that the sentence Id entails $P_{\top} \neg p_2$, i.e. the antecedent of 4 above. So, using that result together with 4 and IIId , we obtained the desired conclusion IIe . ■

Clearly, in spite of IIId being in general weaker than IIe , (iii) and (iv) are jointly to the effect that it does not matter which of Cd and Ce we choose as the ‘correct’ formalization of \mathcal{C} ; *provided*, however, that \mathbf{G} can be accepted as a satisfactory dyadic system. I have nothing against assuming this to be the case. Bearing in mind that \mathbf{G} is a generalized version of Hansson’s $\mathbf{DSDL3}$, this attitude of mine should be shared, e.g. by Hansson [1969], Føllesdal and Hilpinen [1971] and Spohn [1975].

9 PROBLEMS UNSOLVED BY THE DYADIC APPROACH; THE NEED FOR TEMPORAL AND QUANTIFICATIONAL RESOURCES IN THE BASIC LANGUAGE OF SATISFACTORY DEONTIC LOGICS; ON THE LOGIC OF ACTION; FAILURE OF LEFT-TO-RIGHT ADEQUACY

Our discussion of Prior’s paradoxes of commitment and Chisholm’s contrary-to duty imperative paradox was mainly designed to show how the idea of dyadic deontic logic naturally arises as an attempt to cope with these difficulties. The Exercises on such adequacy criteria for a logic of commitments as C1–C13 (Section 7.3 above) as well as our Theorem on the Contrary-to-Duty Imperative Paradox and Lemma on IIId and IIe should have given the reader a fairly clear opinion of the virtues of the dyadic approach and a nice explanation why it has proved to be such a powerful trend of thought in the development of modern deontic logic. It is now time to turn to its vices, i.e. to certain problems or problem-areas which the dyadic approach appears unable to handle. Mainly following the admirable survey given in Van Eck [1981], we present a list of such problems or problem-areas:

(I.) The dilemma of commitment and detachment.

- (II.) *Prima facie vs.* actual obligation; the *ceteris paribus* proviso.
- (III.) The ought-implies-can problem.
- (IV.) The Good Samaritan paradox and the Jephta dilemma.
- (V.) The problem of the relationship of act-utilitarianism to deontic logic.

I shall now briefly state these difficulties. After having done so, I shall then, without going into details, indicate what I take to be the proper attitude to them and what conclusions are in my opinion ‘reasonably’ to be drawn from them.

9.1 Survey of difficulties (after Van Eck [1981])

I. The dilemma of commitment and detachment. Suppose we were to accept a dyadic system \mathcal{L} satisfying the Andersonian criterion C8 (Exercise 18 above):

$$(C8) \quad \vdash_{\mathcal{L}} (A \wedge O_A B) \rightarrow OB$$

so that \mathcal{L} allows a *principle of detachment* to be valid for commitment-expressing formulae of the type $O_A B$. Then, provided only that \mathcal{L} is sufficiently strong in other respects (which?), we quickly obtain results like

$$\mathcal{C}d(e) \vdash_{\mathcal{L}} Op_3$$

$$\mathcal{C}d(e) \vdash_{\mathcal{L}} O\neg p_3 \wedge Op_3$$

$$\mathcal{C}d(e) \vdash_{\mathcal{L}} \perp$$

in violation of our requirement that the consistency of \mathcal{C} should be preserved. Hence, if \mathcal{L} is of this kind, the fourth and fifth attempts both break down as solutions to the Chisholm puzzle.

Now, these attempts may be defended by claiming that any ‘correct’ dyadic system must, like our \mathbf{G} and others, not allow detachment for commitment; it must definitely not satisfy the criterion C8. In short, in order for the dyadic solutions to work, detachment should not be possible.

However, detachment is not so easily given up from an intuitive standpoint. Here are some voices from the literature:

In nothing like schema (i) (sc. the one in C8) is valid, how can conditional obligation-sentences play the important role in normative argumentation which they seem to play? (Danielsson [1968, p. 66]).

How can we take seriously a conditional obligation if it cannot, by way of detachment, lead to an unconditional obligation? (Van Eck [1981, p. 23]).

So, on the other hand, we seem to feel that detachment should be possible after all. But we cannot have things both ways, can we? This is the dilemma on commitment and detachment.

II. Prima Facie vs. Actual Obligation; the Ceteris Paribus Proviso. Suppose that at a given time t John promises Suzy to marry her at a certain later time $t + 7$. Assume that the promise gives rise to an obligation for John to marry Suzy at $t + 7$, and that this obligation comes into force at time t . Now, in the meantime between t and $t + 7$, various things might happen that make it impossible for John to fulfill his obligation. For instance, he learns that his mother in Australia is dying, whence there arises, say at time $t + 3$, an obligation for John to go and visit her in Australia immediately. John takes off, but is then unable to marry Suzy at $t + 7$, so he breaks his promise and violates his first obligation.

Following Hintikka [1971] we may characterize this situation as one where an earlier obligation, due to the promise, is *overruled* by a stronger obligation, which arises in the meantime between the moment at which the first obligation comes into force ($= t$) and the moment of its fulfillment ($= t + 7$). Hintikka [1971] goes on to suggest that the famous *prima facie* vs. actual duty distinction (Sir David Ross [1930; 1939], Richard Price [1948]) should somehow be applicable to this situation. Following Van Eck [1981], then, I think we may say that at time $t + 3$ the earlier obligation, though still in force at that time, is a mere *prima facie* duty, whereas the later and stronger obligation has acquired the status of an *actual* duty of John's. Our present problem concerns the explication of this distinction and its formal representation in systems of deontic logic; apparently, the issue was first raised by Hintikka [1971] and further discussed by Purtill [1973], Bergström [1974] and Van Eck [1981]. Furthermore, if we try to bring out the distinction by saying that John's first *prima facie* duty carries an implicit or tacit *ceteris paribus* rider 'other things being equal', whereas his second *actual* duty does not, we face the problem of analyzing the import of *ceteris paribus* provisos, in general as well as in the particular case at hand.

III. The Ought-Implies-Can Problem. My remarks on the celebrated Kantian principle will by necessity be very brief and will fail to do justice to the impressive richness of the literature on it. We ask: does 'ought' imply 'can'? then, if the answer is Yes, in what sense of (at least) (i) 'can' and (ii) 'imply'? Again, there are at least two alternatives under each heading here: (i.i) 'can' means logical possibility, and (i.ii) 'can' means some stronger possibility of a more 'practical' or 'real' kind, which might be explicated as a *temporally dependent* possibility in a sense that seemingly originates with

Montague [1968] and is further developed, e.g. by Chellas [1969] and Van Eck [1981]; moreover, ‘imply’ could mean (ii.i) ordinary logical consequence, or (ii.ii) some different form of consequence, say, the interesting notion of *deontic* consequence proposed in Hintikka [1957] and [1971].

Having thus surveyed some candidates in the area, I just think Van Eck [1981, II. Section 2.2], has given excellent reasons for regarding the combination (i.ii) with (ii.i) as providing the most viable and interesting interpretation of the Kantian principle: the alternative (i.i) seems to make it trivial, and the reasons against (ii.i) and for (ii.ii) are far from clear. But there are independent positive reasons as well for interpreting ‘can’ as temporally dependent, or historical, possibility and ‘imply’ as ordinary logical consequence.

IV. The Good Samaritan Paradox and the Jephtha Dilemma. The first puzzle here goes back at least to Prior [1958] and has been discussed in a number of contributions, of which we only mention Danielsson [1968], Wedberg [1969], Van Fraassen [1972], Castañeda [1968a; 1974], Tomberlin and McGuinness [1977] and Van Eck [1981]. Interestingly, though, Knuuttila [1981] points out that in the fourteenth century versions of the paradox were known to and dealt with by Roger Rossetus in his *Commentary on the Sentences*.

Again, the Jephtha Dilemma (see the *Book of Judges*) was taken by Von Wright [1965] to be an interesting problem case for deontic logic, which illustrates such notions as those of a *predicament* and a *conflict of duty*. It has later been discussed extensively by Van Eck [1981].

The following version of the Good Samaritan paradox is presented in Tomberlin and McGuinness [1977] and goes back to Castañeda [1974]; consider the argument:

- (5) If Bob pays \$500 to the man he will murder one week hence, then Bob will murder a man one week hence.
- (6) It ought to be that Bob pays \$500 to the man he will murder one week hence (because Bob owes that amount of money to the latter).

Therefore:

- (7) It ought to be that Bob will murder a man one week hence.

In this argument, the first premiss, (5), may be taken to be, not only true, but even *logically true*. As for the second, (6), let us just assume it to be true. On the other hand, (7), is plainly false, in spite of the fact that the premisses (5) and (6) are both true. Hence, the argument must be invalid. But, if we translate it into the language of any of the Smiley–Hanson systems \mathcal{L} of Monadic Deontic Logic, which are all closed under the

rule of inference:

$$\frac{A \rightarrow B}{OA \rightarrow OB} \text{ (see Exercise 12 above)}$$

we find that the translation of (7) is \mathcal{L} -derivable from the translations of the premisses (5) and (6). What has gone wrong here?

The Jephtha Dilemma is reminiscent of the famous Morning Star Paradox in quantified modal logic with identity (see, e.g. Kanger [1957a]) and can be stated as follows. Consider the argument:

- (8) Miriam (i.e. the daughter of Jephtha) is identical to the first being that will meet Jephtha on his return home.
- (9) It ought to be that Jephtha immolates the first being that will meet him on his return home (because he has promised God to do so).

Therefore:

- (10) It ought to be that Jephtha immolates Miriam (his own daughter).

Again, here, as it seems, the premisses are true while the conclusion is false. So the argument must be invalid. But if we formalize it in a suitable system \mathcal{L} of deontic logic, it may well turn out that the inference is countenanced as valid in \mathcal{L} . How are we to account for this?

V. The problem of the relationship of Act-Utilitarianism to deontic logic. In Castañeda [1967; 1968], Castañeda points out the following intriguing difficulty for the familiar ethical theory known as Act-Utilitarianism. My statement of the problem will involve some amount of ‘precization’. Let X be any moral agent, let C be any situation or set of circumstances, and let A be any act open to X in C (in the sense that it is possible for X to do A in C). Then, the following is a central thesis of Act-Utilitarianism:

- (U) X ought to do A in C iff for each act A' such that (i) A' is open to X in C and (ii) A' is an alternative to A in C and (iii) A' is distinct from A

we have that the consequences of X 's doing A in C are better than those of X 's doing A' in C .

It may be that condition (iii) in this formulation of (U) is redundant, because entailed by (ii). Next, consider this set of assumptions:

- (11) X ought to do $P \wedge Q$ in C (where $P \wedge Q$ is a certain conjunctive act open to X in C)
- (12) The three acts $P \wedge Q, P, Q$ are all (i) open to X in C , (ii) alternatives to each other in C , and (iii) distinct from one another.
- (13) If X ought to do $P \wedge Q$ in C , then X ought to do P in C and X ought to do Q in C .

THEOREM 23. (after Castañeda [1968]): *The set $\{(11), (12), (13), (U)\}$ is inconsistent.*

Proof. Exercise. (If you are unable to do it, see Castañeda [1968]!) What assumptions about the preference relation *better than* do we minimally have to make in order to establish the present result? ■

We should note here that (13) is reminiscent of the principle asserting that O is distributive over \wedge , which is valid in all the Smiley–Hanson systems of monadic deontic logic. Now, suppose we stick to the assumptions (11) and (12): then we face the tough choice, described by Wedberg [1969], between

- (i) maintaining (13) and rejecting the utilitarian thesis (U) already on grounds of deontic logic; and
- (ii) maintaining (U) and rejecting the deontic-logical principle (13).

Perhaps this is a ‘false dilemma’, though: why not abandon (12) and try to save both (13) and (U)?

I shall not discuss here this proposal and others that might be or have been made. I just like to point out that in Åqvist [1969] an attempt was made to relate Castañeda’s problem to the interesting work done by Bergström [1966] on utilitarian and teleological ethics. The notion of the *alternatives* to an action is seen to play a crucial role in Bergström’s analysis and was further scrutinized by Prawitz [1968; 1970], Bergström [1968] and by other contributors. The discussion quickly turned out to be surprisingly complex and it is difficult to give a fair assessment of its outcome.

9.2 *Diagnosis*

I have now finished my survey of the problem areas I–V. In my opinion, the existence of these difficulties, together with various unsuccessful attempts to overcome them, give considerable support to the diagnosis that

the languages of the current systems of deontic logic are far too poor to function as a satisfactory medium for formulating cues for the moral agent (Van Eck [1981, p. 1]).

I think this conclusion is born out in an especially clear way by the Van Eck treatment of problem II and his fascinating account of how *prima facie* obligations *pass into* actual duties as time elapses. The account is based on a system of temporal logic, more specifically: a system of *temporally relative modal* and *deontic predicate* logic. In my view, the virtues of this system are shown by its capacity to handle, not only the paradoxes of commitment and the contrary-to-duty imperative, but, as Van Eck also shows, the four problem areas I–IV as well. Handle them in a more convincing way than has so far been done up to this date, that is to say. As Van Eck observes in the preface to his [1981], though, he is not alone in having conceived of the idea of constructing a semantics for a notion of *temporally relative necessity* and basing a semantics of *temporal deontic* notions upon it: similar ideas can be found in Åqvist and Hoepelman [1981], going back to Chellas [1969] and Montague [1968] (see problem III above). Also, Thomason [1981] (deriving from an original 1970 version) and [1981a] should be mentioned in the present context. Now, the Van Eck framework appears to be richer than these rival ones, because it uses temporal variables, constants and quantifiers in the *object-language*. And this, I think, makes it more useful for philosophical applications; an illustration of this claim is perhaps the little paper Åqvist [1981], where precisely a Van Eck-type framework is applied to the ancient so-called Protagoras paradox (see also Lenzen [1977] and Smullyan [1978]).

Among recent contributions in the same vein, those of Bailhache [1991] (going back to work done in the early eighties) and [1993] strike me as particularly valuable. See also Åqvist [1997a].

There are strong reasons, then, for enriching the basic language of satisfactory deontic logics with explicit temporal resources. Moreover, problems IV and V nicely show, I take it, the need for *quantificational* resources in that language as well; how could we otherwise even begin to state those problems in an intelligible way? The indispensability of quantifiers in deontic logic was, on general grounds, very well argued by Hintikka already in his [1957] (and later in his [1971]), when he comments on the fundamental work done by Von Wright [1951; 1951a] as well as by Prior [1955]. A system of deontic predicate logic (quantification theory) is also presented in Kanger [1957]; his system is one *with identity* and, interestingly, blocks deontic analogues of the Morning Star paradox such as the Jephta dilemma in the model-theoretic semantics given for it.

Again, the need for quantifiers in deontic logic seems to be one of the main tenets of Castañeda's in an impressively large number of contributions, of which we mention here only Castañeda [1954; 1959; 1981].

We must briefly touch on the following question: given the indispensability of quantifiers in deontic logic, *exactly over what* sort of entities do we have to quantify? agents, patients, times, places, circumstances or what? Hintikka [1957] suggested *individual acts*; in Makinson [1981] this suggestion

is shown to give rise to considerable interpretational difficulties. See also Robison [1964] for further suggestions. In answer to this question I would like here to recommend a very broad, liberal and open-minded attitude: as deontic logicians, we should be prepared to quantify over whatever entities the ethical theory or normative (e.g. legal) system requires us to consider seriously, and to adjust our deontic predicate logic accordingly. We should not, I contend, worry too much about ontological commitments; in today's research situation the important thing is to get the right kind of structure going.

9.2.1 *On the logic of action*

Having now stressed the importance of temporal and quantificational machinery to viable deontic logics, there is a third research trend in our area, to which I like to draw the reader's attention. This trend claims that such logics ought to be combined with a *logic of action*; it is usually taken to have been initiated in Von Wright [1963] and followed up, e.g. in Von Wright [1967] (with comments by Chisholm [1967]) and Von Wright [1974]. However, if we consider the distinguishing mark of a logic of action to be the presence in its basic language of a special 'causal' operator of *agency* (expressing that an agent *brings it about, sees to it, makes it true* that so-and-so is the case), we might just as well credit Kanger [1957], Anderson [1962] and Kanger and Kanger [1966] with the idea. Anyway, the latter authors apply it in attempts to reconstruct and to extend the Hohfeldian system of jural relationships as set forth by Hohfeld [1919]. In this endeavor they are followed by, notably, Pörn [1970], Anderson [1971] and Lindahl [1977]. This movement is highly interesting and promising for the future, and any account of present-day deontic logic would be seriously incomplete if it did not mention it.

Finally, I like to close this Part by making a remark on the Good Samaritan paradox, which is intended to illustrate the notion of *left-to-right adequacy* (Section 5.4 above) and its failure in connection with the Smiley–Hanson systems of monadic deontic logic.

9.2.2 *Remark on the Good Samaritan paradox*

Consider the definitional enrichment L(D1–D14) of L, where D13 and D14 are as follows:

(D13) Bob pays \$500 to the man he will murder one week hence =df p_5

(D14) Bob will murder a man one week hence =df p_6

Extending the translation t in the obvious way, we obtain the following formalization of the sentence (5) in the paradox:

$$t(5) = (p_5 \rightarrow p_6).$$

Note, then, that (5) is in Φ (= the sentence-set of the fragment FNE_6) and that (5) is logically true (presumably). Hence, (5) is in NDL. On the other hand, $t(5)$ is *not* provable in any of the Smiley–Hanson systems \mathcal{L} (why?). So we have a counterexample to the *left-to-right* adequacy of t with respect to NDL and \mathcal{L} .

The import of this counterexample is that there are validities in natural deontic logic (NDL), or relations of ‘natural’ logical consequence, which fail to be representable in certain formal deontic logics, such as \mathcal{L} . The reason is, of course, that we need a *quantificational* formal framework with *definite descriptions* in order adequately to formalize such a sentence as (5); the propositional language L is simply not expressive enough.

We should contrast this counterexample with those met with above, which purported to show that t was not right-to-left adequate with respect to NDL and \mathcal{L} , in the sense that the latter sanctions *more* logical validities than the former. The present situation is precisely the opposite one. The Good Samaritan paradox is usually cited as an instance of failing right-to-left adequacy, just as those of commitment etc. I think it is of some interest to note that it could also be used to illustrate the opposite failure.

III. TEN SMILEY–HANSON SYSTEMS OF MONADIC DEONTIC LOGIC

10 LANGUAGE, PROOF THEORY AND SEMANTICS

10.1 Language

10.1.1 Alphabet

Our alphabet consists of

- (i) a denumerable set Prop of *proposition letters* p, q, r, p_1, p_2, \dots ;
- (ii) the primitive *logical connectives* \top (*verum*), \perp (*falsum*), \neg (negation), O (obligation), P (permission), \wedge (conjunction), \vee (disjunction), \rightarrow (material implication) and \Leftrightarrow (material equivalence); and
- (iii) the parentheses ().

10.1.2 Sentences

(well formed formulas, wffs): The set Σ of all sentences of our language is defined as the smallest set S such that

- (a) every proposition letter in Prop is in S ,
- (b) \top and \perp are in S ,
- (c) if A is in S , then so are $\neg A$, OA and PA ,
- (d) if A, B are in S , then so are $(A \wedge B)$, $(A \vee B)$, $(A \rightarrow B)$ and $(A \Leftrightarrow B)$.

The sentences under (a) and (b) are the *atomic* sentences of the language.

10.1.3 Degrees of logical connectives

\top and \perp are of degree 0; \neg, O, P are of degree 1; and the remaining connectives are all of degree 2.

10.1.4 Definition

$$FA = \text{df } \neg PA \text{ (alternatively: } O\neg A).$$

10.1.5 Conventions for dropping brackets

Brackets are omitted in accordance with these canons:

- (i) Connectives of degree 1 bind more strongly than connectives of degree 2.
- (ii) Among the latter, \wedge and \vee bind more strongly than \rightarrow and \Leftrightarrow .
- (iii) Outer brackets are mostly dropped around sentences.

10.2 Proof theory

The following two *rules of inferences* are common to all the ten Smiley–Hanson systems of monadic deontic logic to be dealt with:

$$(R1) \frac{A, A \rightarrow B}{B} \text{ (modus ponens).}$$

$$(R2) \frac{A}{OA} \text{ (O-necessitation).}$$

Consider next the following list A0–A7 of *axiom schemata*:

- (A0) All truth-functional tautologies (over our present language)
- (A1) $PA \Leftrightarrow \neg O\neg A$
- (A2) $O(A \rightarrow B) \rightarrow (OA \rightarrow OB)$
- (A3) $OA \rightarrow PA$
- (A4) $OA \rightarrow OOA$
- (A5) $POA \rightarrow OA$
- (A6) $O(OA \rightarrow A)$
- (A7) $O(POA \rightarrow A)$

The ten logics to be studied here are called **OK**, **OM**, **OS4**, **OB**, **OS5**, **OK⁺**, **OM⁺**, **OS4⁺**, **OB⁺**, and **OS5⁺**. They are defined as follows (where R1 and R2 are assumed for all):

- OK** = A0–A2
- OM** = A0–A2, A6
- OS4** = A0–A2, A4, A6
- OB** = A0–A2, A6, A7
- OS5** = A0–A2, A4, A5 (note that A6 and A7 are derivable in **OS5**)

Again, let \mathcal{L} be any of these five systems. Then:

$$\mathcal{L}^+ = \mathcal{L}, A3$$

Of these ten deontic logics, **OK** is (apart from unessential differences) identical to the system **F** of Hanson [1965], **OK⁺** to his **D**, **OB⁺** to his **DB**, whereas **OB** is discussed neither by Hanson [1965] nor by Smiley [1963]. The remaining six systems are named exactly as in Smiley [1963].

10.2.1 Provability and consistency

Let \mathcal{L} be any of the ten systems just defined. Then, the set of \mathcal{L} -provable sentences (or the set of \mathcal{L} -theses) is the smallest set $S \subseteq \Sigma$ such that (i) each instance of every axiom schema of \mathcal{L} is in S , and (ii) S is closed under the rules R1 and R2. We write ' $\vdash_{\mathcal{L}} A$ ' to indicate that A is \mathcal{L} -provable. Also, a set S of sentences is \mathcal{L} -inconsistent iff there are B_1, \dots, B_n in S ($n \geq 1$) such that $\vdash_{\mathcal{L}} (B_1 \wedge \dots \wedge B_n) \rightarrow \perp$; and S is \mathcal{L} -consistent otherwise.

Again, we say that a sentence A is \mathcal{L} -derivable from a set S of sentences, in symbols: $S \vdash_{\mathcal{L}} A$, just in case $S \cup \{\neg A\}$ is \mathcal{L} -inconsistent. Clearly, $\vdash_{\mathcal{L}} A$ iff

$\emptyset \mid_{\mathcal{L}} A$, i.e. the \mathcal{L} -provable sentences are exactly those that are \mathcal{L} -derivable from the empty set.

10.3 Semantics

10.3.1 Models

By a *model* we mean a triple $\mathcal{U} = \langle \mathcal{W}, \mathcal{R}, \mathcal{V} \rangle$ where:

- (i) W is a non-empty set (heuristically, of ‘possible worlds’ or ‘possible situations’).
- (ii) $R \subseteq W \times W$ (a binary relation on W , heuristically, of ‘deontic alternatives’ or ‘co-permissibility’).
- (iii) V is an assignment, which associates a truth-value 1 or 0 with each ordered pair $\langle p, x \rangle$ where p is a proposition letter and x is an element of W ; in technical jargon, $V: \text{Prop} \times W \rightarrow \{1, 0\}$.

10.3.2 Truth conditions

Let $\mathcal{U} = \langle \mathcal{W}, \mathcal{R}, \mathcal{V} \rangle$ be any model, let x be any member of W , and let A be in Σ . We want to define what it means for A to be *true at x in \mathcal{U}* , in symbols: $\mid_x^{\mathcal{U}} A$. As usual, the definition is recursive on the length of A :

$$\mid_x^{\mathcal{U}} p \quad \text{iff} \quad V(p, x) = 1 \quad (\text{for any } p \text{ in Prop}).$$

$$\mid_x^{\mathcal{U}} \top.$$

$$\text{not } \mid_x^{\mathcal{U}} \perp.$$

$$\mid_x^{\mathcal{U}} \neg A \quad \text{iff} \quad \text{not } \mid_x^{\mathcal{U}} A.$$

$$\mid_x^{\mathcal{U}} OA \quad \text{iff} \quad \text{for every } y \text{ in } W \text{ such that } xRy, \mid_y^{\mathcal{U}} A.$$

$$\mid_x^{\mathcal{U}} PA \quad \text{iff} \quad \text{for some } y \text{ in } W \text{ such that } xRy, \mid_y^{\mathcal{U}} A.$$

$$\mid_x^{\mathcal{U}} (A \wedge B) \quad \text{iff} \quad \mid_x^{\mathcal{U}} A \quad \text{and} \quad \mid_x^{\mathcal{U}} B.$$

$$\models_x (A \vee B) \text{ iff } \models_x A \text{ or } \models_x B \text{ (or both).}$$

$$\models_x (A \rightarrow B) \text{ iff if } \models_x A, \text{ then } \models_x B.$$

$$\models_x (A \Leftrightarrow B) \text{ iff } (\models_x A \text{ iff } \models_x B).$$

10.3.3 Conditions on R in a model

Corresponding to the five axiom schemata A3–A7 we now list five conditions on the relation R in a model (where we assume the variables ‘ x ’, ‘ y ’, ‘ z ’ to range over W , and where we use the symbols $\&$, \supset , \forall and \exists as a shorthand notation in the metalanguage in the obvious way):

- (R3) R is *serial* in W : $\forall x \exists y (xRy)$
- (R4) R is *transitive* in W : $\forall x, y, z (xRy \& yRz \supset xRz)$
- (R5) R is *Euclidean* in W : $\forall x, y, z (xRy \& xRz \supset yRz)$
- (R6) R is *almost reflexive* in W : $\forall x, y (xRy \supset yRy)$
- (R7) R is *almost symmetric* in W : $\forall x, y, z (xRy \supset (yRz \supset zRy))$

10.3.4 Classification of models

We now use the restrictions on R just listed to obtain a subcategorization of the set of all models into various kinds. Thus, we stipulate that:

- The class of **OK**-models = the class of *all* models (no condition on R being imposed).
- The class of **OM**-models = the class of all models with almost reflexive R .
- The class of **OS4**-models = the class of all models with transitive and almost reflexive R .
- The class of **OB**-models = the class of all models with almost symmetric and almost reflexive R .
- The class of **OS5**-models = the class of all models with Euclidean and transitive R .
- The class of **OK**⁺-models = the class of all models with serial R .
- The class of **OM**⁺-models = the class of all models with serial and almost reflexive R .
- The class of **OS4**⁺-models = the class of all models with serial, transitive and almost reflexive R .

The class of **OB**⁺-models = the class of all models with serial, almost symmetric and almost reflexive R .
 The class of **OS5**⁺-models = the class of all models with serial, Euclidean and transitive R .

In this chain of definitions, we always take the relevant restrictions on R to be relative to the world-set W in a model, so that ‘serial’ means ‘serial in W ’, and so on.

10.3.5 Validity and satisfiability

Let \mathcal{L} be any of the ten systems **OK, OM, OS4, OB, OS5, OK⁺, OM⁺, OS4⁺, OB⁺, OS5⁺**. We say that a sentence A is \mathcal{L} -valid (in symbols: $\models_{\mathcal{L}} A$) iff $\models_x^{\mathcal{U}} A$ for all \mathcal{L} -models \mathcal{U} and for all x in W . Also, we say that a set S of sentences is \mathcal{L} -satisfiable iff there is an \mathcal{L} -model \mathcal{U} and member x of W such that for all sentences A in S , $\models_x^{\mathcal{U}} A$. Clearly, we have that $\models_{\mathcal{L}} A$ iff the unit set $\{\neg A\}$ is not \mathcal{L} -satisfiable.

Again, we may introduce a semantic notion parallel to that of (proof-theoretic) derivability: we say that a sentence A is *semantically \mathcal{L} -entailed* by a set S of sentences (in symbols: $S \models_{\mathcal{L}} A$) iff $S \cup \{\neg A\}$ is not \mathcal{L} -satisfiable.

We then have that $\models_{\mathcal{L}} A$ iff $\emptyset \models_{\mathcal{L}} A$.

11 SEMANTIC SOUNDNESS AND COMPLETENESS OF THE SMILEY–HANSON SYSTEMS

THEOREM 24 (Soundness Theorem). *Let \mathcal{L} be any of the systems **OK, OM, OS4, . . . OS5⁺**. Then, for all $A \in \Sigma$, if $\vdash_{\mathcal{L}} A$, then $\models_{\mathcal{L}} A$. In other words, all \mathcal{L} -provable sentences are \mathcal{L} -valid.*

Proof. [Outlined] For each system \mathcal{L} we must show that (i) every instance of every axiom schema of \mathcal{L} is \mathcal{L} -valid, and that (ii) the rules R1 and R2 preserve \mathcal{L} -validity. Then, we can verify by inductions on the length of proof in \mathcal{L} that if $\vdash_{\mathcal{L}} A$, then $\models_{\mathcal{L}} A$. To do this is a bit tedious, for sure, but

entirely routine. Let us give just one example here in order to illustrate the methodology, or strategy, of argument. ■

EXAMPLE 25. Suppose we want to check that all instances of A5 are indeed **OS5**-valid. Assume otherwise, then, i.e. that there is a sentence A such that, for some **OS5**-model $\mathcal{U} = \langle \mathcal{W}, \mathcal{R}, \mathcal{V} \rangle$ and some x in W , we have:

(1) it is not the case that $\frac{\mathcal{U}}{x} POA \rightarrow OA$

Applying relevant truth conditions sufficiently many times to (1), we reduce it to

(2) $\frac{\mathcal{U}}{x} POA$ and $\frac{\mathcal{U}}{x} P\neg A$.

Applying the truth condition for P , we obtain from (2):

(3) $\frac{\mathcal{U}}{y} OA$, for some y in W with xRy

as well as

(4) $\frac{\mathcal{U}}{z} \neg A$, for some z in W with xRz .

Since \mathcal{U} is an **OS5**-model, R is Euclidean in W ; hence we obtain

(5) yRz (because, by (3) and (4), xRy and xRz).

Then, applying the truth condition for O to (3), we get from (5):

(6) $\frac{\mathcal{U}}{z} A$

which result contradicts (4), as the latter gives us

(7) not $\frac{\mathcal{U}}{z} A$

by the truth condition for \neg . Contradiction.

COROLLARY 26. *Let \mathcal{L} be as usual and let $S \subseteq \Sigma$ be any set of sentences. Then, if S is \mathcal{L} -satisfiable, then S is \mathcal{L} -consistent.*

Proof. Assume otherwise, i.e., that some S is \mathcal{L} -satisfiable but not \mathcal{L} -consistent. Then, by the definition of \mathcal{L} -inconsistency, there are B_1, \dots, B_n in S such that $\vdash_{\mathcal{L}} (B_1 \wedge \dots \wedge B_n) \rightarrow \perp$. Hence, by the Soundness Theorem, $\frac{\mathcal{U}}{\mathcal{L}} (B_1 \wedge \dots \wedge B_n) \rightarrow \perp$. But this means that for some x in the model \mathcal{U} , whose

existence is guaranteed by S being \mathcal{L} -satisfiable, we have $\frac{\mathcal{U}}{x} B_1 \wedge \dots \wedge B_n$

as well as $\frac{\mathcal{U}}{x} (B_1 \wedge \dots \wedge B_n) \rightarrow \perp$, hence $\frac{\mathcal{U}}{x} \perp$. Contradiction. \blacksquare

THEOREM 27 (Completeness Theorem). *Version I (strong completeness). Let \mathcal{L} be as usual and let $S \subseteq \Sigma$. Then, if S is \mathcal{L} -consistent, then S is \mathcal{L} -satisfiable. Version II (weak completeness). Let \mathcal{L} be as usual and let*

$A \in \Sigma$. Then, if $\models_{\mathcal{L}} A$, then $\vdash_{\mathcal{L}} A$. In other words, all \mathcal{L} -valid sentences are \mathcal{L} -provable.

Proof. Let us first see how the weak version can be obtained as a corollary of the strong one. Assume, contrary to the weak version, that for some sentence A , $\models_{\mathcal{L}} A$ but not $\vdash_{\mathcal{L}} A$. Then, $\{\neg A\}$ must be \mathcal{L} -consistent (otherwise, we would have $\{\neg A\} \vdash_{\mathcal{L}} \perp$, $\vdash_{\mathcal{L}} \neg A \rightarrow \perp$, and $\vdash_{\mathcal{L}} A$; but we assumed: not $\vdash_{\mathcal{L}} A$). Therefore, by the strong version I, $\{\neg A\}$ is \mathcal{L} -satisfiable, i.e. for some \mathcal{L} -model \mathcal{U} and for some x in W , $\models_x^{\mathcal{U}} \neg A$, so not $\models_x^{\mathcal{U}} A$. But this result conflicts with $\models_{\mathcal{L}} A$. Contradiction. ■

We are then justified in concentrating our efforts on establishing the strong version I of the Completeness Theorem. We begin by calling attention to the following definitions and lemmata.

DEFINITION 28 (\mathcal{L} -saturated sets). Let \mathcal{L} be as usual and let $x \subseteq \Sigma$ be any set of sentences. We say that x is \mathcal{L} -saturated iff

- (i) x is \mathcal{L} -consistent, and
- (ii) for each sentence A , either $A \in x$ or $\neg A \in x$.

LEMMA 29 (\mathcal{L} -saturated sets). Let x be any \mathcal{L} -saturated set of sentences. Then, for all sentences A, B :

- (i) Every \mathcal{L} -provable sentence is in x .
- (ii) x is closed under modus ponens (if $A \in x$ and $A \rightarrow B \in x$, then $B \in x$).
- (iii) $T \in x$.
- (iv) $\perp \notin x$.
- (v) $\neg A \in x$ iff $A \notin x$.
- (vi) $A \wedge B \in x$ iff $A \in x$ and $B \in x$.
- (vii) $A \vee B \in x$ iff $A \in x$ or $B \in x$.
- (viii) $A \rightarrow B \in x$ iff if $A \in x$ then $B \in x$.
- (ix) $A \Leftrightarrow B \in x$ iff $A \in x$ if and only if $B \in x$.

Proof. Familiar. ■

LEMMA 30 (Lindenbaum's Lemma). *Any \mathcal{L} -consistent set x of sentences can be extended to an \mathcal{L} -saturated set x^+ with $x \subseteq x^+$ (\mathcal{L} being as usual).*

Proof. See, e.g. Makinson [1966, p. 381 f]. ■

LEMMA 31 (Makinson's Lemma). *Let \mathcal{L} be as usual and let x be any \mathcal{L} -saturated set of sentences. Let A be any sentence such that $\neg OA \in x$. Let $x_A = \{B \in \Sigma : OB \in x\} \cup \{\neg A\}$. Then x_A is \mathcal{L} -consistent.*

Proof. (see Makinson [1966, p. 382]). Suppose x_A is not \mathcal{L} -consistent. Then there are sentences B_1, \dots, B_n ($n \geq 0$) such that each $OB_i \in x$ and such that $\vdash_{\mathcal{L}}(B_1 \wedge \dots \wedge B_n \wedge \neg A) \rightarrow \perp$; by virtue of the fact that axiom schema A0 is in every \mathcal{L} , then, such that

$$\vdash_{\mathcal{L}}(B_1 \wedge \dots \wedge B_n) \rightarrow A.$$

Consider first the case where $n = 0$. This means that $\vdash_{\mathcal{L}}A$. Then by the rule R2 of O -necessitation (common to all our \mathcal{L}), we have $\vdash_{\mathcal{L}}OA$. Hence, by the Lemma on \mathcal{L} -saturated sets, $OA \in x$. Thus, OA and $\neg OA$ are both in x , so x is \mathcal{L} -inconsistent. Contradiction.

Consider next the case where $n \geq 1$. Since $\vdash_{\mathcal{L}}(B_1 \wedge \dots \wedge B_n) \rightarrow A$, we have by a tautology under A0 and R1 that $\vdash_{\mathcal{L}}B_1 \rightarrow (B_2 \rightarrow \dots (B_n \rightarrow A) \dots)$. Hence, by R2, $\vdash_{\mathcal{L}}OB_1 \rightarrow (B_2 \rightarrow \dots (B_n \rightarrow A) \dots)$. Hence, using axiom schema A2 (common to all our \mathcal{L}) n times, together with R1 and appropriate tautologies under A0, we obtain that $\vdash_{\mathcal{L}}OB_1 \rightarrow (OB_2 \rightarrow \dots (OB_n \rightarrow OA) \dots)$. Hence, by the Lemma on \mathcal{L} -saturated sets, that sentence is in x . But each $OB_i \in x$, so, by the same Lemma (clause (ii)) applied n times, $OA \in x$. Thus, OA and $\neg OA$ are both in x , so x is \mathcal{L} -inconsistent. Contradiction. ■

DEFINITION 32 (Canonical \mathcal{L} -models). Let \mathcal{L} , as usual, be any of our ten monadic deontic logics, and let S be any \mathcal{L} -consistent set of sentences, so that, by Lindenbaum's Lemma, S^+ is \mathcal{L} -saturated and $S \subseteq S^+$. By the *canonical \mathcal{L} -model generated by S* we mean the structure

$$\mathcal{U}_{\mathcal{L}} = \langle \mathcal{W}_{\mathcal{L}}, \mathcal{R}_{\mathcal{L}}, \mathcal{V}_{\mathcal{L}} \rangle$$

where:

- (i) $\mathcal{W}_{\mathcal{L}}$ = the smallest collection U of \mathcal{L} -saturated sets such that:
 - (a) S^+ is in U .
 - (b) If x is in U , and A is a sentence with $\neg OA \in x$, then $(x_A)^+$ is in U (where x_A is defined as in Makinson's Lemma).
- (ii) $\mathcal{R}_{\mathcal{L}}$ = the binary relation on $\mathcal{W}_{\mathcal{L}}$ such that for all x, y in $\mathcal{W}_{\mathcal{L}}$: $x\mathcal{R}_{\mathcal{L}}y$ iff for all sentences A , whenever $OA \in x$ then $A \in y$.

- (iii) $V_{\mathcal{L}}$ = the assignment defined as follows: for each proposition letter p and each x in $W_{\mathcal{L}}$, $V(p, x) = 1$ iff $p \in x$.

LEMMA 33 (Verification Lemma). *As just defined, $\mathcal{U}_{\mathcal{L}} = \langle W_{\mathcal{L}}, \mathcal{R}_{\mathcal{L}}, \mathcal{V}_{\mathcal{L}} \rangle$ is an \mathcal{L} -model.*

LEMMA 34 (Coincidence Lemma). *For each sentence A and for each x in $W_{\mathcal{L}}$ (as defined above), $\frac{\mathcal{U}_{\mathcal{L}}}{x} A$ iff $A \in x$.*

We shall wait a little with the proofs of these two lemmata. Instead, let us see how they together yield Version I of the Completeness Theorem.

Proof. [Completeness Theorem] (Version I): Letting \mathcal{L} be as usual, assume S to be any \mathcal{L} -consistent set of sentences. We are to show that S is \mathcal{L} -satisfiable. Well, by the Verification Lemma, $\mathcal{U}_{\mathcal{L}}$ (as just defined) is an \mathcal{L} -model. By the Coincidence Lemma, we obtain in particular that for each sentence A , $\frac{\mathcal{U}_{\mathcal{L}}}{S^+} A$ iff $A \in S^+$ (as S^+ , by definition, belongs to $W_{\mathcal{L}}$). Hence, since $S \subseteq S^+$, we have $\frac{\mathcal{U}_{\mathcal{L}}}{S^+} A$ for every A in S . In other words, assuming S to be any \mathcal{L} -consistent set of sentences, we have constructed an \mathcal{L} -model, viz. $\mathcal{U}_{\mathcal{L}}$, such that for some x in $W_{\mathcal{L}}$, viz. S^+ , $\frac{\mathcal{U}_{\mathcal{L}}}{x} A$ for each A in S ; i.e. we have shown S to be \mathcal{L} -satisfiable. ■

We still need one more lemma before being able to establish the Verification Lemma and the Coincidence Lemma (the proofs of which have not yet been given):

LEMMA 35 (Saturation Lemma for canonical \mathcal{L} -models). *Let \mathcal{L} be as usual, let S be any \mathcal{L} -consistent set of sentences, and let $\mathcal{U}_{\mathcal{L}}$ be defined as above. Then, $W_{\mathcal{L}}$ is such that for all sentences A and all x in $W_{\mathcal{L}}$:*

- (i) $OA \in x$ iff for all y in $W_{\mathcal{L}}$ with $xR_{\mathcal{L}}y$, $A \in y$.
- (ii) $PA \in x$ iff there is a y in $W_{\mathcal{L}}$ such that $xR_{\mathcal{L}}y$ and $A \in y$.

Proof. (From now on we shall use $\&$, \supset , \forall , \exists etc. as metalinguistic shorthands with their familiar meanings and use ' x ', ' y ', ' z ' as variables over $W_{\mathcal{L}}$.)

Ad(i): The 'only if' part is easy — assume, for any x, y in $W_{\mathcal{L}}$:

- 1. $OA \in x$ hypothesis
- 2. $xR_{\mathcal{L}}y$ hypothesis

Then:

- | | | |
|----|--|--|
| 3. | $\forall B(OB \in x \supset B \in y)$ | from 2 by the definition of $R_{\mathcal{L}}$ |
| 4. | $A \in y$ | 1,3, universal instantiation,
modus ponens |
| 5. | $OA \in x \supset (xR_{\mathcal{L}}y \supset A \in y)$ | 1–4, rule of conditional proof,
discharging 1 and 2 |
| 6. | $\forall x, y(OA \in x \supset (xR_{\mathcal{L}}y \supset A \in y))$ | x, y any members of $W_{\mathcal{L}}$ |

Number 6 can easily be rewritten as the ‘only if’ half of (i)

Again, to do the ‘if’ part, assume for any x in $W_{\mathcal{L}}$:

- | | | |
|----|---------------|------------|
| 1. | $OA \notin x$ | hypothesis |
|----|---------------|------------|

Then:

- | | | |
|-----|--|--|
| 2. | $\neg OA \in x$ | from 1 by the Lemma on \mathcal{L} -
saturated sets |
| 3. | $\neg A \in x_A$ | by the definition of x_A in
Makinson’s Lemma |
| 4. | $\neg A \in (x_A)^+$ | $x_A \subseteq (x_A)^+$ by Lindenbaum |
| 5. | $A \notin (x_A)^+$ | from 4 by the Lemma on \mathcal{L} -
saturated sets |
| 6. | $(x_A)^+ \in W_{\mathcal{L}}$ | by the definition of $W_{\mathcal{L}}$ and
2 |
| 7. | $\forall B(OB \in x \supset B \in (x_A)^+)$ | by the definition of x_A in
Makinson’s Lemma |
| 8. | $xR_{\mathcal{L}}(x_A)^+$ | from 7 by the definition of
$R_{\mathcal{L}}$ |
| 9. | $\exists y(xR_{\mathcal{L}}y \& A \notin y)$ | from 5,6,8 by existential
generalization, the y at issue
being $(x_A)^+$ |
| 10. | $OA \notin x \supset \exists y(xR_{\mathcal{L}}y \& A \notin y)$ | 1–9, conditional proof, dis-
charging 1 |
| 11. | $\forall y(xR_{\mathcal{L}}y \supset A \in y) \supset OA \in x$ | from 10 by contraposition |

where 11 is the desired ‘if’ half of (i).

Ad (ii): The verification of (ii) can be left to the reader. *Hint*: appeal to the fact that every instance of A1, i.e. $PA \Leftrightarrow \neg O\neg A$, is in every \mathcal{L} -saturated

set.

The proof of the Saturation Lemma for Canonical \mathcal{L} -Models is complete. ■

Let us now deal with our unproven lemmas and start with the easiest one (or, at least, the one with the shortest proof):

Proof. [The Coincidence Lemma] For each wff A and each x in $W_{\mathcal{L}}$, $\frac{\mathcal{U}_{\mathcal{L}}}{x}A$ iff $A \in x$.

The proof proceeds by induction on the length of A .

Basis. A is either (a) \top , or (b) \perp , or (c) some proposition letter p .

- (a) $\frac{\mathcal{U}_{\mathcal{L}}}{x}\top$ and $\top \in x$ (by the truth condition for \top and by the Lemma on \mathcal{L} -saturated sets),
- (b) not $\frac{\mathcal{U}_{\mathcal{L}}}{x}\perp$ and $\perp \notin x$ (correspondingly),
- (c) $\frac{\mathcal{U}_{\mathcal{L}}}{x}p$ iff $V_{\mathcal{L}}(p, x) = 1$ iff $p \in x$ (by the truth condition for proposition letters and by the definition of $V_{\mathcal{L}}$).

Induction Step. The inductive cases for $\neg, \wedge, \vee, \rightarrow$ and \Leftrightarrow are trivial, using the Lemma on \mathcal{L} -saturated sets. Consider then *Case* $A = OB$ (for some wff B): We would like to argue that $\frac{\mathcal{U}_{\mathcal{L}}}{x}OB$ iff for all y in $W_{\mathcal{L}}$ such that $xR_{\mathcal{L}}y$, $\frac{\mathcal{U}_{\mathcal{L}}}{y}B$, iff, for all y in $W_{\mathcal{L}}$ such that $xR_{\mathcal{L}}y$, $B \in y$, iff, $OB \in x$. Well, the first ‘iff’ holds by the definition of truth, the second is guaranteed by the inductive hypothesis, and the third ‘iff’ is simply clause (i) of the Saturation Lemma for canonical \mathcal{L} -models. Thus, we are done. *Case*

$A = PB$: The reasoning is perfectly analogous, the third ‘iff’ being clause (ii) of that lemma.

The proof of the Coincidence Lemma is complete. ■

Proof. *Missing Proof of the Verification Lemma.* As defined in the Definition of Canonical \mathcal{L} -Models, $\mathcal{U}_{\mathcal{L}} = \langle W_{\mathcal{L}}, R_{\mathcal{L}}, V_{\mathcal{L}} \rangle$ is an \mathcal{L} -model.

We have to consider various cases in the proof, depending on how we identify the logic $\mathcal{L} \in \{\mathbf{OK}, \mathbf{OM}, \mathbf{OS4}, \mathbf{OB}, \mathbf{OS5}, \mathbf{OK}^+, \mathbf{OM}^+, \mathbf{OS4}^+, \mathbf{OB}^+, \mathbf{OS5}^+\}$. The detailed demonstration in each case will not be given here; instead the reader is referred to Åqvist [1987, Section 10.1.11] for desired details. This completes our account of the Completeness Theorem for the ten Smiley–Hanson systems of monadic deontic logic. ■

IV. REPRESENTABILITY OF MONADIC DEONTIC LOGICS IN
SYSTEMS OF ALETHIC MODAL LOGIC WITH A PROPOSITIONAL
CONSTANT

12 TEN ALETHIC MODAL LOGICS WITH A PROPOSITIONAL
CONSTANT

In this section we define ten systems $\mathbf{K}_Q, \mathbf{M}_Q, \mathbf{S4}_Q, \mathbf{B}_Q, \mathbf{S5}_Q, \mathbf{K}_Q^+, \mathbf{M}_Q^+, \mathbf{S4}_Q^+, \mathbf{B}_Q^+$ and $\mathbf{S5}_Q^+$ of alethic modal logic with a *prohairesis*, i.e. preference-theoretical, propositional constant Q (after Kanger [1957]). They are all based on a common formal language, which we are now going to describe. Its *alphabet* is like that of the language of the Smiley–Hanson systems except that:

- (i) \Box (necessity) and \Diamond (possibility) replace O and P , respectively, among the primitive logical connectives of degree 1.
- (ii) A propositional constant Q (for ‘optimality’ or ‘admissibility’) is added to the primitive logical connectives of degree 0.

The set Σ of all *sentences* of our new language is then defined as in the old language except that clause (b) reads:

- (b) \top, \perp and Q are in S

and clause (c) reads:

- (c) if A is in S , then so are $\neg A, \Box A$ and $\Diamond A$.

We must point out here explicitly that the set Prop of our new alethic language is assume to be identical to the set Prop of our old, deontic language.

DEFINITION 36.

$$OA = \text{df } \Box(Q \rightarrow A)$$

$$PA = \text{df } \Diamond(Q \wedge A)$$

$$FA = \text{df } \Box(Q \rightarrow \neg A)$$

As for the *proof theory* of our ten alethic systems, the following two *rules of inference* are common to all of them:

$$(R1) \quad \frac{A, A \rightarrow B}{B} \quad (\textit{modus ponens})$$

$$(R2') \quad \frac{A}{\Box A} \quad (\Box\text{-necessitation})$$

Consider then the following list B0–B7 of *axiom schemata*:

- (B0) All truth functional tautologies (over our new language)
- (B1) $\diamond A \Leftrightarrow \neg \Box \neg A$,
- (B2) $\Box(A \rightarrow B) \rightarrow (\Box A \rightarrow \Box B)$,
- (B3) $\diamond Q$,
- (B4) $\Box A \rightarrow \Box \Box A$,
- (B5) $\diamond \Box A \rightarrow \Box A$,
- (B6) $\Box A \rightarrow A$,
- (B7) $\diamond \Box A \rightarrow A$,

Assuming R1 and R2' for all ten alethic modal logics with Q , then, we define them as follows:

- $\mathbf{K}_Q = \text{B0–B2}$
- $\mathbf{M}_Q = \text{B0–B2, B6}$
- $\mathbf{S4}_Q = \text{B0–B2, B4, B6}$
- $\mathbf{B}_Q = \text{B0–B2, B6, B7}$
- $\mathbf{S5}_Q = \text{B0–B2, B5, B6}$ (note that B4 and B7 are derivable in $\mathbf{S5}_Q$)

Again let \mathcal{K} be any of these five systems. Then:

$$\mathcal{K}^+ = \mathcal{K}, \text{B3}$$

We observe that, apart from the presence of Q in the alethic language, the first five systems are familiar from literature on basic modal logic (see e.g. Kripke [1963], Makinson [1966], Lemmon and Scott [1966], Hughes and Cresswell [1968]). The remaining five logics, the + systems, are then formed by adding a consistency postulate for Q , viz. B3, just as in Smiley [1963].

Let \mathcal{K} be any of the ten systems just defined. We introduce the notions of \mathcal{K} -provability, \mathcal{K} -inconsistency, \mathcal{K} -consistency and \mathcal{K} -derivability in perfect analogy with the corresponding \mathcal{L} -notions defined for the Smiley–Hanson deontic logics. We write ' $\vdash_{\mathcal{K}} A$ ' and ' $S \vdash_{\mathcal{K}} A$ ' to indicate, respectively, that the sentence A is \mathcal{K} -provable and that A is \mathcal{K} -derivable from a set S of sentences.

Turning then to the *semantics* for our ten alethic systems, we obviously need a fresh notion of model. So, by an *alethic model* (perhaps we should even say 'alethic prohairetic model', but it is too long) we shall mean an ordered quadruple

$$U = \langle \mathcal{W}, \mathcal{R}^{\S}, \text{opt}, \mathcal{V} \rangle$$

where:

- (i) W is a non-empty set.
- (ii) $R^{\S} \subseteq W \times W$ is a binary relation on W (of ‘alethic alternativeness’ or ‘alethic accessibility’).
- (iii) $\text{opt} \subseteq W$ (heuristically, opt is to be the set of ‘optimal’, ‘best’ or ‘sufficiently good’ elements of W according to some unspecified preference ordering on W).
- (iv) $V : \text{Prop} \times W \rightarrow \{1, 0\}$ (as usual).

Now, let \mathcal{U} be any alethic model, let x be any member of W , and let A be in Σ . The following changes in the definition of *truth at x in \mathcal{U}* are then called for: replace the clauses for O and P by the following, respectively:

$$\begin{aligned} \frac{\mathcal{U}}{x} \Box A & \text{ iff } \text{for every } y \text{ in } W \text{ with } xR^{\S}y, \frac{\mathcal{U}}{y} A. \\ \frac{\mathcal{U}}{x} \Diamond A & \text{ iff } \text{for some } y \text{ in } W \text{ with } xR^{\S}y, \frac{\mathcal{U}}{y} A. \end{aligned}$$

Moreover, we add a clause governing the constant Q :

$$\frac{\mathcal{U}}{x} Q \text{ iff } x \in \text{opt}.$$

Conditions on R^{\S} and opt in alethic models. Corresponding to the five axiom schemata B3–B7 we now list five conditions on R^{\S} and opt in an alethic model (adhering to previously adopted notational conventions):

- r3. R^{\S} is ‘opt-serial’ in W : $\forall x \exists y (xR^{\S}y \ \& \ y \in \text{opt})$
- r4. R^{\S} is transitive in W .
- r5. R^{\S} is Euclidean in W .
- r6. R^{\S} is reflexive in W : $\forall x (xR^{\S}x)$
- r7. R^{\S} is symmetric in W : $\forall x, y (xR^{\S}y \supset yR^{\S}x)$

Classification of alethic models. We summarize our categorization of alethic models in the self-explanatory Table 1:

Validity and satisfiability. Let $\mathcal{K} \in \{\mathbf{K}_Q, \mathbf{M}_Q, \mathbf{S4}_Q, \mathbf{B}_Q, \mathbf{S5}_Q, \mathbf{K}_Q^+, \mathbf{M}_Q^+, \mathbf{S4}_Q^+, \mathbf{B}_Q^+, \mathbf{S5}_Q^+\}$. The notions of \mathcal{K} -*validity*, \mathcal{K} -*satisfiability*, and *semantic \mathcal{K} -entailment* are then defined in perfect analogy with the corresponding \mathcal{L} -notions, and the notations $\frac{\mathcal{U}}{\mathcal{K}} A$ and $S \frac{\mathcal{U}}{\mathcal{K}} A$ will be used with their obvious meaning.

Table 1.

Kind of alethic model	Condition on R^{\S} and opt
K_Q	No restriction on R^{\S} or on opt
M_Q	R^{\S} reflexive (in W)
$S4_Q$	R^{\S} transitive and reflexive
B_Q	R^{\S} symmetric and reflexive
$S5_Q$	R^{\S} Euclidean and reflexive
K_Q^+	R^{\S} opt-serial (in W)
M_Q^+	R^{\S} opt-serial and reflexive
$S4_Q^+$	R^{\S} opt-serial, transitive and reflexive
B_Q^+	R^{\S} opt-serial, symmetric and reflexive
$S5_Q^+$	R^{\S} opt-serial, Euclidean and reflexive (in W)

13 SEMANTIC SOUNDNESS AND COMPLETENESS OF THE TEN ALETHIC SYSTEMS

THEOREM 37. *Let \mathcal{K} be any of the ten systems $\mathbf{K}_Q, \mathbf{M}_Q, \dots, \mathbf{S5}_Q^+$. Then, all \mathcal{K} -provable sentences are \mathcal{K} -valid.*

Proof.[Outlined] Proceed just as in the case of the \mathcal{L} -systems of monadic deontic logic. ■

EXAMPLE 38. Suppose we want to check that the axiom $\diamond Q (=B3)$ is indeed \mathbf{K}_Q^+ -valid. Assume otherwise then, i.e. that for some \mathbf{K}_Q^+ -model $\mathcal{U} = \langle W, R^{\S}, \text{opt}, \mathcal{V} \rangle$ and some x in W , we have:

$$(1) \quad \text{not } \frac{\mathcal{U}}{x} \diamond Q.$$

By the truth conditions for \diamond and Q , (1) amounts to:

$$(2) \quad \text{not } \exists y (xR^{\S}y \ \& \ y \in \text{opt}).$$

But, by the opt-seriality of R^{\S} in \mathbf{K}_Q^+ -models (see the table above), we have:

$$(3) \quad \exists y(xR^{\S}y \ \& \ y \in \text{opt}).$$

Contradiction. Hence B3 is \mathbf{K}_Q^+ -valid.

THEOREM 39 (Completeness Theorem).

Version I (strong completeness). *Let \mathcal{K} be as usual and let $S \subseteq \Sigma$. Then, if S is \mathcal{K} -consistent, then S is \mathcal{K} -satisfiable.*

Version II (weak completeness). *Let \mathcal{K} be as usual. Then, all \mathcal{K} -valid sentences are \mathcal{K} -provable.*

Proof (Outlined). Obtaining the weak version as a corollary of the strong one, we concentrate on the latter. The Definition of and the Lemma (Lss) on \mathcal{L} -saturated sets are restated for the \mathcal{K} -systems without any significant changes. Similarly for Lindenbaum's Lemma. In Makinson's Lemma we replace every reference to O by a reference to \Box and use R2' and B2 in the place of R2 and A2; the Lemma then goes through nicely for the \mathcal{K} -systems as well.

We come next to canonical models:

DEFINITION 40 (Canonical \mathcal{K} -models). Let \mathcal{K} be as usual and let S be any \mathcal{K} -consistent set of sentences. By the *canonical \mathcal{K} -model generated by S* we mean the structure

$$\mathcal{U}_{\mathcal{K}} = \langle W_{\mathcal{K}}, \mathcal{R}_{\mathcal{K}}^{\S}, \text{opt}_{\mathcal{K}}, \mathcal{V}_{\mathcal{K}} \rangle$$

where:

(i) $W_{\mathcal{K}}$ = the smallest collection U of \mathcal{K} -saturated sets such that:

(a) S^+ is in U .

(b) If x is in U , and A is a sentence with $\neg\Box A \in x$, then $(x_A)^+$ is in U (where x_A is defined as in our reformulated Makinson's Lemma).

(ii) $\mathcal{R}_{\mathcal{K}}^{\S}$ = the binary relation on $W_{\mathcal{K}}$ such that for all x, y in $W_{\mathcal{K}}$:

$$xR_{\mathcal{K}}^{\S}y \text{ iff } \forall A(\Box A \in x \supset A \in y).$$

(iii) $\text{opt}_{\mathcal{K}} = \{x \in W_{\mathcal{K}} : Q \in x\}$.

(iv) $\mathcal{V}_{\mathcal{K}}$ = the assignment defined as follows: $\mathcal{V}_{\mathcal{K}}(p, x) = 1$ iff $p \in x$ (for all $p \in \text{Prop}$ and $x \in W_{\mathcal{K}}$).

LEMMA 41 (Verification Lemma.). *As just defined, $\mathcal{U}_K = \langle \mathcal{W}_K, \mathcal{R}_K^{\S}, \text{opt}_K, V_K \rangle$ is a \mathcal{K} -model.*

LEMMA 42 (Coincidence Lemma.). *For each sentence A and each x in $W_K : \frac{\mathcal{U}_K}{x} A$ iff $A \in x$.*

Waiting a little with the proofs of these lemmata, we establish that they together yield the strong completeness of the systems \mathcal{K} by an argument perfectly analogous to the one used in connection with the \mathcal{L} -systems.

Again, the crucial clauses of the *Saturation Lemma for Canonical \mathcal{K} -Models* are as follows:

- (i) $\Box A \in x$ iff for all y in W_K with $xR_K^{\S}y$, $A \in y$.
- (ii) $\Diamond A \in x$ iff there is a y in W_K such that $xR_K^{\S}y$ and $A \in y$.

The proof of this lemma parallels the one given in the \mathcal{L} -case; just replace O by \Box , P by \Diamond , and so on.

Proof. *Proof of the Coincidence Lemma.* There is a new case in the induction basis, viz.

Case $A = Q$. We are to show that $\frac{\mathcal{U}_K}{x} Q$ iff $Q \in x$. Well, we have that $\frac{\mathcal{U}_K}{x} Q$ iff $x \in \text{opt}_K$ iff $Q \in x$; where the first ‘iff’ comes from the truth condition for Q and the second from the definition of opt_K in canonical \mathcal{K} -models (clause (iii)). So we are done.

The novel cases in the induction step are those where $A = \Box B$ and $A = \Diamond B$; they are handled in perfect analogy with the cases $A = OB$ and $A = PB$ in the corresponding proof for the \mathcal{L} -systems. For the critical ‘iff’s, appeal to the Saturation Lemma for Canonical \mathcal{K} -Models. ■

Proof. *Proof of the Verification Lemma.* The cases where $\mathcal{K} \in \{\mathbf{K}_Q, \mathbf{M}_Q, \mathbf{S4}_Q, \mathbf{B}_Q, \mathbf{S5}_Q\}$ are familiar from the literature on basic modal logic (see, e.g. Makinson [1966] and Lemmon and Scott [1966]). The only new thing to be verified in these five cases is that opt_K , as we have defined it, is a subset of W_K ; which is a completely trivial point in view of clause (iii) of our Definition of Canonical \mathcal{K} -Models. As for the remaining five alethic systems, consider:

Case $\mathcal{K} = \mathbf{K}_Q^+$. We are required to show that the relation $R_{K_Q^+}^{\S}$ is opt-serial in $W_{K_Q^+}$ in the sense that $\forall x \exists y (xR_{K_Q^+}^{\S}y \ \& \ y \in \text{opt}_{K_Q^+})$. Well, in regard of any x in $W_{K_Q^+}$, we have by Lss:

- | | | |
|----|--|---|
| 1. | $\Diamond Q \in x$ | B3 for \mathbf{K}_Q^+ |
| 2. | $\exists y(xR_{K_Q^+}^{\S}y \ \& \ Q \in y)$ | from 1 by clause (ii) of the Saturation Lemma for Canonical \mathcal{K} -Models |
| 3. | $\exists y(xR_{K_Q^+}^{\S}y \ \& \ y \in \text{opt}_{K_Q^+})$ | from 2 by the definition of $\text{opt}_{K_Q^+}$ |
| 4. | $\forall x\exists y(xR_{K_Q^+}^{\S}y \ \& \ y \in \text{opt}_{K_Q^+})$ | from 3 by universal generalization, x being <i>any</i> member of $W_{K_Q^+}$ |

where 4 = Q.E.D. The remaining cases present no novelties, so the proof of the Verification Lemma is complete. The Completeness Theorem for the ten alethic \mathcal{K} -systems is thereby fully proved. ■

14 THE PROBLEM OF ISOLATING THE DEONTIC FRAGMENT OF THE \mathcal{K} -SYSTEMS

14.1 Problem

Let Σ be the set of sentences of our *alethic* language (common to the \mathcal{K} -systems) and let Σ_0 be the set of sentences of our *deontic* language (common to the Smiley–Hanson \mathcal{L} -systems); we now need different labels for the two sets. Let \mathcal{K} , as usual, be any of the ten alethic systems with the constant Q . Then, *exactly* which sentences in Σ_0 are provable in \mathcal{K} , using the \mathcal{K} -definitions of O and P ? where the latter are:

$$OA = \text{df } \Box(Q \rightarrow A), \quad PA = \text{df } \Diamond(Q \wedge A).$$

In other words, the problem is to characterize, for each \mathcal{K} , the set of deontic sentences which are provable in \mathcal{K} on the basis of those two definitions (meaning by ‘deontic sentence any member of Σ_0) A third formulation of our task: for each \mathcal{K} , isolate the deontic fragment of \mathcal{K} !

Now, the locution ‘sentence in Σ_0 provable in \mathcal{K} using the \mathcal{K} -definitions of O and P ’, which crops up in these formulations, is not entirely clear, or, at least, could be made more precise. To that purpose, we suggest that the \mathcal{K} -definitions of O and P in effect amount to there being a certain function which maps our deontic language into the alethic one in the following way:

DEFINITION 43 (The translation ϕ from Σ_0 into Σ). For each sentence A in Σ_0 , define $\phi(A) \in \Sigma$ by the following recursive conditions:

- (i) $\phi(p) = p$, for each proposition letter p ,
- (ii) $\phi(\top) = \top$,
- (iii) $\phi(\perp) = \perp$,
- (iv) $\phi(\neg A) = \neg\phi(A)$,
- (v) $\phi(A \wedge B) = \phi(A) \wedge \phi(B)$.

Similarly for $\phi(A \vee B)$, $\phi(A \rightarrow B)$ and $\phi(A \leftrightarrow B)$.

- (vi) $\phi(OA) = \Box(Q \rightarrow \phi(A))$
- (vii) $\phi(PA) = \Diamond(Q \wedge \phi(A))$

Clearly, (vi) and (vii) are the only interesting clauses in this definition, because we easily verify by induction on the length of A that $\phi(A) = A$, provided that A does not contain O or P . Note how (vi) and (vii) correspond to the \mathcal{K} -definitions of O and P . Note also the importance of our assumption that the alethic and the deontic language have *the same* set Prop of proposition letters (why is that assumption important in the present context?)

In the sequel we shall often write ϕA instead of $\phi(A)$.

We need one more definition in order to be able to give a precise formulation of our problem.

DEFINITION 44 (The deontic fragment of \mathcal{K} under ϕ). Let \mathcal{K} be as usual, and let ϕ be the translation from Σ_0 into Σ as just defined. By *the deontic fragment of \mathcal{K} under ϕ* (in symbols: $\text{DF}(\mathcal{K}, \phi)$) we mean the set of sentences A in Σ_0 such that ϕA is provable in \mathcal{K} ; more compactly expressed:

$$\text{DF}(\mathcal{K}, \phi) = \{A \in \Sigma_0 : \vdash_{\mathcal{K}} \phi A\}.$$

Since the translation ϕ is fixed, we may drop the reference to it and speak simply of the deontic fragment of \mathcal{K} , $\text{DF}(\mathcal{K})$, in accordance with the convention

$$\text{DF}(\mathcal{K}) = \text{DF}(\mathcal{K}, \phi)$$

for \mathcal{K} as usual.

A precise version of the problem raised at the beginning of this section is then the following:

14.2 The problem restated

Let \mathcal{K} be any of our ten alethic systems. Let \mathcal{L} be any of the ten Smiley–Hanson deontic logics and let us identify \mathcal{L} with the set of its theses so that $\mathcal{L} = \{A \in \Sigma_0 : \vdash_{\mathcal{L}} A\}$. Then, for which \mathcal{L} , if any, do we have that $\mathcal{L} = \text{DF}(\mathcal{K})$?

Let us illustrate the import of the restated problem a little. Suppose that we claim that (the set of theses of) **OM** is in fact identical to the deontic fragment of **M_Q**. What are we then claiming? According to our definitions, the following:

$$(1) \quad \mathbf{OM} = \{A \in \Sigma_0 : \vdash_{\mathbf{OM}} A\} = \{A \in \Sigma_0 : \vdash_{\mathbf{M}_Q} \phi A\} = \text{DF}(\mathbf{M}_Q).$$

Fortunately, a more intelligible rendering of (1) is available:

$$(2) \quad \text{For each sentence } A \text{ in } \Sigma_0 : \vdash_{\mathbf{OM}} A \text{ iff } \vdash_{\mathbf{M}_Q} \phi A$$

i.e. in plain language, A is provable in **OM** iff its translation ϕA is provable in **M_Q** (for any deontic sentence A).

Smiley [1963] in effect proved this result (2), i.e. that $\mathbf{OM} = \text{DF}(\mathbf{M}_Q)$. He also proved, among other things, that $\mathbf{OS4} = \text{DF}(\mathbf{S4}_Q)$, $\mathbf{OS5} = \text{DF}(\mathbf{S5}_Q)$, $\mathbf{OM}^+ = \text{DF}(\mathbf{M}_Q^+)$, $\mathbf{OS4}^+ = \text{DF}(\mathbf{S4}_Q^+)$ and $\mathbf{OS5}^+ = \text{DF}(\mathbf{S5}_Q^+)$, using algebraic techniques. We shall now restate these Smileyan results and extend them so as to obtain a full solution to the problem raised above. We do so by indicating how to prove a Translation Theorem for monadic deontic logic, applying the Henkin-style model-theoretic technique of saturated sets instead of the matrix method used by Smiley. We think that, by doing so, we not only facilitate the understanding of monadic deontic logics as such, but also will be able to see more clearly their connection with dyadic deontic logics (logics of conditional obligation and permission) and to understand better the transition from the former to the latter.

First of all, let us correlate our alethic systems to the deontic ones by defining a one-one function c from the former onto the latter. The definition of c appears from the self-explanatory Table 2.

We can now state a nice result on deontic logic:

THEOREM 45 (Translation theorem for monadic deontic logic). *(After Smiley [1963]). Let \mathcal{K} be any of the ten alethic systems $\mathbf{K}_Q, \mathbf{M}_Q, \dots, \mathbf{S5}_Q^+$, and let $c(\mathcal{K})$ be its correlate among the ten Smiley–Hanson systems according to the above table. We identify $c(\mathcal{K})$ with the set of its theses. Then, $c(\mathcal{K}) = \text{DF}(\mathcal{K})$; i.e. for each sentence A in Σ_0 : $\vdash_{c(\mathcal{K})} A$ iff $\vdash_{\mathcal{K}} \phi A$.*

The proof, which provides a solution to our present problem, is a bit lengthy, so we devote a special section to it.

Proof. (The Translation Theorem) (very broad outline)

Case $\mathcal{K} = \mathbf{K}_Q$ and $c(\mathcal{K}) = \mathbf{OK}$.

‘Only if’ part: We are to show that $\vdash_{\mathbf{OK}} A$ only if $\vdash_{\mathbf{K}_Q} \phi A$, for $A \in \Sigma_0$. We do so by induction on the length of the supposed **OK**-proof of A .

Basis. The length of the supposed **OK**-proof = 1, so A is an instance of one or other of the axiom schemata A0–A2.

Suppose A is an axiom under A0 so that A is a tautology over the deontic language. Then ϕA is a tautology over the alethic language (the detailed

Table 2.

Alethic system \mathcal{K}	Deontic system $c(\mathcal{K})$
K_Q	OK
M_Q	OM
$S4_Q$	OS4
B_Q	OB
$S5_Q$	OS5
K_Q^+	OK ⁺
M_Q^+	OM ⁺
$S4_Q^+$	OS4 ⁺
B_Q^+	OB ⁺
$S5_Q^+$	OS5 ⁺

proof of this is left to the reader), hence ϕA is an axiom under B0, hence $\overline{\mathbf{K}_Q} \phi A$.

Suppose A is an axiom under A1 so that $A = PB \Leftrightarrow \neg O \neg B$ and $\phi A = \Diamond(Q \wedge \phi B) \Leftrightarrow \neg \Box(Q \rightarrow \phi(\neg B))$, for some $B \in \Sigma_0$. The following is then a \mathbf{K}_Q -proof of ϕA :

1. $\Diamond(Q \wedge \phi B) \Leftrightarrow \neg \Box \neg(Q \wedge \phi B)$ B1
2. $\neg \Box \neg(Q \wedge \phi B) \Leftrightarrow \neg \Box(Q \rightarrow \neg \phi B)$ from B0, B2, R1, R2' by various elementary steps
3. $\Diamond(Q \wedge \phi B) \Leftrightarrow \neg \Box(Q \rightarrow \phi(\neg B))$ 1, 2, B0, R1, definition of ϕ

where 3 = ϕA . Hence, $\overline{\mathbf{K}_Q} \phi A$, as desired.

Again, suppose that A is an instance of A2 so that $\phi A = \Box(Q \rightarrow (\phi B \rightarrow \phi C)) \rightarrow (\Box(Q \rightarrow \phi B) \rightarrow \Box(Q \rightarrow \phi C))$, for some B and C in Σ_0 . The desired result to the effect that $\overline{\mathbf{K}_Q} \phi A$ is readily obtained from B0 and B2 by R2' and R1.

Induction Step. There is an **OK**-proof of A of length > 1 , and either (i)

A is got by applying R1 to some **OK**-thesis B and $B \rightarrow A$, or (ii) A is of the form OB and is obtained by applying R2 to some **OK**-thesis B .

Case (i): By the induction hypothesis ϕB and $\phi(B \rightarrow A)$ are both provable in \mathbf{K}_Q . But, by the definition of ϕ , $\phi(B \rightarrow A) = \phi B \rightarrow \phi A$, so that ϕA follows by R1. Hence, $\vdash_{\mathbf{K}_Q} \phi A$.

Case (ii): By the induction hypothesis we have $\vdash_{\mathbf{K}_Q} \phi B$ in this case. We then obtain $\vdash_{\mathbf{K}_Q} \phi(OB)$ as follows:

1. $Q \rightarrow \phi B$ $\vdash_{\mathbf{K}_Q} \phi B, B0, R1$
2. $\Box(Q \rightarrow \phi B)$ from 1 by R2'
3. $\phi(OB)$ from 2 by the definition of ϕ

where 3 = ϕA . Hence $\vdash_{\mathbf{K}_Q} \phi A$, as desired.

This completes the proof of the ‘only if’ part. ■

‘If’ part: We must show that if $\vdash_{\mathbf{K}_Q} \phi A$, then $\vdash_{\mathbf{OK}} A$, or, contrapositively, that if $\not\vdash_{\mathbf{OK}} A$, (A is *not* **OK**-provable), then $\not\vdash_{\mathbf{K}_Q} \phi A$ (ϕA is *not* \mathbf{K}_Q -provable), for any sentence A in the deontic language. This part is harder, because proof-theoretical methods seem to be less natural here; however, in view of our soundness and completeness results for the \mathcal{L} - and the \mathcal{K} -systems, the problem is not too difficult to cope with.

Strategy of argument. We would like to argue as follows:

1. $\not\vdash_{\mathbf{OK}} A$ hypothesis
2. $\not\vdash_{\mathbf{OK}} A$ from 1 by the completeness of **OK**
3. $\not\vdash_x^{\mathcal{U}} A$, for some **OK**-model $\mathcal{U} = \langle \mathcal{W}, \mathcal{R}, \mathcal{V} \rangle$ and some x in \mathcal{W} from 2 by the definition of **OK**-validity.

Consider that **OK**-model \mathcal{U} . We claim that we can construct from it a corresponding \mathbf{K}_Q -model $\mathcal{U}^* = \langle \mathcal{W}, \mathcal{R}^*, \text{opt}, \mathcal{V} \rangle$ with the property that for all $B \in \Sigma_0$ and all y in \mathcal{W} : $\vdash_y^{\mathcal{U}} B$ iff $\vdash_y^{\mathcal{U}^*} \phi B$. Then:

- | | | |
|----|---------------------------------------|--|
| 4. | $\not\vdash_x^{\mathcal{U}^*} \phi A$ | from 3 by the fact that \mathcal{U}^* exists and has the property mentioned |
| 5. | $\not\vdash_{\mathbf{K}_Q} \phi A$ | from 4 by the definition of \mathbf{K}_Q -validity, \mathcal{U}^* being a \mathbf{K}_Q -model where ϕA fails to be true at some x in W |
| 6. | $\not\vdash_{\mathbf{K}_Q} \phi A$ | from 5 by the soundness of \mathbf{K}_Q |

where 6 is our desired conclusion.

The crux of this argument is obviously isolated at a single point, viz. the construction of the \mathbf{K}_Q -model \mathcal{U}^* from the given \mathbf{OK} -model \mathcal{U} , and the proof that \mathcal{U}^* has the desired property indicated above. On the basis of that construction and proof, the crucial step from 3 to 4 is fully justified and the ‘if’ part is seen to go through in the present case. What remains to be done, then, is to state a definition and to prove a couple of nice lemmata.

DEFINITION 46 (of \mathcal{U}^*). Let $\mathcal{U} = \langle W, R, \mathcal{V} \rangle$ be *any* \mathbf{OK} -model. We define \mathcal{U}^* to be the structure $\langle W, R^*, \text{opt}, V \rangle$ where:

- (i) $R^* = R$.
- (ii) $\text{opt} = \{y \in W : \text{for some } x \text{ in } W, xRy\}$.

Note that W and V are common to \mathcal{U} and \mathcal{U}^* . As for V , this is made possible by our assumption that the alethic and the deontic language have *the same* set Prop of proposition letters. We may also remark that opt is here defined to be what is known as ‘the converse domain’ of the relation R in \mathbf{OK} -models.

LEMMA 47 (Easy Lemma). *As defined, \mathcal{U}^* is a \mathbf{K}_Q -model.*

Proof. Appealing to the definition of a \mathbf{K}_Q -model, we see that it is enough to show (i) that $R^* \subseteq W \times W$, and (ii) that $\text{opt} \subseteq W$, there being no further restrictions on R^{\S} and opt in such alethic models. These points are immediate in view of (i) and (ii) in the definition of the structure \mathcal{U}^* . ■

LEMMA 48 (On relations). *Let \mathcal{U} and \mathcal{U}^* be as in the Definition of \mathcal{U}^* . Then, for all x, y , in W :*

$$xRy \text{ iff } xR^*y \text{ and } y \in \text{opt}.$$

Proof.

Left-to-right: Assume, for any x, y in W :

1. xRy hypothesis
- Then:
2. $\exists x(xRy)$ from 1 by existential generalization
 3. $y \in \text{opt}$ from 2 by the definition of opt in \mathcal{U}^*
 4. xR^*y from 1 by definition of R^* in \mathcal{U}^*
 5. $xR^*y \& y \in \text{opt}$ 3,4, adjunction

where 5 is the desired conclusion.

Right-to-left. This direction is immediate by the definition of R^* . ■

LEMMA 49 (Crucial Lemma). *Let \mathcal{U} and \mathcal{U}^* be as in the Definition of \mathcal{U}^* . Then, for all $A \in \Sigma_0$ and for all x in W : $\frac{\mathcal{U}}{x} A$ iff $\frac{\mathcal{U}^*}{x} \phi A$.*

Proof. By induction on the length of A . By the definition of the translation ϕ , the three cases in the induction basis are seen to be trivial. For the same reason, the inductive cases involving truth-functional connectives go through easily. Consider then:

Case $A = OB$. We are required to show that $\frac{\mathcal{U}}{x} OB$ iff $\frac{\mathcal{U}^*}{x} \phi(OB)$.
Well, for any $B \in \Sigma_0$ and any x in W , we clearly have:

1. $\frac{\mathcal{U}}{x} OB$ iff $\forall y(xRy \supset \frac{\mathcal{U}}{y} B)$ by the definition of truth in \mathcal{U}
2. $\frac{\mathcal{U}^*}{x} \Box(Q \rightarrow \phi B)$ iff $\forall y(xR^*y \& y \in \text{opt} \supset \frac{\mathcal{U}^*}{y} \phi B)$ by the definition of truth in \mathcal{U}^*
3. $\frac{\mathcal{U}}{y} B$ iff $\frac{\mathcal{U}^*}{y} \phi B$ by the induction hypothesis, y being any member of W

Hence:

4. (Right member of 1) iff (right member of 2) from 3 and the Lemma on Relations by elementary steps
5. $\frac{\mathcal{U}}{x} OB$ iff $\frac{\mathcal{U}^*}{x} \Box(Q \rightarrow \phi B)$ from 1,2,4 by the transitivity of 'iff'

where 5 yields the desired result by the definition of ϕ .

Case $A = PB$. The reasoning parallels that of the preceding case; we just make the necessary switches from $O, \Box, \rightarrow, \forall, \supset$ to $P, \Diamond, \wedge, \exists$ and $\&$, respectively.

The proof of the Crucial Lemma is complete.

Armed with the definition of the \mathbf{K}_Q -model \mathcal{U}^* and our three lemmas on it, we have fully justified the decisive step from 3 to 4 in our strategic argument given above. This completes the proof of the ‘if’ part of *Case* $\mathcal{K} = \mathbf{K}_Q$ and $c(\mathcal{K}) = \mathbf{OK}$. That case is thereby fully proved. ■

Remaining Cases. For the details of the remaining nine cases, see Åqvist [1987, Section 13.5.2–10]. In the present survey I only want to indicate the main novelty in each case, which appears in the proof of the ‘if’ part at the juncture where, given any $c(\mathcal{K})$ -model \mathcal{U} , we construct a corresponding \mathcal{K} -model \mathcal{U}^* with the ‘right’ properties. Thus, in general, we lay down a definition of this form:

DEFINITION 50 (Definition of \mathcal{U}). Let $\mathcal{U} = \langle \mathcal{W}, \mathcal{R}, \mathcal{V} \rangle$ be any $c(\mathcal{K})$ -model, so that R satisfies the appropriate restriction. Define \mathcal{U}^* to be the structure $\langle W, R^*, \text{opt}, V \rangle$ where:

- (i) R^* = the binary relation on W such that for all x, y in W : xR^*y iff
- (ii) $\text{opt} = \{y \in W : \text{for some } x \text{ in } W, xRy\} =$ the converse domain of R in W .

Having filled in the blank in (i) for each case, one goes on to state and prove a

LEMMA 51 (Easy). *As defined, \mathcal{U}^* is a \mathcal{K} -model*

as well as the

LEMMA 52 (On relations). *Let \mathcal{U} and \mathcal{U}^* be as in the above Definition of \mathcal{U}^* . Then, for all x, y in W : xRy iff xR^*y and $y \in \text{opt}$.*

Using this lemma on Relations, we give an inductive proof of the

LEMMA 53 (Crucial). $\frac{\mathcal{U}}{x} A$ iff $\frac{\mathcal{U}^*}{x} \phi A$ for \mathcal{U} and \mathcal{U}^* as above, and for A and x as usual), just as in the case of $\mathcal{K} = \mathbf{K}_Q$ and $c(\mathcal{K}) = \mathbf{OK}$.

Again, armed with the definition of the \mathcal{K} -model \mathcal{U}^* and our three lemmas on it, we justify the decisive step from 3 to 4 in the strategic argument for the ‘if’ part. This will then complete the proof in each of the remaining nine cases.

We now indicate how to fill in the blank in clause (i) of the Definition of \mathcal{U}^* , for various cases.

Case $\mathcal{K} = \mathbf{M}_Q$ and $c(\mathcal{K}) = \mathbf{OM}$. Fill in the blank with this condition: ($x = y$ or xRy).

Case $\mathcal{K} = \mathbf{S4}_Q$ and $c(\mathcal{K}) = \mathbf{OS4}$. Fill in the blank with the same condition!

Case $\mathcal{K} = \mathbf{B}_Q$ and $c(\mathcal{K}) = \mathbf{OB}$. Fill in the blank with the condition ($x = y$ or xRy or yRx)

Case $\mathcal{K} = \mathbf{S5}_Q$ and $c(\mathcal{K}) = \mathbf{OS5}$. Fill in the blank with this condition:

For some natural number $n \geq 1$: $xR^n y$ where \mathcal{R} is the relation on W defined by: xRy iff ($x = y$ or xRy or yRx) and where \mathcal{R}^n is the n th power of the relation \mathcal{R} , defined in the usual inductive way in terms of relative products. Thus, in the present case, R^* is defined as the *chain*, or *proper ancestral*, of the relation \mathcal{R} . Certain inductively provable additional lemmata are then needed to establish the Easy Lemma and the Lemma on Relations in this case, which is more complicated than the preceding ones.

The five remaining + cases. Define R^* just as in the corresponding case *without* +, i.e. the case where the axiomatic systems lack the schemata **B3** and **A3** and where the accessibility relations are not required to be opt-serial or serial in the relevant models.

Our broad outline of the proof of the Translation Theorem for Monadic Deontic Logic is complete. ■

V. FIRST STEPS IN DYADIC DEONTIC LOGIC

15 TWO NEW LANGUAGES AND A PROBLEM

Consider the deontic language common to the Smiley–Hanson monadic systems and its set Σ_0 of well formed sentences. Let us now think of O and P as *dyadic* (i.e. two-place) deontic connectives, expressing *conditional* obligation and permission, respectively. We then obtain a new deontic language, the set of sentences of which will be called Σ_0^2 and is defined as the smallest set S such that:

- (a) Every proposition letter is in S .
- (b) \top and \perp are in S .
- (c) If A is in S , then so is $\neg A$.
- (d) If A, B are in S , then so are $(A \wedge B)$, $(A \vee B)$, $(A \rightarrow B)$ and $(A \Leftrightarrow B)$.
- (e) If A, B are in S , then so are $O_B A$ and $P_B A$.

REMARK 54. Apart from the fact that clause (c) has been curtailed, the new thing about the present deontic language and its set Σ_0^2 is of course embodied in clause (e). So, note that we write $O_B A$ and $P_B A$, where

many authors would write $O(A/B)$ and $P(A/B)$ and where still others would use (BOA) and (BPA) ; the former authors are obviously inspired by the notation familiar from *probability theory*, whereas the latter (e.g. Van Eck [1981]) stick to what might be labeled the *standard binary connective* notation (cf. clause (d) above). The motivation for our choice of notation will appear from what follows; it might be called a *relative necessity* or *sententially indexed modality* notation (cf. e.g. Chellas [1975, Section 5]).

DEFINITION 55.

'Dyadic' Definitions of monadic deontic connectives:

$$\begin{aligned} OA &=df \quad O_{\top}A \\ PA &=df \quad P_{\top}A \\ FA &=df \quad \neg P_{\top}A \quad (\text{alternatively: } O_{\top}\neg A) \end{aligned}$$

Again, consider the alethic language common to the systems \mathcal{K} and its set Σ of well formed sentences. In this language Q was thought of as a propositional *constant*, i.e. as a zero-place connective, thus of degree 0. Now, think of Q as a *monadic* (i.e. one-place) prohairetic connective, so that QA might be read as 'optimally A ', 'ideally A ', or what have you. We then obtain a new alethic language with an additional one-place connective Q ; its set of *sentences* will be called Σ^1 and is defined as the smallest set S such that:

- (a) Every proposition letter is in S .
- (b) \top and \perp are in S .
- (c) If A is in S , then so are $\neg A$, $\Box A$, $\Diamond A$ and QA .
- (d) As usual.

As compared to the old alethic language with Q , the new one has just the nullary connectives \top and \perp (clause (b)), whereas Q reappears among the monadic ones (clause (c)).

15.1 'Alethic' Definitions of dyadic deontic connectives

$$\begin{aligned} Q & \quad (\text{the old propositional constant}) =df \quad Q\top \\ O_BA & =df \quad \Box(QB \rightarrow A), \\ P_BA & =df \quad \Diamond(QB \wedge A), \\ F_BA & =df \quad \Box(QB \rightarrow \neg A). \end{aligned}$$

We can now state the problem announced in the title to this section.

15.2 Problem

Consider the two sets of sentences Σ^1 and Σ_0^2 . As usual, the new alethic language and the new deontic one are assumed to have *the same* set Prop of proposition letters. Corresponding to the definitions in Σ^1 of the dyadic connectives O and P , define a translation ϕ from Σ_0^2 into Σ^1 just as in the case of Σ_0 and Σ , except for the following fresh clauses:

$$(vi) \quad \phi(O_B A) = \Box(Q\phi B \rightarrow \phi A).$$

$$(vii) \quad \phi(P_B A) = \Diamond(Q\phi B \wedge \phi A).$$

Then, find a system \mathcal{L} of dyadic deontic logic and a system \mathcal{K} of alethic modal logic with our new monadic connective Q such that:

- (i) The set of \mathcal{L} -theses is a proper subset of Σ_0^2 .
- (ii) The set of \mathcal{K} -theses is a proper subset of Σ^1 .
- (iii) The set of \mathcal{L} -theses = the dyadic deontic fragment of \mathcal{K} under ϕ as just defined; i.e. we are to have for each sentence A in Σ_0^2 : $\vdash_{\mathcal{L}} A$ iff $\vdash_{\mathcal{K}} \phi A$.

The word ‘proper’ is inserted in requirements (i) and (ii) just in order to make sure that the logics \mathcal{L} and \mathcal{K} are consistent. We now consider, to start with, certain rather weak systems having the desired properties (i)–(iii).

16 THE SYSTEMS $O_{dy}S4$, $O_{dy}S5$, $S4_{Qmo}$ AND $S5_{Qmo}$

The system $O_{dy}S4$ is determined as follows.

Rules of proof:

- (R1) $\frac{A, A \rightarrow B}{B}$ (*modus ponens*)
- (R2) $\frac{A}{O_B A}$ (O_B -necessitation)

Axiom schemata:

- (a0) All truth functional tautologies over Σ_0^2
- (a1) $P_B A \Leftrightarrow \neg O_B \neg A$,
- (a2) $O_B(A \rightarrow C) \rightarrow (O_B A \rightarrow O_B C)$,
- (a3) $O_B(O_B A \rightarrow A)$,
- (a4) $O_B A \rightarrow O_C O_B A$,

The axiomatic system $\mathbf{O}_{dy}\mathbf{S5}$ results from $\mathbf{O}_{dy}\mathbf{S4}$ by omitting schema a3 and by adding in its place the following new schema a5:

- (a5) $P_C O_B A \rightarrow O_B A$,

Note that a3 will be derivable in $\mathbf{O}_{dy}\mathbf{S5}$ as a thesis schema.

The notions of *provability*, consistency, derivability etc. are defined for the systems $\mathbf{O}_{dy}\mathbf{S4}$ and $\mathbf{O}_{dy}\mathbf{S5}$ in the usual straightforward way.

The axiomatic system $\mathbf{S4}_{Qmo}$ is simply the familiar modal calculus $\mathbf{S4}$ over the present alethic language whose set of sentences = Σ^1 ; similarly, the system $\mathbf{S5}_{Qmo}$ is $\mathbf{S5}$ over that alethic language. See Section 12 above.

We now turn to the *semantics* of the four systems just described. By an $\mathbf{O}_{dy}\mathbf{S4}$ -model we shall mean any ordered triple

$$U = \langle W, R, V \rangle$$

where:

- (i) W is a non-empty set and V is a function from $\text{Prop} \times W$ into the set of truth-values $\{1,0\}$; thus, W and V are as usual.
- (ii) R is a function from the set of sentences Σ_0^2 into the set of all binary relations on W , in symbols: $R : \Sigma_0^2 \rightarrow \mathcal{P}(W \times W)$. In other words, then: for each sentence B in Σ_0^2 , $R_B \subseteq W \times W$ so that R_B is a binary relation on W . Moreover, R is to satisfy the following two conditions, corresponding to axiom schemata a3 and a4:
 - (3) For each B in Σ_0^2 and any x, y in W : $xR_B y \supset yR_B y$.
 - (4) For any B, C in Σ_0^2 and x, y, z in W : $xR_C y \ \& \ yR_B z \supset xR_B z$.

Again, by an $\mathbf{O}_{dy}\mathbf{S5}$ -model we mean any $\mathbf{O}_{dy}\mathbf{S4}$ -model $\langle W, R, V \rangle$ where R satisfies the following new restriction that corresponds to the schema a5:

(5) For any B, C in Σ_0^2 and x, y, z in $W : xR_Cy \ \& \ xR_Bz \supset yR_Bz$.

Truth conditions for dyadic deontic connectives: Let $U = \langle \mathcal{W}, \mathcal{R}, \mathcal{V} \rangle$ be any $\mathbf{O}_{dy}\mathbf{S4}$ - or $\mathbf{O}_{dy}\mathbf{S5}$ -model, let x be any member of W , and let A be in Σ_0^2 . The only change in the definition of *truth at x in U* , given for our monadic deontic logics, will concern sentences of the new forms O_BA and P_BA , for which we adopt the following clauses:

$$\begin{aligned} \frac{U}{x} O_B A & \text{ iff for every } y \text{ in } W \text{ such that } xR_B y, \frac{U}{y} A. \\ \frac{U}{x} P_B A & \text{ iff for some } y \text{ in } W \text{ such that } xR_B y, \frac{U}{y} A. \end{aligned}$$

Notions of *validity*, satisfiability and semantic entailment, which are relative to $\mathbf{O}_{dy}\mathbf{S4}$ and $\mathbf{O}_{dy}\mathbf{S5}$, are then introduced in the usual way.

Furthermore, define an $\mathbf{S4}_{Qmo}$ -model to be any ordered quadruple

$$U = \langle \mathcal{W}, \mathcal{R}^\S, \text{opt}, \mathcal{V} \rangle$$

with W, R^\S, V as in an $\mathbf{S4}_Q$ -model so that R^\S is reflexive and transitive relation on W , and where:

$$\text{opt} : \Sigma^1 \rightarrow \mathcal{P}W$$

i.e. opt is a function which to each sentence B in Σ^1 assigns a subset $\text{opt}(B)$ of W as its value.

Truth condition for the monadic Q -connective: The old truth condition for the Kanger constant Q will have to be replaced by the following:

$$\frac{U}{x} QB \text{ iff } x \in \text{opt}(B)$$

which then governs sentences of the form QB .

Again, an $\mathbf{S5}_{Qmo}$ -model is any $\mathbf{S4}_{Qmo}$ -model where R^\S has the additional property of being *symmetric* and, hence, an *equivalence relation*, on W . Validity etc. is defined in the usual way relatively to $\mathbf{S4}_{Qmo}$ and $\mathbf{S5}_{Qmo}$.

THEOREM 56 (Soundness and completeness).

- (i) For each A in Σ_0^2 : A is provable in $\mathbf{O}_{dy}\mathbf{S4}$ / $\mathbf{O}_{dy}\mathbf{S5}$ / iff A is valid in $\mathbf{O}_{dy}\mathbf{S4}$ / $\mathbf{O}_{dy}\mathbf{S5}$ /.
- (ii) For each A in Σ^1 : A is provable in $\mathbf{S4}_{Qmo}$ / $\mathbf{S5}_{Qmo}$ / iff A is valid in $\mathbf{S4}_{Qmo}$ / $\mathbf{S5}_{Qmo}$ /.

Proof. See Åqvist [1987, Sections 15 and 16]. ■

THEOREM 57 (Translation). *For each A in Σ_0^2 : A is provable in $\mathbf{O}_{dy}\mathbf{S4}/\mathbf{O}_{dy}\mathbf{S5}/$ iff ϕA is provable in $\mathbf{S4}_{Qmo}/\mathbf{S5}_{Qmo}/$. In other words, the set of $\mathbf{O}_{dy}\mathbf{S4}/\mathbf{O}_{dy}\mathbf{S5}/$ theses = the dyadic deontic fragment (under ϕ) of $\mathbf{S4}_{Qmo}/\mathbf{S5}_{Qmo}/$.*

Proof. See Åqvist [1987, Sections 15 and 16]. The demonstrations are a little bit tedious. ■

17 TWO NEW SYSTEMS: $\mathbf{O}_{dy}\mathbf{S5}^N$ AND $\mathbf{S5}_{Qmo}^N$

At this juncture we observe that in the systems $\mathbf{S4}_{Qmo}$ and $\mathbf{S5}_{Qmo}$ there are no special axioms governing the monadic operator Q ; correspondingly, there are no restrictions on the function opt in the models for these systems. So, the following is a natural expectation: if we start adding axioms for Q to these systems as well as matching restrictions on opt in their modellings, we should obtain a series of dyadic deontic logics as the deontic fragments of these extended alethic calculi with monadic Q ; and to begin with, we are particularly interested in dyadic deontic logics that are in relevant respects similar to the systems **DSDL1–DSDL3** proposed by Bengt Hansson [1969]. As it turns out, however, $\mathbf{S4}_{Qmo}$ and $\mathbf{S5}_{Qmo}$ are not quite fit to serve as adequate bases for a development of dyadic deontic logic along those lines. But they come close to the basic system we are looking for; only one further step has to be taken.

Consider the following alethic system $\mathbf{S5}_{Qmo}^N$: its set of *theses* is identical to that of $\mathbf{S5}_{Qmo}$, but we want \Box to be interpreted as what Scott [1970] calls *universal necessity* and what Kanger [1957] called ‘analytic’ necessity. This means simply that \Box is to express truth at *every* world (point) in the set (space) W , unconditionally. Technically, we easily achieve this by defining an $\mathbf{S5}_{Qmo}^N$ -model as any structure $\mathcal{U} = \langle \mathcal{W}, \mathcal{R}^\S, \text{opt}, \mathcal{V} \rangle$, where W , opt , V are as usual *and where* $R^\S = W \times W$ (i.e. the universal binary relation on W). So, in contrast to the case of $\mathbf{S5}_{Qmo}$ -models, R^\S is no longer an arbitrary equivalence relation on W , but is now identified with a *particular* equivalence relation on W , viz. $W \times W$; and the set of $\mathbf{S5}_{Qmo}^N$ -models becomes a proper subset of the set of $\mathbf{S5}_{Qmo}$ -models. As for the *completeness* of the system $\mathbf{S5}_{Qmo}^N$ as just characterized, a proof can be extracted from Åqvist [1973, Section 5]; note in particular the treatment and the role of the operator \Box in that essay.

Now, what is the dyadic deontic fragment under ϕ of $\mathbf{S5}_{Qmo}^N$? If you believe it to be $\mathbf{O}_{dy}\mathbf{S5}$ (once again), then try to prove a translation theorem for $\mathbf{O}_{dy}\mathbf{S5}$ and $\mathbf{S5}_{Qmo}^N$ along the familiar lines! You will find that it doesn’t work, because we will be unable to establish either the Easy Lemma or the Lemma on Relations. Instead, the correct answer to the above question is: the following system $\mathbf{O}_{dy}\mathbf{S5}^N$, which we are now going to describe quickly.

Let us reconsider our dyadic deontic language with the set of sentences $= \Sigma_0^2$, and add a pair of one-place modal operators N and M to its stock of primitive logical connectives. $N(M)$ is to express *universal* necessity (possibility) in the sense indicated above. The set of *sentences* of the dyadic deontic language thus enriched will be called $\Sigma_{0,N}^2$; adjusting the formation rule (c) in the obvious way, we have that whenever A is in $\Sigma_{0,N}^2$, so are NA and MA .

As for the *proof theory* of $\mathbf{O}_{dy}\mathbf{S5}^N$, its set of theses is a proper subset of this new set of sentences $\Sigma_{0,N}^2$. More precisely, it is determined by the following rules of inference and axiom schemata:

$$(R1) \quad \frac{A, A \rightarrow B}{B} \quad (\textit{modus ponens})$$

$$(R2'') \quad \frac{A}{NA} \quad (N\text{-necessitation})$$

(a0) All truth functional tautologies over $\Sigma_{0,N}^2$

$$(a1) \quad P_B A \Leftrightarrow \neg O_B \neg A$$

$$(a2) \quad O_B(A \rightarrow C) \rightarrow (O_B A \rightarrow O_B C)$$

$$(a6) \quad O_B A \rightarrow NO_B A$$

$$(a7) \quad NA \rightarrow O_B A$$

(a8) An appropriate set of **S5**-schemata for N and M (e.g. B1, B2, B5 and B6, with N, M respectively replacing \Box, \Diamond).

EXERCISE 58. Derive the schema $P_B A \rightarrow NP_B A$ in $\mathbf{O}_{dy}\mathbf{S5}^N$ as just described! Derive the system $\mathbf{O}_{dy}\mathbf{S5}$ as a subsystem of $\mathbf{O}_{dy}\mathbf{S5}^N$!

Proceeding to the *semantics* for $\mathbf{O}_{dy}\mathbf{S5}^N$, we define an $\mathbf{O}_{dy}\mathbf{S5}^N$ -model as any structure $\mathcal{U} = \langle \mathcal{W}, \mathcal{R}, \mathcal{V} \rangle$, where W, V are as usual and where $R : \Sigma_{0,N}^2 \rightarrow \mathcal{P}(\mathcal{W} \times \mathcal{W})$ is a function from our fresh set of sentences $\Sigma_{0,N}^2$ into the set of all binary relations on W , satisfying the following condition that corresponds to schema (a6):

$$(6) \quad \text{For each } B \text{ in } \Sigma_{0,N}^2 \text{ and any } x, y, z \text{ in } W : xR_B y \supset zR_B y.$$

EXERCISE 59. Show that in any $\mathbf{O}_{dy}\mathbf{S5}^N$ -model R satisfies the restrictions (4) and (5)!

Clearly, we must supplement our earlier definition of *truth at x in \mathcal{U}* , where \mathcal{U} is any $\mathbf{O}_{dy}\mathbf{S5}^N$ -model, with new clauses governing the operators N and M :

$$\begin{aligned} \frac{\mathcal{U}}{x} NA & \text{ iff for each } y \text{ in } W, \frac{\mathcal{U}}{y} A \\ \frac{\mathcal{U}}{x} MA & \text{ iff for some } y \text{ in } W, \frac{\mathcal{U}}{y} A \end{aligned}$$

The notions of validity, satisfiability and semantic entailment, pertaining to $\mathbf{O}_{dy}\mathbf{S5}^N$, are then defined in the usual way.

THEOREM 60 (Soundness and completeness for $\mathbf{O}_{dy}\mathbf{S5}^N$). *For each A in $\Sigma_{0,N}^2$:*

$$\frac{}{\mathbf{O}_{dy}\mathbf{S5}^N A} \text{ iff } \frac{}{\mathbf{O}_{dy}\mathbf{S5}^N A}$$

Proof. See Åqvist [1987, Section 17.2]. ■

17.1 Representation of $\mathbf{O}_{dy}\mathbf{S5}^N$ in $\mathbf{S5}_{Qmo}^N$

In this section we announce the result that the set of $\mathbf{O}_{dy}\mathbf{S5}^N$ -theses is the dyadic deontic fragment under ϕ of $\mathbf{S5}_{Qmo}^N$. Clearly, then, ϕ should be a translation from the new sentence-set $\Sigma_{0,N}^2$ into Σ^1 , which is effected by adding the following clauses to our definition of ϕ :

- (viii) $\phi(NA) = \Box\phi A$,
- (ix) $\phi(MA) = \Diamond\phi A$,

THEOREM 61 (Translation for $\mathbf{O}_{dy}\mathbf{S5}^N$ and $\mathbf{S5}_{Qmo}^N$).

For each A in $\Sigma_{0,N}^2$:

$$\frac{}{\mathbf{O}_{dy}\mathbf{S5}^N A} \text{ iff } \frac{}{\mathbf{S5}_{Qmo}^N \phi A}$$

Proof. See Åqvist [1987, Section 17.3.1]. ■

VI. DEVELOPMENT OF DYADIC DEONTIC LOGIC THROUGH AXIOMATIC ADDITIONS TO THE SYSTEMS $\mathbf{O}_{dy}\mathbf{S5}^N$ AND $\mathbf{S5}_{Qmo}^N$

18 THE DYADIC CALCULI $\mathbf{O}_{dy}\mathbf{S5}^N + \alpha i$

In this part we shall take $\mathbf{O}_{dy}\mathbf{S5}^N$ as our *basic* and, in a certain sense, *minimal* system of dyadic deontic logic and form new calculi by adding to it one or more axiom schemata αi from the following list $\alpha 0$ – $\alpha 4$:

- $\alpha 0.$ $N(A \Leftrightarrow B) \rightarrow (O_A C \Leftrightarrow O_B C)$
- $\alpha 1.$ $O_A A$
- $\alpha 2.$ $O_{A \wedge B} C \rightarrow O_A (B \rightarrow C)$
- $\alpha 3.$ $MA \rightarrow (O_A B \rightarrow P_A B)$
- $\alpha 4.$ $P_A B \rightarrow (O_A (B \rightarrow C) \rightarrow O_{A \wedge B} C)$

To start with, we consider the five systems $\mathbf{O}_{dy}\mathbf{S5}^N + \alpha i$, for $i = 0, 1, \dots, 4$; where $\mathbf{O}_{dy}\mathbf{S5}^N + \alpha i$ is the calculus which results from $\mathbf{O}_{dy}\mathbf{S5}^N$ by adding *just* the schema αi to the latter.

Turning quickly to semantics, we define, for $i = 0, 1, \dots, 4$, an $\mathbf{O}_{dy}\mathbf{S5}^N + \alpha i$ model as any $\mathbf{O}_{dy}\mathbf{S5}^N$ -model $\mathcal{U} = \langle \mathcal{W}, \mathcal{R}, \mathcal{V} \rangle$ where R , in addition to meeting (6), satisfies the condition ρi in the list $\rho 0$ – $\rho 4$ below of restrictions on R ; where A, B are any members of $\Sigma_{0,N}^2$, x, y any members of W , and where, for each A in $\Sigma_{0,N}^2$,

$$\| A \|^\mathcal{U} = \{y \in W : \frac{\mathcal{U}}{y} A\}$$

(in other words, $\| A \|^\mathcal{U}$ is to be the *truth-set* or *extension in \mathcal{U}* of the wff A):

- $\rho 0.$ $\| A \|^\mathcal{U} = \| B \|^\mathcal{U} \supset R_A = R_B$
- $\rho 1.$ $xR_A y \supset \frac{\mathcal{U}}{y} A$
- $\rho 2.$ $xR_A y \ \& \ \frac{\mathcal{U}}{y} B \supset xR_{A \wedge B} y$
- $\rho 3.$ $\| A \|^\mathcal{U} \neq \emptyset \supset \forall x \exists y (xR_A y)$
- $\rho 4.$ $\exists z (xR_A z \ \& \ \frac{\mathcal{U}}{z} B) \supset (xR_{A \wedge B} y \supset (xR_A y \ \& \ \frac{\mathcal{U}}{y} B))$

THEOREM 62 (Soundness and completeness). *For each $i = 0, 1, \dots, 4$ and for each A in $\Sigma_{0,N}^2$: $\frac{\mathcal{U}}{\mathbf{O}_{dy}\mathbf{S5}^N + \alpha i} A$ iff $\frac{\mathcal{U}}{\mathbf{O}_{dy}\mathbf{S5}^N + \alpha i} A$. In other words, the sentences provable in $\mathbf{O}_{dy}\mathbf{S5}^N + \alpha i$ are exactly the sentences valid in that system.*

Proof. See Åqvist [1987, Section 18.0–1]. ■

19 THE ALETHIC CALCULI $\mathbf{S5}_{QMO}^N + \beta I$

Consider the following list $\beta 0$ – $\beta 4$ of axiom schemata that may be added to the system $\mathbf{S5}_{Qmo}^N$; they all govern our monadic operator Q :

- $\beta 0.$ $\Box(A \Leftrightarrow B) \rightarrow \Box(QA \Leftrightarrow QB),$
- $\beta 1.$ $QA \rightarrow A,$
- $\beta 2.$ $(QA \wedge B) \rightarrow Q(A \wedge B),$
- $\beta 3.$ $\Diamond A \rightarrow \Diamond QA,$
- $\beta 4.$ $\Diamond(QA \wedge B) \rightarrow \Box(Q(A \wedge B) \rightarrow (QA \wedge B)).$

By the system $\mathbf{S5}_{Qmo}^N + \beta i$, for $i = 0, 1, \dots, 4$, we mean the calculus which results from $\mathbf{S5}_{Qmo}^N$ by adding *just* the schema βi to the latter. There are then five systems of this sort to be considered.

Moving on to semantics, we define, for $i = 0, 1, \dots, 4$, an $\mathbf{S5}_{Qmo}^N + \beta i$ model as any structure $\mathcal{U} = \langle \mathcal{W}, \mathcal{R}^{\S}, \text{opt}, V \rangle$ with W, V as usual, where $R^{\S} = W \times W$ (just as in $\mathbf{S5}_{Qmo}^N$ -models) and where $\text{opt}: \Sigma^1 \rightarrow \mathcal{P}W$ satisfies the condition σ_i in the list $\sigma 0$ – $\sigma 4$ below of restrictions on opt (where A, B are any sentences in Σ^1):

- $\sigma 0.$ $\| A \|_{\mathcal{U}} = \| B \|_{\mathcal{U}} \supset \text{opt}(A) = \text{opt}(B)$
- $\sigma 1.$ $\text{opt}(A) \subseteq \| A \|_{\mathcal{U}}$
- $\sigma 2.$ $\text{opt}(A) \cap \| B \|_{\mathcal{U}} \subseteq \text{opt}(A \wedge B)$
- $\sigma 3.$ $\| A \|_{\mathcal{U}} \neq \emptyset \supset \text{opt}(A) \neq \emptyset$
- $\sigma 4.$ $\text{opt}(A) \cap \| B \|_{\mathcal{U}} \neq \emptyset \supset (\text{opt}(A \wedge B) \subseteq \text{opt}(A) \cap \| B \|_{\mathcal{U}})$

THEOREM 63 (Soundness and completeness). *For each $i = 0, 1, \dots, 4$ and each A in Σ^1 :*

$$\frac{}{\mathbf{S5}_{Qmo}^N + \beta i} A \quad \text{iff} \quad \frac{}{\mathbf{S5}_{Qmo}^N + \beta i} A$$

Proof. See Åqvist [1987, Section 19.0]. ■

20 WEAK REPRESENTATION OF $O_{dy}\mathbf{S5}^N + \alpha i$ IN $\mathbf{S5}_{Qmo}^N + \beta i$; IS FULL REPRESENTABILITY LOST?

Bearing in mind that ϕ is now a translation from $\Sigma_{0,N}^2$ into Σ^1 (with fresh clauses for N and M , see Section 17.1 above), we state the following result:

THEOREM 64 (Weak translation for $O_{dy}\mathbf{S5}^N + \alpha i$ and $\mathbf{S5}_{Qmo}^N + \beta i$). *For each $i = 0, 1, \dots, 4$ and each A in $\Sigma_{0,N}^2$:*

$$\frac{}{O_{dy}\mathbf{S5}^N + \alpha i} A \quad \text{only if} \quad \frac{}{\mathbf{S5}_{Qmo}^N + \beta i} \phi A.$$

In other words, the set of $\mathbf{O}_{dy}\mathbf{S5}^N + \alpha i$ theses \subseteq the dyadic deontic fragment under ϕ of $\mathbf{S5}_{Qmo}^N + \beta i$. Note that in this theorem '=' has been weakened to ' \subseteq ' and 'iff' to 'only if'.

Proof. Our task is to give an ordinary 'only if' part demonstration. The new thing here is to verify, for each $i = 0, 1, \dots, 4$, that if A is an axiom under the new schema αi , then its translation ϕA is provable in $\mathbf{S5}_{Qmo}^N + \beta i$. And we easily accomplish this, appealing precisely to the schema βi . ■

As to the converse result, i.e. the 'if' part, I have not been able to establish it; nor do I know whether it holds good or not. But I am inclined to believe that it does; *if* it does, however, its proof will be harder than any one so far met with in this essay — at least, so I believe.

EXERCISE 65. Try to prove the converse of the weak translation theorem stated above! Explain why you got lost, or else: congratulations and many thanks!

We like to add that, even if the full representability of $\mathbf{O}_{dy}\mathbf{S5}^N + \alpha i$ in $\mathbf{S5}_{Qmo}^N + \beta i$ should turn out not to hold, this does not entail that the enterprise of developing dyadic deontic logic and alethic modal logic with monadic Q in a parallel fashion is without considerable heuristic value. In fact, I think, the contrary will prove to be the case.

21 AN ATTEMPTED RECONSTRUCTION AND IDENTIFICATION OF THE HANSSON DYADIC SYSTEMS DSDL1, DSDL2, AND DSDL3: ALETHIC PRELIMINARIES

The main idea proposed in Hansson [1969] is that the concept of *validity* in Von Wright-type deontic logic (Hansson is anxious to point out that he just deals with this type in his paper) can be semantically explained in terms of a *preference relation* 'is at least as ideal as' *among possible worlds*; this claim is to apply whether the Von Wright-type deontic logic be monadic or dyadic. Hansson himself thinks of possible worlds as Boolean valuations in the sense familiar from the teaching of elementary propositional calculus. We shall not follow him in making this identification, however, because our Kripkean semantical technique has already supplied us with an independent notion of (a set of) possible worlds. Again, given a preference relation (ordering, ranking) R on a set of possible worlds W , we are automatically equipped with the notion of the *R-maximal* ('best', 'optimal', under R) elements of W and of various (perhaps all) subsets of W . We could then give the following informal characterization of the function *opt* in our models \mathcal{U} for alethic systems with monadic $\mathbf{Q}(\mathbf{S4}_{Qmo}$ etc.):

$\text{opt}(\top) =$ the R -maximal elements of $\| \top \|^{\mathcal{U}}$, i.e. of W as a whole.

Remember here that the *set* $\text{opt} \subseteq W$ in models for the alethic systems with the *propositional constant* Q is simply to be equated with this set $\text{opt}(\top)$. Moreover, in general, we should have for any sentence A in Σ^1 :

$\text{opt}(A) =$ the R -maximal elements of $\| A \|^{\mathcal{U}}$, i.e. of the set of worlds in W where A is true (= the extension in \mathcal{U} of the wff A).

In the light of these heuristic preliminaries we now supplement our alethic $\mathbf{S5}_{Qmo}^N$ -models with a Hanssonian preference relation on W , consider some possible conditions on it, and see what happens when one interprets the sentences in Σ^1 relatively to these new enriched structures. Later on, we are going to perform a similar operation on our dyadic deontic models and the sentence-set $\Sigma_{0,N}^2$.

DEFINITION 66 (Various sorts of \succsim -supplemented alethic models). Let $\mathcal{U} = \langle \mathcal{W}, \mathcal{R}^{\S}, \text{opt}, \succsim, V \rangle$ be any structure where

- (i) $W \neq \emptyset$ (as usual),
- (ii) $R^{\S} = W \times W$ (as has now become usual),
- (iii) $\text{opt}: \Sigma^1 \rightarrow \mathcal{P}W$ (as usual),
- (iv) $\succsim \subseteq W \times W$ (novelty),
- (v) $V: \text{Prop} \times W \rightarrow \{1, 0\}$ (as usual).

If you like, call any ordered quintuple of this sort a *minimal alethic H-model*. Note that we place no further conditions on opt or on \succsim in minimal alethic H -models. Furthermore, we say:

- (b) \mathcal{U} is an *alethic H-model* iff opt and \succsim *jointly* satisfy the following condition (for each A in Σ^1):
 - $\delta 0.$ $\text{opt}(A) = \{x \in \| A \|^{\mathcal{U}} : (\forall y \in \| A \|^{\mathcal{U}}) x \succsim y\}$.
- (c) \mathcal{U} is an *alethic H₁-model* iff \succsim , in addition to meeting $\delta 0$ jointly with opt , satisfies this condition $\delta 1$:
 - $\delta 1.$ \succsim is *reflexive* in W (i.e. for all x in W , $x \succsim x$).
- (d) \mathcal{U} is an *alethic H₂-model* iff \succsim , in addition to meeting $\delta 0$ and $\delta 1$, satisfies this condition $\delta 2$ (for each A in Σ^1):
 - $\delta 2.$ If $\| A \|^{\mathcal{U}} \neq \emptyset$, then $\{x \in \| A \|^{\mathcal{U}} : (\forall y \in \| A \|^{\mathcal{U}}) x \succsim y\} \neq \emptyset$.

(e) \mathcal{U} is an *alethic H_3 -model* iff \succsim , in addition to meeting $\delta 0$, $\delta 1$ and $\delta 2$, satisfies this condition $\delta 3$:

$\delta 3.$ \succsim is *transitive* in W .

(f) \mathcal{U} is an *alethic strong H_3 -model* iff \succsim , in addition to meeting $\delta 0$, $\delta 1$, $\delta 2$ and $\delta 3$, satisfies this condition $\delta 4$:

$\delta 4.$ \succsim is *strongly connected* (total, complete) in W ;

i.e. for all x, y in W : $x \succsim y$ or $y \succsim x$ (or both).

LEMMA 67 (On \succsim -supplemented alethic models). (b) *In the inductive definition of truth at x in \mathcal{U} , where \mathcal{U} is an alethic H -models, the clause for Q is equivalent to the following:*

$$\frac{\mathcal{U}}{x}QA \quad \text{iff} \quad \frac{\mathcal{U}}{x}A \ \& \ \forall y(\frac{\mathcal{U}}{y}A \supset x \succsim y)$$

(b') *Let \mathcal{U} be any alethic H -model so that opt and \succsim jointly satisfy $\delta 0$. Then opt satisfies the three conditions $\sigma 0$, $\sigma 1$ and $\sigma 2$, given in Section 19 above.*

(c) *Let \mathcal{U} be any alethic H_1 -model. Then opt satisfies the three conditions just mentioned.*

(d) *Let \mathcal{U} be any alethic H_2 -model. Then opt satisfies these conditions as well as $\sigma 3$.*

(e-f) *Let \mathcal{U} be any alethic H_3 -model or alethic strong H_3 -model. Then opt satisfies all the five conditions $\sigma 0$ – $\sigma 4$.*

Proof. See Åqvist [1987, Section 21]. ■

THEOREM 68 (Soundness). *The present result concerns axiomatic extensions of the alethic system $\mathbf{S5}_{Qmo}^N$; we are thus dealing with subsets of Σ^1 . The result is presented in the right-most column of Table 3; in the head of that column, the locution ‘matching kind of validity’ means, of course, the same as ‘truth at all points in every \succsim -supplemented alethic model of the corresponding kind’. And the corresponding kinds of models are then to be found in the leftmost column, and the appropriate restrictions on \succsim in the middle one.*

Proof. See Åqvist [1987, Section 21]. ■

REMARK 69.

(i) Questions of completeness have been left open.

Table 3.

Kind of alethic model supplemented with \succcurlyeq	Restriction(s) on \succcurlyeq in such a model	Axiomatic extension of $\mathbf{S5}_{Q_{mo}}^N$, sound with respect to the matching kind of validity
minimal H -	none	$\mathbf{S5}_{Q_{mo}}^N$ itself
H -	$\delta 0$	$\mathbf{S5}_{Q_{mo}}^N +$ every βi with $i = 0, 1, 2$
H_1 -	$\delta 0$ and $\delta 1$	ditto
H_2 -	$\delta 0, \delta 1$ and $\delta 2$	$\mathbf{S5}_{Q_{mo}}^N +$ every βi with $i = 0, 1, 2, 3$
H_3 -	$\delta 0, \delta 1, \delta 2$ and $\delta 3$	$\mathbf{S5}_{Q_{mo}}^N +$ every βi with $i = 0, 1, 2, 3, 4$
strong H_3 -	$\delta 0, \delta 1, \delta 2, \delta 3$ and $\delta 4$	ditto

- (ii) Certain possible kinds of \succcurlyeq -supplemented alethic models have been left out of consideration, e.g. alethic H -models where \succcurlyeq satisfies $\delta 1$ and $\delta 3$ (but not necessarily $\delta 2$) as well as such where \succcurlyeq satisfies $\delta 3$ and $\delta 4$ (and hence $\delta 1$; but not necessarily $\delta 2$).

22 ATTEMPTED IDENTIFICATION OF HANSSON DYADIC SYSTEMS: \succcurlyeq -SUPPLEMENTED DEONTIC MODELS

In this section we supplement our dyadic deontic $\mathbf{O}_{dy}\mathbf{S5}^N$ -models with a Hanssonian preference relation \succcurlyeq , consider possible conditions on it, and see what happens when we interpret the sentences in the beautiful set $\Sigma_{0,N}^2$ relatively to these enriched structures. The exposition will parallel the one given in the last section.

DEFINITION 70 (Various sorts of \succcurlyeq -supplemented dyadic deontic models). Let $\mathcal{U} = \langle \mathcal{W}, \mathcal{R}, \succcurlyeq, \mathcal{V} \rangle$ be any structure

- (i) $W \neq \emptyset$ (as usual)

- (ii) $R : \Sigma_{0,N}^2 \rightarrow \mathcal{P}(W \times W)$ (as has now become usual)
- (iii) $\succcurlyeq \subseteq W \times W$ (novelty)
- (iv) $V : \text{Prop} \times W \rightarrow \{1, 0\}$ (as usual)

Then we say:

- (a) \mathcal{U} is a *minimal deontic H-model* iff R meets condition (6) (see Section 17 above).
- (b) \mathcal{U} is a *deontic H-model* iff R and \succcurlyeq jointly satisfy the following condition $\gamma 0$ (for each A in $\Sigma_{0,N}^2$ and any x, y in W):

$$\gamma 0. \quad xR_A y \quad \text{iff} \quad \left| \frac{\mathcal{U}}{y} A \right. \& \forall z \left(\left| \frac{\mathcal{U}}{z} A \right. \supset y \succcurlyeq z \right).$$
- (c) \mathcal{U} is a *deontic H₁-model* iff \succcurlyeq meets the reflexivity condition $\delta 1$ as well as $\gamma 0$.
- (d) \mathcal{U} is a *deontic H₂-model* iff \succcurlyeq meets the ‘Limit Condition’ $\delta 2$ as well as $\delta 1$ and $\gamma 0$; where $\delta 2$ now applies to any sentence in $\Sigma_{0,N}^2$.
- (e) \mathcal{U} is a *deontic H₃-model* iff \succcurlyeq satisfies the transitivity condition $\delta 3$ as well as $\delta 2$, $\delta 1$ and $\gamma 0$.
- (f) \mathcal{U} is a *deontic strong H₃-model* iff \succcurlyeq satisfies the connectedness requirement $\delta 4$ in addition to meeting $\delta 3$, $\delta 2$, $\delta 1$ and $\gamma 0$.

LEMMA 71 (\succcurlyeq -supplemented dyadic deontic models).

- (b) Let \mathcal{U} be any deontic H-model. Then, by $\gamma 0$, the inductive clauses for O and P in the definition of truth at x in \mathcal{U} become equivalent to the following:

$$\begin{aligned} \left| \frac{\mathcal{U}}{x} O_B A \right. & \quad \text{iff} \quad \forall y \left(\left(\left| \frac{\mathcal{U}}{y} B \right. \& \forall z \left(\left| \frac{\mathcal{U}}{z} B \right. \supset y \succcurlyeq z \right) \right) \supset \left| \frac{\mathcal{U}}{y} A \right. \right) \\ \left| \frac{\mathcal{U}}{x} P_B A \right. & \quad \text{iff} \quad \exists y \left(\left(\left| \frac{\mathcal{U}}{y} B \right. \& \forall z \left(\left| \frac{\mathcal{U}}{z} B \right. \supset y \succcurlyeq z \right) \right) \& \left| \frac{\mathcal{U}}{y} A \right. \right). \end{aligned}$$

- (b’) Let \mathcal{U} be any deontic H-model. Then R satisfies condition (6) (stated in Section 17 above) as well as the three conditions $\rho 0, \rho 1$ and $\rho 2$ (stated in Section 18 above).
- (c) Let \mathcal{U} be any deontic H₁-model. Then R satisfies those four conditions just mentioned.

- (d) Let \mathcal{U} be any deontic H_2 -model. Then R satisfies those four conditions as well as ρ_3 .
- (e-f) Let \mathcal{U} be any deontic H_3 -model or a deontic strong H_3 -model. Then R satisfies (6) as well as all five conditions ρ_0 – ρ_4 .

Proof. Straightforward and left as an exercise. ■

THEOREM 72 (Soundness). *The present result concerns axiomatic extensions of the dyadic deontic system $\mathbf{O}_{dy}\mathbf{S5}^N$; we are thus dealing with subsets of $\Sigma_{0,N}^2$. We state the result in the form of a table (Table 4) analogous to the one at the end of the last theorem (Theorem 68).*

Table 4.

Kind of dyadic deontic model supplemented with \succcurlyeq	Restriction(s) on \succcurlyeq and/or R in such a model	Axiomatic extension of $\mathbf{O}_{dy}\mathbf{S5}^N$, sound with respect to the matching kind of validity
minimal H -	(6)	$\mathbf{O}_{dy}\mathbf{S5}^N$ itself
H -	γ_0	$\mathbf{O}_{dy}\mathbf{S5}^N$ + every α_i with $i = 0, 1, 2$
H_1 -	γ_0 and δ_1	$\mathbf{O}_{dy}\mathbf{S5}^N$ + every α_i with $i = 0, 1, 2$
H_2 -	γ_0, δ_1 and δ_2	$\mathbf{O}_{dy}\mathbf{S5}^N$ + every α_i with $i = 0, 1, 2, 3$
H_3 -	$\gamma_0, \delta_1, \delta_2$ and δ_3	$\mathbf{O}_{dy}\mathbf{S5}^N$ + every α_i with $i = 0, 1, 2, 3, 4$
strong H_3 -	$\gamma_0, \delta_1, \delta_2, \delta_3$ and δ_4	$\mathbf{O}_{dy}\mathbf{S5}^N$ + every α_i with $i = 0, 1, 2, 3, 4$

Proof. Use the soundness result for $\mathbf{O}_{dy}\mathbf{S5}^N$ + every α_i , for relevant choices of i , together with the Lemma on \succcurlyeq -supplemented dyadic deontic models. ■

REMARK 73. Our new \succ -supplemented deontic models obviously engender new ‘matching kinds of validity’, such as deontic H -validity, deontic H_1 -validity etc. Are any of the axiomatic extensions of $\mathbf{O}_{dy}\mathbf{S5}^N$, which appear in the table above, *complete* with respect to the kind of validity associated with them by the table? If so, which?

We shall try to answer some of these completeness questions elsewhere. Meanwhile, we make a first attempt at an identification of the Hansson systems **DSDL1**, **DSDL2** and **DSDL3** and start with a few preliminary observations.

- (I) The *language* of these three systems is poorer than that of $\mathbf{O}_{dy}\mathbf{S5}^N$ in the following respects: (a) it lacks the operators N and M of universal necessity and possibility; (b) its set of well formed *sentences* differs from $\Sigma_{0,N}^2$ in not allowing iterations and overlapping of dyadic deontic operators, nor any mixed formulas, e.g. of the type $O_BA \rightarrow A$. Thus, in the language used by Hansson, there are, for one thing, no instances of any of our axiom schemata a3–a7. On the other hand, the set of sentences of Hansson’s language should clearly be a *subset* of $\Sigma_{0,N}^2$ (inasmuch as we are at all able to discuss his systems in our present framework). We attempt the following characterization of it.

Let Π be the smallest set which contains as its members all proposition letters in our set Prop as well as \top and \perp , and which is closed under $\neg, \wedge, \vee, \rightarrow$ and \Leftrightarrow . Thus, Π is simply the set of wffs of the familiar propositional calculus with *verum* and *falsum*. We then define Θ (= the set of sentences of our reconstructed Hansson language) to be the smallest set S such that:

- (a) If A, B are in Π , then O_BA and P_BA are in S .
- (b) If C, D are in S , then so are $\neg C, (C \wedge D), (C \vee D), (C \rightarrow D)$ and $(C \Leftrightarrow D)$.

Clearly, then, we have that $\Theta \subseteq \Sigma_0^2 \subseteq \Sigma_{0,N}^2$.

- (II) As for the *semantics* of the Hansson dyadic system, we pointed out at the beginning of the previous section that we were going to use Kripkean possible worlds rather than Boolean valuations in the basic set on which \succ is defined; this approach naturally leads to our present sort of deontic models. Now, as characteristic conditions on \succ , Hansson [1969, p. 395 f.] adopts the following:

For the system DSDL1 :	reflexivity ($\delta 1$).
For the system DSDL2 :	limitedness ($\delta 2$; in addition to $\delta 1$).
For the system DSDL3 :	transitivity ($\delta 3$) and strong connectedness ($\delta 4$) (in addition to $\delta 1$ and $\delta 2$).

As for the notion of *truth* as applied to sentences in Θ of the forms $O_B A$ and $P_B A$, Hansson proposes analogues of the two conditions stated under (b) in the Lemma on \succ -supplemented dyadic deontic models (we disregard here the fact that Hansson's own concept of \succ -maximality does not completely coincide with ours).

22.1 Semantic identification of DSDL1, DSDL2 and DSDL3

Let A be in $\Sigma_{0,N}^2$, and let $\overline{\overline{H_1(H_2, \text{strong } H_3)}} A$ mean that A is true at every world in every deontic H_1 - (H_2 -, strong H_3 -)model. We then suggest the following characterization of the Hansson systems as subsets of $\Sigma_{0,N}^2$:

- (i) **DSDL1** = $\{A \in \Theta : \overline{H_1} A\}$
- (ii) **DSDL2** = $\{A \in \Theta : \overline{H_2} A\}$
- (iii) **DSDL3** = $\{A \in \Theta : \overline{\overline{\text{strong } H_3}} A\}$

So, for $i = 1, 2$, **DSDL i** is the set of deontically H_i -valid sentences in Θ , and **DSDL3** is the set of deontically *strong* H_3 -valid sentences in Θ .

What about axiomatic characterizations of the Hansson systems as deductive calculi? If such were available, our identification of them would be more satisfactory from the proof theoretical point of view. As things stand right now, however, we only have the following somewhat insufficient result:

22.2 Partial syntactic identification of DSDL1, DSDL2 and DSDL3

Let us introduce the following abbreviations:

- E** = the set of theses of $\mathbf{O}_{dy} \mathbf{S5}^N$ + every αi with $i = 0, 1, 2$
- F** = the set of theses of $\mathbf{O}_{dy} \mathbf{S5}^N$ + every αi with $i = 0, 1, 2, 3$
- G** = the set of theses of $\mathbf{O}_{dy} \mathbf{S5}^N$ + every αi with $i = 0, 1, 2, 3, 4$

Furthermore, let \mathbf{E}/Θ ($\mathbf{F}/\Theta, \mathbf{G}/\Theta$) = $\mathbf{E}(\mathbf{F}, \mathbf{G})$ restricted to the set Θ ; i.e. $\mathbf{E} \cap \Theta$ etc. Then we have three groups of more or less obvious results:

I. Soundness results	II. Unsoundness results	III. Incompleteness results
(i) $\mathbf{E}/\Theta \subseteq \mathbf{DSDL1}$	(iv) $\mathbf{F}/\Theta \not\subseteq \mathbf{DSDL1}$	(vii) $\mathbf{DSDL2} \not\subseteq \mathbf{E}/\Theta$
(ii) $\mathbf{F}/\Theta \subseteq \mathbf{DSDL2}$	(v) $\mathbf{G}/\Theta \not\subseteq \mathbf{DSDL1}$	(viii) $\mathbf{DSDL3} \not\subseteq \mathbf{E}/\Theta$
(iii) $\mathbf{G}/\Theta \subseteq \mathbf{DSDL3}$	(vi) $\mathbf{G}/\Theta \not\subseteq \mathbf{DSDL2}$	(ix) $\mathbf{DSDL3} \not\subseteq \mathbf{F}/\Theta$

Proof. As for Group I, appeal to our last soundness theorem; as for Groups II and III, appeal in addition to deontic analogues of the Exercises on alethic H -, H_1 -, and H_2 -models studied in Åqvist [1987, Section 21]. ■

What makes the given syntactic identification only a partial one is, of course, the fact that as yet we do not know whether the *converses* of (i)–(iii) hold, so that we could strengthen ‘ \subseteq ’ to ‘ $=$ ’. Also, if it should turn out that \mathbf{G}/Θ is not complete with respect to strong deontic H_3 -validity among the members of Θ , perhaps \mathbf{G}/Θ is complete with respect to deontic H_3 -validity in Θ *simpliciter*?

23 ON THE COMPLETENESS PROBLEM FOR THE DYADIC DEONTIC LOGIC \mathbf{G}

As in the last section we let \mathbf{G} be the (set of theses of the) system $\mathbf{Q}_{dy}\mathbf{S5}^N$ + every σi with $i 0, 1, \dots, 4$. Thus $\mathbf{G} \subseteq \Sigma_{0,N}^2$, its rules of proof are *modus ponens* (R1) and N -necessitation (R2''), its axiom schemata are a0–a2, a6–a8 (Section 17 above) as well as $\sigma 0$ – $\sigma 4$ (Section 18).

The system \mathbf{G} , as just characterized in purely axiomatic terms, is by far the most important dyadic deontic logic dealt with in the present chapter—recall that in Section 4 *supra* we defined a *strongly normal dyadic* deontic logic as one containing precisely the system \mathbf{G} . Obviously, then, the problem of finding an adequate *semantical* characterization relative to which \mathbf{G} can be proved *complete* is an equally important one. In the original version of this chapter I conjectured that \mathbf{G} was complete with respect to strong H_3 -validity in the sense of the last section; for a ‘possible’, rather complicated proof of this conjectured result I referred the reader to Åqvist [1987, Section 23.3].

I am now convinced that the completeness problem for the system \mathbf{G} has a much simpler solution than was suggested by my earlier conjectured proof. In the remainder of this section I shall then outline that simpler solution as first presented in two recent papers by Åqvist [1996; 1997]. Again, in the three final sections (Sections 24–26) of this chapter I shall present some further recent results on the crucial dyadic system \mathbf{G} .

23.1 Improved semantics for G

DEFINITION 74 (\mathbf{G} -structures and truth at a point in a \mathbf{G} -structure). By a \mathbf{G} -structure we mean any ordered triple

$$\mathcal{U} = \langle W, V, best \rangle$$

where

- (i) $W \neq \emptyset$
- (ii) $V : \text{Prop} \times W \rightarrow \{1, 0\}$
- (iii) $best : \Sigma_{0,N}^2 \rightarrow \mathcal{P}W$.

We can now tell what it means for any sentence A in $\Sigma_{0,N}^2$ to be *true at* a point (“world”) $x \in W$ in a \mathbf{G} -structure \mathcal{U} [in symbols: $\frac{\mathcal{U}}{x} A$], starting out with obvious clauses like

$$\frac{\mathcal{U}}{x} p \text{ iff } V(p, x) = 1 \text{ (for any } p \text{ in Prop)}$$

$$\frac{\mathcal{U}}{x} \top$$

$$\text{not } \frac{\mathcal{U}}{x} \perp$$

and so on for molecular sentences having Boolean connectives as their main operator. We then handle sentences having modal and dyadic deontic operators as their main operator as follows:

$$\frac{\mathcal{U}}{x} NA \text{ iff for each } y \text{ in } W : \frac{\mathcal{U}}{y} A$$

$$\frac{\mathcal{U}}{x} MA \text{ iff for some } y \text{ in } W : \frac{\mathcal{U}}{y} A$$

$$\frac{\mathcal{U}}{x} O_B A \text{ iff for each } y \text{ in } best(B) : \frac{\mathcal{U}}{y} A$$

$$\frac{\mathcal{U}}{x} P_B A \text{ iff for some } y \text{ in } best(B) : \frac{\mathcal{U}}{y} A$$

DEFINITION 75 (\mathbf{G} -models, \mathbf{G} -validity and \mathbf{G} -satisfiability). We now focus our attention on a special kind of \mathbf{G} -structures called “ \mathbf{G} -models”. By a \mathbf{G} -model we mean any \mathbf{G} -structure satisfying the following five conditions

on the function $best$, where, as usual, we let $\|A\|^{\mathcal{U}}$, or $\|A\|$ for short, be the extension in \mathcal{U} of A :

- $\sigma 0$ $\|A\| = \|B\|$ only if $best(A) = best(B)$
- $\sigma 1$ $best(A) \subseteq \|A\|$
- $\sigma 2$ $best(A) \cap \|B\| \subseteq best(A \wedge B)$
- $\sigma 3$ $\|A\| \neq \emptyset$ only if $best(A) \neq \emptyset$
- $\sigma 4$ $best(A) \cap \|B\| \neq \emptyset$ only if $best(A \wedge B) \subseteq best(A) \cap \|B\|$

for any sentences A, B in $\Sigma_{0,N}^2$. The notions of \mathbf{G} -validity and \mathbf{G} -satisfiability are then defined in the usual way.

REMARK 76. Conditions $\sigma 0$ – $\sigma 4$ are very much like the so-named conditions on the function opt in Section 19 above. But note that opt was defined for all sentences in the alethic language of $\mathbf{S5}_{Qmo}^N$, whereas $best$ is defined for those in the dyadic deontic language of $\mathbf{O}_{dy}\mathbf{S5}^N$ and \mathbf{G} .

THEOREM 77 (Soundness and Completeness of the system \mathbf{G}).

Weak version: for each A in $\Sigma_{0,N}^2$: A is \mathbf{G} -provable iff A is \mathbf{G} -valid.

Strong version: for each $S \subseteq \Sigma_{0,N}^2$: S is \mathbf{G} -consistent iff S is \mathbf{G} -satisfiable.

Proof. (sketchy). The soundness parts are unproblematic. So we concentrate on the ‘only if’ half of the strong version, from which the ‘if’ half of the weak one is immediate.

Let S be any \mathbf{G} -consistent set of sentences, and let S^+ be a maximal \mathbf{G} -consistent extension of S , the existence of which is guaranteed by Lindenbaum’s Lemma. Form the *canonical \mathbf{G} -structure generated by S^+* in the sense of the structure

$$\mathcal{U}^{S^+} = \langle W, V, best \rangle$$

where

- (i) W = the set of maximal \mathbf{G} -consistent sets x of sentences such that for all A in $\Sigma_{0,N}^2$: if $NA \in S^+$, then $A \in x$.
- (ii) V = the assignment defined as follows: for each p in $Prop$ and each x in W , $V(p, x) = 1$ iff $p \in x$.
- (iii) $best$ = the function from $\Sigma_{0,N}^2$ into $\mathcal{P}(W)$ defined by setting, for all sentences B , $best(B) = \{x \in W : \text{for all sentences } A, \text{ if } O_B A \in S^+, \text{ then } A \in x\}$.

Omitting details we can then prove that, as just defined, the generated canonical \mathbf{G} -structure \mathcal{U}^{S^+} satisfies all lemmata needed for our desired completeness result. The most interesting one among them is the Verification Lemma, to the effect that \mathcal{U}^{S^+} is a \mathbf{G} -model satisfying the five conditions σ_0 – σ_4 on the function *best*. A proof to precisely that effect is easily obtained as follows: define our three-place relation R by the requirement

$$(*) \quad xR_B y \text{ iff } y \in \text{best}(B) \text{ (for all } x, y \text{ in } W \text{ and all } B \text{ in } \Sigma_{0,N}^2)$$

On the basis of this definition, we quickly verify that our present truth conditions for $O_B A$ and $P_B A$ are equivalent to those given in Section 16 *supra*, that R meets condition (6) laid down in Section 17 *supra*, and that for each $i = 0, 1, \dots, 4$, the condition σ_i on *best* is equivalent to the restriction ρ_i on R (Section 18). Again, this result enables us to transform the proof given in Åqvist [1987, Section 18.1, pp. 161–165] into a proof that the canonical \mathbf{G} -structure \mathcal{U}^{S^+} is indeed a \mathbf{G} -model, as desired. ■

24 AN INFINITE HIERARCHY OF EXTENSIONS OF \mathbf{G} : THE DYADIC DEONTIC LOGICS $\mathbf{G}m[m = 1, 2, \dots]$

In this and the following sections of the present chapter we intend to shed some more light on the system \mathbf{G} by studying an infinite hierarchy $\mathbf{G}m[m = 1, 2, \dots]$ of extensions of that system. The soundness and completeness of every system in that hierarchy is then asserted in a Theorem, for the proof of which we refer the reader to Åqvist [1996]. The main semantical technical device employed in our study of these extensions of \mathbf{G} is this: in the models of each system $\mathbf{G}m$ in the hierarchy, we work with a set

$$\{\text{opt}_1, \text{opt}_2, \dots, \text{opt}_m\}$$

which is to be a *partition* of the set W of ‘possible worlds’ into exactly m non-empty, pairwise disjoint and together exhaustive ‘optimality’ classes, viewed as so many *levels of perfection*. Intuitively, we think of opt_1 as the set of ‘best’ [optimal] members of W as a whole, opt_2 as the set of best members of $W - \text{opt}_1$ [the ‘second best’ members of W], opt_3 as the set of best members of $W - (\text{opt}_1 \cup \text{opt}_2)$ [the ‘third best’ members of W]; and so on. Now, we shall represent each level of perfection in the object-language of the systems by a so-called *systematic frame constant*. The truth conditions and axioms governing those constants can then be seen to play a highly important, characteristic role in our axiomatization.

Thus, the primitive logical *vocabulary* of the systems $\mathbf{G}m$ (m any positive integer) results from that of \mathbf{G} by adding to the latter an infinite family

$$\{Q_i\} i = 1, 2, \dots$$

of *systematic frame constants*, indexed by the set of positive integers. As just explained, the Q_i are to represent different ‘levels of perfection’ in the models of the system $\mathbf{G}m$. The set *Sent* of their well-formed sentences (formulas, wffs) is then defined in the straightforward way—we think of the Q_i as zero-place connectives on a par with \top and \perp .

We begin the presentation of the new dyadic deontic logics $\mathbf{G}m$ by outlining their *proof theory*. The rules of proof *modus ponens* and *N-necessitation* are common to \mathbf{G} and the $\mathbf{G}m[m = 1, 2, \dots]$. In addition to the *axiom schemata* of \mathbf{G} , each system $\mathbf{G}m$ has the following:

- $\alpha 5.$ $Q_i \rightarrow \neg Q_j$, for all positive integers i, j with $1 < i \neq j < \omega$
- $\alpha 6.$ $P_B Q_i \rightarrow ((Q_1 \vee \dots \vee Q_{i-1}) \rightarrow \neg B)$, for all i with $1 < i \leq m$
- $\alpha 7.$ $Q_1 \rightarrow (O_B A \rightarrow (B \rightarrow A))$
- $\alpha 8.$ $(Q_1 \wedge O_B A \wedge B \wedge \neg A) \rightarrow P_B (Q_1 \vee \dots \vee Q_{i-1})$,
for all i with $1 < i \leq m$
- $\alpha 9.$ $Q_1 \vee \dots \vee Q_m$
- $\alpha 10.$ $MQ_1 \wedge \dots \wedge MQ_m$.

Then, the *axiomatic system* $\mathbf{G}m[m = 1, 2, \dots]$ is determined by the axiom schemata $\alpha 0$ – $\alpha 2$, $\alpha 6$ – $\alpha 8$ and $\alpha 9$ – $\alpha 10$ (and the usual rules of proof). Moreover, we define the notions of *provability*, *derivability*, [in] *consistency* and *maximal consistency* for the systems $\mathbf{G}m$ in the straightforward way.

Turning next to the *semantics* of the logics $\mathbf{G}m$, we define, for any positive integer m , a $\mathbf{G}m$ -*structure* as an ordered quintuple

$$U = (W, V, \{\text{opt}_i\}_{i=1,2,\dots,m}, \text{best})$$

where

- (i) $W \neq \emptyset$ [W is a non-empty set of ‘possible worlds’].
- (ii) $V: \text{Prop} \rightarrow \text{pow}(W)$ [V is a valuation function which to each propositional variable assigns a subset of W].
- (iii) $\{\text{opt}_i\}_{i=1,2,\dots}$ is an infinite sequence of subsets of W .
- (iv) m is the positive integer under consideration.
- (v) $\text{best}: \text{Sent} \rightarrow \text{pow}(W)$ [best is a function which to each sentence in the $\mathbf{G}m$ -language assigns a subset of W , heuristically, the set of *best* worlds in the extension (truth-set) of the sentence under consideration].

The definition of a sentence being *true at a point in* a $\mathbf{G}m$ -structure remains as in the case of \mathbf{G} , or \mathbf{G} -structures, except for the following fresh clause governing our frame constants:

$$\frac{U}{x} Q_i \text{ iff } x \in \text{opt}_i \quad (\text{for all positive integers } i).$$

We now focus our attention on a special kind of $\mathbf{G}m$ -structures called ‘ $\mathbf{G}m$ -models’. By a $\mathbf{G}m$ -model we shall mean any $\mathbf{G}m$ -structure \mathcal{U} where $\{\text{opt}_i\}$, m and best satisfy the following additional conditions:

Exactly m Non-empty levels of Perfection

This condition requires the set $\{\text{opt}_1, \text{opt}_2, \dots, \text{opt}_m\}$ to be a *partition* of W in the sense that

- (a) $\text{opt}_i \cap \text{opt}_j = \emptyset$, for all positive integers i, j with $1 \leq i \neq j \leq m$
- (b) $\text{opt}_1 \cup \dots \cup \text{opt}_m = W$
- (c) $\text{opt}_i \neq \emptyset$, for each i with $1 \leq i \leq m$.
- (d) $\text{opt}_i = \emptyset$, for each i with $m < i < \omega$.

The second condition is one on our ‘choice’ function best; it is intended to capture the intuitive meaning of that function:

$$\gamma^0. \quad x \in \text{best}(B) \quad \text{iff} \quad \begin{array}{l} \frac{\mathcal{U}}{x} B \text{ and for each } y \text{ in } W : \text{ iff} \\ \frac{\mathcal{U}}{y} B, \text{ then } x \succcurlyeq y. \end{array}$$

Here, the weak preference relation \succcurlyeq , ‘is at least as good (ideal) as’ is to be understood as follows. First of all, by clauses (a) and (b) in the condition *Exactly m Non-empty levels of Perfection*, we have that for each x in W there is *exactly one* positive integer i with $1 \leq i \leq m$ such that $x \in \text{opt}_i$. We then define a ‘ranking’ function r from W into the closed interval $[1, m]$ of integers by setting

$$r(x) = \text{the } i, \text{ with } 1 < i < m, \text{ such that } x \in \text{opt}_i.$$

Finally, we define \succcurlyeq as the binary relation on W such that for all x, y in W :

$$x \succcurlyeq y \text{ iff } r(x) \leq r(y).$$

Armed with the notion of a $\mathbf{G}m$ -model, we define, for $m = 1, 2, \dots$, those of $\mathbf{G}m$ -validity and $\mathbf{G}m$ -satisfiability in the obvious way.

THEOREM 78. (Soundness and completeness of the systems $\mathbf{G}m[m = 1, 2, \dots]$)

Weak version: For each A in *Sent*: A is $\mathbf{G}m$ -provable iff A is $\mathbf{G}m$ -valid.

Strong version: For each $S \subseteq \text{Sent}$: S is $\mathbf{G}m$ -consistent iff S is $\mathbf{G}m$ -satisfiable.

Proof. See Åqvist [1996]. Also, we observe that a proof that the generated canonical $\mathbf{G}m$ -structure \mathcal{U}^{S^+} satisfies our condition γ^0 on the function best is easily extracted from the proof given in Åqvist [1993] and [1987, Ch VI, Section 23.3.6, pp. 187–191] that the three-place relation R satisfies essentially the same condition (use the definition (*) in the last section!). ■

25 ON THE RELATION OF THE ‘CORE’ SYSTEM \mathbf{G} TO THE LOGICS $\mathbf{G}m[m = 1, 2, \dots]$

In the present section we deal with the system \mathbf{G} and state a result to the effect that \mathbf{G} is the *intersection* of all the logics $\mathbf{G}m[m = 1, 2, \dots]$ (identifying as usual a ‘logic’ with the set of its theses, or sentences provable in it). Thus, the result answers the question how our crucial system \mathbf{G} is related to the $\mathbf{G}m$.

THEOREM 79. *For each \mathbf{G} -sentence A (i.e. member of $\Sigma_{0,N}^2$):*

$$\vdash_{\mathbf{G}} A \text{ iff for each positive integer } m, \vdash_{\mathbf{G}m} A.$$

Proof. See Åqvist [1997, Section 3]. Let us just outline the main structure of our proof as given in that paper. The non-trivial direction here is the right-to-left one, the contraposed version of which asserts the following: if A is not \mathbf{G} -provable, then there exists a positive integer m such that A is not $\mathbf{G}m$ -provable (either). We then argue as follows:

1. $\not\vdash_{\mathbf{G}} A$ hypothesis
2. $\not\vdash_{\mathbf{G}} \frac{\mathcal{U}}{\quad}$ from 1 by the weak completeness of \mathbf{G}
3. $\not\vdash_x \frac{\mathcal{U}}{\quad}$, for some \mathbf{G} -model $\mathcal{U} = \langle W, V, \text{best} \rangle$ and some x in W = from 2 by the definition of \mathbf{G} -validity.

Let $\mathcal{U}^* = \langle W^*, V^*, \text{best}^* \rangle$ be the *filtration* of \mathcal{U} through the set of sub-sentences of A (in the sense rigorously defined in my 1997 paper mentioned above), and let $[x]$ be the equivalence class of x under a certain equivalence relation on W (also defined in the paper). We then obtain:

4. $\not\vdash_{[x]} \frac{\mathcal{U}^*}{\quad}$ from 3 by the Filtration Lemma for \mathbf{G} proved in Åqvist [1997].

We now observe that the filtration \mathcal{U}^* is necessarily a *finite* \mathbf{G} -model, so that there can be at most a *finite* number of levels of perfection compatible with and definable on \mathcal{U}^* . Again, this means that we can construct, for some positive integer m , a $\mathbf{G}m$ -models

$$\mathcal{U}^{*+} = \langle W^*, V^*, \{\text{opt}_i\}_{i=1,2,\dots,m}, \text{best}^* \rangle$$

with the property that

5. $\not\vdash_{[x]} \frac{\mathcal{U}^{*+}}{\quad}$ from 4 by the fact that the new items opt_i and m do not affect the truth-value of the \mathbf{G} -sentence A

and then argue:

- | | |
|--------------------------------------|--|
| 6. $\frac{}{\vdash_{\mathbf{G}m}}$ | from 5 by the definition of $\mathbf{G}m$ -validity |
| 7. $\frac{}{\vdash_{\mathbf{G}m}} A$ | from 6 by the soundness of each system $\mathbf{G}m$ |

where 7 is our desired conclusion. In Åqvist [1997, Section 3] we then finish the proof by providing a detailed careful justification of the two crucial steps 4 and 5 in the above overall argument. Among other things, our proof is seen to profit from the fact that the system \mathbf{G} is known to be *deductively equivalent*, under appropriate definitions, to a certain logic \mathbf{PR} of *preference*, as shown in Åqvist [1987, Appendix, §33]. ■

26 REPRESENTABILITY OF DYADIC DEONTIC LOGICS IN ALETHIC MODAL LOGICS WITH SYSTEMATIC FRAME CONSTANTS

In this final section of the present chapter we point out that the dyadic deontic logics $\mathbf{G}m$ are *representable* in a hierarchy of alethic modal logics $\mathbf{H}m[m = 1, 2, \dots]$, which lack deontic operators in their primitive vocabulary, but which are such that we can *define* those operators in them, somewhat in the spirit of the well known Andersonian reduction. The detailed proof of this result in effect forms the bulk of Åqvist [1996]; here, we just present enough material so as to enable us to state that result in an intelligible way.

Consider the result of banishing the dyadic deontic operators O and P from the *primitive* logical vocabulary of the systems $\mathbf{G}m[m = 1, 2, \dots]$. Then, for any positive integer m , let the *axiomatic system* $\mathbf{H}m$ of alethic modal logic with frame constants be determined by the rules of proof *modus ponens* and N -necessitation, and the axiom schemata $\alpha 0$ (= all tautologies over the present reduced language), $\alpha 8$ (= $\mathbf{S5}$ -schemata for N, M), $\alpha 5$, $\alpha 9$ and $\alpha 10$; i.e. by those axiom schemata in $\mathbf{G}m$ that do not contain occurrences of O or P . Clearly each system $\mathbf{G}m$ is an extension of $\mathbf{H}m$.

As to the *semantics* of the alethic modal logics $\mathbf{H}m[m = 1, 2, \dots]$, a $\mathbf{H}m$ -*structure* will be the ordered quadruple that results from deleting the function *best* in a $\mathbf{G}m$ -*structure*, and a $\mathbf{H}m$ -*model* will be a $\mathbf{H}m$ -structure satisfying (a)–(d) in the requirement *Exactly m Non-empty levels of Perfection* (whereas the condition γ^0 on *best* vanishes altogether). We then have the following result:

THEOREM 80. (Soundness and completeness of the systems $\mathbf{H}m[m = 1, 2, \dots]$)

Weak version: For every sentence A : A is **Hm**-provable iff A is **Hm**-valid.

Strong version: For each set S of sentences: S is **Hm**-consistent iff S is **Hm**-satisfiable.

Proof. See Åqvist [1996]. ■

What is the interest of the just considered infinite hierarchy **Hm** of alethic modal logics? We take it to be this: although the operators (for conditional obligation) and **P** (for conditional permission) are not primitive in the language of the **Hm**, they can be *defined* in those systems as follows:

$$\begin{aligned}
 \text{Def O.} \quad O_B A &= \text{df } [M(Q_1 \wedge B) \supset N((Q_1 \wedge B) \supset A)] \wedge \\
 &[(\neg M(Q_1 \wedge B) \wedge M(Q_2 \wedge B)) \supset N(Q_2 \wedge B \supset A)] \wedge \dots \wedge \\
 &[(\neg M(Q_1 \wedge B) \wedge \dots \wedge \neg M(Q_{m-1} \wedge B) \wedge M(Q_m \wedge B)) \supset \\
 &N(Q_m \wedge B \supset A)].
 \end{aligned}$$

$$\begin{aligned}
 \text{Def P.} \quad P_B A &= \text{df } M(Q_1 \wedge B \wedge A) \vee \\
 &(\neg M(Q_1 \wedge B) \wedge M(Q_2 \wedge B \wedge A)) \vee \dots \vee \\
 &(\neg M(Q_1 \wedge B) \wedge \dots \wedge \neg M(Q_{m-1} \wedge B) \wedge M(Q_m \wedge B \wedge A)).
 \end{aligned}$$

We can then prove the following:

THEOREM 81 (Deductive Equivalence for **Hm** and **Gm**). *Let **Hm**+Def O+Def P be the result of adding the definitions Def O and Def P supra to the alethic system **Hm**. Then, for all $m = 1, 2, \dots$, **Hm** + Def O + Def P is deductively equivalent to **Gm** in the sense that the following two conditions are satisfied:*

- (i) **Hm** + Def O + Def P contains **Gm**.
- (ii) Each of Def O and Def P is provable in the form of an equivalence in **Gm**.

Proof. See Åqvist [1996]. ■

An alternative, more ‘semantical’ method of representing the dyadic deontic systems **Gm** in the alethic modal logics **Hm** is this: define recursively

a certain *translation* ϕ from the set of $\mathbf{G}m$ -sentences into the set of $\mathbf{H}m$ -sentences by the stipulations:

$$\begin{aligned}\phi(p) &= p, \text{ for each propositional variable } p \text{ in Prop} \\ \phi(\top) &= \top \\ \phi(\perp) &= \perp \\ \phi(Q_i) &= Q_i, \text{ for each positive integer } i \\ \phi(\neg A) &= \neg\phi(A) \\ \phi(A \wedge B) &= (\phi(A) \wedge \phi(B))\end{aligned}$$

and similarly for $\mathbf{G}m$ sentences having $\vee, \rightarrow, \Leftrightarrow$ as their principal sign.

$$\begin{aligned}\phi(NA) &= N\phi A \\ \phi(MA) &= M\phi A\end{aligned}$$

where we have written ϕA instead of $\phi(A)$ to the right. Finally, we have two characteristic clauses corresponding to *Def O* and *Def P*:

$$\begin{aligned}\phi(O_B A) &= [M(Q_1 \wedge \phi B) \supset N((Q_1 \wedge \phi B) \supset \phi A)] \wedge \\ &\quad [(\neg M(Q_1 \wedge \phi B) \wedge M(Q_2 \wedge \phi B)) \supset N(Q_2 \wedge \phi B \supset \phi A)] \wedge \dots \wedge \\ &\quad [(\neg M(Q_1 \wedge \phi B) \wedge \dots \wedge \neg M((Q_{m-1} \wedge \phi B) \wedge M(Q_m \wedge \phi B)) \supset \\ &\quad N(Q_m \wedge \phi B \supset \phi A)]\end{aligned}$$

Similarly for $\phi(P_B A)$: write it out as an m -termed disjunction!

We then have the following result:

THEOREM 82 (Translation for $\mathbf{G}m$ and $\mathbf{H}m$). *For each positive integer m , and for each $\mathbf{G}m$ -sentence A :*

$$\vdash_{\mathbf{G}m} A \text{ iff } \vdash_{\mathbf{H}m} \phi A.$$

Proof. Again, see Åqvist [1996]. The left-to-right direction is more or less immediate from the proof of the Deductive Equivalence theorem *supra*. The proof of the right-to-left is reminiscent of that of the Theorem on the relation of \mathbf{G} to the $\mathbf{G}m$ in respect of utilizing a relevant completeness result in the second step. ■

Combining the present Translation theorem with the Theorem on the relation of \mathbf{G} to the $\mathbf{G}m$, we obtain the obvious

COROLLARY 83. *For any \mathbf{G} -sentence A : $\vdash_{\mathbf{G}} A$ iff for all $m = 1, 2, \dots$, $\vdash_{\mathbf{H}m} \phi A$.*

Proof. Immediate from the two theorems just mentioned. ■

Research carried out under the auspices of the Bank of Sweden Tercentenary Foundation project RJ 79/23 on criminal intent and negligence.

Uppsala Universitet, Sweden.

BIBLIOGRAPHY

Within the boundaries of a reasonable-size bibliography it is now, i.e. in 1982, impossible to do justice to the existing literature on deontic logic, especially if one is to include such topics as the logic of imperatives, ethical and legal theory, and what have you. Laudable attempts have been made in the past, though: the bibliographies of Anderson [1956] (together with a *Supplementary Bibliography* (1966)), Rescher [1966], Von Wright [1968], Chellas [1969] and Føllesdal and Hilpinen [1971] are still of a manageable size. *Really* comprehensive bibliographies are: Berkemann and Strasser [1974] (around 800 items) and Conte and Di Bernardo [1977] (approaching 1500 items!). So, naturally, my own present attempt will be fairly selective; and it remains unclear to me exactly what principle of selection is being applied. Anyway, here we go:

DEONTIC LOGIC AND CONTRARY-TO-DUTIES

1 INTRODUCTION

Deontic logic is concerned with the logical analysis of such normative notions as *obligation*, *permission*, *right* and *prohibition*. Although its origins lie in systematic legal and moral philosophy, deontic logic has begun to attract the interest of researchers in other areas, particularly computer science, management science and organisation theory. Among the application areas which have already received some attention in the literature are: issues of knowledge representation in the design of legal expert systems; the formal specification of aspects of computer systems, for instance in regard to security and access control policies, fault tolerance, and database integrity constraints; the formal characterisation of aspects of organisational structure, pertaining for example to the responsibilities and powers which agents are required or authorised to exercise. The “ Δ EON” workshop proceedings provide some illustrations of work in these areas (see [Δ EON91; Δ EON94; Δ EON96]).

Deontic logic is one of the formal tools needed in the design and specification of *normative systems*, where the latter are understood to be sets of agents (human or artificial) whose interactions can fruitfully be regarded as norm-governed; the norms prescribe how the agents ideally should and should not behave, what they are permitted to do, and what they have a right to do. Importantly, the norms allow for the possibility that actual behaviour may at times deviate from the ideal, i.e. that violations of obligations, or of agents’ rights, may occur.

In [Jones and Sergot, 1992; Jones and Sergot, 1993] Jones and Sergot argue that it is precisely when the possibility of norm violation is kept open that deontic logic has a potentially useful role to play. If agents can always be assumed to behave in conformity to norm, the normative dimension ceases to be of interest: the actual does not depart from the ideal, so nothing is lost by *merely* describing what the agents in fact do. Thus, although it is correct to say that deontic logic deals with the logic of *obligation*, *permission* and other normative notions, a more insightful characterisation, Jones and Sergot suggest, views deontic logic as essentially concerned with representing and reasoning about the distinction between the actual and the ideal. Systems for which that distinction is relevant are genuinely normative systems, and their specification will ordinarily include “secondary” norms which indicate what is to be done in circumstances in which actual behaviour has deviated from the ideal. The methodological guidelines proposed in [Jones and Sergot, 1992; Jones and Sergot, 1993] strongly suggest

that “secondary” norms of this kind (first dubbed “contrary-to-duty” in [Chisholm, 1963]) will be a prominent feature of normative systems, and thus that any adequate deontic logic must accommodate them. However, the analysis of contrary-to-duty obligation sentences has proved to be a task of some considerable complexity. And it is this issue — at the very core of deontic logic — which this chapter addresses.

The plan is as follows: we first (Section 2) describe Standard Deontic Logic, and a number of its defects, including problems regarding the representation of conditional obligation sentences. In the course of Section 3 we examine a number of different theories which have attempted to accommodate contrary-to-duty obligation sentences (CTDs), and in the course of this examination we identify several criteria — eight in all — which, we argue, an adequate treatment of Chisholm’s puzzle about CTDs should meet. Some of these criteria are not tied to Chisholm’s problem, but apply quite generally to the analysis of CTDs. Section 4 presents a revised, and in parts considerably modified version of the [Carmo and Jones, 1997] theory of CTDs; its application to a number of CTD “scenarios” is investigated in some detail in Section 5, and this provides a further impression of the broad range of representational and reasoning issues which a CTD theory must address. Section 6 examines some possible counter-examples to the proposed analysis, thereby relating its treatment of CTD problems to other well-known issues in deontic logic, concerning — in particular — the closure of deontic operators under logical consequence, and the representation of conflicts of obligations. Section 7 offers further observations on alternative approaches based on temporal logic, the logic of action, and preference orderings, respectively. The overall aim of the chapter is to supply a rather detailed overview of a group of problems at the heart of deontic logic, and a guide to existing attempts to solve them.

2 DEONTIC LOGIC: THE STANDARD APPROACH

2.1 *Standard Deontic Logic*

The standard approach to deontic logic takes it to be a branch of modal logic, interpreting the necessity operator \Box as expressing ethical/legal necessity, i.e. as meaning “it is obligatory that”, and denoting it by O; accordingly, the dual possibility operator $\Diamond = \neg\Box\neg$ is interpreted as expressing “it is permitted that” (and is denoted by P), and the impossibility modal construction $\Box\neg$ is interpreted as expressing “it is forbidden that” (and is often denoted by F).

Axiomatically, the weakest deontic logic (called standard deontic logic, SDL for short) is then obtained by replacing the modal necessity schema (T) ($\Box A \rightarrow A$: unacceptable for a deontic interpretation, since what is

obligatory may fail to be the case) by the (D) schema (which requires that what is obligatory is permitted). Thus, following the Chellas classification [Chellas, 1980], SDL is the weakest normal modal system of type KD; that is, its theorems can be characterized as the smallest set of formulas that includes all instances of the following axiom schemas, and that is closed under the O-necessitation rule and Modus Ponens (MP).

Axiom schemas

- (PC) All instances of tautologies
(PC stands for Propositional Calculus)
- (K) $O(A \rightarrow B) \rightarrow (OA \rightarrow OB)$
- (D) $(OA \rightarrow PA)$

Rules

$$\text{O-necessitation: } \frac{A}{OA}$$

$$\text{Modus Ponens (MP): } \frac{A, A \rightarrow B}{B}$$

We here employ capital letters (A, B, C, \dots) to stand for arbitrary formulas (well-formed sentences of the underlying propositional modal logic), and we use lower case letters (p, q, \dots) for arbitrary atomic sentences, and \perp and \top to denote, respectively, a contradiction and a tautology; parentheses will be omitted following the usual precedence rules for the operators; the Boolean connectives will be denoted by $\neg, \wedge, \vee, \rightarrow$ and \leftrightarrow ; in the meta-language we denote such connectives by “not”, “and”, “or”, “if ... then ...” (or “implies”) and “iff” (if and only if), and in the meta-language we also avail ourselves of the universal and the existential quantifiers (these do not appear in the object language: we are concerned only with propositional modal logics). Moreover, as usual, we will use $\vdash A$ (respectively $\not\vdash A$) to denote that A is a theorem (respectively, A is not a theorem) of the underlying logical system; and, following the traditional philosophical/logical approach to deduction, we say (cf. [Chellas, 1980; Hughes and Cresswell, 1984]) that A is deducible from a set of hypotheses Γ , written $\Gamma \vdash A$ (or simply $A_1, \dots, A_n \vdash A$ if Γ is finite), iff A belongs to the smallest set of formulas that contains Γ and the theorems and that is closed under (MP).¹

¹In this way we get a Boolean, compact, deductive system (see e.g. [Bull and Segerberg, 2001]). Non-Boolean axiomatic approaches to deduction, where non-tautological rules may also be applied to the hypotheses, and not only to the theorems, may be found in some works in the field of mathematical logic, such as [Hamilton, 1978; Mendelson, 1979].

Semantically, the models \mathcal{M} of SDL are standard models [Chellas, 1980]: $\mathcal{M} = (W, R, V)$, where W is a non-empty set (the set of worlds), R is a binary relation on W and V is an assignment to each atomic sentence of a set of worlds; informally, $V(p)$ denotes the set of worlds where p is true. In order to validate the schema (D) we require that the accessibility relation R is serial, i.e. $(\forall w)(\exists v)wRv$ (using w, v, \dots to denote worlds and, as usual, writing wRv instead of $\langle w, v \rangle \in R$). The deontic interpretation of the accessibility relation is as follows: wRv iff v is a deontic alternative to, or an ideal version of, w . The truth of a formula A in a world w of a model \mathcal{M} is denoted by $\mathcal{M} \models_w A$ and is defined as usual: for instance, $\mathcal{M} \models_w \bigcirc A$ iff $(\forall v)$ (if wRv then $\mathcal{M} \models_v A$); thus, informally, $\bigcirc A$ is true in a world w iff A is true in all ideal versions of w . A formula A is true in a model \mathcal{M} , written $\mathcal{M} \models A$, iff A is true in all the worlds of the model \mathcal{M} ; and a formula A is valid, written $\models A$, iff A is true in all models.

2.2 SDL and its problems

It is widely accepted that SDL is not adequate as a basic deontic logic. In fact, few systems of logic have been as heavily criticised as SDL; SDL gives rise to a set of “paradoxes” (theorems of SDL that many have deemed to be counter-intuitive) and there are some deontic concepts and constructions which apparently cannot be expressed in SDL in a consistent manner. Some of the main examples will be given below. We have essentially two aims here: first, without any claims to originality, we comment on the reasons underlying the so-called paradoxes; secondly, we indicate which of these problems have a counterpart in other areas of applied modal logic (e.g., epistemic, doxastic and action logics), and which seem to be particular to deontic logic.

A first group of paradoxes has its origin in the closure of the \bigcirc -operator under logical consequence (that is, in the fact that SDL, like any normal modal logic, contains the (RM)-rule: “if $\vdash A \rightarrow B$ then $\vdash \bigcirc A \rightarrow \bigcirc B$ ”). Some well known examples are:

- Ross paradox: $(\vdash \bigcirc A \rightarrow \bigcirc (A \vee B))$

“If it is obligatory to mail the letter, then it is obligatory to mail the letter or to burn it”

The question of the significance of this paradox has been the subject of considerable dispute. Whereas some claim that the second obligation (the one in the consequent) is a counter-intuitive consequence of the first, since it seems to leave open to the agent a choice to mail or to burn the letter, others maintain that the consequent does not leave a choice of this kind, because burning the letter is clearly not a way of meeting the obligation expressed by the antecedent. Given

the perspective on deontic logic advocated in Section 1, however, we should also look at the problem from the point of view of *violation*: supposing that A is obligatory and that A is not the case, how many obligations have been violated? If we accept the Ross theorem, then not only has the obligation that A been violated, but — in addition — for *each* state of affairs B which actually fails to obtain, an obligation that $A \vee B$ has *also* been violated. This is a peculiar result; it contrasts, of course, with how things look from a *fulfilment* perspective; for if the obligation that A is fulfilled, then so are all the other obligations which can be derived by application of the Ross theorem. (We are assuming, as is natural, that within SDL violation of an obligation OC is to be expressed as the conjunction $OC \wedge \neg C$.)

- Free Choice Permission paradox:

This paradox has to do with the fact that (in SDL) $\not\vdash P(A \vee B) \rightarrow (PA \wedge PB)$, whereas — ordinarily — if it is permitted that A or B this would be understood to imply that A is permitted and B is permitted. We include this paradox in this group, since the reason why we cannot add $P(A \vee B) \rightarrow (PA \wedge PB)$, as a new axiom, to SDL is the fact that, by the (RM)-rule, $\vdash PA \rightarrow P(A \vee B)$, which together with $P(A \vee B) \rightarrow (PA \wedge PB)$ would imply $PA \rightarrow (PA \wedge PB)$; so permission to go to the cinema would imply permission to kill the President! Moreover, from any permission we could then deduce $P\perp$, which is inconsistent with the fact that $\vdash O\top$. However, in common with some other researchers, we think that this “paradox” is a pseudo-problem: if what we want to express is that both A and B are permitted, then we should simply represent that formally by $PA \wedge PB$ (instead of by $P(A \vee B)$).

- Good Samaritan paradox:

“If it is obligatory that Mary helps John who has had an accident, then it is obligatory that John has an accident”

On the assumption that “Mary helps John who has had an accident” is represented as the conjunction “Mary helps John and John has had an accident”, then the antecedent of the above conditional takes the form “ $O(A \wedge B)$ ”. Since, tautologically, a conjunction implies each of its conjuncts, the (RM)-rule yields the SDL theorem: $\vdash O(A \wedge B) \rightarrow OB$. In our view, the formal concepts needed to deal with problems about contrary-to-duty obligations can also provide an appropriate analysis of the Good Samaritan problem. So we return to this issue below, in Section 6.

- Deontic/epistemic paradox:

“If it is obligatory that Mr. X knows that his wife commits adultery, then it is obligatory that X’s wife commits adultery”

We here assume, as is usual, that the (T)-schema holds for the epistemic operator. So this problem is again a result of the fact that, in SDL, any logical consequence of that which is obligatory is itself obligatory.

We note that the closure of the necessity operator under logical consequence is also a source of problems for other applications of modal logic, for instance epistemic and doxastic logics, where the assumption that every agent knows (believes) every logical consequence of what he knows (believes) is an extreme idealisation. In the logic of action, too, it is surely not acceptable to suppose that an agent brings about all the logical consequences of that which he brings about (cf. [Elgesem, 1993]).²

A second problem of SDL has to do with the O -necessitation rule itself, according to which any tautology (more generally, any theorem) is obligatory, which is incompatible with the idea that obligations should be possible to fulfill and possible to violate. Similar problems occur with this rule in the epistemic and doxastic logics, where it requires that an agent knows (or believes) all theorems (called in [Hintikka, 1975] the “logical omniscience problem”), and in the logic of action, where it is in general supposed that that which can be brought about must be avoidable (see, e.g., [Elgesem, 1993; Santos and Carmo, 1996]).

A third problem of SDL is that, because of the (D)-schema, it is not possible to express consistently a conflict of obligations, even though, as a matter of fact, normative systems may indeed contain conflicting obligations. We shall return to this issue later in this chapter. But, again, we note at this point that this is not a problem only of deontic logic: similar problems may appear, for instance, in the logic of belief.

However, it is fair to say that, for most deontic logicians, the problem of how to represent *conditional obligation sentences* has been their principal reason for seeking an alternative to SDL. Let us denote by $O(B/A)$ the “conditional obligation of B , given A ”; so $O(B/A)$ is intended to mean that “it is obligatory that B , if A is the case”. In SDL there are two possible ways to represent such sentences:

$$\text{(option1)} \quad O(B/A) =_{\text{df}} A \rightarrow O B$$

$$\text{and (option2)} \quad O(B/A) =_{\text{df}} O(A \rightarrow B)$$

²In [Konolige and Pollack, 1993] it is argued that this problem, called the “side-effect problem” in [Bratman, 1987], is even worse for the logic of intentions - a logic which, it has been suggested, has very close similarities to deontic logic (see [Pörn, 1977; Jones, 1991]).

Note first what these two options have in common. With both of them we get (within SDL):

- (UN) $\vdash O B \leftrightarrow O (B/\top)$
 (SA) $\vdash O (B/A) \rightarrow O (B/A \wedge C)$

The first theorem is generally seen as a good property, and has been accepted by many authors on the grounds that an unconditional obligation is a particular (limiting) case of a conditional obligation, where the condition is a logical truth. Here, however, we shall adopt the opposite view, in line with the opinion expressed by Carlos Alchourrón in [1993, pp. 62], who argued that (UN) was one of the wrong steps followed by almost all researchers in deontic logic.

(SA) is known as the “principle of strengthening of the antecedent”; it is problematic, since it appears to make the expression of defeasible (conditional or unconditional³) obligations impossible; but of course it is a commonplace feature of obligations that they are subject to exceptions. Consider, for instance, a conditional obligation to the effect that, if your aged mother is sick, then you should help her. Such a conditional obligation might well leave room for exceptions, just as penguins might be the exception to the generalisation that birds fly; supposing for example that your young child has been injured in a car accident, and urgently needs you at the hospital, the obligation to help your sick, aged mother may well be deemed to have been defeated, or overturned. But again this problem (which has some connections with the problem of how to deal with conflicting obligations) is not a specific issue of deontic logic; the problem of how to deal with defeasible conditionals appears in many other areas and has been a source of intensive research.

So far we have not yet found a problem that sets deontic logic apart from other branches of modal logic. But we here return to the point emphasised in the introduction and suggest that the issue of how to represent contrary-to-duty obligation sentences (CTDs) — obligations which come into force when some other obligation is violated — seems to be a specific problem of deontic logic. It has sometimes been proposed, however, that CTD obligations may be seen as handling exceptions to (primary) obligations. Although we accept that there may be some connections between the problem of how to deal with CTDs and the problems concerning allowable exceptions and default reasoning, it should be stressed that there are also crucially important differences (cf. [Prakken and Sergot, 1994]): when a CTD obligation comes into force because of some violation, we do not want then to say that the violated obligation has been defeated; it has not been overturned, it has been violated! We need to be able to integrate in

³Note that combining the two previous theorems we get $\vdash O B \rightarrow O (B/A)$, and so an unconditional obligation remains obligatory under any condition.

a single logical framework the ability to make deductions at two different levels: on the level of what *ideally* should be the case, and on the level of what *actually* should be the case, given the circumstances (where, of course, the circumstances might include the fact that what has happened deviates from the ideal). The simultaneous specification of both ideal behavior and of what to do when actual behavior deviates from the ideal is a central task of deontic logic.

3 CONTRARY-TO-DUTIES

3.1 Chisholm's CTD-paradox and SDL

Consider the following set of four sentences, formulated by Chisholm in 1963 [Chisholm, 1963]:

EXAMPLE 1.

- (a) It ought to be that a certain man go to help his neighbours.
- (b) It ought to be that if he goes he tell them he is coming.
- (c) If he does not go, he ought not to tell them he is coming.
- (d) He does not go.

There is widespread *agreement* in the literature that, from the intuitive point of view, this set is consistent, and its members are logically independent of each other; and there is a good deal of *disagreement* in the literature as regards which *further* requirements an adequate formal representation of the Chisholm set should meet. We start by discussing whether the Chisholm set can be represented in SDL in a way that meets this set of two minimum requirements, leaving the discussion of other further requirements to later.

It is straightforward to represent sentences (a) and (d) in SDL; the question is how to represent (b) and (c), since they express conditional obligations. Let us leave that open for the moment, and represent them by the use of our binary conditional obligation operator above; we then get (using “tell” and “help” in an obvious way as abbreviations of the sentences concerned):

- (a) $O \text{ help}$ (or $O (\text{help}/\top)$, since in $\text{SDL} \vdash O \text{ help} \leftrightarrow O (\text{help}/\top)$)
- (b) $O (\text{tell} / \text{help})$
- (c) $O (\neg\text{tell} / \neg\text{help})$
- (d) $\neg\text{help}$

In regard to the representation of conditional obligations in SDL, recall the two alternatives:

$$\text{(option1)} \quad \text{O}(B/A) =_{\text{df}} A \rightarrow \text{O} B$$

$$\text{and (option2)} \quad \text{O}(B/A) =_{\text{df}} \text{O}(A \rightarrow B)$$

With (option1) we get the following results:

$$\vdash \neg A \rightarrow \text{O}(B/A)$$

$$\text{(FD)} \quad \vdash A \wedge \text{O}(B/A) \rightarrow \text{O} B$$

Given that an expression of the form $\text{O}(B/A)$ is intended to mean that, in circumstances A , B is obligatory, the first of these two results is clearly problematic. From the fact that it is not raining we should not be able to deduce that, in circumstances where it is raining, it is obligatory that the President be assassinated. The other theorem has to do with the fundamental issue of how we can detach new (unconditional) obligations from conditional obligations, and it states a kind of “factual detachment” principle, allowing the deduction of the *actual obligations* of the agent, that is, the obligations which arise given the *actual facts* of the situation.

With (option2) we get the following results:

$$\vdash \text{O} \neg A \rightarrow \text{O}(B/A)$$

$$\text{(DD)} \quad \vdash \text{O} A \wedge \text{O}(B/A) \rightarrow \text{O} B$$

According to the first theorem everything is obligatory on the condition that some forbidden fact is the case: thus (option 2) clearly does not allow us to express CTDs. The second theorem represents a kind of “deontic detachment” principle, allowing the deduction of the *ideal obligations* of the agent, i.e. the further obligations which arise if he behaves in a way which conforms with some existing set of obligations.

The surface structures of lines (b) and (c) in the original Chisholm set might be taken to indicate that, within SDL, (option 2) should be chosen for (b), and (option 1) for (c), giving:

(a) O help

(b) $\text{O}(\text{help} \rightarrow \text{tell})$

(c) $\neg \text{help} \rightarrow \text{O} \neg \text{tell}$

(d) $\neg \text{help}$

This was Chisholm's choice, and he rightly went on to point out that this formalisation yields an inconsistency, since O tell is derivable from (a) and (b), whilst $O \neg$ tell is derivable from (c) and (d) (and an inconsistency follows by the (D)-schema).

If, alternatively, we use (option 1) for both lines (c) and (b), then the resulting set is consistent, but logical independence is lost, since (b) will then be a consequence of (d). Likewise, if (option 2) were adopted for both (b) and (c), then (c) would be a consequence of (a) by the (RM)-rule. So, in SDL, the conclusion is that the Chisholm set cannot be represented in a way which satisfies both of the two minimum requirements of consistency and logical independence.

3.2 *Some further requirements on the representation of CTDs*

A number of deontic logicians have argued that the problems raised by CTDs involve in an essential way either a temporal dimension or actions. We shall have a good deal more to say about these lines of approach later on (especially in Section 7), but for the moment we just want to register agreement with Prakken and Sergot [Prakken and Sergot, 1994; Prakken and Sergot, 1996], who have indicated that there are examples of CTD scenarios where it is far from obvious how considerations of the temporal or action dimensions might be applicable. Consider:

EXAMPLE 2.

- (a) There ought to be no dog.
- (b) If there is no dog, there ought to be no warning sign.
- (c) If there is a dog, there ought to be a warning sign.
- (d) There is a dog.

EXAMPLE 3.

- (a) There must be no fence.
- (b) -
- (c) If there is a fence, then it must be a white fence.
- (d) There is a fence.

Examples of these kinds suggest that a treatment of CTD's which is tied to temporal or action aspects will not be sufficiently general in its scope.

A further question which existing treatments of CTD's raise is this: are lines (b) and (c) of the Chisholm set to be assigned fundamentally different

logical forms? The theory we develop below gives a negative answer to this question, and supplies a uniform treatment of deontic conditionals. Our view is that, in the absence of strong arguments to the contrary, the surface forms of (b) and (c) should be deemed to be merely stylistic variants of essentially the same type of underlying logical structure. In particular, we reject the position taken in [Prakken and Sergot, 1994; Prakken and Sergot, 1996], where it is argued that (b) and (c) should be given distinct logical representations just because (c), unlike (b), is a contrary-to-duty conditional, expressing as it does the obligation which comes into force when the obligation expressed by line (a) is violated. Prakken and Sergot's approach makes the assignment of logical form to deontic conditionals a highly context-dependent matter, with the consequence that any insertion or deletion of a norm may require that some revision then has to be made to the formalisation of some other norm in the set; (e.g., deleting line (a) of the Chisholm set would require, on their approach, a change in the formalisation of line (c)). Likewise, the form initially assigned to a given sentence might have to be revised in virtue of what turns out to be *derivable* from other sentences; suppose, for instance that "if A then it is obligatory that B " is in the initial set, and is assumed not to be a CTD; if it then transpires that "it is obligatory that not A " is derivable from other members of the initial set, then the conditional becomes a CTD and its logical form has to be changed accordingly. This change may, in turn, have further repercussions regarding what can be derived ... and so on. Now with a *small* initial set, such as Chisholm's, it will of course be relatively easy to see where changes need to be made; but with a large corpus of norms it is not difficult to imagine that the problem could become intractable. The disadvantages which accrue from this kind of context-dependence of logical form are so great, in our opinion, that any approach to the analysis of CTDs which manages to avoid it is - other things being equal - to be preferred.

Thus, we have so far identified the following requirements that an adequate formalisation of the Chisholm set should meet:

- (i) consistency;
- (ii) logical independence of the members;
- (iii) applicability to (at least apparently) timeless and actionless CTD-examples;
- (iv) analogous logical structures for the two conditional sentences, (b) and (c).

One important group of deontic logics that satisfy these requirements employs a primitive dyadic conditional obligation operator $\mathbb{O}(-/_-)$, where

$O(B/A)$ is read “it is obligatory that B , given that A ”. These logics usually take the unconditional obligation $O B$ to be equivalent to $O(B/\top)$, and they represent the Chisholm set as follows:

- (a) $O(\text{help} / \top)$
- (b) $O(\text{tell} / \text{help})$
- (c) $O(\neg\text{tell} / \neg\text{help})$
- (d) $\neg\text{help}$

Following [Lower and Belzer, 1983] we can distinguish between two main “families” of dyadic deontic logics, according to the kind of detachment principles they support: one supports the “factual detachment” principle (FD), and we call it the “FD-family”;⁴ the other supports the “deontic detachment” principle (DD), and we call it the “DD-family”.⁵

Returning again to the Chisholm set, it is clear that (as for its proposed representation within SDL) acceptance of *both* (FD) and (DD) would permit the derivation of $O \neg\text{tell}$ (by (FD) on lines (c) and (d)) and $O \text{tell}$ (by (DD) on lines (a) and (b)). If the (D)-schema is accepted, then the situation arising from adoption of both (FD) and (DD) would of course be one of *logical* inconsistency. But even if the (D)-schema is not accepted, so that the conjunction $O \text{tell} \wedge O \neg\text{tell}$ is not deemed to be *logically* inconsistent, the derivation from the Chisholm set of a *conflict of obligations* of the type expressed by this conjunction is surely unacceptable from the intuitive point of view. The situation described by the Chisholm set does not present the agent concerned with a *moral dilemma*, on our view. Requirement (i), above, should be understood as one to the effect that a conjunction of the form $O A \wedge O \neg A$ should not be derivable from the formal representation of the set, regardless of whether that conjunction is deemed *logically* inconsistent.

Of course, neither the FD-family nor the DD-family accepts *both* (FD) and (DD). Nevertheless, it might be suggested that a fully adequate representation of the Chisholm set should be able to capture, in a way which generates neither inconsistency nor a moral dilemma, *both* the fact that — given the circumstances, and particularly the occurrence of the violation of the obligation expressed by line (a) — the agent’s actual obligation is

⁴In general the logics in this family have a semantics based on minimal models (proposed, independently, by Dana Scott and Montague, and popularised by [Chellas, 1980]). As representatives of this family [Lower and Belzer, 1983] mention [Mott, 1973; al-Hibri, 1978; Chellas, 1974]; however, as regards [Chellas, 1974] it is not entirely clear whether Chellas commits himself to acceptance of (FD).

⁵[Lewis, 1974] presents an overview of several members of the DD-family. These logics introduce, in the semantics, a preference relation between the worlds, that orders the worlds according to their ideality; then $O(B/A)$ is true at a world iff there is some world where $A \wedge B$ is true and that is more ideal than any world where $A \wedge \neg B$ is true. See also, below, Sections 7.1 and 7.3.

not to tell his neighbours he is coming, *and* the fact that — under ideal circumstances, in the absence of violation of the obligation expressed by line (a) — the agent’s obligation would be to help his neighbours and to tell them he is coming. Accepting these suggestions, we offer three further requirements which we believe an adequate representation of the Chisholm set should meet:

- (v) capacity to derive *actual* obligations;
- (vi) capacity to derive *ideal* obligations;⁶
- (vii) capacity to represent the fact that a *violation* of an obligation has occurred.

Neither the FD-family nor the DD-family meet both (v) and (vi).⁷ We will return later to the issues raised by (vii).

3.3 The “pragmatic oddity”

One of the logics that fulfills all these requirements is the one proposed in [Jones and Pörn, 1985]. Jones and Pörn adopt a completely different approach from that of the dyadic deontic logics, and define a deontic logic where non-normal obligation operators are obtained as Boolean combinations of normal modal operators, following a strategy that had already been used in the field of action logic by Kanger and by Pörn.

Taking as its point of departure the observation that SDL fails in its attempt to capture CTDs because — from the semantical point of view - SDL considers only the *ideal* versions of each world, Jones and Pörn propose, in addition to SDL’s accessibility relation, a second accessibility relation which picks out the *sub-ideal* versions of a given world (and they further require that each world is either an ideal or a sub-ideal version of itself).

Then they introduce into the logical language two modal necessity operators,⁸Note that the notation employed here for the operators differs in most cases from that used in [Jones and Pörn, 1985]. here denoted by $\boxed{\rightarrow}$ and $\boxed{\rightarrow\rightarrow}$. The first of these is just the obligation operator of SDL, so that an

⁶Some might call them *prima facie obligations*. However, we avoid using this term here since its meaning in the literature seems to us to be far from clear. Furthermore, [Prakken and Sergot, 1997] provide good reasons for supposing that the term is most at home in the discussion of defeasibility, rather than CTDs.

⁷In [Jones, 1993] it is argued that a further problem of the (FD)-family is that they reject the “principle of strengthening of the antecedent” (SA) whilst at the same time accepting unrestricted factual detachment. The problem is that one of the reasons for rejecting (SA) is that one wants to be able to represent conjunctions of the form $\bigcirc (B/A) \wedge \bigcirc (\neg B/A \wedge C)$, without getting logical inconsistency or moral dilemma of the form $\bigcirc B \wedge \bigcirc \neg B$, even in circumstances in which both A and C are true.

expression of the form $\boxed{i \rightarrow} A$ is true at a given world w iff A is true at all of the ideal versions of w . By contrast, $\boxed{s \rightarrow} A$ is true at a given world w iff A is true at all of the sub-ideal versions of w . (A sub-ideal version w_1 , of w , is informally seen as a version of w in which at least one of the obligations in force at w is violated.) The duals of $\boxed{i \rightarrow}$ and $\boxed{s \rightarrow}$ are, respectively, \blacklozenge and $\blacklozenge_{\rightarrow}$.

Finally they introduce both a deontic necessity operator $\boxed{\rightarrow}$, defined as follows:

$$\boxed{\rightarrow} A =_{\text{df}} \boxed{i \rightarrow} A \wedge \boxed{s \rightarrow} A$$

and an actual-obligation operator Ought , defined by:

$$\text{Ought } A =_{\text{df}} \boxed{i \rightarrow} A \wedge \blacklozenge_{\rightarrow} \neg A$$

(the second conjunct guarantees that $\vdash \neg \text{Ought } \top$).

The Chisholm set is then represented in [Jones and Pörn, 1985] as follows:

- (a) Ought help
- (b) $\boxed{\rightarrow} (\text{help} \rightarrow \text{Ought tell})$
- (c) $\boxed{\rightarrow} (\neg \text{help} \rightarrow \text{Ought } \neg \text{tell})$
- (d) $\neg \text{help}$

The set, on this representation, is consistent and its members are logically independent of each other. Lines (c) and (d) imply $\text{Ought } \neg \text{tell}$ (note that $\boxed{\rightarrow}$ is a “success” operator, i.e. it satisfies the (T)-schema), and lines (a) and (b) imply $\boxed{i \rightarrow} \text{Ought tell}$. Furthermore, the conjunction of (a) and (d) may be taken as expressing the fact that the unconditional obligation to help the neighbours has been violated; and, had it been the case that “(d’) help”, rather than (d), were true, then from (b) one could have deduced the actual obligation to tell, Ought tell . Apparently, all is well!

However, [Prakken and Sergot, 1994; Prakken and Sergot, 1996] point out that the Jones and Pörn treatment of Chisholm, in common with a number of others, generates what they call the “pragmatic oddity”: line (a), together with the derived actual obligation $\text{Ought } \neg \text{tell}$, require that, in all ideal versions of the given world, the agent concerned goes to help his neighbours but does not tell them he is coming — a result which appears highly counterintuitive.

Prakken and Sergot correctly point out that, *for a number of cases*, a reasonable temporal interpretation is available which enables the pragmatic oddity to be avoided. For instance, perhaps the obligation expressed in line (a) would ordinarily be understood as an obligation to go to help the

neighbours *no later than a particular time, t*. Then, if line (d) were to be true after time *t*, the accessible deontically ideal worlds would be characterised in such a way that, after time *t*, these worlds would require that the agent does not tell his neighbours he is coming (but they would not, of course, also require that he goes to help, since it would then be too late).

However, as we indicated above, Prakken and Sergot also point out that there are instances of the Chisholm set which may be interpreted in such a way that the temporal dimension is completely absent ([Jones, 1993, pp. 153-4] makes a similar point). Example 2, above, is one such case: a very ordinary way of understanding that set takes each sentence to be true at one and the same moment of time, and — without any insertion of *temporal* qualifications concerning *when* there ought to be no dog, or *when* there ought to be a warning sign — allows the conclusion to be drawn that there ought, in the circumstances, to be a warning sign, *without* thereby generating the pragmatic oddity, i.e., *without* forcing the further conclusion that, in all ideal versions of the given situation, there is no dog but there is a sign warning of one.

Unfortunately, Prakken and Sergot offer little by way of explanation of the pragmatic oddity: they say little about what it is that creates the sense of oddity. In [Carmo and Jones, 1997] we suggest an explanation which exploits a parallel between examples of type Example 2, which on the [Jones and Pörn, 1985] analysis exhibit the pragmatic oddity *simpliciter*, and examples like Example 3 above (also due to Prakken and Sergot) which, by virtue of some assumed logical truth, are inconsistent when formalised in the style of [Jones and Pörn, 1985] (according to which, in all ideal versions of the given world, there is a white fence and no fence at all!). The suggested parallel is as follows: as represented in the language of [Jones and Pörn, 1985], Example 2 exhibits the pragmatic oddity because an inconsistency *would* be generated were one to add to the example the further constraint that it ought not to be the case that there is both no dog and a sign warning of one. The sense of oddity arises because there is an interpretation of Example 2 according to which it remains consistent even if supplemented with that further constraint; and the problem with the [Jones and Pörn, 1985] approach is that it fails to capture *that* interpretation.

Thus we add another requirement which an adequate representation of CTDs should satisfy:

- (viii) capacity to avoid the pragmatic oddity (interpreted according to the previous diagnosis).

3.4 Two attempts to resolve the “pragmatic oddity”

In [Prakken and Sergot, 1994; Prakken and Sergot, 1996], Prakken and Sergot argue that the proper response to the problems raised by Example 2 —

and in particular the problem of pragmatic oddity — is to assign distinct logical forms to primary obligations, on the one hand, and CTD obligations, on the other. For CTD obligations, they relativise an obligation operator to a specific “context of violation”; more precisely, an expression of the form $O_A B$ is intended to be read as “there is a secondary obligation that B given that, or presupposing, the sub-ideal context A ”, or “given that A , which is a violation of some primary obligation, there is a secondary, compromise obligation that B ” [Prakken and Sergot, 1996, section 5]. They emphasise that expressions of the form $O_A B$ are not to be read as conditional primary obligations. “The expression $O_A B \dots$ represents a particular kind of obligation. There is no meaningful sense \dots in which the obligation $O B$ can be detached from the expression $O_A B$ ” [*loc.cit.*]. Their representation of Example 2 takes the form:

- (a) $O \neg \text{dog}$
- (b) $\neg \text{dog} \rightarrow O \neg \text{sign}$
- (c) $\text{dog} \rightarrow O_{\text{dog}} \text{sign}$
- (d) dog

We shall not pursue the Prakken and Sergot 94 treatment of CTDs here (although we return to their work briefly in Section 7). Suffice it to say that their approach (in [Prakken and Sergot, 1994; Prakken and Sergot, 1996]) rejects the fourth of our requirements for a satisfactory theory in this area. For them, the choice of logical form for an apparently conditional deontic sentence will itself be dependent on which other norms are contained in, or derivable from, the set of norms being formalised.⁹

In [Carmo and Jones, 1995]¹⁰ we attempted a different kind of approach to the problem of the pragmatic oddity, distinguishing between “ideal obligations” (line (a) in Examples 1, 2 and 3, for instance) and “actual obligations”, which indicate what is to be done given the (perhaps less-than-ideal) circumstances. The operator O_a , for representing actual obligations, was defined in the same way as the Ought-operator of [Jones and Pörn, 1985], described above. As regards ideal obligations, the basic model-theoretic

⁹There are also some difficulties in understanding how $O_A B$ should be interpreted, particularly since Prakken and Sergot insist that A (in $O_A B$) necessarily represents a context of violation. For instance, the formula $(P A \wedge O_A B) \rightarrow O B$ is valid, on their account (where P is the permission operator), but not trivially so. As we see it, intuitively the conjunction in the antecedent of this conditional (given their reading of $O_A B$) could only be false, so it should imply anything. Furthermore, what can they possibly mean by the claim that $O B$ is an abbreviation of $O_{\top} B$? Are we to suppose that it is obligatory that B only if the tautology represents a context of violation?

¹⁰We there adapt the logic proposed in [Carmo and Jones, 1994; Carmo and Jones, 1996] for the analysis of deontic integrity constraints.

idea was to distinguish between ideal *versions* of a given world (the fundamental feature of SDL), and *ideal worlds themselves*. Accordingly, we divided the set of possible worlds W into two mutually exclusive sub-sets, the set of ideal worlds and the set of sub-ideal worlds; importantly for our purposes, we allowed that a world w_1 could be an ideal *version* of a given (*sub-ideal*) world w *without* also itself being an ideal *world*. And we fixed truth conditions for expressions of the form $O_i B$ (“it ought ideally to be the case that B ”) in terms of the truth of B *in all ideal worlds* and falsity *in some sub-ideal world*.¹¹

We represented Example 2 in the following way:

- (a) $O_i \neg \text{dog}$
- (b) $\boxed{\Rightarrow} (\neg \text{dog} \rightarrow O_a \neg \text{sign})$
- (c) $\boxed{\Rightarrow} (\text{dog} \rightarrow O_a \text{sign})$
- (d) dog

All the requirements (i)–(viii) are met by this analysis. In particular, the pragmatic oddity disappears because the conjunction $O_i \neg \text{dog} \wedge O_a \text{sign}$, which is clearly derivable from (a)–(d), does not imply that, in all ideal versions of the given world, there is no dog but a sign warning of one. What the conjunction *does* say, essentially, is that in all ideal *worlds* there is no dog, but in all ideal *versions* of the given (clearly sub-ideal) world there is a warning sign. The proposal worked well for this and a number of other examples, and we have defined a complete axiomatization for the logic.

However, as we now see things, this approach suffered from a defect similar to the one we have criticised in relation to [Prakken and Sergot, 1994; Prakken and Sergot, 1996]: the assignment of logical form for some of the norms in the set is dependent on the other norms in it. In [Prakken and Sergot, 1994; Prakken and Sergot, 1996] this was reflected in the use of different obligation operators for representing the deontic conditionals expressed by lines (b) and (c); in [Carmo and Jones, 1995] it is reflected in the use of different obligation operators for representing line (a) and lines (b) and (c). So, in order to capture the *general* issue motivating the adoption of adequacy requirement (iv), it should be reformulated as follows:

- (iv) the assignment of logical form to each of the norms in the set should be independent of the other norms in it.

¹¹The second conjunct simply guarantees the violability of ideal obligations (i.e. $\models \neg O_i \top$). [Carmo and Jones, 1995] contains discussion of possible connections between the notions of ideal/sub-ideal world and ideal/sub-ideal versions of a world, but we omit those details here.

A related observation is that problems appear within the [Carmo and Jones, 1995] approach if we add to the Chisholm set other norms that interact in some significant way with the norms in the original set. In particular, serious difficulties arise as soon as a “second-level” of CTDs is considered. Suppose, for instance, that lines (e) and (f), below, are added to Example 2:

- (e) If there is a dog and no warning sign, there ought to be a high fence.
- (f) There is no warning sign.

The [Carmo and Jones, 1995] representation of this extended set is:

- (a) $O_i \neg \text{dog}$
- (b) $\Box (\neg \text{dog} \rightarrow O_a \neg \text{sign})$
- (c) $\Box (\text{dog} \rightarrow O_a \text{sign})$
- (d) dog
- (e) $\Box (\text{dog} \wedge \neg \text{sign} \rightarrow O_a \text{fence})$
- (f) $\neg \text{sign}$

And the pragmatic oddity now re-appears, since the conjunction $O_a \text{sign} \wedge O_a \text{fence}$ is derivable. So, in all ideal versions of the given world, there is a sign and a fence. (If this does not seem “odd”, imagine that the sign says “Beware of the unfenced dog”: it may well be forbidden to have both a sign of that kind and a fence. Thus the pragmatic oddity, in the sense of our proposed diagnosis, re-emerges.)

The problem of “further levels” of CTDs would force the [Carmo and Jones, 1995] approach to allow the possibility of an infinity of obligation operators: the need to associate (in some way or other) a context to each obligation operator seems to re-appear.

4 CONTRARY-TO-DUTIES: A NEW APPROACH

On one very common interpretation of the set (a)–(f) above, the actual obligation which *applies* in the circumstances is the obligation to put up a fence, and it applies because the other two obligations (not to have a dog, and to put up a sign if there is a dog) have been violated. As we have emphasised above, it would be incorrect to say that the obligations not to have a dog, and to put up a sign if there is a dog, have been *defeated*, or *overturned*; they have been *violated*, and any proper representation of the situation must register the fact that, because of these violations, the obligation which becomes actual is the obligation to erect a fence. But how are these points to be articulated in a formal theory? To that question we now turn.

4.1 Motivation

Consider again Example 2, particularly lines (a), (c) and (d). The norms governing, or in force in, the situation are that there ought to be no dog, and that if there is a dog there ought to be a warning sign; and the relevant fact is that there is a dog. So what is the actual obligation, of the agent concerned, in these circumstances? To erect a warning sign? But why not insist on getting rid of the dog, rather than on erecting a warning sign¹²? We wish to suggest that the answer to such questions turns on the *status* assigned to the fact that there is a dog — in the following sense: so long as there is a dog, but this, for one reason or another, is not deemed to be a *fixed, unalterable* feature of the situation, then the actual obligation which applies is that there ought to be no dog. However, as soon as, for one reason or another, the fact that there is a dog is deemed *fixed*, i.e., it is seen as a *necessary*, unavoidable feature of the situation, so that — in consequence — the practical possibility of satisfying the obligation that there ought to be no dog has to all intents and purposes been eliminated, then the actual obligation which applies is that there ought to be a warning sign.¹³

What do we mean when we say that *for some reason or another* a fact of the situation — in this case that there is a dog — may be deemed a fixed, necessary, unalterable feature of that situation? Well, there are various ways in which this “fixity” might arise; those who proposed temporal solutions to the problems associated with CTDs focussed on *one* of these ways. If books shall be returned by date due, then if you still have the books after the date due there is no way *that* obligation can be met. It is too late! It is unalterably the case that the books are not returned by the date due, and consequently the possibility of satisfying the obligation to return the books by date due has been eliminated.

But temporal reasons, although very common, are not the only reasons why things become fixed, in the sense of necessity or unalterability we here seek to explicate; for instance, it is not for temporal reasons that the deed of killing, once done, cannot be undone. What explains fixity in this case is not temporal necessity, but rather causal necessity. Nor need temporal considerations have any role to play in explaining why the presence of a dog may be, to all intents and purposes, an unalterable feature of the situation; it may, for some reason, be practically impossible in the situation to remove the dog; perhaps, for instance, its owner stubbornly refuses to remove it, and nobody else dares attempt the feat. The presence of the dog is a fixed fact: the dog remains unless the intervention of some agent leads to its

¹²Remember that, in keeping with our analysis of the pragmatic oddity, we seek an answer to these questions which is compatible with a further assumption to the effect that there ought not to be *both* no dog *and* a warning sign.

¹³Some remarks in a similar spirit are to be found in [Hansson, 1971, section XIII: “on the interpretation of circumstances”].

removal, and no agent is prepared to perform the required action. From the practical point of view — from the point of view of deciding which obligation actually applies to the situation — the key feature is that the possibility of satisfaction of the requirement that there be no dog is effectively eliminated.

As a further illustration, consider next the example of the “considerate assassin”.¹⁴

EXAMPLE 4.

- (a) You should not kill Mr. X.
- (b) -
- (c) But if you kill Mr. X, you should offer him a cigarette.

When does the assassin have an actual obligation to offer Mr. X a cigarette? After killing him? But then it is too late! One intuitively acceptable interpretation is that the assassin’s actual obligation to offer Mr. X a cigarette arises when he firmly decides that he is going to kill Mr. X. It is then that it becomes a settled or fixed fact that Mr. X will be killed, and then that the assassin’s actual obligation is to offer a cigarette.

Notice that the examples indicate that two different notions of necessity — and their associated notions of possibility — need to be considered. Mr. X, once killed, cannot be offered a cigarette because nobody has the ability or the opportunity to make offers to the dead, just as nobody has the ability or opportunity to return a book by date due if the date due has passed. On the other hand, the dog-owner may have both the ability and the opportunity to remove the dog, and the assassin may have both the ability and the opportunity to refrain from killing Mr. X; but once each has made a firm and definite decision (to keep the dog and to kill Mr. X, respectively), then to all intents and purposes the persistent presence of the dog and the future performance of the assassination become fixed features of the respective situations; so questions about which actual obligations arise in these situations have to be answered in the light of the fact that alternatives in which there is no dog, or no assassination, are not actually available.

Now it may well be that the judge, at the assassin’s trial, insists that the assassin should never have decided to commit the murder, just as it may be that the manager of the housing estate refuses to accept that the dog owner was entitled to decide that he would keep his dog. Furthermore, it is a well known feature of, for instance, disputes in legal cases, that the parties to the dispute may disagree about what an agent was able to do, or

¹⁴This example can also be found in [Prakken and Sergot, 1996] (using “the witness” instead of “Mr. X”). In fact [Prakken and Sergot, 1996] provides an excellent survey of the principal examples of CTDs, and we use them in Section 5 to test the adequacy of our proposal.

what he had the opportunity to do. But the existence of disagreements of these kinds is perfectly compatible with the approach to CTD scenarios we develop below. For it will not be the task of our logical system to determine the reasons which justify the classification of some fact as settled. Rather, what the system will do is this: first, it will specify the role of assumptions about two types of fixity in reasoning about actual and ideal obligations; and, second, it will show which actual/ideal obligations can be derived from a given set of norms *when some facts are taken to be fixed in the one sense or the other*.¹⁵

4.2 *The new theory and its fundamental semantic features*

We now present the basic features of a modal-logical language designed to capture the approach to CTDs described above in a way that conforms to the constraints, or requirements, (i)–(viii). We shall then show how the new language may be applied to the Chisholm set, and to the analysis of some other problematic CTD “scenarios”.

We adopt the following approach to the formal representation of these scenarios: their *deontic component* (the obligation norms which they explicitly contain) will be represented throughout in terms of a dyadic, conditional obligation operator $O(_/_)$; their *factual component* will be represented by means of either unmodalised sentences, or modalised sentences in two categories. These two categories correspond to the two notions of necessity (and their associated dual notions of possibility) which we shall employ to articulate the ideas regarding fixity, or unalterability, of facts alluded to in the previous subsection.

From the deontic and factual components taken together, some further obligation sentences may be derivable. The *derived obligation sentences* are of two types, pertaining to *actual* obligations and *ideal* obligations, respectively. There is an intimate conceptual connection between these two notions of derived obligation, on the one hand, and the two notions of necessity/possibility used in characterising the factual component, on the other.

Consider first the dyadic conditional obligation operator. How do we wish to interpret a sentence of the kind “if there is a dog then there shall be a warning sign”? On our view, this sentence is to be understood as saying that in any context in which the presence of a dog is a fixed, unalterable fact, it is obligatory to have a warning sign, if this is possible. We think of a *context* as a set of worlds — the set of relevant worlds for the situation at hand. So the above sentence is to be understood as saying that, for any context in which there is a dog (i.e., for any context in which there is a dog in each world of that context), if it is possible to have a warning sign then

¹⁵Our thanks to Layman Allen for raising a question at the Sesimbra Δ EON96 Workshop related to this point.

it is obligatory to have a warning sign.¹⁶ In order to capture this idea we introduce in our models a function $ob:\wp(W) \rightarrow \wp(\wp(W))$ which picks out, for each context, the propositions which represent that which is obligatory in that context. That is, $\|B\| \in ob(X)$ (where $\|B\|$ denotes the truth set of B in the model in question) if and only if the proposition expressed by B represents something obligatory in context X . Accordingly, we say that a sentence $O(B/A)$ is true in a model if and only if, in any context X where A is true and B is possible (i.e. in any context having A true in each of its worlds and B true in at least one of its worlds), it is obligatory that B .¹⁷

On the basis of this operator we could now derive the obligations that were applicable in each context, *assuming* that our language contained a means of representing contexts. *The question is:* what are the types of contexts that we need to be able to talk about in our formal language, given that we want to be able to derive sentences of two kinds, describing *actual* obligations and *ideal* obligations, respectively? We answer this question in terms of the two notions of necessity.

The first of these will be denoted by $\boxed{\rightarrow}$, and its dual possibility notion denoted by \diamond . Intuitively, $\boxed{\rightarrow}$ is intended to capture that which — in a particular situation — is *actually* fixed, or unalterable, given (among other factors) what the agents concerned have decided to do and not to do. In, for instance, the “dog scenario” (Example 2), if the agents concerned have firmly decided that the dog is not going to be removed, then the sentence $\boxed{\rightarrow}$ dog is true of that situation (the presence of the dog is *actually* an unalterable fact). On the other hand, if some actual possibility existed for getting rid of the dog, then the situation would be appropriately described by $\diamond\neg$ dog (i.e. $\neg\boxed{\rightarrow}$ dog). Which *actual obligations* arise in the dog scenario will depend, in particular, on whether or not $\diamond\neg$ dog is true.

We must emphasise one important difference between this notion of necessity/possibility and the second one we employ. For the reasons discussed in the previous subsection, we do not exclude, *a priori*, that a sentence of the form $\boxed{\rightarrow}A$ might be true even though the agents concerned have the ability and the opportunity to see to it that $\neg A$. That is, we shall want to consider scenarios where, despite their abilities and opportunities for action, the agents have firmly resolved not to see to it that $\neg A$, and where — given that this is what the agents have decided — there is (for all intents and purposes) no way that A could be false.

¹⁶We are here using the term “obligatory” in a *weak sense*; in a *strict sense*, for a sentence B to be obligatory in a context X we would also claim that there must exist at least one world in X where B is false (i.e., we would insist, for the strict sense, that obligations must be violable). However, our actual and ideal obligations, to be defined next, will be considered in this *strict sense*.

¹⁷We also add the further requirement that the conjunction of A and B is not contradictory, in order to avoid some “absurd” vacuous conditional obligations, and as one of the conditions needed to secure the result that if $O(B/A)$ is true then $\|B\| \in ob(\|A\|)$.

In order to capture the semantics of the necessity operator $\boxed{\rightarrow}$, our semantic models will contain a function, av , which picks out (for any given world w) a set of worlds $av(w)$ — the set of worlds which are the *actual versions* of w (the *open alternatives* for the current world w), those which constitute the context that it is actually relevant to take into account in determining which obligations are actually in force, or actually apply, at w . Accordingly, a sentence of the form $\boxed{\rightarrow}A$ will be said to be true at a given world w if and only if A is true at *all* of the worlds contained in $av(w)$.

Given the way the function ob is understood, the set of propositions $ob(av(w))$ will be the set of propositions which represent that which is obligatory in the context $av(w)$ (that is to say, in the context of the alternatives that are actually open at w). In line with this, we shall say that a sentence of the form $O_a A$ (read as “it is actually obligatory that A ”, or “it actually ought to be the case that A ”) is true at a world w only if the proposition expressed by A is one of those propositions picked out by ob for the argument $av(w)$. In addition, the truth of $O_a A$ at w will require that there is at least one world in $av(w)$ where the sentence A is false; the reason for this second requirement is that that which is actually obligatory might actually fail to obtain.

The second of the two notions of necessity will be denoted by $\boxed{\square}$, and its dual possibility notion denoted by $\boxed{\diamond}$. Intuitively, $\boxed{\square}$ is intended to capture that which — in a particular situation — is not only actually fixed, but would still be fixed even if different decisions had been made, by the agents concerned, regarding how they were going to behave. For instance, certain features of the situation will be such that it is beyond the power of the agents to change them — they may lack the ability, or the opportunity, or both. Of such features it is appropriate to say that they are fixed in the sense that they *could not have been* avoided by the agents concerned, no matter what they had done. It is not even *potentially* possible for the agents to alter them. In the original Chisholm scenario, for example, if the bridge that leads to the man’s neighbours’ house has been destroyed by a storm, and the man is unable to repair it, then clearly it is a necessary feature of the situation, in this second sense of necessity, that he does not help his neighbours. This is to be understood in contrast to the situation in which it is potentially possible for the agent to go to his neighbours’ house to help them, but the agent has made a definite decision, from which he will not budge, not to go. His will is firm, and thus in all actual relevant alternatives open to the agent he does not go to help them (and so actually he ought not to tell them he is coming). But given that he has the ability and opportunity to go, it is *potentially* possible — in the sense expressed by the $\boxed{\diamond}$ operator — that he does so¹⁸, and so we want then be able to derive

¹⁸So the best short readings for these two pairs of operators we can offer are the following:

that his *ideal* obligation was to go and to tell them he was coming.

To articulate the semantics of the second pair of notions of necessity and possibility, we introduce into the models a function, pv , which picks out (for any given world w) a set of worlds $pv(w)$ — the set of worlds which are the *potential versions* of w . These worlds will constitute the context it is relevant to take into account in determining which *ideal* obligations hold at w (“*what should have been done*”). A sentence of the form $\Box A$ will be said to be true at a given world w if and only if A is true at all of the worlds contained in $pv(w)$. Furthermore, given the way the function ob is understood, the set of propositions $ob(pv(w))$ will be the set of propositions which represent that which is obligatory in the context $pv(w)$. Thus we shall say that a sentence of the form $O_i A$ (read as “it is ideally obligatory that A ”, or “it ideally ought to be the case that A ”) is true at a world w only if the proposition expressed by A is one of those propositions picked out by ob for the argument $pv(w)$. In addition, the truth of $O_i A$ at w will require that there is at least one world in $pv(w)$ where the sentence A is false — since that which is ideally obligatory might potentially fail to obtain.

Finally, we define the notion of violation in terms of the notion of ideal obligation, as follows:

$$\text{viol}(A) =_{\text{df}} O_i A \wedge \neg A$$

This choice is in accordance with the intuitive idea that ideal obligations express what should have been done, and fits in well with our treatment of the pragmatic oddity and other features of CTD scenarios, as will become clearer when we analyse a number of examples in some detail. Briefly, the main points may already be explained as follows: in, for instance, the dog scenario, if it is a fixed fact that there is a dog (i.e., if $\Box \text{dog}$ is true), but it is *actually* possible that a sign may be erected and *potentially* possible that there is no dog, then we shall be able to derive that it is actually obligatory that a sign is erected and ideally obligatory that there is no dog. The pragmatic oddity will be avoided because it will not, in *these* circumstances, be possible to derive an actual obligation that there be no dog. Nevertheless, we still of course want to say that an obligation (that there be no dog) has been violated, and this result is secured if violation is characterised as above. As the formal analysis of this example will show,

-
- $\Diamond A$: it is actually possible that A
 - $\blacklozenge A$: it is potentially possible that A
 - $\Box A$: it is not actually possible that $\neg A$
 - $\blackbox A$: it is not potentially possible that $\neg A$

(In a number of cases, the natural reading of statements about potential possibility will be in the past tense.)

we shall also be able to derive a second violation in this situation, if no sign has been erected.

The semantic models described next will be subject to various constraints, designed to achieve a particular pattern of relationships between the dyadic obligation operator, the two types of necessity/possibility operators, and the operators for actual and ideal obligations.

4.3 Syntax and semantics of the formal language

Syntax

Alphabet:

- a set of (natural language) terms (dog, fence, sign, ...) for atomic sentences
- $\neg, \wedge, \vee, \rightarrow, \leftrightarrow$ (sentential connectives)
- $(,)$ (parentheses)
- $\boxed{\rightarrow}$ (dual: $\diamond =_{df} \neg \boxed{\rightarrow} \neg$)
- $\boxed{\square}$ (dual: $\diamond =_{df} \neg \boxed{\square} \neg$)
- $O (/)$ (dyadic deontic operator)
- O_a (monadic deontic operator - for actual obligation)
- O_i (monadic deontic operator - for ideal obligation)

Rules for construction of well-formed sentences: as usual

- $\text{viol}(A) =_{df} O_i A \wedge \neg A$

Semantics

Models:

$\mathcal{M} = \langle W, av, pv, ob, V \rangle$, where:

- 1) $W \neq \emptyset$
- 2) V - a function assigning a truth set to each atomic sentence
- 3) $av : W \rightarrow \wp(W)$
(alternatively: $Ra \subseteq W \times W$ and $av(w) = \{w_1 : wR_a w_1\}$)
such that:

- 3-a) $av(w) \neq \emptyset$
- 4) $pv : W \rightarrow \wp(W)$
 (alternatively: $Rp \subseteq W \times W$ and $pv(w) = \{w_1 : wR_p w_1\}$)
 such that:
- 4-a) $av(w) \subseteq pv(w)$
- 4-b) $w \in pv(w)$
- 5) $ob : \wp(W) \rightarrow \wp(\wp(W))$
 such that (where X, Y, Z designate arbitrary sets of members of W):
- 5-a) $\emptyset \notin ob(X)$
- 5-b) if $Y \cap X = Z \cap X$, then $(Y \in ob(X) \text{ iff } Z \in ob(X))$
- 5-c) if $Y, Z \in ob(X)$, then $Y \cap Z \in ob(X)$
- 5-d) if $Y \subseteq X$ and $Y \in ob(X)$ and $X \subseteq Z$, then $((Z - X) \cup Y) \in ob(Z)$

Truth in a world w in a model $\mathcal{M} = \langle W, av, pv, ob, V \rangle$ is characterised as follows (where $\|A\| = \|A\|^{\mathcal{M}} = \{w \in W : \mathcal{M} \models_w A\}$):

$$\mathcal{M} \models_w p \quad \text{iff} \quad w \in V(p)$$

... (the usual truth conditions for the connectives $\neg, \wedge, \vee, \rightarrow$ and \leftrightarrow)

$$\mathcal{M} \models_w \boxed{\rightarrow} A \quad \text{iff} \quad av(w) \subseteq \|A\|$$

$$\mathcal{M} \models_w \boxed{\square} A \quad \text{iff} \quad pv(w) \subseteq \|A\|$$

$$\mathcal{M} \models_w \bigcirc (B/A)^{19} \quad \text{iff}$$

$$\|A\| \cap \|B\| \neq \emptyset \text{ and}$$

$$(\forall X)(\text{if } X \subseteq \|A\| \text{ and } X \cap \|B\| \neq \emptyset, \text{ then } \|B\| \in ob(X))$$

$$\mathcal{M} \models_w \bigcirc_a A \quad \text{iff} \quad \|A\| \in ob(av(w)) \text{ and } av(w) \cap \|\neg A\| \neq \emptyset$$

$$\text{(i.e. iff } \|A\| \in ob(av(w)) \text{ and } av(w) \cap (W - \|A\|) \neq \emptyset)$$

$$\mathcal{M} \models_w \bigcirc_i A \quad \text{iff} \quad \|A\| \in ob(pv(w)) \text{ and } pv(w) \cap \|\neg A\| \neq \emptyset$$

¹⁹An alternative would be to define the dyadic obligation operator in the *strict sense* referred to in footnote 16, in which case $\mathcal{M} \models_w \bigcirc (B/A)$ iff $\|A\| \cap \|B\| \neq \emptyset$ and $\|A\| \cap \|\neg B\| \neq \emptyset$ and $(\forall X)(\text{if } X \subseteq \|A\| \text{ and } X \cap \|B\| \neq \emptyset \text{ and } X \cap \|\neg B\| \neq \emptyset, \text{ then } \|B\| \in ob(X))$. In that case we would require that if $Y \in ob(X)$ then $X \cap (W - Y) \neq \emptyset$; and the truth in a world w of $\bigcirc_a A$ (respectively $\bigcirc_i A$) would be defined as follows: $\mathcal{M} \models_w \bigcirc_a A$ iff $\|A\| \in ob(av(w))$ (resp. $\mathcal{M} \models_w \bigcirc_i A$ iff $\|A\| \in ob(pv(w))$). With both approaches we get exactly the same semantics for $\bigcirc_a A$ and $\bigcirc_i A$.

(Note that the definition of $\mathcal{M} \models_w O(B/A)$ entails that if $\mathcal{M} \models_w O(B/A)$, then $\|B\| \in ob(\|A\|)$.)

A sentence A is said to be *true in a model* $\mathcal{M} = \langle W, av, pv, ob, V \rangle$, written $\mathcal{M} \models A$, iff $\|A\|^{\mathcal{M}} = W$; and A is said to be *valid*, written $\models A$, iff $\mathcal{M} \models A$ in all models \mathcal{M} .

Some comments about the conditions:

- i) As would be expected, the set $av(w)$ is required to be a subset of $pv(w)$, for any w (condition 4-a), so that actual possibility entails potential possibility. Conditions 3-a) and 4-b) are also obvious.

In [Carmo and Jones, 1997]²⁰ we required that $w \in av(w)$ (which implies 3-a) and, together with 4-a), also implies 4-b)). Although in most scenarios it makes sense to say that the actual world is always an actual alternative to itself, we sometimes need to be able to describe situations where A is not yet the case, but nevertheless in all relevant future alternatives open to the agent, A is the case. Consider, for instance, the scenario of the “considerate assassin” (Example 4): there may be situations where, although the assassin has not yet killed Mr. X, in all the relevant future alternatives open to the assassin Mr. X is going to be killed by him (because the assassin has so decided); the natural way to represent this situation in our logic is: $\neg\text{kill} \wedge \boxed{\rightarrow}\text{kill}$. But of course this can only be expressed consistently if we do not require that, for all $w, w \in av(w)$.

There exist other conditions that it may seem natural to impose on av and pv , such as the transitivity of both the actual and potential relations. But, for simplicity, we consider here only those conditions which appear to have a direct bearing on the analysis of the key examples of CTD scenarios in Section 5.

- ii) Condition 5-a) means that we do not accept that a contradiction might be obligatory.
- iii) Condition 5-b) means that if, from the point of view of a context X , two propositions Y and Z are indistinguishable, then one of them is obligatory iff the other is (this corresponds to a kind of “contextual” RE-rule).

It is also appropriate at this point to state some of the main consequences of condition 5-b), and to attach numbered labels to them, in order to facilitate later discussion of a possible weakening of 5-b).

²⁰Where we use va , vp and pi , instead of the more suggestive names, av , pv and ob , used in this chapter.

Since $Y \cap X = (Y \cap X) \cap X$, we get as particular cases of 5-b):

5-b1) if $Y \in ob(X)$, then $Y \cap X \in ob(X)$

5-b2) if $Y \cap X \in ob(X)$, then $Y \in ob(X)$

On the other hand, using 5-a) and 5-b1) we get the condition (which in turn implies 5-a)):

5-ab) if $Y \in ob(X)$, then $Y \cap X \neq \emptyset$

- iv) Condition 5-c) requires that the conjunction of two obligatory propositions within a context X is also obligatory in that context. A natural extension of condition 5-c) would be to require the closure of ob under arbitrary intersections (and not only under finite intersections):

5-c+) if $\beta \subseteq ob(X)$ and $\beta \neq \emptyset$, then $(\bigcap \beta) \in ob(X)$

(where β is any set of subsets of W , $(\bigcap \beta)$ is defined as:

$$(\bigcap \beta) = \{w \in W : (\forall X \in \beta)(w \in X)\}$$

If we impose this stronger condition then we would get $(\bigcap ob(X)) \in ob(X)$, if $ob(X)$ is non-empty; note also that, by 5-b1), if $ob(X) \neq \emptyset$ then $(\bigcap ob(X)) \subseteq X$; if $ob(X) = \emptyset$ then, by definition, $(\bigcap ob(X)) = W$. However, for reasons to be explained, what we shall in fact propose later is a *weakening* of condition 5-c).

- v) Condition 5-d) states that if a subset Y of X is an obligatory proposition in a context X , then in a bigger context Z it is obligatory to be either in Y or else in that part of Z which is not in X .

Taking into account condition 5-b), it may be shown that each of the following conditions is equivalent to 5-d) - they can sometimes be used to simplify proofs:

5-bd1) if $Y \subseteq X$ and $Y \in ob(X)$ and $X \subseteq Z$, then $((W - X) \cup Y) \in ob(Z)$

5-bd2) if $Y \in ob(X)$ and $X \subseteq Z$, then $((Z - X) \cup Y) \in ob(Z)$

5-bd3) if $Y \in ob(X)$ and $X \subseteq Z$, then $((W - X) \cup Y) \in ob(Z)$

5-bd4) if $Y \in ob(X)$ and $X \subseteq Z$, then $((W - X) \cup (X \cap Y)) \in ob(Z)$

Using conditions 5-b), 5-c) and 5-d), we can also prove that

$$\text{if } Z \in ob(X) \text{ and } Z \in ob(Y), \text{ then } Z \in ob(X \cup Y).$$

4.4 *Syntactic/axiomatic characterisation of the modal operators*

In what follows we introduce the axioms and rules for the various modal operators. For some of the axioms and theorems we introduce special labels

— if there is no standard label — in order to facilitate reference to them later on.

Characterisation of \Box :

1. \Box is a normal modal operator of type KT.

Characterisation of $\Box\rightarrow$:

2. $\Box\rightarrow$ is a normal modal operator of type KD.

Relationship between \Box and $\Box\rightarrow$:

3. $\Box A \rightarrow \Box\rightarrow A$ (axiom schema ($\Box \rightarrow \Box\rightarrow$))

Characterisation of O :

4. $\neg O(\perp/A)$ (the schema $\neg N$ for $O : (O - \neg N)$)
5. $O(B/A) \wedge O(C/A) \rightarrow O(B \wedge C/A)$
(the schema C for $O : (O - C)$)
6. Restricted principle of strengthening of the antecedent - 1:
 $O(B/A) \rightarrow O(B/A \wedge B)$ (SA1)
7. the *RE-rule* with respect to (w.r.t.) the *antecedent*:
if $\vdash (A \leftrightarrow B)$ then $\vdash O(C/A) \leftrightarrow O(C/B)$
8. the “*contextual RE-rule*” w.r.t. the *consequent*:
if $\vdash C \rightarrow (A \leftrightarrow B)$ then $\vdash O(A/C) \leftrightarrow O(B/C)$

Relationship between O and \Box :

9. $\Diamond O(B/A) \rightarrow \Box O(B/A)$ ($\Diamond O \rightarrow \Box O$)
10. Restricted principle of strengthening of the antecedent - 2:
 $\Diamond(A \wedge B \wedge C) \wedge O(C/B) \rightarrow O(C/A \wedge B)$ (SA2)

Characterisation of O_a / O_i :

11. $O_a A \wedge O_a B \rightarrow O_a (A \wedge B)$ ($O_a - C$)
 $O_i A \wedge O_i B \rightarrow O_i (A \wedge B)$ ($O_i - C$)

Relationships between O_a (respectively: O_i) and $\Box\rightarrow$ (resp.: \Box):

12. $\boxed{\rightarrow} A \rightarrow (\neg O_a A \wedge \neg O_a \neg A) \quad (\neg O_a)$
 $\boxed{\square} A \rightarrow (\neg O_i A \wedge \neg O_i \neg A) \quad (\neg O_i)$
13. $\boxed{\rightarrow} (A \leftrightarrow B) \rightarrow (O_a A \leftrightarrow O_a B) \quad (\leftrightarrow O_a)$
 $\boxed{\square} (A \leftrightarrow B) \rightarrow (O_i A \leftrightarrow O_i B) \quad (\leftrightarrow O_i)$

Relationships between O, O_a (resp.: O_i) and $\boxed{\rightarrow}$ (resp.: $\boxed{\square}$):

14. Restricted factual detachment:
 $O(B/A) \wedge \boxed{\rightarrow} A \wedge \diamond B \wedge \diamond \neg B \rightarrow O_a B \quad (O_a - FD)$
 $O(B/A) \wedge \boxed{\square} A \wedge \diamond B \wedge \diamond \neg B \rightarrow O_i B \quad (O_i - FD)$
15. $O(B/A) \wedge \diamond(A \wedge B) \wedge \diamond(A \wedge \neg B) \rightarrow O_a(A \rightarrow B) \quad (O \rightarrow O_a \rightarrow)$
 $O(B/A) \wedge \diamond(A \wedge B) \wedge \diamond(A \wedge \neg B) \rightarrow O_i(A \rightarrow B) \quad (O \rightarrow O_i \rightarrow)$

Notes:

- i) Simply using Propositional Calculus, we can deduce from 3. ($\boxed{\square} \rightarrow \boxed{\rightarrow}$) the following useful theorem:

$$\vdash \diamond \diamond A \rightarrow \diamond A \quad (\diamond \rightarrow \diamond)$$

- ii) From the contextual RE-rule (8.) it follows that if $\vdash A \leftrightarrow B$ then $\vdash O(A/C) \leftrightarrow O(B/C)$; thus O is classical w.r.t. to both of its arguments.
- iii) Some comments are in order regarding axiom 9. It reflects the fact that norms which comprise the deontic component of a CTD scenario are themselves taken to be fixed, in the sense that they are features of the scenario which the agents concerned have neither the ability nor the opportunity to change. We maintain that this is a reasonable assumption to make, given that our concern is *not* with the dynamics of normative systems, but with the determination of which ideal and actual obligations may be derived from a *fixed* set of norms, given the facts of the case.

But it might be asked whether our analysis of the given norms (i.e., of the dyadic deontic conditionals) is *compatible* with the obvious fact that norms are man-made and may be subject to change. Our answer is that there is no incompatibility here: were we to switch our interest from normative statics to normative dynamics, one natural move — from the semantic point of view — would be to treat the *models* of our current semantics as the *worlds* of a semantical framework for the investigation of normative dynamics.

- iv) Axiom 10. embodies only a weak restriction on strengthening of the antecedent and it is clear that our dyadic deontic conditionals are not “exception-allowing” default conditionals. Any attempt to re-define them as default conditionals — and thus to eliminate 10. from the class of theorems — would have to be accompanied by elimination of the factual detachment principles expressed in 14. (cf. footnote 7, above). The factual detachment principles would then need to be replaced by a theory of default reasoning, defining the conditions under which sentences about actual and ideal obligations could be drawn as default conclusions from any given deontic and factual scenario. In our view, changes of *this* kind in the underlying logic of deontic conditionals would have no direct bearing on how the CTD problems themselves are to be handled.
- v) The counterpart to axiom 12. (first part) also held in the system DL of [Jones and Pörn, 1985], where their modality Ought represented actual obligation. The point captured by this axiom is as follows: if it is not actually possible that A is false, then A is not actually obligatory (for if it is guaranteed that A is true, any such obligation has been discharged); in addition, $\neg A$ is not actually obligatory (for that which it is not actually possible to realise cannot be actually obligatory). However, the fact that it is not *actually* possible that $\neg A$ does not rule out the possibility that, *ideally*, it ought not to be the case that A .

- vi) Using the axiom schemas $(\leftrightarrow O_a)$ and $(\leftrightarrow O_i)$, we can prove the *RE-rules*:

if $\vdash (A \leftrightarrow B)$ then $\vdash O_a A \leftrightarrow O_a B$

and

if $\vdash (A \leftrightarrow B)$ then $\vdash O_i A \leftrightarrow O_i B$

Thus both O_a and O_i are classical operators.

- vii) Using the schemas $(\neg O_a)$ and $(\neg O_i)$, we can deduce the following theorems:

$$\begin{array}{llll} \vdash \neg O_a \top & (O_a - \neg N) & \vdash \neg O_i \top & (O_i - \neg N) \\ \vdash \neg O_a \perp & (O_a - OD) & \vdash \neg O_i \perp & (O_i - OD) \end{array}$$

And any classical operator with (OD) and (C) also has the schema (D) as a theorem; a revision of the logic which avoids (D) will be discussed in Section 6.

It is important that neither O_a nor O_i validates the schema (M) — the converse of (C) — otherwise we would get the (RM) -rule, to be discussed further in Section 6.1.

- viii) We write just (FD) , instead of $(O_a - FD)$ or $(O_i - FD)$, whenever it is clear from the context to which of the two obligation operators we are referring.

RESULT 1.

The previous axiomatisation is *sound*.²¹

Hint to the proof:

- 1.-4. Besides the relevant truth conditions, simply use (respectively) the condition: 4-b), 3-a), 4-a), and 5-a) (for this last case recall that $\mathcal{M} \models_w O(B/A)$ implies $\|B\| \in ob(\|A\|)$).
5. Use 5-c) and 5-ab) (plus the relevant truth condition); condition 5-ab) is needed only to prove that $\|A \wedge B \wedge C\| \neq \emptyset$.
6. Trivial (simply use the relevant truth condition).
- 7.-8. It is trivial to prove that these rules preserve truth in a model (and so also preserve validity, as desired). For the contextual RE-rule use condition 5-b).
- 9.-10. Simply use the relevant truth condition.
(w.r.t. 10., note that $\mathcal{M} \models_w \Diamond(A \wedge B \wedge C)$ implies $\|A \wedge B \wedge C\| \neq \emptyset$.)
- 11.-13. Besides the relevant truth conditions, use (respectively): 5-c), 5-ab), and 5-b).
14. Simply use the relevant truth conditions.
15. Using conditions 5-b) and 5-d), prove that if $\mathcal{M} \models_w O(B/A)$ and $Z \cap \|A\| \cap \|B\| \neq \emptyset$, then $((W - \|A\|) \cup \|B\|) \in ob(Z)$; and then apply that result with $Z = av(w)$ (resp. $pv(w)$).

End-proof

The next result provides a list of some other useful theorems and rules concerning the obligation operators.

RESULT 2.

- i) $\vdash O(B/A) \leftrightarrow O(A \wedge B/A)$
- ii) $\vdash \neg O(A/\perp) \quad \vdash \neg O(\neg A/A)$
- iii) $\vdash \Diamond \neg O(B/A) \rightarrow \Box \neg O(B/A) \quad (\Diamond \neg O \rightarrow \Box \neg O)$
- iv) $\vdash \Diamond(A \wedge B) \wedge O(A \rightarrow B/\top) \rightarrow O(B/A)$
- v) if $\vdash A \rightarrow B$ then $\vdash \Diamond(A \wedge C) \wedge O(C/B) \rightarrow O(C/A)$

²¹Some completeness results are also available, but are not reproduced in this chapter.

- vi) $\vdash \boxed{\rightarrow} A \rightarrow (O_a B \rightarrow O_a (A \wedge B)) \quad (O_a \rightarrow O_a \wedge)$
 $\vdash \boxed{\square} A \rightarrow (O_i B \rightarrow O_i (A \wedge B)) \quad (O_i \rightarrow O_i \wedge)$
- vii) Restricted deontic detachment:²²
 $\vdash O_a A \wedge O(B/A) \wedge \diamond(A \wedge B) \rightarrow O_a (A \wedge B) \quad (O_a - DD)$
 $\vdash O_i A \wedge O(B/A) \wedge \diamond(A \wedge B) \rightarrow O_i (A \wedge B) \quad (O_i - DD)$

Hint to the proof:

- i) From the contextual RE-rule, since $\vdash A \rightarrow (B \leftrightarrow A \wedge B)$.
- ii) From the contextual RE-rule and $(O - \neg N)$ (since $\vdash \perp \rightarrow (\perp \leftrightarrow A)$ and $\vdash A \rightarrow (\perp \leftrightarrow \neg A)$).
- iii) From $(\diamond O \rightarrow \square O)$.
- iv) Since $\vdash \diamond(A \wedge B) \rightarrow \diamond(A \wedge \top \wedge (A \rightarrow B))$, using (SA2) we get $\vdash \diamond(A \wedge B) \wedge O(A \rightarrow B/\top) \rightarrow O(A \rightarrow B/A \wedge \top)$, and the desired theorem follows by using the RE-rule (w.r.t. the antecedent) and the contextual RE-rule (since $\vdash A \rightarrow ((A \rightarrow B) \leftrightarrow B)$).
- v) If $\vdash A \rightarrow B$ then $\vdash \diamond(A \wedge C) \rightarrow \diamond(A \wedge B \wedge C)$; by (SA2), $\vdash \diamond(A \wedge C) \wedge O(C/B) \rightarrow O(C/A \wedge B)$; the theorem follows by the RE-rule w.r.t. the antecedent (since $\vdash A \rightarrow B$ implies $\vdash A \wedge B \leftrightarrow A$).
- vi) From $(\leftrightarrow O_a)$, since $\vdash \boxed{\rightarrow} A \rightarrow \boxed{\square} (B \leftrightarrow A \wedge B)$. (Analogously for O_i .)
- vii) Using axioms $(O \rightarrow O_a \rightarrow)$ and $(O_a - C)$, we deduce $\vdash \diamond(A \wedge \neg B) \rightarrow (O_a A \wedge O(B/A) \wedge \diamond(A \wedge B) \rightarrow O_a (A \wedge B))$; by axiom $(\leftrightarrow O_a)$, we deduce $\vdash \neg \diamond(A \wedge \neg B) \rightarrow (O_a A \rightarrow O_a (A \wedge B))$ (since $\vdash \neg \diamond(A \wedge \neg B) \rightarrow \boxed{\rightarrow} (A \leftrightarrow A \wedge B)$); thus $\vdash O_a A \wedge O(B/A) \wedge \diamond(A \wedge B) \rightarrow O_a (A \wedge B)$. (Analogously for O_i .)

End-proof

As can be seen in the next section, the theorems that play the dominant

²²We note, however, that we cannot detach $O_a B(O_i B)$ from the antecedent of these theorems. In fact, even the “weaker” formulas below are *not valid*:

$$O_a A \wedge O(B/A) \wedge \diamond(A \wedge B) \wedge \diamond(A \wedge \neg B) \rightarrow O_a B$$

$$O_i A \wedge O(B/A) \wedge \diamond(A \wedge B) \wedge \diamond(A \wedge \neg B) \rightarrow O_i B.$$

Although it may seem, at first sight, that the failure of these implications represents a weakness of the logic, the analysis of some examples, to follow, indicates that it is — on the contrary — an advantage.

role in determining what may, or may not, be derived from a chosen representation of a CTD scenario are:

- the factual detachment axioms (FD);
- axioms $(O \rightarrow O_a \rightarrow)$ and $(O \rightarrow O_i \rightarrow)$;
- the deontic detachment theorems (DD);
- axioms $(\neg O_a)$ and $(\neg O_i)$;
- axioms $(\leftrightarrow O_a)$ and $(\leftrightarrow O_i)$;
- and the theorems $(O_a \rightarrow O_a \wedge)$ and $(O_i \rightarrow O_i \wedge)$.

Besides these theorems, we will also make extensive use of the T -normality of \square ; the D -normality of \boxrightarrow ; axiom $(\square \rightarrow \boxrightarrow)$ and theorem $(\diamond \rightarrow \diamond)$.

5 THE ANALYSIS OF SOME CTD SCENARIOS

We shall focus on six scenarios which exhibit CTD structures: Scenario 1 is the Chisholm set — Example 1 above; Scenario 2 is the extended version of Example 2 — “the dog scenario” involving “contrary-to-contrary-to-duties”; Scenario 3 is “the white fence” - Example 3 above; Scenario 4 is “the gentle murderer”; Scenario 5 is “the considerate assassin” — Example 4 above; Scenario 6 is the so-called “Reykjavic scenario”²³.

The scenarios illustrate the range of problems which a theory of CTD should be able to handle; and they enable us to exhibit the expressive and deductive capabilities of our logical system.

²³This is also discussed in [Belzer, 1987] and [McCarty, 1994], and is one of the many examples considered in [Prakken and Sergot, 1994; Prakken and Sergot, 1996].

SCENARIO 1. *The Chisholm Set**The deontic component*

- (d1) It ought to be that a certain man go to help his neighbours
- (d2) It ought to be that if he goes he tell them he is coming
- (d3) If he does not go, he ought not to tell them he is coming

Logical representation

- (d1) $O(\text{help} / \top)$
- (d2) $O(\text{tell} / \text{help})$
- (d3) $O(\neg \text{tell} / \neg \text{help})$

Assumptions regarding the representation of the facts

In this example we assume the following obvious hypotheses regarding the representation of the facts:

- (a) $\text{help} \rightarrow \boxed{\rightarrow} \text{help}$ (thus, by $(\boxed{\rightarrow} - D)$, $\boxed{\rightarrow} \neg \text{help} \rightarrow \neg \text{help}$)
- (b) $\text{tell} \rightarrow \boxed{\rightarrow} \text{tell}$ (analogously, $\boxed{\rightarrow} \neg \text{tell} \rightarrow \neg \text{tell}$)

Moreover, we also assume that

- (c) $(\text{help} \wedge \neg \text{tell}) \rightarrow \boxed{\rightarrow} \neg \text{tell}$ (but not $\neg \text{tell} \rightarrow \boxed{\rightarrow} \neg \text{tell}$)

since when the agent concerned has helped his neighbours but did not tell them he was coming, it makes no sense to consider any actual alternative where he tells them he is coming. On the other hand, although in some of the cases it might be reasonable to accept both $\neg \text{help} \rightarrow \boxed{\diamond} \neg \text{help}$ and $\neg \text{tell} \rightarrow \boxed{\diamond} \neg \text{tell}$, we shall not adopt either of these assumptions. (Nevertheless, by $(\boxed{\square} - T)$, we have, for any sentence A , $\vdash A \rightarrow \boxed{\diamond} A$.)

CASE 1.1.

Factual component

- (f1) X (the agent concerned) decides not to go to help his neighbour (and, of course, he has not yet gone to help them).

- (f2) But it is potentially possible for X to help and to tell and potentially possible for X to help and not to tell.
- (f3) X has not in fact told that he is coming, although it is still actually possible that he does tell and actually possible that he does not tell.

Logical representation

- (f1) $\boxed{\rightarrow} \neg \text{help}$
- (f2) $\diamond(\text{help} \wedge \text{tell}) \wedge \diamond(\text{help} \wedge \neg \text{tell})$
- (f3) $\neg \text{tell} \wedge \diamond \text{tell} \wedge \diamond \neg \text{tell}$

(Note that, without assumption (a), we would represent (f1) as $\neg \text{help} \wedge \boxed{\rightarrow} \neg \text{help}$, since we have not adopted the T -schema for $\boxed{\rightarrow}$.)

Conclusions

In virtue of the factual detachment axioms (FD), we may derive the following:

$$* \quad \text{viol}(\text{help}) \wedge O_a \neg \text{tell}$$

that is to say, X violates his obligation to help his neighbours, and is actually (given the circumstances) under an obligation not to tell them he is coming. It is also possible to derive the conclusion that X violates his obligation to “help and tell”, since it is also possible to deduce, in virtue of the deontic detachment theorem (DD), that $O_i(\text{help} \wedge \text{tell})$. We remark here (cf. footnote 22 regarding Result 2-vii)) that it is not also possible to conclude that X has violated an obligation to tell *simpliciter*, since that particular obligation would not come into effect until X’s helping was a fixed fact. This result seems to accord well with intuition.

Note also that the pragmatic oddity, as we have diagnosed it, is avoided, for we could consistently add to the deontic component above an obligation to the effect that X ought not both go to help and not say that he is coming, i.e., an obligation of the form $O(\neg \text{help} \vee \text{tell} / \top)$.

CASE 1.2.

Factual component

- (f1) X has helped his neighbours and told them he was coming.
- (f2) But it was potentially possible that X did not help his neighbours.

Logical representation

- (f1) $\text{help} \wedge \text{tell}$
 (by assumptions (a) and (b), this implies $\boxed{\rightarrow}(\text{help} \wedge \text{tell})$)
- (f2) $\diamond\neg\text{help}$

Conclusions

We may derive the following (using (FD) and (DD)):

- * $O_i \text{help} \wedge O_i (\text{help} \wedge \text{tell}) \wedge \text{help} \wedge \text{tell}$

So, X has met his ideal obligations, and no actual obligation arises (as can be seen by taking into account $(\neg O_a)$).

CASE 1.3.

Factual component

- (f1) X has helped his neighbours and he did not tell them he was coming.
- (f2) It was potentially possible that he both helped and told, as well as that he did not help them.

Logical representation

- (f1) $\text{help} \wedge \neg\text{tell}$
 (by assumptions (a) and (c), this implies $\boxed{\rightarrow}(\text{help} \wedge \neg\text{tell})$)
- (f2) $\diamond(\text{help} \wedge \text{tell}) \wedge \diamond\neg\text{help}$

Conclusions

We may derive the following (using (FD) and (DD)):

- * $O_i \text{help} \wedge \text{help} \wedge \text{viol}(\text{help} \wedge \text{tell})$

So, X meets his ideal obligation to help, but violates his obligation to help and tell; and no actual obligations are derivable.

CASE 1.4.

Factual component

- (f1) X has helped his neighbours, although it was potentially possible that he did not help them.
- (f2) X did not tell his neighbours he was coming, since that was potentially impossible for X to do (imagine that there were no available means of communication).

Logical representation

(f1) $\text{help} \wedge \Diamond \neg \text{help}$ (recall that, by (a), $\text{help} \rightarrow \Box \text{help}$)

(f2) $\Box \neg \text{tell}$

Conclusions

We may derive the following (using (FD)):

* $O_i \text{ help} \wedge \text{help}$

So, X has not violated any obligation: the obligation sentence O_i (help \wedge tell) cannot be derived, because it would be impossible to satisfy such an obligation; furthermore, X has met his ideal obligation to help. No actual obligations are derivable.

CASE 1.5.

Factual component

(f1) It is not potentially possible for X to help his neighbours (for some reason or other — perhaps, for instance, there are no available means for X to travel to his neighbours' house); however, X tells his neighbours he is coming, but he might not have told them so.

Logical representation

(f1) $\Box \neg \text{help} \wedge \text{tell} \wedge \Diamond \neg \text{tell}$

Conclusions

We may derive the following (again using (FD)):

* $\text{viol}(\neg \text{tell})$

SCENARIO 2. *The dog example – extended with a second-level CTD*

The deontic component

- (d1) There ought to be no dog
- (d2) If there is no dog, there ought not to be a warning sign
- (d3) If there is a dog, there ought to be a warning sign
- (d4) If there is a dog and no warning sign, there ought to be a high fence

Logical representation

- (d1) $O(\neg\text{dog} / \top)$
- (d2) $O(\neg\text{sign} / \neg\text{dog})$
- (d3) $O(\text{sign} / \text{dog})$
- (d4) $O(\text{fence} / \text{dog} \wedge \neg\text{sign})$

Assumptions regarding the representation of the facts

We here adopt no specific hypotheses regarding the representation of the facts.

CASE 2.1.

Factual component

- (f1) There is a dog, and it is actually possible to keep it or to get rid of it (and there is no information regarding the possibility of having, or not, a sign or a fence).

Logical representation

- (f1) $\text{dog} \wedge \Diamond\text{dog} \wedge \Diamond\neg\text{dog}$

Conclusions

We may derive the following regarding violation and actual obligation:

$$* \quad \text{viol}(\neg\text{dog}) \wedge O_a \neg\text{dog}$$

So, there is a violation of the obligation not to have a dog, and there is an actual obligation to get rid of it.

CASE 2.2.

Factual component

- (f1) There is a dog and it is not actually possible that there is not a dog (i.e., the presence of the dog is actually fixed), but it was potentially possible that there was no dog.

Logical representation

$$(f1) \text{ dog} \wedge \boxed{\rightarrow} \text{dog} \wedge \diamond \neg \text{dog}$$

Conclusions

We may derive the following regarding violation and actual obligation:

$$* \quad \text{viol}(\neg \text{dog})$$

There is a violation of the prohibition against having a dog, and no actual obligations may be derived - although it is possible to derive

$$\diamond \text{sign} \wedge \diamond \neg \text{sign} \rightarrow O_a \text{ sign}$$

CASE 2.3.

Factual component

- (f1) There is a dog and that fact is actually fixed (i.e., it is not actually possible that there is not a dog), but there might potentially have been no dog.
- (f2) There is no sign and it is not actually possible that there is a sign, but there might potentially have been both a dog and a sign.
- (f3) There is not a fence, and both the presence and the absence of a fence are actual possibilities.

Logical representation

$$(f1) \text{ dog} \wedge \boxed{\rightarrow} \text{dog} \wedge \diamond \neg \text{dog}$$

$$(f2) \neg \text{sign} \wedge \boxed{\rightarrow} \neg \text{sign} \wedge \diamond (\text{dog} \wedge \text{sign})$$

$$(f3) \neg \text{fence} \wedge \diamond \neg \text{fence} \wedge \diamond \text{fence}$$

Conclusions

We may derive, in particular, the following violations and actual obligation:

$$* \quad \text{viol}(\neg \text{dog}) \wedge \text{viol}(\text{dog} \rightarrow \text{sign}) \wedge \text{viol}(\text{dog} \wedge \neg \text{sign} \rightarrow \text{fence}) \wedge O_a \text{ fence}$$

The ideal obligation that there be no dog is obtained by applying (FD). By application of the axiom schema $(O \rightarrow O_i \rightarrow)$, we derive that:

- (i) it is ideally obligatory that if there is a dog then there is a sign

(note that, from (f1) and (f2) we get $\text{dog} \wedge \neg \text{sign}$, and so $\Diamond(\text{dog} \wedge \neg \text{sign})$; the application of $(\text{O} \rightarrow \text{O}_i \rightarrow)$ is then trivial, taking into account (d3) and (f2));

and

(ii) it is ideally obligatory that if there is a dog and no sign then there is a fence

(for instance, from (f1), (f2) and (f3), plus the normality of \Box , deduce $\Diamond(\text{dog} \wedge \neg \text{sign} \wedge \text{fence})$ and $\Diamond(\text{dog} \wedge \neg \text{sign} \wedge \neg \text{fence})$, which imply (by $(\Diamond \rightarrow \Diamond)$) $\Diamond(\text{dog} \wedge \neg \text{sign} \wedge \text{fence})$ and $\Diamond(\text{dog} \wedge \neg \text{sign} \wedge \neg \text{fence})$, and then use $(\text{O} \rightarrow \text{O}_i \rightarrow)$ and (d4)).

Axiom (FD) enables us to derive that, given the circumstances, the actual obligation is to put up a fence.

SCENARIO 3. *The white fence case - Example 3*

The deontic component

- (d1) There must be no fence
- (d2) But, if there is a fence it must be white

Logical representation

- (d1) $\text{O}(\neg \text{fence} / \top)$
- (d2) $\text{O}(\text{white-fence} / \text{fence})$

Assumptions regarding the representation of the facts

- $\Box(\text{white-fence} \rightarrow \text{fence})$

CASE 3.1.

Factual component

- (f1) There is no fence, and it is still actually possible not to erect a fence and actually possible to erect a fence, white or not.

Logical representation

- (f1) $\neg \text{fence} \wedge \Diamond \neg \text{fence} \wedge \Diamond \text{white-fence} \wedge \Diamond(\text{fence} \wedge \neg \text{white-fence})$
(Note that, by the assumption made, from $\Diamond \text{white-fence}$ we can derive $\Diamond(\text{fence} \wedge \text{white-fence})$.)

Conclusions

We may derive the following regarding ideal/actual obligations:

$$* \quad O_i \neg\text{fence} \wedge O_i (\text{fence} \rightarrow \text{white-fence}) \wedge \neg\text{fence} \wedge \\ O_a \neg\text{fence} \wedge O_a (\text{fence} \rightarrow \text{white-fence})$$

There is an ideal obligation not to have a fence and an ideal obligation that if there is a fence then it must be white; neither of these ideal obligations has been violated; and both persist as actual obligations.

CASE 3.2

Factual component

- (f1) There is a white fence, and it is actually fixed that there will be a fence, possibly white or of another colour.
 (f2) But it was potentially possible not to have a fence.

Logical representation

- (f1) $\text{white-fence} \wedge \boxed{\rightarrow} \text{fence} \wedge \blacklozenge \text{white-fence} \wedge \blacklozenge (\text{fence} \wedge \neg\text{white-fence})$
 (f2) $\blacklozenge \neg\text{fence}$

Conclusions

We may derive, in particular, the following violation, and ideal and actual obligations:

$$* \quad \text{viol}(\neg\text{fence}) \wedge O_i (\text{fence} \rightarrow \text{white-fence}) \wedge \\ O_a (\text{fence} \rightarrow \text{white-fence}) \wedge O_a \text{white-fence}$$

The ideal obligation not to have a fence has been violated and does not persist as an actual obligation, since it can no longer actually be fulfilled; the obligation to the effect that if there is a fence then it must be white has not been violated, and it persists as an actual obligation. We may also derive the actual obligation to have a white fence.

SCENARIO 4. *The gentle murderer**The deontic component*

(d1) You should not kill Mr. X

(d2) But, if you kill Mr. X, you should do it gently

Logical representation(d1) $O(\neg\text{kill} / \top)$ (d2) $O(\text{kill-gently} / \text{kill})$ *Assumptions regarding the representation of the facts*

We make the following assumptions:

- (a) $\Box(\text{kill-gently} \rightarrow \text{kill})$
(thus: $(\text{kill-gently} \rightarrow \text{kill})$ and $\Box(\text{kill-gently} \rightarrow \text{kill})$)
- (b) $\text{kill} \rightarrow \Box\text{kill}$
- (c) $\text{kill-gently} \rightarrow \Box\text{kill-gently}$
- (d) $\text{kill} \wedge \neg\text{kill-gently} \rightarrow \Box\neg\text{kill-gently}$

In the cases discussed below, assumptions (b), (c) and (d) are relevant only in regard to determining that no actual obligations arise. Note that the difference between Scenarios 4 and 3 is that the counterparts to assumptions (b), (c) and (d) cannot be adopted for Scenario 3.

CASE 4.1

Factual component

- (f1) The assassin has killed Mr. X, but gently.
- (f2) It was potentially possible for the assassin not to kill and potentially possible that he killed “non-gently”.

Logical representation

- (f1) kill-gently
 - (f2) $\Diamond\neg\text{kill} \wedge \Diamond(\text{kill} \wedge \neg\text{kill-gently})$
- (Note that $\vdash \text{kill-gently} \rightarrow \Diamond\text{kill-gently}$.)

Conclusions

We may derive the following (using (FD) and $(O \rightarrow O_i \rightarrow)$):

$$* \quad \text{viol}(\neg\text{kill}) \wedge O_i(\text{kill} \rightarrow \text{kill-gently}) \wedge \text{kill-gently}$$

The assassin has violated his obligation not to kill and has fulfilled his obligation to kill Mr. X gently if he was going to kill him; no actual obligation arises; (using, for instance, (f1), (a) and (b) we can derive \Box kill: so, it is actually impossible to fulfil the obligation not to kill Mr. X; also we cannot derive an actual obligation to kill gently, since that cannot actually be violated, taking into account (c)).

CASE 4.2.

Factual component

- (f1) The assassin has killed Mr. X and not gently.
- (f2) It was potentially possible for the assassin not to kill and potentially possible for him to kill gently.

Logical representation

- (f1) $\text{kill} \wedge \neg\text{kill-gently}$
- (f2) $\Diamond\neg\text{kill} \wedge \Diamond\text{kill-gently}$

Conclusions

We may derive the following:

$$* \quad \text{viol}(\neg\text{kill}) \wedge \text{viol}(\text{kill} \rightarrow \text{kill-gently})$$

The assassin has violated both his obligation not to kill and his obligation to kill gently if he does kill; no actual obligation arises; (use (f1), (b) and (d)).

CASE 4.3.

Factual component

- (f1) It has been proved (in court) that the “assassin” has killed Mr. X, but gently (and this is admitted by the “assassin”).
- (f2) The “assassin” argues in court that he had no other choice, i.e. that it was potentially impossible for him not to kill Mr. X, because a real assassin had told him that he would kill his son if he (the “assassin”) did not kill Mr. X. The prosecution argues that it was potentially possible for the “assassin” not to kill Mr. X (for instance because he could ask the police for protection for his son).

Logical representation of the facts according to the point of view of the defence

- (f1) kill-gently
 (f2) \square kill \wedge \diamond \neg kill-gently

Conclusions

Since it was impossible not to kill Mr. X the ideal obligation not to kill cannot be derived; using (FD) we can derive the ideal obligation to kill gently, and this obligation was fulfilled.

Logical representation of the facts according to the point of view of the prosecution

- (f1) kill-gently
 (f2) \diamond \neg kill \wedge \diamond (kill \wedge \neg kill-gently)

Conclusions

As in case 4.1, we can derive $\text{viol}(\neg\text{kill})$. So, the prosecution argues: the “assassin” should be considered guilty.

Conclusions

Of course it may well be suggested that the tactic of the defence here is most unwise. Perhaps they should first accept the prosecution’s claim that it was potentially possible for the “assassin” to refrain from killing, and thus that the “assassin” was ideally obliged not to kill; but then the defence should point out that obviously the “assassin” acted under duress, because of the threat to his son, and thus that the option of not killing was not one which the “assassin” could reasonably be expected to choose.

Again we note here that the logic does not determine the status of the facts; but its language is capable of representing the opposing views concerning their status - in this case, concerning what is taken to be potentially possible. The logic’s task is to show which conclusions regarding obligations and violations follow from a given set of norms, once a particular proposal has been made as to the status of the facts.

SCENARIO 5. *The considerate assassin**The deontic component*

(d1) You should not kill Mr. X

(d2) But, if you kill Mr. X, you should offer him a cigarette

Logical representation(d1) $O(\neg\text{kill} / \top)$ (d2) $O(\text{offer} / \text{kill})$ *Assumptions regarding the representation of the facts*(a) $\text{kill} \rightarrow \boxed{\rightarrow} \text{kill}$ (b) $\text{offer} \rightarrow \boxed{\rightarrow} \text{offer}$ (c) $\text{kill} \wedge \neg\text{offer} \rightarrow \boxed{\rightarrow} \neg\text{offer}$

CASE 5.1.

Factual component

(f1) The assassin has not yet killed Mr. X and has not offered him a cigarette.

(f2) It is still actually possible for the assassin to kill Mr. X and to offer him a cigarette or to kill and not offer a cigarette or not to kill and offer him a cigarette or not to kill and not offer him a cigarette.

Logical representation(f1) $\neg\text{kill} \wedge \neg\text{offer}$ (f2) $\diamond(\text{kill} \wedge \text{offer}) \wedge \diamond(\text{kill} \wedge \neg\text{offer}) \wedge \diamond(\neg\text{kill} \wedge \text{offer}) \wedge \diamond(\neg\text{kill} \wedge \neg\text{offer})$ *Conclusions*We may derive the following (using (FD), $(O \rightarrow O_a \rightarrow)$, and $(O \rightarrow O_i \rightarrow)$):

$$* \quad O_i \neg\text{kill} \wedge O_i (\text{kill} \rightarrow \text{offer}) \wedge \neg\text{kill} \wedge \neg\text{offer} \wedge O_a \neg\text{kill} \wedge O_a (\text{kill} \rightarrow \text{offer})$$

The assassin has not violated his ideal obligations not to kill Mr. X and to offer Mr. X a cigarette if he was going to kill him, and these obligations persist as actual obligations.

CASE 5.2

Factual component

- (f1) The assassin has not yet killed Mr. X but he has firmly decided to kill him.
 (f2) It is actually possible for the assassin to offer or not a cigarette.

Logical representation

- (f1) $\neg\text{kill} \wedge \boxed{\rightarrow}\text{kill}$
 (f2) $\diamond\text{offer} \wedge \diamond\neg\text{offer}$

Conclusions

We may derive, in particular:

$$* \quad O_i \neg\text{kill} \wedge O_a (\text{kill} \wedge \text{offer}) \wedge O_a \text{offer}$$

Given that it is actually a fixed fact that the assassin is going to kill Mr. X, his actual obligation is to offer Mr. X a cigarette. Of course, his ideal obligation is not to kill. Note that from $O_a \text{offer}$ (by $(O \rightarrow O_a \rightarrow)$) we can derive $O_a (\text{kill} \rightarrow \text{offer})$; and the obligation $O_a (\text{kill} \wedge \text{offer})$ can then be obtained by (f1) and $(O_a \rightarrow O_a \wedge)$. We shall comment on this conclusion in Section 6, below, but note at this point that $O_a \text{kill}$ is *not* derivable.

SCENARIO 6. *The Reykjavik scenario**The deontic component*

Consider the following instructions given to officials accompanying Reagan and Gorbachov at the Reykjavik meeting:

- (d1) The secret shall be told neither to Reagan nor to Gorbachov
 (d2) But if the secret is told to Reagan it shall also be told to Gorbachov
 (d3) And if the secret is told to Gorbachov it shall also be told to Reagan

Logical representation

Suppose that 'r' represents 'Reagan knows the secret' and that 'g' represents 'Gorbachov knows the secret'

- (d1) $O (\neg r \wedge \neg g / \top)$
 (d2) $O (g/r)$
 (d3) $O (r/g)$

Comments on the logical representation of the deontic component

- (a) Sentence (d1) ought to be represented in the form indicated and not as $O(\neg r/\top) \wedge O(\neg g/\top)$. The reason is that there is no “absolute” obligation according to which, e.g., Reagan is not to know the secret (in just any context in which that would be possible); what is “absolutely” obligatory is that neither of them knows the secret. In fact, if the above alternative formulation of (d1) were to be employed, then in the situation where, for instance, the secret has been told to Gorbachov but not to Reagan, it would be possible to derive conflicting actual obligations, and that derivation would be intuitively correct. It is a merit of the logic proposed that it would detect such a conflict. (A similar point is made in [Prakken and Sergot, 1994; Prakken and Sergot, 1996] in their discussion of this scenario.)
- (b) A possible alternative representation of (d2)+(d3) would be (d2+3): $O(g \wedge r/g \vee r)$. (Although it would then be possible to generate the same conclusions as from (d2)+(d3), different patterns of derivation would be involved.)

Assumptions regarding the representation of the facts

We make the following assumptions:

- (a) $r \rightarrow \boxed{\rightarrow} r$
 (b) $g \rightarrow \boxed{\rightarrow} g$
 (c) $\diamondrightarrow(r \wedge g)$ (which gives: $\diamondrightarrow r$ and $\diamondrightarrow g$, as well as $\diamond(r \wedge g)$)
 (d) $\neg r \rightarrow \diamondrightarrow \neg r$
 (e) $\neg g \rightarrow \diamondrightarrow \neg g$

CASE 6.1.

Factual component

- (f1) The secret has not yet been told to either of them

Logical representation

- (f1) $\neg r \wedge \neg g$

Conclusions

$$* \quad O_i(\neg r \wedge \neg g) \wedge \neg r \wedge \neg g \wedge O_a(\neg r \wedge \neg g)$$

The obligation to tell the secret to neither of them has not been violated, and persists as an actual obligation. Application of (FD) is instrumental in the derivation of these conclusions.

CASE 6.2

Factual component

- (f1) Reagan knows the secret but Gorbachov does not
- (f2) But it was potentially possible that neither of them knew

Logical representation

- (f1) $r \wedge \neg g$
- (f2) $\Diamond(\neg r \wedge \neg g)$

Conclusions

* $\text{viol}(\neg r \wedge \neg g) \wedge O_a g$ (it suffices to use (FD))

We may also derive $O_a(r \wedge g)$, by direct application of $(O_a \rightarrow O_a \wedge)$, on the basis of the prior derivation of $O_a g$. On the other hand, if we employ (d2+3) instead of (d2) and (d3), we get $O_a(r \wedge g)$ by direct application of (FD), and then on the basis of that result we can use $(\leftrightarrow O_a)$ to obtain $O_a g$.

CASE 6.3

Factual component

- (f1) The secret has been told at the same time to Reagan and Gorbachov

Logical representation

- (f1) $r \wedge g \wedge \Diamond(\neg r \wedge \neg g)$

Conclusions

* $\text{viol}(\neg r \wedge \neg g)$

There is violation of the obligation to tell neither of them, and no actual obligations are now derivable.

CASE 6.4

Factual component

- (f1) One, and only one, of Reagan and Gorbachev has been told the secret
- (f2) It might potentially have been the case that neither of them was told

Logical representation

(f1) $(r \vee g) \wedge \neg(r \wedge g)$

(f2) $\Diamond(\neg r \wedge \neg g)$

Conclusions

* $\text{viol}(\neg r \wedge \neg g) \wedge O_a(r \wedge g)$

Note that the derivation of $O_a(r \wedge g)$ requires the use of (FD), and then the application of $(O_a \rightarrow O_a \wedge)$; the derivation could be made directly by application of (FD) if (d2+3) were used to represent the second and third lines of the deontic component.

6 EVALUATING THE PROPOSED APPROACH

6.1 Closure under implication

Our ideal/actual obligation operators are not closed under the (RM)-rule. Since we have $(\neg N)$ (for both O_i and O_a), and since the operators are classical, closure under the (RM)-rule would yield the result that any ideal or actual obligation implies a contradiction. But even if O_i and O_a had been defined in such a way that $(\neg N)$ were not valid, there are still reasons for not wanting the (RM)-rule; as we remarked in Section 2.2, from the point of view of *violation* the Ross problem — which acceptance of the (RM)-rule would generate — does seem to be genuine. So, given the focus on violation in our approach, the Ross problem is to be avoided.

This was a main reason for not supplementing our models with respect to ‘*ob*’. If we had imposed that “if $Y \subseteq Z$ and $Y \in \text{ob}(X)$, then $Z \in \text{ob}(X)$ ”, then although we would not get the (RM)-rule in its full generality (because of the second conjunct in the truth conditions for actual and ideal obligation sentences), we would still get weaker versions of it, such as: “if $\models A \rightarrow B$ then $\models \Diamond \neg B \rightarrow (O_i A \rightarrow O_i B)$ ”,²⁴ that are strong enough to generate the Ross problem.

Nevertheless, some would maintain²⁵ that at least weaker versions of the (RM)-rule are needed, since if, for instance, it is forbidden to kill, it seems strange that we cannot also derive that it is forbidden to strangle.

The claim seems to be this: for a particular class of pairs of sentences (A, B) , the conditional relation between A and B is such that it should license the derivation of “if B is forbidden then A is also forbidden”. Suppose that we introduce a connective \Rightarrow to express the kind of conditional

²⁴Using condition 5-b), we would even get the stronger result “ $\models (\Box(A \rightarrow B) \wedge \Diamond \neg B) \rightarrow (O_i A \rightarrow O_i B)$ ” (and “ $\models (\Box(A \rightarrow B) \wedge \Diamond \neg B) \rightarrow (O_a A \rightarrow O_a B)$ ” with respect to actual obligations).

²⁵We are grateful to Henry Prakken for this criticism.

relation concerned (leaving its semantics open for the moment). Instances of this conditional relationship (taken from the scenarios analysed in Section 5) would be (white-fence \Rightarrow fence) and (kill-gently \Rightarrow kill), besides the previously mentioned (strangle \Rightarrow kill). Using this connective, one possible way of interpreting the claim, in terms of our approach, might be to require the validity of the following sentences:

$$(\$i) (A \Rightarrow B) \wedge \Diamond A \rightarrow (O_i \neg B \rightarrow O_i \neg A)$$

$$(\$a) (A \Rightarrow B) \wedge \Diamond A \rightarrow (O_a \neg B \rightarrow O_a \neg A)$$

It would not be a difficult matter to define appropriate truth conditions for \Rightarrow and to relate them to the semantics of ‘ob’ in such a way as to secure the validity of these two sentences. But we do not pursue this line here, since we think that, in terms of our approach, there are reasons for supposing that they should not be deemed valid.

To see why, recall again the gentle murderer scenario, supposing that “A” is “kill-gently” and “B” is “kill”. (In what follows we will concentrate on (\$i) although a similar argument could be raised against (\$a).) Consider the case where it was potentially possible to kill or not to kill, and potentially possible to kill gently or not to kill gently. According to (\$i) we would derive that there is an ideal obligation not to kill gently. Is this an acceptable derivation? We think not. In our opinion what we should derive — as we do in our logic — is that $O_i \neg \text{kill} \wedge O_i (\text{kill} \rightarrow \text{kill-gently})$.

Of course, if the assassin kills gently he violates the prohibition to kill, and that is indeed secured by our logic: assuming the obvious hypothesis that $\Box (\text{kill-gently} \rightarrow \text{kill})$ then we may derive

$$(*) O_i \neg \text{kill} \rightarrow (\text{kill-gently} \rightarrow \text{viol}(\text{kill}))$$

The fact that we can derive (*) goes a long way towards accommodating the point behind Prakken’s criticism, we believe.

6.2 Axiom ($\leftrightarrow O_a$) and condition 5-b)

First possible counter-example:

Suppose that Mr. X has an actual obligation to help his friend move on Saturday, and suppose that Mr. X (firmly) decides that he will help his friend move on Saturday if and only if he will borrow his brother’s convertible on Saturday. Thus we will have $O_a \text{help} \wedge \Box (\text{help} \leftrightarrow \text{borrow})$ and, using axiom ($\leftrightarrow O_a$), we derive $O_a \text{borrow}$. However, it has been suggested²⁶ that Mr. X might have an actual obligation to help his friend, but not an actual obligation to borrow the convertible. We disagree: the

²⁶We are grateful to Donald Nute for this criticism.

central point, as we see it, is that the truth of $\boxed{\rightarrow}$ ($\text{help} \leftrightarrow \text{borrow}$) means that it is not actually possible that either Mr. X helps his friend and does not borrow the convertible or Mr. X borrows the convertible and does not help his friend. Given that actual impossibility, there can be an actual obligation to help the friend if and only if there is an actual obligation to borrow the convertible. The fact that the decision to help a friend involves a commitment to another person, whereas the decision to borrow the car perhaps does not, is irrelevant to the conception of actual obligation we wish to explicate.

Second possible counter-example:

Suppose that Mr. X has an actual obligation to go to the cinema on Saturday, and suppose that Mr. X decides that he will go to the cinema on Saturday if and only if his friend, Mr. Y, also goes to the cinema on Saturday. Thus we will have $O_a \text{ go-X} \wedge \boxed{\rightarrow} (\text{go-X} \leftrightarrow \text{go-Y})$ and we derive $O_a \text{ go-Y}$. Does this mean that Mr. Y has an actual obligation to go to the cinema on Saturday? Clearly not! Examples of this sort indicate that there are cases where the formal language needs to be extended to include means of indexing decisions to particular agents, and means of relativising obligations to particular agents. Then it could be made explicit that X has taken the decision, that X bears the obligation to go to the cinema, and that X also bears the obligation to secure Y's presence.

Third possible counter-example:

Recall Case 5.2, from “the considerate assassin” scenario, in Section 5. The facts were: (f1) “The assassin has not yet killed Mr. X but he has firmly decided to kill him” and (f2) “It is actually open for the assassin to offer or not a cigarette”; from these facts, and the norms, and some background assumptions, we concluded not only that the assassin has an actual obligation to offer Mr. X a cigarette ($O_a \text{ offer}$), but also (using the theorem $(O_a \rightarrow O_a \wedge)$, which follows from the axiom $(\leftrightarrow O_a)$) that the assassin has an actual obligation to kill Mr. X and to offer him a cigarette ($O_a (\text{kill} \wedge \text{offer})$). This result may seem odd, just because it seems odd to say that someone has an actual obligation to kill (and whatever). But there is a good reason why this result should indeed be forthcoming. For remember that it is a fixed fact that the assassin will kill Mr. X — it is assumed that it is actually impossible not to kill; thus, whatever actual obligations now come into force do so in the context of that assumption. Importantly, $O_a \text{ kill}$ cannot be derived from $O_a (\text{kill} \wedge \text{offer})$, and clearly there cannot be an actual obligation to kill, since it must be actually possible that that which is actually obligatory fails to obtain.

There is a connection between the last point and the Good Samaritan paradox of SDL mentioned in Section 2.2. In our view, the proper response to the Good Samaritan scenario is as follows: it is a fixed fact of the situation that a man X has been robbed. The actual obligation to help him thus arises

in the context of that fixed fact, and so it is appropriate to represent the content of the actual obligation in terms of a conjunction: “X is robbed and X is helped”. In our system, in contrast to SDL, it does *not* follow that there is an obligation to rob; and we have a good explanation for why it should not follow, for that which is actually fixed cannot actually be otherwise, and thus cannot be the object of an actual obligation.

6.3 Violations, and ideal and actual obligations

Violations of conditional obligations

A sentence of form $\text{viol}(B)$ is true if we can deduce from a set of deontic norms, and a set of facts, both that ideally it ought to be the case that B ($O_i B$) and that B is not the case ($\neg B$). However, it might be suggested that a normgiver often wants to express explicitly in the object language sentences of the form “violation(deontic norm) \rightarrow Sanction”. The question is how “violation($O(B/A)$)” could be represented in our system?²⁷

Our answer is that “violation($O(B/A)$)” can be characterized as:

$$O(B/A) \wedge \Diamond(A \wedge B) \wedge A \wedge \neg B$$

The explanation is as follows:

Suppose $O(B/A)$. Two factual situations are then possible:

- First possibility: $\Box A$ is the case.

Then (by (FD) and ($\neg O_i$)) we derive an ideal obligation $O_i B$ iff $\Diamond B \wedge \Diamond \neg B$. And in order to get $\text{viol}(B)$ we must have $\neg B$ (which implies $\Diamond \neg B$). Thus a violation occurs if $\Diamond B \wedge \neg B$, which is equivalent, given that $\Box A$, to $\Diamond(A \wedge B) \wedge A \wedge \neg B$.

- Second possibility: $\neg \Box A$ is the case.

In this case (using axiom ($O \rightarrow O_i \rightarrow$)) we derive from $O(B/A)$ an ideal obligation of the form $O_i(A \rightarrow B)$ if $\Diamond(A \wedge B) \wedge \Diamond(A \wedge \neg B)$. And in order to get $\text{viol}(A \rightarrow B)$ we must have $A \wedge \neg B$ (which implies $\Diamond(A \wedge \neg B)$). Thus a violation occurs if $\Diamond(A \wedge B) \wedge A \wedge \neg B$.

In the absence of other conditional obligations, no other ideal obligations can be deduced from $O(B/A)$. The only other way we could deduce an ideal obligation from $O(B/A)$, would be if we already had $O_i A$ and $\Diamond(A \wedge B)$, in which case we could deduce,

²⁷We are grateful to Henry Prakken for posing us this question.

by (DD), the further obligation $O_i(A \wedge B)$. We omit further details here, but it may be shown that this case too provides no difficulties for the proposed characterisation of “violation($O(B/A)$)”.

Violation vs non-fulfillment

Consider the following new case of the Reykjavik scenario (Scenario 6 in Section 5):

Factual component

Suppose that the following facts hold at three different points in time ($t_1 < t_2 < t_3$):

- (t_1 -f1) Neither Gorbachov nor Reagan knew the secret (which official 007 knows), and official 007 tells the secret to Reagan
- (t_2 -f1) Official 007 has not yet told the secret to Gorbachov
- (t_3 -f1) Official 007 tells the secret to Gorbachov

Logical representation of the facts

- (t_1 -f1) $r \wedge \neg g \wedge \Diamond(\neg r \wedge \neg g)$
- (t_2 -f1) $\neg g \wedge \Box r$
- (t_3 -f1) $g \wedge \Diamond\neg g \wedge \Box r$

Conclusions

- At time t_1 : $\text{viol}(\neg r \wedge \neg g) \wedge O_a g$
- At time t_2 : $O_i g \wedge \neg g \wedge O_a g$
- At time t_3 : $O_i g \wedge g$

The natural reading of these conclusions is as follows: at time t_1 , Official 007 has violated his obligation to tell neither of them the secret, and gets an actual obligation to tell the secret to Gorbachov; at time t_2 , Official 007 has an ideal obligation to tell the secret to Gorbachov, which he has not yet fulfilled, and which persists as an actual obligation; at time t_3 , Official 007 has fulfilled his ideal obligation to tell the secret to Gorbachov, and has no actual obligation.

However, according to our definition of violation, we derive that at time t_2 007 has violated his ideal obligation $O_i g$. Is this an intuitively correct interpretation of the situation at t_2 ? Surely, we can say that at time t_2 there exists a violation of the deontic norm (d_2) ($O(g/r)$), in the sense described above. But should we conclude that at t_2 the obligation $O_i g$ has been violated, or rather that it has not yet been fulfilled?

This suggests that in some cases where there is a clear temporal dimension involved it may be natural to distinguish between the violation of

an obligation, on the one hand, and the situation in which an obligation has not been fulfilled, on the other. The way we have defined violation $(O_i A \wedge \neg A)$ would perhaps more appropriately be said to correspond to the latter, weaker notion, since that definition does not rule out the actual possibility of fulfilling the (ideal) obligation concerned $(O_i A \wedge \neg A \wedge \Diamond A)$; whereas violation in the full sense of the obligation $O_i A$ implies that falsity of A is an actual necessity. Analogously, we may wish to distinguish between different degrees of fulfillment of an ideal obligation. We do not pursue this point here, but it seems clear that our formal language as it stands is expressive enough to capture some of the distinctions concerned.

Relationship between ideal and actual obligations

In our approach, there is no direct logical connection between the notions of actual and ideal obligation. However, a reasonable question to raise is this: should it not be supposed that an ideal obligation which it is still actually possible to fulfill and actually possible to violate entails an actual obligation to the same effect? An affirmative answer would require the validity of the following sentence:

$$O_i A \wedge \Diamond \neg A \wedge \Diamond A \rightarrow O_a A \quad (O_i \rightarrow O_a)$$

This result would be secured were the following model condition to be adopted:

$$5\text{-e) if } Y \subseteq X \text{ and } Z \in ob(X) \text{ and } Y \cap Z \neq \emptyset, \text{ then } Z \in ob(Y)$$

In [Carmo and Jones, 1997], we conjecture that a condition of this kind could be adopted without untoward consequences. However, the situation is not quite so simple; 5-e) may conflict with the other conditions on our models.²⁸ A deeper analysis shows that the problem depends fundamentally on the combination of 5-d) and 5-e), together with 5-c), for reasons we now explain.

Consider the graphical description in Figure 1 and suppose $Y \in ob(X)$. Then, by condition 5-d), $((Z - X) \cup Y) \in ob(Z)$: if a subset Y of X is an obligatory proposition in a context X , then in a bigger context Z it should be the case that either we are not in X or we are in Y . With respect to the set S , 5-d) does not require $((S - X) \cup Y) \in ob(S)$, contrary to what we would obtain if we also adopted condition 5-e) — taking also into account 5-b).

²⁸The following counter-example is due to Bjørn Kjos-Hanssen: Suppose $O(A/\top)$ is true in a model where $W = \{\alpha_1, \alpha_2, \alpha_3\}$ and $\|A\| = \{\alpha_1\}$; then it can be shown that the conditions 5-b) and 5-d), together with the truth of $O(A/\top)$, imply that if $\alpha_1 \in X$, then $ob(X) = \{Z : \alpha_1 \in Z\}$. Thus, supposing $Y = \{\alpha_2, \alpha_3\}$, if 5-e) is also assumed, then we would get (from $ob(W)$) that $\{\alpha_1, \alpha_2\} \in ob(Y)$ and $\{\alpha_1, \alpha_3\} \in ob(Y)$; and, from 5-b), we would get $\{\alpha_2\} \in ob(Y)$ and $\{\alpha_3\} \in ob(Y)$, and a contradiction would follow from 5-c) and 5-a).

Figure 1.

But $((S - X) \cup Y) \in ob(S)$ means that $(S - X) \in ob(S)$! Is this acceptable? And, if the deontic norms also require that $X \in ob(S)$, we would derive a conflict of obligations. The following case of the dog scenario illustrates the point.

Factual component

Suppose that the facts are as follows:

- (f1) there is no dog and there is a sign warning of one; and it was also potentially possibly to have no dog and no sign, or to have a dog and no sign, or to have a dog and a sign
- (f2) the agent is firmly decided to have a sign (for instance, because he wants to frighten possible robbers), and it is still actually possibly to have, or not, a dog

Logical representation

- (f1) $\neg \text{dog} \wedge \text{sign} \wedge \Diamond(\neg \text{dog} \wedge \neg \text{sign}) \wedge \Diamond(\text{dog} \wedge \neg \text{sign}) \wedge \Diamond(\text{dog} \wedge \text{sign})$
- (f2) $\Box \text{sign} \wedge \Diamond \text{dog} \wedge \Diamond \neg \text{dog}$

From these facts, as our logic stands, we can derive that the ideal obligation not to have a dog has not been violated, and that there was a violation of the ideal obligation not to have a sign if there is no dog; with respect to the actual obligations, we derive the actual obligation not to have a dog. If we now adopt condition 5-e), and introduce $(O_i \rightarrow O_a)$ as a new axiom schema, then, since we have $O_i(\neg \text{dog} \rightarrow \neg \text{sign})$, $\Diamond(\neg \text{dog} \rightarrow \neg \text{sign})$ and $\Diamond \neg(\neg \text{dog} \rightarrow \neg \text{sign})$, we would derive also $O_a(\neg \text{dog} \rightarrow \neg \text{sign})$; and, since $\Box \text{sign} \rightarrow \Box((\neg \text{dog} \rightarrow \neg \text{sign}) \leftrightarrow \text{dog})$, we derive $O_a \text{dog}$, conflicting with $O_a \neg \text{dog}$. So the question is, in this situation which conclusion should follow, from the intuitive point of view: simply the actual obligation not to have a dog, or a conflict of obligations?

If intuition indicates that a conflict of obligations should not be derivable from this scenario, then 5-e) and $(O_i \rightarrow O_a)$ must not be adopted. Then

there will be no direct logical connection between ideal and actual obligations - each of them will be derived, independently, directly from the deontic norms, taking into account the relevant context; nevertheless, whenever an ideal obligation $O_i A$ is deduced from a deontic norm $O(A/B)$ by factual detachment (FD), we may still also deduce $\Diamond \neg A \wedge \Diamond A \rightarrow O_a A$.

If, on the contrary, intuition indicates there does indeed exist a conflict of obligations in the previous situation, then we should adopt condition 5-e), and we should weaken condition 5-c) so that conflicting obligations can be expressed without logical contradiction. For reasons to be explained in the next sub-section, we think it is necessary to weaken 5-c). Although we do not here commit ourselves to acceptance of 5-e), we note in passing that its adoption would have some further interesting consequences, besides providing a direct link between ideal and actual obligations.

First consequence: relationships between $O(B/A)$ and $O(A \rightarrow B/\top)$, and the “pragmatic oddity”

Recall Result 2-iv) in subsection 4.4): $\vdash \Diamond(A \wedge B) \rightarrow (O(A \rightarrow B/\top) \rightarrow O(B/A))$. Adopting condition 5-e) (plus 5-b1) and 5-d), the formula below would also become valid:²⁹

$$O(B/A) \rightarrow O(A \rightarrow B/\top) \quad (O \rightarrow O \rightarrow)$$

Thus, to represent a deontic conditional by $O(B/A)$ rather than by $O(A \rightarrow B/\top)$ would become almost a question of taste (the former is only slightly more general). Moreover, were $(O \rightarrow O \rightarrow)$ to be adopted as a new axiom, we could conclude that the “pragmatic oddity”, as we have diagnosed it, does not introduce anything really new to the original Chisholm set, since $O(B/A) \rightarrow O(\neg(A \wedge \neg B)/\top)$ — and so, for instance, $O(\neg \text{sign} / \neg \text{dog}) \rightarrow O(\neg(\neg \text{dog} \wedge \text{sign}) / \top)$.

Second consequence: redefinition of $\mathcal{M} \models_w O(B/A)$

With the condition 5-e) (plus 5-ab)), the condition for $\mathcal{M} \models_w O(B/A)$ becomes equivalent to the following, simpler, condition:

$$\mathcal{M} \models_w O(B/A) \quad \text{iff} \quad \|B\| \in ob(\|A\|)$$

²⁹It is trivial to see that $\mathcal{M} \models_w O(B/A)$ implies $\|A \rightarrow B\| \neq \emptyset$. On the other hand, let Z be such that $Z \cap \|A \rightarrow B\| \neq \emptyset$. We have $\mathcal{M} \models_w O(B/A)$ implies $\|B\| \in ob(\|A\|)$; by condition 5-bd3), this implies $\|A \rightarrow B\| \in ob(\|A\| \cup Z)$; thus, by condition 5-e), $\|A \rightarrow B\| \in ob(Z)$.

6.4 *Unrelated deontic norms, contrary-to-duties and conflicting obligations*

Consider again the Case 5.2 of the “considerate assassin” example (Scenario 5 of Section 5):

Factual situation

- (f1) The assassin has not yet killed Mr. X but has firmly decided to kill him
- (f2) It is actually possible for the assassin to offer, or not, to Mr. X a cigarette

and suppose now that there is also *another deontic norm applicable to the situation* saying that it is forbidden to offer cigarettes. Thus we have:

- (d1) $O(\neg\text{kill} / \top)$
- (d2) $O(\text{offer} / \text{kill})$
- (d3) $O(\neg\text{offer} / \top)$
- (f1) $\neg\text{kill} \wedge \boxed{\rightarrow}\text{kill}$
- (f2) $\diamond\text{offer} \wedge \diamond\neg\text{offer}$

In this case we get, using (FD): O_a offer (from (f1), (f2) and (d2)) and $O_a \neg\text{offer}$ (from (f2) and (d3)), and thus a contradiction (since O_a verifies schemas (C) and (OD)). Is this a problem? We think not. There is a reasonable interpretation of this situation according to which it does contain a conflict of obligations; the logical system we have described was not designed to solve conflicts of obligations, but it should certainly be able to detect them when — as here — they arise. The key feature of this scenario is as follows: (d2) was designed to be “a CTD w.r.t. (d1)”, i.e. to describe the obligations in force in a context of violation of the obligation specified by (d1); but (d1) and the new sentence (d3) express unrelated, or independent, deontic norms; (d2) cannot be seen to be “a CTD w.r.t. (d3)”, and so the obligation not to offer a cigarette “transports down”³⁰ to the context ($\boxed{\rightarrow}\text{kill}$) of violation of (d1), and a conflict is obtained according to (d2).

“Now one may ask how this conflict should be resolved and, of course, one plausible option is to regard (d2) as an exception to (d3) and to formalize this with a suitable nonmonotonic defeat mechanisms. However, it is important to note that this is a separate issue, which has nothing to do with the CTD aspects of the example”. This remark is quoted from [Prakken and Sergot, 1994, pp.310-311] (replacing their sentences (2) and (3) by our

³⁰Using the terminology of [Prakken and Sergot, 1994; Prakken and Sergot, 1996], where a similar result is obtained for this case.

(d2) and (d3)); and we fully agree with it, although we leave entirely open the question of how conflicts of obligations might be *resolved*, since that is a matter falling outside the logical analysis of CTDs themselves.

The above example indicates that semantical condition 5-c) needs to be weakened; consider also the following observation,³¹ that in our logic any two “unrelated deontic norms” on the same “antecedent” will give rise to a contradiction, in the following sense:

Suppose that both $O(B/A)$ and $O(C/A)$ are true in a model \mathcal{M} , and suppose that $\|A\| \cap \|B\| \cap \|\neg C\| \neq \emptyset$ and $\|A\| \cap \|C\| \cap \|\neg B\| \neq \emptyset$. Then, defining $X = (\|A\| \cap \|B\| \cap \|\neg C\|) \cup (\|A\| \cap \|C\| \cap \|\neg B\|)$, we get $\|B\| \in ob(X)$ and $\|C\| \in ob(X)$; and, from condition 5-c), it follows that $(\|B\| \cap \|C\|) \in ob(X)$, contradicting 5-ab).

Our response is to replace 5-c) by 5-c⁻):

5-c⁻) if $Y, Z \in ob(X)$ and $Y \cap Z \cap X \neq \emptyset$, then $Y \cap Z \in ob(X)$

It is easy to see that a weakening of this kind does not affect the theorems used in our analysis of the CTD scenarios. This move is in keeping with our belief (a) that sets of norms, as human artifacts, may indeed be imperfectly designed and thus contain the possibility for generating conflicting obligations; and (b) that it is the task of the logic to identify such conflicts when they arise, and to supply conflict-free representations of those CTD scenarios which are, from the intuitive point of view, normatively consistent.

6.5 Axiomatisation revisited

Given the weakening of condition 5-c), in order to obtain a *sound* axiomatisation we need to replace the axioms $(O - C)$, $(O_a - C)$ and $(O_i - C)$ by the weaker schemas:

$$5'. \quad \Diamond(A \wedge B \wedge C) \wedge O(B/A) \wedge O(C/A) \rightarrow O(B \wedge C/A) \quad (O - C^-)$$

$$11'. \quad \Diamond(A \wedge B) \wedge O_a A \wedge O_a B \rightarrow O_a(A \wedge B) \quad (O_a - C^-)$$

$$\Diamond(A \wedge B) \wedge O_i A \wedge O_i B \rightarrow O_i(A \wedge B) \quad (O_i - C^-)$$

All the other axioms remain unchanged. Moreover, it is easy to see that all the theorems stated in Result 2 (of Subsection 4.4) are retained.

On the other hand, if we were also to adopt condition 5-e), then the axiom schemas $(O \rightarrow O_a \rightarrow)$ and $(O \rightarrow O_i \rightarrow)$ would be replaced by the new axiom $(O \rightarrow O \rightarrow)$ (since the latter, in conjunction with (FD), allows

³¹We are grateful to Henry Prakken for this criticism.

the derivation of the former pair), and we would also add $(O_i \rightarrow O_a)$ as a new axiom. Obviously, it is then possible to deduce some new theorems³².

7 A FURTHER LOOK AT SOME OTHER APPROACHES

7.1 Temporal approaches

A number of researchers have maintained that the problems raised by the Chisholm set essentially involve a temporal dimension, and that previously proposed solutions fail in as much as they do not capture this dimension. In this section we review some aspects of temporal deontic approaches and compare them with ours.

Temporal approaches to the semantics of deontic notions are generally based on tree-structures, representing branching time with the same past and open to the future. Following [Chellas, 1980, section 6.3], we can think of *time* as an ordered set T of moments (or *instants*), and — in order to regard the possible worlds as time-stretched — define them as functions from T into an otherwise unspecified set of momentary world-states S ; we use the term *history* to denote this specific interpretation of a possible world, and, in the models, we denote by H the set of the possible histories. Thus we can define the tree-like structures as a tuple $\langle T, <, S, H, V \rangle$, where:

- T and S are non-empty sets;
 - $<$ is a strict linear order on T (i.e. $<$ is irreflexive, transitive and $(\forall i_1, i_2 \in T) (i_1 < i_2 \text{ or } i_2 < i_1 \text{ or } i_1 = i_2)$);
 - H is a non-empty subset of the set of all functions from T into S , satisfying the following restriction (where $h \equiv_i h'$ iff $h(i_1) = h'(i_1)$ at every instant $i_1 \leq i$):
- (*) $(\forall h, h' \in H) (\forall i \in T) (\text{if } h(i) = h'(i) \text{ then } h \equiv_i h')$.

Constraint (*) is intended to give the tree-like form to the temporal structures, allowing branching to the future, but not to the past.

On top of these structures, temporal deontic logics typically define one necessity modal operator plus obligation operators (either monadic or dyadic³³). However, a main difference appears in the way the temporal dimension is syntactically reflected in the formal language. One family of logics indexes

³²For instance, we can prove that $\vdash \Diamond((A \vee C) \wedge B) \wedge O(B/A) \wedge O(B/C) \rightarrow O(B/A \vee C)$ as follows: by $(O \rightarrow O \rightarrow)$ we deduce $\vdash O(B/A) \wedge O(B/C) \rightarrow O(A \rightarrow B/\top) \wedge O(C \rightarrow B/\top)$; and the new theorem then follows by $(O - C^-)$ and Result 2-iv).

³³We are excluding from this comparison the analysis of other deontic operators, such as permission operators, or the obligation-related operators proposed in [Brown, 1996].

the modal and deontic operators with temporal terms; as representatives of the “indexed” family, we may mention [van Eck, 1981] and [Lower and Belzer, 1983].³⁴ Another family introduces temporal operators that can be iterated with the modal and deontic operators; as representatives of the “non-indexed” family we may mention [Chellas, 1980, sections 6.3 and 6.4], [Åqvist and Hoepelman, 1981], [Thomason, 1981; Thomason, 2001] and [Brown, 1996]. Although the indexed family is more expressive and less abstract than the other family, this difference is not essential in regard to deontic aspects. So we shall introduce a uniform setting where we can abstract from such differences and concentrate on the main distinctions they provide regarding the deontic notions.

In order to see how the truth-value of a sentence can be evaluated within the temporal framework, we first need to extend the tree structures with a valuation of the atomic sentences. Tree-like models are then tuples $\langle T, <, S, H, V \rangle$, where:

- V assigns to each atomic sentence p a subset of $H \times T$, satisfying:

$$(**) (\forall i \in T) (\forall h, h' \in H) \\ (\text{if } h(i) = h'(i) \text{ then } (\langle h, i \rangle \in V(p) \text{ iff } \langle h', i \rangle \in V(p)))$$

Informally, $\langle h, i \rangle \in V(p)$ iff p is true at the time instant i in the world-state $h(i)$.

Constraint $(**)$ is intended to capture the idea that the truth-value of an atomic sentence is a function solely of the actual current world state, and independent of its past and future. We are here assuming that the atomic sentences take the simple form of propositional variables, thus avoiding most of the complications introduced by a first order component, such as the one considered in [van Eck, 1981].

With respect to truth in a model, we can follow Prior’s “Ockhamist” approach to indeterminist time [Prior, 1967], and say that a sentence A is true in $\mathcal{M}(= \langle \mathcal{T}, <, \mathcal{S}, \mathcal{H}, \mathcal{V} \rangle)$ iff A is true at all pairs $\langle h, i \rangle$ (belonging to $H \times T$). Thus the basic semantic unit for the truth analysis is the pair $\langle h, i \rangle$: intuitively i denotes the current instant; although the intuition behind h is less obvious, we may see h as fixing the current and past states and pointing out a possible future (that we may call *actual*, or *prima facie*, following Prior). So $\|A\|^{\mathcal{M}} = \{\langle h, i \rangle \in H \times T : \mathcal{M} \models_{\langle h, i \rangle} A\}$ and $\|p\|^{\mathcal{M}} = V(p)$; as usual, we write $\|A\|$, leaving \mathcal{M} implicit.

Many temporal operators can be defined in terms of this semantical framework, and the various “non-indexed” temporal deontic logics vary a good deal with respect to the kinds of temporal operators they consider.

³⁴In [Lower and Belzer, 1983] the dyadic O -operator is not time-indexed, but all the other modal/ deontic operators are.

Just to give one example, we can define a “sometime in the (actual) future” operator as follows (corresponding past operators are defined similarly):

$$\mathcal{M} \models_{\langle h, i \rangle} \text{F}A \quad \text{iff} \quad (\exists i < i_1) \mathcal{M} \models_{\langle h, i_1 \rangle} A$$

(dual: G; for past: P and H)

On the other hand, as we have mentioned, the “indexed” temporal deontic logics do not adopt any temporal operator; instead, they allow a direct reference to the underlying time structure in the proper formal (object) language. More precisely, they include time variables and possibly other time terms³⁵ t, t_1, \dots which refer to the time instants through a function v , added to the temporal models, that applies each term into an element of T . Their languages may be seen as a Boolean combination of two sublanguages: the sublanguage of time and the modal/deontic sublanguage, where the latter is built from atomic sentences of the form p_t (for t a time term), with time-indexed modal and deontic operators, and sentential connectives. Interestingly, if we ignore this time indexing, we can see that the modal/deontic sublanguages of the indexed and the non-indexed temporal deontic logics are analogous. So, if we could “separate” the time index from the modal/deontic operators, we would get a uniform semantical and logical setting for analysing the modal/deontic component of both types of temporal deontic logics, with obvious advantages for the purposes of comparison. This can be achieved by means of the temporal realisation operator of [Rescher and Urquhart, 1971]: (t) , for t a time term (R_t in [Rescher and Urquhart, 1971]), semantically defined as follows:

$$\mathcal{M} \models_{\langle h, i \rangle} (t)A \quad \text{iff} \quad \mathcal{M} \models_{\langle h, v(t) \rangle} A$$

Intuitively, $(t)A$ signifies that A is true at time t , and using this operator we can translate each modal/deontic indexed sentence into a non-indexed sentence, with the same meaning, by replacing each p_t by $(t)p$, and each modal/deontic operator $\#_t$ by $(t)\#$. For instance, the sentence $t < t_1 \rightarrow \text{O}_{t_1} p_t$, valid in [van Eck, 1981]’s logic, is translated to $t < t_1 \rightarrow (t_1)\text{O} (t)p$.

Turning now to the modal/deontic component of temporal deontic logics, we start by noting that they all introduce a necessity modality, expressing some kind of “inevitability”. However, a main division appears here between the temporal deontic logics — independently of whether or not they are indexed — regarding which of the following two types of necessity operator they adopt; for instance [Åqvist and Hoepelman, 1981], [Thomason, 1981; Thomason, 2001], [Lower and Belzer, 1983] and [Brown, 1996] adopt the first, whilst [Chellas, 1980] and [van Eck, 1981] opt for the second:

³⁵For particular known numerical time structures T , it is usually considered that T is directly “included” in the formal language, allowing the existence of constants and functions, and supposing that terms (of sort T) can be written in the formal language as in the semantics (e.g. in the form $t + 1$). The same assumption will be made here whenever appropriate.

$$\mathcal{M} \models_{\langle h, i \rangle} \boxed{A} \quad \text{iff} \quad (\forall h' \in H) (\text{if } h \equiv_i h' \text{ then } \mathcal{M} \models_{\langle h', i \rangle} A)$$

(dual: \blacklozenge)

$$\mathcal{M} \models_{\langle h, i \rangle} \boxed{\bullet} A \quad \text{iff} \quad (\forall h' \in H) (\text{if } h \approx_i h' \text{ then } \mathcal{M} \models_{\langle h', i \rangle} A)$$

where $h \approx_i h'$ iff $h(i_1) = h'(i_1)$, at every $i_1 < i$

(dual: \blacklozenge)

Informally, \boxed{A} means “for all histories, with the same past and present”, and $\boxed{\bullet} A$ means “for all histories, with the same past”. Obviously, $\boxed{\bullet} A \rightarrow \boxed{A} A$ is a valid sentence within this semantics.³⁶

A similar division also appears in the way the deontic components are defined, as we explain below.

Starting with the analysis of the unary obligation operator O , with the exception of [Brown, 1996], all the mentioned works employ a *normal* logic for O , which can be obtained as follows: enrich the temporal models $\mathcal{M} = \langle T, <, S, H, V, v \rangle$ with a new component (“best” histories) $bh : H \times T \rightarrow \wp(H)$, and define

$$\mathcal{M} \models_{\langle h, i \rangle} \text{O} A \quad \text{iff} \quad (\forall h' \in bh(\langle h, i \rangle)) \mathcal{M} \models_{\langle h', i \rangle} A$$

Obviously, the function bh must satisfy some conditions, besides the non-emptiness of each $bh(\langle h, i \rangle)$ required by all of these researchers. Importantly, we can distinguish between (a) those approaches — the ones that employ \boxed{A} — that can be said to interpret bh intuitively as giving the “best” histories that are still open, given the past and present (which are fixed); they adopt the following conditions (or conditions that imply them):

- $bh(\langle h, i \rangle) \subseteq \{h' : h \equiv_i h'\}$
- if $h \equiv_i h'$ and $i_1 \leq i$ then $bh(\langle h, i_1 \rangle) = bh(\langle h', i_1 \rangle)$

and (b) those approaches — the ones that opt for $\boxed{\bullet}$ — that can be said to interpret bh intuitively as giving the “best” histories, that were open, given the (fixed) past; they adopt:

- $bh(\langle h, i \rangle) \subseteq \{h' : h \approx_i h'\}$
- if $h \approx_i h'$ and $i_1 < i$ then $bh(\langle h, i_1 \rangle) = bh(\langle h', i_1 \rangle)$

³⁶The symbol $\boxed{}$ is normally used for both of them, but since we want to distinguish them - and since the symbol $\boxed{}$ has already been used for potential necessity — we use \boxed{A} and $\boxed{\bullet}$. We also note that, for an integer-like time, we can express $\boxed{\bullet}$ as $Y \boxed{A} X$, where Y and X denote the previous and next time operators, semantically defined as follows: $\mathcal{M} \models_{\langle h, i \rangle} Y A$ iff $\mathcal{M} \models_{\langle h, i-1 \rangle} A$ and $\mathcal{M} \models_{\langle h, i \rangle} X A$ iff $\mathcal{M} \models_{\langle h, i+1 \rangle} A$.

(In what follows we shall use \odot whenever we want to stress that we are referring to the unary obligation operator under this latter class of approaches.)

Some comparison can already be made between these temporal deontic approaches and our own. In fact, it is not difficult to see that the operators \blacksquare and \boxed{A} have some similarities with the operators for, respectively, potential and actual necessity, \square and $\boxed{\rightarrow}$, *in those contexts where they are assigned a specifically temporal reading*. More generally, it is easy to find connections between each pair of operators (\blacksquare, \odot) and (\boxed{A}, O) , and our pairs (\square, O_i) and $(\boxed{\rightarrow}, O_a)$. However, there are also some relevant differences. We compare them both at a technical level and from the point of view of their motivation, starting with the former.

As regards the relationships between each necessity operator and its associated obligation operator, we note that — as for our corresponding operators — what is obligatory must be possible to fulfil; that is, the following sentences are valid:

$$\begin{aligned} O A &\rightarrow \blacklozenge A \\ \odot A &\rightarrow \blacklozenge A \end{aligned}$$

However, in contrast to ours, these logics do not require that what is obligatory must also be violable. On the contrary, all necessary truths (in their sense of necessary) are (vacuously) obligatory; that is, the following sentences are valid:

$$\begin{aligned} \boxed{A} A &\rightarrow O A \\ \blacksquare A &\rightarrow \odot A \end{aligned}$$

Thus, since $A \leftrightarrow \boxed{A} A$ is valid if A does not include reference to the future, if one wanted to require that an obligation must be both possible to fulfil and violable, then in order for $O A$ to be true the sentence A would have to be characterised in such a way that it refers to the future; in the non-indexed logics this would imply that A can never be a propositional variable and must include future operators (such as F or X); in the indexed case, $O_t p_{t_1}$ could be true only if $t_1 > t$; (for a general sentence $O_t A$ one would need to require that the “temporality of” A is greater than t ; this notion is from trivial: see e.g. [van Eck, 1981]). On our approach, by contrast, we can simply write $O_a p$,³⁷ abstracting both from the exact time

³⁷The possibility of violation can be described in our logic by the valid sentence $O_a A \rightarrow \blacklozenge \neg A$, where for cases where there is a meaningful temporal interpretation, we can see $\blacklozenge \neg A$ as saying that there is a future instant within some of the alternatives open to the agent where A is not the case. Note that, in contrast to what happens with \boxed{A} , our operator $\boxed{\rightarrow}$ does not verify the (T) -schema.

instant t where this obligation appears (as in the non-indexed logics), and from the description of the other aspects related with the time of occurrence of the “events” encoded in p .

Consider now $(\boxed{\bullet}, \odot)$ and $(\boxed{}, O_i)$. There seems to be a main technical difference between $\boxed{}$ and $\boxed{\bullet}$. For the latter, the potential alternatives (using our terminology) to the actual current world-state correspond to the alternatives that were open immediately before the current instant, i.e., at $t_c - 1$, supposing that t_c denotes the current instant and assuming here, and in what follows, an integer-like time. On the other hand, the potential alternatives to the actual current world-state, as described by our operator $\boxed{}$, include the alternatives that were open at some relevant time before the current time instant, but not necessarily the one immediately before.

Even in cases where it is appropriate to give a temporal interpretation to our operators, it is necessary to consider only two time instants, on our view: the current instant t_c (the one relevant to determining the actual obligations), and some previous time instant t^* , relative to which an assessment is made of the potential possibilities which were open to the agent — an assessment which, in turn, will determine the agent’s ideal obligations at t_c and his violations at t_c .

As regards \odot , it appears that for the analysis of violations only the instant $t_c - 1$, immediately preceding t_c , is relevant. The informal idea seems to be that one can violate only those obligations that require that something be done immediately. But then there is a problem if the obligation was in fact incurred at some time t^* prior to $t_c - 1$: how is the persistence of the obligation to be represented? As is noted in [Prakken and Sergot, 1997], the issue of the persistence of obligations through time has been poorly studied within the temporal approaches to deontic logic, despite its apparently close connections with CTD-problems. One of the main exceptions is [Brown, 1996], where there is some discussion of persistence conditions according to which an obligation persists until it is (definitely) fulfilled or violated. In [Thomason, 2001] we also find a condition related with the persistence of obligations, a condition that more or less corresponds (in our temporal semantics) to: if $i \leq i_1$ and $h_1 \in bh(\langle h, i \rangle)$, then $bh(\langle h_1, i_1 \rangle) = bh(\langle h, i \rangle) \cap \{h' : h \equiv_{i_1} h_1\}$. However, on the one hand, this condition seems too strong, since it seems not to allow the appearance of other obligations between i and i_1 ; and, on the other hand, since it only refers to $h_1 \in bh(\langle h, i \rangle)$, it says nothing about how an obligation persists over time when some *other* obligation is violated.

Besides these technical similarities and differences, there is one *fundamental* difference between the motivation underlying our approach and the one underlying the temporal approaches. This difference has to do with the reasons why a history h_1 , which was considered an alternative to the actual history h at some time instant $i - 1$ (so that $h_1 \approx_i h$), is no longer taken to be an alternative to h at i (i.e., not $h_1 \equiv_i h$). For the temporal

approaches, the essential reason why, at i , h_1 is no longer an alternative to h , is that a state $h(i)$ makes h_1 impossible (that is, $h_1(i) \neq h(i)$). On the other hand, in our approach, in cases for which a temporal interpretation can meaningfully be assigned to our necessity operators, we would say that our worlds roughly correspond to the pairs $\langle h, i \rangle$; and although $av(\langle h, i \rangle)$ would be seen as a subset of $\{\langle h_1, j \rangle : h_1 \equiv_i h \text{ and } j > i\}$ (satisfying the condition that if $j, k > i$ then $\langle h_1, j \rangle \in av(\langle h, i \rangle)$ iff $\langle h_1, k \rangle \in av(\langle h, i \rangle)$), it need not necessarily be equal to the set $\{\langle h_1, j \rangle : h_1 \equiv_i h \text{ and } j > i\}$; thus a pair $\langle h_1, j \rangle$ may belong to $av(\langle h, i - 1 \rangle)$, but may fail to belong to $av(\langle h, i \rangle)$, even if $h_1 \equiv_i h$ and $j > i$. The essential reason for this is that the agent may have decided to exclude from the worlds that are actual alternatives to $\langle h, i \rangle$ all the worlds provided by the history h_1 , even if this history is still potentially possible to follow. This fundamental difference between our theory and the temporal approaches is the key to understanding why we are able to accommodate such a CTD-scenario as the gentle murderer, which remains problematic for the temporal approach.

We next note that there is a significant difference between our dyadic obligation operator and those proposed in, e.g., [Åqvist and Hoepelman, 1981] and [van Eck, 1981], both of which see the unary O as a limiting case of the dyadic O , in the sense that OA is an abbreviation of $O(A/\top)$. As we have indicated above, we reject a move of this kind; we view unary obligations (of types O_i and O_a) as derivable from the dyadic, in ways that depend on the context, and on matters pertaining to the satisfiability and violability of obligation. The rejection of the idea that OA is an abbreviation of $O(A/\top)$ is also a feature of the temporal-based approach in [Lower and Belzer, 1983], to which we now turn.

Loewer and Belzer's 3D-logic involves a combination of a temporal approach with a preference-based approach. Briefly, the basic idea of [Lower and Belzer, 1983] appears to be the following: there is a hypothetical time instant zero, at which some deontic norms are assumed to come into force; these are expressed by the use of a dyadic O -operator, which is not time-indexed. Actual obligations, expressed by means of a time-indexed unary operator O_t , evolve from this moment on in ways determined by the deontic norms and by the facts which are taken to be settled at each time t (settledness being represented by means of an operator of type \boxed{A}_t). They also use a notion of "ethical sufficiency", and introduce two versions of sentences of the form $R(A, B)$, one time-indexed and one not, intended to express the idea that B is ethically sufficient for A . (We omit here the details of their semantical analysis of R .)

Although they have little to say regarding ideal obligations and their violations, they do offer a suggestion to the effect that ideal obligation of A can be defined as an abbreviation of $O(A/\top)$; in our opinion this would lead to difficulties in cases where at the instant zero some of the deontic norms cannot be potentially satisfied. Consider, for instance, a case of Scenario

3 in which it is potentially impossible not to have a fence - suppose that the fence is installed in such a way that the agent concerned has neither the ability nor the opportunity to remove it; were $O_i A$ to be defined as an abbreviation of $O(A/\top)$, then $O_i \neg$ fence would be derived, instead of — as in our logic — O_i white-fence.

The semantics of the dyadic O is defined *à la* Lewis, imposing a ranking \leq on the members of H . This ranking \leq is then connected with the model component (“best” histories) $bh : H \times T \rightarrow \wp(H)$. In their own words, the intuitive idea is the following [Lower and Belzer, 1983, pp. 308]: “Our basic idea for connecting the ranking \leq with F (here denoted by “ bh ”), that is connecting conditional obligations with actual obligations is this: At the first instant of time t_0 , we will assume that some of the histories which are ideal according to \leq can be achieved. But as time proceeds, events and the actions of men may render the ideal histories unattainable. Still at every moment the actual obligation is to bring about one among those best histories that remain”.

The factual and deontic detachment principles that are validated by their semantics are as follows:

$$O(B/A) \wedge R(B/A) \wedge \boxed{A} \wedge \Diamond_t B \wedge \Diamond_t B \rightarrow O_t B$$

$$O(B/A) \wedge R(B/A) \wedge O_t A \wedge \Diamond_t B \wedge \Diamond_t B \rightarrow O_t B$$

Ignoring the “ethical sufficiency” operator R , their factual detachment principle strongly resembles a “temporal version” of ours (although, as in the previous logics, they do not require that an obligation must be violable). On the other hand, their deontic detachment principle is stronger than ours, and, for the reasons that we have previously mentioned, we suspect that it is too strong, particularly if one also wants to address the problem of violations of ideal obligations: recall our conclusions in Case 1.1, Section 5 above.

Finally, some further comments about the representation of CTD-scenarios within the temporal deontic approaches, as compared to our own.

Of the temporal approaches here analysed that explicitly discuss the representation of CTD-scenarios ([Åqvist and Hoepelman, 1981], [van Eck, 1981] and [Lower and Belzer, 1983]), the one most similar to ours is [Lower and Belzer, 1983]. In fact, it is the only one of the three that respects our requirement (iv) on the representation of CTD scenarios, and — like us — Lower and Belzer make a distinction between the “deontic norms” applicable to a situation (expressed through the dyadic O) and the specific obligations that can be deduced from them given the facts of the case. However, it appears that they opt to represent the first sentence of the Chisholm set by a time-indexed actual obligation rather than as a deontic norm expressed in terms of the dyadic O -operator.

An important difference remains: in our approach, given the “deontic norms”, in order to derive which violations may have occurred and what

the actual obligations are, we need only consider what it was potentially and actually possible to do. No specific reference to any time instant is needed, in contrast to what happens in [Lower and Belzer, 1983] and other indexed temporal approaches, where sometimes one is forced to introduce time instants in the representation of cases in a way that seems more or less artificial, since their specific values are irrelevant. Moreover, as we have emphasised, our potential and actual necessitation operators are not tied to *temporal* settledness, and so can be used to represent cases where a temporal dimension is absent. In short, we think that our theory offers patterns of representation which are more abstract and simpler than those supplied by the typical temporal deontic approaches.

Of course, whenever it *is* essential to state the exact time of realisation of some obligatory state of affairs — for instance because there is an obligation to do something by a specific deadline — then an indexed temporal logic seems to be necessary. The simplicity of the logic will always depend on the degree of abstraction that we want to achieve, and when we choose, for instance, to use a deontic propositional language we abstract from many features — the temporality of some state of affairs being just one of these. But this abstraction is justifiable precisely on the grounds of the simplicity that it provides for illustrating the *essential* features underlying CTD-reasoning.

7.2 *Action-based approaches*

In the work of Castañeda, and of those influenced by him, it has frequently been maintained that the problems that beset deontic logic can be solved if proper recognition is given to the role of the concept of action. It is perhaps fair to say that Castañeda's own work is not always easy to penetrate, but fortunately in this case two papers by James Tomberlin [1983; 1986] supply both an outline introduction to Castañeda's system of deontic logic, and an appraisal of (respectively) his treatments of the Chisholm set and the Good Samaritan. And, judging by his replies — published in the same sources — Castañeda accepted that Tomberlin provided a faithful account of his position. We focus here on just those aspects which seem essential in regard to the analysis of the Chisholm set.

“Central to Castañeda's enterprise, we encounter his pivotal distinction between *practitions* and *propositions*” [Tomberlin, 1983, pp. 204]. Propositions are understood in the usual way, whereas practitions are understood, roughly, as the semantical content of such sentences as commands, orders, requests, entreaties. Within the scope of deontic operators, such as “it is obligatory that ...”, both types of components may occur: propositions indicate the circumstance, or condition, of a deontic judgment, whereas practitions indicate “. . . the target or focus of the deontic operator; components of this sort are *actions practically considered*. . .” [Tomberlin, 1983, pp. 235]. However, deontic operators are assumed to apply to practitions

only, and thus a mixed scope formula, within the scope of a deontic operator, will have a practition as its content. Deontic judgments are said to belong to different families, where each family determines a particular sense or type of obligation, permission, and so on. This type is indicated in the formal language by an index on the deontic operator.

Let us turn immediately to the representation of the Chisholm set, stating in due course those principles of Castañeda's logic which are relevant to an assessment of that representation. Suppose that the type of obligation concerned is denoted by "s", and that we use p, q, \dots to stand for propositions, and p^*, q^*, \dots to stand for practitions. Then line 1 of the Chisholm set is assigned the form:

$$1. O_s p^*$$

whereas line 4 expresses a proposition and is accordingly represented by:

$$4. \neg p$$

As regards line 3 (the CTD), Castañeda insists that it must be understood as specifying what is obligatory in those circumstances in which the obligation expressed by line 1 is violated. He insists, then, on factual detachment, requiring that 1 and 3 must together imply

$$5. O_s \neg q^*$$

Accordingly, 3 is assigned the following form, where \rightarrow is the material conditional:

$$3. \neg p \rightarrow O_s \neg q^*$$

Line 2 is interpreted as an obligation sentence with a mixed component within the scope of the deontic operator:

$$2. O_s (p \rightarrow q^*)$$

The crucial point to note now is that lines 1 and 2 do *not* imply

$$6. O_s q^*$$

because the embedded antecedent in line 2 is a proposition, whereas the scope formula in line 1 is a practition. So, the claim is, in essence: distinguish properly action components and propositional components, and incorporate that distinction in the representation of the set, and the inconsistency which Chisholm's formalisation contained will disappear. Although Castañeda's deontic logic contains the theorem

$$(CasK) \quad O_s (p^* \rightarrow q^*) \rightarrow (O_s p^* \rightarrow O_s q^*)$$

its application is of course restricted to instances where both the component sentences in the antecedent express propositions. *This* representation of the Chisholm set, then, is consistent.

Before moving on to Tomberlin's criticisms, note that it is already clear that Castañeda's solution generates the pragmatic oddity, in virtue of lines 1 and 5. Outlining the basic feature of Castañeda's semantics of obligation sentences, Tomberlin says that a sentence of the form $O_s p^*$ "... is true at a world w if and only if the proposition p^* belongs to every world v such that v is deontically compossible with w ..." [Tomberlin, 1983, pp. 237]. Then in all the worlds which are deontically compossible with the given world in which the four sentences of the Chisholm set are true, the agent concerned helps his neighbours (by line 1) but does not tell them he is coming (by line 5).

Note that

$$(TC1) \quad (p \rightarrow O_s q^*) \leftrightarrow O_s (p \rightarrow q^*)$$

is a theorem of Castañeda's system. It follows immediately that line 4 implies line 2, and thus that the requirement of logical independence is not met. Tomberlin and Castañeda are among the very few deontic logicians who do not accept this requirement; we do not discuss their reasons for this rejection here — the reader is referred to [Tomberlin, 1983] and Castañeda's reply — but choose rather to focus on Tomberlin's criticism of Castañeda's treatment of the Chisholm set, which also begins from the observation that (TC1) is a theorem. What troubles Tomberlin is that, in virtue of (TC1), line 4 also implies

$$7. O_s (p \rightarrow \neg q^*)$$

Putting lines 2 and 7 together we have: it is obligatory that if X goes to help his neighbours then he tells them he is coming, and it is obligatory that if X goes to help his neighbours then he does not tell them he is coming. This is clearly an intuitively unacceptable consequence — it would not be implied by a *proper* representation of the Chisholm set!

So what has gone wrong? Tomberlin's view, in brief, is that line 2 is not the correct way to represent the second line of the Chisholm set. By virtue of (TC1), which he seems inclined to accept, line 2 is equivalent to a conditional obligation and thus, ignoring the negation signs, has the same logical structure as line 3. But Tomberlin is of the opinion that the second sentence of the Chisholm set should be understood as expressing an obligation *simpliciter*, of the form:

$$2'. O_s (p^* \rightarrow q^*)$$

But then, of course, as he immediately notes, the original Chisholm “paradox” re-emerges, since line 1 and line 2' together imply line 6, by (CasK).

Tomberlin advocates an alternative line of solution to the Chisholm problem, within the framework of Castañeda's deontic logic. “Biting the bullet”, as he puts it, one should accept that *another* aspect of Castañeda's deontic logic — that deontic operators can be relativised to different senses of obligation - has a key role to play in the representation of the Chisholm set. As Tomberlin sees it, the four sentences of the Chisholm set can be assumed to be both true and mutually consistent if and only if the sense or type of obligation pertaining to the third line is *different from* the sense or type of obligation expressed by the first and second lines. So, the first two lines are obligation sentences whose truth conditions refer to deontically perfect worlds (he calls these absolute obligations), whereas the third line is an obligation sentence whose truth conditions refer to worlds which — like the actual world in which line 4 is true - are deontically imperfect.

At this point, naturally, we begin to experience a gentle sense of *déjà vu*. Tomberlin is here treading one of the paths we investigated in Section 3, above, and which — as we there tried to indicate — leads only to further troubles. How would he cope with second-level CTDs of the kind exhibited by Scenario 2 (the dog-sign-fence example)? By introducing a third sense of obligation, i.e., a second sense of imperfection or sub-ideality? Clearly, this proliferation of senses of the fundamental deontic notions is to be avoided. To embrace it is to admit defeat.

Despite the difficulties that arise for Tomberlin's own positive proposal, it does seem clear that his criticism of Castañeda casts considerable doubt on whether the proposition/practition distinction has any role to play in solving Chisholm's puzzle. Our conclusion is that Castañeda failed to supply an analysis of deontic conditionals that both copes with the pragmatic oddity and generates suitable deontic and factual detachment principles. And we should add, with Prakken and Sergot, the observation that such CTD examples as Scenario 3 (the white fence) are apparently devoid of any action component whatsoever.

Nevertheless, we think that there is at least the following to be said for the action approach: the two notions of necessity to which we assigned a crucial role in the analysis of CTD scenarios are intimately connected to praxiological concepts, in particular *decision*, *ability* and *opportunity*. A more elaborate development of our logical system should make these connections explicit. But, even when that is done, we very much doubt that the resulting picture will provide confirmation of *Castañeda's* account of the role of action concepts.

It is suggested in [Hilpinen, 1993, pp. 89] that one interesting way to understand Castañeda's distinction is “. . . to consider it from the standpoint of dynamic deontic logic. In (propositional) dynamic logic, the non-logical

expressions are divided into action terms and propositions, and the deontic operators behave in the same way as in Castañeda's deontic logic . . . : they transform action terms into deontic propositions or statements . . . the way in which the distinction between action terms and propositions is made in the semantics of dynamic logic corresponds nicely to Castañeda's conception of propositions as descriptions of the circumstances under which an action is considered or performed."

Existing work (e.g., [Meyer, 1988]) falls short of providing convincing evidence that an approach to deontic logic based on dynamic logic holds the key to solving CTD problems. One difficulty, as Hilpinen himself notes [Hilpinen, 1993, pp. 94, footnote 4], is that the fourth line of the Chisholm set appears to have "... no plausible representation in Meyer's dynamic deontic logic". Hilpinen's suspicion is confirmed in a later paper by Meyer, Wieringa and Dignum [1997], in which they offer a representation of what they call the 'ought-to-do' version of the Chisholm set in a deontic logic (named PDeL) based on dynamic logic. Concerning their representation they make the following remark: "... the fourth premise of the set ... cannot be represented in PDeL. In some sense, statements of actions in PDeL and the underlying dynamic logic are of a hypothetical nature: 'if one (would) perform the action, the following holds'. The implication implicit in a formula $[\alpha]\varphi$ is therefore more like a conditional in conditional logic. As such, it is not really important what actually happens. Here and in the sequel we shall just ignore the fourth assertion in the formal representation" [Meyer, Wieringa and Dignum, 1997, § 1.6.3]. (The formula $[\alpha]\varphi$ says that execution of action α leads to some state(s) where φ holds.) However, in the context of analysing CTD scenarios, what actually happens is — as we have seen — of paramount importance.

Meyer, Wieringa and Dignum further maintain that it is necessary to distinguish explicitly between the logic of 'ought-to-do' and the logic of 'ought-to-be', and accordingly they also offer an analysis of the 'ought-to-be' version of the Chisholm set. We refer the reader to their paper for the details [Meyer, Wieringa and Dignum, 1997, § 1.5], but note that their 'ought-to-be' logic relies essentially on the availability of an indefinite number of distinct obligation operators, each of which is relativised to a particular 'frame of reference', as they put it. They do not offer precise criteria for determining when one has moved from one frame of reference to another, but they take it for granted that the first three lines of the Chisholm set involve reference to three distinct frames of reference, one for each of the obligations contained. Not surprisingly, problems of inconsistency are thereby avoided, but at the cost of introducing an indefinite number of obligation operators, and in the absence of clear guidelines determining how many operators the representation of a given scenario will need.

7.3 Preference-based approaches

“SDL cannot distinguish between various grades or levels of non-ideality; in the semantics of SDL worlds are either ideal or non-ideal. Yet the expression ‘if you kill, kill gently’ says that some non-ideal worlds are more ideal than other non-ideal worlds; it says: presupposing that one kills, then in those non-ideal worlds that best measure up to the deontically perfect worlds, one kills gently. In formalising CTD reasoning the key problem is formalisation of what is meant by ‘best measure up’ ” [Prakken and Sergot, 1997, p. 244]. This passage is quoted from the most detailed study currently available of the treatment of CTD-phenomena within a preference-based approach to the semantics of obligation sentences. The passage captures very succinctly the reason why a number of researchers in deontic logic have accepted the idea that an appropriate semantics for obligation sentences calls for an ordering on possible worlds, in terms of preference or relative goodness. As the authors note, the idea stems from Bengt Hansson [1971], with the later work of David Lewis [1974] providing a more comprehensive investigation of the semantical framework involved.

Prakken and Sergot’s paper, although in parts rather dense — it is best read as a sequel to [Prakken and Sergot, 1996] — explores in considerable depth the Hansson–Lewis analysis of dyadic deontic logic, assesses its shortcomings in regard to the treatment of CTDs, and offers a remedy for them which draws on techniques deriving from the study of default reasoning. We shall not attempt to give a summary of their final position, but confine ourselves to a few observations.

A significant feature of the Prakken and Sergot account of the Hansson–Lewis approach is that they add a notion of alethic necessity, the function of which is in part to clarify the nature of detachment properties. As was pointed out in Section 3.2, above, the characteristic feature of the DD-family of dyadic deontic logics (to which the Hansson–Lewis approach belongs) is that it validates the deontic detachment principle, but does not validate the factual detachment property. Expressed in terms of the notation used by Prakken and Sergot in [Prakken and Sergot, 1997], this means that

$$(DD) \quad O [B]A \rightarrow (O B \rightarrow O A)$$

is valid, whereas

$$(FD) \quad O [B]A \rightarrow (B \rightarrow O A)$$

is not. (Formulas of the form $O [B]A$ express what Prakken and Sergot call *contextual obligations*, and they correspond to formulas of the form $O (A/B)$ in the Lewis notation. The formula $O A$ is an abbreviation of $O [\top]A$, where \top is any tautology.) However, since

$$(\Box O) \quad \Box B \rightarrow O B$$

is valid in the Prakken and Sergot extended version of Hansson-Lewis, (DD) immediately yields

$$(SFD) \quad O[B]A \rightarrow (\Box B \rightarrow O A)$$

Prakken and Sergot call this principle ‘strong factual detachment’, and they say of the alethic necessity operator that it expresses the notion ‘objectively settled’. They do not say much by way of further characterisation of ‘objectively’, except that they want to distinguish it from necessity in a subjective sense, “. . . such as when an agent decides to regard it as settled *for him* that there will be a fence” [Prakken and Sergot, 1997, p. 241]. They have the further interesting comment to make about the import of (SFD) for CTD contexts: “For CTD obligations this form of strong factual detachment seems very appropriate, but it must be read with extreme care. As long as it is possible to avoid violation of a primary obligation $O \neg B$ a CTD obligation $O[B]A$ remains restricted to the context; it is only if the violation of $O \neg B$ is unavoidable, if $\Box B$ holds, that the CTD obligation comes into full effect, pertains to the context \top ” [*loc. cit.*]. Note, however, that if $\Box B$ holds, then $O B$ holds, and thus — since the (D)-schema is valid in their system — $\neg O \neg B$ holds. That is, going back to the dog-and-sign scenario, one could detach the obligation to put up a sign only in circumstances in which there was no longer an obligation not to have a dog!

These observations bring to the fore one of the most basic differences between our approach and that adopted by Prakken and Sergot: there is a quite fundamental disagreement between us regarding what an adequate theory of CTD scenarios should be expected to achieve. As we see matters, it is of paramount importance that the theory can show which actual obligations are derivable in circumstances of violation of some primary obligation, and can do so without also requiring that the sentence expressing the primary obligation must be false. A deontic logic which cannot show what actually ought to be done *in circumstances of violation* is, in our view, of limited interest. Prakken and Sergot’s theory, by contrast, belongs to a tradition in deontic logic which, it seems, takes the detachment of actual obligations to be a matter of no particular importance.

The notion of ‘settledness’ Prakken and Sergot employ is peculiar, at least with respect to its relation to the concept of obligation. How can that which is settled, unalterable, be obligatory? Surely that which is genuinely obligatory must be violable! Here again is a basic point of contrast between our approach and that of Prakken and Sergot. The principles $(\neg O_a)$ and $(\neg O_i)$ — Section 4.4, above — express, we believe, the correct connection between settledness and obligation concepts, and they also play a key role, as we saw in Section 5, in determining the consequences which can be drawn from various CTD scenarios.

Returning to Prakken and Sergot’s discussion of the Hansson–Lewis framework, it should be noted that a prime reason for their dissatisfaction with

that framework resides in the fact that it fails to capture a reading of the ‘extended’ considerate assassin scenario according to which that scenario is inconsistent. (This scenario was discussed above, Section 6.4, in response to some critical questions from Prakken. It extends the considerate assassin scenario by adding the further requirement that it is forbidden to offer cigarettes. See [Prakken and Sergot, 1997, § 6.1].) The underlying problem, as they diagnose it, is that the Hansson–Lewis semantics “. . . allows for the possibility of sub-ideal worlds but has very little to say about what they are like and nothing to say about how they compare with ideal worlds” [Prakken and Sergot, 1997, p. 250]. Their attempted solution involves a rather complex extension of the Hansson–Lewis framework, adapting techniques from the study of default reasoning in order to provide a means of ranking sub-ideal worlds with respect to the degree to which they measure up to ideal worlds.

We shall not here attempt to summarise these complexities. But from the point of view of comparison with our own theory, we observe in particular that Prakken and Sergot chose to impose on their investigation two constraints which we feel — for reasons discussed, in particular, in Section 6, above — are best rejected: they insist on retaining the (D)-schema for obligation sentences, and they refuse to abandon the consequential closure principle expressed by

$$\Box (A \rightarrow C) \rightarrow (O [B]A \rightarrow O [B]C)$$

(However, one of the factors which further complicates their account is that they also introduce a notion they call ‘explicit obligation’, which is *not* closed under consequence.)

Our rejection of the (D)-schema and consequential closure, our insistence on the importance of (a restricted form of) factual detachment, our exploitation of a distinction between actual and ideal obligations, and our characterisation of the relationship between settledness and obligation — all of these factors mark fundamental differences between our theory and that of Prakken and Sergot. But perhaps none of these constitutes the *most* fundamental difference. For we have not found it necessary at all to resort to the use of an explicit preference ordering in the semantics, in order to capture an adequate representation of the various CTD scenarios. Recall Lewis’ claim in [Lewis, 1974, pp. 3]: “A mere division of worlds into the ideal and the less-than-ideal will not meet our needs. We must use more complicated value structures that somehow bear information about comparisons or gradations of value.” The treatment of the Chisholm scenario in [Jones and Pörn, 1985] deliberately attempted to indicate that Lewis was wrong: the semantics used a “mere division” into two types of worlds, defined two accessibility relations pertaining to them, and defined some simple relations between these relations. But it imposed no ranking, no ordering, on the possible worlds. Yet it supplied the basis for an analysis of the Chisholm

set that met all the standard adequacy criteria . . . until Prakken and Sergot identified the “pragmatic oddity”. The question then became: is a preference ordering in the semantics essential in order to cope with the pragmatic oddity, and to cope with a broader class of CTD-phenomena, including but not limited to those exposed by the Chisholm set? In contrast to Prakken and Sergot, our answer to the last question is negative; the alternative strategy is to focus on another of the notions mentioned by Hansson which, as we have seen, also plays a role for both Loewer and Belzer and Prakken and Sergot: the notion of settledness or fixity of the facts. Our basic conjecture is that, properly characterised, and appropriately connected to the notions of actual and ideal obligation, the concept(s) of settledness provide the fundamental key to unravelling the tangled knot of CTD-problems.

Future research, we trust, will facilitate comparison of the preference-based approach and the approach which has formed the core of this chapter, with a view to furthering our understanding of the Contrary-to-Duty, and thus of normative reasoning itself.

POSTSCRIPT (SEPTEMBER, 2001)

The writing of this chapter was completed in 1999. Of relevant material that has been published since that time, we would like in particular to mention Makinson and van der Torre’s work on “input/output” logics, which the authors claim to be applicable to the treatment of CTD-problems; see Makinson and van der Torre [2000; 2001].

ACKNOWLEDGEMENTS

Some of the research here reported was carried out within the Portuguese research projects no. PCSH/C/OGE/1038/95-MAGO, and PCEX/P/MAT/46/96-ACL, and the ESPRIT Basic Research Working Group 8319 MODELAGE (“A Common Formal Model of Cooperating Intelligent Agents”). Andrew Jones also wishes to thank the PRAXIS XXI Programme of the Portuguese Research Council for its support in the Spring of 1996. Finally, the authors are very grateful to Henry Prakken, Donald Nute, Bjørn Kjos-Hanssen and Marek Sergot for their criticisms and comments.

At the time of completion of the writing of this chapter, José Carmo was at the Department of Mathematics, Instituto Superior Technico, Lisbon, Portugal; and Andrew Jones was at the Department of Philosophy and Norwegian Research Centre for Computers and Law, University of Oslo, Norway.

José Carmo

Department of Mathematics, University of Madeira, Portugal.

Andrew Jones

PREFACE TO THE SECOND EDITION

It is with great pleasure that we are presenting to the community the second edition of this extraordinary handbook. It has been over 15 years since the publication of the first edition and there have been great changes in the landscape of philosophical logic since then.

The first edition has proved invaluable to generations of students and researchers in formal philosophy and language, as well as to consumers of logic in many applied areas. The main logic article in the *Encyclopaedia Britannica 1999* has described the first edition as ‘the best starting point for exploring any of the topics in logic’. We are confident that the second edition will prove to be just as good!

The first edition was the second handbook published for the logic community. It followed the North Holland one volume *Handbook of Mathematical Logic*, published in 1977, edited by the late Jon Barwise. The four volume *Handbook of Philosophical Logic*, published 1983–1989 came at a fortunate temporal junction at the evolution of logic. This was the time when logic was gaining ground in computer science and artificial intelligence circles.

These areas were under increasing commercial pressure to provide devices which help and/or replace the human in his daily activity. This pressure required the use of logic in the modelling of human activity and organisation on the one hand and to provide the theoretical basis for the computer program constructs on the other. The result was that the *Handbook of Philosophical Logic*, which covered most of the areas needed from logic for these active communities, became their bible.

The increased demand for philosophical logic from computer science and artificial intelligence and computational linguistics accelerated the development of the subject directly and indirectly. It directly pushed research forward, stimulated by the needs of applications. New logic areas became established and old areas were enriched and expanded. At the same time, it socially provided employment for generations of logicians residing in computer science, linguistics and electrical engineering departments which of course helped keep the logic community thriving. In addition to that, it so happens (perhaps not by accident) that many of the Handbook contributors became active in these application areas and took their place as time passed on, among the most famous leading figures of applied philosophical logic of our times. Today we have a handbook with a most extraordinary collection of famous people as authors!

The table below will give our readers an idea of the landscape of logic and its relation to computer science and formal language and artificial intelligence. It shows that the first edition is very close to the mark of what was needed. Two topics were not included in the first edition, even though

they were extensively discussed by all authors in a 3-day Handbook meeting. These are:

- a chapter on non-monotonic logic
- a chapter on combinatory logic and λ -calculus

We felt at the time (1979) that non-monotonic logic was not ready for a chapter yet and that combinatory logic and λ -calculus was too far removed.¹ Non-monotonic logic is now a very major area of philosophical logic, alongside default logics, labelled deductive systems, fibring logics, multi-dimensional, multimodal and substructural logics. Intensive re-examinations of fragments of classical logic have produced fresh insights, including at time decision procedures and equivalence with non-classical systems.

Perhaps the most impressive achievement of philosophical logic as arising in the past decade has been the effective negotiation of research partnerships with fallacy theory, informal logic and argumentation theory, attested to by the Amsterdam Conference in Logic and Argumentation in 1995, and the two Bonn Conferences in Practical Reasoning in 1996 and 1997.

These subjects are becoming more and more useful in agent theory and intelligent and reactive databases.

Finally, fifteen years after the start of the Handbook project, I would like to take this opportunity to put forward my current views about logic in computer science, computational linguistics and artificial intelligence. In the early 1980s the perception of the role of logic in computer science was that of a specification and reasoning tool and that of a basis for possibly neat computer languages. The computer scientist was manipulating data structures and the use of logic was one of his options.

My own view at the time was that there was an opportunity for logic to play a key role in computer science and to exchange benefits with this rich and important application area and thus enhance its own evolution. The relationship between logic and computer science was perceived as very much like the relationship of applied mathematics to physics and engineering. Applied mathematics evolves through its use as an essential tool, and so we hoped for logic. Today my view has changed. As computer science and artificial intelligence deal more and more with distributed and interactive systems, processes, concurrency, agents, causes, transitions, communication and control (to name a few), the researcher in this area is having more and more in common with the traditional philosopher who has been analysing

¹I am really sorry, in hindsight, about the omission of the non-monotonic logic chapter. I wonder how the subject would have developed, if the AI research community had had a theoretical model, in the form of a chapter, to look at. Perhaps the area would have developed in a more streamlined way!

such questions for centuries (unrestricted by the capabilities of any hardware).

The principles governing the interaction of several processes, for example, are abstract and similar to principles governing the cooperation of two large organisations. A detailed rule based effective but rigid bureaucracy is very much similar to a complex computer program handling and manipulating data. My guess is that the principles underlying one are very much the same as those underlying the other.

I believe the day is not far away in the future when the computer scientist will wake up one morning with the realisation that he is actually a kind of formal philosopher!

The projected number of volumes for this Handbook is about 18. The subject has evolved and its areas have become interrelated to such an extent that it no longer makes sense to dedicate volumes to topics. However, the volumes do follow some natural groupings of chapters.

I would like to thank our authors and readers for their contributions and their commitment in making this Handbook a success. Thanks also to our publication administrator Mrs J. Spurr for her usual dedication and excellence and to Kluwer Academic Publishers for their continuing support for the Handbook.

Dov Gabbay
King's College London

Logic	IT			
	Natural language processing	Program control specification, verification, concurrency	Artificial intelligence	Logic programming
Temporal logic	Expressive power of tense operators. Temporal indices. Separation of past from future	Expressive power for recurrent events. Specification of temporal control. Decision problems. Model checking.	Planning. Time dependent data. Event calculus. Persistence through time—the Frame Problem. Temporal query language. temporal transactions.	Extension of Horn clause with time capability. Event calculus. Temporal logic programming.
Modal logic. Multi-modal logics	generalised quantifiers	Action logic	Belief revision. Inferential databases	Negation by failure and modality
Algorithmic proof	Discourse representation. Direct computation on linguistic input	New logics. Generic theorem provers	General theory of reasoning. Non-monotonic systems	Procedural approach to logic
Non-monotonic reasoning	Resolving ambiguities. Machine translation. Document classification. Relevance theory	Loop checking. Non-monotonic decisions about loops. Faults in systems.	Intrinsic logical discipline for AI. Evolving and communicating databases	Negation by failure. Deductive databases
Probabilistic and fuzzy logic	logical analysis of language	Real time systems	Expert systems. Machine learning	Semantics for logic programs
Intuitionistic logic	Quantifiers in logic	Constructive reasoning and proof theory about specification design	Intuitionistic logic is a better logical basis than classical logic	Horn clause logic is really intuitionistic. Extension of logic programming languages
Set theory, higher-order logic, λ-calculus, types	Montague semantics. Situation semantics	Non-well-founded sets	Hereditary finite predicates	λ -calculus extension to logic programs

Imperative vs. declarative languages	Database theory	Complexity theory	Agent theory	Special comments: A look to the future
Temporal logic as a declarative programming language. The changing past in databases. The imperative future	Temporal databases and temporal transactions	Complexity questions of decision procedures of the logics involved	An essential component	Temporal systems are becoming more and more sophisticated and extensively applied
Dynamic logic	Database updates and action logic	Ditto	Possible actions	Multimodal logics are on the rise. Quantification and context becoming very active
Types. Term rewrite systems. Abstract interpretation	Abduction, relevance	Ditto	Agent's implementation rely on proof theory.	
	Inferential databases. Non-monotonic coding of databases	Ditto	Agent's reasoning is non-monotonic	A major area now. Important for formalising practical reasoning
	Fuzzy and probabilistic data	Ditto	Connection with decision theory	Major area now
Semantics for programming languages. Martin-Löf theories	Database transactions. Inductive learning	Ditto	Agents constructive reasoning	Still a major central alternative to classical logic
Semantics for programming languages. Abstract interpretation. Domain recursion theory.		Ditto		More central than ever!

Classical logic. Classical fragments	Basic back-ground language	Program synthesis	A basic tool	
Labelled deductive systems	Extremely useful in modelling		A unifying framework. Context theory.	Annotated logic programs
Resource and substructural logics	Lambek calculus		Truth maintenance systems	
Fibering and combining logics	Dynamic syntax	Modules. Combining languages	Logics of space and time	Combining features
Fallacy theory				
Logical Dynamics	Widely applied here			
Argumentation theory games		Game semantics gaining ground		
Object level/metalevel			Extensively used in AI	
Mechanisms: Abduction, default relevance			ditto	
Connection with neural nets				
Time-action-revision models			ditto	

	Relational databases	Logical complexity classes	The workhorse of logic	The study of fragments is very active and promising.
	Labelling allows for context and control.		Essential tool.	The new unifying framework for logics
Linear logic			Agents have limited resources	
	Linked databases. Reactive databases		Agents are built up of various fibred mechanisms	The notion of self-fibring allows for self-reference
				Fallacies are really valid modes of reasoning in the right context.
			Potentially applicable	A dynamic view of logic
				On the rise in all areas of applied logic. Promises a great future
			Important feature of agents	Always central in all areas
			Very important for agents	Becoming part of the notion of a logic
				Of great importance to the future. Just starting
			A new theory of logical agent	A new kind of model

REWRITING LOGIC AS A LOGICAL AND SEMANTIC FRAMEWORK

1 INTRODUCTION

The relationships between logic and computation, and the mutual interactions between both fields, are becoming stronger and more pervasive than they have ever been. In fact, our way of thinking about both logic and computation is being altered quite strongly. For example, there is such an increasingly strong connection—in some cases to the point of complete identification—between computation and deduction, and such impressive progress in compilation techniques and computing power, that the frontiers between logical systems, theorem provers, and declarative programming languages are shifting and becoming more and more tenuous, with each area influencing and being influenced by the others.

Similarly, in the specification of languages and systems there is an increasing shift from mathematically precise but somewhat restricted formalisms towards specifications that are not only mathematical, but actually logical in nature, as exemplified, for example, by specification formalisms such as algebraic specifications and structural operational semantics. In this way, languages and systems that in principle may not seem to bear any resemblance to logical systems and may be completely “conventional” in nature, end up being conceptualized primarily as *formal* systems.

However, any important development brings with it new challenges and questions. Two such questions, that we wish to address in this paper are:

- *How can the proliferation of logics be handled?*
- *Can flexible logics allowing the specification and prototyping of a wide variety of languages and systems with naturalness and ease be found?*

Much fruitful research has already been done with the aim of providing adequate answers to these questions. Our aim here is to contribute in some measure to their ongoing discussion by suggesting that rewriting logic [Meseguer, 1992] seems to have particularly good properties recommending its use as both a *logical framework* in which many other logics can be represented, and as a general *semantic framework* in which many languages and systems can be naturally specified and prototyped.

1.1 *Rewriting logic as a logical framework*

In our view, the main need in handling the proliferation of logics is primarily conceptual. What is most needed is a *metatheory* of logics helping us to better understand and explore the boundaries of the “space” of all logics, present and future, and to relate in precise and general ways many of the logics that we know or wish to develop.

Following ideas that go back to the original work of Goguen and Burstall [1984] on *institutions*, we find very useful understanding the space of all logics as a *category*, with appropriate translations between logics as the arrows or morphisms between them. The work on institutions has been further developed by their original proponents and by others [Goguen and Burstall, 1986; Goguen and Burstall, 1992; Tarlecki, 1984; Tarlecki, 1985], and has influenced other notions proposed by different authors [Mayoh, 1985; Poigné, 1989; Fiadeiro and Sernadas, 1988; Meseguer, 1989; Harper *et al.*, 1989a; Salibra and Scollo, 1993; Ehrig *et al.*, 1991; Astesiano and Cerioli, 1993]. Some of the notions proposed are closely related to institutions; however, in other cases the main intent is to substantially expand the primarily model-theoretic viewpoint provided by institutions to give an adequate treatment of proof-theoretic aspects such as entailment and proof structures. The theory of general logics [Meseguer, 1989] that we present in summary form in Section 2 is one such attempt to encompass also proof-theoretic aspects, and suggests not just one space or category of logics, but several, depending on the proof-theoretic or model-theoretic aspects that we wish to focus on.

In our view, the quest for a *logical framework*, understood as a logic in which many other logics can be represented, is important but is not the primary issue. Viewed from the perspective of a general space of logics, such a quest can in principle—although perhaps not in all approaches—be understood as the search within such a space for a logic \mathcal{F} such that many other logics \mathcal{L} can be represented in \mathcal{F} by means of mappings $\mathcal{L} \rightarrow \mathcal{F}$ that have particularly nice properties such as being conservative translations.

Considered in this way, and assuming a very general axiomatic notion of logic and ambitious enough requirements for a framework, there is in principle no guarantee that such an \mathcal{F} will necessarily be found. However, somewhat more restricted successes such as finding an \mathcal{F} in which all the logics of “practical interest,” having finitary presentations of their syntax and their rules, can be represented can be very valuable and can provide a great economy of effort. This is because, if an implementation for such a framework logic exists, it becomes possible to implement through it all the other “object logics” that can be adequately represented in the framework logic.

Much work has already been done in this area, including the Edinburgh logical framework LF [Harper *et al.*, 1993; Harper *et al.*, 1989; Gardner, 1992] and meta-theorem provers such as Isabelle [Paulson, 1989], λ Prolog

[Nadathur and Miller, 1988; Felty and Miller, 1990], and Elf [Pfenning, 1989], all of which adopt as framework logics different variants of higher-order logics or type theories. There has also been important work on what Basin and Constable [1993] call *metalogical* frameworks. These are frameworks supporting reasoning about the metalogical aspects of the logics being represented. Typically, this is accomplished by reifying as “data” the proof theory of the logic being represented in a process that is described in [Basin and Constable, 1993] as *externalizing* the logic in question. This is in contrast to the more *internalized* form in which logics are represented in LF and in meta-theorem provers, so that deduction in the object logic is mirrored by deduction—for example, type inference—in the framework logic. Work on metalogical frameworks includes the already mentioned paper by Basin and Constable [1993], who advocate constructive type theory as the framework logic, work of Matthews, Smaill, and Basin [1993], who use Feferman’s FS_0 [Feferman, 1989], a logic designed with the explicit purpose of being a metalogical framework, earlier work by Smullyan [1961], and work by Goguen, Stevens, Hobley, and Hilberdink [1992] on the 2OBJ meta-theorem prover, which uses order-sorted equational logic [Goguen and Meseguer, 1992; Goguen *et al.*, 2000].

A difficulty with systems based on higher-order type theory such as LF is that it may be quite awkward and of little practical use to represent logics whose structural properties differ considerably from those of the type theory. For example, linear and relevance logics do not have adequate representations in LF, in a precise technical sense of “adequate” [Gardner, 1992, Corollary 5.1.8]. Since in metalogical frameworks a direct connection between deduction in the object and framework logics does not have to be maintained, they seem in principle much more flexible in their representational capabilities. However, this comes at a price, since the possibility of directly using an implementation of the framework logic to implement an object logic is compromised.

In relation to this previous work, rewriting logic seems to have great flexibility to represent in a natural way many other logics, widely different in nature, including equational, Horn, and linear logics, and any sequent calculus presentation of a logic under extremely general assumptions about such a logic. Moreover, quantifiers can also be treated without problems. More experience in representing other logics is certainly needed, but we are encouraged by the naturalness and directness—often preserving the original syntax and rules—with which the logics that we have studied can be represented. This is due to the great simplicity and generality of rewriting logic, since in it all syntax and structural axioms are user-definable, so that the abstract syntax of an object logic can be represented as an algebraic data type, and is also due to the existence of only a few general “meta” rules of deduction relative to the rewrite rules given by a specification, where such a specification can be used to describe with rewrite rules the rules of deduc-

tion of the object logic in question. In addition, the direct correspondence between proofs in object logics and proofs in the framework logic can often be maintained in a *conservative* way by means of maps of logics, so that an implementation of rewriting logic can directly support an implementation of an object logic. Furthermore, given the directness with which logics can be represented, the task of proving conservativity is in many cases straightforward. Finally, although we do not discuss this aspect which is left for a subsequent paper, externalization of logics to support metalogical reasoning is also possible in rewriting logic.

Another important difference is that most approaches to logical frameworks are proof-theoretic in nature, and thus they do not address the model theories of the logics being represented. By contrast, several of the representations into rewriting logic that we consider—such as those for equational logic, Horn logic, and linear logic—involve both models and proofs and are therefore considerably more informative than purely proof-theoretic representations.

The fact that rewriting logic is *reflective* [Clavel and Meseguer, 1996; Clavel and Meseguer, 1996a] has very important practical consequences for its use as a logical framework. Note that a representation map $\Psi : \mathcal{L} \rightarrow RWLogic$ for a logic \mathcal{L} is by its very nature a *metatheoretic* construction above the object levels of both \mathcal{L} and $RWLogic$. In particular, Ψ includes as one of its key components a function $\Psi_{Th} : Th_{\mathcal{L}} \rightarrow Th_{RWLogic}$ translating theories in \mathcal{L} into rewrite theories. However, thanks to the fact that the finitely presentable rewrite theories can be reified as an abstract data type $RWL\text{-}ADT$, for \mathcal{L} a logic having a finitary presentation of its syntax and its deduction rules, and such that Ψ maps finitely presented theories in \mathcal{L} to finitely presented rewrite theories, we can often *reify* a metatheoretic construction such as Ψ inside rewriting logic by first defining an abstract data type $\mathcal{L}\text{-}ADT$ representing the finitely presentable theories of \mathcal{L} , and then reifying Ψ itself as an equationally defined function $\overline{\Psi} : \mathcal{L}\text{-}ADT \rightarrow RWL\text{-}ADT$. In this way, the translation Ψ becomes itself expressible and executable inside rewriting logic.

1.2 Rewriting logic as a semantic framework

As we have already mentioned, the distinction between a logical system and a language or a model of computation is more and more in the eyes of the beholder, although of course efficiency considerations and the practical uses intended may indeed strongly influence the design choices. A good case in point is the isomorphism between the Petri net model of concurrent computation [Reisig, 1995] and the tensor fragment of linear logic [Girard, 1987] (see [Martí-Oliet and Meseguer, 1991] and references therein). Therefore, even though at the most basic mathematical level there may be little distinction between the general way in which a logic, a programming language,

a system, or a model of computation are represented in rewriting logic, the criteria and case studies to be used in order to judge the merits of rewriting logic as a semantic framework are different from those relevant for its use as a logical framework.

One important consideration is that, from a computational point of view, rewriting logic deduction is intrinsically *concurrent*. In fact, it was the search for a general concurrency model that would help unify the somewhat bewildering heterogeneity of existing models that provided the original impetus for the first investigations on rewriting logic [Meseguer, 1992]. Since the generality and naturalness with which many concurrency models can be expressed in rewriting logic has already been illustrated at length in [Meseguer, 1992], only a brief summary is given in this paper. However, the CCS [Milner, 1989] and the concurrent object-oriented programming models are discussed in some detail to provide relevant examples.

Concurrent object-oriented programming is of particular interest. Given that the semantics of object-oriented programs is still poorly understood, and that the semantics of concurrent object-oriented systems is even less well understood, the ease with which rewriting logic can be used to give a precise semantics to concurrent object-oriented programs and to make such programs declarative is quite encouraging. In this paper, only the basic ideas of such a semantics are sketched; a much more detailed account can be found in [Meseguer, 1993].

The similarities between rewriting logic and structural operational semantics [Plotkin, 1981; Kahn, 1987] already noted in [Meseguer, 1992] are further explored in this paper. We give examples showing that different styles of structural operational semantics can be regarded as special cases of rewriting logic. The two main differences are the greater expressive power of rewriting logic due to the ability for rewriting modulo user-definable axioms, and the fact that rewriting logic is a full-fledged logic with both a proof and a model theory, whereas structural operational semantics accounts are only proof-theoretic.

Deduction with constraints can greatly increase the efficiency of theorem provers and logic programming languages. The most classical constraint solving algorithm is syntactic unification, which corresponds to solving equations in a free algebra, the so-called Herbrand model, and is used in resolution. However, much more efficient deduction techniques than those afforded by resolution can be obtained by building in additional knowledge of special theories in the form of constraint solving algorithms such as, for example, semantic unification, or equalities and inequalities in a numerical domain. In the past few years many authors have become aware that many constraint solving algorithms can be specified declaratively using rewrite rules. However, since constraint solving is usually nondeterministic, the usual equational logic interpretation of rewrite rules is clearly inadequate as a mathematical semantics. By contrast, rewriting logic completely avoids

such inadequacies and can serve as a semantic framework for logical systems and languages using constraints, including parallel ones.

The frame problem in artificial intelligence is caused by the need, typical of classical logic representations, to specify changes of state by stating not only what changes, but also what does not change. This is basically due to the essentially Platonic character of classical logic. Since rewriting logic is by design a logic of change that allows sound and complete deductions about the transitions of a system whose basic changes are axiomatized by rewrite rules, the difficulties associated with the frame problem disappear [Martí-Oliet and Meseguer, 1999]. In addition, the conservative mappings of Horn logic with equality and of linear logic studied in Sections 4.2 and 4.3, respectively, directly show how other logics of change recently proposed [Hölldobler and Schneeberger, 1990; Große *et al.*, 1996; Große *et al.*, 1992; Masseron *et al.*, 1990; Masseron *et al.*, 1993] can be subsumed as special cases. Added benefits include the straightforward support for concurrent change and the logical support for object-oriented representation.

The paper begins with a summary of the theory of general logics proposed in [Meseguer, 1989] that provides the conceptual basis for our discussion of logical frameworks. Then the rules of deduction and the model theory of rewriting logic are introduced, and the Maude and MaudeLog languages based on rewriting logic are briefly discussed. This is followed by a section presenting examples of logics representable in the rewriting logic framework. The role of rewriting logic as a semantic framework is then discussed and illustrated with examples. The paper ends with some concluding remarks.

2 GENERAL LOGICS

A general axiomatic theory of logics should adequately cover all the key ingredients of a logic. These include: a *syntax*, a notion of *entailment* of a sentence from a set of axioms, a notion of *model*, and a notion of *satisfaction* of a sentence by a model. A flexible axiomatic notion of a *proof calculus*, in which proofs of entailments, not just the entailments themselves, are first class citizens should also be included. This section gives a brief review of the required notions and axioms that will be later used in our treatment of rewriting logic as a logical framework; a more detailed account with many examples can be found in [Meseguer, 1989].

2.1 *Syntax*

Syntax can typically be given by a *signature* Σ providing a grammar on which to build *sentences*. For first-order logic, a typical signature consists of a list of function symbols and a list of predicate symbols, each with a prescribed number of arguments, which are used to build up sentences by

means of the usual logical connectives. For our purposes, it is enough to assume that for each logic there is a category **Sign** of possible signatures for it, and a functor sen assigning to each signature Σ the set $sen(\Sigma)$ of all its sentences.

2.2 Entailment systems

For a given signature Σ in **Sign**, *entailment* (also called *provability*) of a sentence $\varphi \in sen(\Sigma)$ from a set of axioms $\Gamma \subseteq sen(\Sigma)$ is a relation $\Gamma \vdash \varphi$ which holds if and only if we can prove φ from the axioms Γ using the rules of the logic. We make this relation relative to a signature.

In what follows, $|\mathcal{C}|$ denotes the collection of objects of a category \mathcal{C} .

DEFINITION 1. [Meseguer, 1989] An *entailment system* is a triple $\mathcal{E} = (\mathbf{Sign}, sen, \vdash)$ such that

- **Sign** is a category whose objects are called *signatures*,
- $sen : \mathbf{Sign} \rightarrow \mathbf{Set}$ is a functor associating to each signature Σ a corresponding set of Σ -sentences, and
- \vdash is a function associating to each $\Sigma \in |\mathbf{Sign}|$ a binary relation $\vdash_\Sigma \subseteq \mathcal{P}(sen(\Sigma)) \times sen(\Sigma)$ called Σ -entailment such that the following properties are satisfied:
 1. *reflexivity*: for any $\varphi \in sen(\Sigma)$, $\{\varphi\} \vdash_\Sigma \varphi$,
 2. *monotonicity*: if $\Gamma \vdash_\Sigma \varphi$ and $\Gamma' \supseteq \Gamma$ then $\Gamma' \vdash_\Sigma \varphi$,
 3. *transitivity*: if $\Gamma \vdash_\Sigma \varphi_i$, for all $i \in I$, and $\Gamma \cup \{\varphi_i \mid i \in I\} \vdash_\Sigma \psi$, then $\Gamma \vdash_\Sigma \psi$,
 4. *\vdash -translation*: if $\Gamma \vdash_\Sigma \varphi$, then for any $H : \Sigma \rightarrow \Sigma'$ in **Sign**, $sen(H)(\Gamma) \vdash_{\Sigma'} sen(H)(\varphi)$.

Except for the explicit treatment of syntax translations, the axioms are very similar to Scott's axioms for a consequence relation [Scott, 1974].

DEFINITION 2. [Meseguer, 1989] Given an entailment system \mathcal{E} , its category **Th** of *theories* has as objects pairs $T = (\Sigma, \Gamma)$ with Σ a signature and $\Gamma \subseteq sen(\Sigma)$. A *theory morphism* $H : (\Sigma, \Gamma) \rightarrow (\Sigma', \Gamma')$ is a signature morphism $H : \Sigma \rightarrow \Sigma'$ such that if $\varphi \in \Gamma$, then $\Gamma' \vdash_{\Sigma'} sen(H)(\varphi)$.

A theory morphism $H : (\Sigma, \Gamma) \rightarrow (\Sigma', \Gamma')$ is called *axiom-preserving* if it satisfies the condition that $sen(H)(\Gamma) \subseteq \Gamma'$. This defines a subcategory **Th**₀ with the same objects as **Th** but with morphisms restricted to be axiom-preserving theory morphisms. Notice that the category **Th**₀ does not depend at all on the entailment relation \vdash .

2.3 Institutions

The axiomatization of a model theory is due to the seminal work on *institutions* by Goguen and Burstall [1984; 1992].

DEFINITION 3. [Goguen and Burstall, 1984] An *institution* is a 4-tuple $\mathcal{I} = (\mathbf{Sign}, sen, \mathbf{Mod}, \models)$ such that

- \mathbf{Sign} is a category whose objects are called *signatures*,
- $sen : \mathbf{Sign} \rightarrow \mathbf{Set}$ is a functor associating to each signature Σ a set of Σ -sentences,
- $\mathbf{Mod} : \mathbf{Sign} \rightarrow \mathbf{Cat}^{op}$ is a functor that gives for each signature Σ a category whose objects are called Σ -models, and
- \models is a function associating to each $\Sigma \in |\mathbf{Sign}|$ a binary relation $\models_{\Sigma} \subseteq |\mathbf{Mod}(\Sigma)| \times sen(\Sigma)$ called Σ -satisfaction satisfying the following *satisfaction condition* for each $H : \Sigma \rightarrow \Sigma'$ in \mathbf{Sign} : for all $M' \in |\mathbf{Mod}(\Sigma')|$ and all $\varphi \in sen(\Sigma)$,

$$M' \models_{\Sigma'} sen(H)(\varphi) \iff \mathbf{Mod}(H)(M') \models_{\Sigma} \varphi.$$

The satisfaction condition just requires that, for any syntax translation between two signatures, a model of the second signature satisfies a translated sentence if and only if the translation of this model satisfies the original sentence. Note that \mathbf{Mod} is a contravariant functor, that is, translations of models go backwards.

Given a set of Σ -sentences Γ , we define the category $\mathbf{Mod}(\Sigma, \Gamma)$ as the full subcategory of $\mathbf{Mod}(\Sigma)$ determined by those models $M \in |\mathbf{Mod}(\Sigma)|$ that satisfy all the sentences in Γ , i.e., $M \models_{\Sigma} \varphi$ for each $\varphi \in \Gamma$.

Since the definition above of the category of theories \mathbf{Th}_0 only depends on signatures and sentences, it also makes sense for an institution.

2.4 Logics

Defining a *logic* is now almost trivial.

DEFINITION 4. [Meseguer, 1989] A *logic* is a 5-tuple $\mathcal{L} = (\mathbf{Sign}, sen, \mathbf{Mod}, \vdash, \models)$ such that:

- $(\mathbf{Sign}, sen, \vdash)$ is an entailment system,
- $(\mathbf{Sign}, sen, \mathbf{Mod}, \models)$ is an institution,

and the following *soundness condition* is satisfied: for any $\Sigma \in |\mathbf{Sign}|$, $\Gamma \subseteq sen(\Sigma)$, and $\varphi \in sen(\Sigma)$,

$$\Gamma \vdash_{\Sigma} \varphi \implies \Gamma \models_{\Sigma} \varphi,$$

where, by definition, the relation $\Gamma \models_{\Sigma} \varphi$ holds if and only if $M \models_{\Sigma} \varphi$ holds for any model M that satisfies all the sentences in Γ .

The logic is called *complete* if the above implication is in fact an equivalence.

2.5 Proof calculi

A given logic may admit many different proof calculi. For example, in first-order logic we have Hilbert style, natural deduction, and sequent calculi among others, and the way in which proofs are represented and generated by rules of deduction is different for each of these calculi. It is useful to make proofs relative to a given theory T whose axioms we are allowed to use in order to prove theorems.

A proof calculus associates to each theory T a *structure* $P(T)$ of proofs that use axioms of T as hypotheses. The structure $P(T)$ typically has an *algebraic structure* of some kind so that we can obtain new proofs out of previously given proofs by operations that mirror the rules of deduction of the calculus in question. We need not make a choice about the particular types of algebraic structures that should be allowed for different proof calculi; we can abstract from such choices by simply saying that for a given proof calculus there is a category \mathbf{Str} of such structures and a functor $P : \mathbf{Th}_0 \rightarrow \mathbf{Str}$ assigning to each theory T its structure of proofs $P(T)$. Of course, it should be possible to extract from $P(T)$ the underlying set $proofs(T)$ of all the proofs of theorems of the theory T , and this extraction should be functorial. Also, each proof, whatever it is, should contain information about what theorem it is a proof of; this can be formalized by postulating a “projection function” π_T (parameterized by T in a natural way) that maps each proof $p \in proofs(T)$ to the sentence φ that it proves. Of course, each theorem of T must have at least one proof, and sentences that are not theorems should have no proof. To summarize, a *proof calculus* [Meseguer, 1989] consists of an entailment system together with:

- A functorial assignment P of a structure $P(T)$ to each theory T .
- An additional functorial assignment of a set $proofs(T)$ to each structure $P(T)$.
- A natural function π_T assigning a sentence to each proof $p \in proofs(T)$ and such that, for Γ the axioms of T , a sentence φ is in the image of π_T if and only if $\Gamma \vdash \varphi$.

It is quite common to encounter proof systems of a specialized nature. In these calculi, only certain signatures are admissible as syntax—e.g., finite signatures—, only certain sentences are allowed as axioms, and only certain sentences—possibly different from the axioms—are allowed as conclusions. The obvious reason for introducing such specialized calculi is that

proofs are simpler under the given restrictions. In computer science the choice between an efficient and an inefficient calculus may have dramatic practical consequences. For logic programming languages, such calculi do (or should) coincide with what is called their *operational semantics*, and mark the difference between a hopelessly inefficient theorem prover and an efficient programming language. In practice, of course, we are primarily interested in proof calculi and proof subcalculi that are computationally effective. This is axiomatized by the notion of an (*effective*) *proof subcalculus* which can be found in [Meseguer, 1989].

2.6 Mapping logics

The advantage of having an axiomatic theory of logics is that the “space” of all logics (or that of all entailment systems, institutions, proof calculi, etc.) becomes well understood. This space is not just a collection of objects bearing no relationship to each other. In fact, the most interesting fruit of the theory of general logics outlined in this section is that it gives us a method for *relating* logics in a general and systematic way, and to exploit such relations in many applications. The simplest kind of relation is a *sublogic* (subentailment system, etc.) relation. Thus, first-order equational logic and Horn logic are both sublogics of first-order logic with equality. However, more subtle and general ways of relating logics are possible. For example, we may want to represent the universal fragment of first-order logic in a purely functional way by taking all the predicates and formulas to be *functions* whose value is either *true* or *false* so that a universal formula then becomes an equation equating a given term to *true*. The general way of relating logics (entailment systems, etc.) is to consider *maps* that interpret one logic into another. A detailed treatment of such maps is given in [Meseguer, 1989]; here we summarize some of the key ideas.

Let us first discuss in some detail *maps of entailment systems*. Basically, a map of entailment systems $\mathcal{E} \rightarrow \mathcal{E}'$ maps the language of \mathcal{E} to that of \mathcal{E}' in a way that respects the entailment relation. This means that signatures of \mathcal{E} are functorially mapped to signatures of \mathcal{E}' , and that sentences of \mathcal{E} are mapped to sentences of \mathcal{E}' in a way that is coherent with the mapping of their corresponding signatures. In addition, such a mapping α must respect the entailment relations \vdash of \mathcal{E} and \vdash' of \mathcal{E}' , i.e., we must have $\Gamma \vdash \varphi \Rightarrow \alpha(\Gamma) \vdash' \alpha(\varphi)$. It turns out that for many interesting applications, including the functional representation of first-order logic sketched above, one wants to be more general and allow maps that send a signature of \mathcal{E} to a *theory* of \mathcal{E}' . These maps extend to maps between theories, and in this context the coherence with the mapping at the level of signatures is expressed by the notion of *sensible functor* defined in [Meseguer, 1989].

DEFINITION 5. [Meseguer, 1989] Given entailment systems $\mathcal{E} = (\mathbf{Sign}, sen, \vdash)$ and $\mathcal{E}' = (\mathbf{Sign}', sen', \vdash')$, a *map of entailment systems* $(\Phi, \alpha) : \mathcal{E} \rightarrow \mathcal{E}'$ consists of a natural transformation $\alpha : sen \Rightarrow \Phi; sen'$ and an α -sensible functor¹ $\Phi : \mathbf{Th}_0 \rightarrow \mathbf{Th}'_0$ satisfying the following property:

$$\Gamma \vdash_{\Sigma} \varphi \implies \Gamma' \cup \alpha_{\Sigma}(\Gamma) \vdash'_{\Sigma'} \alpha_{\Sigma}(\varphi),$$

where, by convention, $(\Sigma', \Gamma') = \Phi(\Sigma, \Gamma)$.

We say that (Φ, α) is a *conservative map of entailment systems* when the above implication is an equivalence.

The property of being conservative may be essential for many applications. For example, since proof calculi are in a sense computational engines on which the design and implementation of theorem provers and logic programming languages can be based, we can view the establishment of a map of proof calculi having nice properties, such as conservativity, as a proof of correctness for a *compiler* that permits implementing a system based on the first calculus in terms of another system based on the second. Besides establishing correctness, the map itself specifies the compilation function.

A *map of institutions*² $\mathcal{I} \rightarrow \mathcal{I}'$ is similar in its syntax part to a map of entailment systems. In addition, for models we have a natural functor $\beta : \mathbf{Mod}'(\Phi(\Sigma)) \rightarrow \mathbf{Mod}(\Sigma)$ “backwards” from the models in \mathcal{I}' of a translated signature $\Phi(\Sigma)$ to the models in \mathcal{I} of the original signature Σ , and such a mapping respects the satisfaction relations \models of \mathcal{I} and \models' of \mathcal{I}' , in the sense that $M' \models' \alpha(\varphi) \iff \beta(M') \models \varphi$.

DEFINITION 6. [Meseguer, 1989] Given institutions $\mathcal{I} = (\mathbf{Sign}, sen, \mathbf{Mod}, \models)$ and $\mathcal{I}' = (\mathbf{Sign}', sen', \mathbf{Mod}', \models')$, a *map of institutions* $(\Phi, \alpha, \beta) : \mathcal{I} \rightarrow \mathcal{I}'$ consists of a natural transformation $\alpha : sen \Rightarrow \Phi; sen'$, an α -sensible functor $\Phi : \mathbf{Th}_0 \rightarrow \mathbf{Th}'_0$, and a natural transformation $\beta : \Phi^{op}; \mathbf{Mod}' \Rightarrow \mathbf{Mod}$ such that for each $\Sigma \in |\mathbf{Sign}|$, $\varphi \in sen(\Sigma)$, and $M' \in |\mathbf{Mod}'(\Phi(\Sigma, \emptyset))|$ the following property is satisfied:

$$M' \models'_{\Sigma'} \alpha_{\Sigma}(\varphi) \iff \beta_{(\Sigma, \emptyset)}(M') \models_{\Sigma} \varphi,$$

where Σ' is the signature of the theory $\Phi(\Sigma, \emptyset)$.

A *map of logics* has now a very simple definition. It consists of a pair of maps: one for the underlying entailment systems, and another for the underlying institutions, such that both maps agree on how they translate signatures and sentences.

¹We refer to [Meseguer, 1989] for the detailed definition of α -sensible functor. Basically, what is required is that the provable consequences of the theory $\Phi(\Sigma, \Gamma)$ are entirely determined by $\Phi(\Sigma, \emptyset)$ and by $\alpha(\Gamma)$. Note that α depends only on signatures, not theories.

²Such maps are different from the “institution morphisms” considered by Goguen and Burstall in [1984; 1992].

DEFINITION 7. [Meseguer, 1989] Given logics $\mathcal{L} = (\mathbf{Sign}, sen, \mathbf{Mod}, \vdash, \models)$ and $\mathcal{L}' = (\mathbf{Sign}', sen', \mathbf{Mod}', \vdash', \models')$, a *map of logics* $(\Phi, \alpha, \beta) : \mathcal{L} \rightarrow \mathcal{L}'$ consists of a functor $\Phi : \mathbf{Th}_0 \rightarrow \mathbf{Th}'_0$, and natural transformations $\alpha : sen \Rightarrow \Phi; sen'$ and $\beta : \Phi^{op}; \mathbf{Mod}' \Rightarrow \mathbf{Mod}$ such that:

- $(\Phi, \alpha) : (\mathbf{Sign}, sen, \vdash) \rightarrow (\mathbf{Sign}', sen', \vdash')$ is a map of entailment systems, and
- $(\Phi, \alpha, \beta) : (\mathbf{Sign}, sen, \mathbf{Mod}, \models) \rightarrow (\mathbf{Sign}', sen', \mathbf{Mod}', \models')$ is a map of institutions.

We say that (Φ, α, β) is *conservative* when if (Φ, α) is so as a map of entailment systems.

There is also a notion of map of proof calculi, for which we refer the reader to [Meseguer, 1989].

2.7 The idea of a logical framework

As we have already explained in the introduction, viewed from the perspective of a general space of logics that can be related to each other by means of mappings, the quest for a *logical framework* can be understood as the search within such a space for a logic \mathcal{F} (the *framework* logic) such that many other logics (the *object* logics) such as, say, \mathcal{L} can be represented in \mathcal{F} by means of mappings $\mathcal{L} \rightarrow \mathcal{F}$ that have good enough properties. The minimum requirement that seems reasonable to make on a representation map $\mathcal{L} \rightarrow \mathcal{F}$ is that it should be a *conservative* map of entailment systems. Under such circumstances, we can reduce issues of provability in \mathcal{L} to issues of provability in \mathcal{F} , by mapping the theories and sentences of \mathcal{L} into \mathcal{F} using the conservative representation map. Given a computer implementation of deduction in \mathcal{F} , we can use the conservative map to prove theorems in \mathcal{L} by proving the corresponding translations in \mathcal{F} . In this way, the implementation for \mathcal{F} can be used as a generic theorem prover for many logics.

However, since maps between logics can, as we have seen, respect additional logical structure such as the model theory or the proofs, in some cases a representation map into a logical framework may be particularly informative because, in addition to being a conservative map of entailment systems, it is also a map of institutions, or a map of proof calculi. For example, when rewriting logic is chosen as a logical framework, appropriate representation maps for equational logic, Horn logic, and propositional linear logic can be shown to be maps of institutions also (see Section 4). In general, however, since the model theories of different logics can be very different from each other, it is not reasonable to expect or require that the representation maps into a logical framework will always be maps of institutions. Nevertheless,

what it can always be done is to “borrow” the additional logical structure that \mathcal{F} may have (institution, proof calculus) to endow \mathcal{L} with such a structure, so that the representation map does indeed preserve the extra structure [Cerioli and Meseguer, 1996].

Having criteria for the adequacy of maps representing logics in a logical framework is not enough. An equally important issue is having criteria for the *generality* of a logical framework, so that it is in fact justified to call it by that name. That is, given a candidate logical framework \mathcal{F} , how many logics can be adequately represented in \mathcal{F} ? We can make this question precise by defining the *scope* of a logical framework \mathcal{F} as the class of entailment systems \mathcal{E} having conservative maps of entailment systems $\mathcal{E} \rightarrow \mathcal{F}$. In this regard, the axioms of the theory of general logics that we have presented are probably too general; without adding further assumptions it is not reasonable to expect that we can find a logical framework \mathcal{F} whose scope is the class of *all* entailment systems. A much more reasonable goal is finding an \mathcal{F} whose scope includes all entailment systems of “practical interest,” having finitary presentations of their syntax and their rules of deduction. Axiomatizing such finitely presentable entailment systems and proof calculi so as to capture—in the spirit of the more general axioms that we have presented, but with stronger requirements—all logics of “practical interest” (at least for computational purposes) is a very important research task.

Another important property that can help measuring the suitability of a logic \mathcal{F} as a logical framework is its *representational adequacy*, understood as the naturalness and ease with which entailment systems can be represented, so that the representation $\mathcal{E} \rightarrow \mathcal{F}$ mirrors \mathcal{E} as closely as possible. That is, a framework requiring very complicated encodings for many object logics of interest is less representationally adequate than one for which most logics can be represented in a straightforward way, so that there is in fact little or no “distance” between an object logic and its corresponding representation. Although at present we lack a precise definition of this property, it is quite easy to observe its absence in particular examples. We view representational adequacy as a very important practical criterion for judging the relative merits of different logical frameworks.

In this paper, we present rewriting logic as a logic that seems to have particularly good properties as a logical framework. We conjecture that the scope of rewriting logic contains all entailment systems of “practical interest” for a reasonable axiomatization of such systems.

2.8 Reflection

We give here a brief summary of the notion of a universal theory in a logic and of a reflective entailment system introduced in [Clavel and Meseguer, 1996]. These notions axiomatize reflective logics within the theory of general

logics [Meseguer, 1989]. We focus here on the simplest case, namely entailment systems. However, reflection at the proof calculus level—where not only sentences, but also proofs are reflected—is also very useful; definitions for that case are also in [Clavel and Meseguer, 1996].

A reflective logic is a logic in which important aspects of its metatheory can be represented at the object level in a consistent way, so that the object-level representation correctly simulates the relevant metatheoretic aspects. Two obvious metatheoretic notions that can be so reflected are theories and the entailment relation \vdash . This leads us to the notion of a universal theory. However, universality may not be absolute, but only relative to a class \mathcal{C} of *representable* theories. Typically, for a theory to be representable at the object level, it must have a finitary description in some way—say, being recursively enumerable—so that it can be represented as a piece of language.

Given an entailment system \mathcal{E} and a set of theories \mathcal{C} , a theory U is \mathcal{C} -*universal* if there is a recursive injective function, called a *representation function*,

$$\overline{(_ \vdash _)} : \bigcup_{T \in \mathcal{C}} \{T\} \times \text{sen}(T) \longrightarrow \text{sen}(U)$$

such that for each $T \in \mathcal{C}$, $\varphi \in \text{sen}(T)$,

$$T \vdash \varphi \iff U \vdash \overline{T \vdash \varphi}.$$

If, in addition, $U \in \mathcal{C}$, then the entailment system \mathcal{E} is called \mathcal{C} -*reflective*.

Note that in a reflective entailment system, since U itself is representable, representation can be iterated, so that we immediately have a “reflective tower”

$$T \vdash \varphi \iff U \vdash \overline{T \vdash \varphi} \iff U \vdash \overline{U \vdash \overline{T \vdash \varphi}} \dots$$

3 REWRITING LOGIC

This section gives the rules of deduction and semantics of rewriting logic, and explains its computational meaning. The Maude and MaudeLog languages, based on rewriting logic, are also briefly discussed.

3.1 Basic universal algebra

Rewriting logic is parameterized with respect to the version of the underlying equational logic, which can be unsorted, many-sorted, order-sorted, or the recently developed membership equational logic [Bouhoula *et al.*, 2000; Meseguer, 1998]. For the sake of simplifying the exposition, we treat here the *unsorted* case.

A set Σ of function symbols is a ranked alphabet $\Sigma = \{\Sigma_n \mid n \in \mathbb{N}\}$. A Σ -algebra is then a set A together with an assignment of a function

$f_A : A^n \rightarrow A$ for each $f \in \Sigma_n$ with $n \in \mathbb{N}$. We denote by T_Σ the Σ -algebra of ground Σ -terms, and by $T_\Sigma(X)$ the Σ -algebra of Σ -terms with variables in a set X . Similarly, given a set E of Σ -equations, $T_{\Sigma,E}$ denotes the Σ -algebra of equivalence classes of ground Σ -terms modulo the equations E ; in the same way, $T_{\Sigma,E}(X)$ denotes the Σ -algebra of equivalence classes of Σ -terms with variables in X modulo the equations E . Let $[t]_E$ or just $[t]$ denote the E -equivalence class of t .

Given a term $t \in T_\Sigma(\{x_1, \dots, x_n\})$ and terms $u_1, \dots, u_n \in T_\Sigma(X)$, we denote $t(u_1/x_1, \dots, u_n/x_n)$ the term in $T_\Sigma(X)$ obtained from t by *simultaneously substituting* u_i for x_i , $i = 1, \dots, n$. To simplify notation, we denote a sequence of objects a_1, \dots, a_n by \bar{a} ; with this notation, $t(u_1/x_1, \dots, u_n/x_n)$ can be abbreviated to $t(\bar{u}/\bar{x})$.

3.2 The rules of rewriting logic

A *signature* in rewriting logic is a pair (Σ, E) with Σ a ranked alphabet of function symbols and E a set of Σ -equations. Rewriting will operate on equivalence classes of terms modulo the set of equations E . In this way, we free rewriting from the syntactic constraints of a term representation and gain a much greater flexibility in deciding what counts as a *data structure*; for example, string rewriting is obtained by imposing an associativity axiom, and multiset rewriting by imposing associativity and commutativity. Of course, standard term rewriting is obtained as the particular case in which the set E of equations is empty. Techniques for rewriting modulo equations have been studied extensively [Dershowitz and Jouannaud, 1990] and can be used to implement rewriting modulo many equational theories of interest.

Given a signature (Σ, E) , *sentences* of rewriting logic are “sequents” of the form $[t]_E \rightarrow [t']_E$, where t and t' are Σ -terms possibly involving some variables from the countably infinite set $X = \{x_1, \dots, x_n, \dots\}$. A *theory* in this logic, called a *rewrite theory*, is a slight generalization of the usual notion of theory as in Definition 2 in that, in addition, we allow the axioms—in this case the sequents $[t]_E \rightarrow [t']_E$ —to be labelled. This is very natural for many applications, and customary for automata—viewed as labelled transition systems—and for Petri nets, which are both particular instances of our definition.

DEFINITION 8. A *rewrite theory* \mathcal{R} is a 4-tuple $\mathcal{R} = (\Sigma, E, L, R)$ where Σ is a ranked alphabet of function symbols, E is a set of Σ -equations, L is a set of *labels*, and R is a set of pairs $R \subseteq L \times T_{\Sigma,E}(X)^2$ whose first component is a label and whose second component is a pair of E -equivalence classes of terms, with $X = \{x_1, \dots, x_n, \dots\}$ a countably infinite set of variables. Elements of R are called *rewrite rules*³. We understand a

³To simplify the exposition the rules of the logic are given for the case of *unconditional* rewrite rules. However, all the ideas presented here have been extended to conditional

rule $(r, ([t], [t']))$ as a labelled sequent and use for it the notation $r : [t] \longrightarrow [t']$. To indicate that $\{x_1, \dots, x_n\}$ is the set of variables occurring in either t or t' , we write $r : [t(x_1, \dots, x_n)] \longrightarrow [t'(x_1, \dots, x_n)]$, or in abbreviated notation $r : [t(\bar{x})] \longrightarrow [t'(\bar{x})]$.

Given a rewrite theory \mathcal{R} , we say that \mathcal{R} *entails* a sequent $[t] \longrightarrow [t']$ and write $\mathcal{R} \vdash [t] \longrightarrow [t']$ if and only if $[t] \longrightarrow [t']$ can be obtained by finite application of the following *rules of deduction*:

1. **Reflexivity.** For each $[t] \in T_{\Sigma, E}(X)$,

$$\frac{}{[t] \longrightarrow [t]}.$$

2. **Congruence.** For each $f \in \Sigma_n$, $n \in \mathbb{N}$,

$$\frac{[t_1] \longrightarrow [t'_1] \quad \dots \quad [t_n] \longrightarrow [t'_n]}{[f(t_1, \dots, t_n)] \longrightarrow [f(t'_1, \dots, t'_n)]}.$$

3. **Replacement.** For each rewrite rule in the theory R of the form $r : [t(x_1, \dots, x_n)] \longrightarrow [t'(x_1, \dots, x_n)]$,

$$\frac{[w_1] \longrightarrow [w'_1] \quad \dots \quad [w_n] \longrightarrow [w'_n]}{[t(\bar{w}/\bar{x})] \longrightarrow [t'(\bar{w}'/\bar{x})]}.$$

4. **Transitivity.**

$$\frac{[t_1] \longrightarrow [t_2] \quad [t_2] \longrightarrow [t_3]}{[t_1] \longrightarrow [t_3]}.$$

Equational logic (modulo a set of axioms E) is obtained from rewriting logic by adding the following rule:

5. **Symmetry.**

$$\frac{[t_1] \longrightarrow [t_2]}{[t_2] \longrightarrow [t_1]}.$$

With this new rule, sequents derivable in equational logic are *bidirectional*; therefore, in this case we can adopt the notation $[t] \leftrightarrow [t']$ throughout and call such bidirectional sequents *equations*.

A nice consequence of having defined rewriting logic is that concurrent rewriting, rather than emerging as an operational notion, actually coincides with deduction in such a logic.

DEFINITION 9. Given a rewrite theory $\mathcal{R} = (\Sigma, E, L, R)$, a (Σ, E) -sequent $[t] \longrightarrow [t']$ is called a *concurrent \mathcal{R} -rewrite* (or just a *rewrite*) if and only if it can be derived from \mathcal{R} by means of the rules 1-4, i.e., $\mathcal{R} \vdash [t] \longrightarrow [t']$.

rules in [Meseguer, 1992] with very general rules of the form

$$r : [t] \longrightarrow [t'] \text{ if } [u_1] \longrightarrow [v_1] \wedge \dots \wedge [u_k] \longrightarrow [v_k].$$

This increases considerably the expressive power of rewrite theories, as illustrated by several of the examples presented in this paper.

3.3 *The meaning of rewriting logic*

A logic worth its salt should be understood as a method of correct reasoning about some class of entities, not as an empty formal game. For equational logic, the entities in question are sets, functions between them, and the relation of identity between elements. For rewriting logic, the entities in question are *concurrent systems* having *states*, and evolving by means of *transitions*. The *signature* of a rewrite theory describes a particular structure for the states of a system—e.g., multiset, binary tree, etc.—so that its states can be distributed according to such a structure. The *rewrite rules* in the theory describe which *elementary local transitions* are possible in the distributed state by concurrent local transformations. The rules of rewriting logic allow us to reason correctly about which *general* concurrent transitions are possible in a system satisfying such a description. Clearly, concurrent systems should be the *models* giving a semantic interpretation to rewriting logic, in the same way that algebras are the models giving a semantic interpretation to equational logic. A precise account of the model theory of rewriting logic, giving rise to an initial model semantics for Maude modules and fully consistent with the above system-oriented interpretation, is sketched in Section 3.5 and developed in full detail for the more general conditional case in [Meseguer, 1992].

Therefore, in rewriting logic a sequent $[t] \longrightarrow [t']$ should not be read as “[t] equals [t'],” but as “[t] becomes [t'].” Clearly, rewriting logic is a logic of *becoming* or *change*, not a logic of equality in a static sense. The apparently innocent step of adding the symmetry rule is in fact a *very strong* restriction, namely assuming that *all change is reversible*, thus bringing us into a timeless Platonic realm in which “before” and “after” have been identified.

A related observation, which is particularly important for the use of rewriting logic as a logical framework, is that $[t]$ should not be understood as a *term* in the usual first-order logic sense, but as a *proposition* or *formula*—built up using the *connectives* in Σ —that asserts being in a certain *state* having a certain *structure*. However, unlike most other logics, the logical connectives Σ and their structural properties E are entirely *user-definable*. This provides great flexibility for considering many different state structures and makes rewriting logic very general in its capacity to deal with many different types of concurrent systems, and also in its capacity to represent many different logics. For the case of concurrent systems, this generality is discussed at length in [Meseguer, 1992] (see also [Martí-Oliet and Meseguer, 1999] for the advantages of this generality in the context of unifying AI logics of action). In a similar vein, but with a broader focus, Section 5 discusses the advantages of rewriting logic as a general semantic framework in which to specify and prototype languages and systems. Finally, Section 4 explores the generality of rewriting logic as a logical framework in which logics can

be represented and prototyped.

In summary, the rules of rewriting logic are rules to reason about *change in a concurrent system*, or, alternatively, metarules for reasoning about *deduction in a logical system*. They allow us to draw valid conclusions about the evolution of the system from certain basic types of change known to be possible, or, in the alternative viewpoint, about the correct deductions possible in a logical system. Our present discussion is summarized as follows:

<i>State</i>	\leftrightarrow	<i>Term</i>	\leftrightarrow	<i>Proposition</i>
<i>Transition</i>	\leftrightarrow	<i>Rewriting</i>	\leftrightarrow	<i>Deduction</i>
<i>Distributed</i>	\leftrightarrow	<i>Algebraic</i>	\leftrightarrow	<i>Propositional</i>
<i>Structure</i>		<i>Structure</i>		<i>Structure</i>

Section 4 will further clarify and illustrate each of the correspondences in the last two columns of the diagram, and Section 5 will do the same for the first two columns.

3.4 The Maude and MaudeLog languages

Rewriting logic can be used directly as a wide spectrum language supporting specification, rapid prototyping, and programming of concurrent systems. As explained later in this paper, rewriting logic can also be used as a logical framework in which other logics can be naturally represented, and as a semantic framework for specifying languages and systems. The Maude language [Meseguer, 1993; Clavel *et al.*, 1996] supports all these uses of rewriting logic in a particularly modular way in which modules are rewrite theories and in which functional modules with equationally defined data types can also be declared in a functional sublanguage. The examples given later in this paper illustrate the syntax of Maude. Details about the language design, its semantics, its parallel programming and wide spectrum capabilities, and its support of object-oriented programming can be found in [Meseguer, 1992; Meseguer and Winkler, 1992; Meseguer, 1993; Meseguer, 1993b]. Here we provide a very brief sketch that should be sufficient for understanding the examples presented later.

In Maude there are three kinds of *modules*:

1. *Functional modules*, introduced by the keyword `fmod`,
2. *System modules*, introduced by the keyword `mod`, and
3. *Object-oriented modules*, introduced by the keyword `omod`.

Object-oriented modules can be reduced to a special case of system modules for which a special syntax is used; therefore, in essence we only have functional and system modules. Maude's functional and system modules are respectively of the form

- `fmod \mathcal{E} endfm`, and
- `mod \mathcal{R} endm`,

for \mathcal{E} an equational theory and \mathcal{R} a rewrite theory⁴. In functional modules, equations are declared with the keywords `eq` or `ceq` (for conditional equations), and in system or object-oriented modules with the keywords `ax` or `cax`. In addition, certain equations, such as any combination of associativity, commutativity, or identity, for which rewriting modulo is provided, can be declared together with the corresponding operator using the keywords `assoc`, `comm`, `id`. Rules can only appear in system or object-oriented modules, and are declared with the keywords `r1` or `cr1`.

In Maude a module can have *submodules*, which can be imported with either `protecting` or `including` qualifications stating the degree of integrity enjoyed by the submodule when imported by the supermodule.

The version of rewriting logic used for Maude in this paper is *order-sorted*⁵. This means that rewrite theories are typed (types are called *sorts*) and can have subtypes (subsorts), and that function symbols can be overloaded. In particular, functional modules are order-sorted equational theories [Goguen and Meseguer, 1992] and they form a sublanguage similar to OBJ [Goguen *et al.*, 2000].

Like OBJ, Maude has also *theories* to specify semantic requirements for interfaces and to make high level assertions about modules. They are of the three kinds:

1. *Functional theories*, introduced by the keyword `fth`,
2. *System theories*, introduced by the keyword `th`, and
3. *Object-oriented theories*, introduced by the keyword `oth`.

Also as OBJ, Maude has *parameterized modules* and *theories*, again of the three kinds, and *views* that are theory interpretations relating theories to modules or to other theories.

Maude can be further extended to a language called MaudeLog that unifies the paradigms of functional programming, Horn logic programming, and concurrent object-oriented programming. In fact, Maude’s design is based on a general axiomatic notion of “logic programming language” based on the general axiomatic theory of logic sketched in Section 2 [Meseguer, 1989; Meseguer, 1992b]. Technically, a unification of paradigms is achieved by mapping the logics of each paradigm into a richer logic in which the

⁴This is somewhat inaccurate in the case of system modules having functional submodules because we have to “remember” that the submodule is functional.

⁵The latest version of Maude [Clavel *et al.*, 1996] is based on the recently developed membership equational logic, which extends order-sorted equational logic and at the same time has a simpler and more general model theory [Bouhoula *et al.*, 2000; Meseguer, 1998].

paradigms are unified. In the case of Maude and MaudeLog, what is done is to define a new logic (rewriting logic) in which concurrent computations, and in particular concurrent object-oriented computations, can be expressed in a natural way, and then to formally relate this logic to the logics of the functional and relational paradigms, i.e., to equational logic and to Horn logic, by means of maps of logics that provide a simple and rigorous unification of paradigms. As it has already been mentioned, we actually assume an order-sorted structure throughout, and therefore the logics in question are: order-sorted rewriting logic, denoted *OSRWLogic*, order-sorted equational logic, denoted *OSEqtl*, and order-sorted Horn logic, denoted *OSHorn*.

The logic of equational programming can be embedded within (order-sorted) rewriting logic by means of a map of logics

$$OSEqtl \longrightarrow OSRWLogic.$$

The details of this map of logics are discussed in Section 4.1. At the programming language level, such a map corresponds to the inclusion of Maude's functional modules (essentially identical to OBJ modules) within the language.

Since the power and the range of applications of a multiparadigm logic programming language can be substantially increased if it is possible to solve queries involving *logical variables* in the sense of relational programming, as in the Prolog language, we are naturally led to seek a unification of the three paradigms of functional, relational and concurrent object-oriented programming into a single multiparadigm logic programming language. This unification can be attained in a language extension of Maude called MaudeLog. The integration of Horn logic is achieved by a map of logics

$$OSHorn \longrightarrow OSRWLogic$$

that systematically relates order-sorted Horn logic to order-sorted rewriting logic. The details of this map are discussed in Section 4.2.

The difference between Maude and MaudeLog does not consist of any change in the underlying logic; indeed, both languages are based on rewriting logic, and both have rewrite theories as programs. It resides, rather, in an enlargement of the set of *queries* that can be presented, so that, while keeping the same syntax and models, in MaudeLog we also consider queries involving existential formulas of the form

$$\exists \bar{x} \ [u_1(\bar{x})] \longrightarrow [v_1(\bar{x})] \wedge \dots \wedge [u_k(\bar{x})] \longrightarrow [v_k(\bar{x})].$$

Therefore, the sentences and the deductive rules and mechanisms that are now needed require further extensions of rewriting logic deduction. In particular, solving such existential queries requires performing *unification*, specifically, given Maude's typing structure, order-sorted *E*-unification for a set *E* of structural axioms [Meseguer *et al.*, 1989].

3.5 The models of rewriting logic

We first sketch the construction of initial and free models for a rewrite theory $\mathcal{R} = (\Sigma, E, L, R)$. Such models capture nicely the intuitive idea of a “rewrite system” in the sense that they are systems whose states are E -equivalence classes of terms, and whose transitions are concurrent rewrites using the rules in R . By adopting a logical instead of a computational perspective, we can alternatively view such models as “logical systems” in which formulas are validly rewritten to other formulas by concurrent rewrites which correspond to proofs for the logic in question. Such models have a natural *category* structure, with states (or formulas) as objects, transitions (or proofs) as morphisms, and sequential composition as morphism composition, and in them dynamic behavior exactly corresponds to deduction.

Given a rewrite theory $\mathcal{R} = (\Sigma, E, L, R)$, the model that we are seeking is a category $\mathcal{T}_{\mathcal{R}}(X)$ whose objects are equivalence classes of terms $[t] \in T_{\Sigma, E}(X)$ and whose morphisms are equivalence classes of “proof terms” representing proofs in rewriting deduction, i.e., concurrent \mathcal{R} -rewrites. The rules for generating such proof terms, with the specification of their respective domain and codomain, are given below; they just “decorate” with proof terms the rules 1-4 of rewriting logic. Note that we always use “diagrammatic” notation for morphism composition, i.e., $\alpha; \beta$ always means the composition of α followed by β .

1. **Identities.** For each $[t] \in T_{\Sigma, E}(X)$,

$$\overline{[t] : [t]} \longrightarrow [t]$$

2. **Σ -structure.** For each $f \in \Sigma_n$, $n \in \mathbb{N}$,

$$\frac{\alpha_1 : [t_1] \longrightarrow [t'_1] \quad \dots \quad \alpha_n : [t_n] \longrightarrow [t'_n]}{f(\alpha_1, \dots, \alpha_n) : [f(t_1, \dots, t_n)] \longrightarrow [f(t'_1, \dots, t'_n)]}$$

3. **Replacement.** For each rewrite rule $r : [t(\bar{x}^n)] \longrightarrow [t'(\bar{x}^n)]$ in R ,

$$\frac{\alpha_1 : [w_1] \longrightarrow [w'_1] \quad \dots \quad \alpha_n : [w_n] \longrightarrow [w'_n]}{r(\alpha_1, \dots, \alpha_n) : [t(\bar{w}/\bar{x})] \longrightarrow [t'(\bar{w}'/\bar{x})]}$$

4. **Composition.**

$$\frac{\alpha : [t_1] \longrightarrow [t_2] \quad \beta : [t_2] \longrightarrow [t_3]}{\alpha; \beta : [t_1] \longrightarrow [t_3]}$$

Convention. In the case when the same label r appears in two different rules of R , the “proof terms” $r(\bar{\alpha})$ can sometimes be ambiguous. We assume that such ambiguity problems have been resolved by disambiguating the

label r in the proof terms $r(\bar{\alpha})$ if necessary; with this understanding, we adopt the simpler notation $r(\bar{\alpha})$ to ease the exposition.

Each of the above rules of generation defines a different operation taking certain proof terms as arguments and returning a resulting proof term. In other words, proof terms form an algebraic structure $\mathcal{P}_{\mathcal{R}}(X)$ consisting of a graph with nodes $T_{\Sigma, E}(X)$, with identity arrows, and with operations f (for each $f \in \Sigma$), r (for each rewrite rule), and $_;$ (for composing arrows). Our desired model $\mathcal{T}_{\mathcal{R}}(X)$ is the quotient of $\mathcal{P}_{\mathcal{R}}(X)$ modulo the following equations⁶:

1. **Category.**

(a) *Associativity.* For all α, β, γ ,

$$(\alpha; \beta); \gamma = \alpha; (\beta; \gamma).$$

(b) *Identities.* For each $\alpha : [t] \longrightarrow [t']$,

$$\alpha; [t'] = \alpha \quad \text{and} \quad [t]; \alpha = \alpha.$$

2. **Functoriality of the Σ -algebraic structure.** For each $f \in \Sigma_n$, $n \in \mathbb{N}$,

(a) *Preservation of composition.* For all $\alpha_1, \dots, \alpha_n, \beta_1, \dots, \beta_n$,

$$f(\alpha_1; \beta_1, \dots, \alpha_n; \beta_n) = f(\alpha_1, \dots, \alpha_n); f(\beta_1, \dots, \beta_n).$$

(b) *Preservation of identities.*

$$f([t_1], \dots, [t_n]) = [f(t_1, \dots, t_n)].$$

3. **Axioms in E .** For each axiom $t(x_1, \dots, x_n) = t'(x_1, \dots, x_n)$ in E , for all $\alpha_1, \dots, \alpha_n$,

$$t(\alpha_1, \dots, \alpha_n) = t'(\alpha_1, \dots, \alpha_n).$$

4. **Exchange.** For each rule $r : [t(x_1, \dots, x_n)] \longrightarrow [t'(x_1, \dots, x_n)]$ in R ,

$$\frac{\alpha_1 : [w_1] \longrightarrow [w'_1] \quad \dots \quad \alpha_n : [w_n] \longrightarrow [w'_n]}{r(\bar{\alpha}) = r(\bar{[w]}); t'(\bar{\alpha}) = t(\bar{\alpha}); r(\bar{[w']})}.$$

⁶In the expressions appearing in the equations, when compositions of morphisms are involved, we always implicitly assume that the corresponding domains and codomains match.

Note that the set X of variables is actually a parameter of these constructions, and we need not assume X to be fixed and countable. In particular, for $X = \emptyset$, we adopt the notation $\mathcal{T}_{\mathcal{R}}$. The equations in 1 make $\mathcal{T}_{\mathcal{R}}(X)$ a category, the equations in 2 make each $f \in \Sigma$ a functor, and 3 forces the axioms E . The exchange law states that any rewrite of the form $r(\bar{\alpha})$ —which represents the *simultaneous* rewriting of the term at the top using rule r and “below,” i.e., in the subterms matched by the variables, using the rewrites $\bar{\alpha}$ —is equivalent to the sequential composition $r(\overline{[w]}); t'(\bar{\alpha})$, corresponding to first rewriting on top with r and then below on the subterms matched by the variables with $\bar{\alpha}$, and is also equivalent to the sequential composition $t(\bar{\alpha}); r(\overline{[w']})$ corresponding to first rewriting below with $\bar{\alpha}$ and then on top with r . Therefore, the exchange law states that rewriting at the top by means of rule r and rewriting “below” using $\bar{\alpha}$ are processes that are independent of each other and can be done either simultaneously or in any order. Since $[t(x_1, \dots, x_n)]$ and $[t'(x_1, \dots, x_n)]$ can be regarded as functors $\mathcal{T}_{\mathcal{R}}(X)^n \rightarrow \mathcal{T}_{\mathcal{R}}(X)$, from the mathematical point of view the exchange law just asserts that r is a *natural transformation*, i.e.,

LEMMA 10. [Meseguer, 1992] For each rewrite rule $r : [t(x_1, \dots, x_n)] \rightarrow [t'(x_1, \dots, x_n)]$ in R , the family of morphisms

$$\{r(\overline{[w]}) : [t(\overline{w/x})] \rightarrow [t'(\overline{w/x})] \mid \overline{[w]} \in T_{\Sigma, E}(X)^n\}$$

is a natural transformation $r : [t(x_1, \dots, x_n)] \Rightarrow [t'(x_1, \dots, x_n)]$ between the functors $[t(x_1, \dots, x_n)], [t'(x_1, \dots, x_n)] : \mathcal{T}_{\mathcal{R}}(X)^n \rightarrow \mathcal{T}_{\mathcal{R}}(X)$.

The exchange law provides a way of *abstracting* a rewriting computation by considering immaterial the order in which rewrites are performed “above” and “below” in the term; further abstraction among proof terms is obtained from the functoriality equations. The equations 1-4 provide in a sense the *most abstract* “true concurrency” view of the computations of the rewrite theory \mathcal{R} that can reasonably be given.

The category $\mathcal{T}_{\mathcal{R}}(X)$ is just one among many *models* that can be assigned to the rewrite theory \mathcal{R} . The general notion of model, called an \mathcal{R} -*system*, is defined as follows:

DEFINITION 11. Given a rewrite theory $\mathcal{R} = (\Sigma, E, L, R)$, an \mathcal{R} -*system* \mathcal{S} is a category \mathcal{S} together with:

- a (Σ, E) -algebra structure given by a family of functors

$$\{f_{\mathcal{S}} : \mathcal{S}^n \rightarrow \mathcal{S} \mid f \in \Sigma_n, n \in \mathbb{N}\}$$

satisfying the equations E , i.e., for any $t(x_1, \dots, x_n) = t'(x_1, \dots, x_n)$ in E we have an identity of functors $t_{\mathcal{S}} = t'_{\mathcal{S}}$, where the functor $t_{\mathcal{S}}$ is defined inductively from the functors $f_{\mathcal{S}}$ in the obvious way.

- for each rewrite rule $r : [t(\bar{x})] \rightarrow [t'(\bar{x})]$ in R a natural transformation $r_{\mathcal{S}} : t_{\mathcal{S}} \Rightarrow t'_{\mathcal{S}}$.

An \mathcal{R} -homomorphism $F : \mathcal{S} \rightarrow \mathcal{S}'$ between two \mathcal{R} -systems is then a functor $F : \mathcal{S} \rightarrow \mathcal{S}'$ such that it is a Σ -algebra homomorphism—i.e., $f_{\mathcal{S}} * F = F^n * f_{\mathcal{S}'}$, for each f in Σ_n , $n \in \mathbb{N}$ —and such that “ F preserves R ,” i.e., for each rewrite rule $r : [t(\bar{x})] \rightarrow [t'(\bar{x})]$ in R we have the identity of natural transformations⁷ $r_{\mathcal{S}} * F = F^n * r_{\mathcal{S}'}$, where n is the number of variables appearing in the rule. This defines a category $\mathcal{R}\text{-Sys}$ in the obvious way.

The above definition captures formally the idea that the models of a rewrite theory are *systems*. By a “system” we mean a machine-like entity that can be in a variety of *states*, and that can change its state by performing certain *transitions*. Such transitions are transitive, and it is natural and convenient to view states as “idle” transitions that do not change the state. In other words, a system can be naturally regarded as a *category*, whose objects are the states of the system and whose morphisms are the system’s transitions.

For *sequential* systems such as labelled transition systems this is in a sense the end of the story; such systems exhibit *nondeterminism*, but do not have the required algebraic structure in their states and transitions to exhibit true concurrency. Indeed, what makes a system *concurrent* is precisely the existence of an additional *algebraic structure* [Meseguer, 1992]. First, the states themselves are distributed according to such a structure; for example, for Petri nets [Reisig, 1995] the distribution takes the form of a multiset. Second, concurrent transitions are themselves distributed according to the same algebraic structure; this is what the notion of \mathcal{R} -system captures, and is for example manifested in the concurrent firing of Petri nets, the evolution of concurrent object-oriented systems [Meseguer, 1993] and, more generally, in any type of concurrent rewriting.

The expressive power of rewrite theories to specify concurrent transition systems is greatly increased by the possibility of having not only transitions, but also *parameterized transitions*, i.e., *procedures*. This is what rewrite rules with variables provide. The family of states to which the procedure applies is given by those states where a component of the (distributed) state is a substitution instance of the lefthand side of the rule in question. The rewrite rule is then a *procedure* which transforms the state *locally*, by replacing such a substitution instance by the corresponding substitution instance of the righthand side. The fact that this can take place concurrently with other transitions “below” is precisely what the concept of a *natural transformation* formalizes. The following table summarizes our present discussion:

⁷Note that we use diagrammatic order for the *horizontal*, $\alpha * \beta$, and *vertical*, $\gamma; \delta$, composition of natural transformations [Mac Lane, 1971].

<i>System</i>	\longleftrightarrow	<i>Category</i>
<i>State</i>	\longleftrightarrow	<i>Object</i>
<i>Transition</i>	\longleftrightarrow	<i>Morphism</i>
<i>Procedure</i>	\longleftrightarrow	<i>Natural Transformation</i>
<i>Distributed Structure</i>	\longleftrightarrow	<i>Algebraic Structure</i>

A detailed proof of the following theorem on the existence of initial and free \mathcal{R} -systems for the more general case of conditional rewrite theories is given in [Meseguer, 1992], where the soundness and completeness of rewriting logic for \mathcal{R} -system models is also proved.

THEOREM 12. $\mathcal{T}_{\mathcal{R}}$ is an initial object in the category $\mathcal{R}\text{-Sys}$. More generally, $\mathcal{T}_{\mathcal{R}}(X)$ has the following universal property: Given an \mathcal{R} -system \mathcal{S} , each function $F : X \rightarrow |\mathcal{S}|$ extends uniquely to an \mathcal{R} -homomorphism $F^{\natural} : \mathcal{T}_{\mathcal{R}}(X) \rightarrow \mathcal{S}$.

Preorder, poset, and algebra models

Since \mathcal{R} -systems are an “essentially algebraic” concept⁸, we can consider classes Θ of \mathcal{R} -systems defined by the satisfaction of additional equations. Such classes give rise to full subcategory inclusions $\Theta \hookrightarrow \mathcal{R}\text{-Sys}$, and by general universal algebra results about essentially algebraic theories [Barr and Wells, 1985] such inclusions are *reflective* [Mac Lane, 1971], i.e., for each \mathcal{R} -system \mathcal{S} there is an \mathcal{R} -system $R_{\Theta}(\mathcal{S}) \in \Theta$ and an \mathcal{R} -homomorphism $\rho_{\Theta}(\mathcal{S}) : \mathcal{S} \rightarrow R_{\Theta}(\mathcal{S})$ such that for any \mathcal{R} -homomorphism $F : \mathcal{S} \rightarrow \mathcal{D}$ with $\mathcal{D} \in \Theta$ there is a unique \mathcal{R} -homomorphism $F^{\diamond} : R_{\Theta}(\mathcal{S}) \rightarrow \mathcal{D}$ such that $F = \rho_{\Theta}(\mathcal{S}); F^{\diamond}$. The assignment $\mathcal{S} \mapsto R_{\Theta}(\mathcal{S})$ extends to a functor $\mathcal{R}\text{-Sys} \rightarrow \Theta$, called the *reflection functor*.

Therefore, we can consider subcategories of $\mathcal{R}\text{-Sys}$ that are defined by certain equations and be guaranteed that they have initial and free objects, that they are closed by subobjects and products, etc. Consider for example the following equations:

$$\begin{aligned} \forall f, g \in \text{Arrows}, f = g \text{ if } \partial_0(f) = \partial_0(g) \wedge \partial_1(f) = \partial_1(g) \\ \forall f, g \in \text{Arrows}, f = g \text{ if } \partial_0(f) = \partial_1(g) \wedge \partial_1(f) = \partial_0(g) \\ \forall f \in \text{Arrows}, \partial_0(f) = \partial_1(f), \end{aligned}$$

where $\partial_0(f)$ and $\partial_1(f)$ denote the source and target of an arrow f respectively. The first equation forces a category to be a preorder, the addition of the second requires this preorder to be a poset, and the three equations

⁸In the precise sense of being specifiable by an “essentially algebraic theory” or a “sketch” [Barr and Wells, 1985]; see [Meseguer, 1992] for more details.

together force the poset to be *discrete*, i.e., just a set. By imposing the first one, the first two, or all three, we get full subcategories

$$\mathcal{R}\text{-Alg} \subseteq \mathcal{R}\text{-Pos} \subseteq \mathcal{R}\text{-Preord} \subseteq \mathcal{R}\text{-Sys}.$$

A routine inspection of $\mathcal{R}\text{-Preord}$ for $\mathcal{R} = (\Sigma, E, L, R)$ reveals that its objects are preordered Σ -algebras (A, \leq) —i.e., preordered sets with a Σ -algebra structure such that all the operations in Σ are monotonic—that satisfy the equations E and such that for each rewrite rule $r : [t(\bar{x})] \rightarrow [t'(\bar{x})]$ in R and for each $\bar{a} \in A^n$ we have $t_A(\bar{a}) \leq t'_A(\bar{a})$. The poset case is entirely analogous, except that the relation \leq is a partial order instead of being a preorder. Finally, $\mathcal{R}\text{-Alg}$ is the category of ordinary Σ -algebras that satisfy the equations $E \cup eq(R)$, where $eq(r : [t] \rightarrow [t']) = \{t_1 = t_2 \mid t_1 \in [t] \text{ and } t_2 \in [t']\}$, and $eq(R) = \bigcup \{eq(r : [t] \rightarrow [t']) \mid [t] \rightarrow [t'] \in R\}$.

The reflection functor associated with the inclusion $\mathcal{R}\text{-Preord} \subseteq \mathcal{R}\text{-Sys}$ sends $\mathcal{T}_{\mathcal{R}}(X)$ to the familiar \mathcal{R} -rewriting relation⁹ $\rightarrow_{\mathcal{R}(X)}$ on E -equivalence classes of terms with variables in X . Similarly, the reflection associated to the inclusion $\mathcal{R}\text{-Pos} \subseteq \mathcal{R}\text{-Sys}$ maps $\mathcal{T}_{\mathcal{R}}(X)$ to the partial order $\leq_{\mathcal{R}(X)}$ obtained from the preorder $\rightarrow_{\mathcal{R}(X)}$ by identifying any two $[t], [t']$ such that $[t] \rightarrow_{\mathcal{R}(X)} [t']$ and $[t'] \rightarrow_{\mathcal{R}(X)} [t]$. Finally, the reflection functor into $\mathcal{R}\text{-Alg}$ maps $\mathcal{T}_{\mathcal{R}}(X)$ to $T_{\mathcal{R}}(X)$, the free Σ -algebra on X satisfying the equations $E \cup eq(R)$; therefore, the classical *initial algebra semantics* of (functional) equational specifications reappears here associated with a very special class of models which—when viewed as systems—have only trivial identity transitions.

4 REWRITING LOGIC AS A LOGICAL FRAMEWORK

The adequacy of rewriting logic as a logical framework in which other logics can be represented by means of maps of logics or of entailment systems is explored by means of relevant examples, including equational, Horn, and linear logic, a general approach to the treatment of quantifiers, and a very general method for representing sequent presentations of a logic.

4.1 Mapping equational logic

As mentioned in Section 3.2, one can get equational logic from rewriting logic by adding the symmetry rule. Moreover, the syntax of rewriting logic includes equations in order to impose structural axioms on terms. Therefore, it should not be surprising to find out that there are many connections between both logics.

⁹It is perhaps more suggestive to call $\rightarrow_{\mathcal{R}(X)}$ the *reachability relation* of the system $\mathcal{T}_{\mathcal{R}}(X)$.

Even in the case of equational logic it can be convenient to allow sometimes a distinction between structural axioms and equations, so that an equational theory can then be described as a triple (Σ, E, Q) , with Q a set of equations of the form $[u]_E = [v]_E$. This increases the expressiveness of equational theories, because we can allow more flexible description of equations—for example, omitting parentheses in the case when E contains an associativity axiom—and also supports a built-in treatment of the structural axioms in equational deduction. Indeed, this is fully consistent with the distinction made in OBJ3 and in Maude’s functional modules between the equational *attributes* of an operator—such as associativity, commutativity, etc.—which are declared together with the operator, and the equations given, which are used modulo such attributes.

In order to define a map of entailment systems

$$(\Phi, \alpha) : \text{ent}(\text{OSEqtl}) \longrightarrow \text{ent}(\text{OSRWLogic})$$

in principle we need to map an equation $[u]_E = [v]_E$ to a sequent, and the obvious choices are either $[u]_E \longrightarrow [v]_E$ or $[v]_E \longrightarrow [u]_E$. However this choice involves giving a fixed orientation to an equation, with the well-known problems that this causes. To avoid this choice, we would like to give the equation *both* orientations. We can achieve this by slightly generalizing Definition 5 of map of entailment systems in such a way that a sentence is mapped to a set of sentences¹⁰. In our case, α maps an equation $[u]_E = [v]_E$ to the set of sequents $\{[u]_E \longrightarrow [v]_E, [v]_E \longrightarrow [u]_E\}$, and Φ maps an equational theory $T = (\Sigma, E, Q)$ to the rewrite theory $\Phi(T) = (\Sigma, E, L, \alpha(Q))$, where $\alpha(Q) = \bigcup\{\alpha(e) \mid e \in Q\}$, and L is a labelling of the rewrite rules such that, for example, each rule is labelled by itself. This map satisfies

$$(\Sigma, E, Q) \vdash_{EL} e \iff (\Sigma, E, L, \alpha(Q)) \vdash_{RL} \alpha(e).$$

This can be easily proved by induction on the deduction rules of equational logic, using the fact that all the rules of rewriting logic are also rules of equational logic and the following lemma.

LEMMA 13.

$$(\Sigma, E, L, \alpha(Q)) \vdash_{RL} [u] \rightarrow [v] \iff (\Sigma, E, L, \alpha(Q)) \vdash_{RL} [v] \rightarrow [u].$$

Therefore, we have a *conservative* map of entailment systems.

In order to extend this map to a map of logics, a simple idea concerning models is to send a $\Phi(T)$ -system \mathcal{C} to $R_{\mathbf{Alg}}(\mathcal{C})$, where $R_{\mathbf{Alg}}$ is the reflection functor associated with the inclusion $\Phi(T)\text{-Alg} \subseteq \Phi(T)\text{-Sys}$, as discussed

¹⁰This generalization is also very useful in relating other logics; see for example [Meseguer, 1998].

in Section 3.5. By definition, $R_{\mathbf{Alg}}(\mathcal{C})$ is a model of the equational theory T . However, this map does *not* satisfy the condition in Definition 6 of map of institutions. The difficulty is that, in general, from an equation $t = t'$ one can deduce that there is a chain $t \rightarrow t_1 \leftarrow t_2 \cdots t_n \leftarrow t'$, but not that $t \rightarrow t'$, as the reader familiar with term rewriting knows. To solve this problem, we consider a different quotient of the underlying (Σ, E) -algebra $|\mathcal{C}|$ in which two objects A and B are identified if and only if there exist morphisms $f : A \rightarrow B$ and $g : B \rightarrow A$ in \mathcal{C} . In this way, we obtain a (Σ, E) -algebra $\beta_T(\mathcal{C})$ that satisfies all the sentences in Q . Moreover, the condition in Definition 6 of map of institutions holds for this map. In short, we have obtained a conservative map of logics

$$(\Phi, \alpha, \beta) : OSEqtl \longrightarrow OSRWLogic.$$

There is also another map of logics

$$(\Phi', \alpha', \beta') : OSEqtl \longrightarrow OSRWLogic$$

that, instead of sending equations to sequents, sends equations to equations. This requires making explicit the fact, left implicit in Section 3, that equations can also be considered as sentences of rewriting logic, where, by definition,

$$(\Sigma, E, L, R) \vdash_{RL} t = t' \iff E \vdash_{EL} t = t'.$$

From this point of view, Φ' maps an equational theory (Σ, E) to the rewrite theory $(\Sigma, E, \emptyset, \emptyset)$, and at the level of sentences α' is just an inclusion, trivially satisfying the requirement for a map of entailment systems. Note that in this context the distinction between structural axioms and equations is not necessary.

With respect to the models, β'_T maps a $(\Sigma, E, \emptyset, \emptyset)$ -system \mathcal{C} to the underlying (Σ, E) -algebra structure on $|\mathcal{C}|$, trivially satisfying also the condition in Definition 6 and being therefore a map of institutions. Notice that (Φ', α', β') is *conservative* in a straightforward way.

On the opposite direction there is also a map of logics

$$(\Psi, \gamma, \delta) : OSRWLogic \longrightarrow OSEqtl$$

mapping a rewrite theory (Σ, E, L, R) to the equational theory $(\Sigma, E, \gamma(R))$ where γ removes the labels from the rules and turns the sequent signs “ \longrightarrow ” into equality signs. For the models, $\delta_{\mathcal{R}}$ is the inclusion $\mathcal{R}\text{-Alg} \subseteq \mathcal{R}\text{-Sys}$ defined in Section 3.5.

Notice that the composition of maps of logics $(\Phi, \alpha, \beta); (\Psi, \gamma, \delta)$ is the identity.

4.2 Mapping Horn logic

Horn logic signatures are of the form (F, P) , with F a set of function symbols and P a set of predicate symbols. In the order-sorted case such symbols have ranks $f : s_1 \dots s_n \rightarrow s$, and $p : s_1 \dots s_n$, specified by strings of sorts in the poset of sorts S . Models are F -algebras M together with, for each predicate symbol $p : s_1 \dots s_n$, a subset $p_M \subseteq M_{s_1} \times \dots \times M_{s_n}$, which can alternatively be viewed as a characteristic function $p_M : M_{s_1} \times \dots \times M_{s_n} \rightarrow Bool$ to the two element Boolean algebra $Bool$. Satisfaction of a Horn clause

$$q_1(\bar{u}_1), \dots, q_n(\bar{u}_n) \Rightarrow p(\bar{t})$$

in a model M can be expressed as either the subset containment of the intersection of the interpretations of $q_1(\bar{u}_1), \dots, q_n(\bar{u}_n)$ in M inside the corresponding interpretation of $p(\bar{t})$, or, in a characteristic function description, as the functional inequality

$$q_1(\bar{u}_1)_M \text{ and } \dots \text{ and } q_n(\bar{u}_n)_M \leq p(\bar{t})_M$$

between the corresponding interpretations in M of the conjunction of the premises and of the conclusion as characteristic functions, where the inequality between the functions means inequality of their values for each of the arguments in the Boolean algebra ordering. A *homomorphism* $f : M \rightarrow M'$ between two such models is an F -homomorphism which in addition satisfies $(f_{s_1} \times \dots \times f_{s_n})(p_M) \subseteq p_{M'}$ for each $p : s_1 \dots s_n$, or in characteristic function form the functional inequality

$$p_M \leq (f_{s_1} \times \dots \times f_{s_n}); p_{M'}.$$

Horn logic is a particularly simple logic that does not use the full power of classical first-order logic and is in fact compatible with a variety of other nonclassical interpretations such as for example intuitionistic logic. It is therefore reasonable to enlarge the class of models just described by keeping the F -algebra parts as before, but allowing instead interpretations of the predicate symbols p as “characteristic functions”

$$p_M : M_{s_1} \times \dots \times M_{s_n} \rightarrow M_{Prop}$$

into a partially ordered set M_{Prop} of “propositions” which is not required to be fixed, i.e., it can vary from model to model. We require of any such poset the “bare minimum” structure of having a top element *true*: $Prop \ Prop \rightarrow Prop$ that is monotonic and has *true* as its neutral element. Of course, $Bool$ is one such poset, where conjunction is interpreted as *and*. Satisfaction of Horn clauses can be defined by a functional inequality just as before, but changing $Bool$ by the appropriate poset M_{Prop} being chosen for the model.

The natural generalization of the notion of homomorphism $f : M \rightarrow M'$ is to again require an F -homomorphism for the operations in F , whereas for predicate symbols $p : s_1 \dots s_n$ we require the functional inequality

$$(\dagger) \quad p_M; f_{Prop} \leq (f_{s_1} \times \dots \times f_{s_n}); p_{M'}$$

where $f_{Prop} : M_{Prop} \rightarrow M'_{Prop}$ is an additional component of the homomorphism, namely, a monotonic function preserving *true* and conjunction “up to inequality” between the posets of propositions M_{Prop} and M'_{Prop} chosen for the models M and M' , in the sense that we have $f_{Prop}(true_M) \leq true_{M'}$, and $f_{Prop}(x, y) \leq f_{Prop}(x), f_{Prop}(y)$, for $x, y \in M_{Prop}$. This defines a category of models (F, P) -**Mod**.

In addition, we can consider the generalization to Horn theories of the form (F, P, E, H) where E is a set of F -equations, and H is a set of Horn clauses involving the predicates in P but not equations (again, equations in E can be viewed as structural axioms forming part of the signature). A model satisfies this theory when the underlying F -algebra satisfies all the equations in E and the model satisfies the Horn clauses in H , defining in this way a full subcategory (F, P, E, H) -**Mod** of (F, P) -**Mod**. We denote by $OSHorn^=$ the logic whose theories are such generalized Horn theories (F, P, E, H) with equational axioms E , and whose models we have just described.

The map of logics

$$(\Phi, \alpha, \beta) : OSHorn^= \rightarrow OSRWLogic$$

that we define now is a considerable simplification and extension of the map described in [Meseguer, 1992b].

A Horn theory (F, P, E, H) is mapped to a rewrite theory

$$\Phi(F, P, E, H) = (F \cup P^\diamond, E \cup ACI, \{*\} \cup H, \{x_{Prop} \rightarrow true\} \cup H^\diamond),$$

where

- $F \cup P^\diamond$ is the order-sorted signature that extends F by adding the additional sort *Prop*, a constant *true* : *Prop*, a binary operator $_ , _$ on *Prop*, and, for each predicate symbol $p : s_1 \dots s_n$ in P , an operator $p : s_1 \dots s_n \rightarrow Prop$;
- *ACI* is the set of associativity, commutativity, and identity (*true*) structural axioms for the conjunction operator $_ , _$;
- “*” is the label for the rewrite rule $x_{Prop} \rightarrow true$, where x_{Prop} is a variable of sort *Prop*;
- H^\diamond is a set of rewrite rules labelled by the Horn clauses H themselves in such a way that a Horn clause of the form $q_1(\bar{u}_1), \dots, q_n(\bar{u}_n) \Rightarrow p(\bar{t})$ labels the rewrite rule $q_1(\bar{u}_1), \dots, q_n(\bar{u}_n) \rightarrow p(\bar{t})$, whereas a Horn clause of the form $p(\bar{t})$ labels the rewrite rule $true \rightarrow p(\bar{t})$.

At the level of sentences, α maps each Horn clause to its corresponding labelled rewrite rule in the above manner.

As to models, given a Horn theory T , a $\Phi(T)$ -system consists of a category \mathcal{C}_s for each sort s in the poset S , and a category \mathcal{P} for the sort *Prop*, together with a collection of functors satisfying the equations in $\Phi(T)$ and natural transformations interpreting the rewrite rules in $\Phi(T)$. The functor β_T sends such a system to the T -model consisting of the underlying (order-sorted) algebra structure on the family of sets $\{\mathcal{C}_s \mid s \in S\}$, and the poset $R_{\mathbf{Pos}}(\mathcal{P})$, where $R_{\mathbf{Pos}}$ is the reflection functor associated to the inclusion $\Phi(T)\text{-Pos} \subseteq \Phi(T)\text{-Sys}$, discussed in Section 3.5. By definition of this reflection functor, $A \leq B$ in $R_{\mathbf{Pos}}(\mathcal{P})$ if and only if there is a morphism $A \rightarrow B$ in \mathcal{P} . Therefore, a Horn clause $q_1(\bar{u}_1), \dots, q_n(\bar{u}_n) \Rightarrow p(\bar{t})$ is satisfied by this T -model if and only if there is a morphism in \mathcal{P} interpreting the rewrite sequent $q_1(\bar{u}_1), \dots, q_n(\bar{u}_n) \longrightarrow p(\bar{t})$ if and only if this sequent is satisfied by the original $\Phi(T)$ -system. Thus, (Φ, α, β) is indeed a map of institutions.

Notice that, by the conditions for \mathcal{R} -homomorphisms in Definition 11, for the homomorphisms in the image of β_T the functional inequality (\dagger) above becomes an equality. In addition, β_T maps free $\Phi(T)$ -systems to (weakly) free Horn T -models; since the entailment relation coincides with satisfaction in free models (see the proof of Theorem 3.13 in [Meseguer, 1992]), this provides a short proof of the fact that (Φ, α) is indeed a map of entailment systems, and moreover, it is *conservative*.

The same discussion applies to the case of preorders instead of posets, by considering the reflection functor associated to the inclusion $\Phi(T)\text{-Preord} \subseteq \Phi(T)\text{-Sys}$, which would have given a slightly more general notion of model for a Horn theory in which propositions would form a preorder.

4.3 Mapping linear logic

In this section, we describe a map of logics $LinLogic \longrightarrow OSRWLogic$ mapping theories in full quantifier-free first-order linear logic to rewrite theories. We do not provide much motivation for linear logic, referring the reader to [Girard, 1987; Troelstra, 1992; Martí-Oliet and Meseguer, 1991] for example. We need to point out, nonetheless, the way linear logic satisfies the conditions given in Definition 1 of entailment system. If one thinks of formulas as sentences and of the turnstile symbol “ \vdash ” in a sequent as the entailment relation, then this relation is not monotonic, because in linear logic the structural rules of weakening and contraction are forbidden, so that, for example, we have the sequent $A \vdash A$ as an axiom, but we cannot derive either $A, B \vdash A$ or even $A, A \vdash A$. The point is that, for Σ a linear logic signature, the elements of $sen(\Sigma)$ should not be identified with *formulas* but with *sequents*. Viewed as a way of generating sequents, i.e., identifying our entailment relation \vdash with the closure

of the horizontal bar relation among linear logic sequents, the entailment of linear logic is indeed reflexive, monotonic, and transitive. This idea is also supported by the categorical models for linear logic [Seely, 1989; Martí-Oliet and Meseguer, 1991], in which sequents are interpreted as morphisms, and leads to a very natural correspondence between the models of rewriting and linear logic.

Expressing linear logic in rewriting logic

We use the syntax of the Maude language to write down the map of entailment systems from linear logic to rewriting logic. Note that any sequence of characters starting with either “---” or “***” and ending with “end-of-line” is a comment. Moreover, we usually drop the equivalence class square brackets, adopting the convention that a term t denotes the equivalence class $[t]_E$ for the appropriate set of structural axioms E .

We first define the *functional* theory $\text{PROPO}[X]$ which introduces the syntax of propositions as a parameterized abstract data type. The parameterization permits having additional structure at the level of atoms if desired. In order to provide a proper treatment of negation, only equations are given, and no rewrite rules are introduced in this theory; they are introduced afterwards in the $\text{LINLOG}[X]$ theory. The purpose of the equations in the $\text{PROPO}[X]$ theory is to push negation to the atom level, by using the dualities of linear logic; this is a well-known process in classical and linear logic.

```
fth ATOM is
  sort Atom .
endfth

--- linear logic syntax
fth PROPO[X :: ATOM] is
  sort Prop0 .
  subsort Atom < Prop0 .
  ops 1 0 ⊥ ⊤ : -> Prop0 .
  op _⊥ : Prop0 -> Prop0 .
  op _⊗_ : Prop0 Prop0 -> Prop0 [assoc comm id: 1] .
  op _⊗⊗_ : Prop0 Prop0 -> Prop0 [assoc comm id: ⊥] .
  op _⊕_ : Prop0 Prop0 -> Prop0 [assoc comm id: 0] .
  op _&_ : Prop0 Prop0 -> Prop0 [assoc comm id: ⊤] .
  op !_ : Prop0 -> Prop0 .
  op ?_ : Prop0 -> Prop0 .

  vars A B : Prop0 .
  eq (A ⊗ B)⊥ = A⊥ ⊗⊗ B⊥ .
  eq (A ⊗⊗ B)⊥ = A⊥ ⊗ B⊥ .
  eq (A & B)⊥ = A⊥ ⊕ B⊥ .
```

```

eq (A ⊕ B)⊥ = A⊥ & B⊥ .
eq (!A)⊥ = ?(A⊥) .
eq (?A)⊥ = !(A⊥) .
eq A⊥⊥ = A .
eq 1⊥ = ⊥ .
eq ⊥⊥ = 1 .
eq ⊤⊥ = 0 .
eq 0⊥ = ⊤ .
endft

```

Note that the equations can be used as oriented rules from left to right at the implementation level in order to obtain a canonical form for expressions in `Prop0`.

The `LINLOG[X]` theory introduces linear logic propositions and the rules of the logic. Propositions are of the form `[A]` for `A` an expression in `Prop0`. All logical connectives work similarly for `Prop0` expressions and for propositions, except negation, which is defined only for `Prop0` expressions.

Some presentations of linear logic are given in the form of one-sided sequents $\vdash \Gamma$ where negation has been pushed to the atom level, and there are no rules for negation in the sequent calculus [Girard, 1987]. In this section, in order to make the connections with category theory and with rewriting logic more direct, we prefer to use standard sequents of the more general form $\Gamma \vdash \Delta$. In a later section, we will also use one-sided sequents just in order to reduce the number of rules.

The style of our formulation adopts a categorical viewpoint for the proof theory and semantics of linear logic [Seely, 1989; Martí-Oliet and Meseguer, 1991]. This style exploits the close connection between the models of linear logic and those of rewriting logic which are also categories, as we have explained in Section 3.5. Without going into details that the reader can find for example in [Martí-Oliet and Meseguer, 1991] and the references therein, the tensor and linear implication connectives are interpreted in a closed symmetric monoidal category $(\mathcal{C}, \otimes, \multimap)$. Negation is interpreted by means of a dualizing object \perp and the definition $A^\perp = A \multimap \perp$ (with this definition of negation, \mathcal{C} becomes a $*$ -autonomous category [Barr, 1979]). The categorical product $\&$ interprets additive conjunction. The interpretation of the exponential $!$ is given by a comonad $(!A, !A \rightarrow A, !A \rightarrow !!A)$ that maps the comonoid structure $\top \leftarrow A \rightarrow A \& A$ into a comonoid structure $1 \leftarrow !A \rightarrow !A \otimes !A$ via isomorphisms $!\top \cong 1$ and $!(A \& A) \cong !A \otimes !A$.

The dual connectives \wp , \oplus , and $?$ can be defined using negation: $A \wp B = (A^\perp \otimes B^\perp)^\perp = A^\perp \multimap B$, $A \oplus B = (A^\perp \& B^\perp)^\perp$, $?A = (!A^\perp)^\perp$. Without negation, \oplus needs the presence of coproducts and $?$ is interpreted by means of a monad with a monoid structure.

When seeking the minimal categorical structure required for interpreting linear logic, an important question is how to interpret the connective \wp without using negation, and how to axiomatize its relationship with the

tensor \otimes . Cockett and Seely have answered this question with the notion of a *weakly distributive category* [Cockett and Seely, 1992]. A weakly distributive category consists of a category \mathcal{C} with two symmetric tensor products $\otimes, \wp : \mathcal{C} \times \mathcal{C} \rightarrow \mathcal{C}$, and a natural transformation $A \otimes (B \wp C) \rightarrow (A \otimes B) \wp C$ (weak distributivity) satisfying some coherence equations¹¹. Negation is added to a weakly distributive category by means of a function $(_)^\perp : |\mathcal{C}| \rightarrow |\mathcal{C}|$ on the objects of \mathcal{C} , and natural transformations $1 \rightarrow A \wp A^\perp$ and $A \otimes A^\perp \rightarrow \perp$ satisfying some coherence equations. Cockett and Seely then prove that the concepts of weakly distributive category with negation and of $*$ -autonomous category are equivalent, providing in this way a categorical semantics for linear logic in which the *par* connective \wp is primitive and is not defined in terms of tensor and negation.

In the following theory, the rewrite rules for \otimes, \wp , and negation correspond to the natural transformations in the definition of a weakly distributive category, as explained above. The rules for $\& (\oplus, \text{respectively})$ mirror the usual definition of final object and product (initial object and coproduct, respectively). Finally, the axioms and rules for the exponential $! (? , \text{respectively})$ correspond to the comonad with a comonoid structure (monad with monoid structure, respectively). Note that some rules are redundant, but we have decided to include them in order to make the connectives less interdependent, so that, for example, if the connective $\&$ is omitted we do not need to add new rules for the modality $!$.

```

A linear logic formula is built from a set of propositional constants using the logical constants and connectives of linear logic. Notice that linear implication $A \multimap B$ is not necessary because it can be defined as $A^\perp \wp B$.

Representing a linear logic theory in rewriting logic

A *linear theory* T in propositional linear logic consists of a finite set C of propositional constants and a finite set S of double-sided sequents of the form $A_1, \dots, A_n \vdash B_1, \dots, B_m$, where each A_i and B_j is a linear logic formula built from the constants in C . Given such a theory T , it is interpreted in rewriting logic as follows.

First, we define a functional theory to interpret the propositional constants in C . For example, if $C = \{a, b, c\}$ we would define

```
fth C is
  sort Atom .
  ops a b c : -> Atom .
endft
```

Then, we can instantiate the parameterized theory $\text{LINLOG}[X]$ using this functional theory, with the default view $\text{ATOM} \rightarrow C$:

```
make LINLOG0 is LINLOG[C] endmk
```

A linear logic formula A (with constants in C) is interpreted in LINLOG0 as the term $[A]$ of sort Prop . For example, the formula $(a \otimes b)^\perp \oplus (! (a \& c^\perp))^\perp$ is interpreted as the term

$$[(a \otimes b)^\perp \oplus (! (a \& c^\perp))^\perp]$$

which, using the equations for negation in $\text{PROPO}[X]$ and the structural axioms in $\text{LINLOG}[X]$, is equal to the term

$$([a^\perp] \wp [b^\perp]) \oplus ?([a^\perp] \oplus [c]).$$

Finally, we extend the theory LINLOG0 by adding a rule

```
r1 [A1] \otimes ... \otimes [An] => [B1] \wp ... \wp [Bm] .
```

for each sequent $A_1, \dots, A_n \vdash B_1, \dots, B_m$ in the linear theory T . For example, if

$$T = \{a \otimes b, !c \oplus a \vdash a, (c \oplus b)^\perp, \\ a \wp b, ?(c^\perp) \vdash (?b \wp !c)^\perp, a \oplus b\},$$

the corresponding rewrite theory is

```
th LINLOG(T) is
  including LINLOG0 .
  r1 [a] \otimes [b] \otimes (![c] \oplus [a]) => [a] \wp ([c^\perp] \& [b^\perp]) .
  r1 ([a] \wp [b]) \otimes ?[c^\perp] => (![b^\perp] \otimes ?[c^\perp]) \wp ([a] \oplus [b]) .
endt
```

Note that this technique can also be used to interpret quantifier-free first-order linear logic formulas, where, instead of propositional constants, we have literals built using functions and predicates. In general, we can allow any abstract data type ADT defining constants, functions and predicates. Then, we define the instantiation

```
make LINLOGO is LINLOG[ADT] endmk
```

which is finally extended with the corresponding rules to a theory $\text{LINLOG}(T)$ corresponding to the desired theory T .

The main result is the following conservativity theorem.

THEOREM 14. Given a linear theory T , a sequent $A_1, \dots, A_n \vdash B_1, \dots, B_m$ is provable in linear logic from the axioms in T if and only if the sequent

$$[A_1] \otimes \dots \otimes [A_n] \longrightarrow [B_1] \wp \dots \wp [B_m]$$

is a $\text{LINLOG}(T)$ -rewrite, i.e., it is provable in rewriting logic from the rewrite theory $\text{LINLOG}(T)$.

To show that a linear logic proof can be translated into a rewriting logic proof, the idea is similar to the proof of the soundness theorem for the categorical semantics of linear logic, where a sequent is interpreted as a morphism (see [Martí-Oliet and Meseguer, 1991, Theorem 40]). What is important to realize is that the categorical constructions of these morphisms can be seen as rewriting logic proofs; for example, functoriality corresponds to the *Congruence* rule of rewriting logic, something made completely explicit in the categorical semantics of rewriting logic, as outlined in Section 3.5 and developed in detail in [Meseguer, 1992].

The map of logics

The fully detailed development in the previous sections provides a map of entailment systems between linear logic and rewriting logic, which is conservative because of Theorem 14. We have already discussed briefly the models of linear logic in Section 4.3 by way of motivation to the rules in the theory $\text{LINLOG}[X]$. Now, in order to complete the construction of the map of logics $\text{LinLogic} \longrightarrow \text{OSRWLogic}$, we need a way of getting a (categorical) model of a linear theory T from a rewrite system that is a model of the rewrite theory $\text{LINLOG}(T)$.

The first thing to note, recalling the definition of \mathcal{R} -system in Section 3.5, is that for each rewrite rule in R we require just a natural transformation in the system, but we do not impose any coherence or uniqueness conditions on these natural transformations. For this reason, a $\text{LINLOG}(T)$ -system interprets $A \& B$ as a weak product instead of a product, for example. A way of obtaining uniqueness would be considering the generalized rewrite

theories defined in [Meseguer, 1992b], but we do not need that for our purposes here. On the other hand, the attributes of the operations, like associativity or commutativity, are interpreted as identities, instead of the more general natural isomorphisms, thus satisfying all coherence conditions automatically.

In general, given a linear theory $T = (C, S)$, a $\text{LINLOG}(T)$ -system consists of an algebra \mathcal{A} interpreting all the structure of the functional theory $\text{PROPO}[C]$, a category \mathcal{C} with all the morphisms necessary to interpret the rewrite rules in the theory $\text{LINLOG}[C]$ and the rules corresponding to all the sequents in S , and an injective homomorphism $\mathcal{A} \rightarrow |\mathcal{C}|$ that, without loss of generality, we can consider to be an inclusion. Note that, as \mathcal{A} is closed under all the operations in the theory $\text{LINLOG}[C]$, the full subcategory of \mathcal{C} generated by \mathcal{A} has the same structure as \mathcal{C} , and, in addition, there is a function $(_)^\perp : \mathcal{A} \rightarrow \mathcal{A}$ interpreting negation. Therefore, this full subcategory is *almost* a weakly distributive category with negation, products, coproducts, a comonad with a comonoid structure, and a monad with a monoid structure. What is possibly missing is the satisfaction of a set of equations between morphisms which ensure that all this structure is really what we want.

Thus, in order to get a Girard category \mathcal{L} from the original $\text{LINLOG}(T)$ -system, we do the quotient of the full subcategory of \mathcal{C} generated by \mathcal{A} by this set of equations. Clearly, there is a morphism $A \rightarrow B$ in \mathcal{L} if and only if there is a morphism $A \rightarrow B$ in \mathcal{C} , i.e., \mathcal{L} satisfies a linear sequent if and only if \mathcal{C} satisfies the rewriting logic version of that sequent. This is true because the constants in \mathcal{C} are interpreted always as the corresponding constants in \mathcal{A} , and variables in a sequent are also interpreted as elements of \mathcal{A} (note that variables appear in a theory ADT that is used to instantiate $\text{PROPO}[X]$). In summary, we have a *conservative* map of logics $\text{LinLogic} \rightarrow \text{OSRWLogic}$.

4.4 Quantifiers

In Section 4.3 we have defined a map of logics between quantifier-free linear logic and rewriting logic. In this section, we show how to extend that map at the level of entailment systems to quantifiers. The choice of linear logic to illustrate the treatment of quantifiers is irrelevant; we could have chosen any other logic. It has only the expository advantage of building upon an example already introduced in this paper. In fact, our equational treatment of quantification, inspired by ideas of Laneve and Montanari on the definition of the lambda calculus as a theory in rewriting logic [Laneve and Montanari, 1992; Laneve and Montanari, 1996], is very general and encompasses not only existential and universal quantification, but also lambda abstraction and other such binding mechanisms.

The main idea is to internalize as operations in the theory the notions

of free variables and substitution that are usually defined at the metalevel. Then, the typical definitions of such notions by structural induction on terms can be easily written down as equations in the theory, but, more importantly, we can consider terms modulo these axioms and we can also use the operation of substitution explicitly in the rules introducing or eliminating quantifiers. This is similar to the lambda calculus with explicit substitutions defined by Abadi, Cardelli, Curien, and Lévy in [1991], and to the work on binding structures by Talcott [1993].

We begin by presenting the example of the lambda abstraction binding mechanism in the lambda calculus, as defined by Laneve and Montanari in [1992] (see also [Laneve and Montanari, 1996], where this technique is generalized to combinatory reduction systems). Since in this case the syntax is much simpler, the main ideas can become more explicit and clearer to the reader.

We assume a parameterized functional module `SET[X]` that provides finite sets over a parameter set `X` with operations `_U_` for union, `_-_` for set difference, `{_}` for singleton, `emptyset` for the empty set, and a predicate `_is-in_` for membership.

```

--- variable names
fth VAR is
  sort Var .
  protecting SET[Var] .
  op new : Set -> Var .
  var S : Set .
  eq new(S) is-in S = false . *** new variable
endft

--- lambda calculus syntax with substitution
fmod LAMBDA[X :: VAR] is
  including SET[X] .
  sort Lambda .
  subsort Var < Lambda .
  op λ_ : Var Lambda -> Lambda . *** variables
  op _ : Lambda Lambda -> Lambda . *** lambda abstraction
  op _[_/_] : Lambda Lambda Var -> Lambda . *** application
  op fv : Lambda -> Set . *** substitution
  op fv : Lambda -> Set . *** free variables

  vars X Y : Var .
  vars M N P : Lambda .

  *** Free variables
  eq fv(X) = {X} .
  eq fv(λX.M) = fv(M) - {X} .
  eq fv(MN) = fv(M) U fv(N) .
  eq fv(M[N/X]) = (fv(M) - {X}) U fv(N) .
    
```

```

*** Substitution equations
eq X[N/X] = N .
ceq Y[N/X] = Y if not(X == Y) .
eq (MN)[P/X] = (M[P/X])(N[P/X]) .
eq (λX.M)[N/X] = λX.M .
ceq (λY.M)[N/X] = λY.(M[N/X])
    if not(X == Y) and (not(Y is-in fv(N)) or not(X is-in fv(M))) .
ceq (λY.M)[N/X] = λ(new(fv(MN))).(M[new(fv(MN))/Y])[N/X]
    if not(X == Y) and Y is-in fv(N) and X is-in fv(M) .
endfm

```

Note that substitution is here another term constructor instead of a meta-syntactic operation. Of course, using the above equations, all occurrences of the substitution constructor can be eliminated. After having defined in the previous functional module the class of lambda terms with substitution, we just need to add the equational axiom of alpha conversion and the beta rule in the following module:

```

--- lambda calculus rules
mod ALPHA-BETA[X :: VAR] is
  including LAMBDA[X] .
  vars X Y : Var .
  vars M N : Lambda .

*** Alpha conversion
cax λX.M = λY.(M[Y/X]) if not(Y is-in fv(M)) .

*** Beta reduction
r1 (λX.M)N => M[N/X] .
endm

```

In order to introduce quantifiers, we can develop a similar approach, by first introducing substitution in the syntax together with the quantifiers, and then adding rewrite rules for the new connectives. In the same way that we had to duplicate the logical connectives in both theories `PROPO[X]` and `LINLOG[X]` in Section 4.3 in order to have a correct treatment of negation, we also have to duplicate the operations and equations for substitution in the two modules `FO-PROPO[X]` and `FO-LINLOG[X]` below. This technicality, due to the treatment of negation, makes the exposition somewhat longer, but should not obscure the main ideas about the treatment of quantification that have been illustrated more concisely before with the lambda calculus example.

We assume an abstract data type ADT defining constants, functions and predicates over a set `Var` of variable names. Substitution must also be defined in this module. For example, we can have something like the following module:

```

fmod ADT[X :: VAR] is
  including SET[X] .
  sort Term .                *** terms
  subsort Var < Term .       *** variables are terms
  op c : -> Term .           *** constant symbol
  op f : Term Term -> Term . *** function symbol
  sort Atom .                *** atomic formulas
  op p : Term Term -> Atom . *** predicate symbol

  op va : Term -> Set .       *** set of variables
  op va : Atom -> Set .       *** set of variables
  op _[_/_] : Term Term Var -> Term . *** substitution
  op _[_/_] : Atom Term Var -> Atom . *** substitution

  vars X Y : Var .          vars T U V : Term .
  var P : Atom .

  *** Set of variables
  eq va(X) = {X} .
  eq va(c) = emptyset .
  eq va(f(T,V)) = va(T) U va(V) .
  eq va(p(T,V)) = va(T) U va(V) .
  eq va(V[T/X]) = (va(V) - {X}) U va(T) .
  eq va(P[T/X]) = (va(P) - {X}) U va(T) .

  *** Substitution equations
  eq X[T/X] = T .
  ceq Y[T/X] = Y if not(X == Y) .
  eq c[T/X] = c .
  eq f(U,V)[T/X] = f(U[T/X],V[T/X]) .
  eq p(U,V)[T/X] = p(U[T/X],V[T/X]) .
endfm

--- linear logic syntax with quantifiers

endm

```

In this way, we have defined a map of entailment systems

$$\text{ent}(\text{FOLinLogic}) \longrightarrow \text{ent}(\text{OSRWLogic})$$

which is also *conservative*.

4.5 Mapping sequent systems

In Section 4.3, we have mapped linear logic formulas to terms, and linear logic sequents to rewrite rules in rewriting logic. There is another map of entailment systems between linear logic and rewriting logic in which linear sequents become also terms, and rewrite rules correspond to rules in a Gentzen sequent calculus for linear logic. In order to reduce the number of rules of this calculus, we consider one-sided linear sequents in this section, but a completely similar treatment can be given for two-sided sequents. Thus, a linear logic sequent will be a turnstile symbol “ \vdash ” followed by a multiset M of linear logic formulas, that in our translation to rewriting logic will be represented by the term $\vdash M$. Using the duality of linear logic

negation, a two-sided sequent $A_1, \dots, A_n \vdash B_1, \dots, B_m$ can in this notation be expressed as the one-sided sequent $\vdash A_1^\perp, \dots, A_n^\perp, B_1, \dots, B_m$.

First, we define a parameterized module for multisets. The elements in the parameter are considered singleton multisets via a subsort declaration `Elem < Mset`, and there is a multiset union operator `_,_` which is associative, commutative, and has the empty multiset `null` as neutral element. Note that what makes the elements of `Mset` multisets instead of lists is the attribute `comm` of commutativity of the union operator `_,_`.

```
fth ELEM is
  sort Elem .
endft

fmod MSET[X :: ELEM] is
  sort Mset .
  subsort Elem < Mset .
  op null : -> Mset .
  op _,_ : Mset Mset -> Mset [assoc comm id: null] .
endfm
```

Now we can use this parameterized module to define the main module for sequents¹² and give the corresponding rules. A sequent calculus rule of the form

$$\frac{\vdash M_1, \dots, \vdash M_n}{\vdash M}$$

becomes the rewrite rule

```
r1 \vdash M1 ... \vdash Mn => \vdash M .
```

on the sort `Configuration`. Recalling that “`---`” introduces a comment, this rule can be written as

```
r1  \vdash M1 ... \vdash Mn
    => -----
        \vdash M .
```

This displaying trick that makes it possible to write a sequent calculus rule in a similar way to the usual presentation in logical textbooks is due to K. Futatsugi.

¹²The multiset structure is one particular way of building in certain *structural rules*, in this case *exchange*. Many other such data structuring mechanisms are as well possible to build in, or to drop, desired structural properties. Appropriate parameterized data types can similarly be used for this purpose. For example, we use later a data type of lists to define 2-sequents in which exchange is not assumed.

```

--- one-sided sequent calculus for linear logic

    => -----
        ⊢ M,∀X.A
    if not(X is-in fv(M)) .

```

```

*** Existential
r1  ⊢ M,A[T/X]
    => -----
        ⊢ M.∃X.A .
endm

```

Note that in the module `FO-PROPO[X]` (via the reused theory `PROPO[X]`) we have imposed associativity and commutativity attributes for some connectives, making syntax a bit more abstract than usual. However, in this case, this has no significance at all, except for the convenient fact that we only need a rule for \oplus instead of two; of course, these attributes can be removed if a less abstract presentation is preferred.

Given a linear theory $T = (C, S)$ (where we can assume that all the sequents in S are of the form $\vdash A_1, \dots, A_n$), we instantiate the parameterized module `LL-SEQUENT[X]` using a functional module `C` that interprets the propositional constants in C , as in Section 4.3, and then extend it by adding a rule

```
r1 empty => ⊢ A1, ..., An .
```

for each sequent $\vdash A_1, \dots, A_n$ in S , obtaining in this way a rewrite theory `LL-SEQUENT(T)`.

With this map we have also an immediate conservativity result:

THEOREM 15. Given a linear theory T , a linear logic sequent $\vdash A_1, \dots, A_n$ is provable in linear logic from the axioms in T if and only if the sequent

```
empty → ⊢ A1, ..., An
```

is provable in rewriting logic from the rewrite theory `LL-SEQUENT(T)`.

It is very important to realize that the technique used in this conservative map of entailment systems is very general and it is in no way restricted to linear logic. Indeed, it can be applied to any sequent calculus, be it for intuitionistic, classical or any other logic. In general, we need an operation

```
op _⊢_ : FormList FormList -> Sequent .
```

that turns two lists of formulas (multisets, or sets in some cases) into a term representing a sequent. Then we have a sort `Configuration` representing multisets of sequents, with a union operator written using empty syntax. A sequent calculus rule

$$\frac{G_1 \vdash D_1, \dots, G_n \vdash D_n}{G \vdash D}$$

becomes a rewrite rule

```
r1 (G1 ⊢ D1) ... (Gn ⊢ Dn) => (G ⊢ D) .
```

on the sort `Configuration`, that we have displayed above also as

$$\text{r1} \quad \frac{(G_1 \vdash D_1) \dots (G_n \vdash D_n)}{(G \vdash D) .}$$

in order to make even clearer that the rewrite rule and the sequent notations in fact capture the same idea. In the particular case of linear logic the situation is somewhat simplified by the use of one-sided sequents. Notice also that sometimes the rewrite rule can be conditional to the satisfaction of some auxiliary side conditions like, for example, in the rule for the universal quantifier in the module above.

As another example illustrating the generality of this approach, we sketch a presentation in rewriting logic of the *2-sequent calculus* defined by Masini and Martini in order to develop a proof theory for modal logics [Masini, 1993; Martini and Masini, 1993]. In their approach, a *2-sequent* is an expression of the form $\Gamma \vdash \Delta$, where Γ and Δ are not lists of formulas as usual, but they are lists of lists of formulas, so that sequents are endowed with a vertical structure. For example,

$$\frac{A, B \quad D}{C \vdash \frac{E, F}{G}}$$

is a 2-sequent, which will be represented in rewriting logic as

$$A, B; C \vdash D; E, F; G.$$

In order to define 2-sequents, we first need a parameterized module for lists, assuming a module `NAT` defining a sort `Nat` of natural numbers with zero `0`, a successor function `s_`, an addition operation `_+_`, and an order relation `_<=_`, as well as a module `BOOL` defining a sort `Bool` of truth values `true`, `false` and corresponding Boolean operations.

```
fmod LIST[X :: ELEM] is
  protecting NAT BOOL .
  sort List .
  subsort Elem < List .
  op nil : -> List .
  op _;_ : List List -> List [assoc id: nil] .
  op length : List -> Nat .
  op _in_ : Elem List -> Bool .

  vars E E' : Elem .
  vars L L' : List .
  eq length(nil) = 0 .
  eq length(E) = s0 .
```

```

eq length(L;L') = length(L) + length(L') .
eq E in nil = false .
eq E in E' = if E == E' then true else false .
eq E in (L;L') = (E in L) or (E in L') .
endfm

```

This module is instantiated twice in order to get the module of 2-sequents, using a sort of formulas `Form` whose definition is not presented here, and that should have an operation

```
op []_ : Form -> Form .
```

corresponding to the modality \Box .

```

make 2-LIST is
LIST[LIST[Form]*(op _;_ to _,_)]*(sort List to 2-List,
                                op length to depth)
endmk

```

Note that in the 2-LIST module the concatenation operation `_;` is renamed to `_,_` in the case of lists of formulas, whereas in the case of lists of lists of formulas, called 2-lists, the notation `_;` is kept. Also, to emphasize the vertical structure of 2-sequents, the operation `length` for 2-lists is renamed to `depth`.

Now we can define 2-sequents as follows:

```

fmod 2-SEQUENT is
protecting 2-LIST .
sort 2-Sequent .
op _\_ : 2-List 2-List -> 2-Sequent .
endfm

```

The basic rules for the modality \Box are

$$\frac{\begin{array}{c} \Gamma \\ \alpha \\ \beta, A \\ \Gamma' \end{array} \vdash \Delta}{\begin{array}{c} \Gamma \\ \alpha, \Box A \\ \beta \\ \Gamma' \end{array} \vdash \Delta} (\Box-L) \qquad \frac{\begin{array}{c} \Delta \\ \Gamma \vdash \alpha \\ A \end{array}}{\Gamma \vdash \begin{array}{c} \Delta \\ \alpha, \Box A \end{array}} (\Box-R)$$

where Γ, Γ', Δ denote 2-lists, α, β denote lists of formulas, and the rule $\Box-R$ has the side condition that $depth(\Gamma) \leq depth(\Delta) + 1$, i.e., the formula A is the only formula in the last level of the 2-sequent.

These rules are represented in rewriting logic as follows.

```

mod 2-SEQUENT-RULES is
  protecting 2-SEQUENT .
  sort Configuration .
  subsort 2-Sequent < Configuration .
  op empty : -> Configuration .
  op _ : Configuration Configuration -> Configuration
                                     [assoc comm id: empty] .

  vars R R' S : 2-List .
  vars L L' : List .
  var A : Form .
  rl   R ; L ; L',A ; R' ⊢ S
      => -----
          R ; L,[]A ; L' ; R' ⊢ S .

  crl  R ⊢ S ; L ; A
      => -----
          R ⊢ S ; L,[]A
      if depth(R) <= s(depth(S)) .
endm

```

The dual rules for the modality \diamond are treated similarly.

This general method of viewing sequents as rewrite rules can even be applied to systems more general than traditional sequent calculi. Thus, besides the possibilities of being one-sided or two-sided, one-dimensional or two-dimensional, etc., a “sequent” can for example be a sequent presentation of natural deduction, a term assignment system, or even any predicate defined by structural induction in some way such that the proof is a kind of tree, as for example the operational semantics of CCS given later in Section 5.3 and any other use of the so-called structural operational semantics (see [Hennessy, 1990] and Section 5.4 later), including type-checking systems. The general idea is to map a rule in the “sequent” system to a rewrite rule over a “configuration” of sequents or predicates, in such a way that the rewriting relation corresponds to provability of such a predicate.

4.6 Reflection in rewriting logic

Clavel and Meseguer have shown in [1996; 1996a] that rewriting logic is reflective in the sense of Section 2.8. That is, there is a rewrite theory \mathcal{U} with a finite number of operations and rules that can simulate any other finitely presentable rewrite theory \mathcal{R} in the following sense: given any two terms t, t' in \mathcal{R} , there are corresponding terms $\langle \overline{\mathcal{R}}, \overline{t} \rangle$ and $\langle \overline{\mathcal{R}}, \overline{t'} \rangle$ in \mathcal{U} such that we have

$$\mathcal{R} \vdash t \longrightarrow t' \iff \mathcal{U} \vdash \langle \overline{\mathcal{R}}, \overline{t} \rangle \longrightarrow \langle \overline{\mathcal{R}}, \overline{t'} \rangle.$$

Moreover, it is often possible to reify inside rewriting logic itself a representation map $\mathcal{L} \rightarrow \text{OSRWLogic}$ for the finitely presentable theories of \mathcal{L} .

Such a reification takes the form of a map between the abstract data types representing the finitary theories of \mathcal{L} and of *OSRWLogic*. In this section we illustrate this powerful idea with the linear logic mapping defined in Section 4.3.

We have defined a linear theory T as a finite set C of propositional constants together with a finite set S of sequents of the form $A_1, \dots, A_n \vdash B_1, \dots, B_m$, where each A_i and B_j is a linear logic formula built from the constants in C . Note that with this definition, all linear theories are finitely presentable. First, we define an abstract data type LL-ADT to represent linear theories. A linear theory is represented as a term $\langle C \mid G \rangle$, where C is a list of propositional constants (that is, identifiers), and G is a list of sequents written in the usual way. Moreover, all the propositional constants in G must be included in C . To enforce this condition, we use a sort constraint [Meseguer and Goguen, 1993], which is introduced with the keyword `set` and defines a subsort `LLTheory` of a sort `LLTheory?` by means of the given condition. In the functional module below, we do not give the equations defining the auxiliary functions `const` that extracts the constants of a list of sequents, and the list containment predicate `_=<_`. These functions are needed to write down the sort constraint for theories.

```
fmod LL-ADT is
  protecting QID .
  sorts Ids Formula Formulas Sequent .
  sorts Sequents LLTheory? LLTheory .

  subsort Id < Formula .
  ops 1 0  $\perp$   $\top$  : -> Formula .
  op  $\otimes$  : Formula Formula -> Formula .
  op  $\wp$  : Formula Formula -> Formula .
  op  $\oplus$  : Formula Formula -> Formula .
  op  $\&$  : Formula Formula -> Formula .
  op !_ : Formula -> Formula .
  op ?_ : Formula -> Formula .
  op  $\perp$  : Formula -> Formula .

  subsort Formula < Formulas .
  op null : -> Formulas .
  op  $\_,\_$  : Formulas Formulas -> Formulas [assoc comm id: null] .
  op ( $\_ \vdash \_$ ) : Formulas Formulas -> Sequent .

  subsort Id < Ids .
  op nil : -> Ids .
  op  $\_,\_$  : Ids Ids -> Ids [assoc id: nil] .

  subsort Sequent < Sequents .
  op nil : -> Sequents .
```

```

op _,_ : Sequents Sequents -> Sequents [assoc id: nil] .
op <_|_> : Ids Sequents -> LLTheory? .

var C : Ids .

endfm

```

An order-sorted rewrite theory has much more structure, and therefore the corresponding RWL-ADT is more complex, but the basic ideas are completely similar as we sketch here. First we have an order-sorted signature, declaring sorts, subsorts, constants, operations, and variables. Then, in addition, we have equations and rules. Thus, a finitely presentable rewrite theory is represented as a term $\langle S \mid E \mid R \rangle$, where S is a term representing a signature, E is a list of equations, and R is a list of rules. In turn, the term S has the form $\langle T ; B ; C ; O ; V \rangle$ where each subterm corresponds to a component of a signature as mentioned before. In addition, several sort constraints are necessary to ensure for example that the variables used in equations and rules are included in the list of variables. Just to give the flavor of the construction, here is a small fragment of the module RWL-ADT, where we have omitted most of the list constructors, operations to handle conditional equations and rules, and sort constraints.

```

sorts Sort Subsort Constant Op Var .
sorts Term Equation Rule Signature RWLTheory .

op sort{ _ } : Id -> Sort .
subsort Sort < Sorts .
op nil : -> Sorts .
op __ : Sorts Sorts -> Sorts [assoc id: nil] .
op ( _<_ ) : Id Id -> Subsort .
subsort Subsort < Subsorts .

op ( cons{ _ } : sort{ _ } ) : Id Id -> Constant .
subsort Constant < Constants .
op nil : -> Constants .
op _,_ : Constants Constants -> Sorts [assoc id: nil] .

op ( op{ _ } : _ -> sort{ _ } ) : Id Sorts Id -> Op .
subsort Op < Ops .
op ( var{ _ } : sort{ _ } ) : Id Id -> Var .
subsort Var < Vars .

```

```

op <_:_;_:_;_:_> : Sorts Subsorts Constants Ops Vars -> Signature .
subsort Var < Term .
subsort Constant < Term .

op op{_[_]}[_] : Id Terms -> Term .
op _,_ : Terms Terms -> Terms [assoc id: nil] .

op (=__) : Term Term -> Equation .
subsort Equation < Equations .
op (=>_) : Term Term -> Rule .
subsort Rule < Rules .
op <_||_> : Signature Equations Rules -> RWLTheory .
    
```

Having defined the abstract data types to represent both linear and rewrite theories, we define a function $\overline{\Phi}$ mapping a term in `LLTheory` representing a linear theory T to a term in `RWLTheory` representing the corresponding rewrite theory `LINLOG(T)` as defined in Section 4.3. First note that the rewrite theory `LINLOG` presented in Section 4.3 gives rise to a term in `RWLTheory` that we denote

$$\langle\langle T_{LL} ; B_{LL} ; C_{LL} ; O_{LL} ; V_{LL} \rangle \mid E_{LL} \mid R_{LL} \rangle.$$

The representation $\langle C \mid F_1 \vdash G_1, \dots, F_n \vdash G_n \rangle$ of a linear logic theory is then mapped by $\overline{\Phi}$ to the following term

$$\langle\langle T_{LL} ; B_{LL} ; \text{cons}(C), C_{LL} ; O_{LL} ; V_{LL} \rangle \mid E_{LL} \mid R_{LL}, ([\text{tensor}(F_1)] \Rightarrow [\text{par}(G_1)]), \dots, ([\text{tensor}(F_n)] \Rightarrow [\text{par}(G_n)]) \rangle$$

where the auxiliary operations `cons`, `tensor` and `par` are defined as follows, and correspond exactly to the description in Section 4.3.

```

op tensor : Formulas -> Formula .
op par : Formulas -> Formula .
op cons : Ids -> Constants .

var F : Formula .    vars F1 F2 : Formulas .
var I : Id .         var L : Ids .

eq tensor(null) = 1 .
eq tensor(F) = F .
eq tensor(F1,F2) = tensor(F1)  $\otimes$  tensor(F2) .
eq par(null) =  $\perp$  .
eq par(F) = F .
eq par(F1,F2) = par(F1)  $\wp$  par(F2) .
eq cons(nil) = nil .
eq cons(I,L) = (cons{I}:sort{Atom}),cons(L) .
    
```

We can summarize the reification $\overline{\Phi} : \text{LL-ADT} \rightarrow \text{RWL-ADT}$ of the map of logics $\Phi : \text{LinLogic} \rightarrow \text{OSRWLogic}$ we have just defined by means of the following commutative diagram:

$$\begin{array}{ccc}
 \text{LL-ADT} & \xrightarrow{\overline{\Phi}} & \text{RWL-ADT} \\
 \downarrow & & \downarrow \\
 \text{LinLogicTh} & \xrightarrow{\Phi} & \text{OSRWLogicTh}
 \end{array}$$

This method is completely general, in that it should apply to any effectively presented map of logics $\Psi : \mathcal{L} \rightarrow \text{RWLogic}$ that maps finitely presentable theories in \mathcal{L} to finitely presentable theories in rewriting logic. Indeed, the effectiveness of Ψ should exactly mean that the corresponding $\overline{\Psi} : \mathcal{L}\text{-ADT} \rightarrow \text{RWL-ADT}$ is a computable function and therefore, by the metatheorem of Bergstra and Tucker [1980], that it is specifiable by a finite set of Church-Rosser and terminating equations inside rewriting logic.

5 REWRITING LOGIC AS A SEMANTIC FRAMEWORK

After an overview of rewriting logic as a general model of computation that unifies many other existing models, the cases of concurrent object-oriented programming and of Milner's CCS are treated in greater detail. Structural operational semantics is discussed as a specification formalism similar in some ways to rewriting logic, but more limited in its expressive capabilities. Rewriting logic can also be very useful as a semantic framework for many varieties of constraint solving in logic programming and in automated deduction. Finally, the representation of action and change in rewriting logic and the consequent solution of the “frame problem” difficulties associated with standard logics are also discussed.

5.1 Generality of rewriting logic as a model of computation

Concurrent rewriting is a very general model of concurrency from which many other models can be obtained by specialization. Except for concurrent object-oriented programming and CCS that are further discussed in Sections 5.2 and 5.3, respectively, we refer the reader to [Meseguer, 1992; Meseguer, 1996] for a detailed discussion of the remaining models, and summarize here such specializations using Figure 1, where RWL stands for rewriting logic, the arrows indicate specializations, and the subscripts \emptyset , AI , and ACI stand for syntactic rewriting, rewriting modulo associativity and identity, and rewriting modulo associativity, commutativity, and identity, respectively.

Figure 1. Unification of models of computation.

Within syntactic rewriting we have labelled transition systems, which are used in interleaving approaches to concurrency; functional programming (in particular Maude’s functional modules) corresponds to the case of *confluent*¹³ rules, and includes the lambda calculus and the Herbrand-Gödel-Kleene theory of recursive functions. Rewriting modulo *AI* yields Post systems and related grammar formalisms, including Turing machines. Besides the general treatment by *ACI*-rewriting of concurrent object-oriented programming, briefly described in Section 5.2, that contains Actors [Agha, 1986], neural networks, graph rewriting, and the dataflow model as a special case [Meseguer, 1996], rewriting modulo *ACI* includes Petri nets [Reisig, 1995], the Gamma language of Banâtre and Le Métayer [1990], and Berry and Boudol’s *chemical abstract machine* [1992] (which itself specializes to CCS [Milner, 1989]; see [Berry and Boudol, 1992] and also the treatment in Section 5.3), as well as Unity’s model of computation [Chandy and Misra, 1988].

The *ACI* case is quite important, since it contains as special subcases a good number of concurrency models that have already been studied. In fact, the associativity and commutativity of the axioms appear in some of those models as “fundamental laws of concurrency.” However, from the perspective of this work the *ACI* case, while being important and useful, does not have a monopoly on the concurrency business. Indeed, “fundamental laws of concurrency” expressing associativity and commutativity are only valid in this particular case. They are for example meaningless for the tree-structured case of functional programming. The point is that the laws satisfied by a concurrent system cannot be determined *a priori*. They essentially depend on the actual distributed structure of the system, which is its algebraic structure.

5.2 Concurrent object-oriented programming

Concurrent object-oriented programming is a very active area of research. An important reason for this interest is the naturalness with which this style of programming can model concurrent interactions between objects in the real world. However, the field of concurrent object-oriented programming seems at present to lack a clear, agreed-upon semantic basis.

Rewriting logic supports a logical theory of concurrent objects that addresses these conceptual needs in a very direct way. We summarize here the key ideas regarding Maude’s object-oriented modules; a full discussion of Maude’s object-oriented aspects can be found in [Meseguer, 1993; Meseguer, 1993b].

An *object* in a given state can be represented as a term

¹³Although not reflected in the picture, rules confluent *modulo* equations *E* are also functional.

```
< 0 : C | a1 : v1, ... , an : vn >
```

where 0 is the object's name, belonging to a set OID of object identifiers, C is its class, the ai 's are the names of the object's *attributes*, and the vi 's are their corresponding values, which typically are required to be in a sort appropriate for their corresponding attribute. The *configuration* is the distributed state of the concurrent object-oriented system and is represented as a multiset of objects and messages according to the following syntax:

```
subsorts Object Message < Configuration .
op __ : Configuration Configuration -> Configuration
      [assoc comm id: null] .
```

where the operator $__$ is associative and commutative with identity `null` and is interpreted as multiset union, and the sorts `Object` and `Message` are subsorts of `Configuration` and generate data of that sort by multiset union. The system evolves by concurrent *ACI*-rewriting of the configuration by means of rewrite rules specific to each particular system, whose lefthand and righthand sides may in general involve patterns for several objects and messages. By specializing to patterns involving only one object and one message, we can obtain an abstract, declarative, and truly concurrent version of the Actor model [Agha, 1986] (see [Meseguer, 1993, Section 4.7]).

Maude's syntax for object-oriented modules is illustrated by the object-oriented module `ACCNT` below which specifies the concurrent behavior of objects in a very simple class `Accnt` of bank accounts, each having a `bal(ance)` attribute, which may receive messages for crediting or debiting the account, or for transferring funds between two accounts. We assume an already defined functional module `INT` for integers with a subsort relation `Nat < Int` and an ordering predicate `_>=_`.

After the keyword `class`, the name of the class (`Accnt` in this case) is given, followed by a “|” and by a list of pairs of the form `a : S` separated by commas, where `a` is an attribute identifier and `S` is the sort inside which the values of such an attribute identifier must range in the given class. In this example, the only attribute of an account is its `bal(ance)`, which is declared to be a value in `Nat`. The three kinds of messages involving accounts are `credit`, `debit`, and `transfer` messages, whose user-definable syntax is introduced by the keyword `msg`. The rewrite rules specify in a declarative way the behavior associated to the `credit`, `debit`, and `transfer` messages.

```
omod ACCNT is
  protecting INT .
  class Accnt | bal : Nat .
  msgs credit debit : OId Nat -> Msg .
  msg transfer_from_to_ : Nat OId OId -> Msg .

  vars A B : OId .
```

```

vars M N N' : Nat .
rl credit(A,M) < A : Accnt | bal: N >
=> < A : Accnt | bal: N + M > .
crl debit(A,M) < A : Accnt | bal: N >
=> < A : Accnt | bal: N - M > if N >= M .
crl transfer M from A to B
< A : Accnt | bal: N > < B : Accnt | bal: N' >
=> < A : Accnt | bal: N - M > < B : Accnt | bal: N' + M >
if N >= M .
endom

```

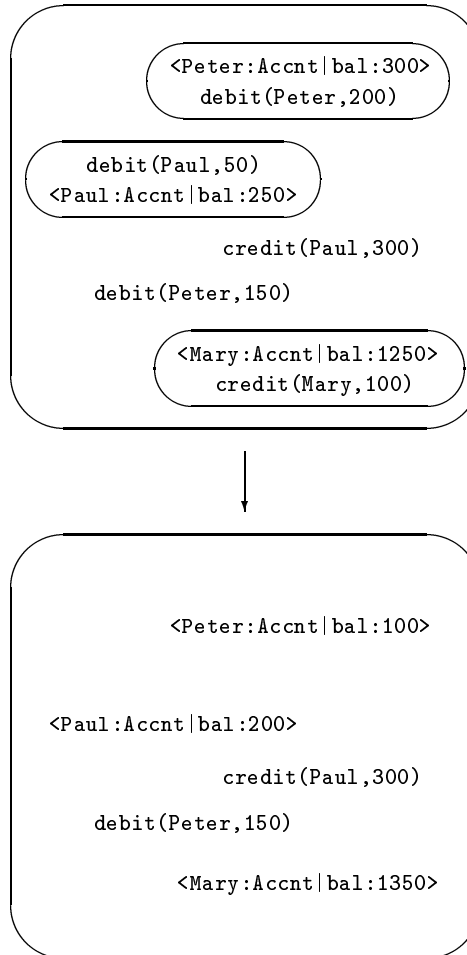

Figure 2. Concurrent rewriting of bank accounts.

The multiset structure of the configuration provides the top level distributed structure of the system and allows concurrent application of the rules. For example, Figure 2 provides a snapshot in the evolution by concurrent rewriting of a simple configuration of bank accounts. To simplify the picture, the arithmetic operations required to update balances have already been performed. However, the reader should bear in mind that the values in the attributes of an object can also be computed by means of rewrite rules, and this adds yet another important level of concurrency to a concurrent object-oriented system, which might be called *intra-object concurrency*.

Intuitively, we can think of messages as “traveling” to come into contact with the objects to which they are sent and then causing “communication events” by application of rewrite rules. In rewriting logic, this traveling is accounted for in a very abstract way by the *ACI* structural axioms. This abstract level supports both synchronous and asynchronous communication and provides great freedom and flexibility to consider a variety of alternative implementations at lower levels.

Although Maude provides convenient syntax for object-oriented modules, the syntax and semantics of such modules can be reduced to those of system modules, i.e., we can systematically translate an object-oriented module `omod \mathcal{O} endom` into a corresponding system module `mod $\mathcal{O}\#$ endm`, where $\mathcal{O}\#$ is a theory in rewriting logic. A detailed account of this translation process can be found in [Meseguer, 1993].

5.3 CCS

Milner’s *Calculus of Communicating Systems* (CCS) [Milner, 1980; Milner, 1989; Milner, 1990] is among the best well-known and studied concurrency models, and has become the paradigmatic example of an entire approach to “process algebras.” We just give a very brief introduction to CCS, referring the reader to Milner’s book [1989] for motivation and a comprehensive treatment, before giving two alternative formulations of CCS in rewriting logic and showing the conservativity of these formulations.

We assume a set A of *names*; the elements of the set $\bar{A} = \{\bar{a} \mid a \in A\}$ are called *co-names*, and the members of the (disjoint) union $\mathcal{L} = A \cup \bar{A}$ are *labels* naming ordinary actions. The function $a \mapsto \bar{a}$ is extended to \mathcal{L} by defining $\bar{\bar{a}} = a$. There is a special action called *silent action* and denoted τ , intended to represent internal behaviour of a system, and in particular the synchronization of two processes by means of actions a and \bar{a} . Then the set of *actions* is $\mathcal{L} \cup \{\tau\}$. The set of processes is intuitively defined as follows:

- 0 is an inactive process that does nothing.
- If α is an action and P is a process, $\alpha.P$ is the process that performs α and subsequently behaves as P .

- If P and Q are processes, $P + Q$ is the process that may behave as either P or Q .
- If P and Q are processes, $P|Q$ represents P and Q running concurrently with possible communication via synchronization of the pair of ordinary actions a and \bar{a} .
- If P is a process and $f : \mathcal{L} \rightarrow \mathcal{L}$ is a relabelling function such that $f(\bar{a}) = \overline{f(a)}$, $P[f]$ is the process that behaves as P but with the actions relabelled according to f , assuming $f(\tau) = \tau$.
- If P is a process and $L \subseteq \mathcal{L}$ is a set of ordinary actions, $P \setminus L$ is the process that behaves as P but with the actions in $L \cup \bar{L}$ prohibited.
- If P is a process, I is a process identifier, and $I =_{def} P$ is a defining equation where P may recursively involve I , then I is a process that behaves as P .

This intuitive explanation can be made precise in terms of the following structural operational semantics that defines a labelled transition system for CCS processes.

Action:

$$\frac{}{\alpha.P \xrightarrow{\alpha} P}$$

Summation:

$$\frac{P \xrightarrow{\alpha} P'}{P + Q \xrightarrow{\alpha} P'} \qquad \frac{Q \xrightarrow{\alpha} Q'}{P + Q \xrightarrow{\alpha} Q'}$$

Composition:

$$\frac{P \xrightarrow{\alpha} P'}{P|Q \xrightarrow{\alpha} P'|Q} \qquad \frac{Q \xrightarrow{\alpha} Q'}{P|Q \xrightarrow{\alpha} P|Q'}$$

$$\frac{P \xrightarrow{a} P' \quad Q \xrightarrow{\bar{a}} Q'}{P|Q \xrightarrow{\tau} P'|Q'}$$

Relabelling:

$$\frac{P \xrightarrow{\alpha} P'}{P[f] \xrightarrow{f(\alpha)} P'[f]}$$

Restriction:

$$\frac{P \xrightarrow{\alpha} P'}{P \setminus L \xrightarrow{\alpha} P' \setminus L} \quad \alpha \notin L \cup \bar{L}$$

Definition:

$$\frac{P \xrightarrow{\alpha} P'}{I \xrightarrow{\alpha} P'} \quad I =_{def} P$$

We now show how CCS can be described and given semantics in rewriting logic. The following modules have been motivated by, but are considerably different from, the corresponding examples in [Meseguer *et al.*, 1992].

```
fth LABEL is
  sort Label .      *** ordinary actions
  op ~_ : Label -> Label .
  var N : Label .
  eq ~N = N .
endft

--- an action is the silent action or a label
fmod ACTION[X :: LABEL] is
  sort Act .
  subsort Label < Act .
  op tau : -> Act .      *** silent action
endfm

fth PROCESSID is
  sort ProcessId .   *** process identifiers
endft

--- CCS syntax
fmod PROCESS[X :: LABEL, Y :: PROCESSID] is
  protecting ACTION[X] .
  sort Process .
  subsort ProcessId < Process .
  op 0 : -> Process .      *** inaction
  op _._ : Act Process -> Process .      *** prefix
  op _+_ : Process Process -> Process [assoc comm idem id: 0] .
  *** summation
  op _|_ : Process Process -> Process [assoc comm id: 0] .
  *** composition
  op _[_/_] : Process Label Label -> Process .
  *** relabelling: [b/a] relabels "a" to "b"
  op _\_ : Process Label -> Process .      *** restriction
endfm
```

Before defining the operational semantics of CCS processes, we need an auxiliary module in order to build contexts in which process identifiers can be associated with processes, providing in this way recursive definitions of processes. A sort constraint [Meseguer and Goguen, 1993], which is introduced with the keyword `sct` and defines a subsort `Context` by means

of a condition, is used to enforce the requirement that the same process identifier cannot be associated with two different processes in a context.

```

--- defining equations and contexts
fmod CCS-CONTEXT[X :: LABEL, Y :: PROCESSID] is
  protecting PROCESS[X,Y] .
  sorts Def Context Context? .
  subsorts Def < Context < Context? .
  op (_ =def _) : ProcessId Process -> Def .
  protecting LIST[ProcessId]*(op _;_ to __) .
  protecting LIST[Def]*(sort List to Context?) .
  op nil : -> Context .
  op pid : Context? -> List .

  var X : ProcessId .      var P : Process .
  var C : Context .        vars D D' : Context? .

  eq pid(nil) = nil .
  eq pid((X =def P)) = X .
  eq pid(D;D') = pid(D) pid(D') .
  sct (X =def P);C : Context if not(X in pid(C)) .
endfm

```

The semantics of CCS processes is usually defined relative to a given context that provides defining equations for all the necessary process identifiers [Milner, 1989, Section 2.4]. The previous module defines the data type of all contexts. We now need to parameterize the module defining the CCS semantics by the choice of a context. This is accomplished by means of the following theory that picks up a context in the sort `Context`.

```

fth CCS-CONTEXT*[X :: LABEL, Y :: PROCESSID] is
  protecting CCS-CONTEXT[X,Y] .
  op context : -> Context .
endft

```

As in the case of linear logic, we have two possibilities in order to write the operational semantics for CCS by means of rewrite rules. On the one hand, we can interpret a transition $P \xrightarrow{\alpha} P'$ as a rewrite, so that the above operational semantics rules become conditional rewrite rules. On the other hand, the transition $P \xrightarrow{\alpha} P'$ can be seen as a term, forming part of a configuration, in such a way that the semantics rules correspond to rewrite rules, as a particular case of the general mapping of sequent systems into rewriting logic that we have presented in Section 4.5.

```

--- CCS transitions
mod CCS1[X :: LABEL, Y :: PROCESSID, C :: CCS-CONTEXT*[X,Y]] is
  sort ActProcess .

```

```

subsort Process < ActProcess .
op {_}_ : Act ActProcess -> ActProcess .
*** {A}P means action A has been performed thus becoming process P

vars P P' Q Q' : Process .    vars L M : Label .
var X : ProcessId .          var A : Act .

*** Prefix
rl A . P => {A}P .

*** Summation
crl P + Q => {A}P' if P => {A}P' .

*** Composition
crl P | Q => {A}(P' | Q) if P => {A}P' .
crl P | Q => {tau}(P' | Q') if P => {L}P' and Q => {~L}Q' .

*** Restriction
crl P \ L => {A}(P' \ L)
    if P => {A}P' and not(A == L) and not(A == ~L) .

*** Relabelling
crl P[M / L] => {M}(P'[M / L]) if P => {L}P' .
crl P[M / L] => {~M}(P'[M / L]) if P => {~L}P' .
crl P[M / L] => {A}(P'[M / L])
    if P => {A}P' and not(A == L) and not(A == ~L) .

*** Definition
crl X => {A}P' if (X =def P) in context and P => {A}P' .
endm

```

In the above module, the rewrite rules have the property of being sort-increasing, i.e., in a rule $[t] \longrightarrow [t']$ the least sort of $[t']$ is bigger than the least sort of $[t]$. Thus, one rule cannot be applied unless the resulting term is well-formed. This prevents, for example, rewrites of the following form:

$$\{A\}(P \mid Q) \longrightarrow \{A\}(\{B\}P' \mid \{C\}Q')$$

because the term on the righthand side is not well formed according to the order-sorted signature of the module $\text{CCS1}[X, Y, C[X, Y]]$. More precisely, the *Congruence* rule of order-sorted rewriting logic, like the corresponding rule of order-sorted algebra [Goguen and Meseguer, 1992], cannot be applied unless the resulting term $f(t_1, \dots, t_n)$ is well formed according to the given order-sorted signature. To illustrate this point further, although $A.P \longrightarrow \{A\}P$ is a correct instance of the *Prefix* rewrite rule, we cannot use the *Congruence* rule to derive

$$(A.P) \mid Q \longrightarrow (\{A\}P) \mid Q$$

because the second term $(\{A\}P) \mid Q$ is not well formed.

The net effect of this restriction is that an `ActProcess` term of the form $\{A1\} \dots \{Ak\}P$ can only be rewritten into another term of the same form $\{A1\} \dots \{Ak\}\{B\}P'$, assuming that $P \longrightarrow \{B\}P'$ is a `CCS1[X,Y,C[X,Y]]`-rewrite. As another example, a process of the form $A.B.P$ can be rewritten first into $\{A\}B.P$ and then into $\{A\}\{B\}P$, but cannot be rewritten into $A.\{B\}P$, because this last term is not well formed. After this discussion, it is easy to see that we have the following conservativity result.

THEOREM 16. Given a `CCS` process P , there are processes P_1, \dots, P_{k-1} such that

$$P \xrightarrow{a_1} P_1 \xrightarrow{a_2} \dots \xrightarrow{a_{k-1}} P_{k-1} \xrightarrow{a_k} P'$$

if and only if P can be rewritten into $\{a1\} \dots \{ak\}P'$ using the rules in the module `CCS1[X,Y,C[X,Y]]`.

Note also that, since the operators `_+_` and `_|_` are declared commutative, one rule is enough for each one, instead of the two rules in the original presentation. On the other hand, we need three rules for relabelling, due to the representation of the relabelling function.

Let us consider now the second possibility, using the same idea described in Section 4.5 for the linear logic sequent calculus, that, as we have already mentioned there, is applicable to many more cases, with a very broad understanding of the term “sequent.”

```

--- CCS operational semantics
mod CCS2[X :: LABEL, Y :: PROCESSID, C :: CCS-CONTEXT*[X,Y]] is
  sort Configuration .

  op (_:-->_) : Act Process Process -> Configuration .
  op empty : -> Configuration .
  op -- : Configuration Configuration -> Configuration
          [assoc comm id: empty] .
  *** a configuration is a multiset of transitions

  vars P P' Q Q' : Process .    vars L M : Label .
  var X : ProcessId .          var A : Act .

  *** Prefix
  rl
    empty
  => -----
    (A : (A . P) --> P) .

  *** Summation

rl      (L : P --> P')
=> -----
      (M : P[M / L] --> P'[M / L]) .

rl      (~L : P --> P')
=> -----
      (~M : P[M / L] --> P'[M / L]) .

crl     (A : P --> P')
=> -----
      (A : P[M / L] --> P'[M / L])
if not(A == L) and not(A == ~L) .

*** Definition
crl     (A : P --> P')
=> -----
      (A : X --> P')
if (X =def P) in context .

endm

```

Except for the difference in the number of rules for some operators, as already pointed out above for the module $\text{CCS1}[X, Y, C[X, Y]]$, this presentation is closer to the original one, and therefore the following conservativity result is immediate.

THEOREM 17. For CCS processes P and P' , a transition $P \xrightarrow{A} P'$ is possible according to the structural operational semantics of CCS if and only if

$$\text{empty} \longrightarrow (A : P \longrightarrow P')$$

is provable in rewriting logic from the rewrite theory $\text{CCS2}[X, Y, C[X, Y]]$.

5.4 Structural operational semantics

Structural operational semantics is an approach originally introduced by Plotkin [1981] in which the operational semantics of a programming language is specified in a logical way, independent of machine architecture or implementation details, by means of rules that provide an inductive definition based on the structure of the expressions in the language. We refer the reader to Hennessy’s book [1990] for a clear introduction to this subject.

Within “structural operational semantics,” two main approaches coexist:

- *Big-step semantics* (also called *natural semantics* by Kahn [1987], Gunter [1991], and Nielson and Nielson [1992], and *evaluation semantics* by Hennessy [1990]). In this approach, the main inductive predicate describes the overall result or value of executing a computation until its termination. For this reason, it is not well suited for languages like CCS where most programs are not intended to be terminating.
- *Small-step semantics* (also called *structural operational semantics* by Plotkin [1981], and Nielson and Nielson [1992], *computation semantics* by Hennessy [1990], and *transition semantics* by Gunter [1991]). In this approach, the main inductive predicate describes in more detail the execution of individual steps in a computation, with the overall computation roughly corresponding to the transitive closure of such small steps. The structural operational semantics of CCS presented at the beginning of Section 5.3 is an example.

Both big-step and small-step approaches to structural operational semantics can be naturally expressed in rewriting logic:

- Big-step semantics can be seen as a particular case of the mapping of sequent systems described in Section 4.5, where semantics rules are mapped to rewrite rules over a “configuration” of sequents or predicates, and the rewriting relation means provability of such a predicate.
- Small-step semantics corresponds to the use of conditional rewrite rules, where a rewrite $t \longrightarrow t'$ means a transition or computation step from a state t to a new state t' as in the explanation of rewriting logic given in Section 3.3. This is illustrated by the $\text{CCS1}[X, Y, C[X, Y]]$ example in Section 5.3. However, as the $\text{CCS2}[X, Y, C[X, Y]]$ example shows, the technique of sequent systems of Section 4.5 can also be used in this case.

Since the CCS example has already been discussed in detail in Section 5.3, we give here another example, describing the operational semantics of the functional language Mini-ML taken with slight modifications from Kahn’s

paper [1987]. The first thing to point out about this example is that the specification of a language's syntax is outside of the structural operational semantics formalism. By contrast, thanks to the order-sorted type structure of rewriting logic, such specification is now given by a functional module in Maude, as follows:

```
fmod NAT-TRUTH-VAL is
  sort Nat .
  op 0 : -> Nat .
  op s : Nat -> Nat .
  sort TruthVal .
  ops true false : -> TruthVal .
endfm

--- syntax: values, patterns and expressions
fmod ML-SYNTAX[X :: VAR] is
  protecting NAT-TRUTH-VAL .
  sorts Exp Value Pat NullPat Lambda .

  subsorts NullPat Var < Pat .
  op () : -> NullPat .
  op (_,_) : Pat Pat -> Pat .
  subsorts TruthVal Nat NullPat < Value .
  op (_,_) : Value Value -> Value .
  subsorts Value Var Lambda < Exp .
  op s : Exp -> Exp .
  op _+_ : Exp Exp -> Exp [comm] .
  op not : Exp -> Exp .
  op _and_ : Exp Exp -> Exp .
  op if_then_else_ : Exp Exp Exp -> Exp .
  op (_,_) : Exp Exp -> Exp .
  op __ : Exp Exp -> Exp .
  op λ_._ : Pat Exp -> Lambda .
  op let=_in_ : Pat Exp Exp -> Exp .
  op letrec=_in_ : Pat Exp Exp -> Exp .
endfm

--- environments are lists of pairs pattern-value
fmod AUX[X :: VAR] is
  protecting ML-SYNTAX[X] .
  sort Pair .
  op <_,_> : Pat Value -> Pair .
  protecting LIST[Pair]*(sort List to Env, op _;_ to __) .
  op Clos : Lambda Env -> Value .
endfm
```

The following module constitutes a direct translation of the natural semantics specification for Mini-ML given by Kahn in [1987], using the general

technique for sequent systems introduced in Section 4.5. Note that the natural semantics rules are particularly well suited for Prolog search, and indeed they are so executed in the system described in [Kahn, 1987].

```

--- natural semantics a la Kahn
mod ML-NAT-SEMANT[X :: VAR] is
  including AUX[X] .
  sort Config .
  op (_|-_-->_) : Env Exp Value -> Config .
  op empty : -> Config .

cr1 [[letrec P = E in F]]V => [[F]](V <P,A>)
    if [[E]]((V <P,A>) => A) .
endm

```

This concludes our discussion of structural operational semantics. Compared with rewriting logic, one of its limitations is the lack of support for structural axioms yielding more abstract data representations. Therefore, the rules must follow a purely syntactic structure, and more rules may in some cases be necessary than if an abstract representation had been chosen. In the case of multiset representations (corresponding to associativity, commutativity, and identity axioms), this has led Milner to favor multiset rewriting presentations [Milner, 1992] in the style of the chemical abstract machine of Berry and Boudol [1992] over the traditional syntactic presentation of structural operational semantics.

5.5 Constraint solving

Deduction can in many cases be made much more efficient by making use of *constraints* that can drastically reduce the search space, and for which special purpose constraint solving algorithms can be much faster than the alternative of expressing everything in a unique deduction mechanism such as some form of resolution.

Typically, constraints are symbolic expressions associated with a particular *theory*, and a constraint solving algorithm uses intimate knowledge about the truths of the theory in question to find solutions for those expressions by transforming them into expressions in *solved form*. One of the simplest examples is provided by standard syntactic unification—the

constraint solver for resolution in first-order logic without equality and in particular for Prolog—where the constraints in question are equalities between terms in a free algebra, i.e., in the so-called Herbrand universe. There are however many other constraints and constraint solving algorithms that can be used to advantage in order to make the representation of problems more expressive and logical deduction more efficient. For example,

- *Semantic unification* (see for example the survey by Jouannaud and Kirchner [1991]), which corresponds to solving equations in a given equational theory.
- *Sorted unification*, either many-sorted or order-sorted [Walther, 1985; Walther, 1986; Schmidt-Schauss, 1989; Meseguer *et al.*, 1989; Smolka *et al.*, 1989; Jouannaud and Kirchner, 1991], where type constraints are added to variables in equations.
- *Higher-order unification* [Huet, 1973; Miller, 1991], which corresponds to solving equations between λ -expressions.
- *Disunification* [Comon, 1991], which corresponds to solving not only equalities but also negated equalities.
- *Solution of equalities and inequalities in a theory*, as for example the solution of numerical constraints built into the constraint logic programming language $CLP(\mathcal{R})$ [Jaffar and Lassez, 1987] and in other languages.

A remarkable property shared by most constraint-solving processes, and already implicit in the approach to syntactic unification problems proposed by Martelli and Montanari [1982], is that the process of solving constraints can be naturally understood as one of applying transformations to a set or multiset of constraints. Furthermore, many authors have realized that the most elegant and simple way to specify, prove correct, or even implement many constraint solving problems is by expressing those transformations as rewrite rules (see for example [Goguen and Meseguer, 1988; Jouannaud and Kirchner, 1991; Comon, 1990; Comon, 1991; Nipkow, 1993]). In particular, the survey by Jouannaud and Kirchner [1991] makes this viewpoint the cornerstone of a unified conceptual approach to unification.

For example, the so-called *decomposition* transformation present in syntactic unification and in a number of other unification algorithms can be expressed by a rewrite rule of the form

$$\begin{aligned} \text{r1 } f(t_1, \dots, t_n) &=?= f(t'_1, \dots, t'_n) \\ &=> (t_1 =?= t'_1) \dots (t_n =?= t'_n) . \end{aligned}$$

where in the righthand side multiset union has been expressed by juxtaposition.

Although the operational semantics of such rewrite rules is very obvious and intuitive, their logical or mathematical semantics has remained ambiguous. Although appeal is sometimes made to equational logic as the framework in which such rules exist, the fact that many of these rules are nondeterministic, so that, except for a few exceptions such as syntactic unification, there is in general not a unique solution but rather a, sometimes infinite, set of solutions, makes an interpretation of the rewrite rules as equations highly implausible and potentially contradictory.

We would like to suggest that rewriting logic provides a very natural framework in which to interpret rewrite rules of this nature and, more generally, deduction processes that are nondeterministic in nature and involve the exploration of an entire space of solutions. Since in rewriting logic rewrite rules go only in one direction and its models do not assume either the identification of the two sides of a rewrite step, or even the possible reversal of such a step, all the difficulties involved in an equational interpretation disappear.

Such a proposed use of rewriting logic for constraint solving and constraint programming seems very much in the spirit of recent rewrite rule approaches to constrained deduction such as those of C. Kirchner, H. Kirchner, and M. Rusinovitch [1990] (who use a general notion of constraint language proposed by Smolka [1989]), Bachmair, Ganzinger, Lynch, and Snyder [1992], Nieuwenhuis and Rubio [1992], and Giunchiglia, Pecchiari, and Talcott [1996]. In particular, the ELAN language of C. Kirchner, H. Kirchner, and M. Vittek [1995] (see also [Borovanský *et al.*, 1996]) proposes an approach to the prototyping of constraint solving languages similar in some ways to the one that would be natural using a Maude interpreter.

Exploring the use of rewriting logic as a semantic framework for languages and theorem-proving systems using constraints seems a worthwhile research direction not only for systems used in automated deduction, but also for parallel logic programming languages such as those surveyed in [Shapiro, 1989], the Andorra language [Janson and Haridi, 1991], concurrent constraint programming [Saraswat, 1992], and the Oz language [Henz *et al.*, 1995].

5.6 *Action and change in rewriting logic*

In the previous sections, we have shown the advantages of rewriting logic as a logical framework in which other logics can be represented, and as a semantic framework for the specification of languages and systems. We would like the class of systems that can be represented to be as wide as possible, and their representation to be as natural and direct as possible. In particular, an important point that has to be considered is the representation of action and change in rewriting logic. In our paper [Martí-Oliet and Meseguer, 1999], we show that rewriting logic overcomes the frame problem, and subsumes and

unifies a number of previously proposed logics of change. In this section, we illustrate this claim by means of an example, referring the reader to the cited paper for more examples and discussion.

The frame problem [McCarthy and Hayes, 1969; Hayes, 1987; Janlert, 1987] consists in formalizing the assumption that facts are preserved by an action unless the action explicitly says that a certain fact becomes true or false. In the words of Patrick Hayes [1987],

“There should be some economical and principled way of succinctly saying what changes an action makes, without having to explicitly list all the things it doesn’t change as well [...]. *That* is the frame problem.”

Recently, some new logics of action and change have been proposed, among which we can point out the approach of Hölldobler and Schneeberger [1990] (see also [Große *et al.*, 1996; Große *et al.*, 1992]), based on Horn logic with equations, and the approach of Masseron, Tollu, and Vauzeilles [1990; 1993], based on linear logic. The main interest of these formalisms is that they need not explicitly state frame axioms, because they treat facts as resources which are produced and consumed. Having proved in Sections 4.2 and 4.3, respectively, that Horn logic with equations and linear logic can be conservatively mapped into rewriting logic, it is not surprising that the advantages of the two previously mentioned approaches are also shared by rewriting logic. In particular, the rewriting logic rules automatically take care of the task of preserving context, making unnecessary the use of any frame axioms stating the properties that do not change when a rule is applied to a certain state.

We illustrate this point by means of a blocksworld example, borrowed from [Hölldobler and Schneeberger, 1990; Masseron *et al.*, 1990].

```
fth BLOCKS is
  sort BlockId .
endft

mod BLOCKWORLD[X :: BLOCKS] is
  sort Prop .
  op table : BlockId -> Prop .      *** block is on the table
  op on : BlockId BlockId -> Prop . *** block A is on block B
  op clear : BlockId -> Prop .      *** block is clear
  op hold : BlockId -> Prop .       *** robot hand is holding block
  op empty : -> Prop .              *** robot hand is empty

  sort State .
  subsort Prop < State .
  op 1 : -> State .
  op _⊗_ : State State -> State [assoc comm id: 1] .
```

Figure 3. Two states of a blockworld.

```

vars X Y : BlockId .
rl pickup(X) : empty ⊗ clear(X) ⊗ table(X) => hold(X) .
rl putdown(X) : hold(X) => empty ⊗ clear(X) ⊗ table(X) .
rl unstack(X,Y) : empty ⊗ clear(X) ⊗ on(X,Y)
=> hold(X) ⊗ clear(Y) .
rl stack(X,Y) : hold(X) ⊗ clear(Y)
=> empty ⊗ clear(X) ⊗ on(X,Y) .
endm
    
```

In order to create a world with three blocks $\{a,b,c\}$, we consider the following instantiation of the previous parameterized module.

```

fmod BLOCKS3 is
  sort BlockId .
  ops a b c : -> BlockId .
endfm

make WORLD is BLOCKWORLD[BLOCKS3] endmk
    
```

Consider the states described in Figure 3; the state I on the left is the initial one, described by the following term of sort `State` in the rewrite theory (Maude program) `WORLD`

```
empty ⊗ clear(c) ⊗ clear(b) ⊗ table(a) ⊗ table(b) ⊗ on(c,a) .
```

Analogously, the final state F on the right is described by the term

```
empty ⊗ clear(a) ⊗ table(c) ⊗ on(a,b) ⊗ on(b,c) .
```

The fact that the plan

```
unstack(c,a);putdown(c);pickup(b);stack(b,c);pickup(a);stack(a,b)
```

moves the blocks from state I to state F corresponds directly to the following WORLD-rewrite (proof in rewriting logic), where we also show the use of the structural axioms of associativity and commutativity:

$$\begin{aligned}
& \text{empty} \otimes \text{clear}(c) \otimes \text{clear}(b) \otimes \text{table}(a) \otimes \text{table}(b) \otimes \text{on}(c,a) \\
& = \\
& \text{empty} \otimes \text{clear}(c) \otimes \text{on}(c,a) \otimes \text{clear}(b) \otimes \text{table}(a) \otimes \text{table}(b) \\
& \longrightarrow \text{Cong}[\text{Repl}[\text{unstack}(c,a)], \text{Refl}] \\
& \text{hold}(c) \otimes \text{clear}(a) \otimes \text{clear}(b) \otimes \text{table}(a) \otimes \text{table}(b) \\
& \longrightarrow \text{Cong}[\text{Repl}[\text{putdown}(c)], \text{Refl}] \\
& \text{empty} \otimes \text{clear}(c) \otimes \text{table}(c) \otimes \text{clear}(a) \otimes \text{clear}(b) \otimes \\
& \hspace{15em} \text{table}(a) \otimes \text{table}(b) \\
& = \\
& \text{empty} \otimes \text{clear}(b) \otimes \text{table}(b) \otimes \text{clear}(c) \otimes \text{table}(c) \otimes \\
& \hspace{15em} \text{clear}(a) \otimes \text{table}(a) \\
& \longrightarrow \text{Cong}[\text{Repl}[\text{pickup}(b)], \text{Refl}] \\
& \text{hold}(b) \otimes \text{clear}(c) \otimes \text{table}(c) \otimes \text{clear}(a) \otimes \text{table}(a) \\
& \longrightarrow \text{Cong}[\text{Repl}[\text{stack}(b,c)], \text{Refl}] \\
& \text{empty} \otimes \text{clear}(b) \otimes \text{on}(b,c) \otimes \text{table}(c) \otimes \text{clear}(a) \otimes \text{table}(a) \\
& = \\
& \text{empty} \otimes \text{clear}(a) \otimes \text{table}(a) \otimes \text{clear}(b) \otimes \text{on}(b,c) \otimes \text{table}(c) \\
& \longrightarrow \text{Cong}[\text{Repl}[\text{pickup}(a)], \text{Refl}] \\
& \text{hold}(a) \otimes \text{clear}(b) \otimes \text{on}(b,c) \otimes \text{table}(c) \\
& \longrightarrow \text{Cong}[\text{Repl}[\text{stack}(a,b)], \text{Refl}] \\
& \text{empty} \otimes \text{clear}(a) \otimes \text{on}(a,b) \otimes \text{on}(b,c) \otimes \text{table}(c) \\
& = \\
& \text{empty} \otimes \text{clear}(a) \otimes \text{table}(c) \otimes \text{on}(a,b) \otimes \text{on}(b,c)
\end{aligned}$$

Hopefully this notation is self-explanatory. For example, the expression $\text{Cong}[\text{Repl}[\text{pickup}(b)], \text{Refl}]$ means the application of the *Congruence* rule of rewriting logic to the two WORLD-rewrites obtained by using *Replacement* with the rewrite rule $\text{pickup}(b)$ and *Reflexivity*. The *Transitivity* rule is used several times to go from the initial state I to the final state F .

Große, Hölldobler, and Schneeberger prove in [1996] (see also [Große *et al.*, 1992; Hölldobler, 1992]) that, in the framework of conjunctive planning, there is an equivalence between plans generated by linear logic proofs as used by Masseron *et al.* [1990; 1993], and the equational Horn logic approach of Hölldobler and Schneeberger [1990]. In the light of the example above, it is not surprising that we can add to the above equivalence the plans generated by proofs in rewriting logic [Martí-Oliet and Meseguer, 1999]. Moreover, this result extends to the case of disjunctive planning [Brüning *et al.*, 1993; Martí-Oliet and Meseguer, 1999]. In our opinion, rewriting logic compares favorably with these formalisms, not only because it subsumes them, but also because it is intrinsically concurrent, and it is more flexible and general, supporting user-definable logical connectives, which can be chosen to fit the problem at hand. In the words of Reichwein, Fiadeiro, and Maibaum [1992],

“It is not enough to have a convenient formalism in which to represent action and change: the representation has to reflect the structure of the represented system.”

In this respect, we show in [Martí-Oliet and Meseguer, 1999] that the object-oriented point of view supported by rewriting logic becomes very helpful in order to represent action and change.

6 CONCLUDING REMARKS

Rewriting logic has been proposed as a logical framework that seems particularly promising for representing logics, and its use for this purpose has been illustrated in detail by a number of examples. The general way in which such representations are achieved is by:

- Representing formulas or, more generally, proof-theoretic structures such as sequents, as *terms* in an order-sorted equational data type whose equations express structural axioms natural to the logic in question.
- Representing the rules of deduction of a logic as rewrite rules that transform certain patterns of formulas into other patterns modulo the given structural axioms.

Besides, the theory of general logics [Meseguer, 1989] has been used as both a method and a criterion of adequacy for defining these representations as conservative maps of logics or of entailment systems. From this point of view, our tentative conclusion is that, at the level of entailment systems, rewriting logic should in fact be able to represent any finitely presented logic via a conservative map, for any reasonable notion of “finitely presented logic.” Making this tentative conclusion definite will require proposing an intuitively reasonable formal version of such a notion in a way similar to previous proposals of this kind by Smullyan [1961] and Feferman [1989].

In some cases, such as for equational logic, Horn logic with equality, and linear logic, we have in fact been able to represent logics in a much stronger sense, namely by conservative maps of logics that also map the models. Of course, such maps are much more informative, and may afford easier proofs, for example for conservativity. However, one should not expect to find representations of this kind for logics whose model theory is very different from that of rewriting logic.

Although this paper has studied the use of rewriting logic as a logical framework, and not as a metalogical one in which metalevel reasoning about an object logic is performed, this second use is not excluded and is indeed one of the most interesting research directions that we plan to study. For this purpose, as stressed by Constable [1995], we regard *reflection* as a key

technique to be employed. Some concrete evidence for the usefulness of reflection has been given in Section 4.6.

The uses of rewriting logic as a semantic framework for the specification of languages, systems, and models of computation have also been discussed and illustrated with examples. Such uses include the specification and prototyping of concurrent models of computation and concurrent object-oriented systems, of general programming languages, of automated deduction systems and logic programming languages that use constraints, and of logical representation of action and change in AI.

From a pragmatic point of view, the main goal of this study is to serve as a guide for the design and implementation of a theoretically-based high-level system in which it can be easy to define logics and to perform deductions in them, and in which a very wide variety of systems, languages, and models of computation can similarly be specified and prototyped. Having this goal in mind, the following features seem particularly useful:

- *Executability*, which is not only very useful for prototyping purposes, but is in practice a must for debugging specifications of any realistic size.
- *Abstract user-definable syntax*, which can be specified as an order-sorted equational data type with the desired structural axioms.
- *Modularity and parameterization*¹⁴, which can make specifications very readable and reusable by decomposing them in small understandable pieces that are as general as possible.
- *Simple and general logical semantics*, which can naturally express both logical deductions and concurrent computations.

These features are supported by the Maude interpreter [Clavel *et al.*, 1996]. A very important additional feature that the Maude interpreter has is good support for flexible and expressive strategies of evaluation [Clavel *et al.*, 1996; Clavel and Meseguer, 1996a], so that the user can explore the space of rewritings in intelligent ways.

POSTSCRIPT (2001)

During the five years that have passed since this paper was last revised until its final publication, the ideas put forward here have been greatly developed by several researchers all over the world. The survey paper [Martí-Oliet and Meseguer, 2001] provides a recent snapshot of the state of the art in the theory and applications of rewriting logic with a bibliography including

¹⁴Parameterization is based on the existence of relatively free algebras in rewriting logic, which generalizes the existence of initial algebras.

more than three hundred papers in this area. Here we provide some pointers to work closely related to the main points developed in this paper, and refer the reader to [Martí-Oliet and Meseguer, 2001] for many more references.

The paper [Clavel *et al.*, 2001] explains and illustrates the main concepts behind Maude’s language design. The Maude system, a tutorial and a manual, a collection of examples and case studies, and a list of related papers are available at <http://maude.csl.sri.com>.

The reflective properties of rewriting logic and its applications have been developed in detail in [Clavel, 2000; Clavel and Meseguer, 2001]. A full reflective implementation developed by Clavel and Martí-Oliet of the map from linear logic to rewriting logic described in Section 4.6 appears in [Clavel, 2000]. Reflection has been used to endow Maude with a powerful module algebra of parameterized modules and module composition operations implemented in the Full Maude tool [Durán, 1999]. Moreover, reflection allows Maude to become a powerful *metatool* that has itself been used to build formal tools such as an inductive theorem prover; a tool to check the Church-Rosser property, coherence, and termination, and to perform Knuth-Bendix completion; and a tool to specify, analyze and model check real-time specifications [Clavel *et al.*, 2000; Clavel *et al.*, 1999; Olveczky, 2000].

A good number of examples of representations of logics in rewriting logic have been given by different authors, often in the form of executable specifications, including a map $HOL \rightarrow Nuprl$ between the logics of the HOL and Nuprl theorem provers, and a natural representation map $PTS \rightarrow RWLogic$ of pure type systems (a parametric family of higher-order logics) in rewriting logic [Stehr, 2002].

Thanks to reflection and to the existence of initial models, rewriting logic can not only be used as a logical framework in which the deduction of a logic \mathcal{L} can be faithfully simulated, but also as a *metalogical framework* in which we can reason about the metalogical properties of a logic \mathcal{L} . Basin, Clavel, and Meseguer [2000] have begun studying the use of reflection, induction, and Maude’s inductive theorem prover enriched with reflective reasoning principles to prove such metalogical properties.

Similarly, the use of rewriting logic and Maude as semantic framework has been greatly advanced. A number of encouraging case studies giving rewriting logic definitions of programming languages have already been carried out by different authors. Since those specifications usually can be executed in a rewriting logic language, they in fact become *interpreters* for the languages in question. In addition, such formal specifications allow both formal reasoning and a variety of formal analyses for the languages so specified. See [Martí-Oliet and Meseguer, 2001] for a considerable number of references related to these topics.

The close connections between rewriting logic and structural operational semantics have been further developed by Mosses [1998] and Braga [2001] in

the context of Mosses’s modular structural operational semantics (MSOS) [Mosses, 1999]. In particular, Braga [2001] proves the correctness of a mapping translating MSOS specifications into rewrite theories. Based on these ideas, an interpreter for MSOS specifications [Braga, 2001] and a Maude Action Tool [Braga *et al.*, 2000; Braga, 2001] to execute Action Semantics specifications have been built using Maude.

The implementation of CCS in Maude has been refined and considerably extended to take into account the Hennessy-Milner modal logic by Verdejo and Martí-Oliet [2000]. The semantic properties of this map from CCS to rewriting logic have been studied in detail in [Carabetta *et al.*, 1998; Degano *et al.*, 2000].

ACKNOWLEDGEMENTS

We would like to thank Manuel G. Clavel, Robert Constable, Harmut Ehrig, Fabio Gadducci, Claude Kirchner, H el ene Kirchner, Patrick Lincoln, Ugo Montanari, Natarajan Shankar, Sam Owre, Miguel Palomino, Gordon Plotkin, Axel Poign e, and Carolyn Talcott for their comments and suggestions that have helped us improve the final version of this paper. We are also grateful to the participants of the May 1993 Dagstuhl Seminar on Specification and Semantics, where this work was first presented, for their encouragement of, and constructive comments on, these ideas.

The work reported in this paper has been supported by Office of Naval Research Contracts N00014-90-C-0086, N00014-92-C-0518, N00014-95-C-0225 and N00014-96-C-0114, National Science Foundation Grant CCR-9224005, and by the Information Technology Promotion Agency, Japan, as a part of the Industrial Science and Technology Frontier Program “New Models for Software Architecture” sponsored by NEDO (New Energy and Industrial Technology Development Organization). The first author was also supported by a Postdoctoral Research Fellowship of the Spanish Ministry for Education and Science and by CICYT, TIC 95-0433-C03-01.

DAVID BASIN, SEÁN MATTHEWS

LOGICAL FRAMEWORKS

1 INTRODUCTION

One way to define a logic is to specify a language and a deductive system. For example, the language of first-order logic consists of the syntactic categories of terms and formulae, and its deductive system establishes which formulae are theorems. Typically we have a specific language in mind for a logic, but some flexibility about the kind of deductive system we use; we are able to select from, e.g., a Hilbert calculus, a sequent calculus, or a natural deduction calculus. A *logical framework* is an abstract characterization of one of these kinds of deductive system that we can use to formalize particular examples. Thus a logical framework for natural deduction should allow us to formalize natural deduction for a wide range of logics from, e.g., propositional logic to intuitionistic type-theories or classical higher-order logic.

Exactly how a logical framework abstractly characterizes a kind of deductive system is difficult to pin-down formally. From a high enough level of abstraction, we can see a deductive system as defining sets; i.e. we have a recursive set corresponding to well-formed syntax, a recursive set corresponding to proofs, and a recursively enumerable set of provable formulae.¹ But this view is really too coarse: we expect a logical framework to be able to capture more than just the sets of well-formed and provable formulae associated with a logic. If this were all that we wanted, then any Turing complete programming language would constitute a logical framework, in so far as it can implement a proof-checker for any logic.

In this chapter we present and examine two different kinds of frameworks, each representing a different view of what a deductive system is: \rightarrow -frameworks (deduction interpreted as reasoning in a weak logic of implication) and ID-frameworks (deduction interpreted as showing that a formula is a member of an inductively defined set). Either of these can be used to formalize any recursively enumerable relation. However, before calling a system a logical framework we will demand that it preserves additional structure. Thus we first consider what are the important and distinguishing characteristics of the different kinds of deductive systems, then we examine frameworks based on different sorts of possible *metallogic* (or *metatheory*) and we show that these are well-suited to representing the deductive systems for certain classes of *object logics* (or *object theories*). By providing procedures by which the deductive system of any object logic in a class can be naturally encoded in some metallogic, we show how effective frameworks are for formalizing particular logics.

¹We make the assumption in this chapter that the property of being a well-formed syntactic entity or a proof is recursive; i.e. we know one when we see it.

When we say that an encoding is *natural* we shall mean not only that it is high-level and declarative but also that there is an appropriate bijection between derivations in the object logic and derivations manipulating the encoding in the metalogic. For example, a Hilbert system can be naturally encoded using an inductive definition where each rule in the object logic corresponds to a rule in the metalogic. Similarly, there are natural encodings of many natural deduction systems in a fragment of the language of higher-order logic, which make use of a simple, uniform, method for writing down rules as formulae of the metalogic, so that it is possible to translate between natural deduction proofs of the object logic and derivations in the metalogic.

The term ‘logical framework’ came into use in the 1980s; however the study of metalogics and methods of representing one logic in another has a longer history in the work of logicians interested in languages for the metatheoretic analysis of logics, and computer scientists seeking conceptual and practical foundations for implementing logic-based systems. Although these motivations differ and are, at least in part, application oriented, behind them we find something common and more general: logical frameworks clarify our ideas of what we mean by a ‘deductive system’ by reducing it to its abstract principles. Thus work on logical frameworks contributes to the work of Dummett, Gentzen, Hacking, Prawitz, and others on the larger question of what is a logic.

1.1 *Some historical background*

Historically, the different kinds of deductive systems have resulted from different views of logics and their applications. Thus the idea of a deductive system as an inductive definition developed out of the work of Frege, Russell, Hilbert, Post, Gödel and Gentzen attempting to place mathematics on firm foundational ground. In particular, Hilbert’s program (which Gödel famously showed to be impossible) was to use the theory of proofs to establish the consistency of all of classical mathematics, using only finitary methods. From this perspective, of *metatheory as proof theory*, a deductive system defines a set of objects in terms of an initial set and a set of rules that generate new objects from old, and a proof is the tree of rule applications used to show that an object is in the set. For Frege and Hilbert these objects were simply theorems, but later Gentzen took them to be sequents, i.e. pairs of collections of formulae. But, either way, a deductive system defines a recursively enumerable set, which is suitable for analysis using inductive arguments.

How should the metatheory used to define these inductive definitions be characterized? Hilbert required it to be finitary, so it has traditionally been taken to be the primitive recursive fragment of arithmetic (which is essentially, e.g., what Gödel [1931] used for his incompleteness theorems). However, despite the endorsement by Hilbert and Gödel, arithmetic is remarkably unsuitable, in the primitives it offers, as a general theory of inductive definitions. Thus, more recent investigations, such as those of Smullyan [1961] and Feferman [1990], have

proposed theories of inductive definitions based on sets of strings or S-expressions, structures more tractable in actual use.

A different view of deductive systems is found in work in computer science and artificial intelligence, where logics have been formalized for concrete applications like machine checked proof. The work of, e.g., de Bruijn [Nederpelt *et al.*, 1994] does not attempt to analyze the meta-theoretic properties of deductive systems, but concentrates rather on common operations, such as binding and substitution. The goal is to provide an abstract characterization of such operations so that deductive systems can be easily implemented and used to prove theorems; i.e. metatheory is seen as providing a *unifying language* for implementing, and ultimately using, deductive systems. A result of this concern with ease in use (i.e. building proofs) rather than ease of metatheoretic analysis (i.e. reasoning about proofs) is that work has emphasized technically more complex, but more usable, notations such as natural deduction, and resulted in frameworks based on higher-order logics and intuitionistic type-theories instead of the inductive definitions of the older proof theory tradition.

1.2 Focus and organization

This chapter presents the concepts underlying the various logical frameworks that have been proposed, examining the relationship between different kinds of deductive systems and metatheory. Many issues thus fall outside our scope. For example, we do not investigate semantically based approaches to formalizing and reasoning about logics, such as the *institutions* of Goguen and Burstall [1992] or the *general logics* of Meseguer [1989]. Even within our focus, we do not attempt a comprehensive survey of all the formalisms that have been proposed. Neither do we directly consider implementation questions, even though computer implementations now play an important role in the field. Further references are given in the bibliography; the reader is referred in particular to the work of Avron *et al.*, Paulson, Pfenning, Pollack, and ourselves, where descriptions of first-hand experience with logical frameworks can be found.

The remainder of this chapter is organized as follows. In §2 we briefly survey three kinds of deductive systems, highlighting details relevant for formalizing abstractions of them. In §3 we consider a logic based on minimal implication as an abstraction of natural deduction. It turns out that this abstraction is closely related to a generalization of natural deduction due to Schroeder-Heister. In §4 we consider in detail a particular metatheory that formalizes this abstraction. We also consider quantification and so-called ‘higher-order syntax’. In §5 we present a case study: the problem of formalizing modal logics. In §6 we examine sequent calculi and their more abstract formalization as consequence relations. In §7 we investigate the relationship between sequent systems and inductive definitions, and present a particular logic for inductive definitions. Finally, we draw conclusions and point to some current and possible future research directions.

2 KINDS OF DEDUCTIVE SYSTEMS

Many different kinds of formalization of deduction have been proposed, for a range of purposes. However in this chapter we are interested in deductive systems designed for the traditional purposes of logicians and philosophers, of investigating the foundations of language and reasoning; in fact we restrict our interest even further, to three kinds of system, which are commonly called *Hilbert calculi*, *sequent calculi* and *natural deduction*. But this restriction is more apparent than real since, between them, these three cover the vast majority of deductive systems that have been proposed. We describe only the details that are important here, i.e. the basic mechanics; for deeper and more general discussion, the reader is referred to Sundholm's articles on systems of deduction elsewhere in this handbook [1983; 1986].

For the purposes of comparison, we shall present, as an example, the same simple logics in each style: propositional logics of minimal and classical implication. The language we will work with then is as follows.

DEFINITION 1. Given a set of atomic propositions P , the language of propositions, L , is defined as the smallest set containing P , where if A and B are in L , then $(A \supset B)$ is in L .

For the sake of readability we assume that \supset associates to the right and omit unnecessary parentheses; for example, we abbreviate $(A \supset (B \supset C))$ as $A \supset B \supset C$. We now proceed to the different presentations.

2.1 Hilbert calculi

Historically, Hilbert calculi are the oldest kind of presentation we consider. They are also, in some technical sense, the simplest. A Hilbert calculus defines a set of *theorems* in terms of a set of *axioms* Ax and a set of *rules of proof* R . A *rule of proof* is a relation between formulae A_1, \dots, A_n and a formula A . A rule is usually written in a two-dimensional format and sometimes decorated with its name. For example

$$\frac{A_1 \dots A_n}{A} \textit{ name}$$

says that by rule *name*, given A_1, \dots, A_n , it follows that A . The set of formulae defined by a Hilbert calculus is the smallest set containing Ax and closed under R ; we call this set a *theory*, and the formulae in it *theorems*.

The set of theorems in a logic of minimal implication can be defined as a Hilbert calculus where the set of axioms contains all instances of the axiom schemata K

$$A \supset B \supset A$$

and S

$$(A \supset B) \supset (A \supset B \supset C) \supset A \supset C.$$

We call these schemata because A , B and C stand for arbitrary formulae in L . In addition, we have one rule of proof, *detachment*, which takes the form

$$\frac{A \supset B \quad A}{B} \text{Det.}$$

The Hilbert calculus defined by K , S and Det is the set of theorems of the minimal (or intuitionistic) logic of implication. We call this theory HJ^{\supset} .²

The set of theorems in a logic of classical implication, HK^{\supset} , is slightly larger than HJ^{\supset} . We can formalize HK^{\supset} by adding to HJ^{\supset} a third axiom schema, for *Peirce's law*

$$((A \supset B) \supset A) \supset A. \tag{1}$$

A proof in a Hilbert calculus consists of a demonstration that a formula is in the (inductively defined) set of theorems. We can think of a proof as either a tree, where the leaves are axioms, and the branches represent rule applications, or as a list of formulae, ending in the theorem, where each entry is either an axiom, or follows from previous entries by a rule. Following common practice, we use the list notation here.

The following is an example of a proof of $A \supset A$ in HJ^{\supset} and thus also in HK^{\supset} :

- | | |
|--|------------|
| 1. $A \supset A \supset A$ | K |
| 2. $(A \supset A \supset A) \supset (A \supset (A \supset A) \supset A) \supset A \supset A$ | S |
| 3. $A \supset (A \supset A) \supset A$ | K |
| 4. $(A \supset (A \supset A) \supset A) \supset A \supset A$ | $Det\ 2,1$ |
| 5. $A \supset A$ | $Det\ 4,3$ |

It turns out that proving theorems in a Hilbert calculus by hand, or even on a machine, is not practical: proofs can quickly grow to be enormous in size, and it is often necessary (e.g. in the proof we have just presented) to invent instances of axiom schemata that have no intuitive relationship to the formula being proven. However Hilbert calculi were never really intended to be used to build proofs, but rather as a tool for the metatheoretic analysis of logical concepts such as deduction. And from this point of view, the most important fact about Hilbert calculi is that they are essentially inductive definitions;³ i.e. well-suited for arguments (about provability) by induction.

²For the proof systems presented in this section, we follow the tradition where the first letter indicates the kind of deduction system (H for Hilbert, N for natural deduction, and L for sequent calculus), the second letter indicates the logic (J for minimal, or intuitionistic logic, and K for classical logic), and superscripts name the connectives.

³The two are so closely related that, e.g., Aczel [1977] identifies them.

2.2 Sequent calculi

Useful though Hilbert calculi are, Gentzen [1934] found them unsatisfactory for his particular purposes, and so developed a very different style that has since become the standard notation for much of proof theory, and which is known as *sequent calculus*.

With a sequent calculus we do not define directly the set of theorems; instead we define a binary ‘sequent’ relation between collections of formulae, Γ and Δ , and identify a subset of instances of this relation with theorems. We shall write this relation as $\Gamma \vdash \Delta$, where Γ is called the *antecedent* and Δ the *succedent*. This is often read as ‘if all the formulae in Γ are true, then at least one of the formulae in Δ is true’.

The rules of a sequent calculus are traditionally divided into two subsets consisting of the *logical* rules, which define logical connectives, and the *structural* rules, which define the abstract properties of the sequent relation itself. The basic properties of any sequent system are given by the following rules which state that \vdash is reflexive for singleton collections (*Basic*) and satisfies a form of transitivity (*Cut*):

$$\frac{}{A \vdash A} \textit{Basic} \qquad \frac{\Gamma \vdash A, \Delta \quad \Gamma', A \vdash \Delta'}{\Gamma, \Gamma' \vdash \Delta, \Delta'} \textit{Cut} \quad (2)$$

A typical set of structural rules is then

$$\begin{array}{cc} \frac{\Gamma \vdash \Delta}{\Gamma, A \vdash \Delta} \textit{WL} & \frac{\Gamma \vdash \Delta}{\Gamma \vdash A, \Delta} \textit{WR} \\ \frac{\Gamma, A, A \vdash \Delta}{\Gamma, A \vdash \Delta} \textit{CL} & \frac{\Gamma \vdash A, A, \Delta}{\Gamma \vdash A, \Delta} \textit{CR} \\ \frac{\Gamma, A, B, \Gamma' \vdash \Delta}{\Gamma, B, A, \Gamma' \vdash \Delta} \textit{PL} & \frac{\Gamma \vdash \Delta, A, B, \Delta'}{\Gamma \vdash \Delta, B, A, \Delta'} \textit{PR} \end{array} \quad (3)$$

which define \vdash to be a relation on finite sets that is also monotonic in both arguments (what we will later call *ordinary*). The names *WL*, *CL* and *PL* stand for *Weakening*, *Contraction* and *Permutation Left* of the sequent, while *WR*, *CR* and *PR* name the same operations on the right.

We can give a deductive system for classical implication, which we call LK^{\supset} , in terms of this sequent calculus by adding logical rules for \supset :

$$\frac{\Gamma \vdash A, \Delta \quad \Gamma', B \vdash \Delta'}{\Gamma, \Gamma', A \supset B \vdash \Delta, \Delta'} \supset\text{-L} \qquad \frac{\Gamma, A \vdash B, \Delta}{\Gamma \vdash A \supset B, \Delta} \supset\text{-R}$$

The names $\supset\text{-L}$ and $\supset\text{-R}$ indicate that these are rules for introducing the implication connective on the left and the right of \vdash . We get a sequent calculus for

minimal implication, LJ^{\supset} , by adding the restriction on \vdash that its succedent is a sequence containing exactly one formula.⁴

Like Hilbert proofs, sequent calculus proofs can be equivalently documented as lists or trees. Since proofs are less unwieldy than for Hilbert calculi, trees are a practical notation. A sequent calculus proof of $A \supset A$ is trivial, so instead we take as an example a proof of Peirce's law (1):

$$\begin{array}{c}
 \frac{}{A \vdash A} \textit{Basic} \\
 \frac{}{A \vdash B, A} \textit{WR} \\
 \frac{}{\vdash (A \supset B), A} \supset\textit{-R} \quad \frac{}{A \vdash A} \textit{Basic} \\
 \frac{}{((A \supset B) \supset A) \vdash A, A} \supset\textit{-L} \\
 \frac{}{((A \supset B) \supset A) \vdash A} \textit{CR} \\
 \frac{}{\vdash ((A \supset B) \supset A) \supset A} \supset\textit{-R}
 \end{array}$$

Notice that it is critical in this proof that the succedent can consist of more than one formula, and that *CR* can be applied. Neither this proof (since *CR* is not available), nor any other, of Peirce's law is possible in LJ^{\supset} .

Technically we can regard a sequent calculus as a Hilbert calculus for a binary connective \vdash ; however the theorems of this system are in the language of sequents over L , not formulae in the language of L itself. The set of theorems a sequent calculus defines is taken to be the set of formulae A in L such that $\vdash A$ is provable, i.e., there is a proof of the sequent $\Gamma \vdash \Delta$, where Γ is empty, and Δ is the singleton A .

2.3 Natural deduction

A second important kind of deductive system that Gentzen [1934] (and subsequently Prawitz [1965]) developed was *natural deduction*. In contrast to the sequent calculus, which is intended as a formalism that supports metatheoretic analysis, natural deduction, as its name implies, is intended to reflect the way people 'naturally' work out logical arguments. Thus Gentzen suggested that, e.g., in order to convince ourselves that the *S* axiom schema

$$(A \supset B) \supset (A \supset B \supset C) \supset A \supset C$$

is true, we would, reading \supset as 'implies', informally reason as follows: 'Assuming $A \supset B$ and then $A \supset B \supset C$ we have to show that $A \supset C$, and to do this, it is enough to show that C is true assuming A . But if A is true then, from the first assumption, B is true, and, given that A and B are true, by the second assumption C is true. Thus the *S* schema is true (under the intended interpretation)'.

⁴As a result, in LJ^{\supset} the structural rules (*WR*, *CR* and *PR*) become inapplicable, and $\Delta = \emptyset$ in the logical rule $\supset\textit{-L}$.

To represent this style of argument *under assumption* we need a new kind of rule, called a *rule of inference*, that allows temporary hypotheses to be made and discharged. This is best explained by example. Consider implication; we can informally describe some of its properties as: (i) if, assuming A , it follows that B , then it follows that $A \supset B$, and (ii) if $A \supset B$ and A , then it follows that B . We might represent this reasoning diagrammatically as follows:

$$\frac{\begin{array}{c} [A] \\ \vdots \\ B \end{array} \supset\text{-}I}{A \supset B} \quad \frac{A \supset B \quad A}{B} \supset\text{-}E \quad (4)$$

where $\supset\text{-}I$ and $\supset\text{-}E$ are to be pronounced as ‘Implication Introduction’ and ‘Implication Elimination’, since they explain how to introduce and to eliminate (i.e. to create and to use) a formula with \supset as the main connective.

We call $A \supset B$ in $\supset\text{-}E$ the *major premise*, and A the *minor premise*. In general, the major premise of an elimination rule is the premise in which the eliminated connective is exhibited and all other premises are minor premises. Square brackets around assumptions indicate that they are considered to be temporary, and made only for the course of the derivation; when applying the rule we can *discharge* these occurrences. Thus, when applying $\supset\text{-}I$, we can discharge (zero or more) occurrences of the assumption A which has been made for the purposes of building a derivation of B , which shows that $A \supset B$. Of course, when applying the $\supset\text{-}I$ rule, there may be other assumptions (so called open assumptions) that are not discharged by the rule. Similarly, the two premises of $\supset\text{-}E$ may each have open assumptions, and the conclusion follows under the union of these.

To finish our account of \supset , we must explain how these rules can be used to build formal proofs. Gentzen formalized natural deduction derivations just like in sequent and Hilbert calculi, as trees, explaining how formulae are derived from formulae. With natural deduction though, there is an added complication: we also have to track the temporary assumptions that are made and discharged. Thus along with the tree of formulae, a natural deduction derivation has a *discharge function*, which associates with each node N in the tree leaf nodes above N that the rule application at node N discharges. Moreover, there is the proviso that each leaf node can be discharged by at most one node. A proof, then, is a derivation where all the assumptions are discharged (i.e. all assumptions are temporary); the formula proven is a theorem of the logic.

A natural deduction proof, with its discharge function, is a complex object in comparison with a Hilbert or sequent proof. However, it has a simple two-dimensional representation: we just decorate each node with the name of the rule to which it corresponds, and a unique number, and decorate with the same number each leaf node of the tree that it discharges. In this form we can document the previously given informal argument of the truth of the S axiom schema as a formal

proof (we only number the nodes that discharge some formula):⁵

$$\begin{array}{c}
 \frac{[A \supset B \supset C]_2 \quad [A]_3 \supset\text{-}E}{B \supset C} \supset\text{-}E \quad \frac{[A \supset B]_1 \quad [A]_3 \supset\text{-}E}{B} \supset\text{-}E \\
 \frac{\quad}{C} \supset\text{-}E \\
 \frac{C}{A \supset C} \supset\text{-}I_3 \\
 \frac{A \supset C}{(A \supset B \supset C) \supset A \supset C} \supset\text{-}I_2 \\
 \frac{(A \supset B \supset C) \supset A \supset C}{(A \supset B) \supset (A \supset B \supset C) \supset A \supset C} \supset\text{-}I_1
 \end{array}$$

Once we have committed ourselves to this formalization of natural deduction, we find that the two rules (4) together define exactly minimal implication, in a deductive system which we call NJ^\supset .

While the claims of natural deduction to be the most intuitive way to reason are plausible, the style does have some problems. First, there is the question of how to encode classical implication. We can equally easily give a direct presentation of either classical or minimal implication, using a Hilbert or sequent calculus, but not using natural deduction. While NJ^\supset is standard for minimal implication, there is, unfortunately, no simple equivalent for classical implication (what we might imagine calling NK^\supset): the standard presentation of classical implication in natural deduction is as part of a larger, functionally complete, set of connectives, including, e.g., negation and disjunction, through which we can appeal to the law of excluded middle. Alternatively we can simply accept Peirce's law as an axiom. We cannot, however, using the language of natural deduction, define classical implication simply in terms of introduction and elimination rules for the \supset connective.

A second problem concerns proofs themselves, which are complex in comparison to the formal representations of proofs in Hilbert or sequent calculi. It is worth noting that a Hilbert calculus can be seen as a special simpler case of natural deduction, since axioms of a Hilbert calculus can be treated as rules with no premises, and the rules of a Hilbert calculus correspond to natural deduction rules where no assumptions are discharged.

3 NATURAL DEDUCTION AND THE LOGIC OF IMPLICATION

Given the previous remarks about the complexity of formalizations of natural deduction, it might seem unlikely that a satisfactory logical framework for it is possible. In fact, this is not the case. In this section we show that there is an abstraction of natural deduction that is the basis of an effective logical framework. Preliminary to this, however, we consider another way of formalizing natural deduction using sequents.

⁵It may help the reader trying to compare this formal proof diagram with the previous informal argument, to read it 'bottom up'; i.e. upwards from the conclusion at the root.

3.1 Natural deduction and sequents

We can describe natural deduction informally as ‘proof under assumption’, so the basic facility needed to formalize such a calculus is a mechanism for managing assumptions. Sequents provide this: assumptions can be stored in the antecedent of the sequent and deleted when they are discharged. Thus, if we postulate a relation \vdash satisfying *Basic* and the structural rules (3), where the succedent is a singleton set, then we can encode NJ^\supset using the rules:⁶

$$\frac{\Gamma, A \vdash B}{\Gamma \vdash A \supset B} \supset\text{-I} \quad \frac{\Gamma \vdash A \supset B \quad \Gamma \vdash A}{\Gamma \vdash B} \supset\text{-E} \quad (5)$$

This view of natural deduction is often technically convenient (we shall use it ourselves later) but it is unsatisfactory in some respects. Gentzen, and later Prawitz, had a particular idea in mind of how natural deduction proofs should look, and they made a distinction between it and the sequent calculus, using proof trees with discharge functions for natural deduction, and sequent notation for sequent calculus. We also later consider ‘natural’ generalizations of natural deduction that cannot easily be described using a sequent notation.

3.2 Encoding rules using implication

The standard notation for natural deduction, based on assumptions and their discharge, while intuitive, is formally complex. Reducing it to sequents allows us to formalize presentations in a simpler ‘Hilbert’ style; however we have also said that this is not altogether satisfactory. We now consider another notation that can encode not only natural deduction but also generalizations that have been independently proposed.

A natural ‘horizontal’ notation for rules can be based on lists $\langle A_1, \dots, A_n \rangle$ and an arrow \rightarrow . Consider the rules (4): we can write the elimination rule in horizontal form simply as

$$\frac{A \supset B \quad A}{B} \equiv \langle A \supset B, A \rangle \rightarrow B$$

and the introduction rule as

$$\frac{\begin{array}{c} [A] \\ \vdots \\ B \end{array}}{A \supset B} \equiv \langle A^\dagger \rightarrow B \rangle \rightarrow A \supset B.$$

In the introduction rule we have marked the assumption A with the symbol \dagger to indicate that it is discharged. But this is actually unnecessary; using this linear

⁶Importantly, we can prove that the relation defined by this encoding satisfies the *Cut* rule above; it thus defines a consequence relation (see §6).

notation, precisely the formulae (here there is only one) occurring on the left-hand side of some \rightarrow -connective in the premise list are discharged.

This new notation is suggestive: Gentzen explicitly motivated natural deduction as a formal notation for intuitive reasoning, and we have now mapped natural language connectives such as ‘follows from’ onto the symbol \rightarrow . Why not make this explicit and read \rightarrow as formal implication, and ‘ $\langle \dots \rangle$ ’ as a conjunction of its components? The result, if we translate into the conventional language of (quantifier free) predicate logic, is just:

$$\begin{aligned} (T(A \supset B) \ \& \ T(A)) \rightarrow T(B) \\ (T(A) \rightarrow T(B)) \rightarrow T(A \supset B) \end{aligned} \tag{6}$$

which, reading the unary predicate symbol T as ‘True’, is practically identical with Gentzen’s natural language formulation.

What is the significance of this logical reading of rules? The casual relationship observed above is not sufficient justification for an identification, and we will see that we must be careful. However, after working out the details, this interpretation provides exactly what we need for an effective logical framework, allowing us to trade the complex machinery of trees and discharge functions for a pure ‘logical’ abstraction.

We separate the investigation of such interpretations into several parts. First, we present a metalogic based on (minimal) implication and conjunction and give a uniform way of translating a set of natural deduction rules \mathcal{R} into a set of formulae \mathcal{R}^* in the metalogic. For an object logic \mathcal{L} presented by a set of natural deduction rules \mathcal{R} , this yields a metatheory \mathcal{L}^* given by the metalogic extended with \mathcal{R}^* . Second, we demonstrate that for any such \mathcal{L} , the translation is *adequate*. This means that \mathcal{L}^* is ‘strong enough’ to derive (the representative of) any formula derivable in \mathcal{L} . Third, we demonstrate that the translation is *faithful*. That is that \mathcal{L}^* is not too strong; we can only derive in \mathcal{L}^* representatives of formulae that are derivable in \mathcal{L} , and further, given such a derivation, we can recover a proof in \mathcal{L} .⁷

3.3 The metatheory and translation

We have previously defined natural deduction in terms of formula-trees and discharge functions. We now describe the logic with which we propose to replace it.

Thus we assume that \rightarrow and $\&$ have at least the properties they have in minimal logic. Above we have provided three separate formalizations of (the implicational fragment of) minimal logic: as a Hilbert calculus, as a sequent calculus, and as natural deduction. Since these all formalize the same set of theorems, we could base our analysis on any of them. However, it will be convenient for our development

⁷Notice that this is a stronger requirement than the model-theoretic requirement of soundness, which requires that we should not be able to prove anything false in the model, but not that we can recover a proof of anything that we have shown to be true.

to use natural deduction.⁸ Even though this may seem circular, it isn't: we simply need some calculus to fix the meaning of these connectives and later to formalize the correctness of our embeddings.

For the rest of this section, we will formalize deductive systems associated with *propositional* logics. We leave the treatment of quantifiers in the object logic, for which we need quantification in the metalogic (here we need only, as we will see, quantifier-free schemata), and a general theory of syntax, to §4. For now, we simply assume a suitable term algebra formalizing the language of the object logic. We will build formulae in the metalogic from the unary predicate T and the connectives \rightarrow and $\&$. To aid readability we assume that $\&$ binds tighter than \rightarrow , which (as usual) associates to the right. Now, let $\text{NJ}^{\rightarrow, \&}$ be the natural deduction calculus based on the following rules:

$$\frac{A \quad B}{A \& B} \&-I \qquad \frac{\begin{array}{c} [A, B] \\ \vdots \\ C \end{array}}{A \& B} \&-E$$

$$\frac{\begin{array}{c} [A] \\ \vdots \\ B \end{array}}{A \rightarrow B} \rightarrow-I \qquad \frac{A \rightarrow B \quad A}{B} \rightarrow-E$$

We also formally define the translation, given by the mapping ‘*’, from rules of natural deduction to the above language. Here A_i varies over formulae in the logic, and Φ_i over the premises (along with the discharged hypotheses) of a rule Θ .

$$\begin{aligned} \left(\frac{\Phi_1 \dots \Phi_n}{A} \right)^* &\rightsquigarrow \Phi_1^* \& \dots \& \Phi_n^* \rightarrow T(A) \\ \left(\frac{[A_1, \dots, A_n]}{A} \right)^* &\rightsquigarrow T(A_1) \& \dots \& T(A_n) \rightarrow T(A) \end{aligned} \tag{7}$$

Note that axioms and rules that discharge no hypotheses constitute degenerate cases, i.e. $A^* \rightsquigarrow T(A)$. We extend this mapping to sets of rules and formulae, i.e. $\mathcal{R}^* \equiv \{\Theta^* \mid \Theta \in \mathcal{R}\}$.

⁸One reason is that we can then directly relate derivability in the metalogic with derivability in the object logic. As is standard [Prawitz, 1965], derivability refers to natural deduction derivations with possibly open assumptions. Provability is a special case where there are no open assumptions. This generalization is also relevant to showing that we can correctly represent particular consequence relations (see §6).

3.4 Adequacy

If A is a theorem of an object logic \mathcal{L} defined by rules \mathcal{R} , then we would like $T(A)$ to be provable in the metatheory $\mathcal{L}^* = \text{NJ}^{\rightarrow, \&} + \mathcal{R}^*$ (i.e. $\text{NJ}^{\rightarrow, \&}$ extended by the rules \mathcal{R}^*). More generally, if A is derivable in \mathcal{L} under the assumptions $\Delta = \{A_1, \dots, A_n\}$, then we would like for $T(A)$ to be derivable in \mathcal{L}^* under the assumptions Δ^* .

Consider, for example, the object logic \mathcal{L} over the language $\{\oplus, \otimes, \times, +\}$ defined by the following rules \mathcal{R} :

$$\frac{\frac{+}{\otimes} \alpha \quad \frac{+}{\times} \beta \quad \frac{\otimes \times}{\oplus} \gamma}{\frac{+}{\oplus} \delta} \quad \begin{array}{c} [+ \\ \vdots \\ \oplus \\ \frac{-}{\oplus} \delta \end{array} \quad (8)$$

We can prove, for example, \oplus by:

$$\frac{\frac{[+]}{\otimes} \alpha \quad \frac{[+]}{\times} \beta}{\frac{\oplus}{\oplus} \delta_1} \gamma \quad (9)$$

Under our proposed encoding, the rules are translated to the following set \mathcal{R}^* :

$$\begin{aligned} T(+) &\rightarrow T(\otimes) & (\alpha^*) \\ T(+) &\rightarrow T(\times) & (\beta^*) \\ T(\otimes) \ \& \ T(\times) &\rightarrow T(\oplus) & (\gamma^*) \\ (T(+) \rightarrow T(\oplus)) &\rightarrow T(\oplus) & (\delta^*) \end{aligned}$$

and we can prove $T(\oplus)$ in the metatheory $\mathcal{L}^* = \text{NJ}^{\rightarrow, \&} + \mathcal{R}^*$ by:

$$\frac{\frac{\frac{[T(+)]_1}{\vdots \Sigma} T(\oplus)}{(T(+) \rightarrow T(\oplus)) \rightarrow T(\oplus)} \delta^* \quad \frac{T(\oplus)}{T(+) \rightarrow T(\oplus)} \rightarrow -I_1}{T(\oplus)} \rightarrow -E$$

where Σ is:

$$\frac{\frac{\frac{\frac{T(+) \rightarrow T(\otimes)}{T(+) \rightarrow T(\otimes)} \alpha^* \quad T(+)}{T(\otimes)} \rightarrow -E \quad \frac{\frac{\frac{T(+) \rightarrow T(\times)}{T(+) \rightarrow T(\times)} \beta^* \quad T(+)}{T(\times)} \rightarrow -E}{T(\otimes) \ \& \ T(\times) \rightarrow T(\oplus)} \gamma^* \quad \frac{T(\otimes) \ \& \ T(\times)}{T(\otimes) \ \& \ T(\times)} \&-I}{T(\oplus)} \rightarrow -E$$

Notice how assumptions in \mathcal{L} are modeled directly by assumptions in \mathcal{L}^* , and how, in general, a rule application in \mathcal{L} corresponds to a fragment of the derivation in \mathcal{L}^* . We have, for instance, the equivalence

$$\frac{\begin{array}{c} [+ \\ \vdots \\ \oplus \\ \hline \delta \\ \oplus \end{array}}{\oplus} \equiv \frac{\frac{\frac{\frac{[T(+)]_1}{\vdots} T(\oplus)}{T(+)} \rightarrow -I_1}{T(+)} \rightarrow T(\oplus)}{T(\oplus)} \rightarrow -E}{(T(+)) \rightarrow T(\oplus)} \delta^* \rightarrow -E$$

Intuitively, then, we use $\rightarrow -E$ to unpack the rule, and $\rightarrow -I$ to gather together the subproofs and discharged hypotheses.

We call the right-hand side of this the corresponding *characteristic fragment* for the rule δ . In the same way there are characteristic fragments for each of the other rules, and out of these we can build a meta-derivation corresponding to any derivation in our original logic. Moreover, these characteristic fragments can be restricted to have a special form. Given a natural deduction rule Θ then Θ^* (in the general case) has the form

$$\frac{(T(A_{1_1}) \& \dots \& T(A_{1_{m_1}}) \rightarrow T(A_1)) \& \dots \& (T(A_{n_1}) \& \dots \& T(A_{n_{m_n}}) \rightarrow T(A_n))}{T(A)},$$

and we can show:

LEMMA 2. *Given a rule Θ , there is a characteristic fragment Σ where for $1 \leq i \leq n$, atomic assumptions $T(A_{i_1}), \dots, T(A_{i_{m_i}})$ are discharged in subderivations of $T(A_i)$, and then these subderivations are combined together with Θ^* to prove $T(A)$. Further, if we insist also that the major premise of an elimination rule is never the result of the application of an introduction rule (i.e. $\rightarrow -I$ or $\& -I$), while the minor premise is always either atomic or the result of the application of an introduction rule, then Σ is unique.*

Proof. By an analysis of the possible structure of Θ . ■

For a rule Θ that does not discharge assumptions, i.e., of the form

$$\frac{A_1 \dots A_n}{A},$$

the characteristic fragment is just a demonstration that, given Θ^* , the rule

$$\frac{T(A_1) \dots T(A_n)}{T(A)}$$

is derivable in \mathcal{L}^* . That is, there is a derivation of $T(A)$ where the only open assumptions are $T(A_1), \dots, T(A_n)$. Note that this standard notion of derivability (see, e.g., Troelstra [1982] or Hindley and Seldin [1986]), can be extended

(see Schroeder-Heister [1984b] and §3.6 below) to account for rules that discharge assumptions; in this extended sense, each characteristic fragment justifies a derived rule that allows us to simulate \mathcal{L} -derivations in \mathcal{L}^* .

Given the existence of characteristic fragments, it is a simple matter to model \mathcal{L} -derivations in \mathcal{L}^* . To begin with, since our metalogic is a natural deduction calculus, we can model assumptions in the encoded logic as assumptions in the metalogic. Each such assumption B_i is modeled by an assumption $T(B_i)$. Now, given a derivation in the object logic, we can inductively replace rules by corresponding characteristic fragments to produce a derivation in \mathcal{L}^* . For example, in (9) we proved \oplus using four rule applications; after we gave a proof in \mathcal{L}^* of $T(\oplus)$ built from the four characteristic fragments that correspond to these applications.

In this form, however, this observation assumes not just a metalogic ($\text{NJ}^{\rightarrow, \&}$) but also a particular proof calculus for the metalogic (natural deduction), which, since we want a purely logical characterization, we want to avoid. It is easy to remove this assumption by observing that A follows from the assumptions A_1 to A_n in $\text{NJ}^{\rightarrow, \&}$ iff $A_1 \& \cdots \& A_n \rightarrow A$ follows without the assumptions. Thus we have a theorem that states the adequacy of encodings of natural deduction calculi in $\text{NJ}^{\rightarrow, \&}$.⁹

THEOREM 3 (Adequacy). *For any natural deduction calculus \mathcal{L} defined by a set of rules \mathcal{R} , if the formula A is derivable under assumptions A_1, \dots, A_n , then $T(A_1) \& \cdots \& T(A_n) \rightarrow T(A)$ is provable in $\mathcal{L}^* = \text{NJ}^{\rightarrow, \&} + \mathcal{R}^*$.*

Notice that the proof is based on translation, and hence is constructive: given a derivation in the object logic we can construct one in the metalogic.

3.5 Faithfulness

In proving adequacy, we only used the metatheory \mathcal{L}^* in a limited way where derivations had a simple structure built by pasting characteristic fragments together. Of course, there are other ways to build proofs in \mathcal{L}^* and it could be that this freedom allows us to derive representations of formulae that are not derivable in \mathcal{L} . We now show that our translation is faithful, i.e. this is not the case.

To see why we have to be careful about faithfulness, consider the following: in the deductive system $\text{NJ}^{\rightarrow, \&}$, the \rightarrow connective is minimal implication (the logic is a conservative extension of NJ^{\rightarrow}). But what happens if we strengthen the metalogic to be classical, e.g. by adding classical negation or assuming Peirce's law? We can still show adequacy of our encodings, since derivations in $\text{NJ}^{\rightarrow, \&}$ remain valid when additional rules are present, but we can also use the encoding to derive formulae that are not derivable in the original system. Consider what happens if we try to prove something that is classically but not minimally valid,

⁹However notice that the translation is only defined on rules without side conditions, i.e. for 'pure' natural deduction; for more idiosyncratic logics, see the discussion in §6.

like, for instance, Peirce's law itself:

$$T(((A \supset B) \supset A) \supset A). \quad (10)$$

Using the axioms in (6), we can reduce this to the problem of proving

$$((T(A) \rightarrow T(B)) \rightarrow T(A)) \rightarrow T(A). \quad (11)$$

But this is itself an instance of Peirce's law, and is provable if \rightarrow is classical implication. Thus $T(\cdot)$ does not here define the set of minimal logic theorems.

If \rightarrow is read as minimal implication, then the same trick does not work. We can still reduce (10) to (11), but we are not able to take the final step of appealing to Peirce's law in the metalogic.

We now show that assuming \rightarrow to be minimal really does lead to a faithful presentation of object logics, by demonstrating a direct relationship between derivations of formulae $T(A)$ in the \mathcal{L}^* and derivations of A in \mathcal{L} .

The desired relationship is not a simple isomorphism: we pointed out in discussing adequacy above, that for each natural deduction rule translated into our logical language, it is possible to find a characteristic fragment, and using these fragments we can translate derivations in \mathcal{L} into derivations in \mathcal{L}^* . However an arbitrary derivation in \mathcal{L}^* may not have a corresponding derivation in \mathcal{L} (it is a simple exercise to construct a proof of $T(\oplus)$ that does not use characteristic fragments). But if we look more carefully at the derivation of $T(\oplus)$ we have given, and the fragments from which it is constructed, we can see that it has a particularly simple structure, and this structure has a technical characterization, similar to that we used for the characteristic fragments themselves. The derivations we build to show adequacy are in what is called *expanded normal form* (ENF): the major premise of an elimination rule (i.e. $\rightarrow E$ or $\& E$) is never the result of the application of an introduction rule (i.e. $\rightarrow I$ or $\& I$), and all minor premises are either atomic or the result of introduction rules. Not all derivations are in ENF, but any derivation can be transformed into one that is. We have the following:

FACT 4 (Prawitz [1971]). There is an algorithm transforming any derivation in $\text{NJ}^{\rightarrow, \&}$ into an equivalent derivation in ENF, and this equivalent derivation is unique.

From this we get the theorem we need; again, like for the statement of adequacy, we abstract away from the deductive system to get a pure logical characterization:

THEOREM 5 (Faithfulness). *For any natural deduction system \mathcal{L} defined by a set of rules \mathcal{R} , if we can prove $T(A_1) \& \dots \& T(A_n) \rightarrow T(A)$ in \mathcal{L}^* , then A is derivable in \mathcal{L} from the assumptions A_1, \dots, A_n .*

Proof. The theorem follows immediately from the existence of ENF derivations and Lemma 6 below. ■

LEMMA 6. *There is an effective transformation from ENF derivations in \mathcal{L}^* of $T(A)$ from atomic assumptions Δ , to natural deduction derivations in \mathcal{L} of A from assumptions $\{B \mid T(B) \in \Delta\}$.*

Proof. We prove this by induction on the structure of ENF derivations. Intuitively, we show that an ENF derivation is built out of characteristic fragments, and thus can easily be translated back into the original deductive system. Consider a derivation Σ of $T(A)$.

Base case: $T(A)$ corresponds to either an assumption in Δ or a (premissless) rule of the encoded theory. The translation then consists either of the assumption A or of the corresponding premissless rule with conclusion A .

Step case: Since the derivation is in ENF and the conclusion is atomic, the last rule applied is an elimination rule; more specifically, the derivation must have the form

$$\frac{\frac{\Phi_1^* \& \cdots \& \Phi_n^* \rightarrow T(A)}{\Phi_1^* \& \cdots \& \Phi_n^* \rightarrow T(A)} \Theta^* \quad \frac{\begin{array}{c} \vdots \Sigma_1 \quad \vdots \Sigma_n \\ \Phi_1^* \quad \cdots \quad \Phi_n^* \\ \hline \Phi_1^* \& \cdots \& \Phi_n^* \end{array} \#}{\Phi_1^* \& \cdots \& \Phi_n^* \rightarrow T(A)} \#}{T(A)} \rightarrow\text{-}E \quad (12)$$

where $\#$ consists only of applications of $\&\text{-}I$ and Θ^* is

$$\Phi_1^* \& \cdots \& \Phi_n^* \rightarrow T(A)$$

for some rule Θ of the encoded system.

By the definition of the encoding, each Φ_i^* , derived by a proof Σ_i , is then of the form

$$T(A_{i_1}) \& \cdots \& T(A_{i_{m_i}}) \rightarrow T(A_i).$$

Since the conclusion of Σ_i proves an implication, and is in ENF, the last rule applied must be $\rightarrow\text{-}I$; thus Σ_i must have the form

$$\frac{\frac{\begin{array}{c} [T(A_{i_1})] \cdots [T(A_{i_{m_i}})] \\ \vdots \Sigma'_i \\ [T(A_{i_1}) \& \cdots \& T(A_{i_{m_i}})]_1 \end{array} T(A_i)}{T(A_i)} \#}{T(A_{i_1}) \& \cdots \& T(A_{i_{m_i}}) \rightarrow T(A_i)} \rightarrow\text{-}I_1$$

with open assumptions Δ , where $\#$ consists only of applications of $\&\text{-}E$, which ‘unpack’ the assumption $T(A_{i_1}) \& \cdots \& T(A_{i_{m_i}})$ into its component propositions. In other words, (12) corresponds to the characteristic fragment for Θ .

By induction we can apply the same analysis to each Σ'_i , taking account not only of the undischarged assumptions Δ , but also the new atomic assumptions $\Delta + \{T(A_{i_1}), \dots, T(A_{i_{m_i}})\}$ which have been introduced, and we are finished. \blacksquare

3.6 Generalizations of natural deduction

The distinction we mentioned above (in §3.1) that Gentzen and Prawitz make between natural deduction and sequent calculi has recently been emphasized by Schroeder-Heister [1984a; 1984b], who has proposed a ‘generalized natural deduction’. This extension, which follows directly from Gentzen’s appeal to intuition to justify natural deduction, is not formalizable using sequents in the way suggested in §3.¹⁰

Consider again Gentzen’s proposed ‘natural language’ analysis of logical connectives. In these terms we can characterize Implication Elimination as

If $A \supset B$ and A , then it follows that B

which we formalize as:

$$\frac{A \supset B \quad A}{B}$$

Now consider the slightly more convoluted

If $A \supset B$ and assuming that if, given that from A we could derive B , we could derive C , then we can derive C .

which is also true. There is a natural generalization of rules that allows us to express this in the spirit of natural deduction; namely,

$$\frac{A \supset B \quad \left[\begin{array}{c} A \\ \hline B \\ \vdots \\ C \end{array} \right]}{C} \quad (13)$$

where we can assume rules as hypotheses (and by generalization, have rules as hypotheses of already hypothetical rules, and so on). Schroeder-Heister shows that it is quite a simple matter to extend the formula-tree/discharge-function formalization to cope with this extension: we simply allow discharge functions to point to subtrees rather than just leaves.

Why is such a generalization interesting? Schroeder-Heister uses it to analyze systematically the intuitionistic logical connectives. However it has more general use, and at least one immediate application: we can use it to encode Peirce’s law without introducing new connectives, as

$$\frac{\left[\begin{array}{c} A \\ \hline B \\ \vdots \\ A \\ \hline A \end{array} \right]}{A}$$

¹⁰Though see Avron [1990] for relevant discussion.

which, in English, is equivalent to

if, by assuming that some B follows from A , it follows that A , then it follows that A .

This provides, finally, a self-contained generalized natural deduction formulation of classical implication. (At least in the sense that the meaning of implication can be defined by rules involving no auxiliary connectives.)

The process of generalization can obviously be continued beyond allowing rules as hypotheses, though. There is no reason why we cannot also have them as conclusions. Thus, for instance, it is clearly true that

$$\frac{A \supset B}{\left(\frac{A}{B} \right)} \rightarrow\text{-}E_C$$

(where round brackets do not, in the manner of square brackets, represent the discharge of an assumption, but simply grouping), which might reasonably be read as:

If $A \supset B$ then from A it follows that B .

By now, however, while our intuition still seems to be functioning soundly, the formula-tree/discharge-function formalization is beginning to break down. It can cope with rules as assumptions, but the more general treatment of both rules and formulae in derivations that we are now proposing is more difficult. With our proposed alternative of the metalogic $\text{NJ}^{\rightarrow, \&}$, on the other hand, the same problems do not arise. In fact one way of looking at the faithfulness argument developed above is as essentially a demonstration that this sort of ‘confusion’ can be unwound for the purpose of recovering a proof in a system that does not in the end allow it. The question then is, how closely does our logic match the traditional formulation?

In the most general case, allowing rules as both hypotheses and conclusions, such a question is not quite meaningful, since we do not have a traditional formulation against which we can compare. However if we limit ourselves to the restricted case where we have rules as assumptions, it is still possible to be properly formal, since we can still compare our encoding to Schroeder-Heister’s more traditional formalization in terms of formula-trees and discharge-functions.

Such a formulation is enough to allow us, by a ‘natural’ generalization of the encoding in (7), to formalize, for instance, (13) as

$$(T(A \supset B) \& ((T(A) \rightarrow T(B)) \rightarrow T(C))) \rightarrow T(C)$$

and $\rightarrow\text{-}E_C$ as

$$T(A \supset B) \rightarrow T(A) \rightarrow T(B).$$

It is now possible, by a corresponding generalization of the notion of deduction (see Schroeder-Heister [1984b]) to show adequacy and faithfulness for this larger class of deductive systems.

Generalized natural deduction and curried rules

Until now we have been using $\text{NJ}^{\rightarrow, \&}$ to encode and reason with deductive systems. If we want to show a direct relationship between the traditional notation of natural deduction and our encoding, then we seem to need both the \rightarrow and $\&$ connectives in the metalogic. However, compare $\rightarrow\text{-}E$ and $\rightarrow\text{-}E_C$; while there seems to be large differences between the two as rules, there is very little either in natural language or in logical framework terms: one is simply the ‘curried’ form of the other; in this case the conjunction seems almost redundant.

On the other hand, one generalization that we have not made so far, and one that is suggested by $\text{NJ}^{\rightarrow, \&}$, is to allow a natural deduction rule with multiple conclusions; e.g. assuming an ordinary conjunction \wedge , have a (tableau-like) rule

$$\frac{A \wedge B}{A, B} \&\text{-}E_{MC}$$

corresponding to the natural language

If $A \wedge B$ then it follows that A and B .

Both of which correspond to the framework formalization

$$T(A \wedge B) \rightarrow T(A) \& T(B).$$

However, there seems to be less of a need for rules of this form: a single encoded rule $C \rightarrow A \& B$ can be replaced by a pair $C \rightarrow A$ and $C \rightarrow B$.

If we are willing to accept this restriction to the language of \rightarrow alone, then we can simplify the metalogic we are using: if we have conjunctions only in the antecedents of implications \rightarrow , they can always be eliminated by ‘currying’ the formulae conjoined in the antecedent, allowing us to dispose of conjunction completely. For example, the curried form of the axiom for $\rightarrow\text{-}E$ in (6) is then

$$T(A \supset B) \rightarrow T(A) \rightarrow T(B).$$

Notice that this form of $\rightarrow\text{-}E$ is indistinguishable from the encoding we give above for $\rightarrow\text{-}E_C$: we are no longer able to distinguish some different rules in generalized natural deduction, and thus we lose the faithfulness/adequacy bijection that we have previously demonstrated. However this problem is not serious: we are only identifying proofs that differ in simple ways, e.g., by the application of curried versus uncurried rules. Furthermore, this possible confusion arises in the case of *generalized* natural deduction, but not in the traditional form.

In the next section we describe a full logical framework based on the ideas we have developed here. In fact it turns out that we can adopt the same notation to formalize not only deductive systems, but also languages, in a uniform manner.

4 FRAMEWORKS BASED ON TYPE-THEORIES

In the last section we established a relationship between natural deduction and the logic of implication. However we considered only reasoning about fragments of propositional logic, and when we turn to predicate logics, we find that the mechanisms of binding and substitution introduce some entirely new problems for us to solve.

The first problem is simply how to encode languages where operators bind variables. Such variable binding operators include standard logical quantifiers, the λ of the λ -calculus, fixedpoint operators like μ in fixedpoint logics, etc. Until now we have been using a simple term algebra to represent syntax, where, e.g. a binary connective like implication is represented by a binary function. However, with the introduction of binding and substitution this approach is less satisfactory. For instance $\forall x. \phi(x)$ and $\forall y. \phi(y)$ are distinct syntactically, but not in terms of the deductive system (any proof of one proves the other). Binding operators also complicate operations performed on syntax; e.g. substitution. The second problem is that proof-rules become more complex: the rules for quantifiers place conditions on the contexts (e.g. insisting that certain variables do not appear free) in which they can be applied.

Now we extend our investigation to deal with these problems, and complete the development of a practical \rightarrow -framework. We tackle the two problems of language encoding and rule encoding together, by introducing the λ -calculus as a representation language into our system. This provides us with a way to encode quantifiers using *higher-order* syntax and then to encode rules for these quantifiers.

There are different ways that we can combine the λ -calculus with a metalogic. One possibility is simply to add it to the term language, extending, e.g., the theory NJ^{\rightarrow} to a fragment of higher-order logic.¹¹ Another, similar, possibility, and one which offers some theoretical advantages, is to use a *type-theory*. We investigate the type-theoretic approach in this section. Type-theories based on the λ -calculus are well-known to be closely related to intuitionistic logics like NJ^{\rightarrow} via ‘Curry-Howard’ (see Howard [1980]), or *propositions-as-types*, isomorphisms, a fact which allows us to carry across much of what we already know about encoding deductive systems from NJ^{\rightarrow} . Moreover, an expressive enough type-theory provides a unified language for representing not just syntax, but also proof-rules and proofs. Thus a type-theoretic logical framework can provide a single solution to the apparently distinct problems of encoding languages and deductive systems: The encoding problems are reduced to declaration of appropriate (higher-order) signatures and the checking problems (e.g. well-formedness of syntax and the correctness of derivations) to the problem of type checking against these signatures.

¹¹ See, e.g., Felty [1989], Paulson [1994] or Simpson [1992], for examples of this approach.

4.1 Some initial observations

We begin by considering the problem of formalizing a binding operator, taking \forall as our example. Consider what happens if we follow through the analysis given above for natural deduction in propositional logic. First we state, in Gentzen style natural language, some of the properties of \forall ; e.g.

if, for arbitrary t , it follows that $\phi(t)$, then it follows that $\forall x. \phi(x)$

and

if it follows that $\forall x. \phi(x)$, then for any t it follows that $\phi(t)$.

These are traditionally represented, in the notation of natural deduction, as

$$\frac{\phi}{\forall x. \phi} \forall\text{-}I \quad \text{and} \quad \frac{\forall x. \phi}{\phi[x \leftarrow t]} \forall\text{-}E$$

where, in $\forall\text{-}I$, the variable x does not appear free in any undischarged assumption, and the notation $\phi[x \leftarrow t]$ denotes the formula ϕ where the term t has been substituted through for x (care being taken to avoid capturing variables). The relationship between these rules and their informal characterizations is less direct here than in the propositional case; for example, we model the statement ‘If, for arbitrary t , it follows that $\phi(t)$ ’ indirectly, by assuming that an arbitrary variable x can stand for an arbitrary term, then ensuring that x really is arbitrary by requiring that it does not occur free in the current assumptions.

Consider how we might use a ‘logical’ language instead of rules by extending our language based on minimal implication. To start with, we need a way of saying that a term is arbitrary, which we can accomplish with universal quantification. Furthermore, unlike in the propositional case, we have two syntactic categories. As well as formulae (fm), we now have terms (tm), and we will use types to formally distinguish between them. If we combine quantification with typing, by writing $(x:y)$ to mean ‘for all x of type y ’, then a first attempt at translating natural language into (semi)formal language results in the following:

$$\begin{aligned} T(\forall x. \phi(x)) &\rightarrow (t:tm)T(\phi(t)) \\ (t:tm)T(\phi(t)) &\rightarrow T(\forall x. \phi(x)) \end{aligned} \tag{14}$$

However while this appears to capture our intuitions, it is not clear that it is formally meaningful. If nothing else, one might question the cavalier way we have treated the distinction between object-level and metalevel languages. In the following sections we show that this translation does in fact properly correspond to the intuitive reading we have suggested.

4.2 Syntax as typed terms

We begin by considering how languages that include variable-binding operators can be represented. We want a method of representing syntax where terms in the

object logic are represented by terms in the metalogic. This representation should be computable and we want too that it is compositional; i.e. that the representative of a formula is built directly from the representatives of its subformulae.

Types provide a starting point for solving these problems. A type system can be used to classify terms into types where well-typed terms correspond to well-formed syntax. Consider the example of first-order logic; this has two syntactic categories, terms and formulae, and, independent of whether we view syntax as strings, trees, or something more abstract, we must keep track of the categories to which subexpressions belong. One way to do this is to tag expressions with their categories and have rules for propagating these tags to ensure that entire expressions are ‘well-tagged’. Even if there is only one syntactic category we still need some notion of well-formed syntax; in minimal logic, for instance, some strings built from implication and variables, such as $\phi \supset \psi$, are well-formed formulae, while others, like $\phi \supset \supset \psi$, are not.

In a typed setting, we can reduce the problem of syntactic well-formedness to the problem of well-typedness by viewing syntax as a typed term algebra: we associate a type of data with each syntactic category and regard operators over syntax as typed functions. For instance, \supset corresponds to a function that builds a formula given two formulae, i.e., a function of type $fm \times fm \rightarrow fm$. Under this reading, and using infix notation, $\phi \supset \psi$ is a well-typed formula provided that ϕ and ψ are both well-typed formulae of type fm , whereas $\phi \supset \supset \psi$ is ill-typed.

This view of syntax as typed terms provides a formalization of the treatment of propositional languages as term algebras that we have informally adopted up to now. We will see that it also provides a basis for formalizing languages with quantification. In fact the mechanism by which this is done is so flexible that it is possible to claim:

THEESIS 7. The typed λ -calculus provides a logical basis for representing many common kinds of logical syntax.

Note that we do not claim that the typed λ -calculus, as we shall use it, is a universal solution applicable to formalizing any language. We cannot, for instance, formalize a syntax based on a non-context-free grammar. Neither can we give a finite signature for languages that require infinitely many (or parameterized) sets of productions. The notation is remarkably flexible nevertheless, and, especially if we refine the type system a little further, can deal with a great many subtle problems — a good example of this can be found in the analysis of the syntax of higher-order logic developed by Harper *et al.* [1993].

The simply typed λ -calculus

We assume that the reader is familiar with the basics of the λ -calculus, e.g. reduction (we denote one-step reduction by \rightarrow_β and its reflexive-transitive closure by \rightarrow_β^*) and conversion ($=_\beta$), and review only syntax and typing here; further details can be found in Barendregt [1984; 1991] or Hindley and Seldin [1986]. We now

define a type theory based on this, called the *simply typed* λ -calculus, or more succinctly λ^\rightarrow . Our development is based loosely on that of Barendregt and anticipates extensions we develop later.

We start by defining the syntax we use:

DEFINITION 8. Fix a denumerable set of variables \mathcal{V} . The terms and types of λ^\rightarrow are defined relative to a signature consisting of a non-empty set of *base types* \mathcal{B} , a set of *constants* \mathcal{K} , and a *constant signature* Σ , which is a set $\{c_i:A_i \mid 1 \leq i \leq n, c_i \in \mathcal{K}, A_i \in \text{Ty}\}$, where the c_i are distinct, and:

- The set of *types* Ty is given by

$$\text{Ty} ::= \mathcal{B} \mid \text{Ty} \rightarrow \text{Ty}.$$

- The set of *terms* \mathcal{T} is given by

$$\mathcal{T} ::= \mathcal{V} \mid \mathcal{K} \mid \mathcal{T}\mathcal{T} \mid \lambda\mathcal{V}^{\text{Ty}}.\mathcal{T}.$$

A variable x occurs *bound* in a term if it is in the scope of a λx and x occurs *free* otherwise. We implicitly identify terms that are identical under a renaming of bound variables.

- A *typing context* is a sequence $x_1:A_1, \dots, x_n:A_n$ of *bindings* where the x_i are distinct variables and $A_i \in \text{Ty}$ for $(1 \leq i \leq n)$.

For convenience, we shall overload the \in relation, extending it from sets to sequences in the obvious manner (i.e. so that $x_i:A_i \in x_1:A_1, \dots, x_n:A_n$ iff $1 \leq i \leq n$).

- A *type assignment relation* \vdash_Σ is a binary relation, indexed by Σ , defined between typing contexts Γ and typing assertions $M:A$ where $M \in \mathcal{T}$ and $A \in \text{Ty}$, by the inference rules:

$$\begin{array}{c} \frac{c:A \in \Sigma}{\Gamma \vdash_\Sigma c:A} \textit{assum} \qquad \frac{\Gamma, x:A \vdash_\Sigma M:B}{\Gamma \vdash_\Sigma (\lambda x^A. M):(A \rightarrow B)} \textit{abst} \\ \frac{x:A \in \Gamma}{\Gamma \vdash_\Sigma x:A} \textit{hyp} \qquad \frac{\Gamma \vdash_\Sigma M:A \rightarrow B \quad \Gamma \vdash_\Sigma N:A}{\Gamma \vdash_\Sigma (MN):B} \textit{appl} \end{array}$$

This definition states that types consist of the closure of a set of base types under the connective \rightarrow and that terms are either variables, constants, applications or (typed) λ -abstractions. The rules constitute a deductive system that defines when a term is well-typed relative to a context and a signature, which in turn assign types to free variables and constants. Notice that we do not have to make explicit the standard side condition for *abst* that the variable x does not appear free in Γ , since this is already implicitly enforced by the requirement that variables in a type context must be distinct.

As an example, if $\{A, B\} \subseteq \text{Ty}$ then

$$\begin{array}{c}
 \frac{x:A \in x:A, y:B}{x:A, y:B \Vdash x:A} \text{assum} \\
 \frac{x:A, y:B \Vdash x:A}{x:A \Vdash \lambda y^B. x:B \rightarrow A} \text{abst} \\
 \frac{x:A \Vdash \lambda y^B. x:B \rightarrow A}{\Vdash \lambda x^A. \lambda y^B. x:A \rightarrow (B \rightarrow A)} \text{abst}
 \end{array} \tag{15}$$

is a proof (for any Σ). Further, it is easy to see that:

FACT 9. Provability for this system (and thus well-typing) is decidable.

A Curry-Howard isomorphism for λ^\rightarrow

The rules for λ^\rightarrow suggest the natural deduction presentation for NJ^\rightarrow (see §3.1): if we rewrite all instances of $\Gamma \Vdash M:A$ in a proof in λ^\rightarrow as $\Gamma, \Sigma \vdash M:A$ and uniformly replace each typing assertion $c:A$, $x:A$, and $M:A$ by the type A , then *abst* and *appl* correspond to $\rightarrow\text{-I}$ and $\rightarrow\text{-E}$, while *hyp* and *assum* together correspond to *Basic*. The following makes this correspondence more precise.

FACT 10.

1. There is a bijection between types in λ^\rightarrow and propositions in NJ^\rightarrow where a proposition in NJ^\rightarrow is provable precisely when the corresponding λ^\rightarrow type is inhabited (has a member).
2. There is a bijection between members of types in λ^\rightarrow and proofs of the corresponding propositions in NJ^\rightarrow .

Part 1 of this characterizes the direct syntactic bijection between types and propositions where base types correspond to atomic propositions¹² and the function space constructor corresponds to the implication connective. The correspondence between provability and inhabitation then follows from the correspondence between the proof-rules of the two systems. Then part 2 refines the bijection to the level of inhabiting terms on the one hand, and proofs on the other.

Fact 10 states an isomorphism between types and propositions that we can characterize as ‘truth is inhabitation’: if $M:A$ then the proposition corresponding to A is provable and, moreover, there is a corresponding notion of reduction in the two settings where β -reduction of M in the λ -calculus corresponds to reduction of the proof A (in the sense of Prawitz).

We exploit this isomorphism in reasoning about encodings in this chapter. In this section we show the correctness of encodings by reasoning about normal forms of terms in type-theory and in §5 we will reason about normal forms of proofs.

¹²This fact holds for the pure version of λ^\rightarrow without constants. We also implicitly assume a bijection between base types and propositional variables.

REMARK 11. For reasoning about the correctness of encodings it is sometimes necessary to use a more complex isomorphism based on both β and η -conversion. It is possible to establish a correspondence between so called long $\beta\eta$ -normal forms¹³ and corresponding classes of derivations in NJ^{\rightarrow} . More details can be found in [Harper *et al.*, 1993].

Representation

In order to represent syntax in λ^{\rightarrow} we define a suitable signature Σ and establish a correspondence between terms in the metalogic and syntax in the object logic. Our signature will consist of a base type for each syntactic category of the object logic and a constant for each constructor in the object logic. We will see that we do not need a type *variable* to formalize variables in the object logic because we can use instead variables of the metalogic. Syntax belonging to a given category in the object logic then corresponds to terms in the metalogic belonging to the type of that category.

This is best illustrated with a simple example: we represent the syntax of minimal logic itself. We follow Church's [1940] convention, where o is the type of propositions, so the signature is the (singleton) set of base types $\{o\}$, and the constant signature is

$$\Sigma \equiv \{imp: o \rightarrow o \rightarrow o\}. \quad (16)$$

The constructor imp builds a proposition from two propositions. With respect to this signature, $imp\ x\ (imp\ y\ z)$ is a term that belongs to o when x , y , and z belong to o ; i.e. $x:o, y:o, z:o \vDash imp\ x\ (imp\ y\ z):o$. This corresponds to the fact that $x \supset (y \supset z)$ is a proposition of minimal logic provided that x , y , and z are propositions.

Thus formulae of minimal logic correspond to well-typed terms of type o . Formulating this correspondence requires some care though: we have to check adequacy and faithfulness for the represented syntax; this amounts to showing that (i) every formula in minimal logic is represented by a term of type o , and (ii) that every term of type o represents a formula in minimal logic.

As a first attempt to establish such a correspondence, consider the following mapping $\ulcorner \cdot \urcorner$, from terms in minimal logic to λ -calculus terms:

$$\begin{aligned} \ulcorner x \urcorner &= x \\ \ulcorner t_1 \supset t_2 \urcorner &= imp\ \ulcorner t_1 \urcorner\ \ulcorner t_2 \urcorner \end{aligned}$$

As an example, under this representation the formula $x \supset (y \supset z)$ corresponds to the term $imp\ x\ (imp\ y\ z)$. The representation function is an injection from propositions to terms of type o , provided that variables are declared to be of type

¹³A term $M = \lambda x_1 \dots x_n. x M_1 \dots M_m$ is in long $\beta\eta$ -normal form when 1) x is an x_i , a constant, or a free variable of M , 2) $x M_1 \dots M_n$ is of base type (i.e. x is applied fully to all possible arguments) and 3) each M_i is in long $\beta\eta$ -normal form.

o in the context. However, it is not surjective: there are too many terms of type o . For example in a context where x is of type $o \rightarrow o$ and y is of type o , then $x y$ is of type o , and so is $\text{imp } ((\lambda z^o. z) y) y$; but neither of these is in the image of $\ulcorner \cdot \urcorner$. The problem with the first example is that the variable x is of higher type (i.e. the function type $o \rightarrow o$) and not a base type in \mathcal{B} . The problem with the second example is that it is not in normal form. Any such term, however, has a unique equivalent β -normal form, which we can compute. In the above example the term has the normal form $\text{imp } y y$, which is $\ulcorner y \supset y \urcorner$. Our correspondence is thus a bijection when we exclude the cases above: we consider only β -normal form terms where free variables are of type o .

THEOREM 12. $\ulcorner \cdot \urcorner$ is a bijection between propositions in minimal logic with propositional variables x_1, \dots, x_n , and β -normal form terms of type o containing only free variables x_1, \dots, x_n , all of type o .

First-order syntax

The syntax of minimal logic is very simple, and we do not need all of λ^\rightarrow to encode it. We can be precise about what we mean by ‘not all’ if we associate types with orders: observe that any type γ has a unique representation as $\alpha_1 \rightarrow \dots \rightarrow \alpha_n \rightarrow \beta$, where \rightarrow associates to the right and β is a base type. Now define the *order* of γ to be 0 if $n = 0$, and $1 + \max(\text{Ord}(\alpha_1), \dots, \text{Ord}(\alpha_n))$ otherwise.¹⁴ In our encoding of minimal propositional logic we have used only the first-order fragment of λ^\rightarrow ; i.e. variables are restricted to the base type o and the only function constant imp is first-order (since its two arguments are of base type); this is another way of saying that an encoding using a simple term algebra is enough.

This raises an obvious question: why adopt a full higher-order notation if a simple first-order notation is enough? Indeed, in a first-order setting, results like Theorem 12 are much easier to prove because there are no complications introduced by reduction and normal forms. The answer is that the situation changes when we introduce quantifiers and other variable binding operators. A ‘naive’ encoding of syntax is still possible but is much more complicated.

Consider, as an example, the syntax of first-order arithmetic. This is defined in terms of two syntactic categories, terms and formulae, which are usually specified as:

$$\begin{aligned} \text{terms } T &::= x \mid 0 \mid sT \mid T + T \mid T \times T \\ \text{formulae } F &::= T = T \mid \neg F \mid F \wedge F \mid F \vee F \mid F \supset F \mid \forall x. F \mid \exists x. F \end{aligned}$$

How should we represent this? A possible first-order notation is as follows: we define a base type v of variables, in addition to types i for terms (i.e. ‘individuals’) and o for formulae. Since variables are also terms, our signature requires a ‘coercion’ function mapping elements of type v to elements of type i . The

¹⁴Note that there is not complete agreement in the literature about the order of base types, which is sometimes defined to be 1, not 0.

rest of the signature is formalized as we would expect; e.g. *plus* is a constant of type $i \rightarrow i \rightarrow i$, atomic formulae are built from the equality relation *eq* of type $i \rightarrow i \rightarrow o$, connectives are defined as propositional functions over *o*, and a quantifier like \forall is formalized by declaring a function constant *all* of type $v \rightarrow o \rightarrow o$ taking a variable and a formula to a formula.

This part of the encoding presents no difficulties. However the problems with first-order representations of a language with binding are not directly in the representation, but rather in the way we will use that representation. It is in the formalization of proof-rules where we encounter the problems, in particular with substitution. Consider, for instance, \forall -*E* in (4.1), where we use the notation $\phi[x \leftarrow t]$; we need to formalize an analogue for our encoding, which we can do by introducing a ternary function, *sub* of type $o \rightarrow i \rightarrow v \rightarrow o$, where $sub(\phi, t, x) = \psi$ is provable precisely when $\phi[x \leftarrow t] = \psi$. With this addition \forall -*E* is axiomatizable as

$$\forall \phi, \psi: o. \forall t: i. \forall x: v. (sub(\phi, t, x) = \psi) \rightarrow T(all\ x\ \phi) \rightarrow T(\psi). \quad (17)$$

There are several ways we might axiomatize the details of *sub*. The most direct approach is simply to formalize the standard textbook account of basic concepts such as free and bound variables, capture, and equivalence under bound variable renaming, which we can easily do by structural recursion on terms and formulae. The definitions are well-known, although complex enough that some care is required, e.g. bound variables must sometimes be renamed to avoid capture. Note too that in (17) we have used the equality predicate over formulae (not to be confused with equality over terms in the object logic, i.e. *eq*), which must either be provided by the metalogic or additionally formalized. Examples of such equational encodings of logics are given by Martí-Oliet and Meseguer [2002].

Other encodings have also been explored: for instance we can use a representation of terms that finesses problems involving bound variable names by eliminating them entirely. Such an approach was originally suggested by de Bruijn [1972] who represents terms with bound variables by replacing occurrences of such variables with ‘pointers’ to the operators that bind them. A related approach has been proposed by Talcott [1993], who has axiomatized a general theory of binding structure and substitution, which can be used as the basis for encoding logics that require such facilities. Another recent development, which is gaining some popularity, is to provide extensions of the λ -calculus that formalize operators for ‘explicit substitutions’ [Abadi *et al.*, 1991].

In all of these approaches, direct or indirect, there is considerable overhead, and not only at the formalization stage itself: when we are building proofs, we have to construct subproofs using the axiomatization of *sub* at every application of \forall -*E*. Being forced to take such micro-steps in the metatheory simply to apply a rule in the object logic is both awkward and tedious. And there is another serious problem that appears when we consider a rule like \forall -*I* in (4.1), where we have a side condition that *the variable x does not appear free in any undischarged*

assumption. There is no direct way, in the language we have been developing, to complete the formalization of this: we cannot reify the semiformal

$$\forall\phi:o.\forall x:v. x \text{ not free in context} \rightarrow T(\phi) \rightarrow T(\text{all } x \phi) \quad (18)$$

into a formal statement (we cannot, in general, refer to contexts in this way).

Again there are ways to get around the problem by complicating the formalization. For instance while we cannot tell which variables are free in the context, we can, under certain circumstances, keep track of those that might be. We can define a new type sv , of sets of variables, with associated algebra and predicates, where, e.g., $\text{notin}(x, c)$ is a predicate on types v and sv that is true iff x does not occur in the set c , and union is a function of type $sv \rightarrow sv \rightarrow sv$ that returns the union of its arguments. In this setting we can then expand $T(\cdot)$ so that rather than being a predicate on o , it is a predicate on o and sv ; this yields the formalization

$$\forall\phi:o.\forall x:v.\forall c:sv. \text{notin}(x, c) \rightarrow T(\phi, c) \rightarrow T(\text{all } x \phi, c).$$

In addition, we have, of course, to modify all the other rules so they keep track of the variables that might be added to the context; for instance $\rightarrow-I$ now has the formalization

$$\forall\phi, \psi:o.\forall c:sv. (T(\phi, c) \rightarrow T(\psi, \text{union}(c, \text{fv}(\phi)))) \rightarrow T(\text{imp } \phi \psi, c),$$

where fv returns the set of variables free in a formula (i.e. for ψ we have added all the free variables of ϕ to the free variables in the context).

Clearly, first-order syntax in combination with \rightarrow is becoming unacceptably complicated at this point, and is far removed from the ‘sketched’ characterization in (14). If part of the motivation of a logical framework is to provide a high-level abstraction of a deductive system, which we can then use to implement particular systems, then, since substitution and binding are standard requirements, we might expect them to be built into the framework, rather than encoded from scratch each time we need them. We thus now examine a very different sort of encoding in terms of λ^\rightarrow that does precisely this.

Higher-order syntax

When using a first-order encoding of syntax, each time we apply a proof-rule like $\forall-E$, we must construct a subproof about substitution. But in λ^\rightarrow we already have a substitution mechanism available that we can exploit if we formalize variable binding operators a bit differently. The formalization is based on what is now commonly called *higher-order syntax*.

We start by observing that in λ^\rightarrow the λ operator binds variables, β -reduction provides the sort of substitution we want, and we have a built-in equivalence that accounts for renaming of bound variables. Higher-order syntax is a way of exploiting this, using higher-order functions to formalize the variable binding operators of

an encoded logic directly, avoiding the complications associated with a first-order encoding.

The idea is best illustrated with an example. If we return to the problem of how to encode the language of arithmetic, then, using higher-order syntax our signature need contain only the two sorts, for terms and formulae; i.e. $\mathcal{B} = \{i, o\}$.

We do not need a sort corresponding to a syntactic category of variables, because now we will represent them directly using variables of the metalogic itself, which are either declared in the context or bound by λ in the metalogic. The signature Σ is then

$$\begin{aligned} \{0:i, s:i \rightarrow i, plus:i \rightarrow i \rightarrow i, times:i \rightarrow i \rightarrow i, eq:i \rightarrow i \rightarrow o, \\ falsum:o, neg:o \rightarrow o, or:o \rightarrow o \rightarrow o, and:o \rightarrow o \rightarrow o, \\ imp:o \rightarrow o \rightarrow o, all:(i \rightarrow o) \rightarrow o, exists:(i \rightarrow o) \rightarrow o\}. \end{aligned} \quad (19)$$

In this signature *all* and *exists* no longer have the (first-order) type $v \rightarrow o \rightarrow o$; instead they are second order, taking as their arguments predicate valued functions (which have first-order types).

Using higher-order syntax, an operator that binds a variable can be conceptually decomposed into two parts. First, if ϕ is an encoded formula, i.e. of type o , possibly including a free metavariable x of type i , then $\lambda x^i. \phi$ is the abstraction of ϕ over x , where x is now bound. The result is, however, of type $i \rightarrow o$, not of type o . Second, we convert $\lambda x^i. \phi$ back into an object of type o , and indicate the variable binding operator we want, by applying that operator to it. For example, applying *all* to $\lambda x^i. \phi$ yields the term *all* ($\lambda x^i. \phi$) of type o . Similarly, for a substitution we reverse the procedure. Given *all* ($\lambda x^i. \phi$), for which we want to generate the substitution instance $\phi[x \leftarrow t]$, we first strip off the operator *all* and apply (in λ^\rightarrow) the result to t , to get $(\lambda x^i. \phi)t$. But in λ^\rightarrow this reduces to $\phi[x \leftarrow t]$. Hence, we needn't formalize explicitly any substitution mechanism for the object logic since we can exploit the substitution that is (already) formalized for the metalogic.

Of course we must check that all of this works. But it is easy to extend adequacy (Theorem 12) for this signature to show that the terms and formulae of first-order arithmetic are correctly represented by normal form members of types i and o respectively.

Now we can formalize \forall -*E* and \forall -*I* in a way that directly reflects the sketch in (14):

$$\begin{aligned} \forall \phi^{i \rightarrow o}. (T(\text{all } \phi) \rightarrow \forall x^i. T(\phi x)) \\ \forall \phi^{i \rightarrow o}. ((\forall x^i. T(\phi x)) \rightarrow T(\text{all } \phi)) \end{aligned} \quad (20)$$

If we compare this with (18) above, we can see how, by using metavariables as object variables, we are able to formalize the side condition ‘ x not free in context’ in (20) by having x bound directly by a universal quantifier at the metalevel.

In conclusion, higher-order syntax provides strong supporting evidence for Thesis 7 by providing a mechanism for using the λ of the metatheory to provide directly the machinery needed for variable binding, substitution, variable renaming,

and the like, which are typically needed for representing and using object logics that contain variable binding operators.

4.3 Rules of proof and dependent types

We have shown how we can use a type-theory to represent syntax, reducing the problem of syntactic well-formedness to the problem of decidable well-typing. We now extend the language we are developing so that we can do the same with proof-rules.

We can use λ^\rightarrow as a representation language for proofs too, but it is too weak to reduce proof checking to type checking alone. To see why, consider the two function symbols *times* and *plus* in the signature defined in (19). Both are of type $i \rightarrow i \rightarrow i$, which means that as far as the typing enforced by λ^\rightarrow is concerned, they are interchangeable; i.e., if t is a well-typed term in λ^\rightarrow , and we replace every occurrence of the constant *times* with the constant *plus*, we get a well-typed term t' . If t is supposed to represent a piece of syntax, this is what we want; for instance if we have used the type-checking of λ^\rightarrow to show that $t \equiv eq(times\ 0\ (s0))\ 0$ is a well-formed formula, i.e. that $t:o$, then we immediately know that t' is a well-formed formula too. Unfortunately, what is useful for encoding syntax makes it impossible to define a type of proofs: in arithmetic we want t , but not t' , to be provable, but we cannot make this distinction in λ^\rightarrow : we cannot define a type pr such that $a:pr$ iff a is the encoding of a proof, since we would not be able to tell whether a ‘proof’ is of t or of t' .

This observation may seem at odds with the relationship between NJ^\rightarrow and λ^\rightarrow established in §3, since we have already used NJ^\rightarrow to encode (propositional) proofs. But in our discussion of the Curry-Howard isomorphism, we were careful to talk about the *propositional fragment* of NJ^\rightarrow , but in order to encode even propositional proofs in NJ^\rightarrow we have used the language of *quantifier-free predicate* logic, not propositional logic, and in order to encode the rules for quantifiers, we needed explicit quantification.

To represent proofs we proceed by extending λ^\rightarrow with *dependent* types, that is, with types that can depend on terms. Specifically, we introduce a new operator, Π , where, if A is a type, and for every $t \in A$, $B[x \leftarrow t]$ is a type, then so is $\Pi x^A. B$. In other words, we use Π to build families of types, $B[x \leftarrow t]$, indexed by A . Π is sometimes called a dependent function space constructor because its members are functions f where, for every $t \in A$, $f(t)$ belongs to the type $B[x \leftarrow t]$. The addition of dependent types generalizes λ^\rightarrow since when x does not occur free in B , the type $\Pi x^A. B$ is simply $A \rightarrow B$ because its members are just the functions from A to B that we have in λ^\rightarrow .

Given dependent function types, we can define the provability relation for a logic as a type-valued function: instead of having pr be a single type, we index it over the formulae it might prove, i.e. we define it to be a function from objects ϕ of type o (i.e. formulae) to the type of proofs of ϕ . Using this, we define typed function constants that correspond to rules of proof. For example, we can now

formalize implication elimination as

$$impe: \Pi x^o. \Pi y^o. pr(imp\ x\ y) \rightarrow pr(x) \rightarrow pr(y)$$

i.e., $impe$ is a function which, given formulae x and y (objects of type o), and terms proving $x \supset y$ and x , returns a term proving y .

We now provide the formal details of an extension of λ^\rightarrow in which we can build dependent types, and show that the approach to representing deductive systems using type systems actually works the way we want.

The metalogic λ^p

The particular theory we present, which we call λ^p , is closely related to the Edinburgh LF type-theory [Harper *et al.*, 1993] and the Π fragment of the AUTOMATH language AUT-PI [de Bruijn, 1980]. Our presentation is based on a similar presentation by Barendregt [1991; 1992], which we have chosen for its relative simplicity.

We define the expressions and types of λ^p together as follows:

DEFINITION 13 (Pseudo-Terms). Let \mathcal{V} be an infinite set of variables and \mathcal{K} be a set of constants that contains at least two elements, $*$ and \square , which are called *sorts*. A set of *pseudo-terms* \mathcal{T} is described by the following grammar

$$\mathcal{T} ::= \mathcal{V} \mid \mathcal{K} \mid \mathcal{T}\mathcal{T} \mid \lambda \mathcal{V}^{\mathcal{T}}. \mathcal{T} \mid \Pi \mathcal{V}^{\mathcal{T}}. \mathcal{T}$$

Π binds variables exactly like λ . Substitution (respecting bound variables) and bound variable renaming are defined in the standard manner.

DEFINITION 14 (A deductive system for λ^p). We define, together, judgments for a *valid signature*, a *valid context* and a *valid typing*. In the following, s ranges over $\{*, \square\}$:

- A *signature* is a sequence given by the grammar

$$\Sigma ::= \langle \rangle \mid \Sigma, c:A$$

where c ranges over \mathcal{K} . A *signature* Σ is *valid* when it satisfies the relation \vdash_s defined by:

$$\frac{}{\vdash_s \langle \rangle} \quad \frac{\vdash_s \Sigma \quad \vdash_s A:s \quad c \notin \text{dom}(\Sigma)}{\vdash_s \Sigma, c:A}$$

- A *context* is a sequence given by the grammar

$$\Gamma ::= \langle \rangle \mid \Gamma, x:A$$

where x ranges over \mathcal{V} . A *context* is *valid* with respect to a valid signature Σ when it satisfies the relation \vdash_c defined by:

$$\frac{}{\vdash_c \langle \rangle} \quad \frac{\vdash_c \Gamma \quad \Gamma \vdash_s A:s \quad x \notin \text{dom}(\Gamma)}{\vdash_c \Gamma, x:A}$$

- A *type assignment relation* \vdash_{Σ} , indexed by a valid signature Σ , is defined between valid typing contexts Γ and typing assertions $a:B$ where $a, B \in \mathcal{T}$ is given by the rules:

$$\begin{array}{c}
\frac{}{\Gamma \vdash_{\Sigma} *:\square} \textit{axiom} \qquad \frac{\Gamma \vdash_{\Sigma} A:* \quad \Gamma, x:A \vdash_{\Sigma} B:s}{\Gamma \vdash_{\Sigma} \Pi x^A. B:s} \textit{form} \\
\frac{c:A \in \Sigma}{\Gamma \vdash_{\Sigma} c:A} \textit{assum} \qquad \frac{\Gamma, x:A \vdash_{\Sigma} b:B \quad \Gamma \vdash_{\Sigma} \Pi x^A. B:s}{\Gamma \vdash_{\Sigma} \lambda x^A. b:\Pi x^A. B} \textit{abst} \\
\frac{x:A \in \Gamma}{\Gamma \vdash_{\Sigma} x:A} \textit{hyp} \qquad \frac{\Gamma \vdash_{\Sigma} f:\Pi x^A. B \quad \Gamma \vdash_{\Sigma} a:A}{\Gamma \vdash_{\Sigma} f(a):B[x \leftarrow a]} \textit{appl} \\
\frac{\Gamma \vdash_{\Sigma} a:B \quad \Gamma \vdash_{\Sigma} B':s \quad B =_{\beta} B'}{\Gamma \vdash_{\Sigma} a:B'} \textit{conv}
\end{array}$$

We use the two sorts $*$ and \square to classify entities in \mathcal{T} into levels. We say that $*$ is the set of types and \square is the set of kinds. As in λ^{\rightarrow} , terms, which are here a subset of the pseudo-terms, belong to types; unlike in λ^{\rightarrow} , types, which are here also pseudo-terms, belong to $*$. For example, if o is a type (i.e. $o:*$), then $\lambda x^o. x$ is a term of type $\Pi x^o. o$, which we can abbreviate as $o \rightarrow o$, since x does not occur free in o . It is possible to build kinds, in limited ways, using the constant $*$; in particular, the rules we give allow the formation of kinds with range $*$, e.g. $o \rightarrow *$ but exclude kinds with domain $*$, e.g. $* \rightarrow o$. Hence we can form kinds like $o \rightarrow *$ that have type-valued functions as members, but we cannot form kinds by quantifying over the set of types.

We state without proof a number of facts about this system. They have been proven in the more general setting of the so-called λ -cube (a family of eight related type systems) and generalized type systems examined by Barendregt [1991; 1992], but see also Harper *et al.* [1993] who show that the closely related LF type-theory has similar properties.

FACT 15. Term reduction in λ^p is Church-Rosser: given $A, B, B' \in \mathcal{T}$, then if $A \xrightarrow{*}_{\beta} B$ and $A \xrightarrow{*}_{\beta} B'$ there exists $C \in \mathcal{T}$ where both $B \xrightarrow{*}_{\beta} C$ and $B' \xrightarrow{*}_{\beta} C$.

FACT 16. Terms in λ^p are strongly normalizing: if $\Gamma \vdash_{\Sigma} A:B$, then A and B are strongly normalizing (all β -reductions starting with A or B terminate).

FACT 17. λ^p satisfies unicity of types: if $\Gamma \vdash_{\Sigma} A:B$ and $\Gamma \vdash_{\Sigma} A:B'$, then $B =_{\beta} B'$.

From the decidability of these operations it follows that:

FACT 18. All judgments of λ^p are decidable.

Relationship to other metalogics

The proof-rules for λ^p extend the rules given for λ^{\rightarrow} in Definition 8. The rules for λ^{\rightarrow} essentially correspond to the identically named rules for λ^p restricted so

that in every typing assertion $a:B$, a is a term of λ^\rightarrow and B is a simple type. The correspondence is not quite exact since in λ^p we have to prove that a signature, context, and type are well-formed (i.e., the first three parts of Definition 8), whereas this is assumed to hold in λ^\rightarrow . The need for this explicit demonstration of well-formedness is also reflected in the second premise of the λ^p rule for abstraction.

An example should clarify the connection between the two systems. In §4.2 we gave a signature Σ for minimal logic

$$\{ \text{imp}: o \rightarrow o \rightarrow o \}.$$

In λ^p we have

$$\Sigma = o:*, \text{imp}: o \rightarrow o \rightarrow o.$$

According to this, if x is of type o , then we can show in λ^p that $\text{imp } x \ x$ is a well-formed proposition, i.e., $\Gamma \vdash_{\Sigma} \text{imp } x \ x:o$ where $\Gamma = x:o$, as follows:

$$\frac{\frac{\frac{\text{imp}: o \rightarrow o \rightarrow o \in \Sigma}{\Gamma \vdash_{\Sigma} \text{imp}: o \rightarrow o \rightarrow o} \text{assum} \quad \frac{x:o \in \Gamma}{\Gamma \vdash_{\Sigma} x:o} \text{hyp}}{\Gamma \vdash_{\Sigma} \text{imp } x:o \rightarrow o} \text{appl} \quad \frac{x:o \in \Gamma}{\Gamma \vdash_{\Sigma} x:o} \text{hyp}}{\Gamma \vdash_{\Sigma} \text{imp } x \ x:o} \text{appl}$$

However, the rules of λ^p formalize a strictly more expressive type-theory than λ^\rightarrow , and correspond, via a Curry-Howard isomorphism, to a more expressive logic. Terms are built, as we have already seen, by declaring function constants that form typed objects from other typed objects, e.g., $\text{imp } x \ x$ above corresponds to a term of type o . An n -ary predicate symbol P , which takes arguments of types s_1, \dots, s_n , has the kind $s_1 \rightarrow \dots \rightarrow s_n \rightarrow *$. The Π -type constructor corresponds either to universal quantification or (in its non-dependent form) implication. For example, given the signature

$$\Sigma = s_1:*, s_2:*, p:s_1 \rightarrow s_2 \rightarrow *$$

we can show that there is a t such that

$$\vdash_{\Sigma} t: (\Pi x^{s_1}. \Pi y^{s_2}. p(x, y)) \rightarrow \Pi y^{s_2}. \Pi x^{s_1}. p(x, y),$$

which corresponds to demonstrating the provability of the formula

$$\vdash_{\Sigma} (\forall x. \forall y. p(x, y)) \rightarrow \forall y. \forall x. p(x, y)$$

in a traditional sorted first-order setting.

In λ^p we generalize λ^\rightarrow so that types can depend on terms. We have not carried through this generalization to allow, e.g., types depending on types, which would allow impredicative higher-order quantification. As a result, and given the above

discussion, logics like λ^p and the LF are often described as first-order. Alternatively, since we can also quantify over functions (as opposed to predicates) at all types, some authors prefer to talk about minimal implicational predicate logic with quantification over all higher types [Simpson, 1992], or ω -order logic (hh^ω) [Felty, 1991], to emphasize that these logics are more than first-order, but are not fully higher-order.

4.4 Representation in λ^p

We have reached the point where the intuitions we have formulated about the relationship between natural deduction calculi and the logic of implication are reduced to a single formal system, the type-theory λ^p . In this system, the problems of encoding the syntax and proof rules of a deductive system are reduced to the single problem of providing a signature Σ and the problems of checking well-formedness of syntax and proof checking are reduced to (decidable) type-checking. We will expand on these points with two examples.

A simple example: minimal logic

A deductive system is encoded in λ^p by a signature that encodes

1. The language of the object logic and
2. The deductive system.

In §4.3 we gave a signature suitable for encoding the language of minimal logic. As we have seen, this consists first of an extension of the signature with types corresponding to syntactic categories and then with function constants over these types. The encoding of the deductive system also proceeds in two stages. First, we represent the basic judgments of the object logic.¹⁵ To do this, for each judgment we augment the signature with a function from the relevant syntactic categories to a type. For minimal logic we have one judgment, that a formula is provable, so we add to the signature a function pr , of kind $o \rightarrow *$, where for any proposition $p \in o$, $pr(p)$ should be read as saying that the formula represented by p is provable. Second, we add constants to the signature that build (representatives of) proofs. Each constant is associated with a type that encodes (under the propositions-as-types correspondence) a proof rule of the object logic. For minimal logic we add constants with types that encode the formulae given in (6) from §3.2, which axiomatize the rules for minimal logic.

¹⁵Recall that *judgments* are assertions such as, e.g., that a proposition is provable. Typically, a logic only has a single judgment, but not always; for instance λ itself, in our presentation, has three judgments: a signature is well-formed, a context is well-formed, and a typing assertion is provable relative to a well-formed signature and context. The reader should be aware of the following possible source of confusion. By using a metalogic we have judgments at two levels: we use the judgment in λ^p that a typing assertion is provable relative to a signature and a context to demonstrate the truth of judgments in some object logic.

Putting the above pieces together, minimal logic is formalized by the following signature.

$$\begin{aligned} \Sigma \equiv & o:*, pr:o \rightarrow *, imp:o \rightarrow o \rightarrow o, \\ & impi:\Pi A^\circ B^\circ. (pr(A) \rightarrow pr(B)) \rightarrow pr(imp A B), \\ & imp:e:\Pi A^\circ B^\circ. pr(imp A B) \rightarrow pr(A) \rightarrow pr(B) \end{aligned}$$

It is an easy exercise to prove in λ^p that this is a well-formed signature.

Now consider how we use this signature to prove the proposition $A \supset A$. We encode this as $imp A A$ and prove it by showing that the judgment $pr(imp A A)$ has a member. We require, of course, that A is a proposition and we formalize this by the context $A:o$, which is well-formed relative to Σ . (In the following proof we have omitted rule names, but these can be easily reconstructed.)

Part I:

$$\frac{\frac{\frac{impi:\Pi A^\circ B^\circ. (pr(A) \rightarrow pr(B)) \rightarrow pr(imp A B) \in \Sigma \quad A:o \in A:o}{A:o \boxtimes impi:\Pi A^\circ B^\circ. (pr(A) \rightarrow pr(B)) \rightarrow pr(imp A B)} \quad A:o \boxtimes A:o \quad A:o \in A:o}{A:o \boxtimes impi A:\Pi B^\circ. (pr(A) \rightarrow pr(B)) \rightarrow pr(imp A B)} \quad A:o \boxtimes A:o}{A:o \boxtimes impi A A:(pr(A) \rightarrow pr(A)) \rightarrow pr(imp A A)}$$

Part II:

$$\frac{\frac{y:pr(A) \in A:o, y:pr(A) \quad \dots}{A:o, y:pr(A) \boxtimes y:pr(A)} \quad A:o \boxtimes pr(A) \rightarrow pr(A):*}{A:o \boxtimes \lambda y^{pr(A)}. y:pr(A) \rightarrow pr(A)}$$

(We have elided the subproof showing that $pr(A) \rightarrow pr(A)$ is well-formed, which is straightforward using the formation rule *form*.) Putting the two parts together gives:

$$\frac{\text{Part I} \quad \text{Part II}}{A:o \boxtimes impi A A (\lambda y^{pr(A)}. y):pr(imp A A)}$$

Note that the reader interested in actually using a metalogic for machine supported proof construction should not be frightened away by the substantial ‘meta-level overhead’ that is associated with carrying out a proof of even very simple propositions like $A \supset A$. Real implementations of logical frameworks can hide much of this detail by partially automating the work of proof construction. Because all the judgments of λ^p are decidable, the well-formedness of signatures and contexts can be checked automatically, as can the typing of the terms that encode proofs.¹⁶

¹⁶This second point is not so important: Although the decidability of syntactic well-formedness is important, in practice, a framework is not used to decide if a given proof is valid, but as an interactive tool for building proofs.

This example shows how both well-formedness and proof checking are uniformly reduced to type checking. With respect to well-formedness of syntax, a proof that the type $pr(impr A A)$ is inhabited is only possible if $impr A A$ is of type o , i.e. it represents a well-formed proposition. That members of type o really represent well-formed propositions follows from adequacy and faithfulness of the representation of syntax, which for this example was argued (for λ^\rightarrow) in §4.2. With respect to proof checking, we have proven that the term $impi A A (\lambda y^{pr(A)}. y)$ inhabits the type $pr(impr A A)$. In the same way that a term of type o represents a proposition, a term of type $pr(p)$ represents a proof of p . In this example, the term represents the following natural deduction proof of $A \supset A$.

$$\frac{[A]_y}{A \supset A} \supset-I_y$$

The exact correspondence (adequacy and faithfulness) between terms and the proofs that they encode can be formalized (see Harper *et al.* [1993] for details), though we do not do this here since it requires first formalizing natural deduction proof trees and the representation of discharge functions. The idea is simple enough though: the proof rule $\supset-I$ is encoded using a constant $impi$, and a well-typed application of this constructs a proof-term formalizing the operation of discharging an assumption. Specifically, $impi$ builds an object (proof representative) of the type (proposition) $pr(impr A B)$ given an object of type $pr(A) \rightarrow pr(B)$, i.e. a proof that can take any object of proof $pr(A)$ (the hypothesis), and from it produce an object of type $pr(B)$.

In the example above the function must construct a proof of $pr(A)$ from $pr(A)$, and $\lambda y^{pr(A)}. y$ does this. In general, the question of which occurrences of $pr(A)$ are discharged and how the proof of B is built is considerably more complex. Consider for example

$$impi A (impr B A) (\lambda x^{pr(A)}. impi B A (\lambda y^{pr(B)}. x)), \quad (21)$$

which is a member of the type $pr(impr A (impr B A))$ in a context where $A:o$ and $B:o$. This term represents a proof where Implication Introduction has been applied twice and the first (reading left to right) application discharges an assumption x and the second discharge (of y) is vacuous. This proof-term corresponds to the following natural deduction proof.

$$\frac{\frac{[A]_x}{B \supset A} \supset-I_y}{A \supset (B \supset A)} \supset-I_x \quad (22)$$

A larger example: first-order arithmetic

A more complex example of a theory that we can easily formalize in λ^p is first-order arithmetic, and in fact we can define this as a direct extension of the system

$$\begin{aligned}
\text{oril} &: \Pi A^\circ B^\circ. pr(A) \rightarrow pr(\text{or } A B) \\
\text{orir} &: \Pi A^\circ B^\circ. pr(B) \rightarrow pr(\text{or } A B) \\
\text{ore} &: \Pi A^\circ B^\circ C^\circ. pr(\text{or } A B) \rightarrow (pr(A) \rightarrow pr(C)) \\
&\quad \rightarrow (pr(B) \rightarrow pr(C)) \rightarrow pr(C) \\
\text{raa} &: \Pi A^\circ. (pr(\text{imp } A \text{ falsum}) \rightarrow pr(\text{falsum})) \rightarrow pr(A) \\
\text{alli} &: \Pi A^{i \rightarrow o}. (\Pi x^i. pr(A(x))) \rightarrow pr(\text{all}(A)) \\
\text{alle} &: \Pi A^{i \rightarrow o} x^i. pr(\text{all}(A)) \rightarrow pr(A(x)) \\
\text{existsi} &: \Pi A^{i \rightarrow o}. \Pi x^i. pr(A(x)) \rightarrow pr(\text{exists}(A)) \\
\text{existse} &: \Pi A^{i \rightarrow o}. \Pi C^\circ. pr(\text{exists}(A)) \rightarrow (\Pi x^i. pr(A(x)) \rightarrow pr(C)) \rightarrow pr(C) \\
\text{ind} &: \Pi A^{i \rightarrow o}. pr(A(0)) \rightarrow (\Pi x^i. pr(A(x)) \rightarrow pr(A(sx))) \rightarrow pr(\text{all}(A))
\end{aligned}$$

Figure 1. Some proof-rules for arithmetic

we have already formalized. We extend the signature with the formalization of the syntax of arithmetic that we developed in §4.2 then we formalize the new rules, axioms and axiom-schemas that we need.

We have formalized some of the proof-rules in Figure 1 and most are self-explanatory. The first five extend minimal logic to propositional logic by adding rules for disjunction and falsum. We use the constant *falsum* to encode \perp (from which we can define negation as *not* $A \equiv \text{imp } A \text{ falsum}$).

In our rules we assume a ‘classical’ falsum, i.e. the rule:

$$\begin{array}{c}
[A \supset \perp] \\
\vdots \\
\perp \\
\hline
A \quad \perp_c
\end{array}$$

encoded as *raa*. If we wanted an ‘intuitionistic’ falsum, we would replace this with the simpler rule encoded by

$$\Pi A^\circ. pr(\text{falsum}) \rightarrow pr(A).$$

For the quantifier rules we have not only given the rules for universal quantification (*alli* and *alle*) but also the rules for existential quantification, given by *existsi* and *existse*.

$$\frac{A[x \leftarrow t]}{\exists x. A} \exists\text{-I} \quad \frac{\begin{array}{c} [A] \\ \vdots \\ C \end{array}}{\exists x. A \quad C} \exists\text{-E}$$

These come with the usual side conditions: in $\forall\text{-I}$, x cannot be free in any undischarged assumptions on which A depends and, for $\exists\text{-E}$, x cannot be free in C or any assumptions other than A upon which (in the subderivation) C depends.

Object Logic		Metalogic
Syntactic Categories terms, individuals	\rightsquigarrow	Base Types $\{i:*, o:*\}$
Connectives & Constructors \vee	\rightsquigarrow	First-Order Constants $or:o \rightarrow o \rightarrow o$
Variable Binding Operators \forall	\rightsquigarrow	Higher-Order Constants $all:(i \rightarrow o) \rightarrow o$
Judgment $\vdash p$	\rightsquigarrow	Type Valued Functions $pr:o \rightarrow *$
Inference Rule $\frac{A}{A \vee B} \vee\text{-IL}$	\rightsquigarrow	Constant Declaration $oril:\Pi A^o B^o. pr(A) \rightarrow pr(or A B)$
Deductive System		Signature Declaration
Deduction		Typing Proof

Figure 2. Correspondence between object logics and their encodings

If we stop with the quantifier rules, the result is an encoding of first-order logic over the language of arithmetic. We have to add more rules to formalize the theory of equality and arithmetic. Thus, for example, *ind* formalizes the induction rule

$$\frac{A[x \leftarrow 0] \quad \begin{array}{c} [A] \\ \vdots \\ A[x \leftarrow sx] \end{array}}{\forall x. A}$$

and enforces the side condition that *x* does not occur free in any assumptions other than those discharged by the application of the rule. The other rules of arithmetic are formalized in a similar fashion.

4.5 Summary

Figure 2 contains a summary. It is worth emphasizing that there is a relationship between the metalogic and the way that it is used, and an \rightarrow -framework like λ^p is well-suited to particular kinds of encodings. The idea behind higher-order syntax and the formalization of judgments using types is to internalize within the metalogic as much of the structure of terms and proofs as possible. By this we mean that syntactic notions and operations are subsumed by operations provided by the framework logic. In the case of syntax, we have seen how variable binding in the object logic is implemented by λ -abstraction in the framework logic and how substitution is implemented by β -reduction. Similarly, when representing proof-

rules and proof-terms, rather than our having to formalize, and then reason explicitly about, assumptions and their discharging, this is also captured directly in the metalogic. Support for this sort of internalization is one of the principles behind the design of these framework logics. The alternative (also possible in λ^p) is to *externalize*, i.e., explicitly represent, such entities. The external approach is taken when using frameworks based on inductive definitions, which we will consider in §7.

5 ENCODING LESS WELL BEHAVED LOGICS

So far, we have restricted our attention to fairly standard, e.g. intuitionistic or classical, logics. We now consider how an \rightarrow -framework can treat the more ‘unconventional’ logics that we encounter in, for example, philosophy or artificial intelligence, for which such simple calculi are not available. As previously observed, most metalogics (and all the examples examined in this chapter) are ‘universal’ in the sense that they can represent any recursively enumerable relation, and thus any logic expressible in terms of such relations. However, there is still the question of how effective and natural the resulting encodings are.

We take as our example one of the more common kinds of philosophical logics: modal logic, i.e. propositional logic extended with the unary \Box connective and the *necessitation* rule (see Bull and Segerberg [1984]). Modal logics, as a group, have common features; for example, ‘canonical’ presentations use Hilbert calculi and, when natural deduction presentations are known, the proof-rules typically are not encodable in terms of the straightforward translation presented in §3.2. In §7 we will see how Hilbert presentations of these logics can be directly encoded as inductive definitions. Here we consider the problem of developing natural deduction presentations in an \rightarrow -framework. We explore two different possibilities, *labelled deductive systems* and *multiple judgment systems*, consider how practical they are, and how they compare.

5.1 Modal logic

We consider two modal logics in this section: K and an important extension, S4. A standard presentation of K is as a Hilbert system given by the axiom schemata

$$\begin{aligned} (A \supset B) \supset (A \supset B \supset C) \supset A \supset C \\ A \supset B \supset A \\ ((A \supset \perp) \supset \perp) \supset A \\ \Box(A \supset B) \supset \Box A \supset \Box B \end{aligned}$$

and the rules

$$\frac{A \supset B \quad A}{B} \textit{Det} \quad \text{and} \quad \frac{A}{\Box A} \textit{Nec}$$

The first of these rules is just the rule of detachment from §2.1, and the second is called necessitation. We get S4 from K by adding the additional axiom schemata:

$$\begin{aligned} \Box A \supset \Box \Box A \\ \Box A \supset A \end{aligned}$$

As noted above, we can see a Hilbert calculus as a special case of a natural deduction calculus, where the rules discharge no assumptions and axioms are premiseless rules.

There is an important difference between Hilbert and natural deduction calculi however, which is in the nature of what they reason about: Hilbert calculi manipulate formulae that are true in all contexts, i.e. valid (theorems), in contrast to natural deduction calculi, which typically manipulate formulae that are true under assumption. This difference causes problems when we try to give natural deduction-like presentations of modal logics, i.e. presentations that allow reasoning under temporary assumptions. The problem can be easily summarized:

PROPOSITION 19. *The deduction theorem (see §7.3) fails for K and S4.*

Proof. First, observe (e.g., semantically using Kripke structures; see §5.2) that $A \supset \Box A$ is not provable in K or S4. However, if the deduction theorem held, we could derive this formula as follows: assume A , then, by necessitation, we have $\Box A$, and by the deduction theorem we would have that $A \supset \Box A$ is a theorem. This is a contradiction. ■

The deduction theorem is a justification for the natural deduction rule \supset -I, but this in turn is precisely the rule that distinguishes natural deduction-like from Hilbert calculi: without it, one collapses into the other.

The problem of natural deduction encodings of modal logics is well known, and various fixes have been proposed. In some of these, the rules \supset -I and \supset -E are kept intact by extending the language of natural deduction itself. For instance if we allow global side conditions on rules then (following Prawitz [1965]) for S4 we have the rules

$$\frac{\begin{array}{c} \vdots * \\ A \end{array}}{\Box A} \supset\text{-I} \quad \text{and} \quad \frac{\Box A}{A} \supset\text{-E}$$

where * means that *all undischarged assumptions are boxed; i.e. of the form $\Box B$* . Notice that given this side condition, the argument we have used to illustrate the failure of the deduction theorem no longer works. But the language of \rightarrow does not provide the vocabulary to express this side condition on \supset -I, so we cannot encode such a proof rule in the same fashion as proof-rules were encoded in §3.2.

5.2 A Kripke semantics for modal logics

A common way of understanding the meaning of formulae in a modal logic is in terms of the *Kripke*, or *possible worlds* semantics (see Kripke [1963] or van Benthem [1984] for details). We shall use this style of interpretation in developing our encodings.

A Kripke model (W, R, V) for a modal logic consists of a nonempty set of *worlds* W , a binary *accessibility* relation R defined over W , and a *valuation* predicate V over W and the propositional variables. We then define a *forcing* relation \Vdash between worlds and formulae as follows: $a \Vdash A$ iff $V(a, A)$ for A atomic; $a \Vdash A \supset B$ iff $a \Vdash A$ implies $a \Vdash B$; and $a \Vdash \Box A$ iff for all $b \in W$ if $a R b$ then $b \Vdash A$.

Using the Kripke semantics, we can classify modal logics by the behavior of R alone. For instance we have

FACT 20. Let R be the accessibility relation of a Kripke model.

- A formula A is a theorem of K iff A is forced at all worlds of all Kripke models.
- A formula A is a theorem of S4 iff A is forced at all worlds of all Kripke models where R is reflexive ($x R x$) and transitive (if $x R y$ and $y R z$, then $x R z$).

It is now possible to see why the deduction theorem fails. Consider a Kripke model (W, R, V) and a formula $A \supset B$. In the deduction theorem we assume, for the sake of argument, A as a new axiom, and show that B is then a theorem; i.e. assuming $\forall a \in W. a \Vdash A$, we show that $\forall a \in W. a \Vdash B$. But it does not follow from this that $A \supset B$ is a theorem; i.e. that $\forall a \in W. a \Vdash A \supset B$.

It is however easy to find a correct ‘semantic’ analogue of the deduction theorem:

FACT 21. For any Kripke model (W, R, V)

$$\forall a \in W. (a \Vdash A \rightarrow a \Vdash B) \rightarrow a \Vdash A \supset B.$$

The problem of providing a natural deduction encoding of a modal logic can be reduced to the problem of capturing this semantic property of \supset in rules that can be directly encoded in the language of implication. We will consider two ways of doing this, which differ in the extent to which they make the Kripke semantics explicit.

5.3 Labelled deductive systems¹⁷

The above analysis suggests one possible solution to our problem: we can internalize the semantics into the deductive calculus. Hence, instead of reasoning with

¹⁷The work described in this section was done in collaboration with Luca Viganò.

formulae, we reason about formulae in worlds; i.e. we work with pairs $a:A$ where a is a world and A is a formula.

Taking this approach, the rules

$$\begin{array}{c}
 \begin{array}{c} [x:A] \\ \vdots \\ x:B \\ \hline x:A \supset B \end{array} \supset-I \quad \begin{array}{c} [x R y] \\ \vdots \\ y:A \\ \hline x:\Box A \end{array} \Box-I \\
 \\
 \begin{array}{c} [x:A \supset \perp] \\ \vdots \\ y:\perp \\ \hline x:A \end{array} \perp-E \quad \begin{array}{c} x:A \supset B \quad x:A \\ \hline x:B \end{array} \supset-E \quad \begin{array}{c} x:\Box A \quad x R y \\ \hline y:A \end{array} \Box-E
 \end{array}$$

define a natural deduction calculus, which we call K_L . (We also require the side conditions that in $\Box-I$ y is different from x and does not occur in the assumptions on which $y:A$ depends, except those of the form $x R y$ that are discharged by the inference.) These rules formalize the meaning of both \supset and \Box in terms of the Kripke semantics; i.e., we locate applications of $\supset-I$ in some particular world, and take account of the other worlds in defining the behavior of \Box and \perp (where it suffices to derive a contradiction in any world). We can show:

FACT 22 (Basin *et al.* [1997a]). $a:A$ is provable in K_L iff A is true in all Kripke models, and therefore, by the completeness of K with respect to the set of all Kripke models, iff A is a theorem of K .

As an example of a proof in K_L of a K theorem, we show that \Box distributes over \supset .

$$\begin{array}{c}
 \frac{\frac{[a:\Box(A \supset B)]_1 \quad [a R b]_3}{b:A \supset B} \Box-E \quad \frac{[a:\Box A]_2 \quad [a R b]_3}{b:A} \Box-E}{\frac{b:B}{a:\Box B} \Box-I_3} \supset-E \\
 \frac{\frac{a:\Box B}{a:\Box A \supset \Box B} \supset-I_2}{a:\Box(A \supset B) \supset \Box A \supset \Box B} \supset-I_1
 \end{array}$$

Further, and essential for our purpose, there are no new kinds of side conditions on the rules of K_L , so we have no difficulty in formalizing these in an \rightarrow -framework.¹⁸ The following is a signature for K_L in λ^p (note that for the sake of

¹⁸There is of course the side condition on $\Box-I$. But this can be formalized in the same way that eigenvariable conditions are formalized in logics with quantifiers, by using universal quantification in the metalogic.

readability we write ‘:’ and R in infix form):

$$\begin{aligned} \Sigma_{K_L} \equiv & w:*, o:*, ‘:’:w \rightarrow o \rightarrow *, R:w \rightarrow w \rightarrow *, \\ & falsum:o, imp:o \rightarrow o \rightarrow o, box:o \rightarrow o, \\ & FalseE:\Pi A^o x^w y^w. (x:imp A falsum \rightarrow y:falsum) \rightarrow x:A, \\ & impI:\Pi A^o B^o x^w. (x:A \rightarrow x:B) \rightarrow x:imp A B, \\ & impE:\Pi A^o B^o x^w. x:A \rightarrow x:imp A B \rightarrow x:B, \\ & boxI:\Pi A^o x^w. (\Pi y^w. x R y \rightarrow y:A) \rightarrow x:box A, \\ & boxE:\Pi A^o x^w y^w. x:box A \rightarrow x R y \rightarrow y:A \end{aligned}$$

The signature reflects that there are two types, a type of worlds w and type of formulae o , and two judgments; one about the relationship between worlds and formulae, asserting that a formula is true at that world, and a second, between two worlds, asserting that the first accesses the second. Adequacy and faithfulness follow by the style of analysis given in §3.

K_L as a base for other modal logics

We can now take K_L as a base upon which to formalize other modal logics. Since modal logics are characterized, in terms of Kripke models, purely in terms of their accessibility relations, to get other modal logics we must simply modify the behavior of R in our encoding. Thus, since S4 corresponds to the class of Kripke models with transitive and reflexive accessibility relations, we can enrich our signature with:

$$\begin{aligned} Ref:& \Pi x^w. x R x \\ Trans:& \Pi x^w y^w z^w. x R y \rightarrow y R z \rightarrow x R z \end{aligned}$$

Again, we can show [Basin *et al.*, 1997a] that this really formalizes S4.

The limits of K_L

It might appear from the discussion above that we can implement any modal logic we want, simply by adding the axioms for the appropriate accessibility relation to K_L . That is, we represent a logic by embedding its semantics in the metalogic, a formalization technique that is sometimes called *semantic embedding* (see van Benthem [1984] or Ohlbach [1993] for details on this approach). We must be careful though; not every embedding based on labelling accurately captures the semantics and different kinds of embeddings capture more structure than others.

Consider K_L again: the rules for \supset and \Box reflect the meaning that the Kripke semantics gives the connectives. On the other hand, the semantics does not explicitly state how the rules for \perp should function using labels. Following from the

rules for \supset , a plausible formalization is

$$\frac{\begin{array}{c} [x:A \supset \perp] \\ \vdots \\ x:\perp \end{array}}{x:A} \perp\text{-E}^-$$

which, like the rule for implication, stays in one world and ignores the existence of different possible worlds. But if we investigate the logic that results from using this rule (instead of $\perp\text{-E}$), we find that it is not complete with respect to the Kripke semantics.

An examination of the Gentzen-style natural language characterization of \perp shows where the problem lies:

If the assumption that $A \supset \perp$ in world x is inconsistent with the interpretation, then A is true in world x .

This says nothing about where the inconsistency might be and specifically does not say that it should be in the world x itself. The role of negation in encoding the semantics of logics is subtle and we lack space to develop this topic here. We therefore restrict ourselves to a few comments; much more detail can be found in [Basin *et al.*, 1997a]. In K_L we assumed that it is enough to be able to show that the inconsistency is in some world. It turns out that this is sufficient for a large class of logics; but again this does not reflect the complete behavior of \perp . Some accessibility relations require a richer metalogic than one based on minimal implication and this may in turn require formalizing all of first or even higher-order logic. In such formalizations, we must take account of the possibility that the inconsistency of an assumption about a world might manifest itself as a contradiction in the theory of the accessibility relation, or *vice versa*. It is possible then to use classical first (or higher-order) logic as a metatheory to formalize the Kripke semantics in a complete way, however the result also has drawbacks. In particular, we lose structure in the proofs available in K_L . In K_L we reason in two separate systems. We can reason in just the theory of the accessibility relation and then use the results of this in the theory of the labelled propositions; however, we cannot go in the other direction, i.e. we cannot use reasoning in the theory of labelled propositions as part of an argument about the relations. This enforced separation provides extra structure that we can exploit, e.g., to bound proof search (see, e.g., [Basin *et al.*, 1997b]). And in spite of enforcing this separation, K_L is a sufficient foundation for a very large class of standard logics.¹⁹

¹⁹In [Basin *et al.*, 1997a] we show that it is sufficient to define almost all the modal logics of the so-called Geach hierarchy, which includes most of those usually of interest, i.e. K, T, S4, S5, etc., though not, e.g., the modal logic of provability G [Boolos, 1993].

5.4 Alternative multiple judgment systems

Using a labelled deductive system, we built a deductive calculus for a modal logic based on two judgments: a formula is true in a world and one world accesses another. But this is only one of many possible presentations. We now consider another possibility, using multiple judgments that distinguish between truth (in a world) and validity that is due originally to Avron *et al.* [1992] (and further developed in [Avron *et al.*, 1998]).

Validity

Starting with K, we can proceed in a Gentzen-like manner, by writing down the behavior of the logical connectives as given by the Kripke semantics. If we abbreviate ‘ A is true in all worlds’ to $V(A)$ (A is valid; i.e. A is a theorem), then we have

$$\frac{V(A \supset B) \quad V(A)}{V(B)} \supset\text{-}E_V \quad \text{and} \quad \frac{V(A)}{V(\Box A)} \Box\text{-}I_V, \quad (23)$$

which can be easily verified against the Kripke semantics (they directly reflect the two rules *Det* and *Nec*). Since the deduction theorem fails, we do not have an introduction rule for \supset in terms of V , neither do we have a rule for \perp .

Thus the first part of the signature for K simply records the rules (23):

$$\begin{aligned} \Sigma_1 \equiv & o:*, \quad V:o \rightarrow *, \\ & \text{False}:o, \quad \text{imp}:o \rightarrow o \rightarrow o, \quad \text{box}:o \rightarrow o, \\ & \text{imp}E_V:\Pi A^\circ B^\circ. V(A) \rightarrow V(\text{imp } A B) \rightarrow V(B), \\ & \text{box}I_V:\Pi A^\circ. V(A) \rightarrow V(\text{box } A) \end{aligned}$$

And, as observed above, we have

LEMMA 23. *The rules encoded in Σ_1 are sound with respect to the standard Kripke semantics of K, if we interpret $V(A)$ as $\forall a. a \Vdash A$.*

The rest of V . The rest of the details about $V(\cdot)$ could be summarized simply by declaring all the axioms of K to be valid. In this case $V(\cdot)$ would simply encode a Hilbert presentation of K. However there is a more interesting possibility, which supports proof under assumption.

Truth in a world

As previously observed we do have a kind of semantic version of the deduction theorem relativized to any given world. We can use this to formalize more about

the meaning of implication and \perp . If we abbreviate ‘ A is true in some arbitrary but fixed world c ’ to $T(A)$, then we have:

$$\frac{T(A \supset B) \quad T(A)}{T(B)} \supset\text{-}E_T \quad \frac{\begin{array}{c} [T(A)] \\ \vdots \\ T(B) \end{array}}{T(A \supset B)} \supset\text{-}I_T \quad \frac{\begin{array}{c} [T(A \supset \perp)] \\ \vdots \\ T(\perp) \end{array}}{T(A)} \perp\text{-}E_T$$

When we talked above about validity we did not have a rule for introducing implication, or reflecting the behavior of \perp . Similarly, when we are talking about truth in some world, we do not have a rule reflecting the behavior of \Box , since that is not dependent on just the one world. Thus for instance, there is no introduction (or elimination) rule for this operator. All we can say is that

$$\frac{T(\Box(A \supset B)) \quad T(\Box A)}{T(\Box B)} \text{Norm}_T$$

And again we can verify these rules against the semantics.

Thus the second part of the signature is

$$\begin{aligned} \Sigma_2 \equiv & T:o \rightarrow *, \\ & \text{imp}E:\Pi A^\circ B^\circ. T(\text{imp } A B) \rightarrow T(A) \rightarrow T(B), \\ & \text{imp}I:\Pi A^\circ B^\circ. (T(A) \rightarrow T(B)) \rightarrow T(\text{imp } A B), \\ & \text{false}E:\Pi A^\circ. (T(\text{imp } A \text{ falsum}) \rightarrow T(\text{falsum})) \rightarrow T(A), \\ & \text{norm}:\Pi A^\circ B^\circ. T(\text{box } (\text{imp } A B)) \rightarrow T(\text{box } A) \rightarrow T(\text{box } B) \end{aligned}$$

and we have

LEMMA 24. *The rules encoded in Σ_1, Σ_2 are sound with respect to the standard Kripke semantics of \mathbf{K} , if we interpret $V(A)$ as in Lemma 23 and $T(A)$ as $c \Vdash A$ where c is a fixed constant.*

Connecting V and T

We have now formalized two separate judgments, defined by the predicates V and T , which we have to connect together. To this end, we introduce two rules, C and R , which intuitively allow us to introduce a validity judgment, given a truth judgment, and eliminate (or use) a validity judgment.

C states that if A is true in an arbitrary world, then it is valid.

$$\frac{T(A)}{V(A)} C$$

For this rule to be sound, we require that the world where A is true really is arbitrary, and this will hold so long as there are no other assumptions $T(A')$ current when we apply it. It is easy to see that this condition is ensured for any proof of the atomic proposition $V(A)$, so long as C is the only rule connecting T and V together, since the form of the rules then ensures that there can be no hypotheses $T(A')$ at a place where C is applied.

The addition of C yields a complete inference system for reasoning about valid formulae. However, the resulting deductive system is awkward: once we end up in the V fragment of the system, which by itself is essentially a Hilbert calculus, we are forced to stay there.

We thus extend our system with an elimination rule for V , to allow us to return to the natural deduction-like T fragment. Important to our justification of the rule C was that the premise followed in an *arbitrary* world. Any further rule that we add must not invalidate this assumption. However we observe that given $V(A)$, then, since A is valid, it is true in an arbitrary world, so adding $T(A)$ as an open assumption to an application of C does not harm the semantic justification of that rule application. We can encode this as the following rule R .

$$\frac{\begin{array}{c} [T(A)] \\ \vdots \\ V(A) \quad V(B) \end{array}}{V(B)} R$$

Taken together, these rules complete our proposed encoding of K .

$$\begin{aligned} \Sigma_{K_{MJ}} &\equiv \Sigma_1, \Sigma_2, \\ &C: \Pi A^o. T(A) \rightarrow V(A), \\ &R: \Pi A^o B^o. V(A) \rightarrow (T(A) \rightarrow V(B)) \rightarrow V(B) \end{aligned}$$

To establish correctness formally, we begin by proving that:

PROPOSITION 25. *If A is a theorem of K , then $V(A)$ is a theorem of the proof calculus encoded as $\Sigma_{K_{MJ}}$.*

Proof. We observe that if A is one of the listed axioms of K , then we can show that $T(A)$, and thus, by C , that $V(A)$. Therefore we need not declare these to be ‘valid’. These, and the rules encoded in Σ_1 allow us to reconstruct any proof in Hilbert K (see also the remarks after Lemma 23 above). ■

Next that:

PROPOSITION 26. *If $V(A)$ is a theorem of the proof calculus encoded as $\Sigma_{K_{MJ}}$, then A is a theorem of K .*

We prove a slight generalization, for which we need

LEMMA 27. For an arbitrary set Γ of theorems of K , if $T(A)$ is a theorem of $\Sigma_{K_{MJ}}$ extended with the axiom set $\{T(x) \mid x \in \Gamma\}$, then A is a theorem of K .

Proof. First notice that only the rules encoded as *impI*, *impE*, *FalseE* and *norm* can occur in a proof of $T(A)$. By Lemma 24, reading $T(A)$ as $c \Vdash A$, only theorems of K follow from this fragment of the proof calculus extended with Γ , where Γ consists of theorems of K . ■

The generalization of Proposition 26 is then

LEMMA 28. For an arbitrary set Γ of theorems of K , if $V(A)$ is a theorem of the proof calculus encoded as $\Sigma_{K_{MJ}}$ extended with $\{T(x) \mid x \in \Gamma\}$, then A is a theorem of K .

Proof. The proof is by induction on the size of a proof Π of $V(A)$. We need to consider three cases: (i) The last rule in the proof is an application of one of the rules encoded in Σ_1 from theorems $V(A_i)$, in which case, by appeal to the induction hypothesis, A_i are theorems of K and thus A is a theorem of K . (ii) The last rule is an application of C , in which case the sub-proof is a proof of the theorem $T(A)$ (there are no undischarged assumptions for the theorem $V(A)$ and hence $T(A)$) and by Lemma 27, A is a theorem of K . (iii) The last rule is an application of R to proofs Π_1 of $V(B)$ from $T(A)$ and Π_2 of the theorem $V(A)$. Since Π_2 is smaller than Π , by the induction hypothesis A is a theorem of K . Then we can transform Π_1 into a proof of the theorem $V(B)$ in the proof calculus formalized as $\Sigma_{K_{MJ}}$ extended with $\{T(x) \mid x \in \Gamma \cup \{A\}\}$ by replacing any appeal to a hypothesis $T(A)$ in Π_1 by an appeal to the axiom $T(A)$. Since the result is a proof no bigger than Π_1 , which in turn is smaller than Π , by appeal to the induction hypothesis, B is a theorem of K . ■

We can combine Propositions 25 and 26 as

THEOREM 29. A is a theorem of K iff $V(A)$ follows from $\Sigma_{K_{MJ}}$.

Encoding other modal logics

We can extend the encoding of K easily to deal with S4; there are in fact several ways we can do this: one possibility (see Avron *et al.* [1992] for more discussion) is to add the rules

$$\frac{\begin{array}{c} [V(\Box A)] \\ \vdots \\ V(B) \end{array}}{V(\Box A \supset B)} \supset\text{-}I_V \quad \text{and} \quad \frac{V(\Box A)}{V(A)} \Box\text{-}E_V$$

(given these rules we can show that the *Norm_T* rule is redundant). This produces an encoding that is closely related to the version of S4 suggested by Prawitz.

An alternative view of K_{MJ}

We have motivated and developed the K_{MJ} presentation of K using a Kripke semantics, as a parallel with K_L . Unlike K_L , however, the interpretation is implicit, not explicit (there is no mention of particular worlds in the final proof calculus) so we are not committed to it. In fact, and importantly, this presentation can be understood from an entirely different perspective that uses just the Hilbert axiomatization itself, as follows.

We observe in §7 that it is possible to prove a deduction theorem for classical propositional logic, justifying the \supset - I rule by proof-theoretic means in terms of the Hilbert presentation. If we examine that proof, then we can see that it is easily modified for the fragment of (our Hilbert presentation of) K *without* the rule *Nec.* But this is precisely the fragment of K that is defined by the T fragment of K_{MJ} . Equally, the system defined by V , can be seen as the full Hilbert calculus.

Thus we can alternatively view the two judgments of K_{MJ} not as indicating whether we are speaking of truth in some world, or truth in all worlds, but rather whether or not we are allowed to apply the deduction theorem. This perspective provides the possibility of an entirely different proof of the correctness of our encoding, based on the standard Hilbert encoding, and without any intervening semantic argument.

5.5 Some conclusions

We have presented two different encodings of two well-known modal logics in this section as examples of approaches to representing nonstandard logics in an \rightarrow -framework. Which approach is preferable depends, in the end, on how the resulting encoding will be used. K_L and $S4_L$ make the semantic foundation of the presentation more explicit. This is advantageous if we take for granted the view that modal logics are the logics of Kripke models since the user is able to exploit the associated intuitions in building proofs. On the other hand this may be a problem if we want to use our encoding in circumstances where our intuitions are different. The opposite holds for K_{MJ} and $S4_{MJ}$: it is more difficult to make direct use of any intuitions we might have from the Kripke semantics, but, since the proof systems involve no explicit, or even necessary, commitment to that interpretation, we have fewer problems in assuming another.²⁰

The solutions we have examined, while tailored for modal logics, do have some generality. However, each different logic must be considered in turn and the approaches presented here may not always be applicable, or the amount of effort in modifying them may be considerable. For instance it is possible to interpret relevance logics in terms of a Kripke semantics that can be adopted as the basis of

²⁰In fact it would be fairly easy to adapt a multiple judgment presentation of $S4$ to the different circumstances of say relevance, or linear, propositional logic, which share many properties with traditional $S4$. Such a project would be considerably more difficult, not to mention questionable, starting from $S4_L$. This issue of commitment to a particular interpretation is discussed at length with regard to labelled deductive systems in general by Gabbay [1996].

a labelled deductive system, similar in style to (though considerably more complex than) K_L (see Basin *et al.* [1998b]). But such an implementation is tricky to use and we reach, eventually, the limits of encodings that are understandable and usable by humans.

6 CONSEQUENCE RELATIONS

In the previous sections we considered an abstraction of natural deduction calculi and in the following section we will consider an abstraction of Hilbert calculi. Here, we consider the third style of proof calculus we mention in the introduction: the sequent calculus. It turns out that, unlike the other two, little work has been done on systems that directly abstract away from sequent calculi in a way that we can use as a logical framework. This certainly does not mean that there has been no work on the principles of the sequent calculus, just that work has concentrated not on the concrete implementational aspects so much as on the abstract properties of the sequent relation, \vdash , which when investigated in isolation is called a *consequence relation*.

Consequence relations provide a powerful tool for systematically analyzing properties of a wide range of logics, from the traditional logics of mathematics to modal or substructural logics, in terms that we can then use as the starting point of an implementation. In fact it is often possible to encode the results of a sequent calculus analysis directly in an \rightarrow -framework.

What, then, is a consequence relation? There are several definitions in the literature (e.g. Avron [1991; 1992], Scott [1974] and Hacking [1979]); we adopt that of Avron, along with his vocabulary, where possible.

DEFINITION 30. A *consequence relation* is a binary relation between finite multisets of formulae Γ, Δ , usually written $\Gamma \vdash \Delta$, and satisfying at least *Basic* and *Cut* in (2) and *PL* and *PR* in (3).²¹

This is, however, a very general definition. In fact most logics that we might be interested in encoding have natural presentations in terms of more constrained *ordinary* consequence relations:²²

DEFINITION 31. A consequence relation is said to be *ordinary* if it satisfies the rules *WL*, *CL*, *WR* and *CR* of (3).

Examples of ordinary consequence relations are LJ^\supset and LK^\supset defined in §2.2,

²¹In the rules given in §2.2, the antecedent and succedent are *sequences* of formulae whereas here they are *multisets*. In practice, the permutation rules *PL* and *PR* are often omitted and multi-sets are taken as primitive, as here. This is not always possible though, e.g., in \mathcal{X} , where the ordering in the sequence matters. Note also that this definition does not take account of variables; for an extension to that case, see Avron [1992].

²²We do not have space to consider the best known exception, the *substructural* logics, e.g. relevance and linear logic. However what we say in this section generalizes, given a suitably modified \rightarrow -framework, to these cases. Readers interested in the (non-trivial) technical details of this modification are referred to [Cervesato and Pfenning, 1996] and, especially, [Ishtiaq and Pym, 1998].

as is the encoding in terms of \vdash of NJ^\supset in §3.1 (even though *Cut* is not a basic property of this presentation, we can show that it is admissible; i.e. we do not change the set of provable sequents if we assume it). Most of the traditional logics of mathematics can be presented as ordinary (in fact, *pure* ordinary, see below) consequence relations.

6.1 The meaning of a consequence relation

While it is possible to treat a consequence relation purely in syntactic terms, often one can be understood, and may have been motivated, by some idea of the ‘meaning’ of the formulae relative to one another. For instance we can read a sequent $\Gamma \vdash \Delta$ of LK^\supset as ‘if all the formulae in Γ are true, then at least one of the formulae in Δ is true.’ Because they have this reading in terms of truth, we call the systems defined by LJ^\supset , LK^\supset and NJ^\supset ‘truth’ consequence relations. Notice that the meaning of ‘truth’ here is not fixed: when we say that something is true we might mean that it is classically true, intuitionistically true, Kripke-semantically true, relevance true, or even something else more exotic.

We can derive a different sort of consequence relation from a Hilbert calculus: if we assume (1) *Basic*, i.e. that $A \vdash A$, (2) that if A is an axiom then $\Gamma \vdash A$, and (3) that for each rule of proof

$$\frac{A_1 \dots A_n}{A}$$

we have that

$$\frac{\Gamma_1 \vdash A_1 \dots \Gamma_n \vdash A_n}{\Gamma_1, \dots, \Gamma_n \vdash A}$$

then it is easy to show that the resulting system satisfies *Cut*, and that $\vdash A$ iff A is a theorem. This is not a truth consequence relation: the natural reading of $\Gamma \vdash A$ is ‘if Γ are *theorems*, then A is a *theorem*’. We thus call \vdash a *validity* consequence relation.

Of course truth and validity are not the only possibilities. We can define consequence relations any way we want,²³ the only restriction we might impose is that in order to be effectively mechanizable on a computer, the relation \vdash should be recursively enumerable.

6.2 Ordinary pure consequence relations and \rightarrow -frameworks

Part of the problem with mechanizing consequence relations, if we formalize them directly, is their very generality. Many systems are based on ordinary consequence relations, and if an encoding forces us to deal explicitly with all the rules that

²³For some examples of other consequence relations which can arise in the analysis of a modal logic, see Fagin *et al.* [1992].

formalize this, then proof construction will often require considerable and tedious structural reasoning. This may explain, in part, why there has been little practical work on logical frameworks based directly on consequence relations.²⁴ However another reason is that an \rightarrow -framework can very effectively encode many ordinary consequence relations directly. In the remainder of this section we explore this reduction, which clarifies the relationship between consequence relations and \rightarrow -frameworks as well as illuminating some of the strengths and weaknesses of \rightarrow -frameworks.

In order to use an \rightarrow -framework for representing consequence relations, it helps if we impose a restriction in addition to ordinaryness.

DEFINITION 32. We say that a consequence relation is *pure* if, given that

$$\frac{\Gamma_1 \vdash \Delta_1 \quad \dots \quad \Gamma_n \vdash \Delta_n}{\Gamma_0 \vdash \Delta_0}$$

holds, then there are Γ'_i, Δ'_i , which are sub-multisets of Γ_i, Δ_i , such that for arbitrary Γ''_i, Δ''_i

$$\frac{\Gamma'_1, \Gamma''_1 \vdash \Delta'_1, \Delta''_1 \quad \dots \quad \Gamma'_n, \Gamma''_n \vdash \Delta'_n, \Delta''_n}{\Gamma'_0, \Gamma''_0 \vdash \Delta'_0, \Delta''_0}.$$

Notice that the consequence relations discussed at the beginning of this section all satisfy the definition of purity; this is also the case for most of the logics we encounter in mathematics. In order to find counterexamples we must look to some of the systems arising in philosophical logic. For instance in modal logic (see §5, and the discussion by Avron [1991]) we get a natural truth consequence relation satisfying the rule

$$\frac{\vdash A}{\vdash \Box A}$$

but not, for arbitrary Γ ,

$$\frac{\Gamma \vdash A}{\Gamma \vdash \Box A}$$

We shall not, here, consider frameworks that can handle general impure consequence relations satisfactorily.

Single conclusioned consequence

As we said earlier, most of the standard logics of mathematics have intuitive presentations as ordinary pure consequence relations. Avron [1991] adds one more restriction before claiming that

²⁴There are, however, many computer implementations of particular sequent calculi, e.g. the PVS system for higher-order logic, by Owre *et al.* [1995], not to mention many tableau calculi, which are, essentially, sequent calculi.

Every ordinary, pure, single-conclusioned [consequence relation] system can, e.g., quite easily be implemented in the Edinburgh LF.

We begin by considering the single conclusioned case, and then follow it with multiple conclusioned consequence relations and systems based on multiple consequence relations.

The encoding is uniform and consists of two parts. We first explain how to encode sequents and then rules. We can encode

$$A_1, \dots, A_n \vdash A$$

as

$$T(A_1) \rightarrow \dots \rightarrow T(A_n) \rightarrow T(A)$$

and it is easy to show that this satisfies Definition 31 of an ordinary consequence relation (in this case, single conclusioned). Notice how the structural properties of the consequence relation are directly reflected by the logical properties of \rightarrow .

We can then represent basic and derived rules expressed in terms of such a consequence relation, *assuming it is pure* as follows. Consider a rule of such a consequence relation \vdash , where, for *arbitrary* Γ_i :

$$\frac{\Gamma_1, A_{(1,1)}, \dots, A_{(1,n_1)} \vdash A_1 \quad \dots \quad \Gamma_m, A_{(m,1)}, \dots, A_{(m,n_m)} \vdash A_m}{\Gamma_1, \dots, \Gamma_m, A_{(0,1)}, \dots, A_{(0,n_0)} \vdash A_0}$$

We can encode this as

$$\begin{aligned} (T(A_{(1,1)}) \rightarrow \dots \rightarrow T(A_{(1,n_1)}) \rightarrow T(A_1)) \rightarrow \dots \\ \rightarrow (T(A_{(m,1)}) \rightarrow \dots \rightarrow T(A_{(m,n_m)}) \rightarrow T(A_m)) \\ \rightarrow T(A_{(0,1)}) \rightarrow \dots \rightarrow T(A_{(0,n_0)}) \rightarrow T(A_0) \end{aligned}$$

leaving the Γ_i implicit (the condition of purity is important because it allows us to do this).

As an example, consider LJ^\supset from §2.2, for which we have the rules

$$\frac{\Gamma \vdash A \quad \Gamma', B \vdash C}{\Gamma, \Gamma', A \supset B \vdash C} \supset-L \quad \frac{\Gamma, A \vdash B}{\Gamma \vdash A \supset B} \supset-R$$

We can encode these rules (assuming a suitable formalization of the language) as

$$T(A) \rightarrow (T(B) \rightarrow T(C)) \rightarrow T(A \supset B) \rightarrow T(C) \quad (24)$$

and

$$(T(A) \rightarrow T(B)) \rightarrow T(A \supset B). \quad (25)$$

Then we can simulate the effect of applying \supset -L, i.e.

$$\frac{F_1, \dots, F_m \vdash A \quad G_1, \dots, G_n, B \vdash C}{F_1, \dots, F_m, G_1, \dots, G_n, A \supset B \vdash C},$$

encoded as (24), to the encoded assumptions

$$T(F_1) \rightarrow \dots \rightarrow T(F_m) \rightarrow T(A) \quad (26)$$

and

$$T(G_1) \rightarrow \dots \rightarrow T(G_n) \rightarrow T(B) \rightarrow T(C). \quad (27)$$

By (26) and (24) we have

$$T(F_1) \rightarrow \dots \rightarrow T(F_m) \rightarrow (T(B) \rightarrow T(C)) \rightarrow T(A \supset B) \rightarrow T(C) \quad (28)$$

which combines with (27) to yield

$$T(F_1) \rightarrow \dots \rightarrow T(F_m) \rightarrow T(G_1) \rightarrow \dots \rightarrow T(G_n) \rightarrow T(A \supset B) \rightarrow T(C),$$

which encodes the conclusion of \supset -L.

From this, it is easy to see that our encoding of LJ^\supset is adequate. We show faithfulness by a modification of the techniques discussed above.

An observation about implementations

Note that the last step, ‘combining’ (28) with (27), actually requires a number of steps in the metalogic; e.g. shuffling around formulae by using the fact that, in the metalogic of the framework itself, $T(A) \rightarrow T(B) \rightarrow T(C)$ is equivalent to $T(B) \rightarrow T(A) \rightarrow T(C)$. But such reasoning must come out somewhere in any formalism of a system based on consequence relations. There is no getting around some equivalent of structural reasoning; the question is simply of how, and where, it is done, and how visible it is to the user.

In fact in actual implementations of \rightarrow -frameworks, e.g., Isabelle [Paulson, 1994], the cost of this structural reasoning is no greater than in a custom implementation since the framework theory itself will be implemented in terms of a pure, ordinary single conclusioned consequence relation; i.e. as a sequent or natural deduction calculus. If we write the consequence relation of the implementation as \Longrightarrow , then it is easy to see that an encoded sequent such as (26) can be quickly transformed into the logically equivalent

$$T(F_1), \dots, T(F_m) \Longrightarrow T(A)$$

at which point it is possible to ‘piggy-back’ the rest of the proof off of \Longrightarrow , and thus make use of the direct (and thus presumably efficient) implementation of its structural properties.

Multiple concluded consequence

Having examined how we might encode ordinary pure single concluded consequence relations in an \rightarrow -framework, we now consider the general case of multiple concluded relations, which occur in standard presentations of many logics (e.g. LK^\supset described in §2.2).

There is no obvious correspondence between such relations and formulae in the language of \rightarrow . However, by refining our encoding a little, we can easily extend Avron's observation to the general case and thereby give a direct and effective encoding of multiple concluded consequence relations. We take as our example the system LK^\supset . For larger developments and applications of this style, the reader is referred to [Pfenning, 2000].

A multiple concluded consequence relation is a pair of multisets of formulae, which we can refer to as 'left' and 'right'; i.e.

$$\overbrace{A_1, \dots, A_n}^{\text{left}} \vdash \overbrace{B_1, \dots, B_m}^{\text{right}}. \quad (29)$$

To encode this we need not one judgment T , but *two* judgments which we call T_L and T_R ; we also define a new propositional constant E . We can encode (29) in an \rightarrow -framework as

$$T_L(A_1) \rightarrow \dots \rightarrow T_L(A_n) \rightarrow T_R(B_1) \rightarrow \dots \rightarrow T_R(B_m) \rightarrow E.$$

This is not quite enough to give us a consequence relation though; unlike in the single concluded case, we do not automatically get that *Basic* is true. However we can remedy this by declaring that

$$T_L(A) \rightarrow T_R(A) \rightarrow E$$

and then we can show that the encoding defines an ordinary consequence relation.

We can then extend the style of encoding described to define, e.g., the right and left rule for implication in LK^\supset , which are

$$(T_L(A) \rightarrow T_R(B) \rightarrow E) \rightarrow T_R(A \supset B) \rightarrow E$$

and

$$(T_R(A) \rightarrow E) \rightarrow (T_L(B) \rightarrow E) \rightarrow T_L(A \supset B) \rightarrow E.$$

As in the single concluded case, a necessary condition for this encoding is that the consequence relation is pure. It is also easy to show that the encoding is adequate and faithful with respect to the derivability of sequents in LK^\supset .

Multiple consequence relation systems

Finally, we come to the problem of how to formalize systems based on more than one consequence relation. Here we will briefly consider just the single concluded case; the same remarks, suitably modified, also apply to the multiple concluded case.

One approach to analyzing a formal system (and quite useful if we want the analysis to be in terms of pure consequence relations) is, rather than using a single relation, to decompose it into a set of relations \vdash_1 to \vdash_n . We can encode each of these relations, and their rules, just like in the single relation case, using predicates T_1 to T_n ; i.e.

$$A_1, \dots, A_n \vdash_i A$$

as

$$T_i(A_1) \rightarrow \dots \rightarrow T_i(A_n) \rightarrow T_i(A).$$

We encounter a new encoding problem with multiple consequence systems. These typically (always, if they are interesting) contain rules that relate consequence relations to each other, i.e., rules where the premises are built from different consequence relations than the conclusion. Consider the simplest example of this, which simply declares that one consequence relation is a subrelation of another (what we might call a *bridge* rule):

$$\frac{\Gamma \vdash_1 A}{\Gamma \vdash_2 A} \text{ bridge}$$

We can encode this as the pair of schemata

$$T_1(A) \rightarrow T_2(A) \tag{30}$$

and

$$(T_1(A) \rightarrow T_2(B)) \rightarrow T_2(A) \rightarrow T_2(B) \tag{31}$$

and show that the resulting encoding is properly closed. That is, given

$$T_1(A_1) \rightarrow \dots \rightarrow T_1(A_n) \rightarrow T_1(B)$$

by (30) we get

$$T_1(A_1) \rightarrow \dots \rightarrow T_1(A_n) \rightarrow T_2(B)$$

then by n applications of (31) we eventually get

$$T_2(A_1) \rightarrow \dots \rightarrow T_2(A_n) \rightarrow T_2(B).$$

As this example shows, working with a multiple consequence relation system in an \rightarrow -framework may require many metalevel steps to simulate a proof step in the object logic (here the number depends on the size of the sequent). More practical experience using such encodings is required to judge whether they are really usable in practice as opposed to just being a theoretically interesting way of encoding multiple consequence relation systems in the logic of \rightarrow .

In fact we have already encountered an example of this kind of an encoding: the multiple judgment encoding of modal logic developed in [Avron *et al.*, 1992; Avron *et al.*, 1998], described in §5.4, can be seen as the encoding of a two consequence relation system for truth and validity where T_1 is T , T_2 is V and *bridge* is implemented by R and C .

7 DEDUCTIVE SYSTEMS AS INDUCTIVE DEFINITIONS

In the introduction we discussed two separate traditions of metatheory: metatheory as a unifying language and metatheory as proof theory. We have shown too how \rightarrow -frameworks fit into the unifying language tradition, and the way different logics can be encoded in them and used to carry out proofs. However, \rightarrow -frameworks are inadequate for proof theory: in exchange for ease of reasoning *within* a logic, reasoning *about* the logic becomes difficult or impossible.

In order better to understand this point, and some of the subtleties it involves, consider the following statements about the (minimal) logic of \supset .

1. $A \supset A$ is a theorem.
2. $A \supset B \supset C$ is true on the assumption that $B \supset A \supset C$ is true.
3. The deduction theorem holds for HJ^{\supset} .
4. The deduction theorem holds for all extensions of HJ^{\supset} with additional axioms.

Statement 1 can be formalized in a metalogic as a statement about provability in any complete presentation of the logic of \supset ; e.g. NJ^{\supset} , LJ^{\supset} or HJ^{\supset} . As a statement about provability we might regard it as, in some sense, a proof-theoretic statement. But as such, it is very weak since, by completeness, it must be provable irrespective of the deductive system used.

Statement 2 expresses a derived rule of the logic of \supset . Its formalization requires that we can reason about the truth of one formula relative to others. As explained in §6, representing this kind of a (truth) consequence relation can easily be reduced to a provability problem in an \rightarrow -framework. For example, in the λ^p encoding of NJ^{\supset} we prove that the type $\Pi A^o B^o C^o. pr(B \supset A \supset C) \rightarrow pr(A \supset B \supset C)$ is inhabited.

As with statement 1, the metalogic must be able to build proofs in the object logic (in this case though under assumptions, encoded using \rightarrow in the metalogic), but proofs themselves need not be further analyzed.

Statement 3 (which we prove in this section) is an example of a metatheoretic statement that is more in the proof theory tradition. In order to prove it we must analyze the structure of arbitrary proofs in the deductive system of HJ^\supset using an inductive argument. The difference between this and the previous example is important: for a proof of statement 2 we need to know which axioms and rules are available in the formalized deductive system, while for a proof of statement 3 we also need to know that no other rules are present, since this is what justifies an induction principle over proofs (the rules of HJ^\supset can be taken as constituting an inductive definition). An \rightarrow -framework like λ^p contains no provisions for carrying out induction over the structure of an encoded deductive system.

Statement 4 is an extension of statement 3, which introduces the problem of *theory structuring*. Structuring object theories to allow metatheoretic results to be ‘imported’ and used in related theories is not a substantial problem in the kinds of metamathematical investigations undertaken by proof theorists, who are typically interested in proving particular results about particular systems. However, for computer scientists working on formal theorem proving, it is enormously important: it is good practice for a user reasoning about complex theories to formalize a collection of simpler theories (e.g. for numbers and arithmetic, sequences, relations, orders, etc.) that later are combined together as needed. So some kind of theory structuring facility is practically important and many systems provide support for it.²⁵

Unfortunately, hierarchical structure in \rightarrow -frameworks is the result of an assumption (necessary anyway for other reasons) that the languages and deductive systems of encoded logics are ‘open to extensions’ (see §7.4 below), something that automatically rules out any arguments requiring induction on the structure of the language²⁶ or proofs of a theory, e.g. the deduction theorem. If we ‘close’ the language or deductive system by explicitly adding induction over the language or proofs, in order to prove metatheorems, it is unsound later to assume those theorems in extensions of the deductive system or language. In §7.4, we suggest that there is a way to avoid this problem if we formulate metatheorems in a metalogic based on inductive definitions.

These examples illustrate that there are different sorts of metatheoretic statements, which are distinguished by how conscious we have to be of the metatheoretic context in order to prove them. The central role of induction in carrying

²⁵ For example HOL [Gordon and Melham, 1993], Isabelle [Paulson, 1994] and their predecessor LCF [Gordon *et al.*, 1979] support simple theory hierarchies where theorems proven in a theory may be used in extensions.

²⁶ An example of a metatheorem for which we need induction over the language, not the derivations, is that *In classical logic, a propositional formula that contains only the \leftrightarrow connective is valid if and only if each propositional variable occurs an even number of times.*

out many kinds of the more general metatheoretic arguments is the reason we now consider logical frameworks based on inductive definitions.

7.1 *Historical background: From Hilbert to Feferman*

What kind of a metalogic is suited for carrying out metatheoretic arguments that require induction on the language or deductive system of the object logic? To answer this question we draw on experience gained by proof theorists dating back to Hilbert, in particular Post and Gödel, and later Feferman, who have asked very similar questions. We can also draw on practical experience over the last 30 years in the use of computers in work with formal systems.

The work of Post and Gödel

In the early part of this century, Post [1943] (see Davis [1989] for a short survey of Post's work) investigated the decidability of logics like that of *Principia Mathematica*. He showed that such systems could be formalized as (what we now recognize as) recursively enumerable classes of strings and that this provided a basis for metatheoretic analysis. Although Post's work is a large step towards answering our question, one important aspect, from our point of view, is missing from his formalization. There is no consideration of *formal* metatheory. Post was interested in a formal characterization of deductive systems, not of their metatheories; he simply assumed, reasonably for his purposes, that arbitrary mathematical principles could be adopted as necessary for the metatheory.

We cannot make the same assumption with a logical framework: we must decide first which mathematical principles we need, and then formalize them. The work of Post is thus complemented, for our purposes, by Gödel's [1931] work on the incompleteness of systems like *Principia Mathematica*, which shows that a fragment of arithmetic is sufficient for complex and general metatheory. Logicians have since been able to narrow that fragment down to the theory of primitive recursive arithmetic, which seems sufficient for general syntactic metatheory.²⁷

The natural numbers, although adequate for Gödel's purposes, are too unwieldy to use as a logical framework. Indeed, a large part of Gödel's paper is taken up with a complicated technical development showing that arithmetic really can represent syntax. The result is unusable in a practical framework: the relationship between syntax and its encoding is only indirectly given by (relatively) complicated arithmetic functions and the numbers generated in the encoding can be enormous. This is in contrast to Post's strings (further investigated in the early sixties by mathematicians such as Smullyan [1961]), which have a simple and direct correspondence with the structures we want to encode, and a compact representation.

²⁷ This is a thesis, of course, not a theorem; and exceptions have to be made for, e.g., proof normalization theorems, for which (as a corollary of Gödel's result itself) we know there can be no single general metatheory.

S-expressions and FS_0

It is possible to build a formal metatheory based on strings, in the manner of Post. However, experience in computer science in formalizing and working with large symbolic systems has shown that there is an even more natural language for modeling formal (and other kinds of symbolic) systems. The consensus of this experience is found in Lisp [McCarthy, 1981; Steele Jr. and Gabriel, 1996], which for more than 30 years has remained the most popular language for building systems for symbolic computation.²⁸ Further, Lisp is not only effective, but its basic data-structure, which has, in large part, contributed to its effectiveness, is remarkably simple: the *S-expression*. This is the data-type freely generated from a base type by a binary function ‘Cons’. Experience with Lisp has shown that just about any syntactic structure can be mapped directly onto S-expressions in such a way that it is very easy to manipulate. In fact, we can even restrict the base type of S-expressions to be a single constant (often called ‘*nil*’) and still get this expressiveness. Further evidence for the effectiveness of Lisp and S-expressions is that one of the most successful theorem proving systems ever built, NQTHM [Boyer and Moore, 1981], verifies recursive functions written in a version of Lisp that uses precisely this class of S-expressions.

An example of a theory that integrates all the above observations is FS_0 , due to Feferman. This provides us with a language in which we can define exactly all the recursively enumerable classes of S-expressions. Moreover, it permits inductive arguments over these inductively defined classes, and thus naturally subsumes both the theory of recursively enumerable classes and primitive recursive arithmetic. It has proved usable too in case-studies of computer supported metatheory, in the proof-theoretic tradition (see Matthews [1992; 1993; 1994; 1997b]). In the rest of this chapter we will use a slightly abstracted version of FS_0 for our discussion.

7.2 *A theory of inductive definitions: FS_0*

FS_0 is a simple minimal theory of inductive definitions, which we present here in an abstract form (we elide details in order to emphasize the general, rather than the particular, features). A full description of the theory is provided by Feferman [1990], while an implementation is described by Matthews [1996].

FS_0 is a theory of inductively defined sets, embedded in first-order logic and based on Lisp-style S-expressions. The class of S-expressions is the least class containing *nil* and closed under the pairing (*cons*) operator, which we write as an infix comma (\cdot, \cdot) , such that $nil \neq (a, b)$ for all S-expressions a and b ; we also assume, for convenience, that comma associates to the right, so that $(a, (b, c))$ can

²⁸This does not mean that there have not been successful programming languages that use strings as their basic data-structure; the SNOBOL family [Griswold, 1981] of languages, for example, is based on the theory of Markoff string transformation algorithms. However it is significant that SNOBOL, in spite of its mathematical elegance in many ways, has never been seen as a general purpose symbolic programming language like Lisp, or been adopted so enthusiastically by such a large and influential programming community.

be abbreviated to (a, b, c) . We then have functions car and cdr , which return the first and second elements of a pair.

Comprehension over first-order predicates is available. We write

$$x \in S \Leftrightarrow P(x) \quad \text{or} \quad S \equiv \{ x \mid P(x) \}$$

to indicate a set S so defined. Such definitions can be parameterized and the parameters are treated in a simple way, thus, for example, we can write

$$x \in S(a, b) \Leftrightarrow (x, a) \in b.$$

We can also define sets explicitly as inductive definitions using the $I(\cdot, \cdot)$ construction: if A and B are sets, then $I(A, B)$ is the least set containing A and closed under the rule

$$\frac{t_1 \quad t_2}{t}$$

where $(t, t_1, t_2) \in B$. Note that we only have inductive definitions with exactly two ‘predecessors’, but this is sufficient for our needs here and, with a little more effort, in general.

Finally, we can reason about inductively defined sets using the induction principle

$$\begin{aligned} \text{Base} \subseteq S \rightarrow \forall a, b, c. (b \in S \rightarrow c \in S \rightarrow \\ (a, b, c) \in \text{Step} \rightarrow a \in S) \rightarrow I(\text{Base}, \text{Step}) \subseteq S. \end{aligned} \quad (32)$$

This says that a set S contains all the members of a set $I(\text{Base}, \text{Step})$ if it contains the members of Base and whenever it contains two elements b and c , and (a, b, c) is an instance of the rule Step , then it also contains a . This induction principle applies to sets, not predicates, but it is easy, by comprehension, to generate one from the other, so this is not a restriction.²⁹

7.3 A Hilbert theory of minimal implication

Having sketched a theory of inductive definitions, we now consider how it might actually be used, both to encode an object logic, and to prove metatheorems. As an example, we encode the theory HJ^\supset (of §2.1) and prove a deduction theorem.

The definition of HJ

The language L_{HJ} We define an encoding $\ulcorner \cdot \urcorner$ of the standard language of implicational logic L_{HJ} (as usual we distinguish metalevel (\rightarrow) from object level (\supset))

²⁹In FS_0 comprehension is restricted to essentially Σ_1^0 predicates with the result that the theory is recursion-theoretically equivalent to primitive recursive arithmetic.

implication) as follows. We define two distinct S-expression constants (e.g. *nil* and (nil, nil)) which we call `atom` and `imp`, then we have

$$\begin{aligned}\ulcorner a \urcorner &= (\text{atom}, \ulcorner a \urcorner) && (a \text{ atomic}) \\ \ulcorner a \supset b \urcorner &= (\text{imp}, \ulcorner a \urcorner, \ulcorner b \urcorner)\end{aligned}$$

(assuming $\ulcorner a \urcorner$ for atomic a to be already, separately, defined). It is easy to see that $\ulcorner \cdot \urcorner$ is an injection from L_{HJ} into the S-expressions, on the assumption that $\ulcorner \cdot \urcorner$ is. For the sake of readability, in the future we will abuse notation, and write simply $a \supset b$ when we mean the schema (imp, a, b) ; i.e. a and b here are variables in the theory of inductive definitions, not propositional variables in the encoded language L_{HJ} .

The theory HJ We now define a minimal theory of implication, HJ, as follows. We have two classes of axioms

$$x \in K \Leftrightarrow \exists a, b. x = (a \supset b \supset a)$$

and

$$x \in S \Leftrightarrow \exists a, b, c. x = ((a \supset b) \supset (a \supset b \supset c) \supset a \supset c)$$

and a rule of detachment

$$x \in Det \Leftrightarrow \exists a, b. x = (b, (a \supset b), a)$$

from which we define the theory HJ to be

$$HJ \equiv I(K \cup S, Det).$$

Using HJ

We can now use HJ to prove theorems of the Hilbert calculus HJ^\supset in the same way that we would use an encoding to carry out natural deduction proofs in an \rightarrow -framework. One difference is that we do not get a direct correspondence between proof steps in the encoded theory and steps in the derivation. However, in this case it is enough to prove first the following lemmas:

$$a \supset b \supset a \in HJ \tag{33}$$

$$(a \supset b) \supset (a \supset b \supset c) \supset a \supset c \in HJ \tag{34}$$

$$a \in HJ \rightarrow (a \supset b) \in HJ \rightarrow b \in HJ \tag{35}$$

Here, and in future, we assume theorems are universally closed. From these, it follows that if A is a theorem of minimal implication, then $\ulcorner A \urcorner \in HJ$.

For example, we show

$$a \supset a \in \text{HJ} \quad (36)$$

with the derivation

1. $a \supset a \supset a \in \text{HJ}$ by (33)
2. $a \supset (a \supset a) \supset a \in \text{HJ}$ by (33)
3. $(a \supset a \supset a) \supset (a \supset (a \supset a) \supset a) \supset a \supset a \in \text{HJ}$ by (34)
4. $(a \supset (a \supset a) \supset a) \supset a \supset a \in \text{HJ}$ by (35),1,3
5. $a \supset a \in \text{HJ}$ by (35),2,4

The steps of this proof correspond, one to one, with the steps of the proof that we gave for HJ^\supset in §2.1. As this example suggests, at least for propositional Hilbert calculi, inductive definitions support object theory where proofs in the metatheory closely mirror proofs in the object theory. (For logics with quantifiers the relationship is less direct, since we have to encode and explicitly reason about variable binding and substitution.)

Proving a deduction theorem for HJ

Let us now consider an example that requires induction over proofs themselves: the deduction theorem for HJ. We only sketch the proof; the reader is referred to Basin and Matthews [2000] for details. Informally, the deduction theorem says:

If B is provable in HJ with the additional axiom A then $A \supset B$ is provable in HJ.

Note that this theorem relates different deductive systems: HJ and its extension with the axiom A . Moreover, as A and B are schematic, ranging over all formulae of HJ, the theorem actually relates provability in HJ with provability in infinitely many extensions, one for each proposition A .

To formalize this theorem we define

$$\text{HJ}[\Gamma] \equiv I(K \cup S \cup \Gamma, \text{Det}); \quad (37)$$

i.e. $\text{HJ}[\Gamma]$ is the deductive system HJ where the axioms are extended by all formulae in the class Γ . Now we can formalize the deduction theorem as

$$b \in \text{HJ}[\{a\}] \rightarrow (a \supset b) \in \text{HJ}, \quad (38)$$

which in FS_0 can be transformed into

$$I(K \cup S \cup \{a\}, \text{Det}) \subseteq \{x \mid (a \supset x) \in \text{HJ}\}.$$

This in turn can be proved by induction on the inductively defined set $I(K \cup S \cup \{a\}, \text{Det})$ using (32). The proof proceeds as follows:

Base case We have to show $K \cup S \cup \{a\} \subseteq \{x \mid (a \supset x) \in \text{HJ}\}$. This reduces, via $x \in K \cup S \cup \{a\} \rightarrow (a \supset x) \in \text{HJ}$, to showing that $(a \supset x) \in \text{HJ}$ given either (i) $x \in K \cup S$ or (ii) $x \in \{a\}$. For (i) we have $x \in \text{HJ}$ and $(x \supset a \supset x) \in \text{HJ}$, and thus, by *Det* that $(a \supset x) \in \text{HJ}$. For (ii) we have $x = a$ and thus have to show that $(a \supset a) \in \text{HJ}$, which we do following the proof of (36) above.

Step case There is only one rule (*Det*) and thus one case: given $b \in \{x \mid (a \supset x) \in \text{HJ}\}$ and $(b \supset c) \in \{x \mid (a \supset x) \in \text{HJ}\}$, prove that $c \in \{x \mid (a \supset x) \in \text{HJ}\}$. This reduces to proving, given $(a \supset b) \in \text{HJ}$ and $(a \supset b \supset c) \in \text{HJ}$ that $(a \supset c) \in \text{HJ}$. This in turn follows by observing that $((a \supset b) \supset (a \supset b \supset c) \supset a \supset c) \in \text{HJ}$ by (34), from which, by (35) twice with the hypotheses, $(a \supset c) \in \text{HJ}$.

Once we have proved the deduction theorem we can use it to build proofs where we reason under assumption in the style of natural deduction. This is useful, indeed in practice essential, if we really wish to use Hilbert calculi to prove anything. However it is also limited since this metatheorem can be applied *only* to HJ. Thus, we next consider how this limitation can be partially remedied.

7.4 Structured theory and metatheory

At the beginning of this section, we discussed two examples of the deduction theorem (statements 3 and 4) where the second stated that the deduction theorem holds not just in HJ^\supset but also in extensions. We return to this example, which illustrates an important difference between ID-frameworks and \rightarrow -frameworks.

Structuring in \rightarrow -frameworks

Let us first examine how theories can be structured in \rightarrow -frameworks. Consider the following: we can easily encode HJ^\supset as (assuming the encoding of the syntax is given separately) the axiom set $\Gamma_{\text{HJ}^\supset}$.

$$\begin{aligned} & T(A \supset B \supset A) \\ & T((A \supset B) \supset (A \supset B \supset C) \supset A \supset C) \\ & T(A) \rightarrow T(A \supset B) \rightarrow T(B) \end{aligned}$$

Then A is a theorem of HJ^\supset iff $\Gamma_{\text{HJ}^\supset} \vdash T(A)$, i.e., $T(A)$ is provable in the metalogic under the assumptions $\Gamma_{\text{HJ}^\supset}$. Now consider the deduction theorem in this setting; we would have to show that

$$\Gamma_{\text{HJ}^\supset} \vdash (T(A) \rightarrow T(B)) \rightarrow T(A \supset B). \quad (39)$$

This is not possible, however.

In an \rightarrow -framework, a basic property of \vdash is weakening; i.e. if $\Gamma \vdash \phi$ then $\Gamma, \Delta \vdash \phi$. This is very convenient for structuring theories: a theorem proven

under the assumptions Γ holds under extension with additional assumptions Δ . For example, Δ might extend our formalization of HJ^\supset to a classical theory of \supset or perhaps to full first-order logic.³⁰ By weakening, given $\Gamma_{\text{HJ}^\supset} \vdash \phi$ we immediately have $\Gamma_{\text{HJ}^\supset}, \Delta \vdash \phi$. Thus we get a natural hierarchy on the object theories we define: theory T' is a subtheory of theory T when its axioms are a subset of those of T . This allows us to reuse proven metatheorems since anything proven for a subtheory automatically follows in any supertheory.

Consider, on the other hand, the extension Δ_K consisting of the axioms

$$\begin{aligned} T(A) &\rightarrow T(\Box A) \\ T(\Box A \supset \Box(A \supset B) \supset \Box B) \end{aligned}$$

with which we can extend $\Gamma_{\text{HJ}^\supset}$ to a fragment of the modal logic K . The deduction theorem *does not* follow in K ; therefore, since by faithfulness we have

$$\Gamma_{\text{HJ}^\supset}, \Delta_K \not\vdash (T(A) \rightarrow T(B)) \rightarrow T(A \supset B),$$

we must also have, by weakening and contraposition,

$$\Gamma_{\text{HJ}^\supset} \not\vdash (T(A) \rightarrow T(B)) \rightarrow T(A \supset B).$$

This suggests that there is an either/or situation: we can have either hierarchically structured theories, as in an \rightarrow -framework, or general inductive metatheorems (like the deduction theorem), as in an ID-framework, but not both. In fact, as we will see, in an ID-framework things are not quite so clear-cut: there is the possibility both to prove metatheorems by induction and to use them in certain classes of extensions.

Structuring in an ID-framework

Part of the explanation of why we can prove (38), but not (39), is that it is not possible to extend the deduction theorem for HJ to arbitrary supertheories: (38) is a statement about HJ and it tells us nothing about anything else. However a theorem about HJ alone is of limited use: in practice we are likely to be interested in HJ^\supset as a fragment of some larger theory. We know, for instance, that the deduction theorem follows for many extensions of HJ (e.g. extensions to larger fragments of intuitionistic or classical logic). The problem is that the induction principle we use to prove the theorem is equivalent to a closure assumption, and such an assumption means that we are not able to use the theorem with extensions.

We seem to have confirmed, from the other side, the trade-off we have documented above for \rightarrow -frameworks: either we can have induction and no theory structuring (as theories are ‘closed’), or vice versa. However, if we look harder,

³⁰ An extension of the deduction theorem to first-order logic, however, is not trivial—we have to treat a new rule, which introduces complex side conditions to the statement of the theorem (Kleene[1952] discusses one way to do this).

there is sometimes a middle way that is possible in ID-frameworks. The crucial point is that an inductive argument does not always rely on *all* the closure assumptions of the most general case. Consider the assumptions that are made in the proof of (38):

- The proof of the base case relies on the fact that the axioms $a \supset b \supset a$ and $a \supset a$ are available in HJ.
- The proof of the step case relies on the fact that the *only* rule that can be applied is *Det*, and that the axiom

$$(a \supset b) \supset (a \supset b \supset c) \supset a \supset c$$

is available.

What bears emphasizing is that we do not need to assume that no axioms other than those explicitly mentioned are available, only that no rules other than *Det* are available.

We can take account of this observation to produce a more general version of (38)

$$b \in \text{HJ}[\Gamma \cup \{a\}] \rightarrow (a \supset b) \in \text{HJ}[\Gamma], \quad (40)$$

which we can still prove in the same way as (38). We call this version *open-ended* since it can be used with any axiomatic extension Γ of HJ. In particular (38) is just (40) where we take Γ to be \emptyset .

Structuring theories with the deduction theorem Unlike (38), we can make effective use of (40) in a hierarchy of theories in a way similar to what is possible in an \rightarrow -framework. The metatheorem can be applied to any extension $\text{HJ}[\Gamma]$ where Γ is a collection of axioms. The fact that in the \rightarrow -framework we can add new rules, not just new axioms, is not as significant as it at first appears, so long as we have that

$$T(A) \rightarrow T(B) \quad \text{iff} \quad T(A \supset B) \quad (41)$$

since we can use this to find an axiomatic equivalent of any rule schema built from \rightarrow and T in terms of \supset .

The above observation, of course, only holds for theories that can be defined in terms of a single predicate T and which include a connective \supset for which (41) is true.³¹

³¹ And, of course, some encodings use more than one metalevel predicate; e.g. in §5.4 we introduce a second predicate V for which there is no equivalent of (41). For these systems we have rules for which no axiomatic equivalent is available. This does not, however, mean that ID-frameworks are necessarily less effective for structuring collections of theories; it just means that we have to be more sophisticated in the way we exploit (41). See, e.g., Matthews [1997b] for discussion of how we can do this by introducing an ‘extra’ layer between the ID-framework and the theory to be encoded.

A further generalization of the deduction theorem

We arrived at the open-ended (40) by observing that other axioms could be present. And as previously observed, no such generalization is possible with arbitrary rules, e.g., the deduction theorem does not hold in \mathbb{K} (which requires extensions by rules, as opposed to axioms). However, a more refined analysis of the step case of the proof is possible, and this leads to a further generalization of our metatheorem.

In the step case we need precisely that the theory is closed under

$$\frac{A \supset B \quad A \supset C}{A \supset D}$$

for each instance of a basic rule

$$\frac{B \quad C}{D}.$$

In the case of *Det* (the only rule in HJ^{\supset}) we can show this by a combination of *Det* and the *S* axiom.

Using our ID-framework we can explicitly formalize these statements as part of the deduction theorem itself, proving a further generalization. If we extend the notation of (37) with a parameter Δ for rules, i.e.,

$$\text{HJ}[\Gamma, \Delta] \equiv I(K \cup S \cup \Gamma, \text{Det} \cup \Delta) \quad (42)$$

then for the base case we have

$$b \in \text{HJ}[\Gamma \cup \{a\}, \Delta] \rightarrow (a \supset b) \in \text{HJ}[\Gamma, \Delta] \quad (43)$$

and

$$(a \supset a) \in \text{HJ}[\Gamma, \Delta] \quad (44)$$

while for the step case

$$\begin{aligned} (d, b, c) \in \Delta &\rightarrow (a \supset b) \in \text{HJ}[\Gamma, \Delta] \\ &\rightarrow (a \supset c) \in \text{HJ}[\Gamma, \Delta] \rightarrow (a \supset d) \in \text{HJ}[\Gamma, \Delta]. \end{aligned} \quad (45)$$

The formulae (43) and (44) follow immediately for any $\text{HJ}[\Gamma, \Delta]$, but (45) isn't always true. Thus, our third deduction theorem has the form

$$(45) \rightarrow b \in \text{HJ}[\Gamma \cup \{a\}, \Delta] \rightarrow (a \supset b) \in \text{HJ}[\Gamma, \Delta], \quad (46)$$

which can be proved in the same way as (40). Note too that this metatheorem generalizes (40), since (40) is just (38) where Δ is \emptyset and the antecedent, which is therefore true, has been removed.

The deduction theorem can even be further generalized, but doing so would take us too far afield. In [Basin and Matthews, 2000] we show how a further generalization of (46) can be specialized to modal logics that extend S4. This generalization allows us to prove

$$b \in \text{S4}[\Gamma \cup \{a\}] \rightarrow (\Box a \supset b) \in \text{S4}[\Gamma].$$

That is, in S4 we can prove a deduction theorem that allows us to reason under ‘boxed’ assumptions $\Box a$.

7.5 Admissible and derived rules

Our examples suggest that inductive definitions offer considerable power and simplicity in organizing metatheories. Each metatheorem states the conditions an extension has to satisfy for it to apply; so once proved, we need only check these conditions before making use of it. Most metatheorems require only that certain axioms and rules are available and therefore hold in all extensions with additional axioms and rules. Others depend on certain things being absent (e.g. rules that do not satisfy certain properties, in the case of the deduction theorem); in such cases, we can prove more restricted theorems that are still usable in appropriate extensions.

How does this kind of metatheory compare with what is possible in theorem provers supporting hierarchical theories? We begin by reviewing the two standard notions of proof-rules. Our definitions are those of Troelstra [1982, § 1.11.1] translated into our notation, where $\mathcal{T}[\Gamma, \Delta]$ is a deductive system \mathcal{T} extended with sets of axioms Γ and rules Δ , e.g. (42).

Fix a language of formulae. A *rule* is an $n + 1$ -ary relation over formulae $\langle F_1, \dots, F_n, F_{n+1} \rangle$ where the F_1, \dots, F_n are the *premises* and F_{n+1} the *conclusion*. A rule is *admissible* for \mathcal{T} iff

$$\vdash_{\mathcal{T}[\emptyset, \emptyset]} F_1 \rightarrow \dots \rightarrow \vdash_{\mathcal{T}[\emptyset, \emptyset]} F_n \rightarrow \vdash_{\mathcal{T}[\emptyset, \emptyset]} F_{n+1}, \quad (\text{adm})$$

and *derivable* for \mathcal{T} iff

$$\forall \Gamma. \vdash_{\mathcal{T}[\Gamma, \emptyset]} F_1 \rightarrow \dots \rightarrow \vdash_{\mathcal{T}[\Gamma, \emptyset]} F_n \rightarrow \vdash_{\mathcal{T}[\Gamma, \emptyset]} F_{n+1}. \quad (\text{der})$$

It follows immediately from the definitions that derivability implies admissibility; however, the converse does not always hold. It is easy to show that Troelstra’s definition of derivability is equivalent to that of Hindley and Seldin [1986]; i.e. $\vdash_{\mathcal{T}[\{F_1, \dots, F_n\}, \emptyset]} F_{n+1}$, and that if a rule is derivable it holds in all extensions of \mathcal{T} with new axioms and rules.

Whereas in \rightarrow -frameworks we can only prove derived rules, logical frameworks based on inductive definitions allow us to prove that rules are admissible, as well as reason about other kinds of rules not fitting the above categories. For example, the languages or deductive systems for the F_i can be different, like in the various

versions of the deduction theorem that we have formalized; our deduction theorems are neither derived nor admissible since their statements involve different deductive systems.

7.6 Problems with ID-frameworks

Our examples provide evidence that a framework based on inductive definitions can serve as an adequate foundation for carrying out metatheory in the proof theory tradition and can be used to structure metatheoretic development. However, some aspects of formal metatheory are more difficult than with an \rightarrow -framework. The most fundamental difficulty, and one that is probably already clear from our discussion in this section, is the way languages are encoded. This is quite primitive in comparison to what is possible in an \rightarrow -framework: for the propositional examples that we have treated here, the view of a language as a recursively enumerable class is direct and effective. But this breaks down for logics with quantifiers and other variable binding operators where the natural equivalence relation for syntax is no longer identity but equivalence under the renaming of bound variables (α -congruence). We have shown (in §4.2) that language involving binding has a natural and direct treatment in an \rightarrow -framework as higher-order syntax. Nothing directly equivalent is available in an ID-framework; we are forced to build the necessary facilities ourselves.

Since the user must formalize many basic syntactic operations in an ID-framework, any treatment of languages involving variable binding operators will be more ‘primitive’ than what we get in an \rightarrow -framework, but how much more primitive is not clear. So far, most experience has been with *ad hoc* implementations of binding (e.g. [Matthews, 1992]) but approaches that are both more sophisticated and more modular are possible, such as the binding structures proposed by Talcott [1993], a generalization of de Bruijn indices as an algebra. As yet, we do not know how effective such notations are.

The other property of ID-frameworks that might be criticized is that they are biased towards Hilbert calculi, which are recognized to be difficult to use. But metatheorems, in particular the deduction theorem, can play an important role in making Hilbert calculi usable in practice. And, if a Hilbert style presentation is not suitable, it may be possible to exploit a combination of the deduction theorem and the intuitions of \rightarrow -frameworks to provide direct encodings of natural deduction [Matthews, 1997b]. The same provisos about lack of experience with effective notations for handling bindings apply here though, since this work only discusses the propositional case.

8 CONCLUSIONS

This chapter does not try to give a final answer to the question of what a logical framework might be. Rather it argues that the question is only meaningful in terms

of some particular set of requirements, and in terms of ‘goodness of fit’; i.e. the relationship between the properties of a proposed metalogic and logics we want to encode.

Our central theme has been the relationship between different kinds of deductive systems and their abstractions as metatheories or metalogics, which we can use to encode and work with instances of them. We have showed that a logic of minimal implication and universal quantification can be used to encode both the language and the proof-rules of a natural deduction or sequent calculus, and then described in detail a particular logic of this type, λ^p . As a contrast, we have also considered how (especially Hilbert) calculi can be abstracted as inductive definitions and we sketched a framework based on this view, FS_0 . We then used the metatheoretic facilities that we get with an ID-framework like FS_0 to explore the relationship between metatheory and object theory, especially in the context of structured collections of theories.

The simple binary distinction between ID and \rightarrow -frameworks, which we make for the sake of space and explication, of course does not describe the whole range of frameworks that have been proposed and investigated. It does, however, help to define the space of possibilities and current research into frameworks can mostly be categorized in its terms.

For instance, research into the problem of the ‘goodness of fit’ relation between the metalogic and the object logic, especially for \rightarrow -frameworks, can be separated into two parts. We have shown that natural deduction calculi for standard mathematical (i.e., classical or intuitionistic, first or higher-order) logics fit well into an \rightarrow -framework. But the further we diverge from standard, mathematical, logics into philosophical (i.e. modal, relevance, etc.) logic the more complex and artificial the encodings become. In order to encode modal logics, for instance, we might introduce either multiple-judgment encodings or take explicit account of a semantics via a labelling. The particular encodings that we have described here are only some among a range of possibilities that could be imagined. A more radical possibility, not discussed here, can be found in, e.g., [Matthews, 1997a], where the possibility of extending a framework directly with a modal ‘validity’ connective is explored. However we do not yet know what the practical limits of these approaches are.³² A similar problem of goodness of fit is also encountered in ID-frameworks, where the ‘natural’ deductive systems are Hilbert calculi and the ‘obvious’ encodings of consequence style systems are impractically unwieldy. Matthews [1997b] suggests how we might encode pure ordinary consequence relation based systems in such a framework in a way that is more effective than, and at least as intuitive as, the ‘naive’ approach of using inductively defined classes.

The particular problems of substructural logics (e.g. linear or relevance logics) have been the subject of substantial research. The consequence relations associated with these logics are not ordinary and hence cannot be encoded using tech-

³²This is essentially a practical, not a theoretical question, since, as we pointed out earlier, an \rightarrow -framework can be used as a Turing complete programming language, so with sufficient ingenuity any deductive system can be encoded.

niques such as those suggested in §6. While labelled or multiple judgment presentations of these logics in an \rightarrow -framework are possible, they seem to be unwieldy; i.e. they ‘fit’ particularly badly. An alternative approach has been explored where the framework itself is modified: minimal implication is replaced or augmented in the framework logic with a substructural or linear implication, which does permit a good fit. In Ishtiaq and Pym [1998] and Cervesato and Pfenning [1996], systems are presented that are similar to λ^p except that they are based on linear implication, which is used to encode variants of linear and other relevance logics. There is also work that, rather than employing either \rightarrow or ID-frameworks, attempts to combine features of both (e.g. McDowell and Miller [1997] and Despeyroux *et al.* [1996]).

In short, then, there are many possibilities and, in the end, no absolute solutions: the suitability of a particular logical framework to a particular circumstance depends on empirical as well as theoretical issues; i.e. before we can choose we have to decide on the range of object logics we envision formalizing, the nature of the metatheoretic facilities that we want, and the kinds of compromises that we are willing to accept.

GÖRAN SUNDHOLM

PROOF THEORY AND MEANING

Dedicated to Stig Kanger on the occasion of his 60th birthday

The meaning of a sentence determines how the truth of the proposition expressed by the sentence may be proved and hence one would expect proof theory to be influenced by meaning-theoretical considerations. In the present chapter we consider a proposal that also reverses the above priorities and determines meaning in terms of proof. The proposal originates in the criticism that Michael Dummett has voiced against a realist, truth-theoretical, conception of meaning and has been developed largely by him and Dag Prawitz, whose normalisation procedures in technical proof theory constitute the main technical basis of the proposal.

In a subject not more than 20–30 years old, and where much work is currently being done, any survey is bound to be out of date when it appears. Accordingly I have attempted not to give a large amount of technicalities, but rather to present the basic underlying themes and guide the reader to the ever-growing literature. Thus the chapter starts with a general introduction to meaning-theoretical issues and proceeds with a fairly detailed presentation of Dummett's argument against a realist, truth-conditional, meaning theory. The main part of the chapter is devoted to a consideration of the alternative proposal using 'proof-conditions', instead of truth-conditions, as the key concept. Finally, the chapter concludes with an introduction to the type theory of Martin-Löf.

I am indebted to Professors Dummett, Martin-Löf and Prawitz, and to my colleague Mr. Jan Lemmens, for many helpful conversations on the topics covered herein and to the editors for their infinite patience. Dag Prawitz and Albert Visser read parts of the manuscript and suggested many improvements.

1 THEORIES OF MEANING, MEANING THEORIES AND TRUTH THEORIES

A *theory of meaning* gives, one might not unreasonably expect, a general account of, or view on, the very concept of meaning: what it is and how it functions. Such theories *about* meaning, however, do not hold undisputed rights to the *appellation*; in current philosophy of language one frequently encounters discussions of theories of meaning for particular languages. Their task is to specify the meaning of all the sentences of the language in question. Following Peacocke [1981] I shall use the term 'meaning theory' for the latter, language-relative, sort of theory and reserve 'theory of meaning' for

the former. Terminological confusion is, fortunately, not the only connection between meaning theories and theories of meaning. On the contrary, the main reason for the study and attempted construction of meaning theories is that one hopes to find a correct theory of meaning through reflection on the various desiderata and constraints that have to be imposed on a satisfactory meaning theory. The study of meaning theories, so to speak, provides the *data* for the theory of meaning. In the present chapter we shall mainly treat meaning theories and some of their connection with (technical) proof theory and, consequently, we shall only touch on the theory of meaning in passing. (On the other hand the whole chapter can be viewed as a contribution to the theory of meaning.)

There is, since Frege, a large consensus that the sentence, rather than the word, is the primary bearer of (linguistic) meaning. The sentence is the least unit of language that can be used to *say* anything. Thus the theory of meaning directs that sentence-meaning is to be central in meaning theories and that word-meaning is to be introduced derivatively: the meaning of a word is the way in which the word contributes to the meaning of the sentences in which it occurs. It is natural to classify the sentences of a language according to the sort of linguistic act a speaker would perform through an utterance of the sentence in question, be it an assertion, a question or a command. Thus, in general, the meaning of a sentence seems to comprise (at least) two elements, because to know the meaning of — in order to understand an utterance of — the sentence in question one would have to know, first to what category the sentence belongs, i.e. one would have to know what sort of linguistic act that would be performed through an utterance of the sentence, and secondly one would have to know the *content* of the act.

This diversity of sentence-meaning, together with the idea that word-meaning is to be introduced derivatively (as a way of contributing to sentence-meaning), poses a certain problem for the putative meaning-theorist. If sentences from different categories have different *kinds* of meaning, it appears that the meaning of a word will vary according to the category of the sentences in which it occurs: uniform word-meanings are ruled out. But this is unacceptable as anyone familiar with a dictionary knows. The word 'door', say, has the same meaning in the three sentences 'Is the door open?', 'The door is open.', and 'Open the door!'. This *prima facie* difficulty is turned into a tool for investigating what internal structure ought to be imposed on a satisfactory meaning theory.

A meaning theory will have to comprise at least two parts: the *theory of sense* and the *theory of force*. The task of the latter is to identify the sort of act performed through an utterance of a sentence and the former has to specify the content of the acts performed. In order to secure the uniformity of word meaning the theory of sense has to be formulated in terms of some *key concept*, in terms of which the content of all sentences is to be given,

and the theory of force has to provide uniform, general, principles relating speech act to content. The meaning of a word is then taken as the way in which the word contributes to the content of the sentences in which it occurs (as given by the key concept in the theory of sense).

The use of such a notion of key concept also allows the meaning theories to account for certain (iterative) unboundedness-phenomena in language, e.g. that whenever A and B are understood sentences, then also ‘ A and B ’ would appear to be meaningful. This is brought under control in the meaning theory by expressing the condition for the application of the key concept P to ‘ A and B ’ in terms of P applied to A and P applied to B .

The most popular candidate for a key concept has undeniably been *truth*: the content of a sentence is given by its ‘truth-condition’. One can, indeed, find many philosophers who have subscribed to the idea that meaning is to be given in terms of truth. Examples would be Frege, Wittgenstein, Carnap, Quine and Montague. It is doubtful, however, if they would accept that the way in which truth serves to specify meaning is as a key concept in a meaning theory (that is articulated into sense and force components respectively). Such a conception of the relation between meaning and truth has been advocated by Donald Davidson, who, in an important series of papers, starting with [1967], and now conveniently collected in his [1984], has proposed and developed the idea that meaning is to be studied via meaning theories. Davidson is quite explicit on the role of truth. It is going to take its rightful place within the meaning theory in the shape of a truth theory in the sense of Tarski [1956, Ch. VIII]. Tarski showed, for a given formal language L , how to define a predicate ‘ $\text{True}_L(x)$ ’ such that for every sentence S of L it is provable from the definition that

$$(1) \quad \text{True}_L(\bar{S}) \text{ iff } f(S).$$

Here ‘ \bar{S} ’ is a *name* of, and $f(S)$ a *translation* of, the object-language sentence S in the language of the meta-theory (= the theory in which the truth definition is given and where all instances of (1) must hold). *Using* the concept of meaning (in the guise of ‘translation’ from object-language to meta-language) Tarski gave a precise definition of what it is for a sentence of L to be true. Davidson reverses the theoretical priorities. Starting with a *truth theory* for L , that is a theory the language of which contains $\text{True}_L(x)$ as a primitive, and where for each sentence S of L

$$(2) \quad \text{True}_L(\bar{S}) \text{ iff } p.$$

holds for some sentence p of the language of the truth theory, he wanted to extract meaning from truth. Simply to consider an arbitrary truth theory will not do not capture meaning, though. It is certainly true that

$$(3) \quad \overline{\text{Snow is white}} \text{ is true-in-English iff snow is white}$$

but, unquestionably and unfortunately, it is equally true that

(4) $\overline{\text{Snow is white}}$ is true-in-English iff grass is green

and the r.h.s. of (4) could not possibly by any stretch of imagination be said to provide even a rough approximation of the meaning of the English sentence

Snow is white.

Furthermore, a theory that had all instances of (2) as axioms would be unsatisfactory also in that it used infinitely many unrelated axioms; the theory would, it is claimed, be ‘unlearnable’.

Thus one might attempt to improve on the above simple-minded (2) by considering truth theories that are formulated in a meta-language that contains the object-language and that give their ‘*T*-theories’ (the instances of (2)), not as axioms, but as derivable from homophonic recursion clauses, e.g.

(5) for all \bar{A} and \bar{B} of L,
 $\text{True}_L(\overline{\bar{A} \text{ and } \bar{B}} \text{ iff } \text{True}_L(\bar{A} \text{ and } \text{True}_L(\bar{B}))$

and

(6) for all \bar{A} of L,
 $\text{True}_L(\overline{\text{not-}\bar{A}} \text{ iff not-True}_L(\bar{A}))$.

Here one uses the word mentioned in the sentence on the l.h.s. when giving the condition for its truth on the r.h.s.; cf. the above remarks on the iterative unboundedness phenomena.

The treatment of quantification originally used Tarski’s device of ‘satisfaction relative to assignment by sequences’, where, in fact, one does not primarily recur on truth, but on satisfaction, and where truth is defined as satisfaction by all sequences. The problem which Tarski solved by the use of the sequences and the auxiliary notion of satisfaction was how to capture the right truth condition for ‘everything is *A*’ even though the object language does not contain a name for everything to be considered in the relevant domain of quantification. Another satisfactory solution which goes back to Frege, would be to use quantification over finite extensions L^+ of L by means of new names. The interested reader is referred to [Evans, 1977, Section 2] or to [Davies, 1981, Chapter VI] for the (not too difficult) technicalities. A very extensive and careful canvassing of various alternative approaches to quantificational truth-theories is given by Baldwin [1979]. If we bypass the problem solve by Tarski and consider, say, the language of arithmetic, where the problem does not arise as the language contains a numeral for each element of the intended domain of quantification the universal-quantifier clause would be

for all \bar{A} of L,

- (7) $\text{True}_L(\overline{\text{for every number } x, A(x)})$ iff for every numeral \bar{k} ,
 $\text{True}_L(\overline{A(\bar{k}/x)})$.

(here ' $A(\bar{k}/x)$ ' indicates the result of substituting the numeral k for the variable x .)

Unfortunately it is still not enough to consider these homophonic, finitely axiomatised truth theories in order to capture meaning. The basic clauses of a homophonic truth theory will have the form, say,

- (8) for any name \bar{t} of L,
 $\text{True}_L(\overline{t \text{ is red}})$ iff whatever t refers to is red.

If we now change this clause to

- (9) for any \bar{t} in L,
 $\text{True}'_L(\overline{t \text{ is red}})$ iff whatever t refers to is red and grass is green

and keep homophonic clauses for True'_L with respect to 'and' 'not', etc., the result will still be a finitely axiomatised and correct ('true') truth theory for L. We could equally well have chosen any other true contingent sentence instead of 'grass is green'. Seen from the perspective of 'real meaning' the truth condition of the primed theory is best explained as

- (10) $\text{True}'_L(\bar{S})$ iff S and grass is green.

The fact that a true, finitely axiomatised, homophonic truth-theory does not necessarily provide truth conditions that capture meaning was first observed by Foster and Loar in 1976. Various remedies and refinements of the original Davidsonian programme have been explored. We shall briefly consider an influential proposal due to John McDowell [1976; 1977; 1978].

The above attempts to find a meaning theory via truth start with a (true) truth theory and go on to seek further constraints that have to be imposed in order to capture meaning. McDowell, on the other hand, reverses this strategy and starts by considering a satisfactory theory of sense. Such a theory has to give content-ascriptions to the sentences \bar{S} of the language L, say in the general form

- (11) \bar{S} is Q iff p ,

where p is a sentence of the meta-language that gives the content of \bar{S} , and, furthermore, the theory has to interact with a theory of force in such a way that the interpreting descriptions, based on the contents as assigned in (11), do in fact make sense of what speakers say and do when they utter sentences containing \bar{S} . A meaning theory, and thus also its theory

of sense, is part of an overall theory of understanding, the task of which is to make sense of human behaviour (and not just these speech-acts). If the theory of sense can serve as a content-specifying core in such a general theory, then (11) guarantees that the predicate Q is (co-extensional with) truth. But not only that is true; the pathological truth-theories that were manufactured for use in the Foster–Loar counter-examples are ruled out from service as theories of sense because their use would make the meaning theory issue incomprehensible, or outright false, descriptions of what people do. A theory of sense which uses a pathological truth-theory does not make sense. Thus we see that while an adequate theory of sense will be a truth theory, the opposite is false: not every truth theory for a language will be a theory of sense for the language.

In conclusion of the present section let us note the important fact that the Tarski homophonic truth-theories are completely neutral with respect to the underlying logic. The T -theorems are derivable from the basic homophonic recursion clauses using intuitionistic logic only (in fact even minimal logic will do).

No attempt has been made in the present section to achieve either completeness or originality. The very substantial literature on the Davidsonian programme is conveniently surveyed in two texts, [Platts, 1979] and [Davies, 1981], where the latter pays more attention to the (not too difficult) technicalities. Many of the important original papers are included in [Evans and McDowell, 1976], with an illuminating introduction by the editors, and [Platts, 1980], while mention has already been made of [Davidson, 1984]’s collection of essays.

2 INTERMEZZO: CLASSICAL TRUTH AND SEQUENT CALCULI

(Intended for readers of the method ‘semantic tableaux’, cf. Section 6 of Hodges’ chapter or section 3 of Sundholm’s chapter, both in Volume 1 of this *Handbook*.)

It is by now well-known that perhaps the easiest way to prove the completeness of classical predicate logic is to search systematically for a counter-model (or, more precisely, a falsifying ‘semi-valuation’, or ‘model set’) to the formula, or sequent, in question. This systematic search proceeds according to certain rules which are directly read off as necessary conditions from the relevant semantics. For instance, in order to falsify $\forall xA(x) \rightarrow B$, one needs to verify $\forall xA(x)$ and falsify B , and in order to verify $\forall xA(x)$ one has to verify $A(t)$ for every t , etc. Thus the rules for falsification, in fact, also concern rules for verification and *vice versa* (consider verification of, e.g. $\neg B$), and for each logical operator there will be two rules regulating the systematic search for a counter-model, one for verification and one for falsification. These rules turn out to be identical with Gentzen’s [1934–1935] left and

right introduction rules for the same operators. In some cases the search needs to take alternatives into account, e.g. $A \rightarrow B$ is verified by falsifying A or verifying B . Thus one has two possibilities. The failure of the search along a possibility is indicated by that the rules would force one to assign both truth and falsity to one and the same formula. This corresponds, of course, to the axioms of Gentzen's sequent calculi. This method, where failure of existence of counter-models is equivalent to existence of a sequent calculus proof-tree, was discovered independently by Beth, Hintikka, Kanger and Schütte in the 1950s and a brilliant exposition can be found in [Kleene, 1967, Chapter VI], whereas [Smullyan, 1968] is the canonical reference for the various ways of taking the basic insight into account. Prawitz [1975] is a streamlined development of the more technical aspects which provides an illuminating answer to the question as to why the rules that generate counter-models turn out to be identical with the sequent calculus rules. There one also finds a good introduction to the notion of semi-valuation which has begun to play a role in recent investigations into the semantics of natural language (cf. [van Benthem and van Eijck, 1982] for an interesting treatment of the connection between recent work on 'partial structures' in the semantics of natural language and the more proof-theoretical notions that derive from the 'backwards' completeness proofs).

These semantical methods for proving completeness also lend themselves to immediate proof-theoretical applications. The *Cut-free* sequent calculus is complete, but cut is a sound rule. Hence it is derivable. A connection with the topic of our chapter is forged by reversing these proof-theoretic uses of semantical methods. Instead of proving the completeness via semantics, one could start by postulating the completeness of a cut-free formalism, and *read off a semantic* from the left and right introduction rules. (Proof theory determines meaning.) Such an approach was suggested by Hacking [1979] in an attempt towards a criterion for logical constanhood. Unfortunately, his presentation is marred by diverse technical infelicities (cf. [Sundholm, 1981]), and the problem still remains open how to find a workable proposal along these lines.

3 DUMMETT'S ARGUMENT AGAINST A TRUTH-CONDITIONAL VIEW ON MEANING

In the present section I attempt to set out one version of an argument due to Michael Dummett to the effect that truth cannot adequately serve as a key concept in a satisfactory meaning theory. Dummett has presented his argument in many places (cf. the note at the end of the section) and the presentation I offer is not to be attributed to him. In particular, the emphasis on manifestation that can be found in the present version of Dummett's argument I have come to appreciate through the writings of Colin McGinn

[1980] and Crispin Wright [1976]. Dummett's most forceful exposition is still his [1976], which will be referred to as "WTM2".

Dummett's views on the role and function of meaning theories are only in partial agreement with those presented in section 1. The essential difference consists mainly in the strong emphasis on what it is to know a language that can be found in Dummett's writings, and as a consequence his meaning theories are firmly cast in an epistemological mould: "questions about meaning are best interpreted as questions of understanding: a dictum about what the meaning of a sentence consists in must be construed as a thesis about what it is to *know* its meaning" (WTM2, p. 69). The task of the meaning theorist is to give a theoretical (propositional) representation of the complex practical capacity one has when one knows how to speak a language. The knowledge that a speaker will have of the propositions that constitute the theoretical representation in question will, in the end, have to be *implicit* knowledge. Indeed, one cannot demand that a speaker should be able to articulate explicitly; those very principles that constitute the theoretical representation of his practical mastery. Thus a meaning theory that gives such a theoretical representation must also comprise a part that would state what it is to know the other parts implicitly.

The inner structure of a meaning theory that could serve the aims of Dummett will have to be different from the simple bipartite version considered in section 1. Dummett's meaning theories are to be structured as follows. There is to be (ia) a core *theory of semantic value*, which states the condition for the application of the key concept to the sentences of the language, and, furthermore, there must be (ii) a *theory of force*, as before. In between these two, however, there must be (ib) a *theory of sense*, whose task it is to state what it is to know what is stated in the theory of semantic value, i.e. what it is to know the condition for the application of the key concept to a sentence. Thus the theory of sense in the proposals from section 1 does not correspond to the theory of sense_D — 'D' for Dummett — but to the theory of semantic value. (The Fregean origin of Dummett's tripartite structure should be obvious. For further elaboration cf., his [1981].) The theory of sense_D has no matching part in the theories from section 1. The corresponding match is as follows:

<i>Dummett</i>	<i>(Davidson-)McDowell</i>
(ia) Theory of semantic value (applies key concept to sentences)	(i) Theory of sense
(iv) Theory of sense _D (states what it is to know the theory of semantic value)	
(ii) The theory of force	(ii) The theory of force

This difference is what lies at the heart of the matter in the discussion between Dummett and McDowell of whether a theory of meaning ought to be ‘modest’ or ‘fullblooded’ (cf. [McDowell, 1977, Section X]: should one demand that the meaning theory must give a link-up with practical capacities *independently of, and prior to, the theory of force?*

One should also note here that the right home for the theory of sense_D is not quite clear. Here I have made it part of the meaning theory. It could perhaps be argued that a statement of wherein knowledge of meaning consists is something that had better be placed within a theory of meaning rather than in a meaning theory. Dummett himself does not draw the distinction between meaning theories and theories of meaning and one can, it seems to me, find traces of *both* notions in what Dummett calls a ‘theory of meaning’.

Dummett’s argument against the truth-theoretical conception of meaning makes essential use of the assumption that the meaning theories must contain a theory of sense_D, which Dummett explicates in terms of how it can be manifested: since the knowledge is implicit, possession thereof can be construed only in terms of how one manifests that knowledge. Furthermore, this implicit knowledge of meaning, or more precisely, of the condition for applying the key concept to individual sentences, must be *fully* manifested in use. This is Dummett’s transformation of Wittgenstein’s dictum that meaning is use. Two reasons can be offered (cf. [McGinn, 1980, p. 20]). First, knowledge is one of many propositional attitudes and these are, in general, only attributed to agents on the basis of how they are manifested. Secondly, and more importantly, we are concerned with (implicit) knowledge of *meaning* and meaning is, *par excellence*, a vehicle of (linguistic) communication. If there were some components of the implicit knowledge that did not become fully manifest in use, they could not matter for communication and so they would be superfluous.

It was already noted above that the Tarskian truth-theories are completely neutral with respect to the logical properties of truth. What laws are obeyed is determined by the logic that is applied in the meta-theory, whereas the *T*-clauses themselves offer no information on this point. Dummett’s argument is brought to bear not so much against Tarskian truth as against the possibility that the key concept could be ‘recognition-transcendent’. Classical, *bivalent* truth is characterised by the law of bivalence that every sentence is either true or false independently of our capacity to decide, or find out, whichever is the case. Thus, in general, the truth-conditions will be such that they can obtain without us recognising that they do. There are a number of critical cases which produce such undecidable truth-conditions. (It should be noted that ‘undecidable’ is perhaps not the best choice here with its connotations from recursive function theory.) Foremost among these is undoubtedly quantification over infinite or unbounded domains. Fermat’s last theorem and the Reimann hypothesis are both famous examples from

mathematics and their form is purely universal $\forall xA(x)$, with decidable matrix $A(x)$. An existential example would be, say, ‘Somewhere in the universe there is a little green stone-eater’. Other sorts of examples are given by, respectively, counterfactual conditionals and claims about sentience in others, e.g. ‘Ronald Reagan is in pain’. A fourth class is given by statements about (remote) past and future time, e.g. ‘A city will be built here in a thousand years’, or ‘Two seconds before Brutus stabbed Casare thirty-nine geese cackled on the Capitol’.

The knowledge one has of how to apply the key concept cannot in its entirety be statable, explicit knowledge and so the theory of sense_D will have to state, for at least some sentences, how one manifests knowledge of the condition for applying the key concept to them, in ways other than stating what one knows explicitly. Let us call the class of these ‘the non-statable fragment’. (Questions of the ‘division of linguistic labour’ may arise here. Is *the* fragment necessarily unique? Cf. [McGinn, 1980, p. 22].)

Assume now for a *reductio* that bivalent, possibly recognition-transcendent, truth-conditions can serve as key concept in a (Dummettian) meaning theory. Thus the theory of sense_D has to state how one fully manifests knowledge of possibly recognition-transcendent truth-conditions. The ‘possibly’ can be removed: there are sentences in the non-statable fragment with undecidable truth-conditions. In order to see this, remember the four classes of undecidable sentences that were listed above. Demonstrably, undecidable sentences are present in the language and they must be present already in the non-statable fragment, because “the existence of such sentences cannot be due solely to the occurrence of sentences introduced by purely verbal explanations: a language all of whose sentences were decidable would continue to have this property when enriched by expressions so introduced” (WTM2, p. 81). An objection that may be (and has been) raised here is that one could start with a decidable fragment, e.g. the atomic sentences of arithmetic and get the undecidability through addition of new sentence-operators such as quantifiers. That is indeed so, but is not relevant here, where one *starts with a larger language* that, as a matter of fact contains undecidable sentences and then isolates a fragment within this language that also will have this property. Decidable sentences used for definitions could only provide decidable sentences and hence some of the sentences of the full language would be left out. Also it is not permissible to speak of adding, say, the quantifiers as their nature is *sub judice*: the meaning of a quantifier is not something independent of the rest of the language but, like any other word, its meaning is the way it contributes to the meaning of the sentences in which it occurs.

Now the argument is nearly at its end. The theory of sense_D would be *incomplete* in that it could not state what it is to manifest fully implicit knowledge of the recognition-transcendent truth-condition of an undecidable sentence. If the theory attempted to do this, an observational void would

exist without observational warrant. We, as theorists, would be guilty of theoretical slack in our theory, because we could never see the agents manifest their implicit knowledge in response to the truth-conditions obtaining (or not), because *ex hypothesi*, they obtain unrecognisably. The agents, furthermore, could not see them obtain and so, independently of whether or not the theorist can see them response, they cannot manifest their knowledge in response to the truth-condition. (This is a point where the division of linguistic labour may play a role.)

Before we proceed, it might be useful to offer a short schematic summary of Dummett's argument as set out above. (Page references in brackets are to WTM2.)

1. To understand a language is to have knowledge of meaning. (p. 69)
2. Knowledge of meaning must in the end be implicit knowledge. (. 70)
3. Hence the meaning theory must contain a part, call it theory of sense_D, that specifies 'in what having this knowledge consists, i.e. what counts as a manifestation of that knowledge. (pp. 70–71 and p. 127)
4. There are sentences in the language such that the speaker manifests his knowledge of their meaning in ways other than stating the meaning in other words. (The non-statable fragment is non-empty.) (p. 81)
5. Assume now that bivalent truth can serve as key concept. Bivalent truth-conditions are sometimes undecidable and hence recognition-transcendent. (p. 81)
6. Already in the non-statable fragment there must be sentences with recognition-transcendent truth-conditions. (p. 81)
7. Implicit knowledge of recognition-transcendent truth-conditions cannot be manifested, and so the theory of sense_D is incomplete. (p. 82)

Supplementary notes concerning the argument:

- a. Dummett's argument is quite general and does not rest at all on any specific features of the language concerned. When it is applied to a particular area of discourse, or for a particular class of statements, it will lead to a metaphysical anti-realism for the area in question. Many examples of this can be found in Dummett's writings. Thus [1975] and [1977] both develop the argument within the philosophy of mathematics. The intuitionistic criticism of classical reasoning, and the ensuing explanations of the logical constants offered by Heyting, provided the main inspiration for Dummett's work on anti-realism. It should be stressed, however, and as is emphasised by Dummett himself

in [1975], that the semantical argument in favour of a constructivist philosophy of mathematics is very far from Brouwer's own position.

In Dummett [1968–1969] another one of the four critical classes of sentences is studied, viz. those concerning time, and in WTM2, Section 3, a discussion of counterfactual conditionals can be found, as well as a discussion of certain reductionist versions of anti-realism. They arise when the truth of statement A is reduced to the (simultaneous) truth of a certain possibly infinite class of reduction-sentences M_A . If it so happens that the falsity of the conjunction $\bigwedge M_A$ does not entail the truth of the conjunction $\bigwedge M_{\neg A}$, then bivalence will fail for the statement A . Examples of such reductionist versions of anti-realism can be found in phenomenalist reductions of material objects or of sentences in others.

- b. It should be noted that Dummett's anti-realism, while verificationist in nature, must not be conflated with logico-empiricist verificationism. With a lot of simplification the matter can be crudely summarised by noting that for the logical empiricists classical logic was sacrosanct and certain sentences have non-verifiable classical truth-conditions. Hence they have no meaning. Dummett reverses this reasoning: obviously meaningful sentences have no good meaning if meaning is construed truth-conditionally. Hence classical meaning-theories are wrong.
- c. As one should expect, Dummett's anti-realist argument has not been allowed to remain uncontroverted. John McDowell has challenged the demand that the meaning theories should comprise a theory of sense $_D$. In his [1977] and [1978] the criticism is mainly by implication as he is there more concerned with the development of the positive side of his own 'modest' version of a meaning theory, whereas in [1981] he explicitly questions the cogency of Dummett's full-blooded theories. McDowell's [1978a] is an answer to Dummett's [1969], and McDowell in his turn has found a critic in Wright [1980a].

Colin McGinn has been another persistent critic of Dummett's anti-realism and he has launched counter-arguments against most aspects of Dummett's position, cf. e.g. his [1980], [1979] and [1982].

Crispin Wright [1982] challenges Dummett by observing that a Strict Finitist can criticise a Dummettian constructivist in much the same way as a Platonist and so the uniquely privileged position that is claimed for constructivism (as the only viable alternative to classical semantics) is under pressure.

- d. Another sort of criticism is offered by Dag Prawitz [1977, 1978], who, like Wright, is in general sympathy with large parts of Dummett's meaning-theoretical position. Prawitz questions the demand for *full*

manifestation and suggests that the demand for a theory of sense_D be replaced by an *adequacy condition* on meaning theories *T*:

if *T* is to be adequate, it must be possible
to derive in *T* the implication
if *P* knows the meaning of *A*, then *P* shows behaviour *B_A*.
Prawitz [1978, p. 27]

(Here “*B_A*” is a kind of behaviour counted as a sign of grasping the meaning of *A*.)

The difference between this adequacy criterion and the constraints that McDowell imposes on his modest theories is not entirely clear to me. Only if the behaviour is to be shown before, and independently of, the theory of force (whose task it is to issue just the interpreting descriptions that tell what behaviour was exhibited by *P*) could something like a modification of Dummett’s argument be launched and even then it does not seem certain that the desired conclusion can be reached.

- e. In the presentation of Dummett’s argument I have relied solely on WTM2. The anti-realist argument can be found in many places though, e.g. [1973, chapter 14], [1969], [1975] and [1975a] as well as the more recent [1982]. It should be noted that Dummett often cf. e.g., [1969], lays equal or more stress on the acquisition of knowledge rather than its manifestation. Most of the articles mentioned are conveniently reprinted in TE.

Wright [1981], a review of TE, gives a good survey of Dummett’s work. Similarly, in his book [1980] Wright offers extensive discussion of anti-realist themes.

The already mentioned McGinn [1980] and Prawitz [1977], while not in entire agreement with Dummett, both give excellent expositions of the basic issues. It is a virtually impossible task to give a complete survey of the controversy around Dummett’s anti-realist position. In recent years almost every issue of the *Journal of Philosophy*, *Mind* and *Analysis*, as well as the *Proceedings of the Aristotelean Society*, contains material that directly, or indirectly, concerns itself with the Dummettian argument.

4 PROOF AS A KEY CONCEPT IN MEANING THEORIES

As was mentioned above the traditional intuitionistic criticism of classical mathematical reasoning, cf. e.g., van Dalen (see Volume 5 of the second edition of this *Handbook*) was an important source of inspiration for Dummett’s anti-realist argument and it is also to intuitionism that he turns in

his search for an alternative key-concept to be used in the meaning theories in place of the bivalent, recognition-transcendent truth-conditions.

The simplest technical treatment of the truth-conditions approach to semantics is undoubtedly provided by the standard truth-tables (which, of course, are incorporated in the Tarski-treatment for, say, full predicate logic) and it is the corresponding constructive ‘proof-tables’ of Heyting that offer a possibility for Dummett’s positive proposal. Heyting’s explanations of the logical constants, cf. his [1956, Chapter 7] and [1960], can be set out roughly as follows:

A proof of the proposition	is given by
$A \wedge B$	a proof of A and a proof of B
$A \vee B$	a proof of A or a proof of B
$A \rightarrow B$	a method for obtaining proofs of B from proof of A
\perp	nothing
$\forall x \in D A(x)$	a method which for every individual d in D provides a proof of $A(d)$
$\exists x \in D A(x)$	an individual d in D and a proof of $A(d)$.

There are various versions of the above table of explanations, e.g. the one offered by Kreisel [1962], where ‘second clauses’ have been included in the explanations for implication and universal quantification to the effect that one has to include also a proof that the methods really have the properties required in the explanations above. The matter is dealt with at length in [Sundholm, 1983], where an attempt is made to sort out the various issues involved and where extensive bibliographical information can be found, cf. also Section 7 below on the type theory of Martin-Löf.

In the above explanations the meaning of a proposition is given by its ‘proof condition’ and, as was emphatically stressed by Kreisel [1962], in some sense, ‘we recognise a proof when we see one’. Thus it seems that the anti-realistic worries of Dummett can be alleviated with the use of proof as a key concept in meaning theories. (I will return to this question in the next section.) Independently of the desired immunity from anti-realist strictures, however, there are a number of other points that need to be taken into account here.

First among these is a logical gem invented by Prior [1960]. In the Heyting explanations the meaning of a proposition is given by its proof-condition. Conversely, does every proof-condition give a proposition? A positive answer to this question appears desirable, but the notion ‘proof-condition’

needs to be much more elucidated if any headway is to be made here. Prior noted that if by ‘proof-conditions’ one understands ‘rules that regulate deductive practice’ then a negative answer is called for. Let us introduce a proposition-forming operator, or connective ‘*tonk*’ by stipulating that its deductive practice is to be regulated by the following Natural Deduction rules (I here alter Prior’s rules inessentially):

$$\begin{array}{l} \text{tonk } I \quad \frac{A}{A \text{ tonk } B} \quad \frac{B}{A \text{ tonk } B} \\ \\ \text{tonk } E \quad \frac{A \text{ tonk } B}{A} \quad \frac{A \text{ tonk } B}{B} . \end{array}$$

As Prior observes one then readily proves false conclusion from true premises by means of first *tonk I* and then *tonk E*. In fact, given these two rule *any two propositions are logically equivalent* via the following derivation:

$$\frac{\frac{A^1}{A \text{ tonk } B} (\text{tonk } I) \quad \frac{B^2}{A \text{ tonk } B} (\text{tonk } I)}{\frac{B}{A \leftrightarrow B} \quad \frac{A}{1, 2(\leftrightarrow)I}}$$

Thus *tonk* leads to extreme egalitarianism in the underlying logic: from a logical point of view there is only one proposition. This is plainly absurd and something has gone badly wrong. Hence it is clear (and only what could be expected) that some constraints are needed for how the proof-conditions are to be understood; ‘rules regulating deductive practice’ is simply too broad. There is quite a literature dealing with *tonk* and the problems it causes: [Stevenson, 1961; Wagner, 1981; Hart, 1982] and, perhaps most importantly from our point of view, [Belnap, 1962], more about which below. The relevance of the *tonk*-problem for our present interests, was as far as I know, first noted by Dummett [1973, Chapter 13].

A second point to consider is the so-called *paradox of inference*, cf. Cohen and Nagel [1934, pp. 173–176]. This ‘paradox’ arises because of the tension between (a) the fact that the truth of the conclusion is already contained in the truth of the premises, and (b) the fact that logical inference is a way to gain ‘new’ knowledge. Cohen and Nagel formulate it thus:

If in an inference the conclusion is not contained in the premise, it cannot be valid; and if the conclusion is not different from the premise, it is useless; but the conclusion cannot be contained in the premises and also possess novelty; hence inferences cannot be both valid and useful [1934, p. 173]

So there is a tension between the legitimacy (the validity) and the utility of an inference, and one could perhaps reformulate the question posed by the ‘paradox’ as: How can logic function as a useful epistemological tool? For an inference to be legitimate, the process of recognising the premises as true must already have accomplished what is needed for the recognition of the truth of the conclusion, but if it is to be useful the recognition of the truth of the conclusion does not have to be present when the truth of the premises is ascertained. This is how Dummett poses the question in [1975a].

How does one use reasoning to gain new truths? By starting with known premises and drawing further conclusions. In most cases the use of valid inference has very little to do with how one would normally set about to verify the truth of something. For instance, the claim that I have seven coins in my pocket is best established by means of counting them. It would be possible, however, to deduce this fact from a number of diverse premises and some axioms of arithmetic. (The extra premises would be, say that I began the day with a £50 note, and I have then made such and such purchases for such and such sums, receiving such and such notes and coins in return, etc.) This would be a highly *indirect* way in comparison with the straightforward counting process. The utility of logical reasoning lies in that it provides indirect means of learning the truth of statements. Thus in order to account for this usefulness it seems that there must be a gap between the most direct ways of learning the truth and the indirect ways provided by logic. If we now explain meaning in terms of proof, it seems that we close this gap. The direct means, given directly by the meaning, would coincide, so to speak, with the indirect means of reasoning. The indirect means have then been made a part of the direct means of reasoning. (One should here compare the difference between direct and indirect means of recognising the truth with the solution to the ‘paradox’ offered by Cohen and Nagel [1934] that is formulated in terms of a concept called ‘conventional meaning’.)

The constraints we seek on our proof-explanations thus should take into account, on the one hand, that one must not be too liberal as witnessed by *tonk*, and, on the other hand, one must not make the identification between proof and meaning so tight that logic becomes useless.

Already Belnap [1962] noted what was wrong with *tonk* from our point of view. The (new) deductive practice that results from adding *tonk* with its stipulative rules, is not *conservative* over the old one. Using Dummett’s [1975] terminology, there is no *harmony* between the grounds for asserting, and the consequences that may be drawn from, a sentence of the form *A tonk B*. The introduction and elimination rules must, so to speak, match, not just in that each connective has introduction and elimination rules but also in that they must not interfere with the previous practice. Hence it seems natural to let one of the (two classes of) rules serve as meaning-giving and let the other one be chosen in such a way that it(s) members) can be justified according to the meaning-explanation. Such a method of proceeding would

also take care of the ‘paradox’ of inference: one of the two types of rules would now serve as the direct, meaning-given (because meaning-giving!) way of learning the truth and the other would serve to provide the indirect means (in conjunction with other justified rules, of course).

The introduction rules are the natural choice for our purpose, since they are *synthesising* rules; they explain how a proof of, say $A \& B$, can be formed in terms of given proofs of A and of B , and thus some sort of compositionality is present (which is required for a key concept). Tentatively then, the meaning of a sentence is given by what counts as a *direct* (or *canonical*) *proof* of it. Other ways of formulating the same explanation would be to say that the meaning is given by the *direct grounds for asserting*, or by what counts as a *direct verification* of, the sentence in question. An (indirect) proof of a sentence would be a method, or program, for obtaining a direct proof.

In order to see that a sentence is true one does not in general have to produce the direct grounds for asserting it and so the desired gap between truth and truth-as-established-by-the-most-direct-means is open. Note that one could still say that the meaning of a sentence is given by its truth-condition, although the latter, of course, has to be understood in a way different from that of bivalent, and recognition-transcendent, truth: if a sentence is true it is possible to give a proof of it and this in turn can be used to produce a *direct proof*. Thus in order to explain what it is for a sentence to be true one has to explain what a direct proof of the sentence would be and, hence, one has to explain the meaning of the sentence in order to explain its truth-condition.

All of this is highly programmatic and it remains to be seen if, and how, the notion of *direct* (canonical) *proof* (verification, ground for asserting) can be made sense of also outside the confined subject-matter of mathematics. In the next section I shall attempt to spell out the Heyting explanations once again, but now in a modified form that closely links up with the discussion in the present section and with the so-called normalisation theorems in Natural Deduction style proof theory.

5 THE MEANING OF THE LOGICAL CONSTANTS AND THE SOUNDNESS OF PREDICATE LOGIC

In the present section, where knowledge of Natural Deduction rules is presupposed, we reconsider Heyting’s explanations and show that the introduction and elimination rules are sound for the intended meaning.

Thus we assume that A and B are *meaningful sentences*, or *propositions*, and, hence that we know what proofs (and direct proofs) are for them.

The *conjunction* $A \wedge B$ is a proposition, such that a canonical proof of $A \wedge B$ has the form:

$$\frac{\begin{array}{cc} D_1 & D_2 \\ A & B \end{array}}{A \wedge B}$$

where D_1 and D_2 are (not necessarily direct) proofs of A and B , respectively. On the basis of this meaning-explanation of the proposition $A \wedge B$, the rule ($\wedge I$) is seen to be valid. We have to show that whenever the two premises A and B are true then so is $A \wedge B$. When A and B are true, they are so on the basis of proof and hence there can be found two proofs D_1 and D_2 respectively of A and B . These proofs can then be used to obtain a canonical proof of $A \wedge B$, which therefore is true.

Consider the elimination rule ($\wedge E$), say, $\frac{A \wedge B}{B}$, and assume that $A \wedge B$ is true. We have to see that B is true. $A \wedge B$ is true on the basis of a proof D , which by the above meaning-explanation can be used to obtain a canonical proof D_3 of the form specified above. Thus D_2 is a proof of B and thus B is true.

Next we consider the *implication* $A \rightarrow B$, which is a proposition that is true if B is true on the assumption that A is true. Alternatively we may say that a canonical proof of $A \rightarrow B$ has the form

$$\frac{\begin{array}{c} A^1 \\ D \\ B \end{array}}{A \rightarrow B^1}$$

where D is a proof of B using the assumption A . Again, the introduction rule ($\rightarrow I$) is sound, since what has to be shown is that *if* B is true on the hypothesis that A is true, *then* $A \rightarrow B$ is true. But this is directly granted by the meaning explanation above. For the elimination rule we consider

$$\frac{A \rightarrow B \quad A}{B}$$

and suppose that we have proofs D_1 and D_2 of respectively $A \rightarrow B$ and A . As D_1 is a proof it can be used to obtain a canonical proof D_3 and thus we can find a hypothetical proof D of B from A . But then

$$\begin{array}{c} D_2 \\ A \\ D \\ B \end{array}$$

is a proof of B and thus B is true and $(\rightarrow E)$ is a valid rule.

The *disjunction* $A \vee B$ is a proposition, with canonical proofs of the forms

$$\frac{D_1}{A} \quad \text{and} \quad \frac{D_2}{B}$$

$$\frac{}{A \vee B}$$

where D_1 and D_2 are proofs of respectively A and B . The introduction rules are immediately seen to be valid, since they produce canonical proofs of their true premise. For the elimination rule, we assume that $A \vee B$ is true, that C is true on assumption that A is true, and that C is true on assumption that B is true. Thus there are proofs D_1, D_2 and D_3 of, respectively $A \vee B, C$ and C , where the latter two proofs are hypothetical, depending on respectively A and B . The proof D_1 can be used to obtain a canonical proof D_4 of $A \vee \neg B$ in one of the two forms above, say the right, and so D_4 contains a subproof D_5 , that is a proof of B . Then we readily find a proof of C by combining D_5 with the hypothetical D_3 to get a proof of C , which thus is a true proposition.

The *absurdity* \perp is a proposition which has *no* canonical proof. We have to see that the rule $\frac{}{\perp}$ is valid. Thus, we have to see that whenever the proposition \perp is true, then also A is true. But \perp is never true, since a proof of \perp could be used to obtain a *canonical* proof of \perp and by the explanation above there are no direct proofs of \perp .

The *universal quantification* $(\forall x \in M)A(x)$ is a proposition such that its canonical proofs have the form

$$\frac{x \in M^1 \quad D \quad A(x)}{(\forall x \in M)A(x)^1}$$

that is, the proof of D of the premise is a hypothetical, free-variable, proof of $A(x)$ from the assumption that $x \in M$. Again the introduction rule is valid, since if $A(x)$ is true on the hypothesis that $x \in M$, there can be found a hypothetical proof of $A(x)$ from assumption $x \in M$, and thus we immediately obtain a canonical proof of $(\forall x \in M)A(x)$. For the elimination rule $(\forall E)$ consider

$$\frac{(\forall x \in M)A(x) \quad d \in M}{A(d)}$$

and suppose that the premises are true. Thus proofs D_1 and D_2 of, respectively, $(\forall x \in M)A(x)$ and $d \in M$, can be found. As D_1 is a proof it can be

used to obtain a direct proof of its conclusion, and hence we can extract a hypothetical proof of D_3 of $A(x)$ from assumption $x \in M$. Combining D_2 with the free-variable proof D_3 gives a proof

$$\begin{array}{ll} D_2 & ('D_3(d/x)' \text{ indicates the} \\ d \in M & \text{result of substituting} \\ D_3(d/x) & d \text{ for } x \text{ in } D_3.) \\ A(d) & \end{array}$$

of $A(d)$, so the rule $(\forall E)$ is sound.

Finally the *existential quantification* $(\exists x \in M)A(x)$ is a proposition such that its canonical proofs have the $(\exists I)$ form

$$\frac{\begin{array}{ll} D_1 & D_2 \\ A(d) & d \in M \end{array}}{(\exists x \in M)A(x)}$$

Again the introduction rule is immediately seen to be valid as it produces canonical proofs of its conclusion from proofs of the premises. For the elimination rule $(\exists E)$ consider the situation that $(\exists x \in M)A(x)$ is true, and that C is true on the assumptions that x is in M and $A(x)$ is true. Thus there can be found a proof D_3 of $(\exists x \in M)A(x)$ and a hypothetical free-variable proof D_4 of C from hypotheses $x \in M$ and $A(x)$. The proof D_3 can be used to obtain a canonical proof of the form above, and combining the proofs D_1 and D_2 with the hypothetical free-variable proof D_4 we obtain a proof of D :

$$\begin{array}{ll} D_2 & D_1 \\ d \in M & A(d) \\ D_4(d/x) & \\ C & \end{array}$$

Thus the rules of the intuitionistic predicate logic are all valid; no corresponding validation is known for, say, the classical law of Bivalence $A \vee \neg A$ where $\neg A$ is defined as $A \rightarrow \perp$.

The above treatment has been less precise and complete than would be desirable owing to limitations of space. First, questions of syntax have been left out especially where the quantifier rules are concerned, and secondly a whole complex of problems that arises from the fact that we need to know that $A(x)$ is a proposition for any x in M in order to know that, say, $(\forall x \in M)A(x)$ is a proposition has been ignored. The interested reader is referred to the type theory of Martin-Löf [1984] for detailed consideration and careful treatment of (analogues to) these and other lacunae, e.g. how to treat atomic sentences in our presentation.

The above explanations of why the rules of predicate logic are valid all follow the same pattern. The introduction rules are immediately seen to be valid, since canonical proofs are given introductory form. The elimination rules are then seen to be valid by noting that the introduction and elimination rules have the required harmony. The canonical grounds for asserting a sentence do contain sufficient grounds also for the consequences that may be drawn via the elimination rules for the sentence in question. Thus, in fact, we have here made use of the *reduction steps* first isolated and used by Prawitz [1965, 1971], in his proofs of the normalisation theorems for Natural Deduction-style formalisations.

Prawitz has in a long series of papers [1973, 1974, 1975, 1978 and 1980] been concerned to use this technical insight for meaning-theoretical purposes. His main concern, however, has been to give an explication of the notion of valid argument rather than to give direct meaning explanations in terms of proof. In the presentation here, which is inspired by Martin-Löf's meaning-explanations for his type theory, I have been more concerned with the task of giving constructivistic meaning-explanations while relying on the standard explication of validity as preservation of truth for a justification of the standard rules of inference.

One should, however, stop to consider the extent to which the above explanations constitute a meaning theory in the sense of section 1 above. In particular, in section 4 a promise was given to return to the question of decidability. Is it in fact true that the notion of proof is decidable? On our presentation at least this much is true: if we already have a proof it is decidable if it is in canonical form. As to the general question I would be inclined to think that the notion of proof is *semi-decidable*, in that we recognise a proof when we see one, but when we don't see one that does not necessarily mean that there is no proof there. One can compare the situation with understanding a meaningful sentence: we understand a meaningful sentence when we see (or hear!) one but if we don't understand that does not necessarily mean that there is nothing there to be understood. Failure to understand a meaningful sentence seems parallel to failure to follow, or grasp, a proof. Such a position, then, would not make the 'proof-condition' recognition-transcendent; when it obtains it can be seen to obtain, but when it is not seen to obtain no judgement is given (unless, of course it is seen not to obtain). Apart from the question of decidability, an important difference is that in explanations such as the above there is no mention of implicit knowledge and the like. It seems correct to speak of a theoretical representation of a (constructivistic) deductive practice, but it seems less natural to say that these explanations are known to everyone who draws logical inferences.

We used the notion of canonical proof as a key concept in order to provide the explanations, and in the literature one can find a number of alternatives as to how one ought to specify these, cf. the papers by Prawitz listed

above. In particular, one might wish to insist that all parts of a canonical proof should also be canonical (as is the case with the so-called normal derivations obtained by Prawitz in his normalization theorem [1971]). The choice I opted for here was motivated by, first, the success of the meaning-explanations of Martin-Löf in his type theory and, secondly, the fact that in Hallnäs [1983] a successful normalisation of strong set-theoretic systems is carried out using an analogous notion of normal derivation (Tennant's [1982] and his book [1978] are also interesting to the set-theoretically curious; in the former a treatment of the paradoxes is offered along Natural Deduction lines, and the latter contains a neat formulation of the rules of set theory.)

Finally, we should note that the explanations offered here have turned the formal system into an *interpreted formal system* (modulo not inconsiderable imprecision in the formulation of syntax and explanations). This is the main reason for the avoidance of Greek letters in the present Chapter.

6 QUESTIONS OF COMPLETENESS

In section 5 the meaning of the logical constants was explained and the standard deductive practice justified. In the case of classical, bivalent logic we know that the connectives \wedge, \vee and \neg are complete in that any truth-function can be generated from them. Does the corresponding property hold here? Clearly the answer is dependent on how the canonical proofs may be formed. It was shown by Prawitz [1978] and, independently of him, by Zucker and Tragesser [1978] that if we restrict ourselves to purely schematic means for obtaining canonical proofs (and for logical constants this does not seem unreasonable), then an affirmative answer is possible to the above question. As a typical example consider e.g. this Sheffer-stroke (which of course makes sense constructively as well). This is given the introduction rule ($|I$)

$$\frac{\begin{array}{c} A^1 \dots B^2 \\ \vdots \\ \perp \end{array}}{A|B^{1,2}}$$

A definition using \wedge, \rightarrow and \perp is found by putting $A|B =_{\text{def}} A \wedge B \rightarrow \perp$. If there are more premise-derivations in the introduction rule (= the rule for how canonical proofs may be obtained) for each of these one will get an implication of the above sort and they are all joined together by conjunctions. (Here it is presupposed that the rules have only finitely many premises. This does not seem unreasonable.) Finally, if there are more introduction

rules than one, the conjunctions are put together into a disjunction. (Here it is presupposed that there are only finitely many introduction rules. Again this does not seem unreasonable).

Only one case remains, namely that there are no introduction rules. Then there are no canonical proofs to be found and we have got the absurdity. Thus the fragment based on $\rightarrow, \wedge, \vee$ and \perp is complete. For further details refer to the two original papers above as well as Schroeder-Heister [1982]. It should be noted that by Hendry [1981] we know that $A \wedge B$ is equivalent also intuitionistically to $(A \leftrightarrow B) \leftrightarrow (A \vee B)$ and that $A \rightarrow B$ is equivalent to $B \leftrightarrow A \vee B$. Thus also \leftrightarrow, \vee and \perp are complete.

The standard elimination-rules ($\wedge E$) can be replaced by the following rule:

$$\frac{A \wedge B \quad \begin{array}{c} A^1 \dots B^2 \\ \vdots \\ C \end{array}}{C} \quad 1,2$$

which rule seems quite well-motivated by the analogy with the introduction rule $\frac{A \quad B}{A \wedge B}$: everything which can be derived from the two premises A and B used as assumptions can also be derived from $A \wedge B$ alone. The ($\vee E$) rule has exactly this general pattern and the intuitionistic absurdity rule is a degenerate case without minor premise C :

$$\frac{\perp}{C}$$

Only implication does not obey the above pattern. Here the premise of the introduction rule is not just a sentence, but a hypothetical judgement that B is true whenever A is true. Thus, we have a sort of rule as premise: from A go to B , in symbols $A \Rightarrow B$. If we may use such rules as *dischargable* assumptions, one can keep the standard pattern also for implication, viz.

$$\frac{A \rightarrow B \quad \begin{array}{c} A \Rightarrow B^1 \\ \vdots \\ C \end{array}}{C} \quad 1$$

whereas if we try to do the same using implication for the arrow \Rightarrow , we end up with the triviality

$$\frac{A \rightarrow B \quad \begin{array}{c} \vdots \\ C \end{array}}{C} \quad \perp$$

which does not allow us to derive even *modus ponens*.

Using the rule with the higher level assumption $A \Rightarrow B$ one can derive ($\rightarrow E$) as follows:

$$\frac{A \rightarrow B \quad \frac{A}{B} (A \Rightarrow B)^1}{B} \quad \perp$$

Given the use of the rule $A \Rightarrow B$ as an assumption, from premise Q we can proceed to conclusion B , and the use of the major premise $A \rightarrow B$ allows to *discharge the use of the rule* $A \Rightarrow B$.

This type of higher-level assumptions was introduced by Schroeder-Heister [1981] and it is a most interesting innovation in Natural Deduction-formulations of logic, cf. also his [1982] and [1983]. The elimination rule that the Prawitz method gives to the Sheffer-stroke would be

$$\frac{A \wedge B \rightarrow \perp^1 \quad \begin{array}{c} \vdots \\ C \end{array}}{C} \quad \perp$$

which follows the above pattern, but uses implication and conjunction. With the Schroeder-Heister conventions the rule can be given as

$$\frac{(A, B \rightarrow \perp)^1 \quad \begin{array}{c} \vdots \\ C \end{array}}{C} \quad \perp$$

In words, if C is true under the assumptions that we may go from the premise A and B to conclusion \perp , then C is a consequence of $A|B$ alone.

In Schroeder-Heister [1984] an extension of the above results is given and completeness is established also for the predicate calculus language.

The other question of completeness is also considered by Schroeder-Heister [1983]: is every valid inference derivable from the introduction and

elimination rules? This question gets a positive answer, but the concept of validity is extremely restrictive, i.e. the rule $\frac{(A \wedge B) \wedge C}{A}$ is not a valid rule, cf. [1983, p. 374], which (given the concept of validity used in the present paper) it obviously must be. Thus I would consider the problem, first posed by Prawitz [1973], to establish the completeness of the predicate logic, for the present sort of meaning explanations, still to be open.

7 THE TYPE THEORY OF MARTIN-LÖF

Frege [1893], in the course of carrying out his logicist programme, designed a full-scale, completely formal language that was intended to suffice for mathematical practice. By today's standards, an almost unique feature of his attempt to secure a foundation of mathematics is that he uses an *interpreted* formal language for which he provides careful meaning explanations. The language proposed was, as we now know, not wholly successful, owing to the intervention of Russell's paradox. (The effects of the paradox on Frege's explanations of meaning are explored in Aczel [1980] and, from a different perspective, in Thiel [1975] and Martin [1982].) As the formal logic of Frege (and Whitehead–Russell) was transformed gradually into mathematical logic, notably by Tarski and Gödel, interest in the task of giving meaning explanations for interpreted formal languages faded out and after World War II the current distinction between syntax and (Tarskian, model-theoretic) semantics has become firmly entrenched.

The type theory of Martin-Löf [1975, 1982, 1984] represents a remarkable break with this tradition in that it returns to the original Fregean paradigm: interpreted formal language with careful explanations of meaning. Owing to limitations of space I shall not be able to give a detailed, precise description of the system here, (a task for which Martin-Löf [1984] uses close to a hundred ages), but will confine myself to trying to convey the basic flavour of the system.

A possible route to Martin-Löf's theory is through further examination of Heyting's explanations of the meaning of the logical constants. Our tentative semantics in section 5 above made tacit use of a refinement of the explanations: the proof-tables do not give just proofs but *canonical*, or *direct* proofs. A further refinement can be culled from Heyting's own writings. (In Sundholm [1983] a fairly detailed examination of Heyting's writings on this topic is offered.) According to Heyting, in order to prove a theorem one has to carry out certain constructions, 'die gewissen Bedingungen genügen', namely that it produces a mathematical object with certain specified properties, cf. e.g. his remarks on the proposition

"Euler's constant is rational"

in [1931, p. 113]. In Martin-Löf's system, the proof-tables are extended to

contain also the information about the objects that need to be constructed in order to establish the truth of the propositions in question. Thus, taking both refinements into account, the meaning of a proposition is explained by telling what a canonical object for the proposition would be. (A canonical object is not needed in order to assert the proposition; an object (method program) that can be evaluated to canonical form is enough. For more details here, see Martin-Löf [1984].) In fact, according to Martin-Löf, one also has to tell when two such objects are equal. On the other hand, when one defines a set constructively, one has to specify what the canonical elements are and what it is for two elements of the set to be equal elements. Thus, the explanations of what propositions are and of what sets are, are completely analogous and Martin-Löf's system does not differentiate between the two notions.

In ordinary formal theories, that are formulated in the predicate calculus, the derivable objects are *propositions* (or, rather, they are well-formed formulae, i.e. the formalistic counterparts of propositions). This leads to certain difficulties for the standard formulation where logical inference is a relation between proposition. As was already observed by Frege, the correct formulation of *modus ponens* is

$$\frac{A \rightarrow B \text{ is true} \quad A \text{ is true}}{B \text{ is true}};$$

It is simply not correct to say that the proposition B follows from the propositions $A \rightarrow B$ and A . What is correct is that the *truth* of the proposition B follows from the *truth* of $A \rightarrow B$ and the *truth* of A . Thus *the premises and conclusions of logical inferences are not propositions but judgements as to the truth of the propositions*. Furthermore, as Martin-Löf notes, that in order to keep the rules formal, one should also include the information that A and B are propositions in the premises of the rules, e.g.

$$\frac{A \text{ is a prop.} \quad B \text{ is a prop.} \quad A \text{ is true}}{A \vee B \text{ is true}}$$

is how \vee -introduction should be set out. Therefore, as the premises of inferences are judgements, and remembering the identification of propositions and sets, one finds two main sorts of judgements in the theory, namely

$$(a) \quad A \text{ set} \quad ('A \text{ is a set}')$$

and

$$(b) \quad a \in A \quad ('a \text{ is an element of the set } A')$$

(In fact, there are two further forms of judgement, namely ' A is the same set as B ' and ' a and b are equal elements of the set A '.)

In accordance with the above discussion, (a) also does duty for ‘ A is a proposition’ and (b) can also be read as ‘the (proof-)object a is of the right sort for the proposition A , meets the condition specified by the proposition A ’. This reading of (b) is, constructively, a longhand for the judgement ‘(the proposition) A (is) *true*’, which is used whenever it is convenient to suppress the extra information contained in the proof-object. A third reading, deriving from Heyting and Kolmogorov, is possible, where (a) is taken in the sense ‘ A is a *task* (or *problem*)’ and (b) in the sense ‘ a is a method for carrying out the task A (solving the problem A)’. When the task-aspect is emphasised, another reading would be ‘ a is a *program* that meets the *specification* A ’ and the type-theoretical language of Martin-Löf [1982] has, owing to this possibility, had considerable influence as a programming language.

Some feeling for the interaction between propositions and proof-objects may be obtained through consideration of the simple example of *conjunction*. The *proposition* $A \wedge B$ (or *set* $A \times B$) is explained, on the assumption that A and B are propositions, by laying down that a canonical element of $A \times B$ is a pair (a, b) where $a \in A$ and $b \in B$. Thus the \times -introduction rule is correct:

$$\frac{a \in A \quad b \in B}{(a, b) \in A \times B}.$$

Using the shorthand reading, when the proof-objects are left out, we also see that the rule of \wedge -introduction is correct:

$$\frac{A \text{ true} \quad B \text{ true}}{A \wedge B \text{ true}}.$$

For the \wedge -eliminations, we need the use of the *projection-functions* p and q that are associated with the pairing-function. Consider the rule

$$\frac{A \wedge B \text{ true}}{A \text{ true}}.$$

Restoring proof-objects, we see that from an element $c \in A \wedge B$, one has to find an element of A . But c is an element of $A \wedge B$, and so c is equal to (is a method for finding, can be evaluated, or executed, to) a *canonical* element $(a, b) \in A \wedge B$. Applying the projection p , we see that $p(c) = p((a, b)) = a \in A$, so the proper formulation will be

$$\frac{c \in A \wedge B}{p(c) \in A}.$$

It should be mentioned, however, that the conjunction is not a primitive set-formation operation in the language of Martin-Löf. On the contrary, a suitable candidate can be defined from other sets and the appropriate rules derived.

A slightly more complex example is provided by the *universal quantification* $(\forall x \in A)B[x]$ and *implication* $A \rightarrow B$, both of which are treated as variants of the Cartesian product $(\Pi x \in A)B[x]$ of a family of sets. This product may be formed only on the assumption that we have a family of sets over A , that is, provided that $B[x]$ is a set, whenever $x \in A$. Thus the formation rule will take the form

$$\frac{\begin{array}{c} x \in A^1 \\ \vdots \\ A \text{ set } \quad B[x] \text{ set} \end{array}}{(\Pi x \in A)B[x] \text{ set}}.$$

(This serves to illustrate the important circumstance that the basic judgements may depend on assumptions. Better still, we should say that the right premise is a *hypothetical* judgement $B[x]$ set (provided that $x \in A$.) In order to understand the Π -formation rule one needs to know what a canonical element of $(\Pi x \in A)B[x]$ would be; this is told by the Π -introduction rule

$$\frac{\begin{array}{c} x \in A^1 \\ \vdots \\ b[x] \in B[x] \end{array}}{\lambda x.b[x] \in (\Pi x \in A)B[x]}$$

that is, the canonical elements are *functions* $\lambda x b[x]$, such that $b[x] \in B[x]$ provided that $x \in A$. Just as in the case of conjunction, where the elimination rule was taken care of by matching the pairing function with a projection, one will obtain the elimination rule through a similar match between λ -abstraction and function-*application*, *ap*. Thus the rule take the form

$$\frac{f \in (\Pi x \in A)B[x] \quad a \in A}{ap(F, a) \in B[a/x]}.$$

(In order to understand this rule one makes use of an important connection between abstraction and application, namely the law

$$ap(\lambda x.b[x], a) = b[a/x].$$

For the details of the explanation, refer to Martin-Löf [1982] or [1984].)

If the set (proposition) $B[x]$ does not depend on x the product is written as the set of functions B^A (as the proposition $A \rightarrow B$). The rules are obvious, with the exception of \rightarrow -formation:

$$\frac{\begin{array}{c} A \text{ true}^1 \\ \vdots \\ A \text{ prop} \quad B \text{ prop} \end{array}}{A \rightarrow B \text{ prop}}^1.$$

Here the formation rule is stronger than the usual rule (where A and B both have to be propositions) because the right premise is weaker in that B has to be a proposition only when A is true. This concept of implication has been used by Stenlund in an elegant theory of definite descriptions, cf. his [1973] and [1975].

The other quantification is taken care of by means of the *disjoint union* of a family of sets. The Σ -formation rule takes the form

$$\frac{\begin{array}{c} x \in A^1 \\ \vdots \\ A \text{ set} \quad B[x] \text{ set} \end{array}}{(\Sigma x \in A) B[x] \text{ set}}^1.$$

The canonical elements are given by the Σ -introduction rule

$$\frac{a \in A \quad b \in B[a/x]}{(a, b) \in (\Sigma x \in A) B[x]}.$$

On the propositional reading, where the disjoint union is written as the quantifier $(\exists x \in A)B[x]$, we see that in order to establish an existence claim one has to (i) exhibit a suitable witness $a \in A$ and (ii) supply a suitable proof-object b that the witness $a \in A$ does, in fact, satisfy the condition imposed by $B[x]$. The inclusion of the proof-object b allows yet a third use for the disjoint union, namely that of restricted comprehension-terms. What would, on a constructive reading, be meant by ‘an element of the set of x ’s in A such that $B[x]$ ’? At least one would have to include a witness $a \in A$ and information (= a proof-object) establishing that a satisfies the condition $B[x]$. Thus the canonical elements of the restricted comprehension-term $\{x \in A : B[x]\}$ coincide with the canonical elements of the disjoint sum. This representation of ‘such that’ provides the key to the actual development of, say, the theory of real numbers given the set N

of natural numbers. A real number will be an element of N^N such that it obeys a Cauchy-condition.

At this point I will refrain from further development of the language and instead I shall apply the type-theoretic abstractions that have been introduced so far to the notorious ‘donkey-sentence’

(*) Every man who owns a donkey beats it.

The problem here is, of course, that formulations within ordinary predicate logic do not seem to provide any way to capture the back-reference of the pronoun ‘it’. A simple-minded formalisation yields

(**) $\forall x(\text{Man}(x) \wedge \exists y(\text{Donkey}(y) \wedge \text{Own}(x, y)) \rightarrow \text{Beats}(x, ?))$.

There seems to be no way of filling the place indicated by ‘?’, as the donkey has been quantified away by ‘y’.

Using the disjoint-union manner of representation for restricted comprehension-terms one finds that ‘a man who owns a donkey’ is an element of the set

$$\{x \in \text{MAN} : (\exists y \in \text{DONKEY})\text{OWN}[x, y]\}.$$

Such an element, when in canonical form, is a pair (m, b) , where $m \in \text{MAN}$ and b is a proof-object for $(\exists y \in \text{DONKEY})\text{OWN}[m/x, y]$. Thus b , in its turn, when brought to canonical form, will be a pair (d, c) , where d is a **DONKEY** and c a proof-object for $\text{OWN}[m/x, d/y]$. Thus for an element z of the comprehension-term ‘MAN who OWNS a DONKEY’ the left projection $p(z)$ will be a man and the right projection $q(z)$ will be a pair whose left projection $p(q(z))$ will be the witnessing donkey. Putting it all together we get the formulation

(***) $(\forall z \in \{x \in \text{MAN} : (\exists y \in \text{DONKEY})\text{OWN}[x, y]\})\text{BEAT}[p(z), p(q(z))]$.

In this manner, then, the type-theoretic abstractions suffice to solve the problem of the pronominal back-reference in (*). It should be noted here that there is nothing *ad hoc* about the treatment, since all the notions used have been introduced for mathematical reasons in complete independence of the problem posed by (*). On the other hand one should stress that it is not at all clear that one can export the ‘canonical proof-objects’ conception of meaning outside the confined area of constructive mathematics. In particular the treatment of atomic sentences such as ‘OWN[x, y]’ is left intolerably vague in the sketch above and it is an open problem how to remove that vagueness.

Martin-Löf’s type theory has attracted a measure of metamathematical attention. Peter Aczel [1977, 1987, 1980, 1982], in particular, has been a tireless explorer of the possibilities offered by the type theory. Other papers of interest are Diller [1980], Diller and Troelstra [1984] and Beeson [1982].

NOTE ADDED IN PROOF (OCTOBER 1985)

Per Martin-Löf's 'On the meanings of the logical constants and the justifications of the logical laws' in *Atti degli incontri di logica matematica vol. 2*, Scuola di Specializzazione in Logica Matematica, Dipartimento di Matematica, Università di Siena, 1985, pp. 203–281, was not available during the writing of the present chapter. In these lectures, Martin-Löf deals with the topics covered in sections 4–6 above in great detail and carries the philosophical analysis considerably further.

University of Nijmegen, The Netherlands.

GOAL-ORIENTED DEDUCTIONS

1 INTRODUCTION

The topic of this chapter is to present a general methodology for automated deduction inspired by the logic programming paradigm. The methodology can and has been applied to both classical and non-classical logics. It comes without saying that the landscape of non-classical logics applications in computer science and artificial intelligence is now wide and varied, and this Handbook itself is a witness this fact. We will survey the application of goal-directed methods to classical, intuitionistic, modal, and substructural logics. For background information about these logical systems we refer to other chapters of this Handbook and to [Fitting, 1983; Anderson and Belnap, 1975; Anderson *et al.*, 1992; Gabbay, 1981; Troelstra, 1969; Dummett, 2001; Restall, 1999]. Our treatment will be confined to the propositional level.¹

In the area of automated deduction and proof-theory there are several objectives which can be pursued. Methods suitable for one task are not necessarily the best ones for another. Consider propositional classical logic and the following tasks:

1. check if a randomly generated set of clauses is unsatisfiable;
2. given a formula A check whether A is valid;
3. given a set Γ containing say 5,000 formulas and a formula A check whether $\Gamma \vdash A$;
4. (saturation) given a set of formulas Γ generate all atomic propositions which are entailed by Γ ;
5. (abduction) given a formula A and a set of formulas Γ such that $\Gamma \not\vdash A$, find a minimal set of atomic propositions S such that $\Gamma \cup S \vdash A$ and satisfies some other constraints.

It is not difficult to see that all these problems can be reduced one to the other. However, it is quite likely that we need different methods to address each one of them efficiently. Consider task 3: Γ may represent a ‘deductive database’ and A a query. It might be that the formulas of Γ have a simple/uniform structure and only a small subset of the formula of Γ are relevant for getting a proof of A (if any): thus a general general

¹The reader of the chapter of Basin and Matthews on logical frameworks can regard our chapter as a goal directed logical framework done in the *object level*.

SAT-algorithm applied $\Gamma \cup \{\neg A\}$ might not be the most natural method, we would prefer a method capable of concentrating on the relevant data and ignoring the rest of Γ . Similar considerations applies to the other tasks. For instance in the case of abduction, we would likely calculate the set of abductive assumptions S from failed attempts to prove the data A , rather than guess an S arbitrarily and then check if it works. Moreover, in some applications we are not only interested to know whether a formula is valid or not, but also to find (and inspect) a proof of it in an understandable format. The goal-directed approach to deduction is useful to support deduction from large databases, abduction procedures, and proof search.

In a few words, the goal-directed paradigm is the same as the one underlying logic programming. The deduction process can be described as follows: we have a structured collection of formulas (called a database) Δ and a goal formula A , and we want to know whether A follows from Δ or not, in a specific logic. Let us denote by

$$\Delta \vdash^? A$$

the query ‘does A follows from Δ ?’ (in a given logic). The deduction is *goal-directed* in the sense that the next step in a proof is determined by the form of the current goal: the goal is stepwise decomposed, according to its logical structure, until we reach its atomic constituents. An atomic goal q is then matched with the ‘head’ of a formula $G' \rightarrow q$ (if any, otherwise we fail) in the database, and its ‘body’ G' is asked in turn. This step can be understood as a resolution step, or as a generalized Modus Tollens. We will see that we can extend this backward reasoning, goal-directed paradigm to most non-classical logics. We can have a logic programming-like proof system presentation for classical, intuitionistic, modal, and substructural logics.

Here is a plan of the chapter: we start revising Horn classical logic as a motivating example, we then consider intuitionistic logic and full classical logic. Then we consider modal logics and substructural logics.

Notation and basic notions

Formulas

By a propositional language \mathcal{L} , we denote the set of propositional formulas built from a denumerable set Var of propositional variables by applying the propositional connectives $\neg, \wedge, \vee, \rightarrow, \perp$.

Unless stated otherwise, we denote propositional variables (also called *atoms*) by lower case letters, and arbitrary formulas by upper case letters. We assign a *complexity* $cp(A)$ to each formula A (as usual):

$$\begin{aligned} cp(q) &= 0 \text{ if } q \text{ is an atom,} \\ cp(\neg A) &= 1 + cp(A), \\ cp(A * B) &= cp(A) + cp(B) + 1, \text{ where } * \in \{\wedge, \vee, \rightarrow\}. \end{aligned}$$

(*Formula substitution*) We define the notion of substitution of an atom q by a subformula B within a formula A . This operation is denoted by $A[q/B]$.

$$p[q/B] = \begin{cases} p & \text{if } p \neq q \\ B & \text{if } p = q \end{cases}$$

$$(\neg A)[q/B] = \neg A[q/B]$$

$$(A * C)[q/B] = A[q/B] * C[q/B] \text{ where } * \in \{\wedge, \vee, \rightarrow\}.$$

Implicational formulas

In much of the chapter we will be concerned with *implicational formulas*. These formulas are generated from a set of atoms by the only connective \rightarrow . We adopt some specific notations for them. We sometimes distinguish the *head* and the *body* of an implicational formula.² The head of a formula A is its rightmost nested atom, whereas the body is the *list* of the antecedents of its head. Given a formula A , we define $Head(A)$ and $Body(A)$ as follows:

$$\begin{aligned} Head(q) &= q, \text{ if } q \text{ is an atom,} \\ Head(A \rightarrow B) &= Head(B). \end{aligned}$$

$$\begin{aligned} Body(q) &= (), \text{ if } q \text{ is an atom,} \\ Body(A \rightarrow B) &= (A) * Body(B), \end{aligned}$$

where $(A) * Body(B)$ denotes the list beginning with A followed by $Body(B)$.

Dealing with implicational formulas, we assume that implication associates on the right, i.e. we write

$$A_1 \rightarrow A_2 \rightarrow \dots \rightarrow A_{n-1} \rightarrow A_n,$$

instead of

$$A_1 \rightarrow (A_2 \rightarrow \dots \rightarrow (A_{n-1} \rightarrow A_n) \dots).$$

It turns out that every implicational formula A can be written as

$$A_1 \rightarrow A_2 \rightarrow \dots \rightarrow A_n \rightarrow q,$$

where we obviously have.

$$Head(A) = q \quad \text{and} \quad Body(A) = (A_1, \dots, A_n).$$

²This terminology is reminiscent of logic programming [Lloyd, 1984].

2 PROPOSITIONAL HORN DEDUCTION

To explain what we mean by goal-directed deduction style, we begin by recalling standard propositional Horn deductions. This type of deduction is usually interpreted in terms of classical resolution, but it is not the only possible interpretation.³ The data are represented by a set of propositional Horn clauses, which we write as

$$a_1 \wedge \dots \wedge a_n \rightarrow b.$$

(or as $a_1 \rightarrow \dots \rightarrow a_n \rightarrow b$, according to the previous convention). The a_i are just propositional variables and $n \geq 0$. In case $n = 0$, the formula reduces to b . This formula is equivalent to:

$$\neg a_1 \vee \dots \vee \neg a_n \vee b.$$

Let Δ be a set of such formulas, we can give a calculus to derive formulas, called ‘goals’ of the form $b_1 \wedge \dots \wedge b_m$. The rules are:

- $\Delta \vdash^? b$ succeeds if $b \in \Delta$;
- $\Delta \vdash^? A \wedge B$ is reduced to $\Delta \vdash^? A$ and $\Delta \vdash^? B$;
- $\Delta \vdash^? q$ is reduced to
- $\Delta \vdash^? a_1 \wedge \dots \wedge a_n$, if there is a clause in Δ of the form

$$a_1 \wedge \dots \wedge a_n \rightarrow q.$$

The main difference from the traditional logic programming convention is that in the latter conjunction is eliminated and a goal is kept as a sequence of atoms b_1, \dots, b_m . The computation does not split because of conjunction, all the subgoals b_i are kept in parallel, and when some b_i succeeds (that is $b_i \in \Delta$) it is deleted from the sequence. To obtain a real algorithm we should specify in which order we scan the database when we search for a clause whose head matches the goal. Let us see an example.

EXAMPLE 1. Let Δ contain the following clauses

- (1) $a \wedge b \rightarrow g$,
- (2) $t \rightarrow g$,
- (3) $p \wedge q \rightarrow t$,
- (4) $h \rightarrow q$,
- (5) $c \rightarrow d$,
- (6) $c \wedge f \rightarrow a$,
- (7) $d \wedge a \rightarrow b$,
- (8) $a \rightarrow p$,
- (9) $f \wedge t \rightarrow h$,
- (10) c ,
- (11) f .

³For a survey on foundations of logic programming, we refer to [Lloyd, 1984] and to [Gallier, 1987].

A derivation of g from Δ can be displayed in the form of a tree and it is shown in Figure 1. The number in front of every non-leaf node indicates the clause of Δ which is used to reduce the atomic goal in that node.

Figure 1. Derivation of Example 1.

We can make a few observations. First, we do not need to consider the whole database, it might even be infinite, and the derivation would be exactly the same; irrelevant clauses, that is those whose ‘head’ do not match with the current goal are ignored. The derivation is driven by the goal in the sense that each step in the proof simply replaces the current goal with the next one.

Notice also that in this specific case there is no other way to prove the goal, and the sequence of steps is entirely determined.

Two weak points of the method can also be noticed. Suppose that when asking for g we use the second formula, then we continue asking for t , then for h , and then we are lead to ask for t again. We are in a loop. An even simpler situation is the following

$$p \rightarrow p \vdash? p.$$

We can keep on asking for p without realizing that we are in a loop. To deal with this problem we should add a mechanism which ensures termination.

Another problem which has a bearing on the efficiency of the procedure is that a derivation may contain redundant subtrees. This occurs when the same goal is asked several times. In the previous example it happens with the subgoal a . In this case, the global derivation contains multiple subderivations of the same goal. It would be better to be able to remember whether a goal has already been asked (and succeeded) in order to avoid the duplication of its derivation. Whereas the problem of termination is crucial in the evaluation of the method (if we are interested in getting an answer eventually), the problem of redundancy will not be considered in this chapter. However, avoiding the type of redundancy we have described has a

dramatic effect on the efficiency of the procedure, for redundant derivations may grow exponentially with the size of the data.

Although the goal-directed procedure does not necessarily produce the shortest proofs, and does not always terminate, still it has the advantage that proofs, when they exist, are easily found. In the next sections we will see how to extend these type of proof systems to several families of non-classical logics.

3 INTUITIONISTIC AND CLASSICAL LOGICS

3.1 Intuitionistic logic

Intuitionistic logic is the most known alternative to classical logic. For background motivation and information we refer to [Troelstra, 1969; Gabbay, 1981]. The reason why we initiate our tour from intuitionistic logic is *simplicity*. A proof procedure for the propositional implicational fragment of intuitionistic logic is just a minor extension of the Horn case. Moreover, the relation with the semantics, the role of cut, the problems, and the possible refinements are better understood for intuitionistic logic.

We recall a Hilbert style axiomatisation of the intuitionistic propositional calculus and the standard Kripke semantics for it. The axiomatization is obtained by considering the following set of axioms and rules we denote by **I**:⁴

1. $(A \rightarrow B \rightarrow C) \rightarrow (A \rightarrow B) \rightarrow A \rightarrow C$
2. $A \rightarrow B \rightarrow A$
3. $A \rightarrow B \rightarrow (A \wedge B)$
4. $A \wedge B \rightarrow A$
5. $A \wedge B \rightarrow B$
6. $(A \rightarrow C) \rightarrow (B \rightarrow C) \rightarrow (A \vee B \rightarrow C)$
7. $A \rightarrow A \vee B$
8. $A \rightarrow B \vee A$
9. $\perp \rightarrow A$.

In addition, it contains the *Modus Ponens* rule:

$$\frac{\vdash A \quad \vdash A \rightarrow B.}{\vdash B}$$

Negation is considered as a derived operator, by $\neg A \stackrel{def}{=} A \rightarrow \perp$.

Given a set of formulas Δ , we can define A is derivable from Δ , $\Delta \vdash A$ by the axiom systems above in the customary way.

⁴This axiom system is *separated*, that is to say, any theorem containing \rightarrow and a set of connectives $S \subseteq \{\wedge, \vee, \neg, \perp\}$ can be proved by using the implicational axioms together with the axiom groups containing just the connectives in S .

If add to **I** any of the axioms below we get classical logic **C**:

Alternative axioms for classical logic

1. (Peirce's axiom) $((A \rightarrow B) \rightarrow A) \rightarrow A$
2. (double negation) $\neg\neg A \rightarrow A$,
3. (excluded middle) $\neg A \vee A$,
4. (\vee, \rightarrow -distribution) $[(A \rightarrow (B \vee C)) \rightarrow [(A \rightarrow B) \vee C]$.

In particular, the addition of Peirce's axiom to the implicational axioms of intuitionistic logic give us an axiomatisation of classical implication.

We introduce a standard model-theoretic semantics of intuitionistic logic, called Kripke semantics.

DEFINITION 2. Given a propositional language \mathcal{L} , a Kripke model for \mathcal{L} is a structure of the form $M = (W, \leq, V)$, where W is a non-empty set, \leq is a reflexive and transitive relation on W , V is a function of type: $W \rightarrow Pow(Var_{\mathcal{L}})$, that is V maps each element of W to a set of propositional variables of \mathcal{L} . We assume the following conditions:

- (1) $w \leq w'$ implies $V(w) \subseteq V(w')$;
- (2) $\perp \notin V(w)$, for all $w \in W$.

Given $M = (W, \leq, V)$, $w \in W$, for any formula A of \mathcal{L} , we define 'A is true at w in M ', denoted by $M, w \models A$ by the following clauses:

- $M, w \models q$ iff $q \in V(w)$;
- $M, w \models A \wedge B$ iff $M, w \models A$ and $M, w \models B$;
- $M, w \models A \vee B$ iff $M, w \models A$ or $M, w \models B$;
- $M, w \models A \rightarrow B$ iff for all $w' \geq w$, if $M, w' \models A$ then $M, w' \models B$;
- $M, w \models \neg A$ iff for all $w' \geq w$ $M, w' \not\models A$.

We say that A is *valid* in M if $M, w \models A$, for all $w \in W$ and we denote this by $M \models A$. We say that A is *valid* if it is valid in every Kripke model M . We also define a notion of entailment between sets of formulas and formulas. Let $\Gamma = \{A_1, \dots, A_n\}$ be a set of formulas and B be a formula, we say that Γ *entails* B denoted by $\Gamma \models B$ ⁵ iff for every model $M = (W, \leq, V)$, for every $w \in W$

if $M, w \models A_i$ for all $A_i \in \Gamma$, then $M, w \models B$.

⁵To be precise, we should write $\models_{\mathbf{I}}$ (and $\vdash_{\mathbf{I}}$) to denote validity and entailment (respectively, provability and logical consequence) in intuitionistic logic **I**. To avoid burdening the notation, we usually omit the subscript unless there is a risk of confusion.

THEOREM 3. *For any set of formulas Γ and formula B , $\Gamma \vdash B$ iff $\Gamma \models B$. In particular $\vdash_{\mathbf{I}} B$ iff $\models_{\mathbf{I}} B$.*

Classical interpretations can be thought as degenerated Kripke models $M = (W, \leq, V)$, where $W = \{w\}$.

3.2 Rules for intuitionistic implication

We start by presenting a goal-directed system for the implicational fragment of intuitionistic logic. We will then refine it and we will expand it with the other connectives later on. We give rules in this section to prove statements of the form $\Delta \vdash A$, where Δ is a set of implicational formulas and A is an implicational formula. We use the usual conventions and we write Γ, A for $\Gamma \cup \{A\}$ and $\Gamma \cup \Delta$ for $\Gamma \cup \Delta$. Our rules hence manipulate queries Q of the form:

$$\Delta \vdash^? A.$$

We call Δ the database and A the goal of the query Q . We use the symbol $\vdash^?$ to indicate that we do not know whether the query succeeds or not. On the other hand the success of Q means that $\Delta \vdash A$ according to intuitionistic logic.

DEFINITION 4.

- (success) $\Delta \vdash^? q$ succeeds if $q \in \Delta$. We say that q is used in this query.
- (implication) from $\Delta \vdash^? A \rightarrow B$ step to

$$\Delta, A \vdash^? B$$
- (reduction) from $\Delta \vdash^? q$ if $C \in \Delta$, with $C = D_1 \rightarrow D_2 \rightarrow \dots \rightarrow D_n \rightarrow q$ (that is $Head(C) = q$ and $Body(C) = (D_1, \dots, D_n)$) then step to

$$\Delta \vdash^? D_i, \text{ for } i = 1, \dots, n.$$

We say that C is used in this step.

A *derivation* \mathcal{D} of a query Q is a tree whose nodes are queries. The root of \mathcal{D} is Q , and the successors of every non-leaf query are determined by exactly one applicable rule (*implication or reduction*) as described above.

We say that \mathcal{D} is *successful* if the *success rule* may be applied to every leaf of \mathcal{D} . We finally say that a query Q *succeeds* if there is a successful derivation of Q .

By definition, a derivation \mathcal{D} might be an infinite tree. However if \mathcal{D} is successful then it must be finite. This is easily seen from the fact that,

in case of success, the height of \mathcal{D} is finite and every non-terminal node of \mathcal{D} has a finite number of successors, because of the form of the rules. Moreover, the databases involved in a deduction need not be finite. In a successful derivation only a finite number of formulas from the database will be used in the above sense.

Notice that the success of a query is defined in a non-deterministic way: a query succeeds if there is a successful derivation. To transform the proof rules into a deterministic algorithm one should give a method to search a successful derivation tree. In this respect we agree that when we come to an atomic goal we first try to apply the success rule and if it fails we try the reduction rule. Then the only choice we have is to indicate which formula, among those of the database whose head matches the current atomic goal, we use to perform a reduction step, if there are more than one. Thinking of the database as a list of formulas, we can choose the first one and remember the point up to which we have scanned the database as a backtracking point. This is exactly as in conventional logic programming [Lloyd, 1984].

EXAMPLE 5. We check

$$b \rightarrow d, a \rightarrow p, p \rightarrow b, (a \rightarrow b) \rightarrow c \rightarrow a, (p \rightarrow d) \rightarrow c \vdash b.$$

Let $\Gamma = \{b \rightarrow d, a \rightarrow p, p \rightarrow b, (a \rightarrow b) \rightarrow c \rightarrow a, (p \rightarrow d) \rightarrow c\}$, a successful derivation of $\Gamma \vdash^? b$ is shown in Figure 2. A quick explanation: (2) is obtained by reduction wrt. $p \rightarrow b$, (3) by reduction wrt. $a \rightarrow p$, (4) and (8) by reduction wrt. $(a \rightarrow b) \rightarrow c \rightarrow a$, (6) by reduction wrt. $p \rightarrow b$, (7) by reduction wrt. $a \rightarrow p$, (9) by reduction wrt. $(p \rightarrow d) \rightarrow c$, (11) by reduction wrt. $b \rightarrow d$, (12) by reduction wrt. $p \rightarrow b$.

We state some simple, but important, properties of the deduction procedure defined above. The proof of them is left to the reader as an exercise.

PROPOSITION 6.

1. (Identity) $\Delta \vdash^? G$ succeeds if $G \in \Delta$;
2. (Monotony) $\Delta \vdash^? G$ succeeds implies $\Delta, \Gamma \vdash^? G$ succeeds;
3. (Deduction Theorem) $\Delta \vdash^? A \rightarrow B$ succeeds iff $\Delta, A \vdash^? B$ succeeds.

The soundness of the proof procedure with respect to the semantics can be proved easily by induction on the height of the computation.

THEOREM 7. If $\Delta \vdash^? A$ succeeds then $\Delta \models A$.

The completeness can be proved in a number of ways. Here we give a semantic proof with respect to the Kripke semantics. The technique is standard: we define a canonical model and we show that provability by the proof procedure coincides with truth in the canonical model.

Figure 2. Derivation for Example 5.

The canonical model M is defined as follows: $M = (W, \subseteq, \emptyset, V)$, where W is the set of finite databases Δ over \mathcal{L} and the evaluation function V is defined by stipulating

$$V(\Delta) = \{p \text{ atom} : \Delta \vdash^? p \text{ succeeds}\}.$$

By the (Monotony property) it is easy to see that M satisfies the increasingness condition (2) of Definition 2. The important property is expressed by the following proposition.

PROPOSITION 8 (Canonical Model Property). *For any $\Delta \in W$ and formula $A \in \mathcal{L}$, we have:*

$$M, \Delta \models A \text{ iff } \Delta \vdash^? A \text{ succeeds}.$$

Let us attempt a proof of the above proposition, we prove the two directions by a simultaneous induction on the complexity of the formula A . If A is an atom then the claim holds by definition.

Let $A \equiv B \rightarrow C$. Consider first the direction (\Rightarrow), suppose $M, \Delta \models B \rightarrow C$, consider $\Delta' = \Delta, B$. Then $\Delta \subseteq \Delta'$. By (Identity), we have $\Delta' \vdash^? B$ succeeds, by induction hypothesis we get $M, \Delta' \models B$. Thus we get $M, \Delta' \models C$

and by induction hypothesis $\Delta' \vdash^? C$ succeeds. Thus $\Delta, B \vdash^? C$ succeeds. By (Deduction Theorem), we finally get $\Delta \vdash^? B \rightarrow C$ succeeds.

Conversely (\Leftarrow), suppose that $\Delta \vdash^? B \rightarrow C$ succeeds, by (Deduction theorem) we get that $\Delta, B \vdash^? C$ succeeds. Let Γ be such that $\Delta \subseteq \Gamma$ and $M, \Gamma \models B$, we have to show that $M, \Gamma \models C$. By induction hypothesis we have $\Gamma \vdash^? B$ succeeds. We know that

- (1) $\Gamma \vdash^? B$ and (2) $\Delta, B \vdash^? C$ succeed.

We could easily conclude if from (1) and (2), we could infer that (3) $\Delta, \Gamma \vdash^? C$ succeeds: namely, since $\Delta \subseteq \Gamma$, (3) is equivalent to $\Gamma \vdash^? C$ succeeds. Thus by induction hypothesis we would get $M, \Gamma \models C$.

The question is: is it legitimate to conclude (3) from (1) and (2)? The answer is 'yes' and it will be shown hereafter. This property is well-known and is called *Cut*. Thus, given the properties of deduction theorem, identity, the canonical model property can be derived from cut. We may observe that the opposite also holds, i.e. that cut can be derived by the canonical model property. To see this suppose that $\Gamma, B \vdash^? C$ and $\Delta \vdash^? B$ succeeds. We get $\Gamma \vdash^? B \rightarrow C$ succeeds. Thus by the canonical model property we get $M, \Gamma \models B \rightarrow C$ and $M, \Delta \models B$. Since, trivially, $\Delta \subseteq \Gamma \cup \Delta$, by the condition (1) of Definition 2, we have $M, \Gamma \cup \Delta \models B$; so that we obtain $M, \Gamma \cup \Delta \models C$, being $\Gamma \subseteq \Gamma \cup \Delta$. By the canonical model property we can conclude that $\Gamma, \Delta \vdash^? C$ succeeds. The equivalence between the canonical model property and cut has been observed in [Miller, 1992].

The completeness is an immediate consequence of the canonical model property.

THEOREM 9 (Completeness for I). *If $\Delta \models A$, then $\Delta \vdash^? A$ succeeds.*

Proof. If $\Delta \models A$ holds, the entailment holds in particular in the canonical model M . thus for every $\Gamma \in W$ if $M, \Gamma \models B$ for every $B \in \Delta$, we have $M, \Gamma \models A$.

By (identity) we have $\Delta \vdash^? B$ succeeds for every $B \in \Delta$. Thus by the canonical model property $M, \Delta \models B$ for every $B \in \Delta$. We hence obtain $M, \Delta \models A$ and by the canonical model property again $\Delta \vdash^? A$ succeeds. ■

We have still to show that cut is admissible.

THEOREM 10 (Admissibility of Cut). *If $\Delta, A \vdash^? B$ and $\Gamma \vdash^? A$ succeed, then also $\Delta, \Gamma \vdash^? B$ succeeds.*

Proof. Assume (1) $\Delta, A \vdash^? B$ and (2) $\Gamma \vdash^? A$ succeed.

The theorem is proved by induction on lexicographically-ordered pairs (c, h) , where $c = cp(A)$, and h is the height of a successful derivation of (1), that is of $\Delta, A \vdash^? B$. Suppose first $c = 0$, then A is an atom p , and we proceed by induction on h . If $h = 0$, B is an atom q and either $q \in \Delta$ or

$q = p = A$. In the first case, the claim trivially follows by Proposition 6. In the second case it follows by hypothesis (2) and Proposition 6.

Let now $h > 0$, then (1) succeeds either by the implication rule or by the reduction rule. In the first case, we have that $B = C \rightarrow D$ and from $\Delta, A \vdash^? C \rightarrow D$ we step to $\Delta, A, C \vdash^? D$, which succeeds by a derivation h' shorter than h . Since $(0, h') < (0, h)$, by the induction hypothesis we get that $\Delta, \Gamma, C \vdash^? D$, succeeds, whence $\Delta, \Gamma \vdash^? C \rightarrow D$ succeeds too. Let (1) succeed by reduction with respect to a formula $C \in \Delta$. Since A is an atom, $C \neq A$. Then $B = q$ is an atom. We let $C = D_1 \rightarrow \dots \rightarrow D_k \rightarrow q$. We have for $i = 1, \dots, k$

$$\Delta, A \vdash^? D_i \text{ succeeds by a derivation of height } h_i < h.$$

Since $(0, h_i) < (0, h)$, we may apply the induction hypothesis and obtain

$$(a_i) \Delta, \Gamma \vdash^? D_i \text{ succeeds, for } i = 1, \dots, k.$$

Since $C \in \Delta \cup \Gamma$, from $\Delta, \Gamma \vdash^? q$ we can step to (a_i) and succeed. This concludes the case of $(0, h)$.

If c is arbitrary and $h = 0$ the claim is trivial. Let $c > 0$ and $h > 0$. The only difference with the previous cases is when (1) succeeds by reduction with respect to A . Let us see that case. Let

$$A = D_1 \rightarrow \dots \rightarrow D_k \rightarrow q \text{ and } B = q.$$

Then we have for $i = 1, \dots, k$ $\Delta, A \vdash^? D_i$ succeeds by a derivation of height $h_i < h$. Since $(c, h_i) < (c, h)$, we may apply the induction hypothesis and obtain

$$(b_i) \Delta, \Gamma \vdash^? D_i \text{ succeeds for } i = 1, \dots, k.$$

By hypothesis (2) we can conclude that

$$(3) \Gamma, D_1, \dots, D_k \vdash^? q \text{ succeeds by a derivation of arbitrary height } h'.$$

Notice that each D_i has a smaller complexity than A , that is $cp(D_i) = c_i < c$. Thus $(c_1, h') < (c, h)$, and we can cut on (3) and (b_1) , so that we obtain

$$(4) \Delta, \Gamma, D_2, \dots, D_k \vdash^? q \text{ succeeds with some height } h''.$$

Again $(c_2, h'') < (c, h)$, so that we can cut (b_2) and (4). By repeating the same argument up to k we finally obtain

$$\Delta, \Gamma \vdash^? q \text{ succeeds.}$$

This concludes the proof. ■

We have given a semantic proof of the completeness of the proof procedure for the implicational fragment of intuitionistic logic. We have given all details (although they are rather easy) since this easy case works as a paradigm for other logics and richer languages. To summarize, the recipe for the semantic proof is the following: (1) give the right formulation of cut and show that it is admissible, (2) define a canonical model, (3) prove the canonical model property as in Proposition 8 and derive the completeness as in Theorem 9.

There are however other ways to prove the completeness depending on the chosen presentation of the logic. If we have a Hilbert-style axiomatization, we can show that every atomic instance of any axiom succeeds, and then show that the set of succeeding formulas is closed under formula substitution and modus ponens (supposing that these properties hold, which is the case for all the logics considered in this chapter). To prove the closure under MP we need again cut. Another possibility, if we have a presentation of the logic in terms of consequence relation rules, like a sequent calculus, we can show that every rule is admissible.

3.3 Loop-free and bounded resource deduction

In the previous section, we have introduced a goal-directed proof method for intuitionistic implicational logic. This method does not give a decision procedure, as it can easily loop: consider the trivial query

$$q \rightarrow q \vdash^? q$$

this query is reduced to itself by the reduction rule, so that the computation does not stop. There are two different strategies to deal with looping computation and termination.

One possibility is to detect the loop and stop the computation as soon as it is detected. The other possibility is to *prevent* any loop by constraining the use of the formulas. To perform loop-checking we need to consider the sequence of goals *and* the relative database from which they have been asked. A moment of reflection shows that it is enough to record only the atomic goals, since the non-atomic ones will always reduce to the same atomic goals by the implication rule. The other relevant information is the database from which they are asked. The same atomic goal may be asked from different databases and such a repetition does not mean that the computation necessarily loops:

EXAMPLE 11.

$$\begin{array}{rcl} & \vdash^? & ((c \rightarrow a) \rightarrow c) \rightarrow (c \rightarrow a) \rightarrow a \\ (c \rightarrow a) \rightarrow c & \vdash^? & (c \rightarrow a) \rightarrow a \\ (c \rightarrow a) \rightarrow c, c \rightarrow a & \vdash^? & a \end{array}$$

$$\begin{array}{rcl}
(c \rightarrow a) \rightarrow c, c \rightarrow a & \vdash^? & c \\
(c \rightarrow a) \rightarrow c, c \rightarrow a & \vdash^? & c \rightarrow a \\
(c \rightarrow a) \rightarrow c, c \rightarrow a, c & \vdash^? & a \\
(c \rightarrow a) \rightarrow c, c \rightarrow a, c & \vdash^? & c \\
& & \textit{success}
\end{array}$$

As you can see the goal **a** repeats twice along the same (and unique) branch, but the second time is asked from an increased database (c has been added). This does not represent a case of loop; we have a loop when we reask the same (atomic) goal from the same database. To detect the loop we need also to record the involved databases. For each computation branch we could record every pair (*atomic goal-database*) in a history list, so that, before making a reduction step, we check whether the same pair is already in the history list. This loop checking ensures termination. The reason is simple, but important. In the case of intuitionistic logic, the database can be regarded as a *set* of formulas (as we have done) so that adding one or more times the same formula does not matter, i.e. the database does not change. This gives decidability: there cannot be infinitely many different databases occurring in one computation branch (supposing that the initial one is finite) since at most a database can contain all subformulas of the initial query. Thus any loop will be detected.

However, the fact that the database is a *set* of formulas can be used to devise a more efficient loop checking mechanism in which we do not have to record the database itself. The idea is simple: we have a loop whenever we repeats the same goal from the same data. Thus we need to record only the atomic goals which are asked from the same database. Whenever we change the database we clear the history. The database changes (grows) when we add a formula not occurring in it by means of the \rightarrow -rule. This improved loop-checking procedure has been proposed in [Heudering *et al.*, 1996] to the purpose of obtaining a terminating sequent calculus for intuitionistic logic. Let H be the list of past atomic goals. The computation rules are modified as follows:

Rule 1 for \rightarrow
 $\Delta \vdash^? A \rightarrow B, H$ succeeds
if $A \notin \Delta$ and $\Delta, A \vdash^? B, \emptyset$ succeeds.

Rule 2 for \rightarrow
 $\Delta \vdash^? A \rightarrow B, H$ succeeds
if $A \in \Delta$ and $\Delta \vdash^? B, H$ succeeds.

Reduction Rule
 $\Delta \vdash^? q, H$ succeeds
if $q \notin H$ and for some $C_1 \rightarrow \dots \rightarrow C_n \rightarrow q$ in Δ we have that for all i
 $\Delta \vdash^? C_i, H * (q)$ succeeds.

EXAMPLE 12.

$$\begin{array}{rcl}
& \vdash^? & ((p \rightarrow q) \rightarrow q) \rightarrow (q \rightarrow p) \rightarrow p, \emptyset \\
(p \rightarrow q) \rightarrow q & \vdash^? & (q \rightarrow p) \rightarrow p, \emptyset \\
(p \rightarrow q) \rightarrow q, q \rightarrow p & \vdash^? & p, \emptyset \\
(p \rightarrow q) \rightarrow q, q \rightarrow p & \vdash^? & q, (p) \\
(p \rightarrow q) \rightarrow q, q \rightarrow p & \vdash^? & p \rightarrow q, (p, q) \\
(p \rightarrow q) \rightarrow q, q \rightarrow p, p & \vdash^? & q, \emptyset \\
(p \rightarrow q) \rightarrow q, q \rightarrow p & \vdash^? & p \rightarrow q, (q) \\
(p \rightarrow q) \rightarrow q, q \rightarrow p & \vdash^? & q, (q) \\
& & \text{fail}
\end{array}$$

In this way one is able to detect a loop (the same atomic goal repeats from the same database), without having to record each pair (database goal).

As we have remarked at the beginning of this section loop-checking is not the only way to ensure termination. A loop is created because a formula used in one reduction step remains available for further reduction steps. It can be used as many times as we wish.

Let us adopt the point of view that each database formula can be used at most once. Thus our rule for reduction becomes

$$\begin{array}{l}
\text{from } \Delta \vdash^? q, \\
\text{if there is } B \in \Delta, \text{ with } B = C_1 \rightarrow \dots \rightarrow C_n \rightarrow q, \text{ step to} \\
\Delta - \{B\} \vdash^? C_i \text{ for } i = 1, \dots, n.
\end{array}$$

The item B is thus thrown out as soon as it is used.

Let us call such a computation *locally linear computation*, as each formula can be used at most once in each path of the computation. That is why we are using the word ‘locally’. One can also have the notion of (globally) linear computation, in which each formula can be used exactly once in the entire computation tree.

Since we take care of usage of formulas, it is natural to regard multiple copies of the same formula as *distinct*. This means that databases can now be considered as *multisets* of formulas. In order to keep the notation simple, we use the same notation as in the previous section. From now on, Γ, Δ , etc. will range on multisets of formulas, and we will also write Γ, Δ to denote the union multiset of Γ and Δ , that is $\Gamma \sqcup \Delta$. To denote a multiset $[A_1, \dots, A_n]$, if there is no risk of confusion we will simply write A_1, \dots, A_n .

We present three notions of proof: (1) the goal-directed computation for intuitionistic logic, (2) the locally linear goal-directed computation (LL-computation), (3) linear goal-directed computation.

DEFINITION 13. We give the computation rules for a query: $\Gamma \vdash^? G$, where Γ is a multiset of formulas and G is a formula.

- (success) $\Delta \vdash^? q$ immediately succeeds if the following holds:

1. for intuitionistic and LL- computation, $q \in \Delta$,
2. for linear computation $\Delta = q$.

- (implication) From $\Delta \vdash^? A \rightarrow B$, we step to

$$\Delta, A \vdash^? B.$$

- (reduction) If there is a formula $B \in \Delta$ with

$$B = C_1 \rightarrow \dots \rightarrow C_n \rightarrow q$$

then from $\Delta \vdash^? q$, we step, for $i = 1, \dots, n$ to

$$\Delta_i \vdash^? C_i,$$

where the following holds

1. in the case of intuitionistic computation, $\Delta_i = \Delta$;
2. in the case of locally linear computation, $\Delta_i = \Delta - [B]$;
3. in the case of linear computation $\sqcup_i \Delta_i = \Delta - [B]$.

It can be shown that the monotony property holds for the LL-computation whereas it does not for the linear computation. Let \mathbf{Q}_L , \mathbf{Q}_{LL} and \mathbf{Q}_I denote respectively the set of succeeding queries in the linear, in the locally linear, and in the intuitionistic computation, then we have

$$\mathbf{Q}_L \subseteq \mathbf{Q}_{LL} \subseteq \mathbf{Q}_I$$

The examples below shows that these inclusions are proper.

EXAMPLE 14.

1. We reconsider Example 11: $c \rightarrow a, (c \rightarrow a) \rightarrow c \vdash^? a$
The formula $c \rightarrow a$ has to be used twice in order for a to succeed. Thus the query fails in the locally linear computation, but it succeeds in the intuitionistic one. This example can be generalized as follows, let:
2. Let $A_0 = c$
 $A_{n+1} = (A_n \rightarrow a) \rightarrow c$.

Consider the following query:

$$A_n, c \rightarrow a \vdash^? a$$

The formula $c \rightarrow a$ has to be used $n + 1$ times locally.

Figure 3. Derivation for Example 15.

EXAMPLE 15. Let us do the full LL-computation for

$$a \rightarrow b \rightarrow c, a \rightarrow b, a \vdash? c$$

The formula a has to be used twice globally, but not locally on each branch of the computation. Thus the locally linear computation succeeds. On the other hand, in the linear computation case, this query fail, as a must be used globally twice.

The example above shows that the *locally linear* proof system of Definition 13 is not the same as the *linear* proof system. First, we do not require that all assumptions must be used, the condition on the success rule. A more serious difference is that we do our ‘counting’ of how many times a formula is used separately on each path of the computation and not globally for the entire computation. The counting in the linear case is global, as can be seen by the condition in the reduction rule.

Another example, the query $A, A \rightarrow A \rightarrow B \vdash? B$ will succeed in our locally linear computation because A is used once on each of two parallel paths. It will not be accepted in the linear computation because A is used globally twice. This is ensured by the condition in the reduction rule.

Linear computation as defined in Definition 13 corresponds to linear logic implication, [Girard, 1987], in the sense that the procedure of linear computation is sound and complete for the implicational fragment of linear logic. This will be shown in Section 5 within the broader context of substructural logics.

The above examples show that we do not have completeness with respect to intuitionistic provability for locally linear computations. Still, the locally linear computation is attractive, because if the database is finite it is always terminating. We shall see in the next section how we can compensate for the use of the locally linear rule (i.e. for throwing out the data) by some other means. However even if the locally linear computation is not complete for the full intuitionistic implicational fragment, one may still wonder whether it works in some particular and significant case. A significant (and well-known) case is shown in the next proposition.

We recall that a formula A is *Horn* if it is an atom, or has the form $p_1 \rightarrow \dots \rightarrow p_n \rightarrow q$, where all p_i and q are atoms.

PROPOSITION 16. *The locally-linear procedure is complete for Horn formulas.*

3.4 Bounded restart rule for intuitionistic logic

We have seen that the locally linear restriction does not retain completeness with respect to intuitionistic provability, as there are examples where formulas need to be used locally several times. We show that we can retain completeness for intuitionistic logic by adding another computation rule. The new rule is called the *bounded restart rule*.

Let us examine more closely why we needed in Example 11 the formula $c \rightarrow a$ several times. The reason was that from other formulas, we got the goal $\vdash^? a$ and we wanted to use $c \rightarrow a$ to continue to the goal $\vdash^? c$. The formula $c \rightarrow a$ was no longer available because it had already been used. In other words, $\vdash^? a$ had already been asked and $c \rightarrow a$ was used. This means that the next goal after $\vdash^? a$ in the history was $\vdash^? c$.

If H is the history of the atomic goals asked, then somewhere in H there is $\vdash^? a$ and immediately afterwards $\vdash^? c$.

We can therefore compensate for the reuse of $c \rightarrow a$ by allowing ourselves to go back in the history to where $\vdash^? a$ was, and allow ourselves to ask all atomic goals that come afterwards. We call this type of move *bounded restart*.

The previous example suggests the following new computation with bounded restart rule.

DEFINITION 17. [Locally linear computation with bounded restart] In the computation with bounded restart, the queries have the form $\Delta \vdash^? G, H$, where Δ is a multiset of formulas and the history H is a sequence of atomic goals. The rules are as follows:

- (success) $\Delta \vdash^? q, H$ succeeds if $q \in \Delta$;
- (implication) from $\Delta \vdash^? A \rightarrow B, H$ step to $\Delta, A \vdash^? B, H$;
- (reduction) from $\Delta \vdash^? q, H$ if $C = D_1 \rightarrow D_2 \rightarrow \dots \rightarrow D_n \rightarrow q \in \Delta$, then we step to

$$\Delta - [C] \vdash^? D_i, H * (q) \text{ for } i = 1, \dots, n;$$

- (bounded restart) from $\Delta \vdash^? q, H$ step to

$$\Delta \vdash^? q_1, H * (q),$$

provided for some H_1, H_2, H_3 , it holds $H = H_1 * (q) * H_2 * (q_1) * H_3$, where each H_i may be empty.

EXAMPLE 18.

$$\begin{array}{rcl}
& & \vdash^? \quad ((c \rightarrow a) \rightarrow c) \rightarrow (c \rightarrow a) \rightarrow a, \emptyset \\
(c \rightarrow a) \rightarrow c & \vdash^? & (c \rightarrow a) \rightarrow a, \emptyset \\
(c \rightarrow a) \rightarrow c, c \rightarrow a & \vdash^? & a, \emptyset \\
(c \rightarrow a) \rightarrow c & \vdash^? & c, (a) \\
& \vdash^? & c \rightarrow a, (a, c) \\
c & \vdash^? & a, (a, c) \\
c & \vdash^? & c, (a, c) \\
& & \text{success}
\end{array}$$

The last step is by bounded restart, it is legal since c follows a in the history.

The locally linear computation with bounded restart is sound and complete for intuitionistic logic. However, before stating the theorem, we want to remark about the meaning of the atoms in the history. To make the things easy, let the query be $\Delta \vdash^? G, (p)$ and G be atomic. Suppose in addition that the query succeeds by a reduction step. Then G will be added to the history list just after p . Let the next goal be p , so that we can apply the bounded restart rule to the query $\Delta \vdash^? p, (p, G)$. The bounded restart step could be performed by reduction if we had the formula $G \rightarrow p$ in the database. Thus the original query is equivalent to the query $\Delta, G \rightarrow p \vdash^? G$. The general correspondence is expressed in the next theorem.

THEOREM 19 (Soundness and completeness of locally linear computation with bounded restart). *For the computation of Definition 17 we have:*
 $\Delta \vdash^? G, (p_1, \dots, p_n)$ succeeds iff $\Delta, G \rightarrow p_n, p_n \rightarrow p_{n-1}, \dots, p_2 \rightarrow p_1 \vdash G$ in intuitionistic logic.

3.5 Restart rule for classical logic

It is interesting to note that by adopting a variation of the bounded restart rule we can obtain a proof procedure for implicational classical logic. The variation is obtained by cancelling any restrictions and simply allowing us to ask any earlier atomic goal. We need not keep the history as a sequence, but only as a *set* of atomic goals. The rule becomes

DEFINITION 20 (Restart rule in the LL-computation). If $a \in H$, from $\Delta \vdash^? q, H$ step to $\Delta \vdash^? a, H \cup \{q\}$.

The formal definition of *locally linear computation with restart* is Definition 17 with the additional restart rule above in place of the bounded restart rule.

EXAMPLE 21.

$$\begin{array}{l}
\vdash^? \quad (a \rightarrow b) \rightarrow a \vdash^? a, \emptyset \\
\vdash^? \quad \vdash^? a \rightarrow b, \{a\} \\
a \vdash^? \quad a \vdash^? b, \{a\} \\
a \vdash^? \quad a, \{a, b\} \text{ by restart} \\
\text{success.}
\end{array}$$

The above query fails in the intuitionistic computation. Thus, this example shows that we are getting a logic which is stronger than intuitionistic logic. Namely, we are getting classical logic. This claim has to be properly proved, of course.

If we adopt the basic computation procedure for intuitionistic implication of Definition 4 rather than the LL-computation, we can restrict the restart rule to always choose the *initial goal* as the goal with which we restart. Thus, we do not need to keep the history, but only the initial goal and the rule becomes more deterministic. On the other hand, the price we pay is that we cannot throw out the formulas of database when they are used.

DEFINITION 22 (Simple computation with restart). The queries have the form

$$\Delta \vdash^? G, (G_0),$$

where G_0 is a goal. The computation rules are the same as in the basic computation procedure for intuitionistic implication of Definition 4 plus the following rule

$$\text{(Restart) from } \Delta \vdash^? q, (G_0) \text{ step to } \Delta \vdash^? G_0, (G_0).$$

It is clear that the initial query of any derivation will have the form $\Gamma \vdash^? A, (A)$.

Given the underlying computation procedure of Definition 4, restarting from an arbitrary atomic goal in the history is equivalent to restart from the initial goal. This is expressed formally in the next proposition, where we let $\vdash_{RI}^?$ and $\vdash_{RA}^?$ be respectively the deduction procedure of Definition 22 and the deduction procedure of Definition 4 extended by the restart rule of Definition 20.

PROPOSITION 23. *For any database Δ and formula G , we have*

$$(1) \Delta \vdash_{RA}^? G, \emptyset \text{ succeeds iff } (2) \Delta \vdash_{RI}^? G, (G) \text{ succeeds.}$$

We show that the proof-procedure obtained by adding the rule of restart from the initial goal to the basic procedure for intuitionistic logic defined in Definition 4 is sound and complete with respect to classical provability.

The idea is to replace the effect of restart from the initial goal by adding a suitable set of formulas which depends on the initial goal. This set of formulas can be seen as representing the negation (or complement) of the goal.

DEFINITION 24. Let A be any formula. The complement of A , denoted by $Cop(A)$ is the following set of formulas:

$$Cop(A) = \{A \rightarrow p \mid p \text{ any atom of the language}\}$$

The set $Cop(A)$ represents the negation of A in our implicational language which does not contain neither \neg , nor \perp .

The crucial, although easy, fact is that we can replace any application of the restart rule by a reduction step using a formula in $Cop(A)$.

LEMMA 25. (1) $\Gamma \vdash^? A$ succeeds by using restart rule iff (2) $\Gamma \cup Cop(A) \vdash^? A$ succeeds without using restart, that is by the intuitionistic procedure of Definition 4.

Now we only have to show that $\Delta \vdash A$ in classical logic iff $\Delta \cup Cop(A) \vdash^? A$ succeeds by the procedure defined in Definition 4. To this purpose we need the following lemma, which shows that $Cop(A)$ works as the negation of A .

LEMMA 26. For any database Δ and formulas G such that $\Delta \supseteq Cop(G)$, and for any goal A , we have if $\Delta \cup \{A\} \vdash^? G$ and $\Delta \cup Cop(A) \vdash^? G$ succeed then also $\Delta \vdash^? G$ succeeds.

THEOREM 27. For any Δ and A , (a) is equivalent to (b) below:

(a) $\Delta \vdash A$ in classical logic,

(b) $\Delta \cup Cop(A) \vdash^? A$ succeeds by the intuitionistic procedure defined in Definition 4.

Proof. (\Leftarrow) Show (b) implies (a).

Assume $\Delta \cup Cop(A) \vdash^? A$ succeeds. Then by the soundness of the computation procedure we get that $\Delta \cup Cop(A) \vdash A$ in intuitionistic logic, and hence in classical logic. Since the *proof* is *finite* there is a finite set of the form $\{A \rightarrow p_1, \dots, A \rightarrow p_n\}$ such that

(a1) $\Delta, A \rightarrow p_1, \dots, A \rightarrow p_n \vdash A$ (in intuitionistic logic).

We must also have that $\Delta \vdash A$, in classical logic, because if there were an assignment h making Δ true and A false, it would also make $A \rightarrow p_i$ all true, contradicting (a1).

The above concludes the proof that (b) implies (a).

(\Rightarrow) Show that (a) implies (b).

We prove that if $\Delta \cup Cop(A) \vdash^? A$ does not succeed then $\Delta \not\vdash A$ in classical logic. Let $\Delta_0 = \Delta \cup Cop(A)$. We define a sequence of databases $\Delta_n, n = 1, 2 \dots$ as follows:

Let B_1, B_2, B_3, \dots be an enumeration of all formulas of the language.

Assume Δ_{n-1} has been defined and assume that $\Delta_{n-1} \vdash^? A$ does not succeed. We define Δ_n :

If $\Delta_{n-1} \cup \{B_n\} \vdash^? A$ does not succeed, let $\Delta_n = \Delta_{n-1} \cup \{B_n\}$. Otherwise from Lemma 26 we must have:

$\Delta_{n-1} \cup Cop(B_n) \vdash^? A$ does not succeed.

and so let $\Delta_n = \Delta_{n-1} \cup Cop(B_n)$.

Finally, let $\Delta' = \bigcup_n \Delta_n$

Clearly $\Delta' \vdash^? A$ does not succeed.

Define an assignment of truth values h on the atoms of the language by $h(p) = \mathbf{true}$ iff $\Delta' \vdash^? p$ succeeds. We now prove that

for any $B, h(B) = \mathbf{true}$ iff $\Delta' \vdash^? B$ succeeds,

by induction on B . For atoms this is the definition.

Let $B = C \rightarrow D$. We prove the two directions by simultaneous induction.

Suppose $\Delta' \vdash^? C \rightarrow D$ succeeds. If $h(C) = \mathbf{false}$, then $h(C \rightarrow D) = \mathbf{true}$ and we are done. Thus, assume $h(C) = \mathbf{true}$. By the induction hypothesis, it follows that $\Delta' \vdash^? C$ succeeds. Since, by hypothesis we have that $\Delta', C \vdash^? D$ succeeds, by cut we obtain that $\Delta' \vdash^? D$ succeeds, and hence by the induction hypothesis $h(D) = \mathbf{true}$.

Conversely, if $\Delta' \vdash^? C \rightarrow D$ does not succeed, we show that $h(C \rightarrow D) = \mathbf{false}$. Let $Head(D) = q$, we get

- (1) $\Delta' \vdash^? D$ does not succeed
- (2) $\Delta', C \vdash^? q$ does not succeed.

Hence by the induction hypothesis on (1) we have $h(D) = \mathbf{false}$. We show that $\Delta' \vdash^? C$ must succeed. Suppose on the contrary that $\Delta' \vdash^? C$ does not succeed. Hence $C \notin \Delta'$. Let $B_n = C$ in the given enumeration. Since $B_n \notin \Delta_n$, by construction, it must be $Cop(C) \subseteq \Delta'$. In particular $C \rightarrow q \in \Delta'$, and hence $\Delta', C \vdash^? q$ succeeds, against (2).

We have shown that $\Delta' \vdash^? C$ succeeds, whence $h(C) = \mathbf{true}$, by the induction hypothesis. Since $h(C) = \mathbf{false}$, we obtain $h(C \rightarrow D) = \mathbf{false}$.

We can now complete the proof. Since $\Delta' \vdash^? A$ does not succeed, we get $h(A) = \mathbf{false}$. On the other hand, for any $B \in \Delta \cup Cop(A)$, $h(B) = \mathbf{true}$ (since $\Delta \cup Cop(A) \subseteq \Delta'$) and $h(A) = \mathbf{false}$. This means that $\Delta \cup Cop(A) \not\vdash A$ in classical logic. This complete the proof. \blacksquare

From the above theorem and Lemma 25 we immediately obtain the completeness of the proof procedure with restart from the initial goal.

THEOREM 28. $\Delta \vdash A$ in classical logic iff $\Delta \vdash^? A, (A)$ succeeds using the restart rule from the initial goal, added to the procedure of Definition 4.

Also the locally linear computation of Definition 17 with the restart rule from any previous goal is sound and complete. A proof is contained in [Gabbay and Olivetti, 2000].

THEOREM 29. [Soundness and completeness of locally linear computation with restart]

$\Delta \vdash^? G, H$ succeeds iff $\Delta \vdash G \vee \bigvee H$ in classical logic.

Observe that we cannot restrict the application of restart to the first atomic goal occurring in the computation, consider:

$$(p \rightarrow q) \rightarrow p, p \rightarrow r \vdash^? r, \emptyset,$$

it succeeds by the following computation:

$$\begin{array}{l} (p \rightarrow q) \rightarrow p, p \rightarrow r \vdash^? r, \emptyset, \\ (p \rightarrow q) \rightarrow p \vdash^? p, \{r\}, \\ \vdash^? p \rightarrow q, \{r, p\}, \\ p \vdash^? q, \{r, p\}, \\ p \vdash^? p, \{r, p\}, \text{ restart from } p. \end{array}$$

However restarting from r , the first atomic goal would not help.

3.6 Termination and complexity

The proof systems based on locally linear computation are a good starting point for designing efficient automated-deduction procedures; on the one hand proof search is guided by the goal, on the other hand derivations have a smaller size since a formula that has to be reused does not create further branching. We now want to remark upon termination of the procedures.

The basic LL- procedure obviously terminates: since formulas are thrown out as soon as they are used in a reduction step, every branch of a given derivation eventually ends with a query which either immediately succeeds, or no further reduction step is possible from it. This was the motivation of the LL-procedure as an alternative to a loop-checking mechanism. Does the (bounded) restart rule preserve this property? As we have stated, it does not, in the sense that a silly kind of loop may be created by restart. Let us consider the following example, here we give the computation for intuitionistic logic, but the example works for the classical case as well:

$$\begin{array}{l}
a \rightarrow b, b \rightarrow a \quad \vdash^? \quad a, \emptyset \\
a \rightarrow b \quad \vdash^? \quad b, (a) \\
\quad \vdash^? \quad a, (a, b) \\
\quad \vdash^? \quad b, (a, b, a) \\
\quad \vdash^? \quad a, (a, b, a, b) \\
\quad \vdots
\end{array}$$

This is a loop created by restart. It is clear that continuing the derivation by restart does not help, as none of the new atomic goals match the head of any formula in the database.

In the case of classical logic, we can modify the restart rules as follows.

$$\begin{array}{l}
\text{From } \Delta \vdash^? q, H \quad \text{step to } \Delta \vdash^? q_1, H \cup \{q\}, \\
\text{provided there exists a formula } C \in \Delta, \text{ with } q_1 = \text{Head}(C), \\
\text{and } q \in H.
\end{array}$$

It is obvious that this restriction preserves completeness.

In the case of intuitionistic logic, the situation is slightly more complex. The atom with which we finally restart must match the head of some formula of the database in order to make any progress. But this atom might only be reachable through a sequence of restart steps which goes further and further back in the history. To handle this situation, we require that the atom chosen for restart matches some head, but we ‘collapse’ several restart steps into a single one. In other words, we allow restart from a previous goal q which is accessible from the current one through a sequence of bounded restart steps.

Given a history $H = (q_1, q_2, \dots, q_n)$ we define an auxiliary binary relation on atomic formulas $q \leq_H q'$ as follows:

1. either q coincides with q' , or
2. q precedes q' in the list H ,
3. or for some q'' one has $q \leq_H q''$ and $q'' \leq_H q'$.

(In other words, $q \leq_H q'$ iff q' is reachable from q by the reflexive-transitive closure of the binary precedence relation generated by the list H . The modified bounded restart rule for intuitionistic logic becomes: from

$$\Delta \vdash^? q, H,$$

step to

$\Delta \vdash^? q', H * (q)$, provided

1. there exists a formula $C \in \Delta$, with $q' = \text{Head}(C)$, $q' \neq q$ and
2. $q \leq_H q'$ holds.

It is easy to see that the above rule ensures the termination of the procedure preserving its completeness.

Moreover we can reformulate the rules for success and reduction by building the bounded restart rule into them, to this purpose we simply restate:

1. (br-success) $\Gamma \vdash^? q, H$ succeeds if there exists q' such that $q \leq_H q'$ and $q' \in \Gamma$;
2. (br-reduction) From $\Gamma, C_1 \rightarrow \dots \rightarrow C_n \rightarrow q' \vdash^? q, H$ if $q \leq_H q'$ steps for $i = 1, \dots, n$ to $\Gamma \vdash^? C_i, H * (q)$.

The proof procedure can be further refined to match the known complexity bound for intuitionistic logic, namely $O(n \log n)$ space. Observe that the history list may be kept linear in the length of the database+goal: only the leftmost and the rightmost occurrence of any atom in H are needed for determining \leq_H . Thus the history length is bounded by $2 * k$ where k is the number of atoms occurring in the initial query. The length of each derivation branch is bounded by the length of the initial query and so is the length of each intermediate query. In searching a proof of a given query, we first apply the implication rule if the goal is an implication; if the goal is atomic we try first (br-success) and if it is not applicable we try (br-reduction).

The proof search space can be then described as a tree that contains AND branchings, corresponding to the (br-reduction steps) with multiple subgoals, and OR branchings corresponding to backtracking points, determined by alternative formulas which can be used in the (br-reduction) steps. The latter are branchings in the proof search space, not in the derivation tree. We assume that subgoals are examined and alternatives are scanned in a fixed manner (for instance from left to right).

To achieve a good space complexity bound, we do not store the whole derivation, we rather perform the proof search in a depth first manner expanding one query at a time. We only store one query at a time, the one which is going to be expanded by the rules. Moreover we keep a copy of the initial query. In addition we use a stack to keep track of the AND branchings and backtracking points, if any. We will not enter into the details of how to store the relevant information in the stack entries, it is described in [Gabbay *et al.*, 1999]. We only observe that: (1) since we can index formulas and subformulas of the initial query, each stack entry will not require more than $O(\log n)$ bits, being n is the length of the initial query. (2) we have a stack entry for each query occurring along a derivation branch. Thus the depth of the stack is bounded by n the length of the initial query. In the whole, an

algorithm to search a derivation will not need more than $O(n \log n)$ space, where n is the length of the initial query. This matches the known optimal upper-bound for intuitionistic logic.

THEOREM 30. *The procedure with bounded restart gives an $O(n \log n)$ -space decision procedure for the implicational fragment of intuitionistic logic.*

The proof procedure based on bounded restart is almost deterministic except for one crucial point: the choice of the database formula to use in a reduction step. Here a sharp difference between classical and intuitionistic logic arises. In intuitionistic logic, the choice is critical: we could make the wrong choice and then have to backtrack to try an alternative formula. In the case of classical logic, backtracking is not necessary, that is, it does not matter which formula we choose to match an atomic goal in a reduction step.

LEMMA 31. *Let*

$$A = A_1 \rightarrow \dots \rightarrow A_n \rightarrow q \text{ and } B = B_1 \rightarrow \dots \rightarrow B_m \rightarrow q.$$

Then (a) is equivalent to (b):

$$(a) \Delta, A \vdash^? B_i, H \cup \{q\} \text{ succeeds for } i = 1, \dots, m;$$

$$(b) \Delta, B \vdash^? A_i, H \cup \{q\} \text{ succeeds for } i = 1, \dots, n.$$

By the previous lemma we immediately have.

PROPOSITION 32. *In any computation of $\Delta \vdash^? q, H$ with restart, no backtracking is necessary. The atom q can match with the head of any $A_1 \rightarrow \dots \rightarrow A_n \rightarrow q \in \Delta$ and success or failure does not depend on the choice of such a formula.*

The parallel property to Lemma 31, Proposition 32 clearly does not hold for the intuitionistic case. This difference gives an intuitive account of the difference of complexity between the intuitionistic and the classical case.⁶

3.7 Extending the language

Conjunction and negation

In this and the next section we extend the language to the full propositional language. We start by considering conjunction. The addition of conjunction to the propositional language does not change the proof system much. Every formula A with conjunctions is equivalent in intuitionistic logic to a conjunction of formulas $\bigwedge_i A_i$, where A_i contain no conjunctions. If we

⁶We recall that intuitionistic provability is PSPACE-complete [Statman, 1979], whereas classical provability is CoNP-complete, although the space requirements are the same.

agree to represent a conjunction of formulas as a *set*, the handling of conjunction is straightforward, we can transform every database and goal into sets of formulas without conjunction. Then we extend the proof procedure to sets of goals S :

From $\Delta \vdash^? S$ step to $\Delta \vdash^? A$ for every $A \in S$.

The computation rule for conjunction can be stated directly:

$\Delta \vdash^? A \wedge B$ succeeds iff $\Delta \vdash^? A$ succeeds and $\Delta \vdash^? B$ succeeds.

We now turn to *negation*. As we have seen, negation can be introduced in classical and intuitionistic logic by adding a constant symbol \perp for falsity and defining the new connective $\neg A$ for negation as $A \rightarrow \perp$. We will adopt this definition. However, we have to modify the computation rules, because we have to allow for the special nature of \perp , namely that $\perp \vdash A$ holds for any A .

DEFINITION 33. [Computations for data and goal containing \perp for intuitionistic and classical logic] The basic procedure is that one defined in 4, (plus the restart rule for classical logic), with the following modifications:

1. Modify (success) rule to read: $\Delta \vdash^? q$ immediately succeeds, if $q \in \Delta$ or $\perp \in \Delta$.
2. Modify (reduction rule) to read: from $\Delta \vdash^? q$ step, for $i = 1, \dots, n$ to

$$\Delta \vdash^? B_i$$

if there is $C \in \Delta$ such that $Head(C) \in \{q, \perp\}$ and $Body(C) = (B_1, \dots, B_n)$.

In Definition 33 we have actually defined two procedures. One is the computation without the restart rule for intuitionistic logic with \perp , and the other is the computation with the restart rule for classical logic. We have to show that the two procedures indeed correctly capture the intended fragment of the respective systems. This is easy to see. The effect of the axiom $\perp \vdash A$ is built into the computation via the modifications in 1. and 2. of Definition 33 and hence we know we are getting intuitionistic logic. To show that the restart rule yields classical logic, it is sufficient to show that the computation

$$(A \rightarrow \perp) \rightarrow \perp \vdash^? A$$

always succeeds with the restart rule. This can also be easily checked.

To complete the picture we show in the next proposition that the computation of $\Delta \vdash^? A$ with restart is the same as the computation of $\Delta \vdash^? (A \rightarrow \perp) \rightarrow A$ without restart. This means that the restart rule

(with original goal A) can be effectively implemented by adding $A \rightarrow \perp$ to the database and using the formula $A \rightarrow \perp$ and the \perp -rules to replace uses of the restart rule. The above considerations correspond to the known translation from classical logic to intuitionistic logic, namely:

$\Delta \vdash A$ in classical logic iff $\Delta \vdash \neg A \rightarrow A$ in intuitionistic logic.

The proof is similar to that one of Lemma 25, namely $Cop(G)$ is a way of representing $G \rightarrow \perp$ without using \perp .

PROPOSITION 34. *For any database Δ and goal G :*

$\Delta \vdash^? G$ succeeds with restart iff $\Delta \cup \{G \rightarrow \perp\} \vdash^? G$ succeeds without restart.

EXAMPLE 35. We check:

$$(q \rightarrow \perp) \rightarrow \perp \vdash^? q, (q)$$

$$(q \rightarrow \perp) \rightarrow \perp \vdash^? q \rightarrow \perp, (q)$$

$$(q \rightarrow \perp) \rightarrow \perp, q \vdash^? \perp, (q).$$

We cannot use the reduction rule here. So, we fail in intuitionistic logic. In classical logic we can use restart to obtain:

$$(q \rightarrow \perp) \rightarrow \perp, q \vdash^? q, (q)$$

and terminate successfully.

The locally linear computation with bounded restart (respectively restart) is complete for the $(\rightarrow, \perp, \wedge)$ -fragment of intuitionistic (classical) logic. The termination and complexity analysis of the previous section applies also to this larger fragment.

Extension to the whole propositional intuitionistic logic

To obtain a goal-directed proof method for full intuitionistic propositional logic we must find a way of handling disjunctive data. The handling of disjunction is more difficult than the handling of conjunction and negation. Consider the formula $a \rightarrow (b \vee (c \rightarrow d))$. We cannot rewrite this formula in intuitionistic logic to anything of the form $B \rightarrow q$, where q is atomic (or \perp).

We therefore have to change our proof procedures to accommodate the general form of an intuitionistic formula with disjunction.

In classical logic disjunctions can be pulled to the outside of formulas using the following equivalences:

1. $(A \vee B \rightarrow C) \equiv (A \rightarrow C) \wedge (B \rightarrow C)$

$$2. (C \rightarrow A \vee B) \equiv (C \rightarrow A) \vee (C \rightarrow B),$$

where \equiv denotes logical equivalence in classical logic. 1. is valid in intuitionistic logic but 2. is not valid. We have seen at the beginning of the section, the axioms governing disjunction. In view of those axioms, it is not difficult to devise rules to handle disjunction:

R1: from $\Delta \vdash^? A \vee B$ step to $\Delta \vdash^? A$ or to $\Delta \vdash^? B$.

R2: from $\Delta, A \vee B \vdash^? C$ step to $\Delta, A \vdash^? C$ and to $\Delta, B \vdash^? C$.

We can try to incorporate the two rules for disjunction within a goal-directed proof procedure for full intuitionistic logic.

DEFINITION 36. Computation rules for full intuitionistic logic with disjunction.

1. The propositional language contains the connectives $\wedge, \vee, \rightarrow, \perp$. Formulas are defined inductively as usual.
2. We define the operation $\Delta + A$, for any formula $A = \bigwedge_i A_i$, as follows: $\Delta + A = \Delta \cup \{A_i\}$ provided A_i are not conjunctions.
3. The computation rules are as follows.

- (suc) $\Delta \vdash^? q$ succeeds if $q \in \Delta$ or $\perp \in \Delta$;
- (conj) from $\Delta \vdash^? A \wedge B$ step to $\Delta \vdash^? A$ and to $\Delta \vdash^? B$;
- (g-dis) from $\Delta \vdash^? A \vee B$ step to $\Delta \vdash^? A$ or to $\Delta \vdash^? B$;
- (imp) from $\Delta \vdash^? A \rightarrow B$ step to $\Delta + A \vdash^? B$;
- (red) from $\Delta \vdash^? G$ if G is an atom q or $G = A \vee B$, if $C \in \Delta$, with $C = A_1 \rightarrow \dots \rightarrow A_n \rightarrow D$ (where D is not an implication) step to
 - (a) $\Delta \vdash^? A_i$, for $i = 1, \dots, n$, and to
 - (b) $\Delta + D \vdash^? G$.
- (c-dis) from $\Delta, A \vee B \vdash^? C$ step to $\Delta + A \vdash^? C$ and to $\Delta + B \vdash^? C$.

The above rules give a sound and complete system for full intuitionistic logic. However the rules are far from satisfactory, in the sense that the goal-directness is lost. For instance, we must be allowed to perform a reduction step not only when the goal is atomic, but also when it is a disjunction, as in the following case

$$A, A \rightarrow B \vee C \vdash^? B \vee C.$$

Similarly, even if the goal is an atom q in the reduction case (red) we cannot require that D in the formula $A_1 \rightarrow \dots \rightarrow A_n \rightarrow D$ is atomic and $D = q$. If there are disjunctions in the database, at every step we can choose to work on the goal or to split the database by (c-dis) rule. Moreover, if there are n disjunctions a systematic application of (c-dis) rule yields 2^n branches. All of this means that if we handle disjunction in the most obvious way we loose the goal-directedness of deduction and the computation becomes very inefficient.

The reason is that if *positive* disjunctions are allowed in a database Γ it is not true that

$$(dp) \Gamma \vdash A \vee B \text{ implies } \Gamma \vdash A \text{ or } \Gamma \vdash B.$$

This property, called *disjunction property*, holds when Γ does not contain positive disjunctions, but fails when it does contain them, as the example above shows. This means that the goal $A \vee B$ cannot be decomposed/reduced to A and to B . In other words, we cannot proceed in a goal-directed fashion. There are three ways to overcome the problem of disjunction. The simplest solution is to kill the problem at the root: do not allow positive occurrences of disjunction in the database. To prevent positive disjunctions means to restrict our consideration to so-called *Harrop formulas*. To introduce them, let us define the two types of formulas D and G by mutual induction as follows:

$$\begin{aligned} D &:= q \mid \perp \mid G \rightarrow D \mid D \wedge D \\ G &:= q \mid \perp \mid G \wedge G \mid G \vee G \mid D \rightarrow G. \end{aligned}$$

A formula is *Harrop* if it is defined according to the D-clauses above. D-formulas are allowed as constituents of the database, whereas G formulas are allowed to be asked as goals. It is easy to extend the goal directed procedure to Harrop formulas. A database will be a set of D-formulas (which are not conjunctions themselves). We just add the rule R1 given above to handle disjunctive goals. This gives us a complete system, which can be optimized by adopting the diminishing resource approach and bounded restart.

Another solution, that we just mention, is to eliminate disjunction by adopting Statman's translation [Statman, 1979]: we can translate every pair database-goal (Γ, G) in a pair (Γ^*, G^*) , such that Γ^*, G^* do not contain disjunction, but contain additional atoms, and it holds (in intuitionistic logic)

$$\Gamma \vdash G \text{ iff } \Gamma^* \vdash G^*.$$

We can then use the proof procedure without disjunction.

However, one can try to cope with the whole propositional intuitionistic logic without limitations, by using additional machinery. There are two difficulties to define a goal-directed procedure. Consider the query $\Gamma \vdash?$

$A \vee B$. We can adopt the rule R1 by continuing for instance with $\Gamma \vdash^? A$, and remember that at a previous step we could have chosen the disjunct B , thus we must be able to go back to $\Gamma \vdash^? B$. The use of history and restart can accomplish the necessary book-keeping mechanism. However, we must take into account that the database may have changed in the meantime, and we must go back to the right database; notice that in general

$$(A \rightarrow B) \vee C \not\equiv A \rightarrow B \vee C \not\equiv B \vee (A \rightarrow C)$$

(although these equivalences hold in classical logic). One way to keep track of the dependency between the goal and database from which it is asked is to use labels. This solution is developed in [Gabbay and Olivetti, 2000], where a labelled goal-directed proof procedure for full intuitionistic logic is given. The labels are partially ordered and can be interpreted as possible worlds.

The other technical trick is to extend suitably the notion of 'Head' of a formula to formulas with positive disjunctions; this is necessary to define the reduction step. For instance, ignoring the labelling and restart mechanism, the query Γ, K , where $K = A \rightarrow (B \vee (C \rightarrow q)) \vdash^? q$, and q is an atom, would be reduced to the queries:

$$\begin{aligned} \Gamma, K \vdash^? A, \\ \Gamma, K, B \vdash^? q, \\ \Gamma, K, C \rightarrow q \vdash^? C. \end{aligned}$$

and q would be recorded in the history.

We shall not give the details of the procedure which can be found in [Gabbay and Olivetti, 2000]. A similar, although much simpler, procedure can be given for classical logic. However, in classical logic the treatment of disjunctive data is not problematic, since on the one hand we can define disjunction using the other connectives (the \rightarrow connective alone suffices as $A \vee B \equiv (A \rightarrow B) \rightarrow B$). On the other hand every formula can be rewritten as a set of clauses of the form:

$$p_1 \wedge \dots \wedge p_n \rightarrow q_1 \vee \dots \vee q_m$$

where $n \geq 0$, and $m > 0$, every p_i is an atom, and every q_j is an atom or is \perp . For data of this sort, a goal-directed procedure is easily designed, see [Gabbay and Olivetti, 2000; Nadathur, 1998; Loveland, 1991; Loveland, 1992].

3.8 Some history

A goal-directed proof system for a (first-order) fragment of intuitionistic and classical logic was first given by Gabbay [Gabbay and Reyle, 1984;

Gabbay, 1985] as a foundation of hypothetical logic programming. A similar system for intuitionistic logic was proposed in [McCarty, 1988a; McCarty, 1988b]. The restart rule was first proposed by Gabbay in his lecture notes in 1984 and the first theoretical results published in [Gabbay, 1985] and then 1985 in [Gabbay and Kriwaczek, 1991].⁷ A similar idea to restart has been exploited by Loveland [1991; 1992], in order to extend conventional logic programming to non-Horn databases; in Loveland's proof procedure the restart rule is a way of implementing reasoning by case-analysis.

The concept of goal-directed computation can also be seen as a generalization of the notion of *uniform proof* as introduced in [Miller *et al.*, 1991]. A uniform proof system is called 'abstract logic programming' [Miller *et al.*, 1991]. The extension of the uniform proof paradigm to classical logic is recently discussed in [Harland, 1997] and [Nadathur, 1998]. The essence of a uniform-proof system is the same underlying the goal-directed paradigm: the proof-search is driven by the goal and the connectives can be interpreted directly as search instructions.

The locally linear computation with bounded restart was first presented by Gabbay [1991] and then further investigated in [Gabbay, 1992], where goal-directed procedures for classical and some intermediate logics are also presented. This refinement is strongly connected to the contraction-free sequent calculi for intuitionistic logic which have been proposed by many people: Dyckhoff [1992], Hudelmaier [1990], and Lincoln *et al.*, [1991]. To see the intuitive connection, let us consider the query:

$$(1) \Delta, (A \rightarrow p) \rightarrow q \vdash^? q, \emptyset$$

we can step by reduction to $\Delta \vdash^? A \rightarrow p, (q)$ and then to $\Delta, A \vdash^? p, (q)$, which, by the soundness corresponds to

$$(2) \Delta, A, p \rightarrow q \vdash^? q.$$

In all the mentioned calculi (1) can be reduced to (2) by a sharpened left-implication rule (here used backwards). This modified rule is the essential ingredient to obtain a contraction-free sequent calculus for **I**, at least for its implicational fragment. A formal connection with these contraction-free calculi has not been studied yet. It might turn out that LL-computations correspond to *uniform proofs* (in the sense of [Miller *et al.*, 1991]) within these calculi.

In [Gabbay and Olivetti, 2000] the goal-directed methods are extended to some *intermediate logics*, i.e. logics which are between intuitionistic and classical logics. In particular, it is given a proof procedure for the family of intermediate logics of Kripke models with finite height, and for Dummett-Gödel logic LC. These proof systems are obtained by adding suitable restart rules to the intuitionistic system.

⁷The lecture notes have evolved also into the book [Gabbay, 1998].

4 MODAL LOGICS OF STRICT IMPLICATION

In this section we examine how to extend the goal-directed proof methods to modal logics. We begin considering a minimal language which contains only *strict implication*, we will then extend it to the full language of modal logics. Strict implication, denoted by $A \Rightarrow B$ is read as ‘necessarily A implies B ’. The notion of necessity (and the dual notion of possibility) are the subject of modal logics. Strict implication can be regarded as a derived notion: $A \Rightarrow B = \Box(A \rightarrow B)$, where \rightarrow denotes material implication and \Box denotes modal necessity. However, strict implication can also be considered as a primitive notion, and has already been considered as such at the beginning of the century in many discussions about the paradoxes of material implication [Lewis, 1912; Lewis and Langford, 1932].

The extension of the goal-directed approach to strict implication and modal logics relies upon the *possible worlds* semantics of modal logics which is mainly due to Kripke.

The strict implication language $\mathcal{L}(\Rightarrow)$ contains all formulas built out from a denumerable set Var of propositional variables by applying the strict implication connective, that is, if $p \in Var$ then p is a formula of $\mathcal{L}(\Rightarrow)$, and if A and B are formulas of $\mathcal{L}(\Rightarrow)$, then so is $A \Rightarrow B$. Let us fix an atom p_0 , we can define the constant $\top \equiv p_0 \Rightarrow p_0$ and let $\Box A \equiv \top \Rightarrow A$.

Semantics

We review the standard Kripke semantics for $\mathcal{L}(\Rightarrow)$.

A Kripke structure M for $\mathcal{L}(\Rightarrow)$ is a triple (W, R, V) , where W is a non-empty set (whose elements are called possible worlds), R is a binary relation on W , and V is a mapping from W to sets of propositional variables of \mathcal{L} . Truth conditions for formulas (of $\mathcal{L}(\Rightarrow)$) are defined as follows:

- $M, w \models p$ iff $p \in V(w)$;
- $M, w \models A \Rightarrow B$ iff for all w' such that wRw' and $M, w' \models A$, it holds $M, w' \models B$.

We say that a formula A is *valid* in a structure M , denoted by $M \models A$, if $\forall w \in W, M, w \models A$. We say that a formula A is *valid* with respect to a given class of structures \mathcal{K} , iff it is valid in every structure $M \in \mathcal{K}$. We sometimes use the notation $\models_{\mathcal{K}} A$. Let us fix a class of structures \mathcal{K} . Given two formulas A and B , we can define the *consequence relation* $A \models_{\mathcal{K}} B$ as

$$\forall M = (W, R, V) \in \mathcal{K} \forall w \in W \text{ if } M, w \models_{\mathcal{K}} A \text{ then } M, w \models_{\mathcal{K}} B.$$

Different modal logics are obtained by considering classes of structures whose relation R satisfies some specific properties. The properties of the accessibility relations we consider are listed in Table 1.

Table 1. Standard properties of the accessibility relation.

Reflexivity	$\forall x xRx$
Transitivity	$\forall x\forall y\forall z xRy \wedge yRz \rightarrow xRz$
Symmetry	$\forall x\forall y xRy \rightarrow yRx$
Euclidean	$\forall x\forall y\forall z xRy \wedge xRz \rightarrow yRz$

Table 2. Some standard modal logics.

We will take into consideration strict implication \Rightarrow as defined in systems **K**, **KT**,⁸ **K4**, **S4**, **K5**, **K45**, **KB**, **KB**^T, and **S5**.⁹

Properties of accessibility relation R in Kripke frames, corresponding to these systems are shown in Table 2.

Letting **S** be one of the modal systems above, we use the notation $\models_{\mathbf{S}} A$ (and $A \models_{\mathbf{S}} B$) to denote validity in (and the consequence relation determined by) the class of structures corresponding to **S**.

4.1 Proof systems

In this section we present proof methods for all modal systems mentioned above. We regard a database as a set of labelled formulas $x_i : A_i$ equipped by a relation α giving connections between labels. The labels obviously represent worlds. Thus, $x_i : A_i$ means that A_i holds at x_i . The goal of a query is asked with respect to a world. The form of databases and goals determine the notion of consequence relation

$$\{x_1 : A_1, \dots, x_n : A_n\}, \alpha \vdash x : A$$

⁸We use the acronym **KT** rather than the more common **T**, as the latter is also the name of a subrelevance logic we will meet in Section 5.

⁹We do not consider here systems containing $D : \Box A \rightarrow \Diamond A$, which correspond to the *seriality* of the accessibility relation, i.e. $\forall x\exists y xRy$ in Kripke frames. The reason is that seriality cannot be expressed in the language of strict implication alone; moreover, it cannot be expressed in any modal language, unless \neg or \Diamond is allowed.

whose intended meaning is that if A_i holds at x_i (for $i = 1, \dots, n$) and the x_i are connected as α prescribes, then A must hold at x .

For different logics α will be required to satisfy different properties such as reflexivity, transitivity, etc., depending on the properties of the accessibility relation of the system under consideration.

DEFINITION 37. Let us fix a denumerable alphabet $\mathcal{A} = \{x_1, \dots, x_i, \dots\}$ of labels. A *database* is a finite graph of formulas labelled by \mathcal{A} . We denote a database as a pair (Δ, α) , where Δ is a finite set of labelled formulas $\Delta = \{x_1 : A_1, \dots, x_n : A_n\}$ and $\alpha = \{(x_1, x'_1), \dots, (x_m, x'_m)\}$ is a set of links. Let $Lab(E)$ denote the set of labels $x \in \mathcal{A}$ occurring in E , and assume that (i) $Lab(\Delta) = Lab(\alpha)$, and (ii) if $x : A \in \Delta, x : B \in \Delta$, then $A = B$.¹⁰

A *trivial database* has the form $(\{x_0 : A\}, \emptyset)$.

The *expansion* of a database (Γ, α) by $y : C$ at x , with $x \in Lab(\Gamma)$, $y \notin Lab(\Gamma)$ is defined as follows:

$$(\Gamma, \alpha) \oplus_x (y : C) = (\Delta \cup \{y : C\}, \alpha \cup \{(x, y)\}).$$

DEFINITION 38. A query Q is an expression of the form:

$$Q = (\Delta, \alpha) \vdash^? x : G, H$$

where (Δ, α) is a database, $x \in Lab(\Delta)$, G is a formula, and H , *the history*, is a set of pairs

$$H = \{(x_1, q_1), \dots, (x_m, q_m)\}$$

where x_i are labels and q_i are atoms. We will often omit the parentheses around the two components of a database and write $Q = \Delta, \alpha \vdash^? x : G, H$. A query from a trivial database $\{x_0 : A\}$ will be written simply as:

$$x_0 : A \vdash^? x_0 : B, H,$$

and if $A = \top$, we sometimes just write $\vdash^? x_0 : B, H$.

DEFINITION 39. Let α be a set of links, we introduce a family of relation symbols $A_\alpha^S(x, y)$, where $x, y \in Lab(\alpha)$. We consider the following conditions:

- (K) $(x, y) \in \alpha \Rightarrow A_\alpha^S(x, y)$,
- (T) $x = y \Rightarrow A_\alpha^S(x, y)$,
- (4) $\exists z (A_\alpha^S(x, z) \wedge A_\alpha^S(z, y)) \Rightarrow A_\alpha^S(x, y)$,
- (5) $\exists z (A_\alpha^S(z, x) \wedge A_\alpha^S(z, y)) \Rightarrow A_\alpha^S(x, y)$,
- (B) $A_\alpha^S(x, y) \Rightarrow A_\alpha^S(y, x)$.

¹⁰We will drop this condition in Section 4.3 when we extend the language by allowing conjunction.

For $\mathbf{K} \in \mathbf{S} \subseteq \{\mathbf{K}, \mathbf{T}, \mathbf{4}, \mathbf{5}, \mathbf{B}\}$, we let $A^{\mathbf{S}}$ be the least relation satisfying all conditions in \mathbf{S} . Thus, for instance, $A^{\mathbf{K45}}$ is the least relation such that:

$$\begin{aligned} A_{\alpha}^{\mathbf{K45}}(x, y) \quad \Leftrightarrow \quad & (x, y) \in \alpha \vee \\ & \vee \exists z(A_{\alpha}^{\mathbf{K45}}(x, z) \wedge A_{\alpha}^{\mathbf{K45}}(z, y)) \vee \\ & \vee \exists z(A_{\alpha}^{\mathbf{K45}}(z, x) \wedge A_{\alpha}^{\mathbf{K45}}(z, y)). \end{aligned}$$

We will use the standard abbreviations (i.e. $A^{\mathbf{S5}} = A^{\mathbf{KT5}} = A^{\mathbf{KT45}}$).

DEFINITION 40 (Modal Deduction Rules). For each modal system \mathbf{S} , the corresponding proof system, denoted by $\mathbf{P}(\mathbf{S})$, comprises the following rules parametrized to predicates $A^{\mathbf{S}}$:

- (success) $\Delta, \alpha \vdash^? x : q, H$ immediately succeeds if q is an atom and $x : q \in \Delta$.
- (implication) From $\Delta, \alpha \vdash^? x : A \Rightarrow B, H$, step to

$$(\Delta, \alpha) \oplus_x (y : A) \vdash^? y : B, H,$$

where $y \notin \text{Lab}(\Delta) \cup \text{Lab}(H)$.

- (reduction) If $y : C \in \Delta$, with $C = B_1 \Rightarrow B_2 \Rightarrow \dots \Rightarrow B_k \Rightarrow q$, with q atomic, then from

$$\Delta, \alpha \vdash^? x : q, H$$

step to

$$\Delta, \alpha \vdash^? u_1 : B_1, H \cup \{(x, q)\},$$

\vdots ,

$$\Delta, \alpha \vdash^? u_k : B_k, H \cup \{(x, q)\},$$

for some $u_0, \dots, u_k \in \text{Lab}(\alpha)$, with $u_0 = y$, $u_k = x$, such that

for $i = 0, \dots, k - 1$, $A_{\alpha}^{\mathbf{S}}(u_i, u_{i+1})$ holds.

- (restart) If $(y, r) \in H$, then, from $\Delta, \alpha \vdash^? x : q, H$, with q atomic, step to

$$\Delta, \alpha \vdash^? y : r, H \cup \{(x, q)\}.$$

Restricted restart

Similar to the case of classical logic, in any deduction of a query Q of the form $\Delta, \alpha \vdash^? x : G, \emptyset$, the *restart rule* can be restricted to the choice of the pair (y, r) , such that r is the uppermost atomic goal occurred in the deduction and y is the label associated to r (that is, the query in which r appears contains $\dots \vdash^? y : r$). Hence, if the initial query is $Q = \Delta, \alpha \vdash^?$

$x : G, \emptyset$ and G is an atom q , such a pair is (x, q) , if G has the form $B_1 \Rightarrow \dots \Rightarrow B_k \Rightarrow r$, then the first pair is obtained by repeatedly applying the implication rule until we reach the query $\dots \vdash^? x_k : r$, with $x_k \notin \text{Lab}(\Delta)$. With this restriction, we do not need to keep track of the history any more, but only of the first pair. An equivalent formulation is to allow restart from the initial goal (and its relative label) even if it is implicational, but the re-evaluation of an implication causes a redundant increase of the database, that is why we prefer the above formulation.

PROPOSITION 41. *If $\Delta, \alpha \vdash^? x : G, \emptyset$ succeeds then it succeeds by a derivation in which every application of restart is restricted restart.*

We have omitted the reference to the specific proof system $P(\mathbf{S})$, since of the previous claim does not depend on the specific properties of the predicates $A^{\mathbf{S}}$ involved in the definition of a proof system $P(\mathbf{S})$. We will omit the reference to $P(\mathbf{S})$ whenever it is not necessary.

We show some examples of the proof procedure.

EXAMPLE 42. In Figure 4 we show a derivation of

$$((p \Rightarrow p) \Rightarrow a \Rightarrow b) \Rightarrow (b \Rightarrow c) \Rightarrow a \Rightarrow c.$$

in $P(\mathbf{K})$. By Proposition 41, we only record the first pair for restart, which, however, is not used in the derivation. As usual in each node we only show the additional data, if any. Thus the database in each node is given by the collection of the formulas from the root to that node. Here is an explanation of the steps: in step (2) $\alpha = \{(x_0, x_1)\}$; in step (3) $\alpha = \{(x_0, x_1), (x_1, x_2)\}$; in step (4) $\alpha = \{(x_0, x_1), (x_1, x_2), (x_2, x_3)\}$; since $A_{\alpha}^{\mathbf{K}}(x_2, x_3)$, by reduction w.r.t. $x_2 : b \Rightarrow c$ we get (5); since $A_{\alpha}^{\mathbf{K}}(x_1, x_2)$ and $A_{\alpha}^{\mathbf{K}}(x_2, x_3)$, by reduction w.r.t. $x_1 : (p \Rightarrow p) \Rightarrow a \Rightarrow b$ we get (6) and (8). the latter immediately succeeds as $x_3 : a \in \Delta$; from (6) we step to (7) which immediately succeeds.

EXAMPLE 43. In Figure 5 we show a derivation of

$$(((a \Rightarrow a) \Rightarrow p) \Rightarrow q) \Rightarrow p) \Rightarrow p$$

in $P(\mathbf{KBT})$, we use restricted restart according to Proposition 41. In step (2), $\alpha = \{(x_0, x_1)\}$. Step (3) is obtained by reduction w.r.t. $x_1 : (((a \Rightarrow a) \Rightarrow p) \Rightarrow q) \Rightarrow p$, as $A_{\alpha}^{\mathbf{KBT}}(x_1, x_1)$. In step (4) $\alpha = \{(x_0, x_1), (x_1, x_2)\}$; step (5) is obtained by restart; step (6) by reduction w.r.t. $x_2 : (a \Rightarrow a) \Rightarrow p$, as $A_{\alpha}^{\mathbf{KBT}}(x_2, x_1)$; in step (7) $\alpha = \{(x_0, x_1), (x_1, x_2), (x_1, x_3)\}$ and the query immediately succeeds.

In order to prove soundness and completeness, we need to give a formal meaning to queries, i.e. to define when a query is valid. We first introduce a notion of *realization* of a database in a model to give a semantic meaning to databases.

DEFINITION 44 (Realization and validity). Let $A^{\mathbf{S}}$ be an accessibility predicate, given a database (Γ, α) and a Kripke model $M = (W, R, V)$,

Figure 4. Derivation for Example 42.

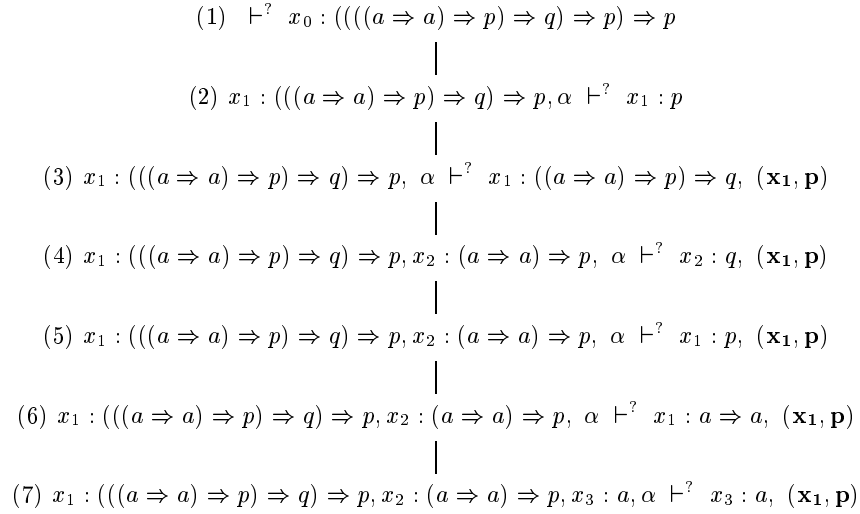

Figure 5. Derivation for Example 43.

a mapping $f : Lab(\Gamma) \rightarrow W$ is called a *realization* of (Γ, α) in M with respect to $A^{\mathbf{S}}$, if the following hold:

1. $A_{\alpha}^{\mathbf{S}}(x, y)$ implies $f(x)Rf(y)$;
2. if $x : A \in \Gamma$, then $M, f(x) \models A$.

We say that a query $Q = \Gamma, \alpha \vdash^? x : G, H$ is *valid* in \mathbf{S} if for every \mathbf{S} -model M and every realization f of (Γ, α) , we have either $M, f(x) \models G$, or for some $(y, r) \in H$, $M, f(y) \models r$.

The soundness of the proof procedure can be proved easily by induction on the length of the computation.

THEOREM 45 (Soundness). *Let $Q = \Gamma, \alpha \vdash^? x : G, H$ succeed in the proof system $P(\mathbf{S})$, then it is valid in \mathbf{S} .*

COROLLARY 46. *If $x_0 : A \vdash^? x_0 : B, \emptyset$ succeeds in $P(\mathbf{S})$, then $A \models_{\mathbf{S}} B$ holds. In particular, if $\vdash^? x_0 : A, \emptyset$ succeeds in $P(\mathbf{S})$, then A is valid in \mathbf{S} .*

To prove completeness we proceed in a similar way to what we did for intuitionistic logic. First we show that cut is admissible. Then we prove completeness by a sort of canonical model construction. The cut rule states the following: let $x : A \in \Gamma$, then if (1) $\Gamma \vdash y : B$ and (2) $\Delta \vdash z : A$ succeed, we can ‘replace’ $x : A$ by Δ in Γ and get a successful query from (1). Since there are labels and accessibility predicates, we must be careful. There are two points to clarify. First, we need to define the involved notion of substitution. Furthermore the proof systems $P(\mathbf{S})$ depend uniformly on predicate $A^{\mathbf{S}}$, and we expect that the admissibility of cut depends on the properties of predicate $A^{\mathbf{S}}$. It turns out that the admissibility of cut (stated in Theorem 48) holds for every proof system $P(\mathbf{S})$, such that $A^{\mathbf{S}}$ satisfies the following conditions:

- (i) $A^{\mathbf{S}}$ is closed under substitution of labels;
- (ii) $A_{\alpha}^{\mathbf{S}}(x, y)$ implies $A_{\alpha \cup \beta}^{\mathbf{S}}(x, y)$;
- (iii) $A_{\alpha}^{\mathbf{S}}(u, v)$ implies $\forall x y (A_{\alpha \cup \{(u,v)\}}^{\mathbf{S}}(x, y) \leftrightarrow A_{\alpha}^{\mathbf{S}}(x, y))$.

These conditions ensure the following properties.

PROPOSITION 47.

- (a) *If $\Gamma, \alpha \vdash^? x : C, H$ succeeds then also $\Gamma[u/v], \alpha[u/v] \vdash^? x[u/v] : C, H[u/v]$ succeeds.*
- (b) *If $A_{\alpha}^{\mathbf{S}}(x, y)$ and $\Gamma, \alpha \cup \{(x, y)\} \vdash^? u : G, H$ succeed, then also $\Gamma, \alpha \vdash^? u : G, H$ succeeds.*

We say that two databases (Γ, α) , (Δ, β) are *compatible for substitution*,¹¹ if

for every $x \in \text{Lab}(\Gamma) \cap \text{Lab}(\Delta)$, for all formulas C , $x : C \in \Gamma \Leftrightarrow x : C \in \Delta$.

If (Γ, α) and (Δ, β) are compatible for substitution, $x : A \in \Gamma$, and $y \in \text{Lab}(\Delta)$, we denote by

$$(\Gamma, \alpha)[x : A/\Delta, \beta, y] = (\Gamma - \{x : A\} \cup \Delta, \alpha[x/y] \cup \beta).$$

the database which results by replacing $x : A$ in (Γ, α) by (Δ, β) at point y .

At this point we can state precisely the result about cut.

THEOREM 48 (Admissibility of cut). *Let predicate $A^{\mathbf{S}}$ satisfy the conditions (i), (ii), (iii) above. If the following queries succeed in the proof system $P(\mathbf{S})$:*

1. $\Gamma[x : A] \vdash^? u : B, H_1$
2. $\Delta, \beta \vdash^? y : A, H_2$.

and (Γ, α) and (Δ, β) are compatible for substitution, then also

3. $(\Gamma, \alpha)[x : A/\Delta, \beta, y] \vdash^? u[x/y] : B, H_1[x/y] \cup H_2$ succeeds in $P(\mathbf{S})$.

The proof proceeds similarly to the one of Theorem 10 and is given in [Gabbay and Olivetti, 2000]. From the theorem we immediately have the following two corollaries.

COROLLARY 49. *Under the same conditions as above, if $x : A \vdash^? x : B$ succeeds and $x : B \vdash^? x : C$ succeeds then also $x : A \vdash^? x : C$ succeeds.*

COROLLARY 50. *If $\mathbf{K} \in \mathbf{S} \subseteq \{\mathbf{K}, \mathbf{4}, \mathbf{5}, \mathbf{B}, \mathbf{T}\}$, then in the proof system $P(\mathbf{S})$ cut is admissible.*

As we have said, we can prove the completeness by a sort of canonical model construction, which is less constructive of the one of Theorem 9. The following properties will be used in the completeness proof.

PROPOSITION 51.

- (Identity) *If $x : A \in \Gamma$, then $\Gamma, \alpha \vdash^? x : A, H$ succeeds.*
- (Monotony) *If $Q = \Gamma, \alpha \vdash^? x : C, H$ succeeds and $\Gamma \subseteq \Delta$, $\alpha \subseteq \beta$, $H \subseteq H'$, then also $\Delta, \beta \vdash^? x : C, H'$ succeeds.*

¹¹This condition is not necessary if we allow the occurrence of several formulas with the same label in a database, as we will do in Section 4.3 when we add conjunction.

THEOREM 52 (Completeness). *Given a query $Q = \Gamma, \alpha \vdash^? x : A, H$, if Q is \mathbf{S} -valid then Q succeeds in the proof system $P(\mathbf{S})$.*

Proof. By contraposition, we prove that if $Q = \Gamma, \alpha \vdash^? x : A, H$ does not succeed in one proof system $P(\mathbf{S})$, then there is an \mathbf{S} -model M and a realization f of (Γ, α) , such that $M, f(x) \not\models A$ and for any $(y, r) \in H$, $M, f(y) \not\models r$.

We construct an \mathbf{S} -model by extending the database, through the evaluation of all possible formulas at every world (each represented by one label) of the database. Since such evaluation may lead, for implication formulas, to create new worlds, we must carry on the evaluation process on these new worlds. Therefore, in the construction we consider an enumeration of pairs (x_i, A_i) , where x_i is a label and A_i is a formula.

Assume $\Gamma, \alpha \vdash^? x : A, H$ fails in $P(\mathbf{S})$. We let \mathcal{A} be a denumerable alphabet of labels and \mathcal{L} be the underlying propositional language. Let (x_i, A_i) , for $i \in \omega$ be an enumeration of pairs of $\mathcal{A} \times \mathcal{L}$, starting with the pair (x, A) and containing infinitely many repetitions, that is

$$(x_0, A_0) = (x, A), \\ \forall y \in \mathcal{A}, \forall F \in \mathcal{L}, \forall n \exists m > n (y, F) = (x_m, A_m).$$

Given such enumeration we define (i) a sequence of databases (Γ_n, α_n) , (ii) a sequence of histories H_n , (iii) a new enumeration of pairs (y_n, B_n) , as follows:

- (step 0) Let $(\Gamma_0, \alpha_0) = (\Gamma, \alpha)$, $H_0 = H$, $(y_0, B_0) = (x, A)$.
- (step $n+1$) Given (y_n, B_n) , if $y_n \in \text{Lab}(\Gamma_n)$ and $\Gamma_n, \alpha_n \vdash^? y_n : B_n, H_n$ fails then proceed according to (a) else to (b).

(a) if B_n is atomic, then we set

$$H_{n+1} = H_n \cup \{(y_n, B_n)\}, \\ (\Gamma_{n+1}, \alpha_{n+1}) = (\Gamma_n, \alpha_n), \\ (y_{n+1}, B_{n+1}) = (x_{k+1}, A_{k+1}), \\ \text{where } k = \max_{t \leq n} \exists s \leq n (y_s, B_s) = (x_t, A_t),$$

else let $B_n = C \Rightarrow D$, then we set

$$H_{n+1} = H_n, \\ (\Gamma_{n+1}, \alpha_{n+1}) = (\Gamma_n, \alpha_n) \oplus_{y_n} (x_m : C), \\ (y_{n+1}, B_{n+1}) = (x_m, D), \\ \text{where } x_m = \min\{x_t \in \mathcal{A} \mid x_t \notin \text{Lab}(\Gamma_n) \cup \text{Lab}(H_n)\}.$$

(b) We set

$$\begin{aligned} H_{n+1} &= H_n, \\ (\Gamma_{n+1}, \alpha_{n+1}) &= (\Gamma_n, \alpha_n), \\ (y_{n+1}, B_{n+1}) &= (x_{k+1}, A_{k+1}), \\ \text{where } k &= \max\{t \leq n \mid \exists s \leq n (y_s, B_s) = (x_t, A_t)\}, \quad \blacksquare \end{aligned}$$

The proof of completeness is made of several lemmas.

LEMMA 53. $\forall k \exists n \geq k (x_k, A_k) = (y_n, B_n)$.

Proof. By induction on k . If $k = 0$, the claim holds by definition. Let $(x_k, A_k) = (y_n, B_n)$.

- (i) if $y_n \notin \text{Lab}(\Gamma_n)$, or $\Gamma_n, \alpha_n \vdash^? y_n : B_n, H_n$ succeeds, or B_n is atomic, then $(x_{k+1}, A_{k+1}) = (y_{n+1}, B_{n+1})$.
- (ii) Otherwise, let $B_n = C_1 \Rightarrow \dots \Rightarrow C_t \Rightarrow r$, ($t > 0$), then $(x_{k+1}, A_{k+1}) = (y_{n+t+1}, B_{n+t+1})$. \blacksquare

LEMMA 54. For all $n \geq 0$, if $\Gamma_n, \alpha_n \vdash^? y_n : B_n, H_n$ fails, then:

$$\forall m \geq n \Gamma_m, \alpha_m \vdash^? y_n : B_n, H_m \text{ fails.}$$

Proof. By induction on $cp(B_n) = c$. if $c = 0$, that is B_n is an atom, say q , then we proceed by induction on $m \geq n + 1$.

- ($m = n + 1$) we have $\Gamma_n, \alpha_n \vdash^? y_n : q, H_n$ fails, then also $\Gamma_n, \alpha_n \vdash^? y_n : q, H_n \cup \{(y_n, q)\}$ fails, whence, by construction,

$$\Gamma_{n+1}, \alpha_{n+1} \vdash^? y_n : q, H_{n+1} \text{ fails.}$$

- ($m > n + 1$) Suppose we have proved the claim up to $m \geq n + 1$, and suppose by way of contradiction that $\Gamma_m, \alpha_m \vdash^? y_n : q, H_m$ fails, but

$$(i) \Gamma_{m+1}, \alpha_{m+1} \vdash^? y_n : q, H_{m+1} \text{ succeeds.}$$

At step m , (y_m, B_m) is considered; it must be $y_m \in \text{Lab}(\Gamma_m)$ and

$$(ii) \Gamma_m, \alpha_m \vdash^? y_m : B_m, H_m \text{ fails.}$$

We have two cases, according to the form of B_m . If B_m is an atom r , as $(y_n, q) \in H_m$, from query (ii) by restart we can step to

$$\Gamma_m, \alpha_m \vdash^? y_n : q, H_m \cup \{(y_m, r)\},$$

that is the same as $\Gamma_{m+1}, \alpha_{m+1} \vdash^? y_n : q, H_{m+1}$, which succeeds and we get a contradiction. If $B_m = C_1 \Rightarrow \dots \Rightarrow C_k \Rightarrow r$, with $k > 0$, then from query (ii) we step in k steps to $\Gamma_{m+k}, \alpha_{m+k} \vdash^? y_{m+k} : r, H_{m+k}$, where $(\Gamma_{m+k}, \alpha_{m+k}) = (\Gamma_m, \alpha_m) \oplus_{y_m} (y_{m+1} : C_1) \oplus_{y_{m+1}} \dots \oplus_{y_{m+k-1}} (y_{m+k} : C_k)$ and $H_{m+k} = H_m$; then, by restart, since $(y_n, q) \in H_{m+k}$, we step to

$$(iii) \Gamma_{m+k}, \alpha_{m+k} \vdash^? y_n : q, H_{m+k} \cup \{(y_{m+k}, r)\}.$$

Since query (i) succeeds, by monotony we have that also query (iii) succeeds, whence query (ii) succeeds, contradicting the hypothesis.

Let $cp(B_n) = c > 0$, that is $B_n = C \Rightarrow D$. By hypothesis $\Gamma_n, \alpha_n \vdash^? y_n : C \Rightarrow D, H_n$, fails. Then by construction and by the computation rules $\Gamma_{n+1}, \alpha_{n+1} \vdash^? y_{n+1} : D, H_{n+1}$, fails, and hence, by the induction hypothesis, $\forall m \geq n+1$,

$$\Gamma_m, \alpha_m \vdash^? y_{n+1} : D, H_m, \text{ fails.}$$

Suppose by way of contradiction that for some $m \geq n+1$, $\Gamma_m, \alpha_m \vdash^? y_n : C \Rightarrow D, H_m$, succeeds. This implies that, for some $z \notin \text{Lab}(\Gamma_m) \cup \text{Lab}(H_m)$,

$$(1) (\Gamma_m, \alpha_m) \oplus_{y_n} (z : C) \vdash^? z : D, H_m, \text{ succeeds.}$$

Since $y_{n+1} : C \in \Gamma_{n+1} \subseteq \Gamma_m$, $\alpha_{n+1} \subseteq \alpha_m$, $H_{n+1} \subseteq H_m$, by monotony, we get

$$(2) \Gamma_m, \alpha_m \vdash^? y_{n+1} : C, H_m, \text{ succeeds.}$$

The databases involved in queries (1) and (2) are clearly compatible for substitution, hence by cut we obtain that $\Gamma_m, \alpha_m \vdash^? y_{n+1} : D, H_m$ succeeds, and we have a contradiction. ■

LEMMA 55.

(i) $\forall m, \Gamma_m, \alpha_m \vdash^? x : A, H_m$ fails, whence

(ii) $\forall m$, if $(y, r) \in H_m$, then $\Gamma_m, \alpha_m \vdash^? y : r, H_m$ fails.

Proof. Left to the reader. ■

LEMMA 56. If $B_n = C \Rightarrow D$ and $\Gamma_n, \alpha_n \vdash^? y_n : C \Rightarrow D, H_n$ fails, then there is a $y \in \mathcal{A}$, such that for $k \leq n$, $y \notin \text{Lab}(\Gamma_k)$ and $\forall m > n$: (i) $(y_n, y) \in \alpha_m$, (ii) $\Gamma_m, \alpha_m \vdash^? y : C, H_m$ succeeds, (iii) $\Gamma_m, \alpha_m \vdash^? y : D, H_m$ fails.

Proof. By construction, we can take $y = y_{n+1}$, the new point created at step $n+1$, so that (i), (ii), (iii) hold for $m = n+1$. In particular

(*) $\Gamma_{n+1}, \alpha_{n+1} \vdash^? y_{n+1} : D, H_{n+1}$ fails.

Since the (Γ, α_m) are not decreasing (w.r.t. inclusion), we immediately have that (i) and (ii) also hold for every $m > n + 1$. By construction, we know that $B_{n+1} = D$, whence by (*) and Lemma 54, (iii) also holds for every $m > n + 1$. ■

Construction of the Canonical model

We define an **S**-model as follows $M = (W, R, V)$, such that

- $W = \bigcup_n \text{Lab}(\Gamma_n)$;
- $xRy \equiv \exists n A_{\alpha_n}^{\mathbf{S}}(x, y)$,
- $V(x) = \{q \mid \exists n x \in \text{Lab}(\Gamma_n) \wedge \Gamma_n, \alpha_n \vdash^? x : q, H_n \text{ succeeds}\}$.

LEMMA 57. *The relation R as defined above has the same properties of $A^{\mathbf{S}}$, e.g. if $\mathbf{S}=\mathbf{S4}$, that is $A^{\mathbf{S}}$ is transitive and reflexive, then so is R and the same happens in all other cases.*

Proof. Left to the reader. ■

LEMMA 58. *for all $x \in W$ and formulas B ,*

$$M, x \models B \Leftrightarrow \exists n x \in \text{Lab}(\Gamma_n) \wedge \Gamma_n, \alpha_n \vdash^? x : B, H_n \text{ succeeds}.$$

Proof. We prove both directions by mutual induction on $cp(B)$. If B is an atom then the claim holds by definition. Thus, assume $B = C \Rightarrow D$.

(\Leftarrow) Suppose for some m $\Gamma_m, \alpha_m \vdash^? x : C \Rightarrow D, H_m$ succeeds. Let xRy and $M, y \models C$, for some y . By definition of R , we have that for some n_1 , $A_{\alpha_{n_1}}^{\mathbf{S}}(x, y)$ holds. Moreover, by the induction hypothesis, for some n_2 , $\Gamma_{n_2}, \alpha_{n_2} \vdash^? y : C, H_{n_2}$ succeeds. Let $k = \max\{n_1, n_2, m\}$, then we have

1. $\Gamma_k, \alpha_k \vdash^? x : C \Rightarrow D, H_k$ succeeds,
2. $\Gamma_k, \alpha_k \vdash^? y : C, H_k$ succeeds,
3. $A_{\alpha_k}^{\mathbf{S}}(x, y)$.

So that from 1. we also have:

- 1'. $(\Gamma_k, \alpha_k) \oplus_x (z : C) \vdash^? z : D, H_k$ succeeds, (with $z \notin \text{Lab}(\Gamma_k) \cup \text{Lab}(H_k)$).

We can cut 1'. and 2., and obtain:

$$\Gamma_k, \alpha_k \cup \{(x, y)\} \vdash^? y : D, H_k \text{ succeeds}.$$

Hence, by 3. and Proposition 47(b) we get $\Gamma_k, \alpha_k \vdash^? y : D, H_k$ succeeds, and by the induction hypothesis, $M, y \models D$,

(\Rightarrow) Suppose by way of contradiction that $M, x \models C \Rightarrow D$, but for all n if $x \in \text{Lab}(\Gamma_n)$, then $\Gamma_n, \alpha_n \vdash^? x : C \Rightarrow D, H_n$ fails. Let $x \in \text{Lab}(\Gamma_n)$, then there are $m \geq k > n$, such that $(x, C \Rightarrow D) = (x_k, A_k) = (y_m, B_m)$ is considered at step $m + 1$, so that we have:

$$\Gamma_m, \alpha_m \vdash^? y_m : C \Rightarrow D, H_m \text{ fails.}$$

By Lemma 56, there is a $y \in \mathcal{A}$, such that (a) for $t \leq m$, $y \notin \text{Lab}(\Gamma_t)$ and (b): $\forall m' > m$ (i) $(y_n, y) \in \alpha_{m'}$, (ii) $\Gamma_{m'}, \alpha_{m'} \vdash^? y : C, H_{m'}$ succeeds, (iii) $\Gamma_{m'}, \alpha_{m'} \vdash^? y : D, H_{m'}$ fails.

By (i) we have xRy holds, by (ii) and the induction hypothesis, we have $M, y \models C$. By (a) and (iii), we get: $\forall n$ if $y \in \text{Lab}(\Gamma_n)$, then $\Gamma_n, \alpha_n \vdash^? y : D, H_n$ fails. Hence, by the induction hypothesis, we have $M, y \not\models D$, and we get a contradiction. ■

Proof of The Completeness Theorem, 52. We are now able to conclude the proof of the completeness theorem. Let $f(z) = z$, for every $z \in \text{Lab}(\Gamma_0)$, where $(\Gamma_0, \alpha_0) = (\Gamma, \alpha)$ is the original database. It is easy to see that f is a realization of (Γ, α) in M : if $A_\alpha^S(u, v)$ then $A_{\alpha_0}^S(u, v)$, hence $f(u)Rf(v)$. If $u : C \in \Gamma = \Gamma_0$, then by identity and the previous lemma we have $M, f(u) \models C$. On the other hand, by Lemma 55, and the previous lemma we have $M, f(x) \not\models A$ and $M, f(y) \not\models r$ for every $(y, r) \in H$. This concludes the proof. ■

By the previous theorem we immediately have the corollary.

COROLLARY 59. *If $A \models_S B$ holds, then $A \vdash^? x_0 : B, \emptyset$, succeeds in $P(\mathbf{S})$. In particular, if A is valid in the modal system \mathbf{S} , then $\vdash^? x_0 : A, \emptyset$, succeeds in $P(\mathbf{S})$.*

4.2 Simplification for specific systems

In this section we show that for most of the modal logics we have considered, the use of labelled databases is not necessary and we can simplify either the structure of databases, or the deduction rules.

If we want to check the validity of a formula A , we evaluate A from a trivial database $\vdash^? x_0 : A, \emptyset$. Restricting our attention to computations from trivial databases, we observe that we can only generate databases which have the form of trees.

DEFINITION 60. A database (Δ, α) is called a *tree-database* if the set of links α forms a tree.

Let (Δ, α) be a tree database and $x \in \text{Lab}(\Delta)$, we define the subdatabase $\text{Path}(\Delta, \alpha, x)$ as the *list* of labelled formulas lying on the path from the root

of α , say x_0 , up to x , that is: $Path(\Delta, \alpha, x) = (\Delta', \alpha')$, where:

$$\begin{aligned} \alpha' &= \{(x_0, x_1), (x_1, x_2), \dots, (x_{n-1}, x_n) \mid x_n = x \\ &\quad \text{and for } i = 1, \dots, n, (x_{i-1}, x_i) \in \alpha\} \\ \Delta' &= \{y : A \in \Delta \mid y \in Lab(\alpha')\}. \end{aligned}$$

PROPOSITION 61. *If a query Q occurs in any derivation from a trivial database, then $Q = \Delta, \alpha \vdash^? z : B, H$, where (Δ, α) is a tree-database.*

From now on we restrict our consideration to tree-databases.

*Simplification for **K**, **K4**, **S4**, **KT**: Databases as Lists*

For systems **K**, **K4**, **S4**, **KT** the proof procedure can be simplified in the sense that: (i) the databases are lists of formulas, (ii) the restart rule is not needed. The key fact is expressed by the following theorem.

THEOREM 62. *If $\Delta, \alpha \vdash^? x : A, \emptyset$ succeeds, then $Path(\Delta, \alpha, x) \vdash^? x : A, \emptyset$ succeeds without using restart.*

Intuitively, only the formulas laying on the path from the root to $x : A$ can be used in a proof of $\Delta, \alpha \vdash^? x : A, \emptyset$. The reason why restart is not needed is related: a restart step, say a restart from $x : q$, is useful only if we can take advantage of formulas at worlds created after the first call of $x : q$ by means of the evaluation of an implicational goal. But these new worlds (being new) do not lay on the path from the root to $x : q$, thus they can be ignored and so can the restart step.

By virtue of this theorem we can reformulate the proof system for logics from **K** to **S4** as follows. A database is simply a list of formulas A_1, \dots, A_n , which stands for the labelled database $(\{x_1 : A_1, \dots, x_n : A_n\}, \alpha)$, where $\alpha = \{(x_1, x_2), \dots, (x_{n-1}, x_n)\}$. A query has the form:

$$A_1, \dots, A_n \vdash^? B$$

which represents $\{x_1 : A_1, \dots, x_n : A_n\}, \alpha \vdash^? x_n : B$. The history has been omitted since restart is not needed. Letting $\Delta = A_1, \dots, A_n$, we reformulate the predicates A^S as relations between formulas within a database $A^S(\Delta, A_i, A_j)$, in particular we can define:

$$\begin{aligned} A^K(\Delta, A_i, A_j) &\equiv i + 1 = j \\ A^{KT}(\Delta, A_i, A_j) &\equiv i = j \vee i + 1 = j \\ A^{K4}(\Delta, A_i, A_j) &\equiv i < j \\ A^{S4}(\Delta, A_i, A_j) &\equiv i \leq j \end{aligned}$$

The rules become:

- (success) $\Delta \vdash^? q$ succeeds if $\Delta = A_1, \dots, A_n$, and $A_n = q$;

- (implication) from $\Delta \vdash^? A \Rightarrow B$ step to $\Delta, A \vdash^? B$;
- (reduction) from $\Delta \vdash^? q$ step to $\Delta_i \vdash^? D_i$, for $i = 1, \dots, k$,
if there is a formula $A_j = D_1 \Rightarrow \dots \Rightarrow D_k \Rightarrow q \in \Delta$, and there are integers $j = j_0 \leq j_1 \leq \dots \leq j_k = n$, such that

$$i = 1, \dots, k, A^{\mathbf{S}}(\Delta, A_{j_{i-1}}, A_{j_i}) \text{ holds and } \Delta_i = A_1, \dots, A_{j_i}.$$

EXAMPLE 63. We show that $((b \Rightarrow a) \Rightarrow b) \Rightarrow c \Rightarrow (b \Rightarrow a) \Rightarrow a$ is a theorem of **S4**.

$$\begin{array}{rcl} & \vdash^? & ((b \Rightarrow a) \Rightarrow b) \Rightarrow c \Rightarrow (b \Rightarrow a) \Rightarrow a \\ (b \Rightarrow a) \Rightarrow b & \vdash^? & c \Rightarrow (b \Rightarrow a) \Rightarrow a \\ (b \Rightarrow a) \Rightarrow b, c & \vdash^? & (b \Rightarrow a) \Rightarrow a \\ (b \Rightarrow a) \Rightarrow b, c, b \Rightarrow a & \vdash^? & a \text{ reduction w.r.t. } b \Rightarrow a \text{ (1)} \\ (b \Rightarrow a) \Rightarrow b, c, b \Rightarrow a & \vdash^? & b \text{ reduction w.r.t. } (b \Rightarrow a) \Rightarrow b \text{ (2)} \\ (b \Rightarrow a) \Rightarrow b, c, b \Rightarrow a & \vdash^? & b \Rightarrow a \\ (b \Rightarrow a) \Rightarrow b, c, b \Rightarrow a, b & \vdash^? & a \text{ reduction w.r.t. } b \Rightarrow a \\ (b \Rightarrow a) \Rightarrow b, c, b \Rightarrow a, b & \vdash^? & b. \end{array}$$

This formula fails in both **KT** and **K4**, and therefore also fails in **K**: reduction at step (1) is allowed in **KT** but not in **K4**; on the contrary, reduction at step (2) is allowed in **K4** but not in **KT**.

Simplification for K5, K45, S5: Databases as Clusters

We can also give an unlabelled formulation of logics **K5**, **K45**, **S5**. The simplification is allowed by the fact that we can define explicitly the accessibility relation.

PROPOSITION 64. Let $Q = \Delta, \alpha \vdash^? x : G, H$ be any query which occurs in a $P(\mathbf{K5})$ deduction from a trivial database $x_0 : A \vdash^? x_0 : B, H_0$. Let $R_\alpha^{\mathbf{K5}}(x, y)$ be defined as follows:

$$\begin{aligned} R_\alpha^{\mathbf{K5}}(x, y) \equiv & (x = x_0 \wedge (x_0, y) \in \alpha) \\ & \vee (\{x, y\} \subseteq \text{Lab}(\alpha) \wedge x \neq x_0 \wedge y \neq x_0). \end{aligned}$$

Then we have $R_\alpha^{\mathbf{K5}}(x, y) \equiv A_\alpha^{\mathbf{K5}}(x, y)$.

COROLLARY 65. Under the same conditions as the last proposition, we have:

$$R_\alpha^{\mathbf{K5}}(x_0, x) \text{ and } R_\alpha^{\mathbf{K5}}(x_0, y) \text{ implies } x = y.$$

PROPOSITION 66. Let $Q = \Delta, \alpha \vdash^? x : G, H$ be any query which occurs in a $P(\mathbf{K45})$ deduction from a trivial database $x_0 : A \vdash^? x_0 : B, H_0$. Let $R_\alpha^{\mathbf{K45}}(x, y)$ be defined as follows:

$$R_{\alpha}^{\mathbf{K45}}(x, y) \equiv \{x, y\} \subseteq \text{Lab}(\alpha) \wedge y \neq x_0.$$

Then we have $R_{\alpha}^{\mathbf{K45}}(x, y) \equiv A_{\alpha}^{\mathbf{K45}}(x, y)$.

PROPOSITION 67. *Let $Q = \Delta, \alpha \vdash^? x : G, H$ be any query which occurs in a $P(\mathbf{S5})$ deduction from a trivial database $x_0 : A \vdash^? x_0 : B, H_0$. Let $R_{\alpha}^{\mathbf{S5}}(x, y)$ be defined as follows:*

$$R_{\alpha}^{\mathbf{S5}}(x, y) \equiv \{x, y\} \subseteq \text{Lab}(\alpha).$$

Then we have $R_{\alpha}^{\mathbf{S5}}(x, y) \equiv A_{\alpha}^{\mathbf{S5}}(x, y)$.

From the previous propositions we can reformulate the proof systems for **K5**, **K45** and **S5** without making use of labels. For **K5** the picture is as follows: either a database contains just one point x_0 , or there is an initial point x_0 which is connected to another point x_1 , and any point excluding x_0 is connected to any other. In the case of **K45**, x_0 is connected also to any point other than itself. Thus, in order to get a concrete structure without labels we must keep distinct the initial world from all the others, and we must indicate what is the current world, that is the world in which the goal formula is evaluated. In case of **K5** we must also identify the (only) world to which the initial world is connected. We are thus led to consider the following structure.

A non-empty database has the form:

$$\Delta = B_0 \mid \mid \quad \text{or} \quad \Delta = B_0 \mid B_1, \dots, B_n \mid B_i, \text{ where } 1 \leq i \leq n,$$

and B_0, B_1, \dots, B_n are formulas. We also define

$$\text{Actual}(\Delta) = \begin{cases} B_0 & \text{if } \Delta = B_0 \mid \mid, \\ B_i & \text{if } \Delta = B_0 \mid B_1, \dots, B_n \mid B_i. \end{cases}$$

This rather odd structure is forced by the fact that in **K5** and **K45** we have reflexivity in all worlds, except in the initial one and therefore, in contrast to all other systems, we have considered so far, the success of

$$\vdash^? x_0 : A \Rightarrow B, \text{ which means that } A \Rightarrow B \text{ is valid,}$$

does not imply the success of

$$x_0 : A \vdash^? x_0 : B, \text{ which means that } A \rightarrow B \text{ is valid (material implication).}^{12}$$

The addition operation is defined as follows:

$$\Delta \oplus A = \begin{cases} B_0 \mid B_1, \dots, B_n, A \mid A & \text{if } \Delta = B_0 \mid B_1, \dots, B_n \mid B_i \\ B_0 \mid A \mid A & \text{if } \Delta = B_0 \mid \mid \\ \top \mid A \mid A & \text{if } \Delta = \emptyset \end{cases}$$

¹²In these two systems the validity of $\Box C$ does not imply the validity of C , as it holds for all the other systems considered in this section.

A query has the form

$$\Delta \vdash^? G, H, \text{ where } H = \{(A_1, q_1), \dots, (A_k, q_k)\}, \text{ with } A_j \in \Delta.$$

DEFINITION 68 (Deduction Rules for **K5** and **K45**).

Given $\Delta = B_0 \mid B_1, \dots, B_n \mid B$, let

$$\begin{aligned} A^{\mathbf{K5}}(\Delta, X, Y) &\equiv (X = B_0 \wedge Y = B_1) \\ &\quad \vee (X = B_i \wedge Y = B_j \wedge i, j > 0) \text{ and} \\ A^{\mathbf{K45}}(\Delta, X, Y) &\equiv (X = B_i \wedge Y = B_j \text{ with } j > 0) \end{aligned}$$

- (success) $\Delta \vdash^? q, H$ succeeds if $Actual(\Delta) = q$.
- (implication) From $\Delta \vdash^? A \Rightarrow B, H$ step to $\Delta \oplus A \vdash^? B, H$.
- (reduction) if $\Delta = B_0 \mid B_1, \dots, B_n \mid B$ and $C = D_1 \Rightarrow \dots \Rightarrow D_k \Rightarrow q \in \Delta$, from $\Delta \vdash^? G, H$ step to

$$B_0 \mid B_1, \dots, B_n \mid C_i \vdash^? D_i, H \cup \{(B, q)\} \text{ for } i = 1, \dots, k,$$

for some $C_0, \dots, C_k \in \Delta$, such that $C_0 = C$, $C_k = B_n$, and $A^{\mathbf{K5}}(\Delta, C_{i-1}, C_i)$ (respectively $A^{\mathbf{K45}}(\Delta, C_{i-1}, C_i)$) holds.

- (restart) If $\Delta = B_0 \mid B_1, \dots, B_n \mid B_i$ and $(B_j, r) \in H$, with $j > 0$, then from $\Delta \vdash^? q, H$, step to

$$B_0 \mid B_1, \dots, B_n \mid B_j \vdash^? r, H \cup \{(B_i, q)\},$$

According to the above discussion, we observe that the check of the validity of $\models A \Rightarrow B$, corresponds to the query

$$\emptyset \vdash^? A \Rightarrow B, \emptyset,$$

which (by the implication rule) is reduced to the query

$$\top \mid A \mid A \vdash^? B, \emptyset.$$

This is different from checking the validity of $A \rightarrow B$ (\rightarrow is the material implication), which corresponds to the query

$$A \mid \mid \vdash^? B, \emptyset.$$

The success of the former query does not imply the success of the latter. For instance in **K5**,

$$\not\models (\top \Rightarrow p) \rightarrow p \text{ and indeed } \top \Rightarrow p \mid \mid \vdash^? p, \emptyset \text{ fails.}$$

On the other hand we have

$\models (\top \Rightarrow p) \Rightarrow p$ and indeed $\top \mid \top \Rightarrow p \mid \top \Rightarrow p \vdash^? p, \emptyset$ succeeds.

The reformulation of the proof system for **S5** is similar, but simpler. In the case of **S5**, there is no need to keep the first formula/world apart from the others. Thus, we may simply define a non-empty database as a pair $\Delta = (S, A)$, where S is a set of formulas and $A \in S$. If $\Delta = (S, A)$, we let

$$Actual(\Delta) = A \text{ and } \Delta \oplus B = (S \cup \{B\}, B).$$

For $\Delta = \emptyset$, we define $\emptyset \oplus A = (\{A\}, A)$. With these definitions the rules are similar to those of **K5** and **K45**, with the following simplifications:

- (reduction) if $\Delta = (S, B)$ and $C = D_1 \Rightarrow \dots \Rightarrow D_k \Rightarrow q \in \Delta$, then from $\Delta \vdash^? G, H$ step to

$$(S, C_i) \vdash^? D_i, H \cup \{(B, q)\}, \text{ where for } i = 1, \dots, k \ C_i \in \Delta \text{ and } C_k = B.$$

- (restart) If $\Delta = (S, B)$ and $(C, r) \in H$, then from $(S, B) \vdash^? q, H$, step to

$$(S, C) \vdash^? r, H \cup \{(B, q)\},$$

EXAMPLE 69. In Figure 6 we show a derivation of the following formula in **S5**

$$((a \Rightarrow b) \Rightarrow c) \Rightarrow (a \Rightarrow d \Rightarrow c) \Rightarrow (d \Rightarrow c).$$

In the derivation we make use of restricted restart, according to Proposition 41. A brief explanation of the derivation: step (5) is obtained by reduction w.r.t. $(a \Rightarrow b) \Rightarrow c$, step (7) by restart, steps (8) and (9) by reduction w.r.t. $a \Rightarrow d \Rightarrow c$, and they both succeed immediately.

4.3 Extending the language

In this section we extend the proof procedures to broader fragments. We first consider a simple extension allowing conjunction. To handle conjunction in the labelled formulation, we simply drop the condition that a label x may be attached to only one formula, thus formulas with the same label can be thought as logically conjuncted. In the unlabelled formulation, for those systems enjoying such a formulation, the general principle is to deal with *sets* of formulas, instead of *single formulas*. A database will be a structured collection of *sets* of formulas, rather than a collection of formulas. The structure is always the same, but the constituents are now sets. Thus, in the cases of **K**, **KT**, **K4** and **S4**, databases will be lists of *sets* of formulas,

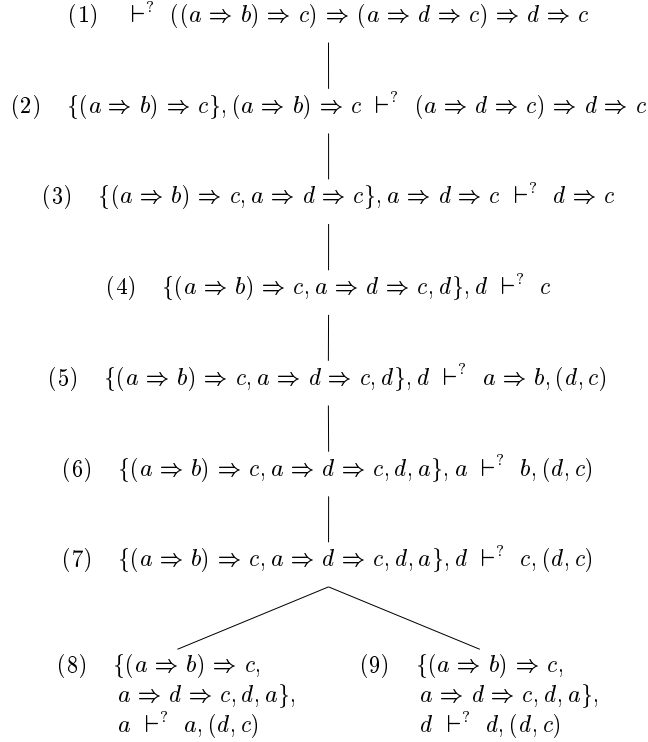

Figure 6. Derivation for Example 69.

whereas in the cases of **K5**, **K45** and **S5**, they will be clusters of *sets* of formulas.

A conjunction of formulas is interpreted as a set, so that queries may contain *sets* of goal formulas.

A formula A of language $\mathcal{L}(\wedge, \Rightarrow)$ is in *normal form* if it is an atom or has form:

$$\bigwedge_i [S_1^i \Rightarrow \dots \Rightarrow S_{n_i}^i \Rightarrow q_i]$$

where S_j^i are conjunctions of formulas in *normal form*. In all modal logics considered in this section (formulated $\mathcal{L}(\wedge, \Rightarrow)$) it holds that every formula has an equivalent one in normal form.

We simplify the notation for NF formulas and replace conjunctions with sets. For example the NF of $(b \Rightarrow (c \wedge d)) \Rightarrow (e \wedge f) \wedge ((g \wedge h) \Rightarrow (k \wedge u))$ is the set containing the following formulas:

$$\{b \Rightarrow c, b \Rightarrow d\} \Rightarrow e, \{b \Rightarrow c, b \Rightarrow d\} \Rightarrow f, \{g, h\} \Rightarrow k, \{g, h\} \Rightarrow u.$$

For the deduction procedures all we have to do is to handle sets of formulas. We define, for $x \in \text{Lab}(\Gamma) \cup \text{Lab}(H)$, $y \notin \text{Lab}(\Gamma) \cup \text{Lab}(H)$ and finite set of formulas $S = \{D_1, \dots, D_t\}$,

$$(\Gamma, \alpha) \oplus_x y : S = (\Delta \cup \{y : D_1, \dots, y : D_t\}, \alpha \cup \{(x, y)\}),$$

then we change the (*implication*) rule in the obvious way:

$$\text{from } \Delta, \alpha \vdash^? x : S \Rightarrow B, H,$$

step to

$$(\Delta, \alpha) \oplus_x y : S \vdash^? y : B, H,$$

where S is a set of formulas in NF and $y \notin \text{Lab}(\Gamma)$, and we add a rule for proving sets of formulas:

$$\text{from } (\Delta, \alpha) \vdash^? x : \{B_1, \dots, B_k\}, H$$

step to

$$(\Delta, \alpha) \vdash^? x : B_i, H \text{ for } i = 1, \dots, k.$$

Regarding the simplified formulations without labels, the structural restrictions in the rules (reduction and success) are applied to the sets of formulas, which are now the constituents of databases, considered as units; the history H , when needed, becomes a set of pairs (S_i, A_i) , where S_i is a set and A_i is a formula. The property of restricted restart still holds for this formulation.

We can extend further extend the $\mathcal{L}(\Rightarrow, \wedge)$ -fragment in two directions. In one direction, we can define a modal analogue of Harrop formulas for intuitionistic logic that we have introduced in Section 3.7. This extension is relevant for logic programming applications [Giordano *et al.*, 1992; Giordano and Martelli, 1994]. In the other direction, we can define a proof system for the whole propositional modal language via a translation into an implicative normal form.

Modal Harrop formulas

We can define a modal analogue of Harrop formulas by allowing disjunction of goals and *local clauses* of the form

$$G \rightarrow q,$$

where \rightarrow denotes ordinary (material) implication. We call them ‘local’, since $x : G \rightarrow q$ can be used only in world x to reduce the goal $x : q$ and it is not usable/visible in any other world. It is ‘private’ to x , whereas the ‘global’ clause $G \Rightarrow q$ can be used to reduce q in any world y accessible from x . It is not a case that modalities have been used to implement visibility rules and structuring mechanisms in logic programming [Giordano *et al.*, 1992;

Giordano and Martelli, 1994]. In order to define a modal Harrop fragment we distinguish D-formulas, which are the constituents of databases, and G-formulas which can occur as goals. The former are further distinct in *modal* D-formulas (MD) and *local* D-formulas (LD).

$$\begin{aligned}
LD &:= G \rightarrow q, \\
MD &:= \top \mid q \mid G \Rightarrow MD, \\
D &:= LD \mid MD, \\
CD &:= D \mid CD \wedge CD; \\
G &:= \top \mid q \mid G \wedge G \mid G \vee G \mid CD \Rightarrow G.
\end{aligned}$$

We also use $\Box G$ and $\Box D$ as syntactic sugar for $\top \Rightarrow G$ and $\top \Rightarrow D$. Notice that atoms are both LD- and MD-formulas (as $\top \rightarrow q \equiv q$); moreover, any non-atomic MD-formula can be written as $G_1 \Rightarrow \dots \Rightarrow G_k \Rightarrow q$. Finally, CD formulas are just conjunction of D-formulas.

For D- and G-formulas as defined above we can easily extend the proof procedure. We give it in the most general formulation for labelled databases. It is clear that one can derive an unlabelled formulation for systems which allow it, as explained in the previous section. In the labelled formulation, queries have the form

$$\Delta, \alpha \vdash^? x : G, H$$

where Δ is a set of D-formulas, G is a G-formula, and $H = \{(x_1, G_1), \dots, (x_k, G_k)\}$, where G_i are G-formulas. The **additional** rules are:

- (true) $\Delta, \alpha \vdash^? x : \top, H$ immediately succeeds.
- (local-reduction) From $\Delta, \alpha \vdash^? x : q, H$ step to
$$\Delta, \alpha \vdash^? x : G, H \cup \{(x : q)\}$$
if $x : G \rightarrow q \in \Delta$.
- (and) From $\Delta, \alpha \vdash^? x : G_1 \wedge G_2, H$ step to
$$\Delta, \alpha \vdash^? x : G_1, H \text{ and } \Delta, \alpha \vdash^? x : G_2, H.$$
- (or) From $\Delta, \alpha \vdash^? x : G_1 \vee G_2, H$ step to
$$\Delta, \alpha \vdash^? x : G_1, H \cup \{(x, G_2)\} \text{ or to } \Delta, \alpha \vdash^? x : G_2, H \cup \{(x, G_1)\}.$$

EXAMPLE 70. Let Δ be the following database

$$\begin{aligned}
x_0 &: [(\Box p \Rightarrow s) \wedge b] \rightarrow q, \\
x_0 &: ((p \Rightarrow q) \wedge \Box a] \Rightarrow r) \rightarrow q, \\
x_0 &: a \rightarrow b.
\end{aligned}$$

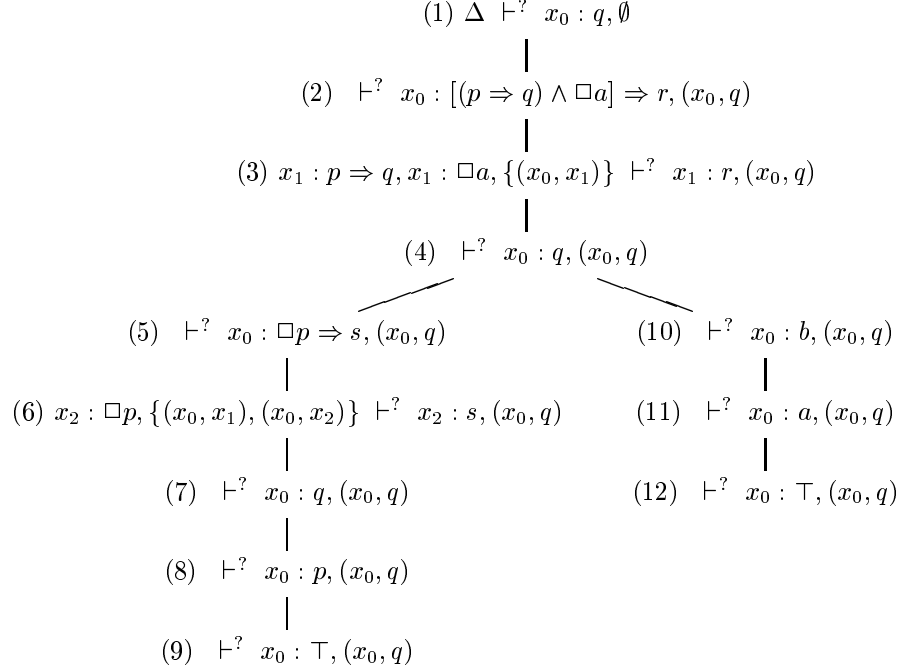

Figure 7. Derivation for Example 70.

We show that $\Delta, \emptyset \vdash^? x_0 : q, \emptyset$ succeeds in the proof system for **KB** and this shows that the formula

$\bigwedge \Delta \rightarrow q$ is valid in **KB**.

A derivation is shown in Figure 7. The property of restricted restart still holds for this fragment, thus we do not need to record the entire history, but only the first pair (x_0, q) . At each step we only show the additional data introduced in that step. A quick explanation of the steps: step (2) is obtained by local reduction w.r.t. $x_0 : [(p \Rightarrow q) \wedge \Box a] \Rightarrow r \rightarrow q$, step (4) by restart, steps (5) and (10) by local reduction w.r.t. $x_0 : [(\Box p \Rightarrow s) \wedge b] \rightarrow q$, step (7) by restart, step (8) by reduction w.r.t. $x_1 : p \Rightarrow q$ since letting $\alpha = \{(x_0, x_1), (x_0, x_2)\}$ $A_\alpha^{\mathbf{KB}}(x_1, x_0)$ holds; step (9) is obtained by reduction w.r.t. $x_2 : \Box p (= \top \Rightarrow p)$ since $R_\alpha^{\mathbf{KB}}(x_2, x_0)$ holds, step (11) by local reduction w.r.t. $x_0 : a \rightarrow b$, step (12) by reduction w.r.t. $x_1 : \Box a (= \top \Rightarrow a)$ since $R_\alpha^{\mathbf{KB}}(x_1, x_0)$ holds.

The soundness and completeness results can be extended to this fragment.

THEOREM 71. $\Delta \vdash^? G, H$ succeeds in $P(\mathbf{S})$ if and only if it is valid.

Extension to the whole propositional language

We can easily extend the procedure to the whole propositional modal language: we just consider the computation procedure for classical logic and we combine it with the modal procedure for $\mathcal{L}(\Rightarrow, \wedge)$. To minimize the work, we can introduce a simple normal form on the set of connectives $(\Rightarrow, \rightarrow, \wedge, \top, \perp)$. It is obvious that this set forms a complete base for modal logic. The normal form is an immediate extension of the normal form for \Rightarrow, \wedge .

PROPOSITION 72. *Every modal formula over the language $(\rightarrow, \neg, \diamond, \square)$ is equivalent to a set (conjunction) of NF-formulas of the form*

$$S_0 \rightarrow (S_1 \Rightarrow (S_2 \Rightarrow \dots \Rightarrow (S_n \Rightarrow q) \dots))$$

where q is an atom, \top , or \perp , $n \geq 0$, and each S_i is a conjunction (set) of NF-formulas.

As usual we omit parentheses, so that the above will be written as

$$S_0 \rightarrow S_1 \Rightarrow S_2 \Rightarrow \dots \Rightarrow S_n \Rightarrow q.$$

In practice we will replace the conjunction by the set notation as we wish. When we need it, we distinguish two types of NF-formulas, (i) those with non-empty S_0 , which are written as above, and (ii) those with empty S_0 , which are simplified to $S_1 \Rightarrow S_2 \Rightarrow \dots \Rightarrow S_n \Rightarrow q$. For a quick case analysis, we can also say that type (i) formulas have the form $S \rightarrow D$, and type (ii) have the form $S \Rightarrow D$, where D is always of type (ii).

For instance, the NF-form of $p \rightarrow \diamond r$ is

$$(p \wedge (r \Rightarrow \perp)) \rightarrow \perp, \text{ or equivalently } \{p, r \Rightarrow \perp\} \rightarrow \perp.$$

This formula has the structure $S_0 \rightarrow q$, where $S_0 = \{p, r \Rightarrow \perp\}$ and $q = \perp$. The NF-form of $\square(\diamond a \rightarrow \diamond(b \wedge c))$ is given by $((a \Rightarrow \perp) \rightarrow \perp) \Rightarrow ((b \wedge c) \Rightarrow \perp) \Rightarrow \perp$. We give below the rules for queries of the form

$$\Gamma, \alpha \vdash^? x : G, H,$$

where Γ is a labelled set of NF-formulas, G is a NF-formula, α is a set of links (as usual), H is a set of pairs $\{(x_1, q_1), \dots, (x_k, q_k)\}$, where q_i is an atom.

DEFINITION 73 (Deduction rules for whole modal logics). For each modal system \mathbf{S} , the corresponding proof system, denoted by $\mathbf{P}(\mathbf{S})$, comprises the following rules, parametrized to predicates $A^{\mathbf{S}}$.

- (success) $\Delta, \alpha \vdash^? x : q, H$ immediately succeeds if q is an atom and $x : q \in \Delta$.
- (strict implication) From $\Delta, \alpha \vdash^? x : S \Rightarrow D, H$ step to

$$(\Delta, \alpha) \oplus_x (y : S) \vdash^? y : D, H,$$

where $y \notin \text{Lab}(\Delta) \cup \text{Lab}(H)$.

- (implication) From $\Delta, \alpha \vdash^? x : S \rightarrow D, H$ step to

$$\Delta \cup \{x : A \mid A \in S\}, \alpha \vdash^? x : D, H.$$

- (reduction) If $y : C \in \Delta$, with $C = S_0 \rightarrow S_1 \Rightarrow S_2 \Rightarrow \dots \Rightarrow S_k \Rightarrow q$, with q atomic, then from

$$\Delta, \alpha \vdash^? x : q, H$$

step to

$$\begin{aligned} \Delta, \alpha \vdash^? u_0 : S_0, H' \\ \Delta, \alpha \vdash^? u_1 : S_1, H' \\ \vdots \\ \Delta, \alpha \vdash^? u_k : S_k, H' \end{aligned}$$

where $H' = H$ if $q = \perp$, and $H' = H \cup \{(x, q)\}$ otherwise, for some $u_0, \dots, u_k \in \text{Lab}(\alpha)$, such that $u_0 = y$, $u_k = x$, and

$$A_\alpha^S(u_i, u_{i+1}) \text{ holds, for } i = 0, \dots, k-1.$$

- (restart) If $(y, r) \in H$, then, from $\Delta, \alpha \vdash^? x : q, H$, with q atomic, step to

$$\Delta, \alpha \vdash^? y : r, H \cup \{(x, q)\}.$$

- (falsity) From $\Delta, \alpha \vdash^? x : q, H$, if $y \in \text{Lab}(\Gamma)$ step to

$$\Delta, \alpha \vdash^? y : \perp, H \cup \{(x : q)\}.$$

- (conjunction) From $(\Delta, \alpha) \vdash^? x : \{B_1, \dots, B_k\}, H$ step to

$$(\Delta, \alpha) \vdash^? x : B_i, H \text{ for } i = 1, \dots, k.$$

If the number of subgoals is 0, i.e. $k = 0$, the above reduction rule becomes the rule for *local clauses* of the previous section. On the other hand if $S_0 = \emptyset$, then the query with goal S_0 is omitted and we have the rule of Section 4.1.

The proof procedure is sound and complete, as asserted in the next theorem, and the completeness proof is just a minor extension of the one of Theorem 52.

THEOREM 74. $\Gamma, \gamma \vdash^? x : G, H$ succeeds if and only if it is valid.

EXAMPLE 75. In **K5** we have $\diamond p \rightarrow \square \diamond p$. This is translated as $((p \Rightarrow \perp) \rightarrow \perp) \rightarrow ((p \Rightarrow \perp) \Rightarrow \perp)$. Below we show a derivation. Some

explanation and remarks: at step (1) we can only apply the rule for falsity, or reduction w.r.t. $y : p \Rightarrow \perp$, since $A_\alpha^{\mathbf{K5}}(x_0, y)$ implies $A_\alpha^{\mathbf{K5}}(y, y)$. We apply the rule for falsity. The reduction at step (2) is legitimate as $A_\alpha^{\mathbf{K5}}(x_0, y)$ and $A_\alpha^{\mathbf{K5}}(x_0, z)$ implies $A_\alpha^{\mathbf{K5}}(y, z)$.

$$\begin{array}{lcl}
& \vdash^? x_0 : ((p \Rightarrow \perp) \rightarrow \perp) \rightarrow ((p \Rightarrow \perp) \Rightarrow \perp) & \\
x_0 : (p \Rightarrow \perp) \rightarrow \perp & \vdash^? x_0 : (p \Rightarrow \perp) \Rightarrow \perp & \\
y : p \Rightarrow \perp, \alpha = \{(x_0, y)\} & \vdash^? y : \perp & (1) \\
& \vdash^? x_0 : \perp \quad \text{rule for } \perp & \\
& \vdash^? x_0 : p \Rightarrow \perp & \\
z : p, \alpha = \{(x_0, y), (x_0, z)\} & \vdash^? z : \perp & (2) \\
& \vdash^? z : p & \\
& \text{success} &
\end{array}$$

This proof procedure is actually a minor extension of the one based on strict-implication/conjunction. The rule for falsity may be source of non-determinism, as it can be applied to any label y . Further investigation should clarify to what extent this rule is needed and if it is possible to restrict its applications to special cases. Another point which deserve investigation is *termination*. The proof procedure we have described may not terminate. The two standard techniques to ensure termination, loop-checking and diminishing-resources, could be possibly applied in this context. Again further investigation is needed to clarify this point, taking into account the known results (see [Viganò, 1999; Heudering *et al.*, 1996]).

4.4 Some history

Many authors have developed analytic proof methods for modal logics, (see the fundamental book by Fitting [1983], and Goré [1999] for a recent and comprehensive survey).

The use of goal-directed methods in modal logic has not been fully explored. The most relevant work in this area is the one by Giordano, Martelli and colleagues [Giordano *et al.*, 1992; Giordano and Martelli, 1994; Baldoni *et al.*, 1998] who have developed goal-directed methods for fragments of first-order (multi-)modal logics. Their work is motivated by several purposes: introducing scoping constructs (such as blocks and modules) in logic programming, representing epistemic and inheritance reasoning. In particular in [Giordano and Martelli, 1994] a family of first-order logic programming languages is defined, based on the modal logic **S4** with the aim of representing a variety of scoping mechanisms. If we restrict our consideration to the propositional level, their languages are strongly related to the one defined in Section 4.3 in the case the underlying logic is **S4**. The largest (propositional) fragment of **S4** they consider, called L_4 , is very close

to the one defined in the previous Section for modal-Harrop formulas, although neither one of the two is contained in the other. The proof procedure they give for L_4 (at the propositional level) is essentially the same as the unlabelled version of P(**S4**) for modal Harrop formulas.

Abadi and Manna [1989] have defined an extension of PROLOG, called *TEMPLOG* based on a fragment of first-order temporal logic. Their language contains the modalities \diamond , \square , and the temporal operator \bigcirc (next). They introduce a notion of temporal Horn clause whose constituents are atoms B possibly prefixed by an arbitrary sequence of next, i.e. $B \equiv \bigcirc^k A$ (with $k \geq 0$). The modality \square is allowed in front of clauses (permanent clauses) and clause-heads, whereas the modality \diamond is allowed in front of goals. The restricted format of the rules allows one to define an efficient and simple goal-directed procedure without the need of any syntactic structuring or labelling. An alternative, although related, extension based on temporal logic has been studied in [Gabbay, 1987].

Farinàs in [1986] describes MOLOG a (multi)-modal extension of PROLOG. His proposal is more a general framework than a specific language, in the sense that the language can support different modalities governed by different logics. The underlying idea is to extend classical resolution by special rules of the following pattern: let B, B' be modal atoms (i.e. atomic formulas possibly prefixed by modal operators), then if $G \rightarrow B$ is a clause and $B' \wedge C_1 \wedge \dots \wedge C_k$ is the current goal, and

$$(*) \models_{\mathbf{S}} B \equiv B' \text{ holds}$$

then the goal can be reduced to $G \wedge C_1 \wedge \dots \wedge C_k$. It is clear that the effectiveness of the method depends on how difficult it is to check (*); in case of conventional logic programming the (*) test is reduced to unification. The proposed framework is exemplified in [Farinàs, 1986] by defining a multi-modal language based on **S5** with necessity operators such as *Knows*(a). In this case one can define a simple matching predicate for the test in (*), and hence an effective resolution rule.

In general, we can distinguish two paradigms in proof systems for modal logics: on the one hand we have *implicit* calculi in which each proof configuration contains a set of formulas implicitly representing a single possible world; the modal rules encodes the shifts of world by manipulating sets of formulas and formulas therein. On the other hand we have explicit methods in which the possible world structure is explicitly represented using labels and relations among them; the rules can create new worlds, or move formulas around them. In between there are ‘intermediate’ proof methods which add some semantic structure to flat sequents, but they do not explicitly represent a Kripke model [Masini, 1992; Wansing, 1994; Goré, 1999].

The use of labels to represent worlds for modal logics is rather old and goes back to Kripke himself. In the seminal work [Fitting, 1983] formulas

are labelled by strings of atomic labels (world prefixes), which represent paths of accessible worlds. The rules for modalities are the same for every system: for instance if a branch contains $\sigma : \Box A$, and σ' is accessible from σ , then one can add $\sigma' : A$ to the same branch. For each system, there are some specific accessibility conditions on prefixes which constraint the propagation of modal formulas. This approach has been recently improved by Massacci [1994]. Basin, Matthews and Viganò have developed a proof-theory for modal logics making use of labels and an explicit accessibility relation [Basin *et al.*, 1997a; Basin *et al.*, 1999; Viganò, 1999]. A related approach was presented in [Gabbay, 1996] and [Russo, 1996]. These authors have developed both sequent and natural deduction systems for several modal logics which are completely uniform.

If we forget the goal-directed feature the proof methods presented in this section clearly belongs to the ‘explicit’-calculi tradition in their labelled version, and to the ‘intermediate’-calculi tradition calculi in their unlabelled version. The sequence of (sets of) formulas represent a sequence of possible worlds. It is not a case that the unlabelled version of \mathbf{K} is strongly related to the two-dimensional sequent calculus by Masini [1992].

5 SUBSTRUCTURAL LOGICS

5.1 Introduction

In this section we consider substructural logics. The denomination *substructural logics* comes from sequent calculi terminology. In sequent calculi, there are rules which introduce logical operators and rules which modify the structure of sequents. The latter are called the *structural rules*. In case of classical and intuitionistic logic these rules are *contraction*, *weakening* and *exchange*. Substructural logics restrict or allow a finer control on structural rules. More generally, substructural logics restricts *the use* of formulas in a deduction. The restrictions may require either that every formula of the database must be used, or that it cannot be used more than once, or that it must be used according to a given ordering of database formulas.

We present the systems of substructural logics, restricted to their implicational fragment, by means of a Hilbert axiomatization and a possible-world semantics.

DEFINITION 76 (Axiomatization of implication). We consider the following list of axioms:

- (id) $A \rightarrow A$;
- (h1) $(B \rightarrow C) \rightarrow (A \rightarrow B) \rightarrow A \rightarrow C$;
- (h2) $(A \rightarrow B) \rightarrow (B \rightarrow C) \rightarrow A \rightarrow C$;

- (h3) $(A \rightarrow A \rightarrow B) \rightarrow A \rightarrow B$;
 (h4) $(A \rightarrow B) \rightarrow ((A \rightarrow B) \rightarrow C) \rightarrow C$;
 (h5) $A \rightarrow (A \rightarrow B) \rightarrow B$;
 (h6) $A \rightarrow B \rightarrow B$.

Together with the following rules:

$$\frac{A \rightarrow B \quad A}{B} (MP)$$

$$\frac{A \rightarrow B}{(B \rightarrow C) \rightarrow A \rightarrow C} (Suff).$$

Each system is axiomatized by taking the closure under modus ponens (MP) and under substitution of the combinations of axioms/rules of Table 3.

Table 3. Axioms for substructural implication.

Logic	Axioms
FL	(id), (h1), (<i>Suff</i>)
T-W	(id), (h1), (h2)
T	(id), (h1), (h2), (h3)
E-W	(id), (h1), (h2), (h4)
E	(id), (h1), (h2), (h3), (h4)
L	(id), (h1), (h2), (h5)
R	(id), (h1), (h2), (h3), (h5)
BCK	(id), (h1), (h2), (h5), (h6)
I	(id), (h1), (h2), (h3), (h5), (h6)

In the above axiomatization, we have not worried about the minimality and independence of the group of axioms for each system. For some systems the corresponding list of axioms given above is redundant, but it quickly shows some inclusion relations among the systems. We just remark that in presence of (h4), (h2) can be obtained by (h1). Moreover, (h4) is a weakening of (h5). The rule of (*Suff*) is clearly obtainable from (h2) and (MP). To have a complete picture we have included also intuitionistic logic **I**, although the axiomatization above is highly redundant (see Section 3.1).

We give a brief explanation of the names of the systems and how they are known in the literature.¹³ **R** is the most important system of *relevant*

¹³The names **R**, **E**, **T**, **BCK**, etc. in this section refer mainly to *the implicative fragment* of the logical systems known in the literature [Anderson and Belnap, 1975]

logic and it is axiomatized by dropping the irrelevant axiom (h6) from the axiomatization of intuitionistic implication.

The system **E** combines relevance and necessity. The implication of **E** can be read at the same time as relevant implication and strict implication. Moreover, we can define

$$\Box A =_{def} (A \rightarrow A) \rightarrow A,$$

and **E** interprets \Box the same as **S4**. **E** is axiomatized by restricting the exchange axiom (h5) to implicational formulas (the axiom (h4)).

The weaker **T** stems from a concern about the use of the two hypotheses in an inference by Modus Ponens: the restriction is that the minor A must not be derived ‘before’ the ticket $A \rightarrow B$. This is clarified by the Fitch-style natural deduction of **T**, for which we refer to [Anderson and Belnap, 1975].

BCK is the system which result from intuitionistic implicational logic by dropping contraction. **L** rejects both weakening and contraction and it is the implicational fragment of linear logic [Girard, 1987] (also commonly known as **BCI** logic).

We will also consider contractionless versions of **E** and **T**, , namely **E-W** and **T-W** respectively.

The weakest system we consider is **FL**,¹⁴ which is related to the *right implicational* fragment of Lambek calculus. This system rejects all sub-structural rules.

We will mainly concentrate on the implicational fragment of the systems mentioned. In Section 5.3, we will extend the proof systems to a fragment similar to Harrop-formulas. For the fragment considered, all the logics studied in this section are subsystems of intuitionistic logic. However, this is no longer true for the fragment comprising an involutive negation, which can be added (and has been added) to each system. In this section we do not consider the treatment of negation. We refer the reader to [Anderson and Belnap, 1975; Anderson *et al.*, 1992] for an extensive discussion.

In Figure 5.1 we show the inclusion relation of the systems we consider in this section.

We give a corresponding semantics for this set of systems. The semantics we refer is a simplification of the one proposed in [Fine, 1974], [Anderson *et al.*, 1992] and elaborated more recently by Došen [1988; 1989].¹⁵

with the corresponding names. The implicational fragments are usually denoted with the subscript \rightarrow . Thus, what we call **R** is denoted in the literature by **R** \rightarrow , and so forth; since we are mainly concerned with the implicational systems we have preferred to minimize the notation, stating explicitly when we make exception to this convention.

¹⁴The denomination of the system is taken from [Ono, 1998; Ono, 1993].

¹⁵Dealing only with the implicational fragment, we have simplified Fine semantics: we do not have *prime* or maximal elements.

Figure 8. Lattice of Substructural Logics.

DEFINITION 77. Let us fix a language \mathcal{L} , a Fine \mathbf{S} -structure¹⁶ M is a tuple of the form:

$$M = (W, \leq, \circ, 0, V),$$

where W is a non empty set, \circ is a binary operation on W , $0 \in W$, \leq is a partial order relation on W , V is a function of type $W \rightarrow Pow(Var)$. In all structures the following properties are assumed to hold:

$$\begin{aligned} 0 \circ a &= a, \\ a \leq b &\text{ implies } a \circ c \leq b \circ c, \\ a \leq b &\text{ implies } V(a) \subseteq V(b). \end{aligned}$$

For each system \mathbf{S} , a \mathbf{S} -structure satisfies a subset of the following conditions, as specified in Table 4

- (a1) $a \circ (b \circ c) \leq (a \circ b) \circ c$;
- (a2) $a \circ (b \circ c) \leq (b \circ a) \circ c$;
- (a3) $(a \circ b) \circ b \leq a \circ b$;
- (a4) $a \circ 0 \leq a$;
- (a5) $a \circ b \leq b \circ a$;
- (a6) $0 \leq a$.

Truth conditions for $a \in W$, we define

- $M, a \models p$ if $p \in V(a)$;

¹⁶We just write \mathbf{S} -structure if there is no risk of confusion.

- $M, a \models A \rightarrow B$ if

$$\forall b \in W (M, b \models A \Rightarrow M, a \circ b \models B).$$

We say that A is *valid* in M (denoted by $M \models A$) if $M, 0 \models A$. We say that A is **S**-valid, denoted by

$$\models_{\mathbf{S}}^{Fine} A \text{ if } A \text{ is valid in every } \mathbf{S}\text{-structure.}$$

Table 4. Algebraic conditions of Fine Semantics.

Logic	(a1)	(a2)	(a3)	(a4)	(a5)	(a6)
FL	*					
T-W	*	*				
T	*	*	*			
E-W	*	*		*		
E	*	*	*	*		
L	*	*		*	*	
R	*	*	*	*	*	
BCK	*	*		*	*	*
I	*	*	*	*	*	*

We have included again intuitionistic logic **I** in Table 4 to show its proper place within this framework. Again this list of semantical conditions is deliberately redundant in order to show quickly the inclusion relation among the systems. The axiomatization given above is sound and complete with respect to this semantics. In particular each axiom (hi) corresponds to the semantical condition (ai).

THEOREM 78 (Anderson *et al.*, 1992, Fine, 1974, Došen, 1989). $\models_{\mathbf{S}} A$ if and only if A is derivable in the corresponding axiom system of Definition 76.

We assume that \circ associates to the left, so we write

$$a \circ b \circ c = (a \circ b) \circ c.$$

5.2 Proof systems

We develop proof methods for the implicative logics: **R**, **BCK**, **E**, **T**, **E-W**, **T-W**, **FL**. As we have seen in the section about modal logics, we can control the use of formulas by labelling data and putting constraints on the labels. In this specific context by labelling data, we are able to record whether they have been used or not and to express the additional conditions needed for each specific system. Formulas are labelled with atomic labels x, y, z . Intuitively these labels can be read as representing at the same time *resources* and *positions* within a database.

DEFINITION 79. Let us fix a denumerable alphabet $\mathcal{A} = \{x_1, \dots, x_i, \dots\}$ of labels. We assume that labels are totally ordered as shown in the enumeration, \mathbf{v}_0 is the first label. A *database* is a finite set of labelled formulas $\Delta = \{x_1 : A_1, \dots, x_n : A_n\}$. We assume that

$$\text{if } x : A \in \Delta \text{ and } x : B \in \Delta, \text{ then } A = B.^{17}$$

We use the notation $Lab(E)$ for the set of labels occurring in an expression E , and we finally assume that $\mathbf{v}_0 \notin Lab(\Delta)$. Label \mathbf{v}_0 will be used for queries from the empty database.

DEFINITION 80. A query Q is an expression of the form:

$$\Delta, \delta \vdash^? x : G$$

where Δ is a database, δ is a finite set of labels not containing \mathbf{v}_0 ; moreover if $x \neq \mathbf{v}_0$ then $x \in Lab(\Delta)$, and G is a formula.

A query from the empty database has the form:

$$\vdash^? \mathbf{v}_0 : G.$$

Let $\max(\delta)$ denote the maximum label in δ according to the enumeration of the labels. By convention, we stipulate that if $\delta = \emptyset$, then $\max(\delta) = \mathbf{v}_0$. The set of labels δ may be thought as denoting the set of resources that are available to prove the goal. Label x in front of the goal has a double role as a ‘position’ in the database from which the goal is asked, and as available resource.

The rules for success and reduction are parametrized to some conditions $Succ^S$ and Red^S that will be defined below.

- (success) $\Delta, \delta \vdash^? x : q$; succeeds if $x : q \in \Delta$ and $Succ^S(\delta, x)$.
- (implication) from $\Delta, \delta \vdash^? x : C \rightarrow G$ step to

$$\Delta \cup \{y : C\}, \delta \cup \{y\} \vdash^? y : G,$$

where $y > \max(Lab(\Delta))$, (whence $y \notin Lab(\Delta)$);

- (reduction) from

$$\Delta, \delta \vdash^? x : q,$$

if there is some $z : C \in \Delta$, with $C = A_1 \rightarrow \dots \rightarrow A_k \rightarrow q$, and there are δ_i , and x_i for $i = 0, \dots, k$ such that:

1. $\delta_0 = \{z\}$, $x_0 = z$,

¹⁷This restriction will be lifted in Section 5.3 where conjunction is introduced in the language.

2. $\bigcup_{i=0}^k \delta_i = \delta$,
3. $Red^S(\delta_0, \dots, \delta_k, x_0, \dots, x_k; x)$

then for $i = 1, \dots, k$, we step to

$$\Delta, \delta_i, \vdash^? x_i : A_i.$$

The conditions for success are either (s1) or (s2) according to each system:

$$(s1) \text{ Succ}^S(\delta, x) \equiv x \in \delta,$$

$$(s2) \text{ Succ}^S(\delta, x) \equiv \delta = \{x\}.$$

The conditions Red^S are obtained as combination of the following clauses:

$$(r0) \ x_k = x;$$

$$(r1) \ \text{for } i, j = 0, \dots, k, \delta_i \cap \delta_j = \emptyset;$$

$$(r2) \ \text{for } i = 1, \dots, k, x_{i-1} \leq x_i \text{ and } \max(\delta_i) \leq x_i;$$

$$(r3) \ \text{for } i = 1, \dots, k, x_{i-1} \leq x_i \text{ and } \max(\delta_i) = x_i;$$

$$(r4) \ \text{for } i = 1, \dots, k, x_{i-1} < x_i, \max(\delta_{i-1}) = x_{i-1} < \min(\delta_i) \text{ and } \max(\delta_k) = x_k.$$

The conditions Red^S are then defined according to Table 5.

Table 5. Restrictions on reduction and success.

Condition	(r0)	(r1)	(r2)	(r3)	(r4)	(Success)
FL	*				*	(s2)
T-W	*	*		*		(s2)
T	*			*		(s2)
E-W	*	*	*			(s2)
E	*		*			(s2)
L		*				(s2)
R						(s2)
BCK		*				(s1)

Notice that

$$(r4) \Rightarrow (r3) \Rightarrow (r2), \text{ and}$$

$$(r4) \Rightarrow (r1).$$

We give a quick explanation of the conditions $Succ^S$ and Red^S . We recall that the component δ represents the set of available resources which must/can be used in a derivation.

For the success rule, in all cases but **BCK**, we have that we can succeed if $x : q$ is in the database, x is the only resource left, and q is asked from position x ; in the case of **BCK** x must be among the available resources, but we do not require that x is the only one left.

The conditions for the reduction rule can be explained intuitively as follows: resources δ are split in several δ_i , for $i = 1, \dots, k$ and each part δ_i must be used in a derivation of a subgoal A_i .

In the case of logics *without contraction* we cannot use a resource twice, therefore by restriction (r1), the δ_i s must be disjointed and z , the label of the formula we are using in the reduction step, is no longer available.

Restriction (r2) imposes that successive subgoals are to be proved from successive positions in the database: only positions $y \geq x$ are ‘accessible’ from x ; moreover each x_i must be accessible from resources in δ_i . Notice that the last subgoal A_k must be proved from x , the position from which the atomic goal q is asked.

Restriction (r3) is similar to (r4), but it further requires that the position x_i is among the available resources δ_i .

Restriction (r4) forces the goal A_i to be proved by using successive disjointed *segments* δ_i of δ . Moreover, z which labels the formula used in the reduction step must be the first (or least) resource among the available ones.

It is not difficult to see that intuitionistic (implicational) logic is obtained by considering success condition (s1) and no other constraint. More interestingly, we can see that **S4**-strict implication is given by considering success condition (s1) and restrictions (r0) and (r2) on reduction. We leave the reader to check that the above formulation coincides with the database-as-list formulation of **S4** we have seen in the previous section. We can therefore consider **S4** as a substructural logic obtained by imposing a restriction on the weakening and the exchange rules. On the other hand, the relation between **S4** and **E** should be apparent: the only difference is the condition on the success rule which controls the weakening restriction.

We can prove that each system is complete with respect to the its axiomatization by a syntactic proof. To this aim, we need to show that every axiom/rule is derivable, and the sets of derivable formulas is closed under substitution and Modus Ponens. The former property is proved by induction on the length of a derivation. The latter property is as usual a straightforward consequence of cut admissibility. This property is proved similarly to Theorem 10, although the details of the proof are more complex, because of the various restrictions on the reduction rule (see [Gabbay and Olivetti, 2000] pages 181–191, Theorem 5.19).

PROPOSITION 81 (Substitution). *If $Q = \Gamma, \gamma \vdash^? x : A$ succeeds, then also $Q' = \Gamma[q/B], \gamma \vdash^? x : A[q/B]$ succeeds.*

PROPOSITION 82 (Modus Ponens). *If $\vdash^? \mathbf{v}_0 : A \rightarrow B$ and $\vdash^? \mathbf{v}_0 : A$ succeed then also $\vdash^? \mathbf{v}_0 : B$ succeeds.*

PROPOSITION 83 (Identity). *If $x : A \in \Gamma$ and $\text{Succ}^{\mathbf{S}}(\gamma, x)$ then $\Gamma, \gamma \vdash^? x : A$ succeeds.*

THEOREM 84 (Completeness). *For every system \mathbf{S} , if A is a theorem of \mathbf{S} , then $\vdash \mathbf{v}_0 : A$ succeeds in the corresponding proof system for \mathbf{S} .*

Proof. By Propositions 81, 82, we only need to show a derivation of an arbitrary atomic instance of each axiom in the relative proof system. In the case of reduction, the condition $\gamma = \bigcup \gamma_i$, will not be explicitly shown, as its truth will be apparent by the choice of γ_i . We assume that the truth of the condition for the success rule is evident and we do not mention it. At each step we only show the current goal, the available resources and the *new* data introduced in the database, if any. Moreover, we justify the queries obtained by a reduction step by writing the relation $\text{Red}^{\mathbf{S}}(\gamma_0, \dots, \gamma_n, x_0, \dots, x_n; x)$ (for suitable γ_i, x_i) under them; the database formula used in the reduction step is identified by γ_0 .

(id) In all systems:

$$\vdash^? \mathbf{v}_0 : a \rightarrow a$$

we step to

$$u : a, \{u\} \vdash^? u : a,$$

which immediately succeeds in all systems.

(h1) In all systems:

$$\vdash^? \mathbf{v}_0 : (b \rightarrow c) \rightarrow (a \rightarrow b) \rightarrow a \rightarrow c.$$

three steps of the implication rule leads to:

$$\begin{array}{l} x_1 : b \rightarrow c, x_2 : a \rightarrow b, x_3 : a, \{x_1, x_2, x_3\} \vdash^? x_3 : c \\ \{x_2, x_3\} \vdash^? x_3 : b \\ \text{Red}^{\mathbf{S}}(\{x_1\}, \{x_2, x_3\}, x_1, x_3; x_3) \\ \{x_3\} \vdash^? x_3 : a \\ \text{Red}^{\mathbf{S}}(\{x_2\}, \{x_3\}, x_2, x_3; x_3). \end{array}$$

(h2) In all systems, but **FL**:

$$\vdash^? \mathbf{v}_0 : (a \rightarrow b) \rightarrow (b \rightarrow c) \rightarrow a \rightarrow c.$$

three steps of the implication rule leads to:

$$\begin{array}{l} x_1 : a \rightarrow b, x_2 : b \rightarrow c, x_3 : a, \{x_1, x_2, x_3\} \vdash^? x_3 : c \\ \quad \quad \quad (*) \{x_1, x_3\} \vdash^? x_3 : b, \\ \quad \quad \quad \text{Red}^{\mathbf{S}}(\{x_2\}, \{x_1, x_3\}, x_2, x_3; x_3) \\ \quad \quad \quad \quad \quad \quad \{x_3\} \vdash^? x_3 : a, \\ \quad \quad \quad \text{Red}^{\mathbf{S}}(\{x_1\}, \{x_3\}, x_1, x_3; x_3). \end{array}$$

the step (*) is allowed in all systems, but those with (r4), namely **FL**.

(h3) In all systems, but those with (r1) or (r4):

$$\vdash^? \mathbf{v}_0 : (a \rightarrow a \rightarrow b) \rightarrow a \rightarrow b.$$

Two steps of the implication rule leads to:

$$x_1 : a \rightarrow a \rightarrow b, x_2 : a, \{x_1, x_2\} \vdash^? x_2 : b.$$

By reduction we step to:

$$\{x_2\} \vdash^? x_2 : a \quad \text{and} \quad \{x_2\} \vdash^? x_2 : a$$

since $\text{Red}^{\mathbf{S}}(\{x_1\}, \{x_2\}, \{x_2\}, x_1, x_2, x_2; x_2)$ holds in all systems without (r1) and (r4).

(h4) In all systems, but those with (r3) or (r4):

$$\vdash^? \mathbf{v}_0 : (a \rightarrow b) \rightarrow ((a \rightarrow b) \rightarrow c) \rightarrow c.$$

two steps of the implication rule leads to:

$$\begin{array}{l} x_1 : a \rightarrow b, x_2 : (a \rightarrow b) \rightarrow c, \{x_1, x_2\} \vdash^? x_2 : c \\ \quad \quad \quad (*) \{x_1\} \vdash^? x_2 : a \rightarrow b \\ \quad \quad \quad \text{Red}^{\mathbf{S}}(\{x_2\}, \{x_1\}, x_2, x_2; x_2) \\ \quad \quad \quad \quad \quad \quad x_3 : a, \{x_1, x_3\} \vdash^? x_3 : b \\ \quad \quad \quad \quad \quad \quad \quad \quad \quad \{x_3\} \vdash^? x_3 : a \\ \quad \quad \quad \text{Red}^{\mathbf{S}}(\{x_1\}, \{x_3\}, x_1, x_3; x_3) \end{array}$$

The step (*) is allowed by (r2), but not by (r3) or (r4) since $\max(\{x_1\}) = x_1 < x_2$.

(h5) In **L,R,BCK**:

$$\vdash^? \mathbf{v}_0 : a \rightarrow (a \rightarrow b) \rightarrow b.$$

two steps of implication rule leads to:

$$\begin{array}{l} x_1 : a, x_2 : a \rightarrow b, \{x_1, x_2\} \vdash^? x_2 : b \\ \{x_1\} \vdash^? x_1 : a \\ Red^S(\{x_2\}, \{x_1\}, x_2, x_1; x_2). \end{array}$$

(h6) In **BCK** we have:

$$\vdash^? \mathbf{v}_0 : a \rightarrow b \rightarrow b.$$

two steps by implication rule leads to:

$$x_1 : a, x_2 : b, \{x_1, x_2\} \vdash^? x_2 : b$$

which succeeds by the success condition of **BCK**. This formula does not succeed in any other system.

(*Suff*) We prove the admissibility of (*Suff*) rule in **FL**. Let $\vdash^? \mathbf{v}_0 : A \rightarrow B$ succeed. Then for any formula C , we have to show that

$$\vdash^? \mathbf{v}_0 : (B \rightarrow C) \rightarrow A \rightarrow C \text{ succeeds.}$$

Let $C = C_1 \rightarrow \dots \rightarrow C_n \rightarrow q$. Starting from

$$\vdash^? \mathbf{v}_0 : (B \rightarrow C_1 \rightarrow \dots \rightarrow C_n \rightarrow q) \rightarrow A \rightarrow C_1 \rightarrow \dots \rightarrow C_n \rightarrow q$$

by the implication rule, we step to $\Delta, \{x_1, \dots, x_{n+2}\} \vdash x_{n+2} : q$, where

$$\begin{array}{l} \Delta = \{x_1 : B \rightarrow C_1 \rightarrow \dots \rightarrow C_n \rightarrow q, x_2 : A, \\ x_3 : C_1, \dots, x_{n+2} : C_n\}. \end{array}$$

From the above query we step by reduction to:

$$\begin{array}{l} Q' = \Delta, \{x_2\} \vdash^? x_2 : B \text{ and} \\ Q_i = \Delta, \{x_{i+2}\} \vdash^? x_{i+2} : C_i \text{ for } i = 1, \dots, n. \end{array}$$

since the conditions for reduction are satisfied. By hypothesis, $\vdash^? \mathbf{v}_0 : A \rightarrow B$ succeeds, which implies, by the implicational rule, that $x_2 : A, \{x_2\} \vdash^? x_2 : B$ succeeds, but then Q' succeeds by monotony. Queries Q_i succeed by Proposition 83. ■

We can prove the soundness semantically. To this purpose we need to interpret databases and queries in the semantics. As usual, we introduce the notion of realization of a database and then of validity of a query.

DEFINITION 85 (Realization). Given a database Γ , and a set of labels γ , an **S-realization** of (Γ, γ) in an **S-structure** $M = (W, \circ, \leq, 0, V)$, is a mapping $\rho : \mathcal{A} \rightarrow W$ such that:

1. $\rho(\mathbf{v}_0) = 0$;
2. if $y : B \in \Gamma$ then $M, \rho(y) \models B$.

In order to define the notion of validity of a query, we need to introduce some further notation. Given an **S-realization** ρ , γ and x , we define

$$\begin{aligned} \rho(\gamma) &= 0 \text{ if } \gamma = \emptyset, \\ \rho(\gamma) &= \rho(x_1) \circ \dots \circ \rho(x_n) \text{ if } \gamma = \{x_1, \dots, x_n\}, \text{ where } x_1 < \dots < x_n \\ \rho(\langle \gamma, x \rangle) &= \rho(\gamma) \text{ if } x \in \gamma, \\ \rho(\langle \gamma, x \rangle) &= \rho(\gamma) \circ 0 \text{ if } x \notin \gamma. \end{aligned}$$

DEFINITION 86 (Valid query). Let $Q = \Gamma, \gamma \vdash^? x : A$, we say that Q is **S-valid** if for every **S-structure** M , for every realization ρ of Γ in M , we have

$$M, \rho(\langle \gamma, x \rangle) \models A.$$

According to the definition above, the **S-validity** of the query $\vdash^? \mathbf{v}_0 : A$ means that the formula A is **S-valid** (i.e. $\models_{\mathbf{S}}^{Fine} A$).

THEOREM 87. *If $Q = \Gamma, \gamma \vdash^? x : A$ succeeds in the proof system for **S** then Q is **S-valid**. In particular, if $\mathbf{v}_0 : A$ succeeds in the proof system for **S**, then $\models_{\mathbf{S}}^{Fine} A$.*

The proof can be done by induction on the length of derivations, by suitably relating the constraints of the reduction rule to the algebraic semantic conditions.

5.3 Extending the language

In this section we show how we can extend the language by some other connectives. We allow extensional conjunction (\wedge), disjunction (\vee), and intensional conjunction or *tensor* (\otimes). The distinction between \wedge and \otimes is typical of substructural logics and it comes from the rejection of some structural rule: \wedge is the usual lattice-inf connective, \otimes is close to a residual operator with respect to \rightarrow . In relevant logic literature \otimes is often called

fusion or *cotenableity* and denoted by \circ .¹⁸ The addition of the above connectives presents some semantic options. The most important one is whether *distribution* (dist) of \wedge and \vee is assumed or not. The list of axioms/rules below characterizes distributive substructural logics.

DEFINITION 88 (Axioms for \wedge, \otimes, \vee).

1. $A \wedge B \rightarrow A$,
2. $A \wedge B \rightarrow B$,
3. $(C \rightarrow A) \wedge (C \rightarrow B) \rightarrow (C \rightarrow A \wedge B)$,
4. $A \rightarrow A \vee B$,
5. $B \rightarrow A \vee B$,
6. $(A \rightarrow C) \wedge (B \rightarrow C) \rightarrow (A \vee B \rightarrow C)$
7. $\frac{A \quad B}{A \wedge B}$
8. $\frac{A \rightarrow B \rightarrow C}{A \otimes B \rightarrow C}$
9. $\frac{A \otimes B \rightarrow C}{A \rightarrow B \rightarrow C}$

(e- \wedge) For **E** and **E-W** only

$$\Box A \wedge \Box B \rightarrow \Box(A \wedge B)$$

where $\Box C =_{def} (C \rightarrow C) \rightarrow C$.

(dist) $A \wedge (B \vee C) \rightarrow (A \wedge B) \vee C$.

As we have said, the addition of distribution (dist) is a semantic choice, which may be argued. However, for the fragment of the language we consider in this section it does not really matter whether distribution is assumed or not. This fragment roughly corresponds to the Harrop fragment of the section of modal logics (see Section 4.3); since we do not allow positive occurrences of disjunction, the presence of distribution is immaterial.¹⁹ We have included distribution to have a complete axiomatization with respect to the semantics we adopt.

¹⁸We follow here the terminology and notation of linear logic [Girard, 1987].

¹⁹In the fragment we consider we trivially have (for any **S**) $\Gamma, \alpha \vdash^? x : A \wedge (B \vee C)$ implies $\Gamma, \alpha \vdash^? x : A \vee (B \wedge C)$, where Γ is a set of D-formulas and A, B, C are G-formulas (see below).

As in the case of modal logics (see Section 4.3), we distinguish D-formulas, which are the constituents of databases, and G-formulas which can be asked as goals.

DEFINITION 89. Let D-formulas and G-formulas be defined as follows:

$$\begin{aligned} D &:= q \mid G \rightarrow D, \\ CD &:= D \mid CD \wedge CD, \\ G &:= q \mid G \wedge G \mid G \vee G \mid G \otimes G \mid CD \rightarrow G. \end{aligned}$$

A database Δ is a finite set of *labelled* D-formulas.

A database corresponds to a \otimes -composition of conjunctions of D-formulas. Formulas with the same label are thought as \wedge -conjoined. Every D-formula has the form

$$G_1 \rightarrow \dots \rightarrow G_k \rightarrow q,$$

In the systems **R**, **L**, **BCK**, we have the theorems

$$(A \rightarrow B \rightarrow C) \rightarrow (A \otimes B \rightarrow C) \quad \text{and} \quad (A \otimes B \rightarrow C) \rightarrow (A \rightarrow B \rightarrow C)$$

Thus, in these systems we can simplify the syntax of (non atomic) D-formulas to $G \rightarrow q$ rather than $G \rightarrow D$. This simplification is not allowed in the other systems where we only have the weaker relation

$$\vdash (A \rightarrow B \rightarrow C) \Leftrightarrow \vdash A \otimes B \rightarrow C.$$

The extent of Definition 89 is shown by the following proposition.

PROPOSITION 90. *Every formula on $(\wedge, \vee, \rightarrow, \otimes)$ without*

- *positive²⁰ (negative) occurrences of \otimes and \vee and*
- *occurrences of \otimes within a negative (positive) occurrence of \wedge*

is equivalent to a \wedge -conjunction of D-formulas (G-formulas).

The reason we have put the restriction on nested occurrences of \otimes within \wedge is that, on the one hand, we want to keep the simple labelling mechanism we have used for the implicational fragment, and on the other we want to identify a common fragment for all systems to which the computation rules are easily extended. The labelling mechanism no longer works if we relax

²⁰Positive and negative occurrences are defined as follows: A occurs positively in A ; if $B\#C$ occurs positively (negatively) in A (where $\# \in \{\wedge, \vee, \otimes\}$), then B and C occur positively (negatively) in A ; if $B \rightarrow C$ occurs positively (negatively) in A , then B occurs negatively (positively) in A and C occurs positively (negatively) in A . We say that a connective $\#$ has a positive (negative) occurrence in a formula A if there is a formula $B\#C$ which occurs positively (negatively) in A .

this restriction. For instance, how could we handle $A \wedge (B \otimes C)$ as a D-formula? We should add $x : A$ and $x : B \otimes C$ in the database. The formula $x : B \otimes C$ cannot be decomposed, unless we use complex labels: intuitively we should split x into some y and z , add $y : B$ and $z : C$, and remember that x, y, z are connected (in terms of Fine semantics the connection would be expressed as $x = y \circ z$).²¹

The computation rules can be extended to this fragment without great effort.

DEFINITION 91 (Proof system for the extended language). We give the rules for queries of the form

$$\Delta, \delta \vdash^? x : G,$$

where Δ is a set of D-formulas and G is a G-formula.

- (success) $\Delta, \delta \vdash^? x : q$ succeeds if $x; q \in \Delta$ and $Succ^S(\delta, x)$.
- (implication) from $\Delta, \delta \vdash^? x : CD \rightarrow G$
if $CD = D_1 \wedge \dots \wedge D_n$, we step to

$$\Delta \cup \{y : D_1, \dots, y : D_n\}, \delta \cup \{y\} \vdash^? y : G$$

where $y > \max(Lab(\Delta))$, (hence $y \notin Lab(\Delta)$).

- (reduction) from $\Delta, \delta \vdash^? x : q$
if there is $z : G_1 \rightarrow \dots \rightarrow G_k \rightarrow q \in \Delta$ and there are δ_i , and x_i for $i = 0, \dots, k$ such that:

1. $\delta_0 = \{z\}$, $x_0 = z$,
2. $\bigcup_{i=0}^k \delta_i = \delta$,
3. $Red^S(\delta_0, \dots, \delta_k, x_0, \dots, x_k; x)$,

then for $i = 1, \dots, k$, we step to

$$\Delta, \delta_i, \vdash^? x_i : G_i.$$

- (conjunction) from $\Delta, \delta \vdash^? x : G_1 \wedge G_2$ step to

$$\Delta, \delta \vdash^? x : G_1 \text{ and } \Delta, \delta \vdash^? x : G_2.$$

- (disjunction) from $\Delta, \delta \vdash^? x : G_1 \vee G_2$ step to

$$\Delta, \delta \vdash^? x : G_i \text{ for } i = 1 \text{ or } i = 2.$$

²¹In some logics, such as **L**, we do not need this restriction since we have the following property: $\Gamma, A \wedge B \vdash C$ implies $\Gamma, A \vdash C$ or $\Gamma, B \vdash C$. Thus, we can avoid introducing extensional conjunctions into the database, and instead introduce only one of the two conjuncts (at choice). This approach is followed by Harland and Pym [1991]. However the above property does not hold for **R** and other logics.

- (tensor) from $\Delta, \delta \vdash^? x : G_1 \otimes G_2$
if there are δ_1, δ_2, x_1 and x_2 such that
 1. $\delta = \delta_1 \cup \delta_2$,
 2. $Red^S(\delta_1, \delta_2, x_1, x_2; x)$,

step to

$$\Delta, \delta_1 \vdash^? x_1 : G_1 \text{ and } \Delta, \delta_2 \vdash^? x_2 : G_2.$$

An easy extension of the method is the addition of the truth constants \mathbf{t} , and \top which are governed by the following axioms/rules

$$\begin{aligned} A &\rightarrow \top, \\ \vdash \mathbf{t} &\rightarrow A \text{ iff } \vdash A. \end{aligned}$$

Plus the axiom of $(\mathbf{t} \rightarrow A) \rightarrow A$ for \mathbf{E} and $\mathbf{E-W}$. We can think of \mathbf{t} as defined by propositional quantification

$$\mathbf{t} =_{def} \forall p(p \rightarrow p).$$

Equivalently, given any formula A , we can assume that \mathbf{t} is the conjunction of all $p \rightarrow p$ such that the atom p occurs in A . Basing on this definition, it is not difficult to handle \mathbf{t} in the goal-directed way and we leave to the reader to work out the rules. The treatment of \top is straightforward.

EXAMPLE 92. Let Δ be the following database:

$$\begin{aligned} x_1 &: e \wedge g \rightarrow d, \\ x_2 &: (c \rightarrow d) \otimes (a \vee b) \rightarrow p, \\ x_3 &: c \rightarrow e, \\ x_3 &: c \rightarrow g, \\ x_4 &: (c \rightarrow g) \rightarrow b. \end{aligned}$$

In Figure 9, we show a successful derivation of

$$\Delta, \{x_1, x_2, x_3, x_4\} \vdash^? x_4 : p$$

in relevant logic \mathbf{E} (and stronger systems). We leave to the reader to justify the steps according to the rules. The success of this query corresponds to the validity of the following formula in \mathbf{E} :

$$\begin{aligned} &[(e \wedge g \rightarrow d) \otimes ((c \rightarrow d) \otimes (a \vee b) \rightarrow p) \otimes ((c \rightarrow e) \wedge \\ &\quad \wedge (c \rightarrow g)) \otimes ((c \rightarrow g) \rightarrow b)] \rightarrow p. \end{aligned}$$

We can extend the soundness and completeness result to this larger fragment. We first extend Definition 77 by giving the truth conditions for the additional connectives.

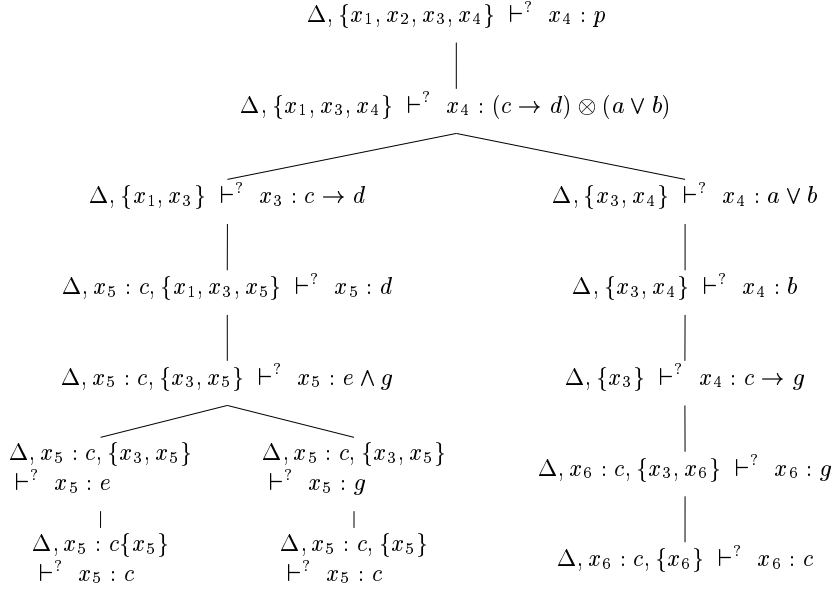

Figure 9. Derivation for Example 92.

DEFINITION 93. Let $M = (W, \circ, 0, V)$ be a **S**-structure, let $a \in W$ we stipulate:

$$M, a \models A \wedge B \text{ iff } M, a \models A \text{ and } M, a \models B,$$

$$M, a \models A \vee B \text{ iff } M, a \models A \text{ or } M, a \models B,$$

$$M, a \models A \otimes B \text{ iff there are } b, c \in W, \text{ s.t. } b \circ c \leq a \text{ and } M, a \models A \text{ and } M, a \models B.$$

It is straightforward to extend Theorem 87 obtaining the soundness of the proof procedure with respect to this semantics. The completeness can be proved by a canonical model construction. The details are given in [Gabbay and Olivetti, 2000], (see Section 6.1). Putting the two results together we obtain:

THEOREM 94. Let $\Gamma, \gamma \vdash^? x : G$ be a query with $\gamma = \{x_1, \dots, x_k\}$ (ordered as shown), and let $S_i = \{A \mid x_i : A \in \Gamma\}$, $i = 1, \dots, k$. The following are equivalent:

1. $\models_{\mathbf{S}}^{Fine} (\bigwedge S_1 \otimes \dots \otimes \bigwedge S_k) \rightarrow G$
2. $\Gamma, \gamma \vdash^? x : G$ succeeds in the system **S**.

5.4 Eliminating the labels

As in the case of modal logics, it turns out that for most of the systems (at least if we consider the implicational fragment), labels are not needed.

PROPOSITION 95.

- If $\Gamma, \gamma \vdash^? x : B$ succeeds, $u : A \in \Gamma$ but $u \notin \gamma$, then $\Gamma - \{u : A\}, \gamma \vdash^? x : B$ succeeds.
- For **R**, **L**, **BCK**, if $\Gamma, \gamma \vdash^? x : B$ succeeds, then for every $y \in \gamma$, $\Gamma, \gamma \vdash^? y : B$ succeeds.
- For **T**, **T-W**, **FL**, if $\Gamma, \gamma \vdash^? x : B$ succeeds then it must be $x = \max(\gamma)$.

Because of the previous proposition, the formulas which can contribute to the proof are those that are listed in γ . Since every copy of a formula gets a different label, labels and ‘usable’ formulas are into a 1-1 correspondence. Moreover in all cases, but **E** and **E-W**, the label x in front of the goal is either irrelevant or it is determined by γ . Putting these facts together, we can reformulate the proof systems for all logics, but **E** and **E-W** without using labels. The restrictions on reduction can be expressed directly in terms of the sequence of database formulas. In other words, formulas and labels become the same things. As an example we give the reformulation of **L** and **FL**. In case of **L**, it is easily seen that the order of formulas does not matter (it can be proved that permuting the database does not affect the success of a query), thus the database can be thought as a multiset of formulas, and the rules become as follows:

1. (success) $\Delta \vdash^? q$ succeeds if $\Delta = q$,
2. (implication) from $\Delta \vdash^? A \rightarrow B$ step to $\Delta, A \vdash^? B$,
3. (reduction) from $\Delta, C \rightarrow \dots \rightarrow C_n \rightarrow q \vdash^? q$ step to $\Delta_i \vdash^? C_i$, where $\Delta = \sqcup_i \Delta_i$, (\sqcup denotes multiset union).

In other words we obtain what we have called the *linear computation* in Section 3.3, Definition 13.

In case of **FL**, the order of the formulas is significant. Thus the rules for success and implication are the same, but in case of implication the formula A is added to the *end* of Δ . The rule of reduction becomes:

(**FL**-reduction) from $C \rightarrow \dots \rightarrow C_n \rightarrow q, \Delta \vdash^? q$ step to $\Delta_i \vdash^? C_i$, where $\Delta = \Delta_1, \dots, \Delta_n$,

in this case “,” denotes concatenation. The reformulation without labels for **R**, **T**, and **T-W**, **BCK** is similar and left to the reader.

5.5 Some history

The use of labels to deal with substructural logics is not a novelty: it has been used for instance by Prawitz [1965], by Anderson and Belnap [1975], to develop a natural-deduction formulation of most relevant logics. The goal-directed proof systems we have presented are similar to their natural deduction systems in this respect: there are not explicit structural rules. The structural rules are *internalized* as restrictions in the logical rules.

Bollen has developed a goal-directed procedure for a fragment of first-order \mathbf{R} [Bollen, 1991]). His method avoids splitting derivations in several branches by maintaining a global proof-state $\Delta \vdash^? [A_1, \dots, A_n]$, where all A_1, \dots, A_n have to be proved (they can be thought as linked by \otimes). If we want to keep all subgoals together, we must take care that different subgoals A_i may happen to be evaluated in different contexts. For instance in

$$C \vdash^? D \rightarrow E, F \rightarrow G$$

according to the implication rule, we must evaluate E from $\{C, D\}$, and G from $\{C, F\}$. Bollen accommodates this kind of context-dependency by indexing subgoals with a number which refers to the part of the database that can be used to prove it. Furthermore, a list of numbers is maintained to remember the usage; in a successful derivation the usage list must contain the numbers of all formulas of the database.

Many people have developed goal-directed procedures for fragments of linear logic leading to the definition of logic programming languages based on linear logic. This follows the tradition of the *uniform proof paradigm* proposed by Miller [Miller *et al.*, 1991]. We notice, in passing, that implicational \mathbf{R} can be encoded in linear logic by defining $A \rightarrow B$ by $A \multimap !A \multimap B$, where $!$ is the exponential operator which enables the contraction of the formula to which is applied. The various proposals differ in the choice of the language fragment. Much emphasis is given to the treatment of the exponential $!$, as it is needed for defining logic programming languages of some utility: in most applications, we need permanent resources or data, (i.e. data that are not ‘consumed’ along a deduction); permanent data can be represented by using the $!$ operator.

Some proposals, such as [Harland and Pym, 1991] and [Andreoli and Pareschi, 1991; Andreoli, 1992] take as basis the multi-consequent (or classical) version of linear logic. Moreover, mixed systems have been studied [Hodas and Miller, 1994] and [Hodas, 1993] which combine different logics into a single language: linear implication, intuitionistic implication and more.²²

²²In [Hodas, 1993], Hodas has proposed a language called \mathbf{O} which combines intuitionistic, linear, affine and relevant implication. The idea is to partition the ‘context’, i.e. the database in several (multi) sets of data corresponding to the different handling of the data according to each implicational logic.

O’Hearn and Pym [1999] have recently proposed an interesting development of linear logic called the *logic of bunched implications*. Their system has strong semantical and categorical motivations. The logic of bunched implications combines a multiplicative implication, namely the one of linear logic and an additive (or intuitionistic) one. The proof contexts, that is the antecedents of a sequent, are structures built by two operators: ‘;’ corresponds to the multiplicative conjunction \otimes and ‘,’ corresponds to the additive conjunction \wedge . These structures are called *bunches*. Similar structures have been used to obtain calculi for distributive relevant logics [Dunn, 1986]. The authors define also an interesting extension to the first-order case by introducing intensional quantifiers. Moreover they develop a goal-directed proof procedure for a Harrop-fragment of this logic and show significant applications to logic programming.

In [Gabbay and Olivetti, 2000], the goal-directed systems are extended to **RM0** where a suitable restart rule takes care of the mingle rule. Moreover, it is shown how the goal-directed method for **R** can be turned into a decision procedure (for the pure implicational part) by adding a suitable loop-checking mechanism. We notice that for contractionless logics, the goal-directed proof-methods of this section can be the base of decision procedures.

To implement goal-directed proof systems for substructural logics, one can import solutions and techniques developed in the context of linear logic programming. For instance, in the reduction and in the \otimes -rule we have to guess a portion of the goal label. A similar problem has been discussed in the linear logic programming community [Hodas and Miller, 1994; Harland and Pym, 1997] where one has to guess a split of the sequent (only the antecedent in the intuitionistic version, both the antecedent and consequent in the ‘classical’ version). A number of solutions have been provided, most of them based on a *lazy* computation of the split parts. Perhaps the most general way to handle this problem has been addressed in [Harland and Pym, 1997] where it is proposed to represent the sequent split by means of Boolean constraints expressed by labels attached to the formulas. Different strategies of searching the partitions correspond to different strategies of solving the constraints (lazy, eager and mixed).

6 DEVELOPMENTS, APPLICATIONS AND MECHANISMS

The goal-directed proof methods presented in this chapter may be useful for several purposes, beyond the mere deductive task. The deductive procedures can be easily extended in order to compute further information, or to support other logical tasks, such as abduction. We show two examples: the computation of interpolants in implicational linear logic, and the computation of abductive explanations in intuitionistic logic. Both of them are

simple extensions of the goal-directed procedures that we have seen in the previous sections. We conclude by a discussion about the extension of the goal-directed methods to the first order case.

6.1 Interpolation for linear implication

By interpolation we mean the following property. Let Q_1 and Q_2 be two sets of atoms; let \mathcal{L}_1 be the language generated by Q_1 and \mathcal{L}_2 by Q_2 ; finally let A, B be formulas with $A \in \mathcal{L}_1$ and $B \in \mathcal{L}_2$. If $A \vdash B$, then there is a formula $C \in \mathcal{L}_1 \cap \mathcal{L}_2$, such that $A \vdash C$ and $C \vdash B$. The formula C is called an *interpolant* of A and B . Here, we consider the interpolation property for implicational linear logic, i.e. \vdash denotes provability in (implicational) linear logic, and A, B contain only implication. We show how the procedure of the previous section can be modified to compute an interpolant. Since the computation is defined for sequents of the form $\Gamma \vdash A$, where Γ is a database (a multiset of formulas in this case), we need to generalize the notion of interpolation to provability statements of this form. As a particular case we will have the usual interpolation property for pair of formulas. To generalize interpolation to database we need first to generalize the provability relation to databases. Let $\Delta = A_1, \dots, A_n$, we define:

$$\begin{aligned} \Gamma \vdash \Delta \text{ iff there are } \Delta_1, \dots, \Delta_n, \text{ such that } \Delta &= \Delta_1 \sqcup \dots \sqcup \Delta_n \text{ and} \\ \Delta_i \vdash A_i \text{ for } i &= 1, \dots, n. \end{aligned}$$

The formulas A_i can be thought as conjuncted by \otimes . Moreover, since $A_i \rightarrow \dots \rightarrow A_n \rightarrow B$, is equivalent to $A_1 \otimes \dots \otimes A_n \rightarrow B$, and \otimes is associative and commutative, we abbreviate the above formula with $\Delta \rightarrow B$, where Δ is the multiset A_1, \dots, A_n . Let $\Gamma \in \mathcal{L}_1$ and $A \in \mathcal{L}_2$, suppose that $\Gamma \vdash A$ holds; an *interpolant* for $\Gamma \vdash A$ is a database $\Pi \in \mathcal{L}_1 \cap \mathcal{L}_2$ such that $\Gamma \vdash \Pi$ and $\Pi \vdash A$. Observe that if $|\Gamma| = 1$, it must be also $|\Pi| = 1$, and we have the ordinary notion of interpolant.

We give a recursive procedure to calculate an interpolant for $\Gamma \vdash A$. We do this by defining a recursive predicate $Inter(\Gamma; \Delta; A; \Pi)$ which is true whenever: $\Gamma \in \mathcal{L}_1$, $\Delta, A \in \mathcal{L}_2$, $\Gamma, \Delta \vdash A$ holds, and Π is an interpolant for $\Gamma \vdash \Delta \rightarrow A$.

- (Succ 1) $Inter(q; \emptyset; q; q)$.
- (Succ 2) $Inter(\emptyset; q; q; \emptyset)$.
- (Imp) $Inter(\Gamma; \Delta; A \rightarrow B, \Pi)$ if $Inter(\Gamma; \Delta, A; B, \Pi)$.
- (Red 1) $Inter(\Gamma, C_1 \rightarrow \dots C_n \rightarrow q; \Delta; q; \Pi)$, if there are $\Gamma_i, \Delta_i, \Pi_i$ for $i = 1, \dots, n$ such that

1. $\Gamma = \sqcup_i \Gamma_i, \Delta = \sqcup_i \Delta_i,$

2. $Inter(\Delta_i; \Gamma_i; C_i; \Pi_i)$ for $i = 1, \dots, n$,
 3. $\Pi = \Pi_1 \sqcup \dots \sqcup \Pi_n \rightarrow q$.
- (Red 2) $Inter(\Gamma; \Delta, C_1 \rightarrow \dots \rightarrow C_n \rightarrow q; q; \Pi)$, if there are $\Gamma_i, \Delta_i, \Pi_i$ for $i = 1, \dots, n$ such that
 1. $\Gamma = \sqcup_i \Gamma_i, \Delta = \sqcup_i \Delta_i, \Pi = \sqcup_i \Pi_i$,
 2. $Inter(\Gamma_i; \Delta_i; C_i; \Pi_i)$ for $i = 1, \dots, n$.

If we want to find an interpolant for $\Gamma \vdash A$, the initial call is $Inter(\Gamma; \emptyset; A; \Pi)$, where Π is computed along the derivation. One can observe that the predicate $Inter$ is defined by following the definition of the goal-directed proof procedure. (Succ 1) and (Succ 2) apply to the case of immediate success, respectively when the atom is in \mathcal{L}_1 , and when it is in \mathcal{L}_2 . Analogously, (Red 1) deals with the case the atomic goal unifies with the head of a formula in \mathcal{L}_1 and (Red 2) when it unifies with the head of a formula in \mathcal{L}_2 . It can be proved that if $\Gamma \vdash A$ the algorithm computes an interpolant. Moreover all interpolants can be obtained by selecting different formulas in the reduction steps. Here is a non trivial example.

EXAMPLE 96. Let

$$A = ((f \rightarrow e) \rightarrow ((a \rightarrow b) \rightarrow c) \rightarrow (a \rightarrow q) \rightarrow (q \rightarrow b) \rightarrow f \rightarrow b) \rightarrow g,$$

and

$$B = (e \rightarrow c \rightarrow d) \rightarrow (d \rightarrow a) \rightarrow (a \rightarrow b) \rightarrow g.$$

One can check that $A \vdash B$ holds; we compute an interpolant, by calling $Inter(A; \emptyset; B; \Pi)$. Let us abbreviate the antecedent of A by A' . Here are the steps, we underline the formula used in a reduction step:

- (1) $Inter(\underline{A}; \emptyset; B; \Pi)$
- (2) $Inter(A; e \rightarrow c \rightarrow d, d \rightarrow a, a \rightarrow b; g; \Pi)$
- (3) $Inter(e \rightarrow c \rightarrow d, d \rightarrow a, a \rightarrow b; \emptyset; A', \Pi_1) \quad \Pi = \Pi_1 \rightarrow g$
- (4) $Inter(e \rightarrow c \rightarrow d, d \rightarrow a, a \rightarrow b; f \rightarrow e, (a \rightarrow b) \rightarrow c, a \rightarrow q, \underline{q \rightarrow b}, f; b, \Pi_1)$
- (5) $Inter(e \rightarrow c \rightarrow d, d \rightarrow a, a \rightarrow b; f \rightarrow e, (a \rightarrow b) \rightarrow c, \underline{a \rightarrow q}, f; q, \Pi_1)$
- (6) $Inter(e \rightarrow c \rightarrow d, \underline{d \rightarrow a}, a \rightarrow b; f \rightarrow e, (a \rightarrow b) \rightarrow c, f; a, \Pi_1)$
- (7) $Inter(f \rightarrow e, (a \rightarrow b) \rightarrow c, f; \underline{e \rightarrow c \rightarrow d}, a \rightarrow b; ; d, \Pi_2)$
 $\Pi_1 = \Pi_2 \rightarrow a$

Now we have a split with $\Pi_2 = \Pi_3, \Pi_4$ and

$$(8) \text{ Inter}(\underline{f \rightarrow e}, f; \emptyset; e; \Pi_3) \quad \text{and} \quad (9) \text{ Inter}(\underline{(a \rightarrow b) \rightarrow c}; a \rightarrow b; ; c, \Pi_4).$$

(8) gives

$$(10) \text{ Inter}(\emptyset; f; f; \Pi_5) \quad \Pi_3 = \Pi_5 \rightarrow e$$

whence $\Pi_5 = \emptyset$. (9) gives

$$(11) \text{ Inter}(a \rightarrow b; \emptyset; a \rightarrow b; \Pi_6) \quad \Pi_4 = \Pi_6 \rightarrow c$$

$$(12) \text{ Inter}(\underline{a \rightarrow b}; a; b; \Pi_6)$$

$$(13) \text{ Inter}(a; \emptyset; a; \Pi_7) \quad \Pi_6 = \Pi_7 \rightarrow b$$

Thus $\Pi_7 = a$ and we have:

$$\Pi_6 = a \rightarrow b,$$

$$\Pi_3 = e,$$

$$\Pi_4 = (a \rightarrow b) \rightarrow c,$$

$$\Pi_2 = e, (a \rightarrow b) \rightarrow c,$$

$$\Pi_1 = e \rightarrow ((a \rightarrow b) \rightarrow c) \rightarrow a,$$

$$\Pi = (e \rightarrow ((a \rightarrow b) \rightarrow c) \rightarrow a) \rightarrow g.$$

Π is evidently in the common language of A and B ; we leave to the reader to check that $A \vdash \Pi$ and $\Pi \vdash B$.

It is likely that similar procedures based on the goal-directed computation can be devised for other logics admitting a goal directed presentation. However, further investigation is needed to see to what extent this approach works for other cases. For instance, the step in (Red 1) is justified by the structural *exchange* law which holds for linear logic. For non-commutative logics the suitable generalization of the interpolation property, which is the base of the inductive procedure, might be more difficult to find.

6.2 Abduction for intuitionistic implication

Abduction is an important kind of inference for many applications. It has been widely and deeply studied in logic programming context (see [Eshghi, 1989] for a seminal work). Abductive inference can be described as follows: given a set of data Γ and a formula A such that $\Gamma \not\vdash A$, find a set of formulas Π such that $\Gamma, \Pi \vdash A$. Usually, there are some further requirements on the possible Π 's, such as *minimality*. The set Π is called an abductive solution for $\Gamma \vdash A$. We define below a metapredicate $Abduce(\Gamma; A; \Pi)$ whose meaning, is that Π is an abductive solution for $\Gamma \vdash A$. The predicate is defined by induction on the goal-directed derivation. Given a formula C and a database Γ , we write $C \rightarrow \Gamma$ to denote the set $\{C \rightarrow D \mid D \in \Gamma\}$.

1. $Abduce(\Gamma; q; \Pi)$ if $q \in \Gamma$ and $\Pi = \emptyset$.
2. $Abduce(\Gamma; q; \Pi)$ if $\forall C \in \Gamma \ q \neq Head(C)$ and $\Pi = \{q\}$.
3. $Abduce(\Gamma; A \rightarrow B; \Pi)$ if $Abduce(\Gamma, A; B; \Pi')$ and $\Pi = A \rightarrow \Pi'$.
4. $Abduce(\Gamma; q; \Pi)$ if there is $C_1 \rightarrow \dots \rightarrow C_n \rightarrow q \in \Gamma$ and Π_1, \dots, Π_n such that
 - (a) $Abduce(\Gamma; C_i, \Pi_i)$ for $i = 1, \dots, n$.
 - (b) $\Pi = \bigcup_i \Pi_i$.

It can be shown that if $Abduce(\Gamma; q; \Pi)$ holds then $\Gamma, \Pi \vdash A$.

EXAMPLE 97. Let $\Gamma = (a \rightarrow c) \rightarrow b, (d \rightarrow b) \rightarrow s \rightarrow q, (p \rightarrow q) \rightarrow t \rightarrow r$. We compute $Abduce(\Gamma; r; \Pi)$. We have

- (1) $Abduce(\Gamma; r; \Pi)$ reduces to
- (2) $Abduce(\Gamma; p \rightarrow q; \Pi_1)$ and (3) $Abduce(\Gamma; t; \Pi_2)$
with $\Pi = \Pi_1 \cup \Pi_2$; (3) gives $\Pi_2 = \{t\}$. (2) is reduced as follows
- (4) $Abduce(\Gamma, p; q; \Pi_3)$ and $\Pi_1 = p \rightarrow \Pi_3$
- (5) $Abduce(\Gamma, p; d \rightarrow b; \Pi_4)$ and (6) $Abduce(\Gamma, p; s; \Pi_5)$
with $\Pi_3 = \Pi_4 \cup \Pi_5$; (6) gives $\Pi_5 = \{s\}$. (5) is reduced as follows
- (7) $Abduce(\Gamma, p, d; b; \Pi_6)$ and $\Pi_4 = b \rightarrow \Pi_6$
- (8) $Abduce(\Gamma, p, d; a \rightarrow c; \Pi_6)$
- (9) $Abduce(\Gamma, p, d, a; c; \Pi_7)$ and $\Pi_6 = a \rightarrow \Pi_7$
(9) gives $\Pi_7 = \{c\}$.

Thus

$$\Pi_6 = \{a \rightarrow c\}$$

$$\Pi_4 = \{b \rightarrow a \rightarrow c\}$$

$$\Pi_3 = \{b \rightarrow a \rightarrow c, s\}$$

$$\Pi_1 = \{p \rightarrow b \rightarrow a \rightarrow c, p \rightarrow s\}$$

$$\Pi = \{p \rightarrow b \rightarrow a \rightarrow c, p \rightarrow s, t\}.$$

One can easily check that $\Gamma, \Pi \vdash r$.

The abductive proof procedure we have exemplified is a sort of metapredicate defined from the goal-directed computation. It can be used to generate possible abductive solutions, that might be then compared and processed further. Of course variants and refinements of the abductive procedures are possible for specific purposes.

6.3 First-order extension

We conclude this chapter by some remarks on the major extension of these methods: the one to the first-order level. The extension is not straightforward. In general, in most non-classical logics there are several options in the interpretation of quantifiers and terms according to the intended semantics (typically, constant domain, increasing domains etc.); moreover, one may adopt either rigid, or non-rigid interpretation of terms. Sometimes the interpretation of quantifiers is not entirely clear, as it happens in substructural logics. However, even when quantifiers are well understood as in intuitionistic and modal logics, a goal-directed treatment of the full language creates troubles analogously to the treatment of disjunction. In particular the treatment of positive occurrences of the existential quantifier is problematic. In classical logic such a problem does not arise as one can always transform the pair (Database, Goal) into a set of universal sentences using Skolem transformation. A similar method cannot be applied to most non-classical logics, where one cannot skolemize the data before the computation starts.

As a difference with the theorem proving view, in the goal-directed approach (following the line of logic programming) one would like to define proof procedures which compute answer-substitutions. This means that the outcome of a successful computation of

$$\Delta \vdash^? G[X],$$

where $G[X]$ stands for $\exists XG[X]$ is not only 'yes', but it is (a most general) substitution X/t , such that $\Delta \vdash G[X/t]$ holds. In [Gabbay and Olivetti, 2000] it is presented a proof procedure for (\rightarrow, \forall) fragment of intuitionistic logic. The procedure is in the style of a logic programming and uses unification to compute answer-substitutions. The proof-procedure checks the simultaneous success of a set of pairs (Database, Goals); this structure is enforced by the presence of shared free variables occurring in different databases arising during the computation. The approach of 'Run-time skolemization' is used to handle universally quantified goals.²³ That is to say the process of eliminating universal quantifiers on the goal by Skolem functions is carried on in parallel with goal reduction. The 'Run-time Skolemisation' approach has been presented in [Gabbay, 1992; Gabbay and Reyle, 1993] and adopted in N-Prolog [Gabbay and Reyle, 1993], a hypothetical extension of Prolog based on intuitionistic logic. A similar idea for classical logic is embodied in the free-variable tableaux, see [Fitting, 1990] and [Hähnle and Schmitt, 1994] for an improved rule. The use of Skolem functions and normal form for intuitionistic proof-search has been studied by many authors, we just mention: [Shankar, 1992], [Pym and Wallen, 1990], and [Sahlin *et al.*, 1992].

²³These would be existentially quantified formulas in classical logic as checking $\Delta \vdash \forall xA$ is equivalent to check $\Delta \cup \{\exists x\neg A\}$ for inconsistency.

It is likely that in order to develop the first-order extensions for others non-classical logics one could take advantage of the labelled proof system. One would like to represent the semantic options on the interpretation of quantifiers by tinkering with the unification and the Skolemisation mechanism. The constraints on the unification and Skolemisation might perhaps be expressed in terms of the labels associated with the formulas and their dependencies. At present the extension of the goal-directed methods to the main families of non-classical logics along these lines is not at hand and it is a major topic of future investigation.

ON NEGATION, COMPLETENESS AND CONSISTENCY

1 INTRODUCTION

In this Chapter we try to understand negation from two different points of view: a syntactical one and a semantic one. Accordingly, we identify two different types of negation. The same connective of a given logic might be of both types, but this might not always be the case.

The syntactical point of view is an abstract one. It characterizes connectives according to the internal *role* they have inside a logic, regardless of any meaning they are intended to have (if any). With regard to negation our main thesis is that the availability of what we call below an internal negation is what makes a logic essentially *multiple-conclusion*.

The semantic point of view, in contrast, is based on the intuitive meaning of a given connective. In the case of negation this is simply the intuition that the negation of a proposition A is true if A is not, and not true if A is true.¹

Like in most modern treatments of logics (see, e.g., [Scott, 1974; Scott, 1974b; Hacking, 1979; Gabbay, 1981; Urquhart, 1984; Wojcicki, 1988; Epstein, 1995; Avron, 1991a; Cleave, 1991; Fagin *et al.*, 1992]), our study of negation will be in the framework of Consequence Relations (CRs). Following [Avron, 1991a], we use the following rather general meaning of this term:

DEFINITION.

(1) A *Consequence Relation* (CR) on a set of formulas is a binary relation \vdash between (finite) multisets of formulas s.t.:

(I) Reflexivity: $A \vdash A$ for every formula A .

(II) Transitivity, or “Cut”: if $\Gamma_1 \vdash \Delta_1, A$ and $A, \Gamma_2 \vdash \Delta_2$, then $\Gamma_1, \Gamma_2 \vdash \Delta_1, \Delta_2$.

(III) Consistency: $\emptyset \not\vdash \emptyset$ (where \emptyset is the empty multiset).

¹We have avoided here the term “false”, since we do not want to commit ourselves to the view that A is false precisely when it is not true. Our formulation of the intuition is therefore obviously circular, but this is unavoidable in intuitive informal characterizations of basic connectives and quantifiers.

(2) A single-conclusion CR is a CR \vdash such that $\Gamma \vdash \Delta$ only if Δ consists of a single formula.

The notion of a (multiple-conclusion) CR was introduced in [Scott, 1974] and [Scott, 1974b]. It was a generalization of Tarski's notion of a consequence relation, which was single-conclusion. Our notions are, however, not identical to the original ones of Tarski and Scott. First, they both considered *sets* (rather than multisets) of formulas. Second, they impose a third demand on CRs: monotonicity. We shall call a (single-conclusion or multiple-conclusion) CR which satisfies these two extra conditions *ordinary*. A single-conclusion, ordinary CR will be called *Tarskian*.²

The notion of a “logic” is in practice broader than that of a CR, since usually several CRs are associated with a given logic. Given a logic \mathcal{L} there are in most cases two major single-conclusion CRs which are naturally associated with it: the external CR $\vdash_{\mathcal{L}}^e$ and the internal CR $\vdash_{\mathcal{L}}^i$. For example, if \mathcal{L} is defined by some axiomatic system AS then $A_1, \dots, A_n \vdash_{\mathcal{L}}^e B$ iff there exists a proof in AS of B from A_1, \dots, A_n (according to the most standard meaning of this notion as defined in undergraduate textbooks on mathematical logic), while $A_1, \dots, A_n \vdash_{\mathcal{L}}^i B$ iff $A_1 \rightarrow (A_2 \rightarrow \dots \rightarrow (A_n \rightarrow B) \dots)$ is a theorem of AS (where \rightarrow is an appropriate “implication” connective of the logic). Similarly if \mathcal{L} is defined using a Gentzen-type system G then $A_1, \dots, A_n \vdash_{\mathcal{L}}^i B$ if the sequent $A_1, \dots, A_n \Rightarrow B$ is provable in G , while $A_1, \dots, A_n \vdash_{\mathcal{L}}^e B$ iff there exists a proof in G of $\Rightarrow B$ from the assumptions $\Rightarrow A_1, \dots, \Rightarrow A_n$ (perhaps with cuts). $\vdash_{\mathcal{L}}^e$ is always a Tarskian relation, $\vdash_{\mathcal{L}}^i$ frequently is not. The existence (again, in most cases) of these two CRs should be kept in mind in what follows. The reason is that semantic characterizations of connectives are almost always done w.r.t. Tarskian CRs (and so here $\vdash_{\mathcal{L}}^e$ is usually relevant). This is not the case with syntactical characterizations, and here frequently $\vdash_{\mathcal{L}}^i$ is more suitable.

2 THE SYNTACTICAL POINT OF VIEW

2.1 Classification of basic connectives

Our general framework allows us to give a completely abstract definition, *independent of any semantic interpretation*, of standard connectives. These characterizations explain why these connectives are so important in almost every logical system.

In what follows \vdash is a fixed CR. All definitions are taken to be relative to \vdash (the definitions are taken from [Avron, 1991a]).

²What we call a Tarskian CR is exactly Tarski's original notion. In [Avron, 1994] we argue at length why the notion of a proof in an axiomatic system naturally leads to *our* notion of single-conclusion CR, and why the further generalization to multiple-conclusion CR is also very reasonable.

We consider two types of connectives. The *internal* connectives, which make it possible to transform a given sequent into an equivalent one that has a special required form, and the *combining* connectives, which allow us to combine (under certain circumstances) two sequents into one which contains exactly the same information. The most common (and useful) among these are the following connectives:

Internal Disjunction: $+$ is an internal disjunction if for all Γ, Δ, A, B :

$$\Gamma \vdash \Delta, A, B \quad \text{iff} \quad \Gamma \vdash \Delta, A + B .$$

Internal Conjunction: \otimes is an internal conjunction if for all Γ, Δ, A, B :

$$\Gamma, A, B \vdash \Delta \quad \text{iff} \quad \Gamma, A \otimes B \vdash \Delta .$$

Internal Implication: \rightarrow is an internal implication if for all Γ, Δ, A, B :

$$\Gamma, A \vdash B, \Delta \quad \text{iff} \quad \Gamma \vdash A \rightarrow B, \Delta .$$

Internal Negation: \neg is an internal negation if the following two conditions are satisfied by all Γ, Δ and A :

- (1) $A, \Gamma \vdash \Delta \quad \text{iff} \quad \Gamma \vdash \Delta, \neg A$
- (2) $\Gamma \vdash \Delta, A \quad \text{iff} \quad \neg A, \Gamma \vdash \Delta .$

Combining Conjunction: \wedge is a combining conjunction iff for all Γ, Δ, A, B :

$$\Gamma \vdash \Delta, A \wedge B \quad \text{iff} \quad \Gamma \vdash \Delta, A \quad \text{and} \quad \Gamma \vdash \Delta, B .$$

Combining Disjunction: \vee is a combining disjunction iff for all Γ, Δ, A, B

$$A \vee B, \Gamma \vdash \Delta \quad \text{iff} \quad A, \Gamma \vdash \Delta \quad \text{and} \quad B, \Gamma \vdash \Delta .$$

Note: The combining connectives are called “additives” in Linear logic (see [Girard, 1987]) and “extensional” in Relevance logic. The internal ones correspond, respectively, to the “multiplicative” and the “intensional” connectives.

Several well-known logics can be defined using the above connectives:

LL_m — **Multiplicative Linear Logic** (without the propositional constants): This is the logic which corresponds to the *minimal* (multiset) CR which includes all the internal connectives.

LL_{ma} — **Propositional Linear Logic** (without the “exponentials” and the propositional constants): This corresponds to the minimal consequence relation which contains all the connectives introduced above.

R_m — **the Intensional Fragment of the Relevance Logic R** :³ This corresponds to the minimal CR which contains all the internal connectives and is *closed under contraction*.

³see [Anderson and Belnap, 1975] or [Dunn, 1986].

***R* without Distribution:** This corresponds to the minimal CR which contains all the connectives which were described above and is closed under contraction.

RM_{I_m} — **the Intensional Fragment of the Relevance Logic *RM_I*:**⁴ This corresponds to the minimal sets-CR which contains all the internal connectives.

Classical Proposition Logic: This of course corresponds to the minimal ordinary CR which has all the above connectives. Unlike the previous logics there is no difference in it between the combining connectives and the corresponding internal ones.

In all these examples we refer, of course, to the *internal* consequence relations which naturally correspond to these logics (In all of them it can be defined by either of the methods described above).

2.2 Internal Negation and Strong Symmetry

Among the various connectives defined above only negation essentially demands the use of multiple-conclusion CRs (even the existence of an internal disjunction does not *force* multiple-conclusions, although its existence is trivial otherwise.). Moreover, its existence creates full symmetry between the two sides of the turnstyle. Thus in its presence, closure under any of the structural rules on one side entails closure under the same rule on the other, the existence of any of the binary internal connectives defined above implies the existence of the rest, and the same is true for the combining connectives.

To sum up: internal negation is the connective with which “the hidden symmetries of logic” [Girard, 1987] are explicitly represented. We shall call, therefore, any multiple-conclusion CR which possesses it *strongly symmetric*.

Some alternative characterizations of an internal negation are given in the following easy proposition.

PROPOSITION 1. *The following conditions on \vdash are all equivalent:*

- (1) \neg is an internal negation for \vdash .
- (2) $\Gamma \vdash \Delta, A$ iff $\Gamma, \neg A \vdash \Delta$
- (3) $A, \Gamma \vdash \Delta$ iff $\Gamma \vdash \Delta, \neg A$
- (4) $A, \neg A \vdash$ and $\vdash \neg A, A$
- (5) \vdash is closed under the rules:

$$\frac{A, \Gamma \vdash \Delta}{\Gamma \vdash \Delta, \neg A} \qquad \frac{\Gamma \vdash \Delta, A}{\neg A, \Gamma \vdash \Delta} .$$

Our characterization of internal negation and of symmetry has been done within the framework of multiple-conclusion relations. Single-conclusion

⁴see [Avron, 1990a; Avron, 1990b].

CRs are, however, more natural. We proceed next to introduce corresponding notions for them.

DEFINITION.

(1) Let $\vdash_{\mathcal{L}}$ be a single-conclusion CR (in a language \mathcal{L}), and let \neg be a unary connective of \mathcal{L} . $\vdash_{\mathcal{L}}$ is called *strongly symmetric* w.r.t. to \neg , and \neg is called an *internal negation* for $\vdash_{\mathcal{L}}$, if there exists a multiple-conclusion CR $\vdash_{\mathcal{L}}^*$ with the following properties:

- (i) $\Gamma \vdash_{\mathcal{L}}^* A$ iff $\Gamma \vdash_{\mathcal{L}} A$
- (ii) \neg is an internal negation for $\vdash_{\mathcal{L}}^*$

(2) A single-conclusion CR $\vdash_{\mathcal{L}}$ is called *essentially multiple-conclusion* iff it has an internal negation.

Obviously, if a CR $\vdash_{\mathcal{L}}^*$ like in the last definition exists then it is unique. We now formulate sufficient and necessary conditions for its existence.

THEOREM 2. $\vdash_{\mathcal{L}}$ is strongly symmetric w.r.t. \neg iff the following conditions are satisfied:

- (i) $A \vdash_{\mathcal{L}} \neg\neg A$
- (ii) $\neg\neg A \vdash_{\mathcal{L}} A$
- (iii) If $\Gamma, A \vdash_{\mathcal{L}} B$ then $\Gamma, \neg B \vdash_{\mathcal{L}} \neg A$.

Proof. The conditions are obviously necessary. Assume, for the converse, that $\vdash_{\mathcal{L}}$ satisfies the conditions. Define: $A_1, \dots, A_n \vdash_{\mathcal{L}}^s B_1, \dots, B_k$ iff for every $1 \leq i \leq n$ and $1 \leq j \leq k$:

$$A_1, \dots, A_{i-1}, \neg B_1, \dots, \neg B_k, A_{i+1}, \dots, A_n \vdash \neg A_i$$

$$A_1, \dots, A_n, \neg B_1, \dots, \neg B_{j-1}, \neg B_{j+1}, \dots, \neg B_k \vdash B_j.$$

It is easy to check that $\vdash_{\mathcal{L}}^s$ is a CR whenever $\vdash_{\mathcal{L}}$ is a CR (whether single-conclusion or multiple-conclusion), and that if $\Gamma \vdash_{\mathcal{L}}^s A$ then $\Gamma \vdash_{\mathcal{L}} A$. The first two conditions imply (together) that \neg is an internal negation for $\vdash_{\mathcal{L}}^s$ (in particular: the second entails that if $A, \Gamma \vdash_{\mathcal{L}}^s \Delta$ then $\Gamma \vdash_{\mathcal{L}}^s \Delta, \neg A$ and the first that if $\Gamma \vdash_{\mathcal{L}}^s \Delta, A$ then $\neg A, \Gamma \vdash_{\mathcal{L}}^s \Delta$). Finally, the third condition entails that $\vdash_{\mathcal{L}}^s$ is conservative over $\vdash_{\mathcal{L}}$. ■

Examples of logics with an internal negation.

1. Classical logic.
2. Extensions of classical logic, like the various modal logics.
3. Linear logic and its various fragments.

4. The various Relevance logics (like R and RM (see [Anderson and Belnap, 1975; Dunn, 1986; Anderson and Belnap, 1992] or RMI [Avron, 1990a; Avron, 1990b]) and their fragments.
5. The various many-valued logics of Łukasiewicz, as well as Sobociński 3-valued logic [Sobociński, 1952].

Examples of logics without an internal negation.

1. Intuitionistic logic.
2. Kleene's 3-valued logic and its extension LPF [Jones, 1986].

Note: Again, in all these examples above it is the *internal* CR which is essentially multiple-conclusion (or not) and has an internal negation. This is true even for classical predicate calculus: There, e.g., $\forall xA(x)$ follows from $A(x)$ according to the *external* CR, but $\neg A(x)$ does not follow from $\neg\forall xA(x)$.⁵

All the positive examples above are instances of the following proposition, the easy proof of which we leave to the reader:

PROPOSITION 3. *Let \mathcal{L} be any logic in a language containing \neg and \rightarrow . Suppose that the set of valid formulae of \mathcal{L} includes the set of formulae in the language of $\{\neg, \rightarrow\}$ which are theorems of Linear Logic,⁶ and that it is closed under MP for \rightarrow . Then the internal consequence relation of \mathcal{L} (defined using \rightarrow as in the introduction) is strongly symmetric (with respect to \neg).*

The next two theorems discuss what properties of $\vdash_{\mathcal{L}}$ are preserved by $\vdash_{\mathcal{L}}^s$. The proofs are straightforward.

THEOREM 4. *Assume $\vdash_{\mathcal{L}}$ is essentially multiple-conclusion.*

1. $\vdash_{\mathcal{L}}^s$ is monotonic iff so is $\vdash_{\mathcal{L}}$.
2. $\vdash_{\mathcal{L}}^s$ is closed under expansion (the converse of contraction) iff so is $\vdash_{\mathcal{L}}$.
3. \wedge is a combining conjunction for $\vdash_{\mathcal{L}}^s$ iff it is a combining conjunction for $\vdash_{\mathcal{L}}$.
4. \rightarrow is an internal implication for $\vdash_{\mathcal{L}}^s$ iff it is an internal implication for $\vdash_{\mathcal{L}}$.

⁵The internal CR of classical logic has been called the “truth” CR in [Avron, 1991a] and was denoted there by \vdash^t , while the external one was called the “validity” CR and was denoted by \vdash^v . On the propositional level there is no difference between the two.

⁶Here \neg should be translated into linear negation, \rightarrow – into linear implication.

Notes:

1) Because $\vdash_{\mathcal{L}}^s$ is strongly symmetric, Parts (3) and (4) can be formulated as follows: $\vdash_{\mathcal{L}}^s$ has the internal connectives iff $\vdash_{\mathcal{L}}$ has an internal implication and it has the combining connectives iff $\vdash_{\mathcal{L}}$ has a combining conjunction.

2) In contrast, a combining disjunction for $\vdash_{\mathcal{L}}$ is not necessarily a combining disjunction for $\vdash_{\mathcal{L}}^s$. It is easy to see that a necessary and sufficient condition for this to happen is that $\vdash_{\mathcal{L}} \neg(A \vee B)$ whenever $\vdash_{\mathcal{L}} \neg A$ and $\vdash_{\mathcal{L}} \neg B$. An example of an essentially multiple-conclusion system with a combining disjunction which does not satisfy the above condition is *RMI* of [Avron, 1990a; Avron, 1990b]. That system indeed does not have a combining conjunction. This shows that a *single-conclusion* logic \mathcal{L} with an internal negation and a combining disjunction does not necessarily have a combining conjunction (unless \mathcal{L} is monotonic). The converse situation is not possible, though: If \neg is an internal negation and \wedge is a combining conjunction then $\neg(\neg A \wedge \neg B)$ defines a combining disjunction even in the single-conclusion case.

3) An internal conjunction \otimes for $\vdash_{\mathcal{L}}$ is also not necessarily an internal conjunction for $\vdash_{\mathcal{L}}^s$. We need here the extra condition that if $A \vdash_{\mathcal{L}} \neg B$ then $\vdash_{\mathcal{L}} \neg(A \otimes B)$. An example which shows that this condition does not necessarily obtain even if $\vdash_{\mathcal{L}}$ is an ordinary CR, is given by the following CR \vdash_{triv} :

$$A_1, \dots, A_n \vdash_{triv} B \quad \text{iff} \quad n \geq 1 .$$

It is obvious that \vdash_{triv} is a Tarskian CR and that every unary connective of its language is an internal negation for it, while every binary connective is an internal conjunction. The condition above fails, however, for \vdash_{triv} .

4) The last example shows also that $\vdash_{\mathcal{L}}^s$ may not be closed under contraction when $\vdash_{\mathcal{L}}$ does, even if $\vdash_{\mathcal{L}}$ is Tarskian. Obviously, $\Gamma \vdash_{triv}^s \Delta$ iff $|\Gamma \cup \Delta| \geq 2$. Hence $\vdash_{triv}^s A, A$ but $\not\vdash_{triv}^s A$. The exact situation about contraction is given in the next proposition.

PROPOSITION 5. *If $\vdash_{\mathcal{L}}$ is essentially multiple-conclusion then $\vdash_{\mathcal{L}}^s$ is closed under contraction iff $\vdash_{\mathcal{L}}$ is closed under contraction and satisfies the following condition:*

$$\text{If } A \vdash_{\mathcal{L}} B \text{ and } \neg A \vdash_{\mathcal{L}} B \text{ then } \vdash_{\mathcal{L}} B .$$

In case $\vdash_{\mathcal{L}}$ has a combining disjunction this is equivalent to:

$$\vdash_{\mathcal{L}} \neg A \vee A .$$

Proof. Suppose first that $\vdash_{\mathcal{L}}$ is closed under contraction and satisfies the condition. Assume that $\Gamma \vdash_{\mathcal{L}}^s \Delta, A, A$. If either Γ or Δ is not empty then this is equivalent to $\neg A, \neg A, \Gamma^* \vdash_{\mathcal{L}} B$ for some Γ^* and B . Since $\vdash_{\mathcal{L}}$ is closed under contraction, this implies that $\neg A, \Gamma^* \vdash_{\mathcal{L}} B$, and so $\Gamma \vdash_{\mathcal{L}}^s \Delta, A$. If both Γ and Δ are empty then we have $\neg A \vdash_{\mathcal{L}} A$. Since also $A \vdash_{\mathcal{L}} A$, the condition implies that $\vdash_{\mathcal{L}} A$, and so $\vdash_{\mathcal{L}}^s A$.

For the converse, suppose $\vdash_{\mathcal{L}}^s$ is closed under contraction. This obviously entails that so is also $\vdash_{\mathcal{L}}$. Assume now that $A \vdash_{\mathcal{L}} B$ and $\neg A \vdash_{\mathcal{L}} B$. Then $A \vdash_{\mathcal{L}}^s B$ and $\vdash_{\mathcal{L}}^s B, A$. Applying cut we get that $\vdash_{\mathcal{L}}^s B, B$, and so $\vdash_{\mathcal{L}}^s B$. It follows that $\vdash_{\mathcal{L}} B$. ■

3 THE SEMANTIC POINT OF VIEW

We turn in this section to the semantic aspect of negation.

3.1 *The General Framework*

A “semantics” for a logic consists of a set of “models”. The main property of a model is that every sentence of a logic is either true in it or not (and not both). The logic is sound with respect to the semantics if the set of sentences which are true in each model is closed under the CR of the logic, and complete if a sentence φ follows (according to the logic) from a set T of assumptions iff every model of T is a model of φ . Such a characterization is, of course, possible only if the CR we consider is Tarskian. *In this section we assume, therefore, that we deal only with Tarskian CRs.* For logics like Linear Logic and Relevance logics this means that we consider only the *external* CRs which are associated with them (see the Introduction).

Obviously, the essence of a “model” is given by the set of sentences which are true in it. Hence a semantics is, essentially, just a set S of theories. Intuitively, these are the theories which (according to the semantics) provide a full description of a possible state of affairs. Every other theory can be understood as a partial description of such a state, or as an approximation of a full description. Completeness means, then, that a sentence φ follows from a theory T iff φ belongs to every superset of T which is in S (in other words: iff φ is true in any possible state of affairs of which T is an approximation).

Now what constitutes a “model” is frequently defined using some kind of algebraic structures. Which kind (matrices with designated values, possible worlds semantics and so on) varies from one logic to another. It is difficult, therefore, to base a general, uniform theory on the use of such structures. Semantics (= a set of theories!) can also be defined, however, purely syntactically. Indeed, below we introduce several types of syntactically defined semantics which are very natural for *every* logic with “negation”. Our investigations will be based on these types.

Our description of the notion of a model reveals that *externally* it is based on two classical “laws of thought”: the law of contradiction and the law of excluded middle. When this external point of view is reflected inside the logic with the help of a unary connective \neg we call this connective a (strong) *semantic negation*. Its intended meaning is that $\neg A$ should be true precisely

when A is not. The law of contradiction means then that only consistent theories may have a model, while the law of excluded middle means that the set of sentences which are true in some given model should be negation-complete. The sets of consistent theories, of complete theories and of normal theories (theories that are both) have, therefore a crucial importance when we want to find out to what degree a given unary connective of a logic can be taken as a semantic negation. Thus complete theories reflect a state of affairs in which the law of excluded middle holds. It is reasonable, therefore, to say that this law semantically obtains for a logic \mathcal{L} if its consequence relation $\vdash_{\mathcal{L}}$ is *determined* by its set of complete theories. Similarly, \mathcal{L} (strongly) satisfies the law of contradiction iff $\vdash_{\mathcal{L}}$ is determined by its set of consistent theories, and it semantically satisfies both laws iff $\vdash_{\mathcal{L}}$ is determined by its set of normal theories.

The above characterizations might seem unjustifiably strong for logics which are designed to allow non-trivial inconsistent theories. For such logics the demand that $\vdash_{\mathcal{L}}$ should be determined by its set of normal theories is reasonable only if we start with a consistent set of assumptions (this is called strong \mathcal{C} -normality below). A still weaker demand (\mathcal{C} -normality) is that any consistent set of assumptions should be an approximation of at least one normal state of affairs (in other words: it should have at least one normal extension).

It is important to note that the above characterizations are independent of the existence of any internal reflection of the laws (for example: in the forms $\neg(\neg A \wedge A)$ and $\neg A \vee A$, for suitable \wedge and \vee). There might be strong connections, of course, in many important cases, but they are neither necessary nor always simple.

We next define our general notion of semantics in precise terms.

DEFINITION. Let \mathcal{L} be a logic in L and let $\vdash_{\mathcal{L}}$ be its associated CR.

1. A *setup* for $\vdash_{\mathcal{L}}$ is a set of formulae in L which is closed under $\vdash_{\mathcal{L}}$. A *semantics* for $\vdash_{\mathcal{L}}$ is a nonempty set of setups which does not include the trivial setup (i.e., the set of all formulae).
2. Let S be a semantics for $\vdash_{\mathcal{L}}$. An *S -model* for a formula A is any setup in S to which A belongs. An *S -model* of a theory T is any setup in S which is a superset of T . A formula is called *S -valid* iff every setup in S is a model of it. A formula A *S -follows* from a theory T ($T \vdash_{\mathcal{L}}^S A$) iff every S -model of T is an S -model of A .

PROPOSITION 6. $\vdash_{\mathcal{L}}^S$ is a (Tarskian) consequence relation and $\vdash_{\mathcal{L}} \subseteq \vdash_{\mathcal{L}}^S$.

Notes:

1. $\vdash_{\mathcal{L}}^S$ is not necessarily finitary even if \vdash is.
2. $\vdash_{\mathcal{L}}$ is just $\vdash_{\mathcal{L}}^{S(\mathcal{L})}$ where $S(\mathcal{L})$ is the set of all setups for $\vdash_{\mathcal{L}}$.

3. If $S_1 \subseteq S_2$ then $\vdash_{\mathcal{L}}^{S_2} \subseteq \vdash_{\mathcal{L}}^{S_1}$.

EXAMPLES.

1. For classical propositional logic the standard semantics consists of the setups which are induced by some valuation in $\{t, f\}$. These setups can be characterized as theories T such that

$$(i) \quad \neg A \in T \text{ iff } A \notin T \quad (ii) \quad A \wedge B \in T \text{ iff both } A \in T \text{ and } B \in T$$

(and similar conditions for the other connectives).

2. In classical predicate logic we can define a setup in S to be any set of formulae which consists of the formulae which are true in some given first-order structure relative to some given assignment. Alternatively we can take a setup to consist of the formulae which are *valid* in some given first-order structure. In the first case $\vdash^S = \vdash^t$, in the second $\vdash^S = \vdash^v$, where \vdash^t and \vdash^v are the “truth” and “validity” consequence relations of classical logic (see [Avron, 1991a] for more details).

3. In modal logics we can define a “model” as the set of all the formulae which are true in some world in some Kripke frame according to some valuation. Alternatively, we can take a model as the set of all formulae which are valid in some Kripke frame, relative to some valuation. Again we get the two most usual consequence relations which are used in modal logics (see [Avron, 1991a] or [Fagin *et al.*, 1992]).

From now on the *following two conditions will be assumed in all our general definitions and propositions*:

1. The language contains a negation connective \neg .
2. For no A are both A and $\neg A$ theorems of the logic.

DEFINITION. Let S be a semantics for a CR $\vdash_{\mathcal{L}}$

1. $\vdash_{\mathcal{L}}$ is strongly complete relative to S if $\vdash_{\mathcal{L}}^S = \vdash_{\mathcal{L}}$.
2. $\vdash_{\mathcal{L}}$ is weakly complete relative to S if for all A , $\vdash_{\mathcal{L}} A$ iff $\vdash_{\mathcal{L}}^S A$.
3. $\vdash_{\mathcal{L}}$ is c -complete relative to S if every consistent theory of $\vdash_{\mathcal{L}}$ has a model in S .
4. $\vdash_{\mathcal{L}}$ is strongly c -complete relative to S if for every A and every *consistent* T , $T \vdash_{\mathcal{L}}^S A$ iff $T \vdash_{\mathcal{L}} A$.

Notes:

1. Obviously, strong completeness implies strong c -completeness, while strong c -completeness implies both c -completeness and weak completeness.
2. Strong completeness means that deducibility in $\vdash_{\mathcal{L}}$ is equivalent to semantic consequence in S . Weak completeness means that theoremhood in $\vdash_{\mathcal{L}}$ (i.e., derivability from the empty set of assumptions) is equivalent to semantic validity (= truth in all models). c -completeness means that consistency implies satisfiability. It becomes identity if only consistent sets can be satisfiable, i.e., if $\{\neg A, A\}$ has a model for no A . This is obviously too strong a demand for paraconsistent logics. Finally, strong c -completeness means that if we restrict ourselves to *normal* situations (i.e., consistent theories) then $\vdash_{\mathcal{L}}$ and $\vdash_{\mathcal{L}}^S$ are the same. This might sometimes be weaker than full strong completeness.

The last definition uses the concepts of “consistent” theory. The next definition clarifies (among other things) the meaning of this notion as we are going to use in it this paper.

DEFINITION. Let \mathcal{L} and $\vdash_{\mathcal{L}}$ be as above. A theory in L *consistent* if for no A it is the case that $T \vdash_{\mathcal{L}} A$ and $T \vdash_{\mathcal{L}} \neg A$, *complete* if for all A , either $T \vdash_{\mathcal{L}} A$ or $T \vdash_{\mathcal{L}} \neg A$, *normal* if it is both consistent and complete. $CS_{\mathcal{L}}$, $CP_{\mathcal{L}}$ and $N_{\mathcal{L}}$ will denote, respectively, the sets of its consistent, complete and normal theories.

Given $\vdash_{\mathcal{L}}$, the three classes, $CS_{\mathcal{L}}$, $CP_{\mathcal{L}}$ and $N_{\mathcal{L}}$, provide 3 different syntactically defined semantics for $\vdash_{\mathcal{L}}$, and 3 corresponding consequence relations $\vdash_{\mathcal{L}}^{CS_{\mathcal{L}}}$, $\vdash_{\mathcal{L}}^{CP_{\mathcal{L}}}$ and $\vdash_{\mathcal{L}}^{N_{\mathcal{L}}}$. We shall henceforth denote these CRs by $\vdash_{\mathcal{L}}^{CS}$, $\vdash_{\mathcal{L}}^{CP}$ and $\vdash_{\mathcal{L}}^N$, respectively. Obviously, $\vdash_{\mathcal{L}}^{CS} \subseteq \vdash_{\mathcal{L}}^N$ and $\vdash_{\mathcal{L}}^{CP} \subseteq \vdash_{\mathcal{L}}^N$. In the rest of this section we investigate these relations and the completeness properties they induce.

Let us start with the easier case: that of $\vdash_{\mathcal{L}}^{CS}$. It immediately follows from the definitions (and our assumptions) that relative to it every logic is strongly c -complete (and so also c -complete and weakly complete). Hence the only completeness notion it induces is the following:

DEFINITION. A logic \mathcal{L} with a consequence relation $\vdash_{\mathcal{L}}$ is strongly consistent if $\vdash_{\mathcal{L}}^{CS} = \vdash_{\mathcal{L}}$.

$\vdash_{\mathcal{L}}^{CS}$ is not a really interesting CR. As the next theorem shows, what it does is just to trivialize inconsistent $\vdash_{\mathcal{L}}$ -theories. Strong consistency, accordingly, might not be a desirable property, certainly not a property that any logic with negation should have.

PROPOSITION 7.

1. $T \vdash_{\mathcal{L}}^{CS} A$ iff either T is inconsistent in \mathcal{L} or $T \vdash_{\mathcal{L}} A$. In particular, T is $\vdash_{\mathcal{L}}^{CS}$ -consistent iff it is $\vdash_{\mathcal{L}}$ -consistent.
2. \mathcal{L} is strongly consistent iff $\neg A, A \vdash_{\mathcal{L}} B$ for all A, B (iff T is consistent whenever $T \not\vdash_{\mathcal{L}} A$).
3. Let \mathcal{L}^{CS} be obtained from \mathcal{L} by adding the rule: from $\neg A$ and A infer B . Then $\vdash_{\mathcal{L}}^{CS} = \vdash_{\mathcal{L}^{CS}}$. In particular: if $\vdash_{\mathcal{L}}$ is finitary then so is $\vdash_{\mathcal{L}}^{CS}$.
4. $\vdash_{\mathcal{L}}^{CS}$ is strongly consistent.

We turn now to \vdash^{CP} and \vdash^N . In principle, each provides 4 notions of completeness. We don't believe, however, that considering the two notions of c -consistency is natural or interesting in the framework of \vdash^{CP} (c -completeness, e.g., means there that every consistent theory has a complete extension, but that extension might not be consistent itself). Accordingly we shall deal with the following 6 notions of syntactical completeness.⁷

DEFINITION. Let \mathcal{L} be a logic and let $\vdash_{\mathcal{L}}$ be its consequence relation.

1. \mathcal{L} is *strongly complete* if it is strongly complete relative to CP .
2. \mathcal{L} is *weakly complete* if it is weakly complete relative to CP .
3. \mathcal{L} is *strongly normal* if it is strongly complete relative to N .
4. \mathcal{L} is *weakly normal* if it is weakly complete relative to N .
5. \mathcal{L} is *c -normal* if it is c -complete relative to N .
6. \mathcal{L} is *strongly c -normal* if it is strongly c -complete relative to N (this is easily seen to be equivalent to $\vdash_{\mathcal{L}}^N = \vdash_{\mathcal{L}}^{CS}$).

For the reader's convenience we repeat what these definitions actually mean:

1. \mathcal{L} is strongly complete iff whenever $T \not\vdash_{\mathcal{L}} A$ there exists a complete extension T^* of T such that $T^* \not\vdash_{\mathcal{L}} A$.
2. \mathcal{L} is weakly complete iff whenever A is not a theorem of \mathcal{L} there exists a complete T^* such that $T^* \not\vdash_{\mathcal{L}} A$.
3. \mathcal{L} is strongly normal iff whenever $T \not\vdash_{\mathcal{L}} A$ there exists a complete and consistent extension T^* of T such that $T^* \not\vdash_{\mathcal{L}} A$.
4. \mathcal{L} is weakly normal iff whenever A is not a theorem of \mathcal{L} there exists a complete and consistent theory T^* such that $T^* \not\vdash_{\mathcal{L}} A$.

⁷In [Anderson and Belnap, 1975] the term "syntactically complete" was used for what we call below "strongly c -normal".

5. \mathcal{L} is *c*-normal if every consistent theory of \mathcal{L} has a complete and consistent extension.
6. \mathcal{L} is strongly *c*-normal iff whenever T is consistent and $T \not\vdash_{\mathcal{L}} A$ there exists a complete and consistent extension T^* of T such that $T^* \not\vdash_{\mathcal{L}} A$.

Our next proposition provides simpler syntactical characterizations of some of these notions in case $\vdash_{\mathcal{L}}$ is finitary.

PROPOSITION 8. *Assume that $\vdash_{\mathcal{L}}$ is finitary.*

1. \mathcal{L} is strongly complete iff for all T, A and B :

$$(*) \quad T, A \vdash_{\mathcal{L}} B \quad \text{and} \quad T, \neg A \vdash_{\mathcal{L}} B \quad \text{imply} \quad T \vdash_{\mathcal{L}} B$$

In case \mathcal{L} has a combining disjunction \vee then $()$ is equivalent to the theoremhood of $\neg A \vee A$ (excluded middle).*

2. \mathcal{L} is strongly normal if for all T and A :

$$(**) \quad T \vdash_{\mathcal{L}} A \quad \text{iff} \quad T \cup \{\neg A\} \quad \text{is inconsistent.}$$

3. \mathcal{L} is strongly *c*-normal iff $(**)$ obtains for every consistent T .

4. \mathcal{L} is *c*-normal iff for every consistent T and every A either $T \cup \{A\}$ or $T \cup \{\neg A\}$ is consistent.

Proof. Obviously, strong completeness implies $(*)$. For the converse, assume that $T \not\vdash B$. Using $(*)$, we extend T in stages to a complete theory such that $T^* \not\vdash B$. This proves part 1. The other parts are straightforward. ■

COROLLARIES.

1. If \mathcal{L} is strongly normal then it is strongly symmetric w.r.t. \neg . Moreover: $\vdash_{\mathcal{L}}^s$ is an ordinary multiple-conclusion CR.
2. If \mathcal{L} is strongly symmetric w.r.t. \neg then it is strongly complete iff $\vdash_{\mathcal{L}}^s$ is closed under contraction.

Proof. These results easily follows from the last proposition and Theorems 2, 4 and 5 above. ■

In the figure below we display the obvious relations between the seven properties of logics which were introduced here (where an arrow means “contained in”). The next theorem shows that no arrow can be added to it:

THEOREM 9. *A logic can be:*

1. *strongly consistent and c-normal without even being weakly complete*
2. *strongly complete and strongly c-normal without being strongly consistent (and so without being strongly normal)*
3. *strongly consistent without being c-normal*
4. *strongly complete, weakly normal and c-normal without being strongly c-normal*
5. *strongly complete and c-normal without being weakly normal*
6. *strongly consistent, c-normal and weakly normal without being strongly c-normal (=strongly normal in this case, because of strong consistency)*
7. *strongly complete without being c-normal.*⁸

Proof. Appropriate examples for 1-6 are given below, respectively, in theorems 12, 18, 33, 19, 35 and the corollary to theorem 19. As for the last part, let \mathcal{L} be the following system in the language of $\{\neg, \rightarrow\}$:⁹

⁸Hence the two standard formulations of the “strong consistency” of classical logic are *not* equivalent in general.

⁹Classical logic is obtained from it by adding $\neg A \rightarrow (A \rightarrow B)$ as axiom (see [Epstein, 1995, Ch. 2L]).

- $Ax1:$ $A \rightarrow (B \rightarrow A)$
- $Ax2:$ $A \rightarrow (B \rightarrow C) \rightarrow (A \rightarrow B) \rightarrow (A \rightarrow C)$
- $Ax3:$ $(\neg A \rightarrow B) \rightarrow ((A \rightarrow B) \rightarrow B)$
- (MP) $\frac{A \quad A \rightarrow B}{B}$.

Obviously, the deduction theorem for \rightarrow holds for this system, since MP is the only rule of inference, and we have $Ax1$ and $Ax2$. This fact, $Ax3$ and proposition 8 guarantee that it is strongly complete. To show that it is not c -normal, we consider the theory $T_0 = \{p \rightarrow q, p \rightarrow \neg q, \neg p \rightarrow r, \neg p \rightarrow \neg r\}$. Obviously, T_0 has no complete and consistent extension. We show that it is consistent nevertheless. For this we use the following structure:

Define in this structure $a \rightarrow b$ as t if $a \leq b$, b otherwise, $\neg x$ as f if $x = t$, t if $x = f$ and $\neg x$ otherwise. It is not difficult now to show that if $T \vdash A$ in the present logic for some T and A , and v is a valuation in this structure such that $v(B) = t$ for all $B \in T$, then $v(A) = t$. Take now $v(p) = 3$, $v(q) = 1$, $v(r) = 2$. Then $v(B) = t$ for all $B \in T_0$, but obviously there is no A such that $v(A) = v(\neg A) = t$. Hence T_0 is consistent. ■

We end this introductory subsection with a characterization of $\vdash_{\mathcal{L}}^{CP}$ and $\vdash_{\mathcal{L}}^N$. The proofs are left to the reader.

PROPOSITION 10.

1. $\vdash_{\mathcal{L}}^{CP}$ is strongly complete, and is contained in any strongly complete extension of $\vdash_{\mathcal{L}}$.
2. Suppose $\vdash_{\mathcal{L}}$ is finitary. $T \vdash_{\mathcal{L}}^{CP} A$ iff for some B_1, \dots, B_n ($n \geq 0$) we have that $T \cup \{B_1^*, \dots, B_n^*\} \vdash_{\mathcal{L}} A$ for every set $\{B_1^*, \dots, B_n^*\}$ such that for all i , $B_i^* = B_i$ or $B_i^* = \neg B_i$.

3. If $\vdash_{\mathcal{L}}$ is finitary, then so is $\vdash_{\mathcal{L}}^{CP}$.

PROPOSITION 11.

1. $\vdash_{\mathcal{L}}^N$ is strongly normal, and is contained in every strongly normal extension of $\vdash_{\mathcal{L}}$.
2. If $\vdash_{\mathcal{L}}$ is finitary then $T \vdash_{\mathcal{L}}^N A$ iff for some B_1, \dots, B_n we have that for all $\{B_1^*, \dots, B_n^*\}$ where $B_i^* \in \{B_i, \neg B_i\}$ ($i = 1, \dots, n$), either $T \cup \{B_1^*, \dots, B_n^*\}$ is inconsistent or $T \cup \{B_1^*, \dots, B_n^*\} \vdash_{\mathcal{L}} A$
3. $\vdash_{\mathcal{L}}^N$ is finitary if $\vdash_{\mathcal{L}}$ is.

3.2 Classical and Intuitionistic Logics

Obviously, classical propositional logic is strongly normal. In fact, most of the proofs of the completeness of classical logic relative to its standard two-valued semantics begin with demonstrating the condition (**) in Proposition 8, and are based on the fact that every complete and consistent theory determines a unique valuation in $\{t, f\}$ - and vice versa. In other words: N here is exactly the usual semantics of classical logic, only it can be characterized also using an especially simple algebraic structure (and valuations in it). One can argue that this strong normality *characterizes* classical logic. To be specific, it is not difficult to show the following claims:

1. classical logic is the only logic in the language of $\{\neg, \wedge\}$ which is strongly normal w.r.t. \neg and for which \wedge is an internal conjunction. Similar claims hold for the $\{\neg, \rightarrow\}$ language, if we demand \rightarrow to be an internal implication and for the $\{\neg, \vee\}$ language, if we demand \vee to be a combining disjunction.
2. Any logic which is strongly normal and has either an internal implication, or an internal conjunction or a combining disjunction contains classical propositional logic.

The next proposition summarizes the relevant facts concerning intuitionistic logic. The obvious conclusion is that although the official intuitionistic negation has some features of negation, it still lacks most. Hence, it cannot be taken as a real negation from our semantic point of view.

PROPOSITION 12. *Intuitionistic logic is strongly consistent and c-normal, but it is not even weakly complete.*

Proof. Strong consistency follows from part 3 of Proposition 7. *c*-normality follows from part 4 of Proposition 8, since in intuitionistic logic if both $T \cup \{A\}$ and $T \cup \{\neg A\}$ are inconsistent then $T \vdash_H \neg A$ and $T \vdash_H \neg \neg A$, and so T is inconsistent. Finally, $\neg A \vee A$ belongs to every complete setup, but is not intuitionistically valid. ■

Note: Intuitionistic logic and classical logic have exactly the same consistent and complete setups, since any complete intuitionistic theory is closed under the elimination rule of double negation. Hence any consistent intuitionistic theory has a classical two-valued model.

What about fragments (with negation) of Intuitionistic Logic? Well, they are also strongly consistent and c -normal, by the same proof. Moreover, $((A \rightarrow B) \rightarrow A) \rightarrow A$ is another example of a sentence which belongs to every complete setup (since $A \vdash_H ((A \rightarrow B) \rightarrow A) \rightarrow A$ and $\neg A \vdash_H ((A \rightarrow B) \rightarrow A) \rightarrow A$), but is not provable. The set of theorems of the pure $\{\neg, \wedge\}$ fragment, on the other hand, is identical to that of classical logic, as is well known. This fragment is, therefore, easily seen to be weakly normal. It is still neither strongly complete nor strongly c -normal, since $\neg\neg A \vdash_H^{CP} A$. ■

Finally, we note the important fact that classical logic can be viewed as the completion of intuitionistic logic. More precisely:

PROPOSITION 13.

1. $\vdash_H^{CS} = \vdash_H$
2. $\vdash_H^{CP} = \vdash_H^N = \text{classical logic}$.

Proof.

2. $\vdash_L^{CP} = \vdash_L^N$ whenever L is strongly consistent (i.e., all nontrivial theories are consistent). In the proof of the previous proposition we have seen also that $\vdash_H^{CP} \neg A \vee A$ and $\vdash_H^{CP} ((A \rightarrow B) \rightarrow A) \rightarrow A$. It is well known, however, that by adding either of these schemes to intuitionistic logic we get classical logic. Hence classical logic is contained in \vdash_H^{CP} . Since classical logic is already strongly complete, \vdash_H^{CP} is exactly classical logic. (Note that this is true for any fragment of the language which includes negation.) ■

3.3 Linear Logic (LL)

In the next 3 subsections we are going to investigate some known substructural logics [Schroeder-Heister and Došen, 1993]. Before doing it we must emphasize again that in this section it is only the external, Tarskian consequence relation of these logics which can be relevant. This consequence relation can very naturally be defined by using the standard Hilbert-type formulations of these logics: $A_1, \dots, A_n \vdash_{\mathcal{L}}^e B$ ($\mathcal{L} = LL, R, RM, RMI$, etc.) iff there exists an ordinary deduction of B from A_1, \dots, A_n in the corresponding Hilbert-type system. This definition is insensitive to the exact choice of axioms (or even rules), provided we take all the rules as rules of derivation and not just as rules of proof. In the case of Linear Logic one can use for this the systems given in [Avron, 1988] or in [Troelstra, 1992]. An

alternative equivalent definition of the various external CRs can be given using the standard Gentzen-types systems for these logics (in case such exist), as explained in the introduction. Still another characterization in the case of Linear Logic can be given using the phase semantics of [Girard, 1987]: $A_1, \dots, A_n \vdash_{LL}^e B$ iff B is true in every phase model of A_1, \dots, A_n . In what follows we shall omit the superscript “ e ” and write just $\vdash_{LL}, \vdash_{LL_m}$, etc.

Unlike in [Girard, 1987] we shall take below negation as one of the connectives of the language of linear logic and write $\neg A$ for the negation of A (this corresponds to Girard’s A^\perp). As in [Avron, 1988] and in the relevance logic literature, we use arrow (\rightarrow) for linear implication.

We show now that linear logic is incomplete with respect to our various notions.

PROPOSITION 14. *$LL_m (LL_{ma}, LL)$ is not strongly consistent.*

PROPOSITION 15. *$LL_m (LL_{ma}, LL)$ is neither strongly complete nor c -normal.*

Proof. Consider the following theory:

$$T = \{p \rightarrow \neg p, \neg p \rightarrow p\} .$$

From the characterization of \vdash_{LL_m} given in [Avron, 1992] it easily follows that has T been inconsistent then there would be a provable sequent of the form: $\neg p \rightarrow p, \neg p \rightarrow p, \dots, \neg p \rightarrow p, p \rightarrow \neg p, \dots, p \rightarrow \neg p \Rightarrow$. But in any cut-free proof of such a sequent the premises of the last applied rule should have an odd number of occurrences of p , which is impossible in a provable sequent of the purely multiplicative linear logic. Hence T is consistent. Obviously, every complete extension of T proves p and $\neg p$ and so is inconsistent. This shows that LL_m is not c -normal. It also shows that p is not provable from T , although it is provable from any complete extension of it, and so LL_m is not strongly complete. ■

PROPOSITION 16. *LL_{ma} (and so also LL) is not weakly complete.*

Proof. $\sim A \oplus A$ is not a theorem of linear logic, but it belongs to any complete theory. ■

It follows that Linear logic (and its multiplicative-additive fragment) has none of the properties we have defined in this section. Its negation is therefore not really a negation from our present *semantic* point of view.

Our results still leave the possibility that LL_m might be weakly complete or even weakly normal. We conjecture that it is not, but we have no counterexample.

We end this section by giving axiomatizations of \vdash_{LL}^{CP} and \vdash_{LL}^N .

PROPOSITION 17.

1. Let LL^{CP} be the full Hilbert-type system for linear logic (as given in [Avron, 1988]) together with the rule: from $!A \rightarrow B$ and $!\neg A \rightarrow B$ infer B . Then $\vdash_{LL}^{CP} = \vdash_{LL^{CP}}$.
2. Let LL^N be LL^{CP} together with the disjunctive syllogism for \oplus (from $\neg A$ and $A \oplus B$ infer B). Then $\vdash_{LL}^N = \vdash_{LL^N}$.

Proof.

1. The necessitation rule (from A infer $!A$) is one of the rules of LL .¹⁰ It follows therefore that B should belong to any complete setup which contains both $!A \rightarrow B$ and $!\neg A \rightarrow B$. Hence the new rule is valid for \vdash_{LL}^{CP} and $\vdash_{LL^{CP}} \subseteq \vdash_{LL}^{CP}$.

For the converse, assume $T \vdash_{LL}^{CP} A$. Then there exist B_1, \dots, B_n like in proposition 10(2). We prove by induction on n that $T \vdash_{LL^{CP}} A$. The case $n = 0$ is obvious. Suppose the claim is true for $n - 1$. We show it for n . By the deduction theorem for LL , $!B_1^* \dots !B_n^* \Rightarrow A$ is derivable from T in LL^{CP} .¹¹ More precisely: $!B_1^* \otimes !B_2^* \dots \otimes !B_n^* \rightarrow A$ is derivable from T for any choice of B_1^*, \dots, B_n^* . Since $!C \otimes !D \leftrightarrow !(C \& D)$ is a theorem of LL , this means that both $!B_n \rightarrow (!(B_1^* \& \dots \& B_{n-1}^*) \rightarrow A)$ and $!\neg B_n \rightarrow (!(B_1^* \& \dots \& B_{n-1}^*) \rightarrow A)$. By the new rule of LL^{CP} we get therefore that $T \vdash_{LL^{CP}} !(B_1^* \& \dots \& B_{n-1}^*) \rightarrow A$, and so $T \vdash_{LL^{CP}} !B_1^* \otimes !B_2^* \otimes \dots \otimes !B_{n-1}^* \rightarrow A$ for all choices of B_1^*, \dots, B_{n-1}^* . An application of the induction hypothesis gives $T \vdash_{LL^{CP}} A$.

2. The proof is similar, only this time we should have (by proposition 11) that $T \cup \{B_1^*, \dots, B_n^*\}$ is either inconsistent in L^N or proves A there. In both cases it proves $A \oplus \perp$ in LL^{CP} . The same argument as before will show that $T \vdash_{LL^{CP}} A \oplus \perp$. Since $\vdash_{LL} \neg \perp$, one application of the disjunctive syllogism will give $T \vdash_{LL^{CP}} A$. It remains to show that the disjunctive syllogism is valid for \vdash_{LL}^N . This is easy, since $\{\neg A, A \oplus B, \neg B\}$ is inconsistent in LL , and so any complete and consistent extension of $\{\neg A, A \oplus B\}$ necessarily contains B . ■

3.4 The Standard Relevance Logic R and its Relatives

In this section we investigate the standard relevance logic R of Anderson and Belnap [Anderson and Belnap, 1975; Dunn, 1986] and its various extensions and fragments. Before doing this we should again remind the reader what consequence relation we have in mind: the ordinary one which is associated

¹⁰Note again that we are talking here about \vdash_{LL}^c !

¹¹In fact, at the beginning it is derivable from T in LL , but for the induction to go through we need to assume derivability in LL^{CP} at each step.

with the standard Hilbert-type formulations of these logics. As in the case of linear logic, this means that we take both rules of R (MP and adjunction) as rules of derivation and define $T \vdash_R A$ in the most straightforward way.

Let us begin with the purely intensional (=multiplicative) fragment of R : R_m . We state the results for this system, but they hold for all its nonclassical various extensions (by axioms) which are discussed in the literature.

THEOREM 18. *R_m is not strongly consistent, but it is strongly complete and strongly c -normal.*

Proof. It is well-known that R_m is not strongly consistent in our sense. Its main property that we need for the other claims is that $T, A \vdash_{R_m} B$ iff either $T \vdash_{R_m} B$ or $T \vdash_{R_m} A \rightarrow B$. The strong completeness of R_m follows from this property by the provability of $(\neg A \rightarrow B) \rightarrow ((A \rightarrow B) \rightarrow B)$ and proposition 8(1).

To show strong c -normality, we note first that a theory T is inconsistent in R_m iff $T \vdash_{R_m} \neg(B \rightarrow B)$ for some B (because $\vdash_{R_m} \neg B \rightarrow (B \rightarrow \neg(B \rightarrow B))$). Suppose now that T is consistent and $T \not\vdash_{R_m} A$. Were $T \cup \{\neg A\}$ inconsistent then by the same main property and the consistency of T we would have that $T \vdash_{R_m} \neg A \rightarrow \neg(B \rightarrow B)$ for some B , and so that $T \vdash_{R_m} (B \rightarrow B) \rightarrow A$ and $T \vdash_{R_m} A$. A contradiction. Hence $T \cup \{\neg A\}$ is consistent and we are done by proposition 8(3). ■

The last theorem is the optimal theorem concerning negation that one can expect from a logic which was designed to be paraconsistent. It shows that with respect to normal “situations” (i.e., consistent theories) the negation connective of R_m behaves exactly as in classical logic. The difference, therefore, is mainly w.r.t. inconsistent theories. Unlike classical logic they are not necessarily trivial in R_m . Strong completeness means, though, that excluded middle, at least, can be assumed even in the abnormal situations.

When we come to R as a whole the situation is not as good as for the purely intensional fragments. Strong c -normality is lost. What we do have is the following:

THEOREM 19. *R is strongly complete, c -normal and weakly normal,¹² but it is neither strongly consistent nor strongly c -normal.*

Proof. Obviously, R is not strongly consistent. It is also well known that $\neg p, p \vee q \not\vdash_R q$. Still q belongs to any complete and consistent extension of the (even classically!) consistent theory $\{\neg p, p \vee q\}$, since $\{\neg p, p \vee q, \neg q\}$ is not consistent in R . It follows that R is not strongly c -normal. On the other hand, to any extension \mathcal{L} of R by axiom schemes it is true that if $T, A \vdash_{\mathcal{L}} C$ and $T, B \vdash_{\mathcal{L}} C$, then $T, A \vee B \vdash_{\mathcal{L}} C$ [Anderson and Belnap, 1975]. Since $\vdash_R A \vee \neg A$, this and proposition 8(1) entail that any such extension is strongly complete. Suppose, next, that T is theory and A a

¹²Weak normality is proved in [Anderson and Belnap, 1975] under the name “syntactical completeness”.

formula such that $T \cup \{A\}$ and $T \cup \{\neg A\}$ are inconsistent (\mathcal{L} as above). Then for some B and C it is the case that $T, A \vdash_{\mathcal{L}} \neg B \wedge B$ and $T, \neg A \vdash_{\mathcal{L}} \neg C \wedge C$. It follows that $T, A \vee \neg A \vdash_{\mathcal{L}} (\neg B \wedge B) \vee (\neg C \wedge C)$. Since $A \vee \neg A$ and $\neg[(\neg B \wedge B) \vee (\neg C \wedge C)]$ are both theorems of R , T is inconsistent in \mathcal{L} . By proposition 8(4) this shows that any such logic is c -normal. Suppose, finally, that $\not\vdash_R A$. Had $\{\neg A\}$ been inconsistent, we would have that for some B , $\neg A \vdash_R \neg B \wedge B$. This, in turn, entails that $A \vee \neg A \vdash_R A \vee (\neg B \wedge B)$, and so that $\vdash_R A \vee (\neg B \wedge B)$. On the other hand, $\vdash_R \neg(\neg B \wedge B)$. By the famous theorem of Meyer and Dunn concerning the admissibility of the disjunctive syllogism in R [Anderson and Belnap, 1975; Dunn, 1986] it would follow, therefore, that $\vdash_R A$, contradicting our assumption. Hence $\{\neg A\}$ is consistent, and so, by the c -normality of R which we have just proved, it has a consistent and complete extension which obviously does not prove A . This shows that R is weakly normal (the proof for RM is identical). ■

COROLLARY. \vdash_R^{CS} is strongly consistent, c -normal and weakly normal, but it is not strongly c -normal.

Note: A close examination of the proof of the last theorem shows that the properties of R which are described there are shared by many of its relatives (like RM , for example). We have, in fact, the following generalizations:

1. Every extension of R which is not strongly consistent is also not strongly c -normal.
2. Every extension of R by axiom-schemes is both strongly complete and c -normal.
3. Every extension of R by axiom schemes for which the disjunctive syllogism is an admissible rule¹³ is weakly normal.

In fact, (1)–(3) are true (with similar proofs) also for many systems weaker than R in the relevance family, like E .

Our results show that $\vdash_R^{CP} = \vdash_R$, but $\vdash_R^N \neq \vdash_R^{CS}$ (since R is not strongly c -normal). Hence \vdash_R^N is a new consequence relation, and we turn next to axiomatize it.

DEFINITION. Let \mathcal{L} be an extension of R by axiom schemes and let \mathcal{L}^N be the system which is obtained from \mathcal{L} by adding to it the disjunctive syllogism (γ) as an extra rule: from $\neg A$ and $A \vee B$ infer B .

THEOREM 20. $\vdash_{\mathcal{L}}^N = \vdash_{\mathcal{L}^N}$.

Proof. To show that $\vdash_{\mathcal{L}^N} \subseteq \vdash_{\mathcal{L}}^N$ it is enough to show that $\neg A, A \vee B \vdash_{\mathcal{L}}^N B$. This was already done, in fact, in the proof of the last theorem. For the converse, assume $T \vdash_{\mathcal{L}}^N A$. Since \mathcal{L} is c -normal (see last note), $T \cup \{\neg A\}$

¹³See [Anderson and Belnap, 1975] and [Dunn, 1986] for examples and criteria when this is the case.

cannot be \mathcal{L} -consistent. Hence $T \cup \{\neg A\} \vdash_{\mathcal{L}} \neg B \wedge B$ for some B . This entails that $T \vdash_{\mathcal{L}} A \vee (\neg B \wedge B)$ and that $T \vdash_{\mathcal{L}^N} A$ exactly as in the proof of the weak normality of R . ■

3.5 The Purely Relevant Logic RMI

The purely relevant logic RMI was introduced in citeAv90a,Av90b. Proof-theoretically it differs from R in that:

- (i) The converse of contraction (or, equivalently, the mingle axiom of RM) is valid in it. This is equivalent to the idempotency of the intensional disjunction $+$ (=“par” of Girard). In the purely multiplicative fragment RMI_m it means also that assumptions with respect to \rightarrow can be taken as coming in *sets* (rather than multisets, as in LL_m or R_m).
- (ii) The adjunction rule $(B, C \vdash B \wedge C)$ as well as the distribution axiom $(A \wedge (B \vee C) \rightarrow (A \wedge B) \vee (A \wedge C))$ are accepted only if B and C are “relevant”. This relevance relation can be expressed in the logic by the sentence $R^+(A, B) = (A \rightarrow A) + (B \rightarrow B)$, which should be added as an extra premise to adjunction and distribution (this sentence is the counterpart of the “mix” rule of [Girard, 1987]).

We start our investigation with the easier case of RMI_m .

THEOREM 21. *Exactly like R_m , RMI_m is not strongly consistent, but it is both strongly complete and strongly c-normal.*

Proof. Exactly like in the case of R_m . ■

Like in classical logic, and unlike the case of R_m , these two main properties of RMI_m are strongly related to simple, intuitive, algebraic semantics. Originally, in fact, RMI_m was designed to correspond to a class of structures which are called in [Avron, 1990a] “full relevant disjunctive lattices” (full r.d.l.). A full r.d.l. is a structure which results if we take a tree and attach to each node b its own two basic truth-values $\{t_b, f_b\}$. To a leaf b of the tree we *can* attach instead a single truth-value I_b which is the negation of itself (its meaning is “both true and false” or “degenerate”). b is called abnormal in this case. Intuitively, the nodes of the tree represent “domains of discourse”. Two domains are relevant to each other if they have a common branch, while b being nearer than a to the root on a branch intuitively means that b has a higher “degree of reality” (or higher “degree of significance”) than a (we write $a < b$ in this case). The operation of \neg (negation) is defined on a full r.d.l. M in the obvious way, while $+$ (relevant disjunction) is defined as follows: Let $|t_a| = |f_a| = |I_a| = a$, and let $\text{val}(t_b) = t$, $\text{val}(f_b) = f$ and $\text{val}(I_b) = I$. Define $x_{\leq+} y$ if either $x = y$ or $|x| < |y|$ or $|x| = |y|$ and $\text{val}(y) = t$. (M, \leq_+) is an upper semilattice. Let

$x + y = \sup_{\leq_+} (x, y)$. An $RM I_m$ -model is a pair (M, v) where M is a full r.d.l. and v a valuation in it (which respects the operations). A sentence A is true in a model (M, v) if $\text{val}(v(A)) \neq f$. Obviously, every model (M, v) determines an $RM I_m$ -setup of all the formulae which are true in it. Denote the collection of all these setups by RDL_m .

PROPOSITION 22. $CP_{RM I_m} = RDL_m$

Proof. It is shown in [Avron, 1990b] that the Lindenbaum algebra of any complete $RM I_m$ -theory determines a model in which exactly its sentences are true. This implies that $CP_{RM I_m} \subseteq RDL_m$. The converse is obvious from the definitions. ■

CROLLARY. [Avron, 1990b]: $RM I_m$ is sound and complete for the semantics of full r.d.l.s. In other words: $T \vdash_{RM I_m} A$ iff A is true in every model of T .

Proof. Checking soundness is straightforward, while completeness follows from the syntactic strong completeness of $RM I_m$ (theorem 21) and the last theorem. ■

The strong c -normality of $RM I_m$ also has an interpretation in terms of the semantics of full r.d.l.s. In order to describe it we need first some definitions:

DEFINITION.

1. A full r.d.l is consistent iff for every x in it $\text{val}(x) \in \{t, f\}$ (i.e., the intermediate truth-value I is not used in its construction). This is equivalent to: $x \neq \neg x$ for all x .
2. A model (M, v) is consistent iff M is consistent.
3. $CRDL_m$ is the collection of the $RM I_m$ -setups which are determined by some consistent model.

Note: On every tree one can base exactly one consistent full r.d.l. (but in general many inconsistent ones).

PROPOSITION 23. $N_{RM I_m} = CRDL_m$.

Proof. In the construction from [Avron, 1990b] which is mentioned in the proof of proposition 22, a complete and consistent theory is easily seen to determine a consistent model. The converse is obvious. ■

In view of the last proposition, the strong c -normality of $RM I_m$ and its two obvious corollaries (weak normality and c -normality) can be reformulated in terms of the algebraic models as follows:

PROPOSITION 24.

1. If T is consistent then $T \vdash_{RM I_m} A$ iff A is true in any consistent model of T .

2. $\vdash_{RMI_m} A$ iff A is true in any consistent model.
3. Every consistent RMI_m -theory has a consistent model.

It follows that if we restrict our attention to consistent RMI_m -theories, we can also restrict our semantics to consistent full r.d.l.s, needing, therefore, only the classical two truth-values t and f , but not I .

Exactly as in the case of R , when we pass to RMI things become more complicated. Moreover, although we are going to show that RMI has *exactly* the same properties as R , the proofs are harder.

THEOREM 25. *RMI is strongly complete.*

Proof. The proof is like the one for R given above, since RMI has the relevant properties of R which were used there (see [Avron, 1990b]). ■

Like in the case of RMI_m , the strong completeness of RMI is directly connected to the semantics of full r.d.l.s. This semantics is extended in [Avron, 1990a; Avron, 1990b] to the full language by defining the operator \wedge on a full r.d.l. as follows: define \leq on M by: $x \leq y$ iff $\text{val}(\neg x + y) \neq f$. (M, \leq) is a lattice. Let $x \wedge y = \inf_{\leq}(x, y)$. The notions of an RMI -model, consistent RMI -model and the truth of a formula A (of the language of RMI) in such models are defined as in the case of RMI_m . The classes of setups RDL and $CRDL$ are also defined like their counterparts in the case of RMI_m . Again we have:

PROPOSITION 26.

1. $CP_{RMI} = RDL$.
2. $N_{RMI} = CRDL$.

Proof. Similar to the proofs of propositions 22 and 23. ■

Again, theorem 25 and 26(1) entail the following result of [Avron, 1990b]:

COROLLARY. *RMI is sound and complete for the semantics of full r.d.l.s.*

THEOREM 27.

1. $\vdash_{RMI} A$ iff A is valid in all the consistent models.
2. RMI is weakly normal.

Proof.

1. Suppose that $\not\vdash_{RMI} A$. Then there is a model (M, v) in which A is not true. Let M' be the consistent full r.d.l based on T_M (the tree on which M is based). Let v' be any valuation in M' which satisfies the following conditions: (i) $|v'(P)| = |v(P)|$ for every atomic P ,

(ii) $v'(P) = v(P)$ whenever $|v(P)|$ is normal in M . It is easy to see that conditions (i) and (ii) are preserved if we replace P by any sentence. In particular $v'(A) = v(A)$ and so A is not valid in the consistent model M' .

2. Immediate from part (1) and proposition 26(2) ■

THEOREM 28.

1. *RMI is c-normal.*

2. *Every consistent RMI-Theory has consistent model.*

Proof. (1) By proposition 8(4) it suffices to prove that if T is consistent and A a sentence then either $T \cup \{A\}$ or $T \cup \{\neg A\}$ is consistent. This is not so easy, however, since like in R , $T \cup \{A\}$ might be inconsistent even if $T \not\vdash \neg A$, while unlike in R , (γ) for \vee is *not* sound for \vdash_{RMI}^N .

Suppose then that $T \cup \{A\}$ and $T \cup \{\neg A\}$ are both inconsistent. Since $\neg B, B \vdash_{RMI} \neg(B \rightarrow B)$, this means, by *RMI* deduction theorem for \supset ¹⁴ that there exist sentences B and C such that $T \vdash_{RMI} A \supset \neg(B \rightarrow B)$, $T \vdash_{RMI} \neg A \supset \neg(C \rightarrow C)$. In order to prove that T is inconsistent it is enough therefore to show that the following theory F_0 is inconsistent:

$$F_0 = \{A \supset \neg(B \rightarrow B) \ , \ \neg A \supset \neg(C \rightarrow C)\} .$$

For this we show that the following sentence φ and its negation are theorems of F_0 (where $a \circ b = \neg(\neg a + \neg b)$):

$$\varphi = (B \vee [\neg A \circ R^+(A + C, B)]) \wedge (C \vee [(A + C) \circ R^+(A + B, C)]) .$$

By the completeness theorem it suffices to show that φ gets a neutral value (I) in every model of F_0 . Let (M, v) be such a model, and denote by R the relevance relation between the nodes of the tree on which M is based. It is easy to see that:

- a) $|v(A)| \not\prec |v(B)| \quad |v(A)| \not\prec |v(C)|$
- b) If $|v(A)| \not\# |v(B)|$ or if $v(A)$ is designated then $v(B)$ is neutral.
- c) If $|v(A)| \not\# |v(C)|$ or if $v(\neg A)$ is designated then $v(C)$ is neutral.

Denote, for convenience, $v(A)$ by a , $v(B)$ by b , $v(C)$ by c , and the two conjuncts of φ by φ_1 and φ_2 respectively. Then:

- (i) If $|b| \not\# (|a| \vee |c|)$ then $v(\varphi_1) = b$. Also we have then that $|c| \leq |a| \vee |c| < |a| \vee |b| = |a + b|$ (since always $(|a| \vee |b|) R (|a| \vee |c|)$). Hence $|c| R |a + b|$ and so $v(\varphi_2) = t_{|a| \vee |b| \vee |c|}$. It follows that $v(\varphi) = b$ and so $v(\varphi)$ is neutral by b) above.

¹⁴See [Avron, 1990b]. The connective \supset is defined there by $a \supset b = b \vee (a \rightarrow b)$.

- (ii) If $|b| R(|a| \vee |c|)$ and either $|a| < |a| \vee |c|$ or $\text{val}(a) = f$ then, by a), $|b| \leq |a| \vee |c|$ and either $|a| \not R |c|$ or $v(\neg A)$ is designated. Hence c is neutral by c). It follows (since either $|a| \not R |c|$ or $\text{val}(a) = f$), that either $|a| \not R |c|$ or $|c| < |a|$. In both cases $v(A + C) = f_{|a| \vee |b| \vee |c|}$, $v(\varphi_2) = c$, and $v(\varphi_1) = t_{|a| \vee |b| \vee |c|}$. Hence $v(\varphi) = c$, which is neutral.
- (iii) If $|b| R(|a| \vee |c|)$, $|a| = |a| \vee |c|$ and a is designated then, by a), $|a| = |a| \vee |b| \vee |c|$. If $\text{val}(a) = I$ then also $\text{val}(b) = I$ and $\text{val}(c) = I$, and so $\text{val}(v(\varphi)) = I$. If $\text{val}(a) = t$ then by b) b is neutral and so $|b| < |a|$ ($|a|$ is normal!). Obviously $|c| < |a|$ in this case, and so $v(\varphi_1) = b$, $v(\varphi_2) = t_{|a|} = a$ and $v(\varphi) = b$, which is neutral.

(2) Immediate from (1) and proposition 26(2). ■

PROPOSITION 29. *RMI is not strongly c-normal.*

Proof. Let ψ_1 and ψ_2 be the two elements of the theory F_0 from the last proof. Let $T = \{\psi_1\}$, $A = \neg\psi_2$. Then T is consistent (even classically!) and A is provable in every consistent and complete extension of T (since F_0 is inconsistent). Hence $T \vdash_{RMI}^N A$. However, $T \not\vdash_{RMI} A$ since it is easy to construct a full model of ψ_1 in which $\neg\psi_2$ is not true. (ψ_1 is neutral in this model.) ■

Like in the case of R , our results show that \vdash_{RMI}^N is stronger than \vdash_{RMI} and \vdash_{RMI}^{CS} . We now construct a formal system for this consequence relation.

DEFINITION. The system *RMIC* is *RMI* strengthened by *M.T.* for \supset :

$$A \supset B, \quad \neg B \vdash \neg A.$$

THEOREM 30.

1. $T \vdash_{RMIC} A$ iff $T \vdash_{RMI}^N A$
2. $\vdash_{RMIC} A$ iff $\vdash_{RMI} A$.

Proof.

1. Obviously, if both $A \supset B$ and $\neg B$ are true in a consistent model (M, v) then so is $\neg A$. Hence if $T \vdash_{RMIC} A$ then $T \vdash_{RMI}^N A$. For the converse, suppose $T \vdash_{RMI}^N A$. Then by Theorem 26 $T \cup \{\neg A\}$ has no consistent model. This means, by Theorem 28, that $T \cup \{\neg A\}$ is inconsistent. Hence $T \vdash_{RMI} \neg A \supset \neg(B \rightarrow B)$ for some B . Since also $\vdash_{RMI} \neg\neg(B \rightarrow B)$, we have that $T \vdash_{RMIC} \neg\neg A$, by applying M.T. Hence $T \vdash_{RMIC} A$.

2. Immediate from 1) and theorem 27(2). ■

Notes:

1. From 30(2) it is clear that the system RMI is closed under M.T. for \supset . By applying this rule to theories we can make, however, any inconsistent theory trivial. This resembles the status of (γ) in R and E . Indeed (γ) may be viewed as M.T. for the usual implication as defined in classical logic. A comparison of theorems 30 and 20 deepens the analogy (note that RMI is *not* an extension of R and 20 fails for it!).
2. Despite 30(2) RMI and $RMIC$ are totally different even for consistent theories, as we have seen in prop. 29. *It is important, however, to note that theory T is consistent in RMI iff it is consistent in $RMIC$.* This follows easily from theorem 28.

3.6 Three Valued Logics

Like in section 2, we consider here only the 3-valued logic which we call in [Avron, 1991b] “natural” (in fact, only those with Tarskian CR). All these logics have the connectives $\{\neg, \wedge, \vee\}$ as defined by Kleene. The weaker ones have only these connectives as primitive. The stronger ones have also an implication connective which reflect their consequence relation.

Suppose the truth-values are $\{t, f, I\}$. t and f correspond to the classical truth values. Hence t is designated, f is not. The 3-valued logics are therefore naturally divided into two main classes: those in which I is not designated, and those in which it is. The first type of logics can be understood as those in which the law of contradiction is valid, but excluded middle is not. The second type – the other way around.

Kleene’s basic 3-valued logic

This logic, which we denote by $K\ell$, has only t as designated and $\{\neg, \vee, \wedge\}$ as primitives. It has no valid formula, but it does have a non-trivial consequence relation, defined by the 3-valued semantics. A setup in this semantics is any set of the form $\{A \mid v(A) = t\}$ where v is a 3-valued valuation, and the consequence relation $\vdash_{K\ell}$ is defined by this semantics. A sound and strongly complete Gentzen-type or natural deduction formulations have been given in several places (see, e.g., [Barringer *et al.*, 1984] or [Avron, 1991b]).

The properties of $\vdash_{K\ell}$ which are relevant to the present paper are summarized in the following theorem:

THEOREM 31.

1. *Like intuitionistic logic, $\vdash_{K\ell}$ is strongly consistent, c-normal but not even weakly complete.*
2. *$\vdash_{K\ell}^{CP}$ is classical logic.*

Proof.

1. Since $\neg A, A \vdash_{K\ell} B$, $\vdash_{K\ell}$ is strongly consistent. Since $\vdash_{K\ell}^{CP} A \vee \neg A$ but $\not\vdash_{K\ell} A \vee \neg A$, $\vdash_{K\ell}$ is not weakly complete.

We turn now to c -normality. First we need a lemma

LEMMA 32. *If T has a 3-valued model then it has also a classical, two valued model.*

Proof of the lemma: It is enough to show that every finite subset of T has a two-valued model (by compactness of classical logic). So let Γ be a finite set which has a 3-valued model. Since De-Morgan laws and the double-negation laws are valid for the three-valued truth tables, we may assume that all the formulas in Γ are in negation normal form. We prove now the claim by induction on the number of \wedge and \vee in Γ . If all the formulas in Γ are either atomic or negations of atomic formula, then the claim is obvious. If $\Gamma = \Gamma_1 \cup \{A \wedge B\}$ then Γ has a model iff $\Gamma_1 \cup \{A, B\}$ has a model, and so we can apply the induction hypothesis to $\Gamma_1 \cup \{A, B\}$. If $\Gamma = \Gamma_1 \cup \{A \vee B\}$ then Γ has a model iff either $\Gamma_1 \cup \{A\}$ or $\Gamma_1 \cup \{B\}$ has, and we can apply the induction hypothesis to the one which does, getting by this a two-valued model for Γ . ■

To complete the proof of the theorem, let T be a consistent $\vdash_{K\ell}$ -theory. The definitions of consistency and of $\vdash_{K\ell}$ imply in this case that it has some 3-valued model. By the lemma it has also a two-valued model. Let T^* be the set of all the formulae that are true in that two-valued model. Then T^* is a $\vdash_{K\ell}$ -setup which is consistent (even classically), complete, and an extension of T .

2. Since $\vdash_{K\ell}^{CP} \neg A \vee A$ and $\neg A \vee C, A \vee B \vdash_{K\ell} C \vee B$, it is easy to show, using (for example) Shoenfield's axiomatization of classical logic in [Shoenfield, 1967] that $\vdash_{C\ell} \subseteq \vdash_{K\ell}^{CP}$. The converse is obvious, since $\vdash_{K\ell} \subseteq \vdash_{C\ell}$ and $\vdash_{C\ell}$ is strongly complete (by $\vdash_{C\ell}$ we mean here classical logic). ■

LPF/L₃

LPF was developed in [Barringer *et al.*, 1984] for the VDM Project. As explained in [Avron, 1991b], it can be obtained from $\vdash_{K\ell}$ by adding an internal implication \supset so that $T, A \vdash_{LPF} B$ iff $T \vdash_{LPF} A \supset B$. The definition of \supset is: $a \supset b = t$ if $a \neq t, b$ if $a = t$. Alternatively one can add to the language Łukasiewicz's implication, or the operator Δ used in [Barringer *et al.*, 1984]. All these connectives are definable from one another with the help of \neg, \wedge and \vee .

THEOREM 33.

1. \vdash_{LPF} is strongly consistent but neither weakly complete nor *c-normal*.
2. \vdash_{LPF}^{CP} is classical logic.

Proof.

1. That \vdash_{LPF} is strongly consistent but not weakly normal follows from the corresponding fact for $\vdash_{K\ell}$, since \vdash_{LPF} is a conservative extension of $\vdash_{K\ell}$. As for *c-normality*, it is enough to note that $\{(A \vee \neg A) \supset B, \neg B\}$ is consistent in *LPF* (take $v(A) = I, v(B) = f$) but obviously has no consistent and complete extension.
2. Again, take any axiomatization of classical logic in the *LPF*-language and check that all the axioms and rules are valid in \vdash_{LPF}^{CP} . ■

The Basic Paraconsistent 3-valued logic PAC

This logic, which we call *PAC* in [Avron, 1991b]¹⁵, has the same language (with the same definitions of the connectives) as $\vdash_{K\ell}$. The difference is that here both *t* and *I* are designated. A setup in the intended semantics is, therefore, this time a set of the form $\{A \mid v(A) = t \text{ or } v(A) = I\}$, where *v* is a three-valued valuation. A sound and strongly complete (relative to the 3-valued semantics) Gentzen-type axiomatization is given in [Avron, 1991b].¹⁶

THEOREM 34.

1. \vdash_{PAC} is strongly complete, weakly normal and *c-normal*. It is neither strongly consistent nor strongly *c-normal*.
2. \vdash_{PAC}^N is identical to classical logic.

¹⁵It is a fragment of several logics which got several names in the literature – see next subsection.

¹⁶Giving a faithful Hilbert-type system is somewhat a problem here, since the set of valid formulas is identical to that of classical logic, but the consequence relation is not.

Proof.

1. The strong completeness theorem for the Gentzen-type system entails that \vdash_{PAC} is finitary. Hence to show strong syntactical completeness it is enough to show that the condition in 8(1) obtains. This is easy. Weak normality is immediate from the fact that $\vdash_{PAC} A$ iff A is a classical tautology (see [Avron, 1991b]) and that $\vdash_{PAC} \subseteq \vdash_{Cl}$. c -normality is proved exactly as for R (it is easy to check that \vdash_{PAC} has all the properties which are used in that proof). It is also easy to check that $\neg p, p \not\vdash_{PAC} q$ and that $\{\neg p, p \vee q\}$ is consistent, that $\neg p, p \vee q \vdash_{PAC}^N q$ but $\neg p, p \vee q \not\vdash_{PAC} q$ (take $v(p) = I, v(q) = f$). Hence \vdash_{PAC} is not strongly c -normal and not strongly consistent.
2. Since all classical tautologies are valid in \vdash_{PAC} and MP for classical implication is valid for $\vdash_{PAC}^N, \vdash_{Cl} \subseteq \vdash_{PAC}^N$. The converse is obvious, since \vdash_{Cl} is strongly c -normal and $\vdash_{PAC} \subseteq \vdash_{Cl}$. ■

 RM_3/J_3

This logic is obtained from PAC by the addition of certain connectives while keeping the same CR. There are two essential ways that this has been done (independently) in the literature (they were shown equivalent in [Avron, 1991b]):

- (i) Adding an implication \rightarrow , defined as in [Sobociński, 1952]. In this way we get the strongest logic in the relevance family: the three-valued extension of RM . It is in this way that this logic arose in the relevance literature. The corresponding matrix is called there M_3 and the logic RM_3 . It can be axiomatized by adding to R the axioms $A \rightarrow (A \rightarrow A)$ and $A \vee (A \rightarrow B)$.
- (ii) Adding an implication \supset , defined by (see [da Costa, 1974]) $a \supset b = t$ if $a = f, a \supset b = b$ otherwise. For this connective the deduction theorem holds. In this form the logic was called J_3 in [D'Ottaviano, 1985] (see also [Epstein, 1995])¹⁷. It was independently investigated also in [Avron, 1986] and in [Rozonoer, 1989]. Strongly complete Hilbert-type formulations with M.P. for \supset as the only rule of inference were given in those papers, and a cut-free Gentzen-type formulation can be found in [Avron, 1991b].

In what follows we shall use the neutral name Pac^* for the CR of PAC in the extended language. The next theorem shows that the main difference between Pac^* and PAC is that Pac^* is *not* weakly normal.

¹⁷[D'Ottaviano, 1985] and [Epstein, 1995] consider a language with more connectives, but we shall not treat them here.

THEOREM 35.

1. Pac^* is strongly complete and c -normal. It is neither strongly consistent nor weakly normal.
2. $\vdash_{Pac^*}^N$ is identical to classical logic.

Proof.

1. Strong completeness and c -normality can easily be proved. Since \vdash_{Pac^*} is a conservative extension of \vdash_{Pac} , it is not strongly consistent. Finally $\vdash_{Pac^*}^N A \wedge \neg A \supset B$, since $\neg(A \wedge \neg A \supset B) \vdash_{Pac^*} A \wedge \neg A$, but $\not\vdash_{Pac^*} A \wedge \neg A \supset B$ (the same argument applies to $(A \wedge \neg A \rightarrow B)$).
2. It is provable in [Dunn, 1970] that classical logic is the only proper extension of RM_3 in the language of $\{\neg, \vee, \wedge, \rightarrow\}$ (from the point of view of theoremhood). Since we have just seen that the set of valid sentences in $\vdash_{Pac^*}^N$ is such a proper extension, and since MP for \rightarrow is valid for it, $\vdash_{Pac^*}^N$ should be identical to \vdash_{Cl} (in this language). The same argument works for the $\{\neg, \vee, \wedge, \supset\}$ language using the results of [Avron, 1986]. Alternatively, it is not difficult to show that by adding $\neg A \wedge A \rightarrow B$ to the Hilbert-type formulation of RM_3 or $\neg A \wedge A \supset B$ to that of J_3 we get classical logic in the corresponding languages. ■

4 CONCLUSION

We have seen two different aspects of negation. From our two points of view the major conclusions are:

- The negation of classical logic is a perfect negation from both syntactical and semantic points of view.
- Next come the intensional fragments of the standard relevance logics (R_m, RMI_m, RM_m). Their negation is an internal negation for their associated internal CR. Relative to the external one, on the other hand, it has the optimal properties one may expect a semantic negation to have in a paraconsistent logic. In the full systems (R, RMI, RM) the situation is similar, though less perfect (from the semantic point of view). It is even less perfect for the 3-valued paraconsistent logic.
- The negation of Linear Logic is a perfect internal negation w.r.t. its associated internal CR. It is not, however, a negation from the semantic point of view. The same applies to Łukasiewicz 3-valued logic.
- The negations of intuitionistic logic and of Kleen's 3-valued logic are not really negations from the two points of view presented here.

In addition we have seen that within our general semantic framework, any consequence relation which is not strongly normal naturally induces one or more derived consequence relations in which its negation better deserves this name. We gave sound and complete axiomatic systems for these derived relations for all the substructural logics we have investigated.

LOGIC AS GENERAL RATIONALITY: A SURVEY

Logic today is urged to confront and solve the problem of reasoning under non-ideal conditions, such as *incomplete information* or *imprecisely formulated statements*, as is the case with *uncertainty*, *approximate* descriptions or linguistic *vagueness*. At the same time, Probability theory has widened its traditional field of analysis (the *expected frequency* of physical phenomena) so as to encompass and analyze general *rational expectations*. Thus, Probability has placed itself in the position of offering Logic a solution for its own long-awaited generalization. The basis for that turns out to be precisely the shared base underlying the two disciplines. This theoretical base predates their common birth, as seen in the early efforts of Bernoulli and Laplace, as well as in Boole's 1854 attempt to formalize the "laws of thought" and then, as he claimed, to "derive Logic and Probability" from them. Once we recover (following Popper's 1938 advice) the underlying *formalism*, we come, by interpreting it in two different directions, back into either *Logic* or *Probability*. The present survey explains the story so far and does the reconstruction work from the logical point of view. The stated aim is to generalize *Logic* so as to cover, as Boole intended, the whole of *rationality*.

INTRODUCTION

This survey could as well be entitled: "*How Logic was once the same as Probability, and then they diverged —and how they may again be formally the same*", or "*Logic and classical Probability: recovering the lost common ground*". Before we begin, let us say that the implied desideratum of the title(s) is long overdue. Indeed, that (a) standard Logic *can* be generalized, and that (b) the natural generalization of Logic *is* —or derives from, or is suggested by— Probability theory seems at present the shared conviction of a number of logicians and probabilists. Thus, to cite a few of the latter, Ramsey wrote (in 1926) that the laws of probability are actually laws of *consistency* (or *rational* behavior), an extension of Formal Logic to cover partial information, and that Probability theory could become the "logic of consistency" which would control and guarantee, as Mathematics does, that our beliefs are not self-contradictory. At about the same time de Finetti concluded that Probability theory is the only possible "logic" to generalize standard Logic. All the same, Patrick Suppes was considering in 1979 that Probability theory is the natural extension of classical deductive inference

rules, while, more recently, Glenn Shafer declared that “probability is not really about numbers; it is about the structure of reasoning”.

Why the technicalities of Probability theory should be viewed today as a powerful *generalizer* of standard Logic and a suitable formal *unifier* of the two may come as a surprise both to probabilists and logicians. Actually, the idea—that we pursue in our generalization below—is very simple: Probability and Logic are but *two interpretations of a same underlying concept*. This is how the founders of both theories saw it and what Popper later explicitly said (and Kolmogorov claimed he had done). But this old notion, over which notable thinkers like Reichenbach or Carnap agonized after the 1930s, is shared nowadays by a surprisingly exiguous minority of specialists (in both disciplines).

Logic and Probability are overwhelmingly seen today as two completely disparate fields, with a very few, if any, points of contact. Logic deals with *reasoning* and *truth*, Probability with inference on poor data. They seem to have nothing in common. Though they both start with a set \mathcal{B} of Boolean-structured objects (respectively *sentences* and *events*—or, confusingly, “propositions”) and though they assign them values in a simple number system containing the one and the zero (here logicians prefer ‘truth’ and ‘falsity’, though), at this point the similarity apparently ends, for the two valuations are perceived to be very different: the probabilistic $P : \mathcal{B} \rightarrow [0, 1]$ obeys a set of axioms set forth by Kolmogorov in the 1930s (that do not actually follow from any particularly “probabilistic” rules but rather reduce it to a simple ‘measure’—in the technical sense—of the “event” objects), while the *logical* valuation is felt to be of a quite different nature and regulated by a semantics set forth by Tarski, also in the thirties, and buttressed by elaborate, specialized logical considerations. Moreover, either field not only has a different type of problem to solve, it also has a different, incompatible set of base concepts and interpretations to work on. And the diverging traditions have bred different strokes of unrelated practitioners and two methodologies that are seen by the mainstream mathematician as far distant (even lying at opposite fields of Mathematics, i.e. *real* vs. *discrete*).

However, this is not how things were seen in the first stages of the modern theories of Probability and Logic. Their founders, notably Bernoulli and Laplace, or Boole and Peirce, dithered a lot on what might “probability” or “truth” mean, and often tended to explain one through the other in incipient, half-baked intersecting intuitions, as can be readily seen by browsing into the original literature. Later developments, as well as the progressively firmer foundations and the more specialized and mutually deviating interpretations that either field painstakingly acquired, created an increasing gap between Probability and Logic, in which both contenders apparently never found a ground or occasion to reconcile into one unified approach (which, as we suggest below, is not only desirable but feasible and even natural).

Why striving to recover an encompassing view should be interesting at all may be not obvious at first, but there are strong reasons for it. First, because, as we said, both theories are two differing interpretations of the same idea. Second, because both probabilists and logicians have recently been hard pressed against the limits of their own disciplines when confronting new challenges with consecrated methods. Prominent challenges include: (1) for probabilists, how to clarify the ultimate meaning, and the practical import, of the apparently obvious idea of “probability” (doubters here include names as Keynes [1921], Ramsey [1926] or de Finetti [1931], and the questions raised prolong well to this day into widely-discussed conundrums as the status of *subjective probability*, *rational belief* or *bayesianism*); or (2) for logicians, how to validate reasoning under *uncertainty* or with *incomplete* or *approximate* information (a problem that eventually gave rise, also around the 1930s, to non-standard formalisms such as the *many-valued logics* of Łukasiewicz [1920] (and [1930], with Tarski) or Kleene [1938], or the attempts at defining a *probability logic* by Reichenbach [1935a,b], discussed by Carnap [1950]).

The material below is structured in two parts: the first is a short survey explaining why Logic and classical Probability were once the same thing—and gave the (common) pioneers (Bernoulli, Hume, Laplace, Boole) lots of cross-supporting arguments—and why they soon diverged to the point of being considered unrelated. The second part—considerably longer—is a summary of how we locate Logic firmly in the Logic/Probability common heritage; it is based on former work by the author (Sales [1982a,b, 92,94,96]) and the starting point is Popper’s 1938 suggestion (see Popper [1959]) to set forth a *unique algebraic uninterpreted formalism* as the common source from which, through distinct interpretations, both Logic *and* Probability can be formally derived as particular instances. The common formal idea we advance is, as will be later explained, that we can postulate an *additive valuation* (in e.g. $[0,1]$) of the elements of a given abstract Boolean structure \mathcal{B} —that is later interpreted by Probability as a (set-theoretic) *event*, and by Logic as a (non-set) *sentence*. Our generalization proceeds from this point on as an exclusively *logical* reading of the common uninterpreted formalism. (The development is satisfactory also in a second, non-formal sense, since it can be seen as a vindication and reconstruction of the pioneers’ historical common source of insights.)

A. The Probability/Logic Interface

1 THE VIEW FROM PROBABILITY

1.1 *Classical Probability*

Around the year 1700, Jakob Bernoulli tried to define the *probability* of a phenomenon as a non-evident and non-subjective something that fortunately had effects: the observable frequency, or relative number of cases in which the phenomenon manifested itself. This number was supposed fixed and objective. So, measuring frequencies was the way to estimate “probability”. Conversely, knowing the probability of a phenomenon allowed to predict its expected frequency. This is, in essence, Bernoulli’s theorem. It is the first clear, albeit implicit, definition of probability. It is also the first instance of a duality that is present since in Probability theory: probability P —a supposedly *objective* property of phenomena— is conceived simultaneously as (1) the ratio of positive cases (call it P_c) and (2) the number we have (call it P_b , b for ‘belief’) to estimate P_c . The first is assumedly an objective reality, the second an inevitably subjective entity that depends on our past history of observations (a paradox that is the common theme of many reflections, like those of e.g. de Finetti). Obviously, the fewer our interactions, the more subjective our P_b estimate is. The idea is that P_b “aproximates” P_c , and the aim is getting $P_b = P_c$ (in some limit situation).

The Rev. Bayes developed Bernoulli’s idea of P_b converging to P_c through observational updates and came up with his celebrated formula (posthumously revealed in 1763) to compute P . Hailed by observational scientists for more than a century, it is now the heart of a debate about what is this Bayes-computed probability. Called “a priori” probability, anti-Bayesians contend it is nothing more than simple, non-objective belief based on a hypothetical view of our ignorance.

Laplace, in 1774 and later, defined probability as P_c , the ratio of favorable *cases*, all assumed having “the same probability”. The obvious circularity raised some eyebrows in the 1920s, but Laplace’s has been the standard and successful definition since, at least for non-sophisticated applications. Note that it places probability clearly on the *frequency* side, and cavalierly dismisses any subjective-sounding *belief* content, perhaps the reason for its long-standing success. Note, too, that *cases* are a logical notion, since they can be defined —and were by Laplace himself— as the *true* instances of a proposition. Thus, Laplace’s [1774,1820] probability can be seen as an early generalization of Logic, particularly of the concept of validity (resp. consistency), now interpretable as “true in all (resp. some) cases”. Some years before this, Hume had already implied too that probability was a generalization of logical inference by considering that, given a proposition

obtained from some conditions or premises, its probability was the proportion of premises (or premise extensions) in which the proposition was satisfied.

The classical probabilists thus conceived probability, more than as something associated with indeterminism or uncertainty, as a measure of our knowledge of phenomena in the presence of incomplete information (or, dually, as a measure of our partial ignorance). This concept was considered objective because, though not directly measurable, (1) it referred to a supposedly objective situation indirectly parameterizable through its observable effects, and (2) it was manipulable through rules of an objective calculus. So, after Laplace, Probability theory came to be dominated by the probability-as-frequency view. This was convenient as it was objective and “scientific” and adequately eschewed the estimation or “belief” problem.

It lasted until the 1920s, when von Mises, dissatisfied with the classical solution, formalized (in 1928) the estimation or approximation problem by postulating a “sample space” Ω , defining frequency in it and computing probability as the result of some limit process, in which the number of observations tended to infinity. Since this was no ordinary limit and the process not quite satisfactory, Kolmogorov [1933] came up with the now universally accepted solution: probability is just the *measure* of an *event* (an event being a set of outcomes); this measure is taken in the mathematical sense, i.e. as a countably additive valuation (though the need for countable additivity has been challenged by many, notably de Finetti [1970] or Popper [1959]). An interesting thing to note: Kolmogorov declared that his formalization was “neutral” in the sense that it was abstract (and thus previous to any interpretation); in his words, probability had to be formal, pure mathematics, merely ruled by axioms. Nevertheless he also declared that his measured entities (in theory merely the members of a σ -algebra over Ω) *are* actually sets. And though he added that this was irrelevant, Popper protested (in 1955) that it *is* relevant in some important cases, and noted that a truly abstract formalization must admit *any* interpretations, including those in which the measured entities are not sets. (But, we add, this is precisely the case of Logic, where we have non-set entities, namely *sentences* from a *language*, not *events* from a *sample space*.) Popper [1959] offered an axiomatic alternative first suggested in 1938, fully developed in 1955, and now fashionable (under the guise of “probabilistic semantics” or “Popper functions”).

1.2 ‘Subjective probability’, ‘Probability logic’ and ‘Logical probability’

Following Keynes’s [1921] lead, Ramsey [1926] was the first to consider that the belief side of probability, already present in Bernoulli or the Bayes’ formula, was the core of the concept, since the “true” value of probability was

beyond our reach and the best we could do is approximate it through a careful, consistent, rational procedure; so he defined probability as *belief* and defined this as a number obtained on the basis of *consistency* considerations about the belief-holder's *rational* behavior (as deducible from betting protocols); the rationality-induced consistency insured that the number, though inevitably "subjective", was nevertheless the most objective measure one could obtain. In a similar spirit, and in same years, Bruno de Finetti [1931,37] approached probability as an inherently non-objective concept. He summarized it in his well-known slogan "probability does not exist" (i.e. objectively, at least "not more than the cosmic ether"), and nothing beyond consistency assures its imagined objectivity. According to him, probability is merely what we expect on the basis of past experience and the assumed consistency of what we do. As a number, probability (which de Finetti [1937,70] constructed formally on the basis of a vector space of rational expectations), is "objective" as far as the procedure to obtain it obeys coherent assumptions.

The "subjective probability" thesis of Ramsey/de Finetti has found continuation till now in the work of Jeffreys [1939], Koopman [1940], Savage [1954] or Jeffrey [1965], to name a few, all of which reject the epithet "subjective"; they prefer to be called simply probabilists and at most admit that the probability they deal with is a (non-subjective) partial or rational belief, i.e. the value we assign propositions in absence of complete information.

On the other hand, in a series of studies beginning in 1932 Hans Reichenbach [1935a,b], a physicist with an interest in foundations, interpreted probability as a logic. The logic (*probability logic* he called it) was not truth-functional, but he could subsume all classical tautologies as particular cases of propositions p that had unit probability (i.e. $|p| = 1$). He obtained formulas for the value (probability) of the connectives which are basically like the ones we obtain below; he says that e.g. $|p \vee q|$ is a function of $|p|$ and $|q|$ *plus* a third parameter k he calls *Kopplungsgrad* or 'degree of coupling' (defined roughly as the relative size of the intersection of overlapping areas or classes to which a measure is applied that coincides with the conditional probability). This is equivalent to what we obtain in our generalization below, but note that Reichenbach never moves out of probability and events: he always speaks of probability in its standard meaning and only in a translation of senses he says he can interpret the probability of an event sequence — a sequence of binary truth values — as its (non-binary) "truth". His world is clearly that of Probability, and what he obtains is a Logic only in the sense that he speaks of truth, albeit probability by another name. Moreover, though his contemporary critics (including Tarski [1935a]) argued against the construction, they did not because of the subsidiary role of truth in it (as a surrogate for a probability of one) but on the arguable ground that a proper logic ought to be truth-functional (see Urquhart's [1986] comment below as to the contrary).

(Work on ‘probability logic’ by Kemeny *et al.* (see Leblanc [1960]), Bacchus [1990], Halpern [1990] or Fagin *et al.* [1990] is not mentioned here because what these authors deal with is not what is understood by that name in the the classical tradition. Instead, they apply the standard treatment of any first-order theory *inside* Logic, i.e. augmenting ordinary first-order logic with a number of specific axioms that syntactically describe the real numbers (or an ordered field) and the probability operations on them, so that the Probability laws can be derived formally as theorems.)

Another indirect view of Logic-as-valuation was the one adopted by Rudolf Carnap [1950,62], starting in the 1940s. The Logic/Probability link began in his case by trying to justify probability logically. In his view (that he called *logical probability* and surmised as theoretical ground on which to base a “logic of induction” to which Popper came to be fiercely opposed), the probability of an event was the proportion or, more generally, the measure (“ratio of ranges of propositions”) of the intervening circumstances (described as logical sentences) concurring in the event. For this measure he said he was inspired by a definition of Wajsberg—which was inspired in turn by proposition *5.15 of Wittgenstein’s [1922] *Tractatus* (ultimately Bolzano-inspired, see below). Carnap hesitated and changed his approach often along the 1950s; for instance, notably, he came to value sentences instead of events, but came back to events later, shortly before giving up the whole scheme. Wittgenstein and Wajsberg’s extensional rendition and Carnap’s use of them is, like Reichenbach’s implicit grounding of probability on rather obscure “overlapping classes”, strongly reminiscent of the Stone representation we obtain below out of our general, non-probabilistic truth valuation of logical sentences. It is interesting to note that Carnap’s logically-described components of events correspond rather precisely to what Laplace had called the (positive i.e. true) “cases” concurring in an event. They are also almost interchangeable with Boole’s *cases* (his “conceivable sets of circumstances”) underlying a logical proposition (or with equivalent descriptions by McColl and Peirce and Wittgenstein, see below).

2 THE VIEW FROM LOGIC

2.1 *The pioneer logicians*

The laplacian idea of having “cases” (a logical concept, we noted) and then measuring the proportion of the true ones seem to have been floating all over. Laplace’s uninfluential contemporary, the Austrian philosopher Bolzano, had this to say about first-order propositions and truth: propositions, he says, have an associated “degree of validity”, a number in $[0,1]$ which equals “the proportion of true ‘variants’” (Bolzano’s “variants” are our term substitutions).

And then Boole [1854], when just after studying classes he sets out to analyze *propositions* (in 1847), conceives them by means of an alternative interpretation of his elective symbol x (already introduced for classes) and says it now stands for the *cases* (defined informally as “conceivable sets of circumstances”) —out of a given hypothetical “universe” (a De Morgan’s idea)— in which the proposition is *true*. In the last chapters of his 1854 book (significantly entitled “An investigation of the laws of thought, on which are founded the mathematical theories of logic and probabilities”) Boole even likens the product $x \cdot y$ of two propositions (i.e. the conjunction value, actually) to the *probability* of simultaneously having them both and the (value of) the sum $x + y$ to the *probability* of having either (provided they are mutually exclusive).

An equivalent idea is present in MacColl’s [1906] partially published reflections (started before 1897), where he says that propositions are generally “variable”, meaning they are sometimes the case, depending on their (basically probabilistic) modality. Peirce [1902], in an unpublished work that deliberately follows MacColl’s steps, sets out to distinguish “necessary” from “contingent” propositions, most being the latter sort, characterized by their (probabilistic) occurrence.

In a similar vein Wittgenstein [1922] considers a little later that propositions reflect —and are basically decomposable into— “states of affairs” (an idea borrowed from Leibniz). That those states of affairs (reminiscent of Laplace’s or Boole’s cases) are in some way a measurable universe whose proportions gave information on the truth of the composite propositions is obvious from the *Tractatus* (and is the inspiration of the extensional view of Wajsberg and Carnap mentioned above).

2.2 ‘Multi-valued logic’

While some probabilists (from Ramsey to Reichenbach) agonized in the 1930s over their base concepts, there was intense soul searching also in the logicians’ camp. The main new idea came from Łukasiewicz in 1930 (down from antecedents since 1918) when he postulated a logic in which “truth” values could take any value from the infinite real $[0,1]$ interval (see Łukasiewicz & Tarski [1930]). To compute the value of composite propositions in his “many-valued logic” he obtained (truth-functional) formulas which are exactly the ones we obtain below except for the fact that they presuppose full *compatibility* (a concept we explain below) among *all* propositions, no matter some are the negation of others. This was not perceived as a problem at the time but *it was*, as some fellow logicians pointed out to him at the 1938 Zurich workshop (see Łukasiewicz [1938]). They considered that either we assign $p \wedge \neg p$ the value $\min(|p|, 1 - |p|)$ given by the formulas (thus blatantly contradicting the basic logical *law of non-contradiction*) or else we assign it the —correct— zero value (meaning *falsity*, so in accor-

dance with ordinary Logic) but then we arbitrarily disobey the postulated truth-functionality. As this predicament found no decisive solution, many-valued logic has continued to this day —along with unexpected offshoots like “fuzzy logic”— consecrating truth-functionality as a rigid principle and thus putting itself *out* of mainstream Logic, of which is a weak incompatible variety (unless we add, as suggested by van Fraassen [1968], some super-valuation mechanism to it). At the end of a detailed survey of multi-valued logic, Alasdair Urquhart [1986] comments that it is hardly surprising that those systems have remained logical toys or curiosities since “there seems to be a fundamental error [truth functionality] at the root”. Some modern cultivators wonder whether it is possible to combine the two best-known formalisms, Probability and Logic, in any way (but Lee [1972] admits that “we do not seem how to do this”); others, like Hamacher [1976], Zimmerman [1977] or Trillas *et al.* [1982], in asking what are the correct truth-value formulas for the fuzzy calculi, hesitate among a variety of candidates, while still another, Minker (with Aronson *et al.* [1980]), would like to know the “truth bounds” of many-valued conclusions obtained from premises.

3 THE VIEW FROM THE OUTSIDE

3.1 Mathematics

Alfred Tarski straightforwardly supposed (in Tarski & Horn [1948]) he had simply a *Boolean algebra* and then set out to analyze thoroughly all possible *measures* in it. So did Gaifman [1962] —and Scott (with Krauss, [1965])— who extended this analysis to first-order logical formulas; these were assigned (additive) values, that were called ‘measures’ by Gaifman (and ‘probabilities’ by Scott). True to mathematicians’ fashion (i.e. approaching topics in uninterpreted, “abstract” formalisms), they did not understand ‘probability’ as other people do; they just used the word as a synonym for *normalized measure* (a *measure* being a σ -additive valuation on the positive reals). In this sense, their “probability” is a blanket term for any common generalization —such as the one we attempt here— for the two (heavily interpreted) fields of Logic and Probability.

Also in this line, J. Łoś [1962] explored general “probability” valuations of logical *sentences* and came up with a (reasonably unsurprising) *representation theorem* of probabilities on a (set-theoretical) space of *models* (or *interpretations*) in the logical sense. Łoś’s line has been consistently followed by Fenstad since 1965. (Fenstad’s papers [1967,68,80,81] have been a source of inspiration for our generalization below.)

3.2 *Philosophy*

Philosophers have also been exploring the common material. A few representative examples are Hintikka and Suppes (both presenting first results in 1965), Stalnaker (in 1968–70), Lewis (in 1972) or Popper (e.g. in 1987, with Miller). The first (Jaakko Hintikka [1968]), inspired by Bar-Hillel’s (and Carnap’s, [1952]) information-measure ideas, was suggesting in 1965 (with Pietarinen, [1968]) various formulas to parameterize the information contained in sentences. Also in 1965, the second (Patrick Suppes [1968]) did a circumscribed analysis of the Modus Ponens logical inference rule from a generalized perspective (what he called ‘probabilistic inference’) in which he got formulas fully consistent with the ones we obtain below. Another philosopher traditionally preoccupied with logic/probability differences (especially those centered on the conditional/conditioning operation), Robert Stalnaker [1970], revealed some fine points (among which our “ $A \rightarrow B$ ” \neq “ $B|A$ ” conceptual and practical distinction). His work and David Lewis’s [1976] have done much to clarify and distinguish concepts shared by logicians and probabilists.

But, prior to these 1960s efforts, the single philosopher to do this most explicitly is surely Popper [1959], in lucid but little known pioneering work. He did not only see (in 1938) that the two concepts were different interpretations of a (yet to be written) formalism —Kolmogorov [1933] also saw this— but he designed one in a very simple and intuitive way by defining a valuation in $[0,1]$ on pairs (a, b) of sentences (of a very elementary language) that was directly constructible by users (i.e. reasoners and probability-estimators alike) and that gave way naturally to a Boolean structure with the usual properties (including measurability). Whatever sense the user gave the valuation (“probability”, “truth likelihood”, “truth content” or simply “truth”) it was the user’s concern. Popper later used his own formalism (and the derived Booleanity assumption) to deduce properties of his ‘truth content’ measure and so emit (with David Miller, [1987]) a post-mortem indictment against Carnap’s [1950,62] “inductive logic”.

3.3 *“Fuzzy Logic”*

From a logical point of view, Fuzzy Logic (under development since 1965) can be considered as an “interpreted” variety of Łukasiewicz & Tarski’s [1930] infinite-valued logic. (“Interpreted” because it adds to many-valued logic an extensional interpretation of predicates in terms of non-standard sets.) Thus, it was already mentioned in a former section, where we considered it as an (unexpected) offshoot of the many-valued logic family, and we dedicated it some short comments. Nevertheless, the overgrown “fuzzy” tradition, now largely applications-oriented, has its own self-contained rules and momentum and is *not* exactly logic nor probability. Nor, it claims, has

barely anything to do with them, with which it is pretendedly “orthogonal”, only devoted to linguistically-motivated imprecision (i.e. *vagueness*).

One may doubt the claim by fuzzy theorists that the issues they currently discuss have no *logical* bearing. On the contrary, they seem fully relevant for logical discussion, so we have dedicated an appendix to comment rather expansively on fuzzy ‘logic’, as well as to mention an early generalization of Logic that arose inside the fuzzy tradition (by B.R. Gaines [1978]).

3.4 *Artificial Intelligence*

Since the moment the first “expert systems” dealt with uncertain information (the obvious cases are Mycin and Prospector), AI as a discipline got involved too in the Probability/Logic dilemma about what is the ultimate nature of “truth” measures of sentences presented to the expert system user (see Shortliffe [1976]). Leaving aside Mycin’s “uncertainty factors” (later revealed to be actually measuring belief *change*, see Heckermann [1986]), the typical measures are Prospector’s “*probability assignments*” (see Duda *et al.* [1976]), that are considered unproblematic and intuitive (to the user, who can easily estimate them), and are combined according to Bayes’ formula as though they were really what their chosen name implied. Whatever the true status (probabilistic, or logical) of the calculus, the formulas on offer happen to become corollaries of our generalized calculus below (where, unlike in AI’s rather *ad hoc* formalisms, nothing is assumed about whether the measures are actually “probabilities” or “truths” or something else).

Nils Nilsson’s [1986] stated goal in his ‘probabilistic logic’ paper (orally anticipated in 1983) was to rationalize past work in the Prospector expert system project (1976-80) and give it a formal background by propounding a ‘probabilistic entailment’ that would do for this formalism what the Modus Ponens rule ($A, A \rightarrow B \vdash B$) does for ordinary Logic. He obtained the well-known bounds for the probability of B (see e.g. our formula (8) below) by Venn diagram techniques, that he extended to the study of convex hulls in a “probability space” of “possible worlds” (the latter terms are both familiar terminology to de Finetti and Łoś readers). As Nilsson [1993] acknowledged later, his method is similar to work by Good [1950] and Smith [1961] (not to mention de Finetti [1937,70]), authors of whom he was unaware at the time. His goal is, in fact, shared by many since the first 1980s—including the present author and others mentioned in previous and later paragraphs. (The Nilsson effort is briefly discussed in the next section.)

The Artificial Intelligence context has continued to breed practical motivation for the Logic/Probability demarcation. A series of special conferences (*‘Uncertainty in A.I.’*) has been called (beginning in 1986, see Kanal & Lemmer [1986]) and given useful insights into the differences and similarity of the once-separate fields, including expert system coefficient analysis by Heckermann [1986], Grosz [1986] and others or the theoretical framework

called *belief networks*, developed for the efficient computation of “probabilities” (or whatever they are) by Judea Pearl [1988]. These contributions to general and practical Logic, worthwhile as they are, have the implicit bias that what is actually manipulated is the *probability* of distribution-driven events (rather than the *belief*, *commitment* or *assertiveness* of linguistic sentences), and thus the interpretations are always loaded with unnecessary concessions to probabilistic terminology and methods. So, for instance, Pearl, whose formalism is nominally about “beliefs”, is nevertheless overwhelmed with computing probability distributions of *facts* and with assuming simplifying conditions (such as independence or conditioning) to obtain the final value; if this assignment is to be a real “belief”, as stated, then presumably the “facts” and their distributional assumptions should be less real and objective than supposed: probably a consistent calculus (consistent in the Ramsey/de Finetti sense) based on possible or estimated (rather than actual) “facts” would suffice—and for this the possible-worlds or the rational-expectations analyses are already at hand (and ready to be usefully supplemented by a practical procedure such as Pearl’s).

An unsuspected benefit of Logic-oriented analysis by Artificial Intelligence practitioners has been their growing awareness that a system of premises (what they tend to call “knowledge base”) from which predictions are made (or actions are taken) is essentially a set of *beliefs* to which the agent is committed. This is now already clear in classic AI textbooks as Genesereth & Nilsson’s [1987], where the distinction is made between inference procedures where the user’s *full* commitment must be kept *throughout* the inference process and those where the belief premises are “qualified” (e.g. modally, with a belief operator) or “quantified” (with a “probability” assignment); in the latter cases, it is assumed, the commitment is less than absolute and the conclusion strength, therefore, less than guaranteed—however formally valid the reasoning may be. This approach is welcome, since it implies that however we treat premises in a logical argument—either as commitment-inducing beliefs or as admittedly weak probes—they all take part in the inference process and share with it a common goal: knowing to what extent can we *rely* on conclusions.

3.5 Probabilistic logic

As mentioned in the previous section, Nilsson [1986] sets out to investigate how Logic would generalize if one were to “assign probabilities instead of truth values to sentences”. Though he calls his probabilities *probabilistic truth values* he treats them as real *probabilities* (at least to the extent that Prospector’s numerical assignments are). This shows clearly in his subsequent treatment of (sentence) conditioning, that he considers plainly a Bayes process and relates to considerations by authors as Pearl, Heckermann, Grosz or Cheeseman (who explicitly deal with *probability* distribu-

tions). Based on entropy considerations by the latter author, Nilsson refines his bounding formulas so as to spot an exact value for the B in his ‘probabilistic entailment’ (= generalized Modus Ponens) rule—that happens to be the midpoint of the bounding interval (compare that with formulas (9-11) below).

Nilsson’s grounding for his ‘probabilistic logic’ is basically semantic: he exhaustively generates and examines the “possible worlds” inherent in a formula; but the way he then discards some of the worlds—before assigning values to them—amounts to introduce consistency considerations. Akin to this method is what Paass [1988] proposes in a survey: assign basic “subjective probabilities”, construct a universe of “relevant propositions”—which turns out to be isomorphic to Shafer’s “frame of discernment” (or to our Θ below)—and then evaluate the resulting probability distributions on it. The computation may be done in Dempster-Shafer’s terms (see Shafer [1976]) or by other methods: linear programming, stepwise simplification, Pearl’s “belief networks” (with interactions) or statistical simulation (see Paass [1988]).

Though they may not use the name (invented by Nilsson), many so-called “probability logics” do not descend from Reichenbach but are really *probabilistic logics* and share Nilsson’s conception and aim: finding a logical foundation for the use of $[0,1]$ *probability* assignments to sentences taking part in an inference. Most of them formally derive their technical motivation and analysis from Gaifman [1962] and Scott & Krauss [1968]. The author of one of the first such ‘probability logics’, Theodore Hailperin [1984]—who also motivates his analysis historically (and also mentions the classics, from Bernoulli to Keynes and beyond)—sets out to generalize “truth” values and Logic in model-theoretical style, through the use of a modified version of the *model* and *consequence* concepts. This is done too by Bolc & Borowik [1992], who base their analysis on Scott & Krauss [1968] and Adams [1966], and by Gerla [1994] in an interesting attempt parallel to ours below.

4 BRIDGING THE GAP

4.1 *Attempts at a synthesis*

That the need for a generalization of Logic is widely felt, and that the time is now come to try it, is attested by the many surveys—and attempts at Logic/Probability synthesis (like the present one)—that are appearing of late (see for instance Gärdenfors [1988], Paass [1988], Garbolino *et al.* [1991], Bolc & Borowik [1992] or Gerla [1994]). But other such efforts deserve mention: Kyburg’s [1993] is an exhaustive survey on logics of “uncertainty” where the author probably respects too much the usual division that insulates the surveyed authors’ self-assigned topics, as he divides his

survey, too prolixly, in “objectivism”, “subjectivism”, Nilsson’s “probabilistic logic”, “belief functions”, “measures”, “probabilities”, “statistical facts”, “updating” and “inference”, where the very exhaustivity gets in the way of a comprehensive attempt at synthesis. Similarly division-respecting are several 1995 drafts by Friedman & Halpern on plausibility measures, where the probabilistic bias dominates—in the terminology, in the chosen operations, etc.—though apparently the original intention was to widen “the measure” to a general “plausibility” concept. In the case of the swift and consistent work done by Dubois & Prade [1987,93], now a respected tradition, here the drawback to attain wide method-independent generality is the self-imposed limitation to (fuzzy) possibility measures—though some convergence with non-fuzzy approaches may occur in the future (see below on subadditivity). For the sake of completeness, we must add here work in progress by two researchers with a long tradition in trying to bridge the Probability/Logic gap: Richard Jeffrey [1995] and Glenn Shafer [1996].

4.2 *Attempts at finding a meaning for the value*

Confronted with the meaning that a “truth value” may have—or may be given—when extended to points in the $[0,1]$ interval, different people have reacted in a number of ways. Here we mention only those who did not surrender to the temptation of subsuming truth value into *probability* (carrying with it a heavily loaded interpretation of theory). Popper [1972] thought that, in terms of theories rather than sentences, truth value could be made to mean *truth content* (of the theory), degree of *approximation* to truth or, interchangeably, its (appropriately defined) *distance to falsehood*. Haack [1974] saw it could also be interpreted as *partial truth*, roughly defined as the proportion of true components of a sentence or theory, or—equivalently—the “truth” of their conjunction. (An unwilling distant relative of Haack’s is the quantum physicists’ interpretation of the “truth” of a probabilistic quantum event sequence, which is similarly defined by reduction—conjunction, actually—to its elementary event components; see e.g. Reichenbach [1935a,b] or Watanabe [1969]). Dana Scott [1973] tried to answer by defining *truth value* as one minus the *error* we commit when ascertaining or deciding it, clearly in analogy with what we do in the observational sciences. Based on ideas advanced in the 1950s by Bar Hillel (with Carnap,[1952]), Johnson-Laird [1975,83] gave too a definition of truth value, albeit indirectly, by positing as a new concept the *informativeness* or “degree of information” of a sentence (a quantity negatively correlated with the “truth-table probability”) to see how it evolves through the reasoning process, with an eye more on guiding the process than on controlling the *degree of truth* (or *assertiveness*, or whatever), which is what Logic puts the proper emphasis on.

4.3 Popper, and Probabilistic Semantics

As repeatedly mentioned above, Popper [1959] (in 1938 and 1955) had decided that Probability and Logic had to be given at last their long-overdue common formalism. Disagreeing with Kolmogorov's [1933] solution (a $[0,1]$ -valuation on sets) because it was already (semi)interpreted—the valued objects were *sets*—and had a bias toward Probability, he proposed instead a totally abstract, uninterpreted system consisting of (1) an elementary algebra of “sentences” (not necessarily Boolean, merely closed by “conjunction” and “negation”), and (2) a $[0,1]$ -valuation $v(a, b)$ on *pairs* of such sentences satisfying very basic and reasonable conditions (see the appendices in Popper [1959]). Such valuations, called “Popper functions”, have become a vogue now (under the name of “probabilistic semantics”), following efforts by Harper [1975], Field [1976] or Leblanc [1979,83] to base ordinary (i.e. “unary”) probability on it. Great advantages of the Popper formalism are:

- the formulas may be interpreted at will either “logically” or “probabilistically”: when in the latter mode, the “sentences” are elementary *events*, the basic operations are *intersection* and *complementation*, and the valuation is just plain *conditional probability* (but with an unsuspected plus: there is no need that the “conditioning” event should be assigned a non-zero (unary) probability)
- there is no need for σ -additivity (as Popper [1959] himself bothers to show), nor is σ -additivity abstract enough for Kolmogorov's [1933] pretendedly neutral formalism to qualify as really neutral (since it is satisfied in an interpretation but discards certain others)
- the resulting quotient algebra *modulo* equi-valuation *is* automatically a *Boolean algebra*, which is not only simple and extraordinarily convenient but, because obtained from very simple assumptions, disarmingly *natural*
- each quotient algebra *class* is interpretable, at will, as an ordinary logical *sentence* or an ordinary probabilistic *event*, and its value turns out to be automatically its *truth value* or, respectively, its (so-called “unary”, i.e. ordinary) *probability*
- the formalism being completely abstract (i.e. uninterpreted) and the interpretation totally free, the “probability” may be—with equal legitimacy—subjective, objective or whatever; in particular it may be Popper's [1962] *truth content*, or its *probability* (the latter is, according to him, the value we give a theory when nothing is known about its *content*, which correlates *negatively* with it)

- likewise, the “truth value” may be *truth* or simple *belief*; in the present author’s view, many other interpretations are equally legitimate, such as “degree of commitment”, “assertive value” or any other that gives us information on the *reliability* —subsuming *truth*— of sentences (including premises and conclusion), and that allows us to have *control* over their behavior along a chain of reasoning
- if one does not accept Popper’s simple conditions, the same result can provably be obtained by accepting alternative and equally simple conditions set forth —independently— by Cox [1961] (and, lately, also the ones by Woodruff [1995]).

As stated, “truth values” may be interpreted in various legitimate ways. Furthermore, any truly abstract formalism requires that they must. In the following sections —to the end of the article— we consider, in genuine Popperian fashion, several fully *logical* interpretations of the “truth value” concept (*belief*, *assertiveness*, etc.), all motivated by what should be included in any study of Logic: *invariance* (of *truth* —or of what the truth value stands for, be it *approximation* to truth, *reliability* or whatever else) along the whole *reasoning* process (assumed formally *valid*). But, compared to the standard Popper schema, our method proceeds just in the reverse direction: where Popper first defines the two-place probability function and then the unary probability is obtained by taking the quotient, we begin instead by a unary valuation and then we subsidiarily define conditioning (that we prefer to call “truth relativity” or “relative truth”) to obtain Popper’s basic two-placed function. The process inversion is unimportant, as we could as well have begun by a two-place valuation (of the *assertive value* —or whatever else— of a sentence *relatively* to the others) and then obtain its *absolute* assertive value by taking the quotient. And note that when we proceed in our direction rather than Popper’s, evaluating the mutually *relative* position of sentences through the α and σ parameters (see below) amounts to just computing the basic two-place Popper function.

B. Steps toward a General Logic of Rationality

5 MOTIVATION

Let us advance what is our aim here by starting with an obvious remark. When we argue, we do not always fully assert what we say. We often make half-hearted assertions of sentences we are not sure about, or we even use as assertions sentences we hardly believe to be the case. And yet we proceed by reasoning from such weak premises. If we admit we do, and want to treat this inside Logic, we need to qualify assertions, or, if possible, to quantify

their strength, and try to follow and control what effects weak assertions may have in the reasoning process, whether and how they affect its logical validity and how we can tell the strength of the conclusion. All this is indeed a proper *logical* subject (that, however, classical logic never set out to confront).

By tradition, Logic is about *truth*; or, more precisely, it is about truth-preserving manipulations that allow us to validate arguments. *Arguments* are lists of sentences that we note by “ $\Gamma \vdash C$ ”, where C is called the *conclusion* and Γ is a –possibly empty, or infinite– list of sentences called *premises*. It is no obligation for sentences to be true (or even to have meaning). We merely use them to see whether certain formal manipulations—the *inference rules*—assure us that the prediction embodied by the conclusion C is *true* whenever the premises are. The whole process is dependent on the truth of the premises: if we cannot assure the truth of *all* of them, the whole procedure becomes redundant. This is how ordinary Logic approaches reasoning.

Now, at least two questions arise. First, suppose we are not sure whether some premise applies, yet we want to know the “truth” of C (or what is left of it, or, in other words, the *reliability* we can still attach to C as a prediction). Second, suppose that we deliberately want to *weaken* some true premise to see whether—or up to what point—the conclusion still *holds* (this is : probe the conclusion’s dependence on its premises, or, in other words, the argument’s “robustness”). By tradition, none of this is approached by Logic (so far). To see how we can generalize Logic to cover weak premises we must get a closer look on how we assign truth to sentences. In Logic the

base material is the *sentence*, say A . (Note A is *not* a set, but merely a member of a given language \mathcal{L} .) Once we interpret it we get what we can call a *proposition*. Then, by looking at what is the case, we get a value (a “truth value”). Following Tarski’s [1935b] well-known schema

(T) ‘ A ’ is true if and only if A is true

the reasoner can verify the sentence (i.e examine the proposition A , obtained by “unquoting” the sentence A) and declare it true whenever the translation A of the object-language sentence A is found true. A is thus assigned the one or *true* value, and we say that A has full credibility and eventually we assert it with the full confidence that truth warrants. If we find A false, we assign it the zero or *false* value and give it null credibility. Note it is the reasoner who is full command of the sentences and the translation process, and thus the only one who can validate their truth. As sentences are used to *assert*, and assertions are defined as “true, believed or merely hypothesized” sentences, it is left to the reasoner who uses them to count actively on the quality of assertions as part of the reasoning process itself (so, for instance,

the reasoner usually qualifies the conclusions, conditioned on the strength the original assertions carried).

Now suppose we are reasoning in Physics and A (a premise) is the positive result of an experiment. If we are sure that A is true, then we are done: we can use it in a reasoning as a true premise and proceed with the assumedly valid argument to obtain the conclusion. But suppose that, as is usually the case in Physics, we have some qualms about the truth of A , so we quantify the error ε of the experiment. Now the “truth” of the assertion ‘result is positive’ is no longer 1 as before but, say, “ $1 - \varepsilon$ ”. We then perform the formal —valid— reasoning. The question now is : what *confidence* —as a function $\varphi(\varepsilon)$ of ε — may we have in the conclusion?

Most reasonings are like this. We perform as though premises were really true, often unconvincedly. They are provably true sometimes, but most of the time they are ‘assumed true’ for the sake of the argument. Now, because the (T) validation process to declare a sentence true is under control of the user (who performs the translation and decides whether the unquoted statement is observed to be the case), so the reasoner is the only one who can qualify the truth with the appropriate provisos, according to the difficulties met in the validation (unquoting) process. It seems only natural to ask this user not only to qualify but to *quantify* (with a number in e.g. [0,1]) what is the degree of credibility (or belief) (s)he assigns it. The user *can* usually do it consistently (this is the “rational” behavior studied by Ramsey [1926]), thereby defining (by de Finetti’s [1937] theorem) an *additive* valuation. (S)he can always assign the sentence A the *value* $v(A)$ —or, as we will write hereafter, $[[A]]$ —; this value (“truth value” we will call it) may be computed in an unspecified way (by betting preferences, belief networks, simulation, statistical survey, or whatever) and based on *any* preferred interpretation of A , be it standard *probability* of A as an event, or Popper’s *truth likelihood* or *truth content* of A as a proposition or theory (that, as Popper found in the 1930s, is negatively correlated with its probability), or its *partial truth* in Haack’s [1974] sense, or Shafer’s [1976] *belief* (and its dual, *plausibility*), or its *reliability*, or the *credibility* of —or the (user’s) *belief* in— A , or whatever (provided the assignment is done consistently). $[[A]]$ represents a rough index of the *confidence* we have in A being the case and —consequently— the force with which we feel we can *assert* A in a particular argument (or the assertiveness we can commit into it). This measure is always possible, provided the user is “rational” in Ramsey’s sense (but “non-rational” measures are also possible: they merely give *non-additive* values; see the final section, on subadditivity). What is measured is the user’s *belief* in and *commitment* to A : a zero value means that the premise is to be taken as false, 1 means that it is a true (and therefore fully assertable) premise or —more often— that it is to be *assumed true* (and fully endorsed), and $v(A) = 1 - \varepsilon$ ($\varepsilon > 0$) means that we can assert A but with some apprehension or risk (that we assume) ε .

Now, approached in a most general way, the problem to solve is as follows. Suppose we have the reasoning $A_1, A_2, \dots \vdash B$. Suppose we assign degrees of confidence or assertiveness to the premises. The question is: what will be the effect of those degrees in the confidence or reliability of B ? (We would thus probe the argument's robustness.) And what if we vary our confidence levels in some premises? Can it happen that, though the reasoning may be formally *valid*, the reliability of B turns out to be zero (thus making the argument *unsound*)? Or does B maintain its "truth" (or reliability = 1) though all the premises get null confidence themselves (thus making B 's truth independent from the premises)? This analysis, like the physicist's $\varphi(\varepsilon)$ estimation problem above, *is* a legitimate logician's concern. (It is what we proceed to develop in our *proof theory* below.)

We illustrate this with an example. This is the well-known sorites about bald men: "If a man with i hairs is not bald then a man with $i - 1$ hairs is still not bald. Suppose a man has n hairs. Therefore, a man with 0 hairs is still not bald". Formally:

$$\frac{A_i \rightarrow A_{i-1} \quad (i : 1, \dots, n)}{A_n} \quad \frac{}{A_0}$$

This is a paradox because the reasoning is formally correct (it consists of merely n applications of the Modus Ponens rule), the $n + 1$ premises are deemed flawless, but the conclusion is outright false (or, more precisely, a *contradictio in terminis*). Usually, it is the length of the argument that is put to blame. There is, however, a more concrete and satisfactory answer we can offer. The n premises $A_i \rightarrow A_{i-1}$ cannot obviously be asserted with the same assurance whatever the index value. That's why the argument fails: for low values of i the premises simply cannot be asserted, even if the rest can, so we can *never* have all premises asserted, and the reasoning is formally valid but vacuously so.

Formally, what happens is that the value $\llbracket A_i \rightarrow A_{i-1} \rrbracket$ decreases with i , so that when i is n (or even, say, around $n/2$ or $n/3$) it is 1 or very near 1, but when i approaches, say, $n/10$ —and surely when it becomes zero—the value of $A_i \rightarrow A_{i-1}$ (= the predisposition we have to assert it —or the willingness to assume the risk) comes down to an exceedingly low number. According to a simple proof theory (that we describe below), the conclusion A_0 has the same truth value, at best, as that lowest of numbers (and, thus, the reasoner would be willing to assert the conclusion just no more than he or she would willing to assert $A_1 \rightarrow A_0$).

Note that, though we use words such as 'belief' or 'commitment' as surrogates for truth, *truth* itself is not merely reducible to belief (or probability): compare de Finetti's well-known position ("probability tells us only what to expect, not what will actually be the case") with the more recent comments of Cohen [1990] (a probabilist), who admits that when we say that

something is true with probability, say, .26, “this result tells us nothing about the truth” of the predicted fact or the postulated hypothesis, which will be –is, actually— true or not regardless of our (expectation-inducing) probability computations. This is not to say that Logic should continue to treat truth exclusively, as it now does. On the contrary, we contend that Logic, as it becomes a *general theory of rationality*, should center on a new object of study: the *assertive value* of sentences (that subsumes *truth* and which we will hereafter call –somewhat misleadingly— *truth value*), because this is what is really manipulated in arguments, and because this concept may let us analyze them in full generality, be it through weak premises, strong conclusions or argument robustness.

6 “TRUTH” VALUATIONS OVER SENTENCES

We assume we have a set \mathcal{L} of sentences that form a Boolean algebra (with respect to the three connectives and two special sentences \perp and \top). Now we have the whole Proof Theory of Sentential Logic by identifying the “ \vdash ” order defined by the Boolean algebra with the deductive consequence relation. Thus the algebra of sentences we started with automatically becomes the Lindenbaum-Tarski algebra of all sentences modulo the interderivability relation “ $\dashv\vdash$ ” given by the \vdash order (i.e. $A \dashv\vdash B$ iff $A = B$). We then assume that all sentences are valued in $[0, 1]$, which we do in the standard way of a *normalized measure* $v : \mathcal{L} \rightarrow [0, 1] : A \mapsto \llbracket A \rrbracket$, by just requiring that \top gets a value of 1 (1 is the only ‘designated value’ we consider) and that the valuation v is *additive* (i.e. $\llbracket A \vee B \rrbracket = \llbracket A \rrbracket + \llbracket B \rrbracket - \llbracket A \wedge B \rrbracket$). So we now have also the whole Model Theory of Sentential Logic.

This “truth” valuation is merely a (finitely additive) *probability* in all technical senses, but here A is a *sentence* (in a language \mathcal{L}), not an *event* (in a sample space Ω). $\llbracket A \rrbracket = 1$, $\llbracket A \rrbracket = 0$ and $\llbracket A \rrbracket = 1/2$ here just mean – respectively— *truth* (or, more precisely, that “ A is taken as truth”), *falsity* and *undecided belief* (when expressly *asserting* the A sentence); this is to be contrasted with (respectively) probabilistic “certainty”, zero-probability or balanced odds (when evaluating the *uncertain* outcome of A as an event). We do not require that the valuations—even when interpreted fully as “truth” valuations—to be “extensional” or “truth-functional” as done in many-valued logics. As for the Booleanity of the sentences, either this is assumed (which is undemanding) or it derives from the “minimal algebra” of sentences suggested by Popper [1959]—or from provably equivalent simple assumptions (e.g. by Cox [1961] or Woodruff [1995]). Also, the additive character of the valuation amounts to having a ‘rational’ (Ramsey [1926]) or ‘coherent’ (De Finetti [1937,70]) *belief*, a concept so akin to ‘strength of assertion’ in Logic as to be all but exchangeable.

From the Booleanity of \mathcal{L} and the above properties of the v valuation we

immediately obtain:

- (1) $\llbracket \neg A \rrbracket = 1 - \llbracket A \rrbracket$
- (2) $\llbracket A \wedge B \rrbracket \leq \min(\llbracket A \rrbracket, \llbracket B \rrbracket)$
 $\llbracket A \vee B \rrbracket \geq \max(\llbracket A \rrbracket, \llbracket B \rrbracket)$
 $\llbracket A \rightarrow B \rrbracket = 1 - \llbracket A \rrbracket + \llbracket A \wedge B \rrbracket$
 $\llbracket A \leftrightarrow B \rrbracket = 1 - \llbracket A \vee B \rrbracket + \llbracket A \wedge B \rrbracket$

7 SENTENCES AS SET EXTENSIONS, AND TRUTH AS MEASURE

Any Boolean Algebra has a *representation* on a set structure (a field of sets) as Stone proved long ago in a famous theorem (see, for example, Koppelberg *et al.* [1989]). Thus, given the Boolean sentence algebra \mathcal{L} , there exist both a set Θ (whatever the meaning we give to its elements θ) and a ‘representation’ function that can be characterized as an isomorphism of \mathcal{L} into the Boolean subalgebra \mathcal{B} of clopens in $\mathcal{P}(\Theta)$, i.e.

$$\rho : \mathcal{L} \longleftrightarrow \mathcal{B} : A \mapsto \mathbf{A} \quad (\mathcal{B} \subset \mathcal{P}(\Theta), \mathbf{A} \subset \Theta).$$

We call the members of Θ *possible worlds*, or *cases* (as Laplace [1774] or Boole [1854]) or *possibilities* (Shafer [1976]) or even *observers*, *states*, etc. Θ is the *universe of discourse* or *reference frame* (the set of *possible worlds*). It coincides with Fenstad’s [1968] *model space* (where the θ s are *interpretations* in the standard logic sense).

We can establish a general, one-to-one correspondence between the two worlds (the language world \mathcal{L} and the referential universe Θ , both made up of “propositions”) and their constituent parts, thus:

$$\begin{array}{lll} \mathcal{L} & \iff & \mathcal{B} \\ A(A \in \mathcal{L}) & \iff & \mathbf{A}(\mathbf{A} \subset \Theta) \\ A \wedge B & \iff & \mathbf{A} \cap \mathbf{B} \\ A \vee B & \iff & \mathbf{A} \cup \mathbf{B} \\ \neg A & \iff & \mathbf{A}^c \\ \top & \iff & \Theta \\ \perp & \iff & \emptyset \\ A \vdash B & \iff & \mathbf{A} \subset \mathbf{B} \end{array}$$

If \mathcal{L} has a finite number of generators, then it has 2^n atoms a and the two bijective correspondences $\mathcal{L} \iff \mathcal{P}(\Theta)$ and $a \iff \{\theta\}$ also hold.

The valuation v and the representation isomorphism ρ induce a $[0,1]$ -valued measure μ in $\mathcal{B} \subset \mathcal{P}(\Theta)$, in such a way that $\mu = v \circ \rho^{-1}$, i.e. $\mu(\mathbf{A}) = \llbracket A \rrbracket$.

Intuitively, the measure $\mu(\{\theta\})$ of each individual θ in a *finite* Θ universe is the relevance or the degree of realizability of the given possible world. The μ measure corresponds to the weighing function λ in Fenstad's [1968] *model space*. As it is known, μ (or λ) is not only additive but –by the compactness property– countably so; thus μ is eligible as a standard “probability” measure (in the technical sense).

8 CONNECTIVES AND SENTENTIAL STRUCTURE

If we want to compute the truth value of composite sentences, the task is easy. For the negation connective, the formula is given by (1) above. For the binary sentences composed of A and B we have the formulas below, where we observe that, besides $\llbracket A \rrbracket$ and $\llbracket B \rrbracket$, we now need a third parameter that we note “ α_{AB} ” and that we call “*compatibility* between A and B ”; its value is defined by $\alpha_{AB} =_{df} 1 - \beta_{AB}$, where:

$$\beta_{AB} = \frac{\min(\llbracket A \rrbracket, \llbracket B \rrbracket) - \llbracket A \wedge B \rrbracket}{\min(\llbracket A \rrbracket, \llbracket B \rrbracket, 1 - \llbracket A \rrbracket, 1 - \llbracket B \rrbracket)}.$$

We call β_{AB} the “*degree of incompatibility* of sentences A and B ” and we rename the denominator by calling it “ Δ_{AB} ”. Then, the formulas for the connectives are:

$\llbracket A \wedge B \rrbracket$	$=$	$\min(\llbracket A \rrbracket, \llbracket B \rrbracket) - \beta_{AB} \cdot \Delta_{AB}$
$\llbracket A \vee B \rrbracket$	$=$	$\max(\llbracket A \rrbracket, \llbracket B \rrbracket) + \beta_{AB} \cdot \Delta_{AB}$
$\llbracket A \rightarrow B \rrbracket$	$=$	$\min(1, 1 - \llbracket A \rrbracket + \llbracket B \rrbracket) - \beta_{AB} \cdot \Delta_{AB}$
$\llbracket A \leftrightarrow B \rrbracket$	$=$	$1 - \llbracket A \rrbracket - \llbracket B \rrbracket - 2 \cdot \beta_{AB} \cdot \Delta_{AB}$

So, by knowing a single value (either of $\llbracket A \wedge B \rrbracket$, $\llbracket A \vee B \rrbracket$, $\llbracket A \rightarrow B \rrbracket$, $\llbracket A \leftrightarrow B \rrbracket$, α_{AB} or β_{AB} —or $\llbracket A|B \rrbracket$ or $\llbracket B|A \rrbracket$, see below) we can compute, via α_{AB} (or β_{AB}), the other seven. The parameter α_{AB} (which is a modern version of Reichenbach's [1935b] “Kopplungsgrad”) acts as an indicator or measure of the “relative position” of \mathbf{A} and \mathbf{B} inside Θ , while “ Δ_{AB} ” is a quadruple minimum that only depends on the values of $\llbracket A \rrbracket$ and $\llbracket B \rrbracket$. Note that if we suppose that $\beta_{AB} = 0$ for *all* A and B then the above formulas are

$$\begin{aligned} \llbracket A \wedge B \rrbracket &= \min(\llbracket A \rrbracket, \llbracket B \rrbracket) \\ \llbracket A \vee B \rrbracket &= \max(\llbracket A \rrbracket, \llbracket B \rrbracket) \\ \llbracket A \rightarrow B \rrbracket &= \min(1, 1 - \llbracket A \rrbracket + \llbracket B \rrbracket) \\ \llbracket A \leftrightarrow B \rrbracket &= 1 - |\llbracket A \rrbracket - \llbracket B \rrbracket| \end{aligned}$$

and coincide with those given in ordinary *many-valued logics*. Instead, if $\beta_{AB} = 1$, the connectives are

$$\begin{aligned} \llbracket A \wedge B \rrbracket &= \max(0, \llbracket A \rrbracket + \llbracket B \rrbracket - 1) \\ \llbracket A \vee B \rrbracket &= \min(1, \llbracket A \rrbracket + \llbracket B \rrbracket) \\ \llbracket A \rightarrow B \rrbracket &= \max(1 - \llbracket A \rrbracket, \llbracket B \rrbracket) \\ \llbracket A \leftrightarrow B \rrbracket &= |\llbracket A \rrbracket + \llbracket B \rrbracket - 1| \end{aligned}$$

and coincide with those given in *threshold logics*.

9 RELATIVE TRUTH

Now suppose we want to express the conjunction value as a product:

$$\llbracket A \wedge B \rrbracket = \llbracket A \rrbracket \cdot \tau.$$

With the current $\mathcal{L}/\mathcal{P}(\Theta)$ representation in mind, we obtain:

$$(3) \quad \tau = \frac{\mu(\mathbf{A} \cap \mathbf{B})}{\mu(\mathbf{A})}$$

We define τ as the *relative truth* “ $\llbracket B|A \rrbracket$ ” (i.e. the “truth of B relative to A ”). Though this definition exactly parallels that of conditional probability, the account we give leaves out any probabilistic interpretation of the concept and retrieves it for exclusively logical contexts.

In particular, if $\llbracket B|A \rrbracket = \llbracket B \rrbracket$ then we say that A and B are *independent*. In that case, the conjunction can be expressed as the product:

$$\llbracket A \wedge B \rrbracket = \llbracket A \rrbracket \cdot \llbracket B \rrbracket.$$

In any other case we say that A and B are mutually *dependent* and speak of the *relative truth* of one with respect to the other. Note the dependence goes both ways and the two situations are symmetric. We have (assuming $\llbracket A \rrbracket \neq 0$):

$$\begin{aligned} \llbracket A \rrbracket \cdot \llbracket B|A \rrbracket &= \llbracket B \rrbracket \cdot \llbracket A|B \rrbracket = \llbracket A \wedge B \rrbracket \quad (\text{a logical “Bayes formula”}) \\ \llbracket B|A \rrbracket &= 1 - \frac{1 - \llbracket A \rightarrow B \rrbracket}{\llbracket A \rrbracket}. \end{aligned}$$

From the latter, note that, in general,

$$\llbracket B|A \rrbracket \neq \llbracket A \rightarrow B \rrbracket.$$

Particularly, we have *always*

$$\llbracket B|A \rrbracket < \llbracket A \rightarrow B \rrbracket$$

except when either $\llbracket A \rrbracket = 1$ or $\llbracket A \rightarrow B \rrbracket = 1$, in which cases (and they are the *only* ones) $\llbracket B|A \rrbracket = \llbracket A \rightarrow B \rrbracket$. (These facts have been repeatedly noticed by many people, notably by Reichenbach [1935b], Popper [1959], Stalnaker [1970] or Lewis [1976].)

When two sentences A and B are *independent* then (and this is a necessary and sufficient condition for that to happen): $\alpha_{AB} = \max(\llbracket A \rrbracket, \llbracket B \rrbracket)$ if $\llbracket A \rrbracket + \llbracket B \rrbracket \leq 1$ = $\max(\llbracket \neg A \rrbracket, \llbracket \neg B \rrbracket)$ if $\llbracket A \rrbracket + \llbracket B \rrbracket \geq 1$ and then the connectives obey the formulas

$$\begin{aligned}\llbracket A \wedge B \rrbracket &= \llbracket A \rrbracket \cdot \llbracket B \rrbracket \\ \llbracket A \vee B \rrbracket &= \llbracket A \rrbracket + \llbracket B \rrbracket - \llbracket A \rrbracket \cdot \llbracket B \rrbracket \\ \llbracket A \rightarrow B \rrbracket &= 1 - \llbracket A \rrbracket + \llbracket A \rrbracket \cdot \llbracket B \rrbracket.\end{aligned}$$

The statement ' $A \rightarrow B$ ' can have, among other readings, one logical ("A is sufficient for B" or "B is necessary for A"), another (loosely) "causal" ("A occurs and B follows"). But because $A \rightarrow B$ is valued in $[0,1]$, its value $\llbracket A \rightarrow B \rrbracket$ (and the values $\llbracket B|A \rrbracket$ and $\llbracket A|B \rrbracket$) now mean only *degrees*, and so $B \rightarrow A$ may be—and usually is—read "evidentially" ("B is evidence for A"). Within such a frame of mind,

- $\llbracket B|A \rrbracket$ (or " $\sigma_{A(B)}$ ") could be termed "degree of *sufficiency* or *causality*" of A (or "*causal support* for B"), to be read as "degree in which A is sufficient for B" or "degree in which A is a cause of B". In view of (3), it is roughly a measure of how much of **A** is contained in **B**.
- $\llbracket A|B \rrbracket$ (or " $\nu_{A(B)}$ ") could be termed "degree of *necessity*" or "*evidence*" of A (or "*evidential support* for A"), to be read as "degree in which A is necessary for B" or "degree in which B is evidence (= support of hypothesis) for A (=the hypothesis)". With (3) in mind, it can be seen as how much of **B** overlaps with **A**.

Such measures may be directly estimated by experts, normally by interpreting the θ s frequently, in terms of *cases*, like Boole [1854], *possibilities* (Shafer [1976]), *elementary events* in Θ , or possible *interpretations*; at any rate, they may be statistically-based or simply imagined, presumably on the basis of past experience or sheer plausibility. Thus, $\sigma_{A(B)}$ in a causal reading of " $A \rightarrow B$ " would be determined by answering the question: "How many times (proportionally) —experience shows— A occurs and B follows?" For $\nu_{A(B)}$, the question would be: "How many times effect B occurs and A has occurred previously?" (Similarly for the evidential reading of " $A \rightarrow B$ ".) Once σ and ν have been guessed, they may be adjusted (via the

$$\frac{\sigma_{A(B)}}{\nu_{A(B)}} = \frac{\llbracket B \rrbracket}{\llbracket A \rrbracket}$$

relation) and then lead —by straightforward computation— to $\llbracket A \rightarrow B \rrbracket$, $\llbracket B \rightarrow A \rrbracket$ and α_{AB} , which allows one to compute all other values for connectives and also to get a picture of the structural relations linking A and B . This process of eliciting the σ value for every $\langle A, B \rangle$ sentence pair is closely equivalent to computing Popper’s *binary probability* function.

Note first that a similar computing process takes place in “Bayesian reasoning”, and in the “approximate reasoning” methods as implemented in marketable expert systems, though none of them satisfactorily explains on what *logical* grounds are the procedures justified, nor can they avoid supplying a (nominally) *probabilistic* account of them. Such an account would be here clearly misplaced, since there is usually neither (a) a sample space of *events*, but a language of *sentences* (i.e. linguistic descriptions —not necessarily of any “event”), nor (b) a measure based on *uncertainty* and *outcomes* (the topics Probability is supposed to deal with) but rather simple *beliefs* or, at most, mere *a priori* estimates, nor (c) an adequate updatable statistical or probabilistic basis to compute the values of the “events” (and their ongoing, dynamical change).

Note also that any reasoning can proceed here in both directions (from A to B and from B to A), because both conditionals $A \rightarrow B$ and $B \rightarrow A$ claim a non-zero value and thus a “causal” top-down reasoning can be complemented by an “evidential” bottom-up reasoning on the same set of given sentences (as also happens in Pearl’s [1988] belief networks).

10 THE GEOMETRY OF LOGIC: DISTANCE, TRUTH LIKELIHOOD, INFORMATION CONTENT AND ENTROPY IN \mathcal{L}

The fact that we have:

$$\llbracket A \leftrightarrow B \rrbracket = 1 - (\llbracket A \vee B \rrbracket - \llbracket A \wedge B \rrbracket)$$

strongly suggests using $1 - \llbracket A \leftrightarrow B \rrbracket = \llbracket A \vee B \rrbracket - \llbracket A \wedge B \rrbracket$ as a measure of the *distance* \overline{AB} (under a given valuation v). So we do. (We remark that all definitions we give here of distance and related concepts are not only applicable to sentences but to *theories* as well, because for a general lattice \mathcal{L} the lattice $\hat{\mathcal{L}}$ of theories derived from each sentence in \mathcal{L} is isomorphic to \mathcal{L} .)

DEFINITION 1. *Distance* (or *Boolean distance*) between two sentences or theories A and B is:

$$\begin{aligned} d(A, B) &=_{df} 1 - \llbracket A \leftrightarrow B \rrbracket \\ &= \llbracket A \vee B \rrbracket - \llbracket A \wedge B \rrbracket \\ &= |\llbracket A \rrbracket - \llbracket B \rrbracket| + 2 \cdot \beta_{AB} \cdot \Delta_{AB} \end{aligned}$$

DEFINITION 2. *Compatible distance* between two sentences or theories A and B is:

$$d^+(A, B) =_{df} |[A] - [B]| = [A] + [B] - 2 \min([A], [B])$$

We now define a *truth likelihood* value for A —approximating Popper’s [1972] (and Miller’s [1978]) *truth likelihood* or *verisimilitude* measure—by making it to equal the distance from A to falsehood, i.e. $d(A, \perp)$. We obtain, immediately:

$$\begin{aligned} d(A, \perp) &= d(\top, \perp) - d(\top, A) = 1 - d(A, \top) \\ &= 1 - d(A \Delta \top, \perp) \\ &= 1 - d(\neg A, \perp) = 1 - [\neg A] = [A] \end{aligned}$$

So here we have a further interpretation of our “truth values” $[A]$ in terms of Popper’s [1972] *truth likelihood* or *verisimilitude*. We might as well consider $[A]$ as a rough measure of *partial truth* or *truth content* of A . In a similar vein, we may recall that Scott [1973] suggested the “truth value” $[A]$ of many-valued logics could be interpreted as *one* (meaning *truth*) less the *error* of A (or rather of a measure settling the truth of A) or the *inexactness* of A (as a theory); in this framework, it comes out that, in our terms, $[A] = 1 - \varepsilon_A$ and $\varepsilon_A = 1 - [A] = d(A, \top)$.

We further observe that, for any sentential letters P and Q , any uniform truth valuation yields $[P] = [\neg P] = .50$, $[P \wedge Q] = .25$ and $[P \vee Q] = .75$, which is like saying that, if all letters are equiprobable, the given values are the probability of the given sentence being true (a number that Johnson-Laird [1975,83] calls, appropriately, “truth-table probability”). This value’s complement to one is reasonably made to correspond to the amount of information—in a loose sense—we have when the sentence is true. This is precisely what Johnson-Laird [1975,83] defines as “degree of information”, “semantical information” or *informativeness* $I(A)$ of a sentence A . (Viewed in our terms, this *information content* $I(A)$ equals $1 - [A]$, or $I(A) = [\neg A] = d(A, \top) = \varepsilon_A$.) The concept, based on Bar-Hillel’s (and Carnap’s, [1952]) ideas, was originally designed to model the reasoning process, assumed to be driven by an increase both of informativeness and parsimony. What is interesting is that the informativeness of composite sentences is computed by combining them according to non-truth-functional rules which yield values that coincide with those predicted by our formulas.

A new measure we can define, which can also be used as an *entropy* (in the sense of De Luca & Termini [1972]), is this one:

DEFINITION 3. *Imprecision* (or, perhaps, “fuzziness”) of a sentence (or theory) A is the value for A of the function

$$f : \mathcal{L} \longrightarrow [0, 1] \text{ such that } f(A) = 1 - d^+(A, \neg A)$$

It is immediate that:

$$f(A) = 2 \min (\llbracket A \rrbracket, 1 - \llbracket A \rrbracket),$$

which is equivalent to saying that the imprecision of a sentence A equals twice the error we make when we evaluate on A the truth of the law of non-contradiction or of the excluded middle by considering there really *is* maximum compatibility between A and $\neg A$. (Actually, there is *null* compatibility, as α_{AB} is provably *zero* when B is $\neg A$.) In connection with this measure, we note in passing that:

- *classical* (two-valued) *logic* is the special case of ours in which *all* sentences in \mathcal{L} have *zero* imprecision.
- ordinary *multi-valued logics* —like Łukasiewicz-Tarski’s L_∞ — are the ones where at least *one* sentence in \mathcal{L} has non-zero imprecision. This measure being —as it is— an error function, imprecision is here just the degree in which these logics fail to distinguish contradictions (their lack of “resolving power”).

11 ELEMENTARY PROOF THEORY FOR GENERAL ASSERTIONS

Once we have valued sentences in $[0, 1]$ we now need a Proof Theory that in the most natural way extends standard logic so as to treat imprecise statements or weak assertions, and measure and control whatever effect they may have on reasoning (as well as to explain some results in approximate reasoning methods from Artificial Intelligence).

To begin with, suppose a valid argument, noted $\Gamma \vdash B$ (where Γ are the premises, or a finite subset of them). Classical logic declares it *valid* if B is derivable from Γ in an appropriate deduction calculus. By the completeness property, this amounts to assert the truth of B whenever the premises in Γ are true. Now, as we said, the ultimate judge of the truth of the premises is the reasoner. It is the reasoner who decides that each premise used is true (or to be considered true). To justify such a decision, the reasoner applies a truth criterion such as Tarski’s [1935b] (T) schema. Thus the reasoner declares A true when assured that what A describes is precisely the case. If the reasoner is not sure of the result of his/her validation or does not want to commit him/herself to it, then the reasoner may choose not to make a full assertion by claiming that A ’s verification does not yield an obvious result. In that case, the reasoner may rather easily “qualify” the assertion by assigning numbers in $[0, 1]$ such as $v(A)$ —that we noted “ $\llbracket A \rrbracket$ ”— or $\varepsilon(A)$ [$= 1 - v(A)$] meaning that the reasoner believes or is willing to assert A to the degree $v(A)$ or assume it with a risk or estimated error of $\varepsilon(A)$.

The proof theory we now sketch is a slightly extended version of the standard one. Here we understand by *proof theory* the usual syntactical deduction procedures *plus* the computation of numerical coefficients that we must perform alongside the standard deductive process. We do that because a final value of zero for the conclusion would invalidate the whole argument as thoroughly as though the reasoning were formally —syntactically— invalid. As always, any formally valid *argument* will have, by definition, the following *sequent* form:

$$\Gamma \vdash B$$

where B is the conclusion and Γ stands for the list —or, rather, the conjunction— of the premises (or, by the compactness property, of a finite number of them). We have, elementarily:

$$(4) \quad \Gamma \vdash B \Rightarrow \llbracket \Gamma \rrbracket \leq \llbracket B \rrbracket.$$

We henceforth assume that we have a *valid argument* (so $\Gamma \vdash B$ will always hold), and that all premises are non-zero (i.e. $\forall i \llbracket A_i \rrbracket > 0$). We distinguish four possible cases:

1. $\llbracket \Gamma \rrbracket = 0$ (i.e. the premises are —materially— *inconsistent*). Here by (4) $\llbracket B \rrbracket$ can be anywhere between 0 and 1; this value is in principle undetermined, and uncontrollably so.
2. $\llbracket B \rrbracket = 0$. This entails, by (4), $\llbracket \Gamma \rrbracket = 0$ and we are in a special instance of the previous case. The reasoning is formally valid, the premises are not asserted, and the conclusion is false.
3. $\llbracket \Gamma \rrbracket \in (0, 1)$ (i.e. the premises are consistent). Then, by (4), $\llbracket B \rrbracket > 0$. We have a formally valid argument, we risk assessing the premises (though with some apprehension) and get a conclusion which can be effectively asserted though by assuming a —bounded— risk. This will be the case we will set to explore below.
4. $\llbracket \Gamma \rrbracket = 1$. This condition means that $\llbracket A_1 \rrbracket = \dots = \llbracket A_n \rrbracket = 1$ and, by (4), $\llbracket B \rrbracket = 1$. So the premises are *all* asserted —with no risk incurred— and the conclusion *holds* unconditionally (remember $\Gamma \vdash B$ is formally valid). This is the classical case studied by ordinary two-valued Logic.

We are interested in examining *case 3* above, i.e. formally valid reasoning *plus* assertable premises (though not risk-free assertions) *plus* assertable conclusion (but at some measurable cost). Cases 3 and 4 characterize in a most general way all *sound* reasoning. Case 2 characterizes *unsound* arguments (since in this case having a formally valid argument $\Gamma \vdash B$ does

not preclude getting an irrelevant conclusion ($\llbracket B \rrbracket = 0$). As this case is the one to avoid, we have:

DEFINITION 4. *Unsoundness* of a valid argument $\Gamma \vdash B$ is having $\llbracket B \rrbracket = 0$ though the premises are themselves non-zero. So:

DEFINITION 5. *Soundness* of a valid argument $\Gamma \vdash B$ is having $\llbracket B \rrbracket > 0$ whenever the premises non-zero.

With that in mind, we can now turn to the basic inference rule, the Modus Ponens (MP). From a strictly logic point of view, this rule is

$$(5) \quad \begin{array}{r} A \quad m \\ A \rightarrow B \quad n \\ \hline B \quad p \end{array}$$

where m , n and p stand for the strength or force (or “truth value”) we are willing to assign each assertion; so, in our terms, m , n and p are just our $\llbracket A \rrbracket$, $\llbracket A \rightarrow B \rrbracket$ and $\llbracket B \rrbracket$. They are numbers in $[0,1]$ that take part in a (numerical) computation which parallels and runs along the logical, purely syntactical deduction process. This is well understood and currently exploited by reasoning systems in Artificial Intelligence that must rely on numerical evaluations —given by users— that amount to *credibility* assignments (or “certainty factors”), *belief* coefficients, or even —rather confusingly— *probabilities* (often just *a priori* probability estimates); this is the case of successful *expert systems* such as Prospector or Mycin. The trouble with such systems is that they tend to view Modus Ponens as a probability rule (this is made explicit in systems of the Prospector type, see Duda *et al.* [1976]). They use it to present the MP rule in this way:

$$(6) \quad \begin{array}{r} A(m) \\ A \rightarrow B(\sigma) \\ \hline B(p) \end{array}$$

where m and p are the ‘probability’ (a rather loose term here) of A and B , and “ $A \rightarrow B(\sigma)$ ” means that “whenever A happens, B happens with probability σ ”. Here σ turns out to be just $v(B|A)$ or “ $\llbracket B|A \rrbracket$ ”, the “relative truth” of B given A ; this concept, modelled on a close analogy —*ceteris paribus*— with that of (probabilistic) conditioning, is what we have defined above (in (3)) and called “degree of sufficiency” σ of A —or of necessity of B —, assumed easily elicitable by experts. So it is just natural, and immediate, to compute the p value thus:

$$p \geq \sigma \cdot m$$

or, in our notation,

$$\llbracket B \rrbracket \geq \llbracket B|A \rrbracket \cdot \llbracket A \rrbracket$$

which is just another version of formula (2).

The problem is that what we have, from our purely logical, probability-rid standpoint, is (5), not (6), and in (5) n is not $\llbracket B|A \rrbracket$ but $\llbracket A \rightarrow B \rrbracket$. Recall that $\llbracket B|A \rrbracket$ and $\llbracket A \rightarrow B \rrbracket$ not only do *not* coincide but mean different things (as repeatedly noticed by logicians, and as explained above). Indeed, $\llbracket A \rightarrow B \rrbracket$ is the value (“truth” we may call it, or “truth minus risk”) we assign to the (logical) assertion $A \rightarrow B$. Instead, $\llbracket B|A \rrbracket$ is a relative measure linking materially, *factually*, A and B (or, better still, the \mathbf{A} and \mathbf{B} sets), with no concern whether a true *logical* relation between them exists; we might even have $\llbracket B|A \rrbracket < \llbracket B \rrbracket$, thereby indicating there exists an *anticorrelation* (thus rather contradicting any—logical or other—reasonable kind of relationship between A and B). So we turn back to our (5) rule; note that $m + n \geq 1$ (this *always* holds) and that $\llbracket B|A \rrbracket$ can be obtained from $\llbracket A \rightarrow B \rrbracket$, or vice versa: $\llbracket A \rightarrow B \rrbracket$ from $\llbracket B|A \rrbracket$ through

$$(7) \quad \llbracket A \rightarrow B \rrbracket = 1 - \llbracket A \rrbracket \cdot (1 - \llbracket B|A \rrbracket)$$

(which is useful, since $\llbracket B|A \rrbracket$ is directly obtainable from experts).

The following theorem states the *soundness* condition for the MP rule.

The Modus Ponens rule

$$\begin{array}{r} A \quad m \\ A \rightarrow B \quad n \\ \hline B \quad p \end{array} \quad (\text{we assume } m \text{ and } n \text{ are both non-zero})$$

is *sound* (and thus $\llbracket B \rrbracket \neq 0$) if one of these four equivalent conditions hold:

1. $m + n > 1$
2. $\llbracket B|A \rrbracket > 0$
3. $\llbracket A \wedge B \rrbracket > 0$
4. Either $\llbracket A \rrbracket + \llbracket B \rrbracket > 1$ (and thus $\llbracket B \rrbracket > 1 - m$) or both A and B are compatible ($\alpha_{AB} > 0$) and not binary-valued.

In both sound and unsound cases we have the following easily computable bounds for the value $\llbracket B \rrbracket$ of the MP conclusion (Sales [1992,96]):

$$(8) \quad \llbracket A \rrbracket + \llbracket A \rightarrow B \rrbracket - 1 \leq \llbracket B \rrbracket \leq \llbracket A \rightarrow B \rrbracket$$

or equivalently, in shorter notation:

$$m + n - 1 \leq p \leq n .$$

(Such bounds have been discovered again and again by quite diverse authors; see e.g. Genesereth & Nilsson [1987]). The lower bound—which equals $\llbracket A \wedge B \rrbracket$ —is reached when $\alpha_{AB} = 1$ and $\llbracket A \rrbracket \geq \llbracket B \rrbracket$, while the upper bound is reached when $\alpha_{AB} = 0$ and $\llbracket A \rrbracket + \llbracket B \rrbracket \geq 1$. Naturally we usually know neither $\llbracket B \rrbracket$ nor α_{AB} beforehand, so we don't know whether the actual value $\llbracket B \rrbracket$ reaches either bound or not, nor which is it; we can merely locate $\llbracket B \rrbracket$ inside the $[m + n - 1, n]$ interval.

But this interval can be narrowed. Since a very reasonable constraint a conditional $A \rightarrow B$ may be expected to fulfill is that A and B be (assumedly) non-independent—and not binary—and *positively* correlated (i.e.: $\llbracket A \wedge B \rrbracket > \llbracket A \rrbracket \cdot \llbracket B \rrbracket$), so we have:

$$(9) \quad \llbracket A \rrbracket + \llbracket A \rightarrow B \rrbracket - 1 \leq \llbracket B \rrbracket < \llbracket B|A \rrbracket.$$

Here, if A and B are fully or strongly compatible, $\llbracket B \rrbracket$ will be nearer the lower bound. Thus, we can only increase our $\llbracket B \rrbracket$ if we are assured that A and B are independent (in the sense that $\llbracket A \wedge B \rrbracket$ equals $\llbracket A \rrbracket \cdot \llbracket B \rrbracket$, see above): we then obtain the highest value $\llbracket B \rrbracket = \llbracket B|A \rrbracket$. On the other hand, the more we confide instead in a strong logical relation between A and B , the more we should lean towards the low value given by

$$(10) \quad \llbracket B \rrbracket = \llbracket A \wedge B \rrbracket = m + n - 1.$$

Under very reasonable elementary hypotheses (like this one: $\llbracket A \rightarrow B \rrbracket > \llbracket A \rightarrow \neg B \rrbracket$ or, equivalently, $\sigma_{A(B)} > 1/2$, see Sales [1996]), we easily get these bounds for $\llbracket B \rrbracket$: $\llbracket A \rrbracket / 2 < \llbracket B \rrbracket \leq \llbracket A \rrbracket$.

Now, if what we want is not an interval, however narrowed, but a precise value for $\llbracket B \rrbracket$ we should favor the lower value, the one given by (10) above. There are lots of reasons (some mentioned in Sales [1996]) for this choice of value in the absence of more relevant information.

But if we want not merely a pair of bounds—or a favored lower bound—for the conclusion B of an MP but the *exact* value $\llbracket B \rrbracket$, the obvious candidate formula for this follows easily: suppose we are given not only $\llbracket B|A \rrbracket$ but also $\llbracket A|B \rrbracket$ (that we note by σ and ν) and we assume them estimated by experts. We then formulate MP as

$$\frac{A(m) \quad A \rightarrow B(\sigma, \nu)}{B(p)}$$

which is exactly (6) except that the conditional has prompted evaluation of relative truths of A and B in both directions. The value is computable at once from the above definition of $\llbracket A|B \rrbracket$:

$$\llbracket B \rrbracket = \frac{\llbracket B|A \rrbracket \cdot \llbracket A \rrbracket}{\llbracket A|B \rrbracket} \quad \text{or} \quad p = \frac{\sigma \cdot m}{\nu}.$$

Note that the above logical formula coincides formally with Bayes's theorem —whence the adjective (“Bayesian”) for any calculus that uses it— except that it deals not with hard-to-compute probabilities of events but with beliefs (or assertion strengths) of sentences. Note also that this value is the one that some *approximate reasoning* systems (e.g. Prospector) unqualifiedly assign to $\llbracket B \rrbracket$ supposedly on purely probabilistic grounds —and falsely assuming that $\llbracket B|A \rrbracket$ is the same as $\llbracket A \rightarrow B \rrbracket$ —; see, for instance, the Genesereth & Nilsson [1987] text, where the logical equation above is said to be Bayes's formula.

If we wanted the MP presented in the more traditional *logical* way (5), first we would directly estimate the truth value $\llbracket A \rightarrow B \rrbracket$ of the conditional, or compute it from σ through (7) —or both, and use each estimate as a cross-check on the other—, so we would now have, along with the expert guess of ν :

$$\frac{\begin{array}{cc} A & m \\ A \rightarrow B & n(\nu) \end{array}}{B \quad p}$$

(where $n = 1 - m \cdot (1 - \sigma)$), and so

$$(11) \llbracket B \rrbracket = \frac{\llbracket A \wedge B \rrbracket}{\llbracket A|B \rrbracket} = \frac{m + n - 1}{\nu}$$

that naturally fits the (9) bounds (when ν runs along from 1 to $\llbracket A \rrbracket$).

12 THREE COROLLARIES AND ONE EXTENSION

A few remarks can be made on some apparent advantages of the “logic-as-truth-valuation” approach that, following the advice of Popper *et alii*, we have advocated and described above. First, we mention three well-known fields that have been traditionally perceived as separate but that now automatically become special cases of a single formulation. Then, in subsection *b*, we hint at an obvious extension of the approach.

12.1 The special cases

1. *Classical* (two-valued) *logic* is the special case of our general logic in which *every* sentence is *binary* (i.e. $\forall A \in \mathcal{L} \llbracket A \rrbracket \in \{0, 1\}$) or, equivalently, in which *every* sentence has *zero* imprecision (i.e. $\forall A \in \mathcal{L} f(A) = 0$).
2. For *three-valued logics* first note that classical examples, especially Kleene's system of strong connectives [1938] and Łukasiewicz's [1920]

L_3 , give the following tables for the values of connectives (where U stands for “undetermined”):

\wedge	0	U	1		\vee	0	U	1		\rightarrow	0	U	1
0	0	0	0		0	0	U	1		0	1	1	1
U	0	X	U		U	U	Y	1		U	U	Z	1
1	0	U	1		1	1	1	1		1	0	U	1

with $X = Y = U$ in both Kleene’s and Łukasiewicz’s tables, and $Z = U$ in Kleene’s (but $Z = 1$ in Łukasiewicz’s).

Now, if we abbreviate the “ $\llbracket A \rrbracket \in (0, 1)$ ” of our general logic by “ $\llbracket A \rrbracket = U$ ” (as in Kleene or Łukasiewicz) the values given in the above tables coincide exactly with those that would have been computed by our formulas, *except* that X , Y and Z would remain undetermined until we knew α_{AB} . In general, our values would match Kleene’s, but in certain cases they would yield differing results:

- (a) If $\llbracket A \rrbracket + \llbracket B \rrbracket \leq 1$ and A and B are *incompatible* (typically because $\mathbf{A} \cap \mathbf{B} = \emptyset$) then $X = 0$.
- (b) If $\llbracket A \rrbracket + \llbracket B \rrbracket \geq 1$ and A and B are *incompatible* (typically because $\mathbf{A} \cup \mathbf{B} = \Theta$) then $Y = 1$.
- (c) If $\llbracket A \rrbracket \leq \llbracket B \rrbracket$ and A and B are *compatible* (typically because $\mathbf{A} \subset \mathbf{B}$) then $Z = 1$.

Note that in the particular case in which B is $\neg A$ we have *always* $\llbracket A \wedge \neg A \rrbracket = 0$ and $\llbracket A \vee \neg A \rrbracket = 1$ for any valuation, so that, for instance, the three classical Aristotelian principles ($\vdash A \rightarrow A$, $\vdash \neg(A \wedge \neg A)$ and $\vdash A \vee \neg A$), which do not hold in these logics (except that the first one does in L_3), do now hold in ours. These three results are perfectly classical and in full agreement with what is to be expected from a (Boolean) logic.

- (d) *Łukasiewicz & Tarski’s* [1930] L_∞ logic, as ours, generalizes classical (two-valued) logic in the sense that it allows the members of the sentential lattice to take values in $[0,1]$ other than 0 or 1. Both systems of logic include classical two-valued logic as a special case. Nevertheless, while L_∞ renounces *Booleanity*, we renounce *functionality* (though not quite, since each connective is actually truth-functional in *three* arguments: $\llbracket A \rrbracket$, $\llbracket B \rrbracket$ and a third parameter such as, e.g., α_{AB}). In fact, if the $\{0, 1\}$ truth set is extended to $[0,1]$ those two properties of classical logic cannot be both maintained, and one must be sacrificed; we find much easier to justify logically, and more convenient, the sacrifice of truth-functionality.

Our general logic admits L_∞ as a special case since, indeed, L_∞ behaves exactly as ours would do if *no* sentence in \mathcal{L} could be recognized as a *negation* of some other and, then, it would be assigned systematically the maximum compatibility ($\alpha = 1$) connective formulas. Naturally that would give an error in the values of composite sentences involving non-fully-compatible subsentences, but it would also restore the lost truth-functionality of two-valued logic. L_∞ amounts —from our perspective— to viewing *all* sentences as having *always* maximum mutual compatibility. That means that L_∞ conceives *all* sentences as *nested* (i.e. for every A and A' , either $\mathbf{A} \subset \mathbf{A}'$ or $\mathbf{A}' \subset \mathbf{A}$) (Sales [1994]). Such a picture is strongly reminiscent of Shafer's [1976] description of conditions present in what he calls *consonant* valuations, and which entails the fiction of a *total*, linear order \vdash in \mathcal{L} —and \subset in $\mathcal{P}(\Theta)$ — (that means a coherent, negationless universe) ... which is probably the best assumption we can make when information on sentences is lacking and negations are not involved —or cannot be identified as such. (Such an option is as legitimate as that of assuming, in the absence of information on sentences, that these are independent.) In L_∞ obvious negations may be a problem, but it can be solved by applying error-correcting *supervaluations* (van Fraassen [1968]) —that our logic supplies automatically. And note that, in particular, the error incurred in by L_∞ when failing to distinguish between a sentence and its negation —thus not being able to recognize a contradiction— is just the quantity we called *imprecision* (or curiously, for the historical record, what Black called *vagueness* and defined formally as we did with imprecision, see Sales [1982b]).

12.2 Ignorance as subadditivity

If we now suppose that \mathcal{L} is still in a Boolean algebra but the v valuation we impose on \mathcal{L} is *subadditive*, i.e.:

$$\{[A \wedge B]\} + \{[A \vee B]\} \geq \{[A]\} + \{[B]\} \text{ (Subadditivity)}$$

(where we note explicitly by the $\{[\]\}$ brackets that v is subadditive), then v can be characterized as a *lower probability* (see Good [1962]) or as a *belief* $Bel(A)$ (in Shafer's [1976] sense). If the inequality sign were inverted, the valuation would become an *upper probability* or (Shafer's) *plausibility* $Pl(A)$. The defective value —the part of the value $v(A)$ attributed neither to A nor to $\neg A$ — can be expressed as:

$$\begin{aligned} \partial(A) &= 1 - (\{[A]\} + \{[\neg A]\}) \\ &= (1 - \{[\neg A]\}) - \{[A]\} \\ &= Pl(A) - Bel(A) \end{aligned}$$

In the finite \mathcal{L} case we know (Shafer [1976]) that a subadditive valuation like $v : \mathcal{L} \rightarrow [0, 1] : A \mapsto \{[A]\}$ —or, better, the measure $\mu : \mathcal{P}(\Theta) \rightarrow [0, 1] : \mathbf{A} \mapsto \mu(\mathbf{A})$ induced on $\mathcal{P}(\Theta)$ by that valuation— defines a function $m : \mathcal{P}(\Theta) \rightarrow [0, 1]$ (called “*basic assignment*” by Shafer) that satisfies:

1. $m(\emptyset) = 0$
2. $\sum_{\mathbf{A} \subset \Theta} m(\mathbf{A}) = 1$

so that the $\mu(\mathbf{A})$ ($= \{[A]\}$) values are computed from this measure through

$$\{[A]\} = \sum_{\mathbf{B} \subset \mathbf{A}} m(\mathbf{B})$$

and, conversely, the $m(\mathbf{A})$ values can be obtained from $\{[A]\}$ ($= \mu(\mathbf{A})$) through

$$m(\mathbf{A}) = \sum_{\mathbf{B} \subset \mathbf{A}} (-1)^{|\mathbf{A}-\mathbf{B}|} \mu(\mathbf{B}) \text{ for any } \mathbf{A} \subset \Theta.$$

$Bel(A)$ and $Pl(A)$ happen to coincide with the traditional concept (in Measure Theory) of *inner measure* (P_*) and *outer measure* (P^*), so that the following chain of equivalences has a transparent meaning (notice Shafer calls $Bel(\neg A)$ “degree of doubt of A ”):

$$\begin{aligned} Pl(A) &= P^*(\mathbf{A}) = \sum_{\mathbf{B} \cap \mathbf{A} \neq \emptyset} m(\mathbf{B}) \\ &= \sum_{\mathbf{B} \subset \Theta} m(\mathbf{B}) - \sum_{\mathbf{B} \subset \mathbf{A}^c} m(\mathbf{B}) \\ &= 1 - P_*(\mathbf{A}^c) = 1 - Bel(\neg A) \end{aligned}$$

We know, also, that an *additive* valuation μ is just a basic assignment m such that $m(\mathbf{A}) = 0$ for all $\mathbf{A} \subset \Theta$ *except* for the singletons $\{\theta\}$ of Θ . This is what Shafer calls ‘*Bayesian belief*’.

Subadditive belief derives from “non-rational” valuations of evidence by a reasoner (in the Ramsey/de Finetti sense). It can model and explain situations like this classic result: Confronted with the question “Should the Government allow public speeches against democracy?”, one user assented 25% of the time. Substituting the word “prohibit” for “allow” elicited a 54% of assenting responses. Since both words are antonyms (the contrary of prohibiting is allowing), it is clear that this user had an unattributed gap left between those two complementary concepts, thus:

$$\{[A]\} + \{[\neg A]\} = .25 + .54 \leq 1$$

which reveals that sentence A (=speeches allowed) was being valued *sub-additively*, and also that “allow” and “fail to prohibit” are here analyzable, in Shafer’s terms, as $Bel(A)$ and $Pl(A)$, respectively, with values .25 (for belief) and .46 (for plausibility).

Ignorance (or, rather *total ignorance*) is the particular instance of sub-additive valuation in which all non-*true* sentences get the zero value, i.e.

$$\{[A]\} = 1 \text{ iff } A = \top, \quad \{[A]\} = 0 \text{ otherwise}$$

(this is what Shafer calls ‘*vacuous* belief function’). It is just the particular instance of valuation in which all non-*true* sentences get the zero value: indeed, we have, for a given A , $\{[A]\} = \{[\neg A]\} = 0$. In a strict parallel with *total ignorance*, subadditive valuations can also adequately formalize *total certainty* (meaning that $\{[A]\} = 1$ while at the same time $\{[B]\} = 0$ for all $B \vdash A$).

Subadditivity enables us to analyze other interesting situations related to Logic. For instance, suppose we have a subadditive valuation assigning A the value $\mu(\mathbf{A}) = \{[A]\} = Bel(A)$, and that a set \mathbf{A}' (not necessarily a subset of \mathbf{A}) can be found in $\mathcal{P}(\Theta)$ such that there is an *additive* valuation which assigns \mathbf{A}' precisely the same value. We denote \mathbf{A}' by “ $\square\mathbf{A}$ ” (where \square is a set-operator) and $A' = \delta(\mathbf{A}')$ by “ $\square A$ ”. So we have:

$$Bel(A) = \{[A]\} = \llbracket \square A \rrbracket$$

The “ \square ” is here a linguistic operator that acts on a sentence A and transforms it into another whose value is the belief (= subadditive truth-value) one can assign non-additively to A , so it seems proper to interpret “ \square ” syntactically as “it is believed that”, and “ \square_α ” or “ $[\alpha]$ ” as “ α (= the name of a subject or agent) believes that”. Further, we would have

$$\begin{aligned} Pl(A) &= 1 - Bel(\neg A) = 1 - \{[\neg A]\} \\ &= 1 - \llbracket \square \neg A \rrbracket = \llbracket \neg \square \neg A \rrbracket = \llbracket \diamond A \rrbracket \end{aligned}$$

where we have defined a new operator “ \diamond ” as an abbreviation for “ $\neg \square \neg$ ” to be interpreted as syntactically as “it is *plausible* that” or “ α admits as credible” (so that “ $\diamond_\alpha A$ ” —or $\langle \alpha \rangle A$ — would read “ α finds that A can be believed”), because α just does not believe the contrary.

Dubois & Prade [1987] speak rather of “necessity” (or “degree of knowledge”) and write $Nec(A) =_{df} \{[A]\}$ (= $\llbracket \square A \rrbracket$), and “possibility” (or “degree of admissibility”) $Poss(A) =_{df} 1 - \{[\neg A]\}$ (= $\llbracket \diamond A \rrbracket$); naturally, $Nec(A) \leq \{[A]\} \leq Poss(A)$ for any A (and also:

$$Nec(A) + Poss(\neg A) = Poss(A) + Nec(\neg A) = 1).$$

If necessity (or knowledge) of A and $\neg A$ are totally incompatible (in the sense that $Nec(\neg A) = 0$ whenever $Nec(A) > 0$) then $Nec(A \vee B) = \max(Nec(A), Nec(B))$ and $Poss(A \wedge B) = \min(Poss(A), Poss(B))$.

It is interesting to notice that a subadditive valuation may be superimposed on a sentential lattice without breaking its Boolean character, so that $A \wedge \neg A = \perp$ (bivalence) and $A \vee \neg A = \top$ (excluded middle) still hold,

while at the same time $\{[A]\} + \{[\neg A]\} \leq 1$. This slightly paradoxical fact may explain that many often-encountered situations —where mere subadditivity ($\{[A]\} + \{[\neg A]\} \leq 1$) was probably the case— have been analyzed historically as invalidating the law of the *excluded middle*, because it was felt that there was a “third possibility” between A and $\neg A$ making for the unattributed value $1 - \{[A]\} - \{[\neg A]\}$, covered neither by A nor $\neg A$. If our analysis is correct, such situations are analyzable in terms of incomplete valuations, but this does not imply the breaking of bivalence of any Boolean algebra (except, naturally, for intuitionistic logic, where the algebra is explicitly non-Boolean).

Subadditivity valuations on a Boolean algebra allow also analysis not only of the concept of *ignorance* and *certainty* (as we sketched above) but of the paradoxes of Quantum Logic as well. These arise, according to the ‘Quantum Logic’ proponents (e.g. Reichenbach in 1944), in explaining why the distributivity fails in this logic, following the standard interpretation of certain experimental results where:

$$p(a) \cdot p(b|a) + p(\bar{a}) \cdot p(b|\bar{a}) < p(b)$$

a relationship we write in this way:

$$(12) \{[A]\} \cdot \{[B|A]\} + \{[\neg A]\} \cdot \{[B|\neg A]\} < \{[B]\}.$$

What is odd is that this inequality is normally interpreted by quantum logicians (e.g. Watanabe) as meaning:

$$(13) (A \wedge B) \vee (\neg A \wedge B) \neq B$$

which obviously signals the breaking of distributivity. However, the even-handed transcription of the value-version (12) into the algebraic one (13) is clearly abusive: (13) is much stronger than (12), since it is equivalent to requiring that (12) hold for *all* conceivable valuations. Actually, in our notation, the reading of the experimental results translates immediately into (12), not (13). From there we conclude that:

$$\{[A \wedge B]\} + \{[\neg A \wedge B]\} < \{[B]\}$$

which is in clear violation of additivity, but not of distributivity. So we need not consider that quantum phenomena occur in a non-Boolean algebra (orthomodular lattices are the preferred alternatives) because a *sub-additively*-valued Boolean lattice surely would do for most quantum-logic applications.

Finally we mention that subadditive valuations can as well satisfactorily model how a scientific explanation frame (i.e. the appropriate lattice of theories that cover any observed or predictable true fact) is dynamically replaced by another once the first can no longer account for observed facts: as the valuation of explanations turns subadditive —reflecting that they

no longer cover all predictable facts— one is naturally forced to replace the original sentential structure of theories by a new one (still a Boolean lattice) provided with a new —now again additive— valuation on it that restores the balance; the augmented lattice generators are the new vocabulary, and the elementary components of the new structure are the required new explanatory elements (atomic theories) for the presently observed facts. Such a simple valuation-revision and lattice-replacement mechanism may serve to illustrate the basic dynamics of theory change in scientific explanation (see Sales [1982b]).

APPENDIX

A ON FUZZY LOGIC

A.1 The “Fuzzy Logic” tradition

In a joint reflection with Richard Bellman in 1964 Lotfi Zadeh, then a process control engineer, considered the nonsense of painstakingly computing numerical predictions in control theory contexts where the situation is complex enough to render them meaningless. So he proposed instead to rely confidently on broad —and inherently *vague*— linguistic descriptions like ‘high’ (for a temperature) or ‘open’ (for a valve) rather than on misleadingly precise values. He then went to suggest (in Zadeh [1965]) a non-standard extensional interpretation of Predicate Calculus. Though first advanced by Karl Menger (in a 1951 note to the French Académie entitled *Ensembles flous et fonctions aléatoires*), the idea was nevertheless original and simple: an atomic predicate sentence like ‘the temperature is high’ is assigned truth values in $[0,1]$ reflecting the applicability of the sentence to circumstances (the actual temperatures); those values then define a “set”, a “fuzzy” set, by considering them to be the values of a generalized *characteristic* or *set membership* function, in a way that is strictly parallel to the standard procedure for defining predicate extensions (e.g. of ‘prime number’) by equating the $\{0,1\}$ truth values with the characteristic function of the set (i.e. ‘the prime numbers’) so that if for instance $\llbracket \text{Prime}(3) \rrbracket = 1$ then $\chi_{\mathbf{Primes}}(3) = 1$, i.e. $3 \in \mathbf{Primes}$ (and so now, accordingly, if e.g. $\llbracket \text{High}(170) \rrbracket = 0.8$ then $\chi_{\mathbf{High_temps}}(170) = 0.8$ or $170 \in_{0.8} \mathbf{High_temps}$).

Some snags soon arose to question the utter simplicity of the scheme, doubts such as: should set inclusion (defined as $\mathbf{A} \subset \mathbf{B}$ iff $\forall x \chi_{\mathbf{A}}(x) \leq \chi_{\mathbf{B}}(x)$) fail if a single point x does not satisfy the relation? or, more fundamentally: what are the appropriate formulas for the connectives? Zadeh had first proposed the usual Lukasiewicz connective formulas (the *min* and the *max* for the \wedge and \vee) but then (in 1970, again with R. Bellman) considered that these were “non-interactive” and to be preferred only in the absence of more relevant information, so he offered further formulas he called “soft”

or “interactive” (the product and sum-minus-product). Bellman and Gierz [1973] showed that under certain pre-established conditions (notably, *truth-functionality*) the only possible connectives were the *min* and the *max*. For a (standard) logician this is an unfortunate result, since the *min* formula when applied to a (0,1)-valued sentence A and its negation $\neg A$ yields always a non-zero value ($\llbracket A \wedge \neg A \rrbracket = \min(\llbracket A \rrbracket, 1 - \llbracket A \rrbracket) \neq 0$), so explicitly *negating* the classical law of non-contradiction (never questioned before by any Logic) and thus placing Fuzzy Logic outside the standard logic mainstream, for which $\neg(A \wedge \neg A)$ is always guaranteed theoremhood (and so, necessarily, $\llbracket A \wedge \neg A \rrbracket = 0$ for any valuation —provided 1 is the only designated value, as we assume). Another unfortunate by-product, this one algebraic in character, is that the neatness and simplicity of the Boolean algebra structure —preservable only by sacrificing truth-functionality— are irrecoverably lost.

Note that (a) Boolean structure had to be sacrificed in Fuzzy Logic just by technical reasons (the *min* formula), not by a deliberate or methodological bias, and that (b) the choice of connectives was historically motivated, in fuzzy-set theory, by pragmatic reasons (prediction accuracy in applications) rather than by logical method: thus, many formulas were tried and discussed (see e.g. Rodder [1975] and Zimmerman [1977]). (Interestingly, while theoreticians stuck to Łukasiewicz’s *min*, practitioners —e.g. Mamdani [1977]— preferred the product, perhaps recognizing that in complex or poorly-known systems the best policy is to suppose sentences *independent* —in our sense, see above—; whence the product.) Anyway, after a brief flurry of discussion in the 1970s about the right connectives, fuzzy-set theory proceeded from then onwards *non-compatibly* by emphasizing that its basic theme is linguistic *vagueness*, not *logic* or *uncertainty*, and that the [0,1]-values are grounded on a (possibly non-additive) valuation called “possibility”, for which a complete subtheory has been elaborated since.

The initially intuitive “fuzzy logic” approach has since become an independent growth industry. From a logical point of view, some foundational points are arguable: (1) the apparently undisputable *truth-functionality* requirement, already present in Łukasiewicz, imposes a radical departure from (ordinary) logic: the sentences *cannot* form any longer a Boolean structure, and traditional logic principles are gone forever; (2) the theory’s justification for using (0,1)-values (values that reflect *imprecision*, since $\llbracket A \rrbracket \in (0, 1)$ implies $f(A) > 0$) is strictly linguistic: the cause of imprecision is attributed solely to the *vagueness* of language and explicitly excludes any non-linguistic component or dimension such as *uncertainty* (considered non-intersectingly to be the domain of Probability theory) or simply *approximation*.

The emphasis fuzzy theorists place on *vagueness* and its “orthogonality” with respect to other causes of unattributed truth value is understandable considering the basic tenets of the theory but questionable from a non-partisan stand.

First: in all cases we finally obtain a number, and this has a transparent function in reasoning: keeping track of our confidence in what we say. In the vagueness case the value we assign is clearly the *degree of applicability* of the sentence to the circumstances at hand (and this is seen by executing the (T) schema); in the uncertainty case it is our “belief” or its “probability” (in some more or less standard sense) what emerges from the (T) evaluation procedure. In either case (*vagueness* or *uncertainty*), what we try to capture and measure is the *degree of approximation* (to truth, or to full reliability) that we can confidently assign the sentence, and what we have in both cases is *imprecision* (difficulties in ascertaining the $\{0,1\}$ truth value and also, consequently, doubts about committing ourselves to it along a whole inference process). Plausibly, it is easier to assign values consistently (in the $[0,1]$ interval) to the sentence, regardless of where or why imprecision arose in the first place, because what we are mainly interested in is the *degree of confidence* we attach to this piece of information we are manipulating through the (hopefully truth-preserving) inferences.

Second: the two dimensions of imprecision, *linguistic* and *epistemic* (for vagueness and uncertainty, resp.), are not so separable as claimed, either conceptually or practically. (We do not consider here occasional claims – often made by Zadeh – that vagueness is *in things* –even in truth–, i.e. it is not linguistic, but ontological). As seen through application of the Tarski (T) schema, when the agent is incapable of making up his/her own mind as to the truth of the (unquoted) sentence, the *cause* for the under-attribution and the origin of the ε residual value need not be considered, only the resulting *confidence* matters. The non-attribution of “normal” (i.e. $\{0,1\}$) truth values may originate in language (i.e. the sentence is *vague*) or in imperfect verification conditions (i.e. the sentence, even being linguistically precise, is nevertheless *uncertain* due to identification or measurement difficulties or other causes), but spotting the source is mostly an academic exercise: consider, for example, the sentence ‘this is probable’, which is imprecise in either or both senses, or the historically motivating illustration by Bellman/Zadeh (the ‘high temperature’ process-control case), where a discrimination of origins, either linguistic (the expression is vague) or epistemic (we don’t know what is the precise case, or we have difficulties in identifying it) is indifferent or pointless.

Moreover, not only such boundary examples cast doubts on the claimed vagueness/uncertainty orthogonality; even the *linguistic* character of fuzziness (or of “possibility”) is arguable. First, because a vague sentence, that to the utterer may mean just that the expression lacks straightforward *applicability* to actual fact, to the hearer –if not involved in the described situation– it may be *epistemic* information about what to expect (for instance, hearing a temperature is “high” may set the unknowing hearer into a –correspondingly imprecise– alert state; (s)he then even may usefully turn

the “membership” or “possibility” number into an *a priori*-probability or belief estimate). Second, because the number we assign to approximate membership in a class, which reflects the *applicability* of the sentence to the observed situation (a semantic quantity shared by the speakers of the language), is *constructed* and continually adjusted by the language speakers on the base of their experience of past cases, in a process which is the same as that of constructing all other $\llbracket A \rrbracket$ assignments, however called (“truths”, “degrees”, “applicabilities”, “probabilities”, “beliefs”, “approximation” or whatever). The process, described above, consists in setting a universe Θ (here the application instances of the sentences in the language) and then considering cases $\theta \in \rho(A)$ (here the θ s are application instances – *utterances*– of A) from past experience; the weighed result is $\llbracket A \rrbracket = \mu(\rho(A))$ (here the *applicability* of the –vague– sentence A , i.e. its “fuzziness”), and the relationship between A and all other sentences can also be user-evaluated through the compatibilities α or the sufficiency/causality degrees σ introduced in the text (in a way that otherwise amounts to Popper’s ‘binary probability’ evaluation process).

This process of *constructing* values may be considered a further instance of our general approach to rationality based on the universe Θ of *cases*, and the resulting number $\llbracket A \rrbracket$ may be used in general reasoning as all other “truth values” are. We thus assure compatibility inside a shared formalism from which Logic, Probability and (e.g.) fuzzy reasoning or belief theories can be derived directly without costly or unnatural translations. To do this we merely need that the different interpretations (including the “fuzzy” one) obey the same laws and have the same formal components: (1) a common sentential language equipped with a *Boolean* structure (easy to justify and convenient for preserving the commonly accepted laws of logic), (2) *coherence* in attributing the values (regardless of the meaning we give them) to assure *additivity*, and (3) a predisposition to sacrifice truth-functionality when required. If the notion of fuzziness, however justified, could be conceived in this way, then the original 1964 Bellman/Zadeh proposal could be subsumed and solved in a very natural way, and we probably could do without a separate, costly and incompatible additional formalism. (In other words, we probably wouldn’t need “fuzzy logic”.)

A.2 Gaines’s ‘Standard Uncertainty Logic’

In an interesting effort, born inside the “fuzzy” tradition, to construct a common formalization by discriminating between algebraic *structures* and truth *valuations* on them —somewhat paralleling and anticipating the aim of our present development— Gaines [1978] set out to define what he called ‘Standard Uncertainty Logic’, that covered and formalized two known sub-cases. This logic postulates (a) a proposition lattice with an algebraic structure that is initially assumed *Boolean* but —by technical reasons—

finally admitted to be merely distributive, and (b) a finitely *additive* valuation of the lattice on the $[0,1]$ interval. Gaines then distinguishes two special cases of his logic: (1) what he calls ‘probability logic’ and defines to be the particular case of his logic where the law of the excluded middle holds, and (2) what he terms ‘fuzzy logic’, defined (in one among several alternative characterizations) to be his logic when that law does not hold. Apparently, Gaines’s encompassing logic should correspond to our general logic above (that covers classical logic as a special case, just as Gaines’s logic becomes his ‘probability logic’ when “all propositions are binary”), but closer examination reveals that Gaines’s confusingly called ‘probability logic’ turns out to be actually coextensional with *classical* logic, while his ‘fuzzy logic’ is, simply, *Lukasiewicz’s* L_∞ . This fact is spelled out by the property he mentions of propositional equivalence (here in our notation):

$$\llbracket A \leftrightarrow B \rrbracket = \min(1 - \llbracket A \rrbracket + \llbracket B \rrbracket, 1 - \llbracket B \rrbracket + \llbracket A \rrbracket)$$

in which the right hand is clearly $1 - |\llbracket A \rrbracket - \llbracket B \rrbracket|$. This is an expression that is deduced from Gaines’s postulates *only* if, necessarily, either $A \vdash B$ or $B \vdash A$ (note this either/or condition—exactly corresponding to our $\alpha_{AB} = 1$ full-compatibility situation—is explicitly mentioned by Gaines as a characteristic property of his ‘fuzzy logic’). So Gaines makes the implicit assumption that the base lattice is *linearly* ordered (perhaps induced to it by the \leq symbol used for the –partial– propositional order in the lattice). A confirmation for this comes from the fact that classical logic principles—that hold, by definition, in his ‘probability logic’—do not hold in this one. No wonder, then, the base lattice cannot be but merely distributive.
