out a calculus, if any, that turns out to be sound and complete with respect to \mathbb{H} . The main question is whether the class of all formulas valid in \mathbb{H} is recursively enumerable. In order to solve this problem, it would be sufficient (but not necessary) to show that the canonical model of **HQL** is isomorphic to the subdirect product of a class of Hilbert lattices. So far, very little is known about this question.

Lattice characterization of Hilbert lattices

As mentioned in the Introduction, the algebraic structure of the set \mathcal{E} of all events in an event-state system $\langle \mathcal{E}, S \rangle$ is usually assumed to be a σ -complete orthomodular lattice. Hilbert lattices, however, satisfy further important structural properties. It will be expedient to recall first some standard lattice theoretical definitions. Let $\mathcal{B} = \langle B, \sqsubseteq, \mathbf{1}, \mathbf{0} \rangle$ be any bounded lattice.

DEFINITION 89 (Atomicity). A bounded lattice \mathcal{B} is *atomic* iff $\forall a \in B - \{\mathbf{0}\}$ there exists an atom b such that $b \sqsubseteq a$.

DEFINITION 90 (Covering property). Let a, b be two elements of a lattice \mathcal{B} . We say that b *covers* a iff $a \sqsubseteq b, a \neq b$, and $\forall c \in B : a \sqsubseteq c \sqsubseteq b \iff a = c$ or $b = c$.

A lattice \mathcal{B} satisfies the *covering property* iff $\forall a, b \in B : a$ covers $a \sqcap b \iff a \sqcup b$ covers b .

DEFINITION 91 (Irreducibility). Let \mathcal{B} be an orthomodular lattice. \mathcal{B} is said to be *irreducible* iff

$$\{a \in B \mid \forall b \in B : a \text{ is compatible with } b\} = \{\mathbf{0}, \mathbf{1}\}.$$

One can prove the following theorem:

THEOREM 92. *Any Hilbert lattice is a complete, irreducible, atomic orthomodular lattice, which satisfies the covering property.*

Are these conditions sufficient for a lattice \mathcal{B} to be isomorphic to (or embeddable into) a Hilbert lattice? In other words, is it possible to capture lattice-theoretically the structure of Hilbert lattices? An important result along these lines is represented by the so-called *Piron–McLaren’s coordinatization theorem* [Varadarajan, 1985].

THEOREM 93 (Piron–McLaren coordinatization theorem). *Any orthomodular lattice \mathcal{B} (of length⁹ at least 4) that is complete, irreducible, atomic with the covering property, is isomorphic to the orthomodular lattice of all (\cdot, \cdot) -closed subspaces of a Hilbertian space $\langle \mathcal{V}, \theta, (\cdot, \cdot), \mathbf{D} \rangle$.*¹⁰

⁹The *length* of a lattice \mathcal{B} is the supremum over the numbers of elements of all the chains of \mathcal{B} , minus 1.

¹⁰A *Hilbertian space* is a 4-tuple $\langle \mathcal{V}, \theta, (\cdot, \cdot), \mathbf{D} \rangle$, where \mathcal{V} is a vector space over a division ring \mathbf{D} , θ is an involutive antiautomorphism on \mathbf{D} , and (\cdot, \cdot) (to be interpreted

Do the properties of the *coordinatized lattice* \mathcal{B} restrict the choice to one of the real, the complex or the quaternionic numbers (\mathbb{Q}) and therefore to a classical Hilbert space? Quite unexpectedly, [Keller, 1980] proved a negative result: there are lattices that satisfy all the conditions of Piron–McLaren’s Theorem; at the same time, they are coordinatized by Hilbertian spaces over non-archimedean division rings. Keller’s counterexamples have been interpreted by some authors as showing the definitive impossibility for the quantum logical approach to capture the Hilbert space mathematics. This impossibility was supposed to demonstrate the failure of the quantum logic approach in reaching its main goal: the “bottom-top” reconstruction of Hilbert lattices. Interestingly enough, such a negative conclusion has been recently contradicted by an important result proved by Solèr [1995]: Hilbert lattices can be characterized in a lattice-theoretical way. Solèr’s result is essentially based on the following Theorem:

THEOREM 94. *Let $\langle \mathcal{V}, \theta, (\cdot, \cdot), \mathbf{D} \rangle$ be an infinite-dimensional Hilbertian space over a division ring \mathbf{D} . Suppose our space includes a k -orthogonal set $\{\psi_i\}_{i \in \mathbb{N}}$, i.e., a family of vectors of \mathcal{V} such that $\forall i : (\psi_i, \psi_i) = k$ and $\forall i, j (i \neq j) : (\psi_i, \psi_j) = 0$. Then $\langle \mathcal{V}, \theta, (\cdot, \cdot), \mathbf{D} \rangle$ is a classical Hilbert space.*

As a consequence, the existence of k -orthogonal sets characterizes Hilbert spaces in the class of all Hilbertian spaces. The point is that the existence of such sets admits of a purely lattice-theoretic characterization, by means of the so-called *angle bisecting condition* [Morash, 1973]. Accordingly, every lattice which satisfies the angle bisecting condition (in addition to the usual conditions of Piron–McLaren’s Theorem) is isomorphic to a classical Hilbert lattice.

9 FIRST-ORDER QUANTUM LOGIC

The most significant logical and metalogical peculiarities of **QL** arise at the sentential level. At the same time the extension of sentential **QL** to a first-order logic seems to be quite natural. Similarly to the case of sentential **QL**, we will characterize first-order **QL** both by means of an algebraic and a Kripkean semantics.

Suppose a standard first-order language with predicates P_m^n and individual constants a_m .¹¹ The primitive logical constants are the connectives \neg, \wedge and the universal quantifier \forall . The concepts of *term*, *formula* and *sentence*

as an inner product) is a definite symmetric θ -bilinear form on \mathcal{V} . Let X be any subset of \mathcal{V} and let $X' := \{\psi \in \mathcal{V} \mid \forall \phi \in X, (\psi, \phi) = 0\}$; X is called *(\cdot, \cdot)-closed* iff $X = X''$. The following condition is required to hold: for any (\cdot, \cdot) -closed set X of \mathcal{V} , $\mathcal{V} = X + X' := \{\psi + \phi : \psi \in X, \phi \in X'\}$.

If \mathbf{D} is either \mathbb{R} or \mathbb{C} or \mathbb{Q} and the antiautomorphism θ is continuous, then $\langle \mathcal{V}, \theta, (\cdot, \cdot), \mathbf{D} \rangle$ turns out to be a classical Hilbert space.

¹¹For the sake of simplicity, we do not assume functional symbols.

are defined in the usual way. We will use $x, y, z, x_1, \dots, x_n, \dots$ as metavariables ranging over the individual variables, and t, t_1, t_2, \dots as metavariables ranging over terms. The existential quantifier \exists is supposed defined by a generalized de Morgan law:

$$\exists x\alpha := \neg\forall x\neg\alpha.$$

DEFINITION 95 (Algebraic realization for first-order **OL**). An *algebraic realization* for (first-order) **OL** is a system $\mathcal{A} = \langle B^C, D, v \rangle$ where:

- (i) $B^C = \langle B^C, \sqsubseteq, ', \mathbf{1}, \mathbf{0} \rangle$ is an ortholattice closed under infinitary *infimum* (\prod) and *supremum* (\sqcup) for any $F \subseteq B^C$ such that $F \in C$ (C being a particular family of subsets of B^C).
- (ii) D is a non-empty set (disjoint from B) called the *domain* of \mathcal{A} .
- (iii) v is the *valuation*-function satisfying the following conditions:
 - for any constant a_m : $v(a_m) \in D$; for any predicate P_m^n , $v(P_m^n)$ is an n -ary attribute in \mathcal{A} , i.e., a function that associates to any n -tuple $\langle \mathbf{d}_1, \dots, \mathbf{d}_n \rangle$ of elements of D an element (*truth-value*) of B^c ;
 - for any *interpretation* σ of the variables in the domain D (i.e., for any function from the set of all variables into D) the pair $\langle v, \sigma \rangle$ (abbreviated by v^σ and called *generalized valuation*) associates to any term an element in D and to any formula a truth-value in B^c , according to the conditions:

$$\begin{aligned} v^\sigma(a_m) &= v(a_m) \\ v^\sigma(x) &= \sigma(x) \\ v^\sigma(P_m^n t_1, \dots, t_n) &= v(P_m^n)(v^\sigma(t_1), \dots, v^\sigma(t_n)) \\ v^\sigma(\neg\beta) &= v^\sigma(\beta)' \\ v^\sigma(\beta \wedge \gamma) &= v^\sigma(\beta) \sqcap v^\sigma(\gamma) \\ v^\sigma(\forall x\beta) &= \prod \{ v^{\sigma[x/\mathbf{d}]}(\beta) \mid \mathbf{d} \in D \}, \text{ where} \\ &\{ v^{\sigma[x/\mathbf{d}]}(\beta) \mid \mathbf{d} \in D \} \in C \end{aligned}$$

($\sigma[x/\mathbf{d}]$ is the interpretation that associates to x the individual \mathbf{d} and differs from σ at most in the value attributed to x).

DEFINITION 96 (Truth and logical truth). A formula α is *true* in $\mathcal{A} = \langle B^C, D, v \rangle$ (abbreviated as $\models_{\mathcal{A}} \alpha$) iff for any interpretation of the variables σ , $v^\sigma(\alpha) = \mathbf{1}$; α is a *logical truth* of **OL** ($\models_{\mathbf{OL}} \alpha$) iff for any \mathcal{A} , $\models_{\mathcal{A}} \alpha$.

DEFINITION 97 (Consequence in a realization and logical consequence). Let $\mathcal{A} = \langle B^C, D, v \rangle$ be a realization. A formula α is a *consequence* of T in \mathcal{A} (abbreviated $T \models_{\mathcal{A}} \alpha$) iff for any element a of B^c and any interpretation

σ : if for any $\beta \in T$, $a \sqsubseteq v^\sigma(\beta)$, then $a \sqsubseteq v^\sigma(\alpha)$; α is a logical consequence of T ($T \models_{\text{OL}} \alpha$) iff for any realization \mathcal{A} : $T \models_{\mathcal{A}} \alpha$.

DEFINITION 98 (Kripkean realization for (first-order) **OL**). A Kripkean realization for (first-order) **OL** is a system $\mathcal{K} = \langle I, R, \Pi^C, U, \rho \rangle$ where:

- (i) $\langle I, R, \Pi^C \rangle$ satisfies the same conditions as in the sentential case; further Π^C is closed under infinitary intersection for any $F \subseteq \Pi^c$ such that $F \in C$ (where C is a particular family of subsets of Π^C);
- (ii) U , called the *domain* of \mathcal{K} , is a non-empty set, disjoint from the set of worlds I . The elements of U are *individual concepts* \mathbf{u} such that for any world i : $\mathbf{u}(i)$ is an *individual* (called the *reference* of \mathbf{u} in the world i). An individual concept \mathbf{u} is called *rigid* iff for any pairs of worlds i, j : $\mathbf{u}(i) = \mathbf{u}(j)$. The set $U_i = \{\mathbf{u}(i) \mid \mathbf{u} \in U\}$ represents the *domain of individuals in the world i* . Whenever $U_i = U_j$ for all i, j we will say that the realization \mathcal{K} has a *constant domain*.
- (iii) ρ associates a meaning to any individual constant a_m and to any predicate P_m^n according to the following conditions:

$\rho(a_m)$ is an individual concept in U .

$\rho(P_m^n)$ is a *predicate-concept*, i.e. a function that associates to any n -tuple of individual concepts $\langle \mathbf{u}_1, \dots, \mathbf{u}_n \rangle$ a proposition in Π^C ;

- (iv) for any interpretation of the variables σ in the domain U , the pair $\langle \rho, \sigma \rangle$ (abbreviated as ρ^σ and called *valuation*) associates to any term t an individual concept in U and to any formula a proposition in Π^C according to the conditions:

$$\begin{aligned} \rho^\sigma(x) &= \sigma(x) \\ \rho^\sigma(a_m) &= \rho(a_m) \\ \rho^\sigma(P_m^n t_1, \dots, t_n) &= \rho(P_m^n)(\rho^\sigma(t_1), \dots, \rho^\sigma(t_n)) \\ \rho^\sigma(\neg\beta) &= \rho^\sigma(\beta)' \\ \rho^\sigma(\beta \wedge \gamma) &= \rho^\sigma(\beta) \cap \rho^\sigma(\gamma) \\ \rho^\sigma(\forall x\beta) &= \bigcap \{ \rho^{\sigma[x/\mathbf{u}]}(\beta) \mid \mathbf{u} \in U \}, \text{ where} \\ &\{ \rho^{\sigma[x/\mathbf{u}]}(\beta) \mid \mathbf{u} \in U \} \in C. \end{aligned}$$

For any world i and any interpretation σ of the variables, the triplet $\langle \rho, i, \sigma \rangle$ (abbreviated as ρ_i^σ) will be called a *world-valuation*.

DEFINITION 99 (Satisfaction). $\rho_i^\sigma \models \alpha$ (ρ_i^σ satisfies α) iff $i \in \rho^\sigma(\alpha)$.

DEFINITION 100 (Verification). $i \models \alpha$ (i verifies α) iff for any σ : $\rho_i^\sigma \models \alpha$.

DEFINITION 101 (Truth and logical truth). $\models_{\mathcal{K}} \alpha$ (α is *true* in \mathcal{K}) iff for any i : $i \models \alpha$;

$\models_{\mathbf{OL}} \alpha$ (α is a *logical truth* of **OL**) iff for any \mathcal{K} : $\models_{\mathcal{K}} \alpha$.

DEFINITION 102 (Consequence in a realization and logical consequence).

$T \models_{\mathcal{K}} \alpha$ iff for any i of \mathcal{K} and any σ : $\rho_i^\sigma \models T \curvearrowright \rho_i^\sigma \models \alpha$;

$T \models_{\mathbf{OL}} \alpha$ iff for any realization \mathcal{K} : $T \models_{\mathcal{K}} \alpha$.

The algebraic and the Kripkean characterization for first-order **OQL** can be obtained, in the obvious way, by requiring that any realization be orthomodular.

In both semantics for first-order **QL** one can prove a coincidence lemma:

LEMMA 103. *Given $\mathcal{A} = \langle \mathcal{B}^C, D, v \rangle$ and $\mathcal{K} = \langle I, R, \Pi^C, U, \rho \rangle$:*

(103.1) *If σ and σ^* coincide in the values attributed to the variables occurring in a term t , then $v^\sigma(t) = v^{\sigma^*}(t)$; $\rho^\sigma(t) = \rho^{\sigma^*}(t)$.*

(103.2) *If σ and σ^* coincide in the values attributed to the free variables occurring in a formula α , then $v^\sigma(\alpha) = v^{\sigma^*}(\alpha)$; $\rho^\sigma(\alpha) = \rho^{\sigma^*}(\alpha)$.*

One can easily prove, like in the sentential case, the following lemma:

LEMMA 104.

(104.1) *For any algebraic realization \mathcal{A} there exists a Kripkean realization $\mathcal{K}^{\mathcal{A}}$ such that for any α : $\models_{\mathcal{A}} \alpha$ iff $\models_{\mathcal{K}^{\mathcal{A}}} \alpha$. Further, if \mathcal{A} is orthomodular then $\mathcal{K}^{\mathcal{A}}$ is orthomodular.*

(104.2) *For any Kripkean realization \mathcal{K} , there exists an algebraic realization $\mathcal{A}^{\mathcal{K}}$ such that for any α : $\models_{\mathcal{K}} \alpha$ iff $\models_{\mathcal{A}^{\mathcal{K}}} \alpha$. Further, if \mathcal{K} is orthomodular then $\mathcal{A}^{\mathcal{K}}$ is orthomodular.*

An axiomatization of first-order **OL** (**OQL**) can be obtained by adding to the rules of our **OL** (**OQL**)-sentential calculus the following new rules:

(PR1) $T \cup \{\forall x \alpha\} \vdash \alpha(x/t)$, where $\alpha(x/t)$ indicates a legitimate substitution).

(PR2) $\frac{T \vdash \alpha}{T \vdash \forall x \alpha}$ (provided x is not free in T).

All the basic syntactical notions are defined in the expected way. One can prove that any consistent set of sentences T admits of a consistent *inductive* extension T^* , such that $T^* \vdash \forall x \alpha(t)$ whenever for any closed term t , $T^* \vdash \alpha(t)$. The “weak Lindenbaum theorem” can be strengthened as follows: for any sentence α , if $T \not\vdash \neg \alpha$ then there exists a consistent and

inductive T^* such that:

$$T \text{ is syntactically compatible with } T^* \text{ and } T^* \vdash \alpha.^{12}$$

One can prove a soundness and a completeness theorem of our calculus with respect to the Kripkean semantics.

THEOREM 105. Soundness.

$$T \vdash \alpha \quad \curvearrowright \quad T \models \alpha.$$

Proof. Straightforward. ■

THEOREM 106. Completeness.

$$T \models \alpha \quad \curvearrowright \quad T \vdash \alpha.$$

Sketch of the proof Like in the sentential case, it is sufficient to construct a canonical model $\mathcal{K} = \langle I, R, \Pi^C, U, \rho \rangle$ such that $T \vdash \alpha$ iff $T \models_{\mathcal{K}} \alpha$.

Definition of the canonical model

- (i) I is the set of all consistent, deductively closed and inductive sets of sentences expressed in a common language \mathcal{L}^K , which is an extension of the original language;
- (ii) R is determined like in the sentential case;
- (iii) U is a set of rigid individual concepts that is naturally determined by the set of all individual constants of the extended language \mathcal{L}^K . For any constant c of \mathcal{L}^K , let \mathbf{u}^c be the corresponding individual concept in U . We require: for any world i , $\mathbf{u}^c(i) = c$. In other words, the reference of the individual concept \mathbf{u}^c is in any world the constant c . We will indicate by $c^{\mathbf{u}}$ the constant corresponding to \mathbf{u} .

- (iv) $\rho(a_m) = \mathbf{u}^{a_m}$;
 $\rho(P_m^n)(\mathbf{u}_1^{c_1}, \dots, \mathbf{u}_n^{c_n}) = \{i \mid P_m^n c_1, \dots, c_n \in i\}$.

Our ρ is well defined since one can prove for any sentence α of \mathcal{L}^K :

$$i \not\vdash \alpha \quad \curvearrowright \quad \exists j \not\vdash i : j \vdash \neg \alpha.$$

As a consequence, $\rho^\sigma(P_m^n t_1, \dots, t_n)$ is a possible proposition.

- (v) Π^C is the set of all “meanings” of formulas (i.e., $X \in \Pi^C$ iff $\exists \alpha \exists \sigma (X = \rho^\sigma(\alpha))$); C is the set of all sets $\{\rho^{\sigma[x/\mathbf{u}]}(\beta) \mid \mathbf{u} \in U\}$ for any formula β .

¹²By Definition 71, T is syntactically compatible with T^* iff there is no formula α such that $T \vdash \alpha$ and $T^* \vdash \neg \alpha$.

One can easily check that \mathcal{K} is a “good” realization with a constant domain.

LEMMA 107. *Lemma of the canonical model.*

For any α , any $i \in I$ and any σ :

$$\rho_i^\sigma \models \alpha \text{ iff } \alpha^\sigma \in i,$$

where α^σ is the sentence obtained by substituting in α any free variable x with the constant $c^{\sigma(x)}$ corresponding to the individual concept $\sigma(x)$.

Sketch of the proof. By induction on the length of α . The cases $\alpha = P_m^n t_1, \dots, t_n$, $\alpha = \neg\beta$, $\alpha = \beta \wedge \gamma$ are proved by an obvious transformation of the sentential argument. Let us consider the case $\alpha = \forall x\beta$ and suppose x occurring in β (otherwise the proof is trivial). In order to prove the left to right implication, suppose $\rho_i^\sigma \models \forall x\beta$. Then, for any \mathbf{u} in U , $\rho_i^{\sigma[x/\mathbf{u}]} \models \beta(x)$. Hence, by inductive hypothesis, $\forall \mathbf{u} \in U$, $[\beta(x)]^{\sigma[x/\mathbf{u}]} \in i$. In other words, for any constant $c^{\mathbf{u}}$ of i : $[\beta(x)]^\sigma(x/c^{\mathbf{u}}) \in i$. And, since i is inductive and deductively closed: $\forall x\beta(x)^\sigma \in i$. In order to prove the right to left implication, suppose $[\forall x\beta(x)]^\sigma \in i$. Then, [by (PR1)], for any constant c of i : $[\beta(x/c)]^\sigma \in i$. Hence by inductive hypothesis: for any $\mathbf{u}^c \in U$, $\rho_i^{\sigma[x/\mathbf{u}^c]} \models \beta(x)$, i.e., $\rho_i^\sigma \models \forall x\beta(x)$. On this ground, similarly to the sentential case, one can prove $T \vdash \alpha$ iff $T \models_{\mathcal{K}} \alpha$. ■

First-order **QL** can be easily extended (in a standard way) to a first-order logic with identity. However, a critical problem is represented by the possibility of developing, within this logic, a satisfactory *theory of descriptions*. The main difficulty can be sketched as follows. A natural condition to be required in any characterization of a ι -operator is obviously the following:

$$\begin{aligned} & \exists x \{ \beta(x) \wedge \forall y [(\beta(y) \wedge x = y) \vee (\neg\beta(y) \wedge \neg x = y)] \wedge \alpha(x) \} \\ & \text{is true} \quad \rightsquigarrow \quad \alpha(\iota x \beta(x)) \text{ is true.} \end{aligned}$$

However, in **QL**, the truth of the antecedent of our implication does not generally guarantee the existence of a particular individual such that $\iota x \beta$ can be regarded as a name for such an individual. As a counterexample, let us consider the following case (in the algebraic semantics): let \mathcal{A} be $\langle \mathcal{B}, D, v \rangle$ where \mathcal{B} is the complete orthomodular lattice based on the set of all closed subspaces of the plane \mathbb{R}^2 , and D contains exactly two individuals $\mathbf{d}_1, \mathbf{d}_2$. Let P be a monadic predicate and X, Y two orthogonal unidimensional subspaces of B such that $v(P)(\mathbf{d}_1) = X$, $v(P)(\mathbf{d}_2) = Y$. If the equality predicate $=$ is interpreted as the standard identity relation (i.e., $v^\sigma(t_1 = t_2) = \mathbf{1}$, if $v^\sigma(t_1) = v^\sigma(t_2)$; $\mathbf{0}$, otherwise), one can easily calculate:

$$v(\exists x [Px \wedge \forall y ((Py \wedge x = y) \vee (\neg Py \wedge \neg x = y))]) = \mathbf{1}.$$

However, for both individuals $\mathbf{d}_1, \mathbf{d}_2$ of the domain, we have:

$$v^{\sigma[x/\mathbf{d}_1]}(Px) \neq 1, v^{\sigma[x/\mathbf{d}_2]}(Px) \neq 1.$$

In other words, there is no precise individual in the domain that satisfies the property expressed by our predicate P !

10 QUANTUM SET THEORIES AND THEORIES OF QUASISSETS

An important application of **QL** to set theory has been developed by [Takeuti, 1981]. We will sketch here only the fundamental idea of this application. Let \mathcal{L} be a standard set-theoretical language. One can construct *ortho-valued models* for \mathcal{L} , which are formally very similar to the usual *Boolean-valued models* for standard set-theory, with the following difference: the set of truth-values is supposed to have the algebraic structure of a complete orthomodular lattice, instead of a complete Boolean algebra. Let \mathcal{B} be a complete orthomodular lattice, and let ν, λ, \dots represent ordinal numbers. An *ortho-valued (set-theoretical) universe* V is constructed as follows:

$$V^{\mathcal{B}} = \bigcup_{\nu \in \mathcal{O}_n} V(\nu), \text{ where:}$$

$$V(0) = \emptyset.$$

$$V(\nu+1) = \{g \mid g \text{ is a function and } Dom(g) \subseteq V(\nu) \text{ and } Rang(g) \subseteq \mathcal{B}\}.$$

$$V(\lambda) = \bigcup_{\nu < \lambda} V(\nu), \text{ for any limit-ordinal } \lambda.$$

($Dom(g)$ and $Rang(g)$ are the *domain* and the *range* of function g , respectively).

Given an ortho-valued universe $V^{\mathcal{B}}$ one can define for any formula of \mathcal{L} the truth-value $\llbracket \alpha \rrbracket^{\sigma}$ in \mathcal{B} induced by any interpretation σ of the variables in the universe $V^{\mathcal{B}}$.

$$\begin{aligned} \llbracket x \in y \rrbracket^{\sigma} &= \bigsqcup_{g \in Dom(\sigma(y))} \{ \sigma(y)(g) \sqcap \llbracket x = z \rrbracket^{\sigma[z/g]} \} \\ \llbracket x = y \rrbracket^{\sigma} &= \prod_{g \in Dom(\sigma(x))} \{ \sigma(x)(g) \rightsquigarrow \llbracket z \in y \rrbracket^{\sigma[z/g]} \} \sqcap \\ &\quad \prod_{g \in Dom(\sigma(y))} \{ \sigma(y)(g) \rightsquigarrow \llbracket z \in x \rrbracket^{\sigma[z/g]} \}. \end{aligned}$$

where \rightsquigarrow is the quantum logical conditional operation ($a \rightsquigarrow b := a' \sqcup (a \sqcap b)$, for any $a, b \in \mathcal{B}$).

A formula α is called *true* in the universe $V^{\mathcal{B}}$ ($\models_{V^{\mathcal{B}}} \alpha$) iff $\llbracket \alpha \rrbracket^{\sigma} = \mathbf{1}$, for any σ .

Interestingly enough, the segment $V(\omega)$ of $V^{\mathcal{B}}$ turns out to contain some important mathematical objects, that we can call *quantum-logical natural numbers*.

The standard axioms of set-theory hold in \mathcal{B} only in a restricted form. An extremely interesting property of $V^{\mathcal{B}}$ is connected with the notion of identity. Differently from the case of Boolean-valued models, the identity relation in $V^{\mathcal{B}}$ turns out to be non-Leibnizian. For, one can choose an orthomodular lattice \mathcal{B} such that:

$$\not\equiv_{V^{\mathcal{B}}} x = y \rightarrow \forall z(x \in z \leftrightarrow y \in z).$$

According to our semantic definitions, the relation $=$ represents a kind of “extensional equality”. As a consequence, one may conclude that two quantum-sets that are extensionally equal do not necessarily share all the same properties. Such a failure of the Leibniz-substitutivity principle in quantum set theory might perhaps find interesting applications in the field of intensional logics.

A completely different approach is followed in the framework of the theories of *quasisets* (or *quasets*). The basic aim of these theories is to provide a mathematical description for collections of microobjects, which seem to violate some characteristic properties of the classical identity relation.

In some of his general writings, Schrödinger discussed the inconsistency between the classical concept of physical object (conceived as an individual entity) and the behaviour of particles in quantum mechanics. Quantum particles – he noticed – lack individuality and the concept of identity cannot be applied to them, similarly to the case of classical objects.

One of the aims of the *theories of quasisets* (proposed by [da Costa *et al.*, 1992]) is to describe formally the following idea defended by Schrödinger: identity is generally not defined for microobjects. As a consequence, one cannot even assert that an “electron is identical with itself”. In the realm of microobjects only an *indistinguishability relation* (an equivalence relation that may violate the substitutivity principle) makes sense.

On this basis, different formal systems have been proposed. Generally, these systems represent convenient generalizations of a Zermelo–Fraenkel like set theory with *urelements*. Differently from the classical case, an urelement may be either a *macro* or a *microobject*. Collections are represented by *quasisets* and classical sets turn out to be limit cases of quasisets.

A somewhat different approach has been followed in the *theory of quasets* (proposed in [Dalla Chiara and Toraldo di Francia, 1993]).

The starting point is based on the following observation: physical kinds and compound systems in QM seem to share some features that are characteristic of intensional entities. Further, the relation between intensions and extensions turns out to behave quite differently from the classical semantic situations. Generally, one cannot say that a quantum intensional notion uniquely determines a corresponding extension. For instance, take the notion of *electron*, whose intension is well defined by the following physical property: mass = 9.1×10^{-28} g, electron charge = 4.8×10^{-10} e.s.u., spin

$= 1/2$. Does this property determine a corresponding *set*, whose elements should be all and only the physical objects that satisfy our property at a certain time interval? The answer is negative. In fact, physicists have the possibility of recognizing, by theoretical or experimental means, whether a given physical system is an electron system or not. If yes, they can also enumerate all the quantum states available within it. But they can do so in a number of different ways. For example, take the spin. One can choose the x -axis and state how many electrons have spin up and how many have spin down. However, we could instead refer to the z -axis or any other direction, obtaining *different collections* of quantum states, all having the same cardinality. This seems to suggest that microobject systems present an irreducibly intensional behaviour: generally they do not determine precise extensions and are not determined thereby. Accordingly, a basic feature of the theory is a strong violation of the extensionality principle.

Quasets are convenient generalizations of classical sets, where both the extensionality axiom and Leibniz' principle of indiscernibles are violated. Generally a quaset has only a cardinal but not an ordinal number, since it cannot be well ordered.

11 THE UNSHARP APPROACHES

The unsharp approaches to QT (first proposed by [Ludwig, 1983] and further developed by Kraus, Davies, Mittelstaedt, Busch, Lahti, Bugajski, Beltrametti, Cattaneo and many others) have been suggested by some deep criticism of the standard logico-algebraic approach. Orthodox quantum logic (based on Birkhoff and von Neumann's proposal) turns out to be at the same time a *total* and a *sharp* logic. It is total because the *meaningful propositions* are represented as closed under the basic logical operations: the conjunction (disjunction) of two meaningful propositions is a meaningful proposition. Further, it is also sharp, because propositions, in the standard interpretation, correspond to *exact* possible properties of the physical system under investigation. These properties express the fact that "the value of a given observable lies in a certain *exact* Borel set".

As we have seen, the set of the physical properties, that may hold for a quantum system, is mathematically represented by the set of all closed subspaces of the Hilbert space associated to our system. Instead of closed subspaces, one can equivalently refer to the set of all *projections*, that is in one-to-one correspondence with the set of all closed subspaces. Such a correspondence leads to a collapse of different semantic notions, which Foulis and Randall described as the "metaphysical disaster" of orthodox QT. The collapse involves the notions of "experimental proposition", "physical property", "physical event" (which represent *empirical* and *intensional* concepts), and the notion of *proposition* as a *set* of states (which corresponds

to a typical *extensional* notion according to the tradition of standard semantics).

Both the total and the sharp character of **QL** have been put in question in different contexts. One of the basic ideas of the unsharp approaches is a “liberalization” of the mathematical counterpart for the intuitive notion of “experimental proposition”. Let P be a projection operator in the Hilbert space \mathcal{H} , associated to the physical system under investigation. Suppose P describes an experimental proposition and let W be a statistical operator representing a possible state of our system. Then, according to one of the axioms of the theory (the *Born rule*), the number $\text{Tr}(WP)$ (the *trace* of the operator WP) will represent the probability-value that our system in state W verifies P . This value is also called *Born probability*. However, projections are not the only operators for which a Born probability can be defined. Let us consider the class $E(\mathcal{H})$ of all linear bounded operators E such that for any statistical operator W ,

$$\text{Tr}(WE) \in [0, 1].$$

It turns out that $E(\mathcal{H})$ properly includes the set $P(\mathcal{H})$ of all projections on \mathcal{H} . The elements of $E(\mathcal{H})$ represent, in a sense, a “maximal” mathematical representative for the notion of experimental proposition, in agreement with the probabilistic rules of quantum theory. In the framework of the unsharp approach, $E(\mathcal{H})$ has been called the set of all *effects*.¹³ An important difference between projections and proper effects is the following: projections can be associated to *sharp* propositions having the form “the value for the observable A lies in the *exact* Borel set Δ ”, while effects may represent also *fuzzy* propositions like “the value of the observable A lies in the *fuzzy* Borel set Γ ”. As a consequence, there are effects E , different from the null projection $\mathbb{0}$, such that no state W can verify E with probability 1. A limit case is represented by the *semitransparent effect* $\frac{1}{2}\mathbb{I}$ (where \mathbb{I} is the identity operator), to which any state W assigns probability-value $\frac{1}{2}$.

From the intuitive point of view, one could say that moving to an unsharp approach represents an important step towards a kind of “second degree of fuzziness”. In the framework of the sharp approach, any physical event E can be regarded as a kind of “clear” property. Whenever a state W assigns to E a probability value different from 1 and 0, one can think that the semantic uncertainty involved in such a situation totally depends on the ambiguity of the state (first degree of fuzziness). In other words, even a pure state in QT does not represent a *logically complete information*, that is able to decide any possible physical event. In the unsharp approaches, instead, one take into account also “genuine ambiguous properties”. This second degree of fuzziness may be regarded as depending on the accuracy

¹³It is easy to see that an effect E is a projection iff $E^2 := EE = E$. In other words, projections are idempotent effects.

of the measurement (which tests the property), and also on the accuracy involved in the operational definition for the physical quantities which our property refers to.

12 EFFECT STRUCTURES

Different algebraic structures can be induced on the class $E(\mathcal{H})$ of all effects. Let us first recall some definitions.

DEFINITION 108 (Involutive bounded poset (lattice)). An involutive bounded poset (lattice) is a structure $\mathcal{B} = \langle B, \sqsubseteq, ', \mathbf{1}, \mathbf{0} \rangle$, where $\langle B, \sqsubseteq, \mathbf{1}, \mathbf{0} \rangle$ is a partially ordered set (lattice) with maximum ($\mathbf{1}$) and minimum ($\mathbf{0}$); $'$ is a 1-ary operation on B such that the following conditions are satisfied: (i) $a'' = a$; (ii) $a \sqsubseteq b \iff b' \sqsubseteq a'$.

DEFINITION 109 (Orthoposet). An *orthoposet* is an involutive bounded poset that satisfies the non contradiction principle:

$$a \sqcap a' = \mathbf{0}.$$

DEFINITION 110 (Orthomodular poset). An *orthomodular poset* is an orthoposet that is closed under the orthogonal sup ($a \sqsubseteq b' \iff a \sqcup b$ exists) and satisfies the orthomodular property:

$$a \sqsubseteq b \iff \exists c \text{ such that } a \sqsubseteq c' \text{ and } b = a \sqcup c.$$

DEFINITION 111 (Regularity). An involutive bounded poset (lattice) \mathcal{B} is *regular* iff $a \sqsubseteq a'$ and $b \sqsubseteq b' \iff a \sqsubseteq b'$.

Whenever an involutive bounded poset \mathcal{B} is a lattice, then \mathcal{B} is regular iff it satisfies the *Kleene condition*:

$$a \sqcap a' \sqsubseteq b \sqcup b'.$$

The set $E(\mathcal{H})$ of all effects can be naturally structured as an involutive bounded poset:

$$\mathcal{E}(\mathcal{H}) = \langle E(\mathcal{H}), \sqsubseteq, ', \mathbf{1}, \mathbf{0} \rangle,$$

where

- (i) $E \sqsubseteq F$ iff for any state (statistical operator) W , $\text{Tr}(WE) \leq \text{Tr}(WF)$ (in other words, any state assigns to E a probability-value that is less or equal than the probability-value assigned to F);
- (ii) $\mathbf{1}, \mathbf{0}$ are the identity (\mathbb{I}) and the null ($\mathbb{0}$) projection, respectively;
- (iii) $E' = \mathbf{1} - E$.

One can easily check that \sqsubseteq is a partial order, $'$ is an order-reversing involution, while $\mathbf{1}$ and $\mathbf{0}$ are respectively the maximum and the minimum with respect to \sqsubseteq . At the same time this poset fails to be a lattice. Differently from projections, some pairs of effects have no infimum and no supremum as the following example shows [Greechie and Gudder, n.d.]:

EXAMPLE 112. Let us consider the following effects (in the matrix-representation) on the Hilbert space \mathbb{R}^2 :

$$E = \begin{pmatrix} \frac{1}{2} & 0 \\ 0 & \frac{1}{2} \end{pmatrix} \quad F = \begin{pmatrix} \frac{3}{4} & 0 \\ 0 & \frac{1}{4} \end{pmatrix} \quad G = \begin{pmatrix} \frac{1}{2} & 0 \\ 0 & \frac{1}{4} \end{pmatrix}$$

It is not hard to see that $G \sqsubseteq E, F$. Suppose, by contradiction, that $L = E \sqcap F$ exists in $E(\mathbb{R}^2)$. An easy computation shows that L must be equal to G . Let

$$M = \begin{pmatrix} \frac{7}{16} & \frac{1}{8} \\ \frac{1}{8} & \frac{3}{16} \end{pmatrix}$$

Then M is an effect such that $M \sqsubseteq E, F$; however, $M \not\sqsubseteq L$, which is a contradiction.

In order to obtain a lattice structure, one has to embed $\mathcal{E}(\mathcal{H})$ into its *MacNeille completion* $\overline{\mathcal{E}(\mathcal{H})}$.

The MacNeille completion of an involutive bounded poset

Let $\langle B, \sqsubseteq, \mathbf{1}, \mathbf{0} \rangle$ be an involutive bounded poset. For any non-empty subset X of B , let $l(X)$ and $u(X)$ represent respectively the set of all lower bounds and the set of all upper bounds of X . Let $MC(B) := \{X \subseteq B \mid X = u(l(X))\}$. It turns out that $X \in MC(B)$ iff $X = X''$, where $X' := \{a \in B \mid \forall b \in X : a \sqsubseteq b'\}$. Moreover, the structure

$$\overline{\mathcal{B}} = \langle MC(B), \subseteq, ', \{\mathbf{0}\}, B \rangle$$

is a complete involutive bounded lattice (which is regular if \mathcal{B} is regular), where $X \sqcap Y = X \cap Y$ and $X \sqcup Y = (X \cup Y)''$.

It turns out that \mathcal{B} is embeddable into $\overline{\mathcal{B}}$, via the map $h : a \rightarrow \langle a \rangle$, where $\langle a \rangle$ is the principal ideal generated by a . Such an embedding preserves the *infimum* and the *supremum*, when existing in \mathcal{B} .

The Mac Neille completion of an involutive bounded poset does not generally satisfies the non contradiction principle ($a \sqcap a' = \mathbf{0}$) and the excluded middle principle ($a \sqcup a' = \mathbf{1}$). As a consequence, differently from the projection case, the Mac Neille completion of $\mathcal{E}(\mathcal{H})$ is not an ortholattice. Apparently, our operation $'$ turns out to behave as a *fuzzy negation*, both in the case of $\mathcal{E}(\mathcal{H})$ and of its Mac Neille completion. This is one of the reasons why proper effects (that are not projections) may be regarded as

representing *unsharp physical properties*, possibly violating the non contradiction principle.

The effect poset $\mathcal{E}(\mathcal{H})$ can be naturally extended to a richer structure, equipped with a new complement \sim , that has an intuitionistic-like behaviour:

E^\sim is the projection operator $P_{Ker(E)}$ whose range is the kernel $Ker(E)$ of E , consisting of all vectors that are transformed by the operator E into the null vector.

By definition, the intuitionistic complement of an effect is always a projection. In the particular case, where E is a projection, it turns out that: $E' = E^\sim$. In other words, the fuzzy and the intuitionistic complement collapse into one and the same operation.

The structure $\langle \mathcal{E}(\mathcal{H}), \sqsubseteq, ', \sim, \mathbf{1}, \mathbf{0} \rangle$ turns out to be a particular example of a *Brouwer Zadeh poset* [Cattaneo and Nisticò, 1986].

DEFINITION 113. A *Brouwer–Zadeh poset* (simply a *BZ-poset*) is a structure $\langle B, \sqsubseteq, ', \sim, \mathbf{1}, \mathbf{0} \rangle$, where

(113.1) $\langle B, \sqsubseteq, ', \mathbf{1}, \mathbf{0} \rangle$ is a regular involutive bounded poset;

(113.2) \sim is a 1-ary operation on B , which behaves like an intuitionistic complement:

- (i) $a \sqcap a^\sim = \mathbf{0}$.
- (ii) $a \sqsubseteq a^{\sim\sim}$.
- (iii) $a \sqsubseteq b \iff b^\sim \sqsubseteq a^\sim$.

(113.3) The following relation connects the fuzzy and the intuitionistic complement:

$$a^{\sim'} = a^{\sim\sim}$$

DEFINITION 114. A *Brouwer Zadeh lattice* is a BZ-poset that is also a lattice.

The Mac Neille completion of a BZ-poset

Let $\mathcal{B} = \langle B, \sqsubseteq, ', \sim, \mathbf{1}, \mathbf{0} \rangle$ be a BZ-poset and let $\overline{\mathcal{B}}$ the Mac Neille completion of the regular involutive bounded poset $\langle B, \sqsubseteq, ', \mathbf{1}, \mathbf{0} \rangle$. For any non-empty subset X of B , let

$$X^\sim := \{a \in B \mid \forall b \in X : a \sqsubseteq b^\sim\}.$$

It turns out that $\overline{\mathcal{B}} = \langle MC(B), \subseteq, ', \sim, \{\mathbf{0}\}, B \rangle$ is a complete BZ-lattice [Giuntini, 1991], which \mathcal{B} can be embedded into, via the map h defined above.

Another interesting way of structuring the set of all effects can be obtained by using a particular kind of partial structure, that has been called *effect algebra* [Foulis and Bennett, 1994] or *unsharp orthoalgebra* [Dalla Chiara and Giuntini, 1994]. Abstract effect algebras are defined as follows:

DEFINITION 115. An *effect algebra* is a partial structure $\mathcal{A} = \langle A, \boxplus, \mathbf{1}, \mathbf{0} \rangle$ where \boxplus is a partial binary operation on A . When \boxplus is defined for a pair $a, b \in A$, we will write $\exists(a \boxplus b)$. The following conditions hold:

- (i) *Weak commutativity*
 $\exists(a \boxplus b) \curvearrowright \exists(b \boxplus a)$ and $a \boxplus b = b \boxplus a$.
- (ii) *Weak associativity*
 $[\exists(b \boxplus c) \text{ and } \exists(a \boxplus (b \boxplus c))] \curvearrowright [\exists(a \boxplus b) \text{ and } \exists((a \boxplus b) \boxplus c)]$
and $a \boxplus (b \boxplus c) = (a \boxplus b) \boxplus c$.
- (iii) *Strong excluded middle*
For any a , there exists a unique x such that $a \boxplus x = \mathbf{1}$.
- (iv) *Weak consistency*
 $\exists(a \boxplus \mathbf{1}) \curvearrowright a = \mathbf{0}$.

From an intuitive point of view, our operation \boxplus can be regarded as an *exclusive disjunction* (*aut*), which is defined only for pairs of logically incompatible events.

An orthogonality relation \perp , a partial order relation \sqsubseteq and a generalized complement $'$ can be defined in any effect algebra.

DEFINITION 116. Let $\mathcal{A} = \langle A, \boxplus, \mathbf{1}, \mathbf{0} \rangle$ be an effect algebra and let $a, b \in A$.

- (i) $a \perp b$ iff $a \boxplus b$ is defined in A .
- (ii) $a \sqsubseteq b$ iff $\exists c \in A$ such that $a \perp c$ and $b = a \boxplus c$.
- (iii) The *generalized complement* of a is the unique element a' such that $a \boxplus a' = \mathbf{1}$ (the definition is justified by the strong excluded middle condition).

The category of all effect algebras turns out to be (categorically) equivalent to the category of all *difference posets*, which have been first studied in [Kôpka and Chovanec, 1994] and further investigated in [Dvurečenskij and Pulmannová, 1994].

Effect algebras that satisfy the non contradiction principle are called *orthoalgebras*:

DEFINITION 117. An *orthoalgebra* is an effect algebra $\mathcal{B} = \langle B, \boxplus, \mathbf{1}, \mathbf{0} \rangle$ such that the following condition is satisfied:

Strong consistency

$$\exists (a \boxplus a) \curvearrowright a = \mathbf{0}.$$

In other words: $\mathbf{0}$ is the only element that is orthogonal to itself.

In order to induce the structure of an effect algebra on $E(\mathcal{H})$, it is sufficient to define a partial sum \boxplus as follows:

$$\exists (E \boxplus F) \text{ iff } E + F \in E(\mathcal{H}),$$

where $+$ is the usual sum-operator. Further:

$$\exists (E \boxplus F) \curvearrowright E \boxplus F = E + F.$$

It turns out that the structure $\langle E(\mathcal{H}), \boxplus, \mathbb{I}, \mathbf{0} \rangle$ is an effect algebra, where the generalized complement of any effect E is just $\mathbb{I} - E$. At the same time, this structure fails to be an orthoalgebra.

Any abstract effect algebra

$$\mathcal{A} = \langle A, \boxplus, \mathbf{1}, \mathbf{0} \rangle$$

can be naturally extended to a kind of total structure, that has been termed *quantum MV-algebra* (abbreviated as QMV-algebra) [Giuntini, 1996].

Before introducing QMV-algebras, it will be expedient to recall the definition of MV-algebra. As is well known, *MV-algebras* (*multi-valued algebras*) have been introduced by Chang [1957] in order to provide an algebraic proof of the completeness theorem for Łukasiewicz' infinite-many-valued logic L_{\aleph} . A "privileged" model of this logic is based on the real interval $[0, 1]$, which gives rise to a particular example of a totally ordered (or linear) MV-algebra.

Both MV-algebras and QMV-algebras are total structures having the following form:

$$\mathcal{M} = (M, \oplus, *, \mathbf{1}, \mathbf{0})$$

where:

- (i) $\mathbf{1}, \mathbf{0}$ represent the certain and the impossible propositions (or alternatively the two extreme truth values);
- (ii) $*$ is the negation-operation;
- (iii) \oplus represents a disjunction (*or*) which is generally non idempotent ($a \oplus a \neq a$).

A (generally non idempotent) conjunction (*and*) is then defined via de Morgan law:

$$a \odot b := (a^* \oplus b^*)^*.$$

On this basis, a pair consisting of an idempotent conjunction *et* (\mathfrak{m}) and of an idempotent disjunction *vel* (\mathfrak{u}) is then defined:

$$a \mathfrak{m} b := (a \oplus b^*) \odot b$$

$$a \mathfrak{u} b := (a \odot b^*) \oplus b.$$

In the concrete MV-algebra based on $[0, 1]$, the operations are defined as follows:

(i) $\mathbf{1} = 1$; $\mathbf{0} = 0$;

(ii) $a^* = 1 - a$;

(iii) \oplus is the *truncated sum*:

$$a \oplus b = \begin{cases} a + b, & \text{if } a + b \leq 1; \\ 1, & \text{otherwise.} \end{cases}$$

In this particular case, it turns out that:

$$a \mathfrak{m} b = \text{Min}\{a, b\}$$

(*a et b* is the minimum between *a* and *b*).

$$a \mathfrak{u} b = \text{Max}\{a, b\}$$

(*a vel b* is the maximum between *a* and *b*).

A standard abstract definition of MV-algebras is the following [Mangani, 1973]:

DEFINITION 118. An *MV-algebra* is a structure $\mathcal{M} = (M, \oplus, *, \mathbf{1}, \mathbf{0})$, where \oplus is a binary operation, $*$ is a unary operation and $\mathbf{0}$ and $\mathbf{1}$ are special elements of M , satisfying the following axioms:

(MV1) $(a \oplus b) \oplus c = a \oplus (b \oplus c)$

(MV2) $a \oplus \mathbf{0} = a$

(MV3) $a \oplus b = b \oplus a$

(MV4) $a \oplus \mathbf{1} = \mathbf{1}$

(MV5) $(a^*)^* = a$

(MV6) $\mathbf{0}^* = \mathbf{1}$

(MV7) $a \oplus a^* = \mathbf{1}$

(MV8) $(a^* \oplus b)^* \oplus b = (a \oplus b^*)^* \oplus a$

In other words, an MV-algebra represents a particular weakening of a Boolean algebra, where \oplus and \odot are generally non idempotent.

A partial order relation can be defined in any MV-algebra in the following way:

$$a \preceq b \text{ iff } a \mathbin{\&}\! \mathbin{\&}\! b = a.$$

Some important properties of MV-algebras are the following:

- (i) the structure $\langle M, \preceq, *, \mathbf{1}, \mathbf{0} \rangle$ is a bounded involutive distributive lattice, where $a \mathbin{\&}\! \mathbin{\&}\! b$ ($a \mathbin{\cup}\! \mathbin{\cup}\! b$) is the *inf* (*sup*) of a, b ;
- (ii) the non-contradiction principle and the excluded middle principles for $*, \mathbin{\&}\! \mathbin{\&}\!, \mathbin{\cup}\! \mathbin{\cup}\!$ are generally violated: $a \mathbin{\cup}\! \mathbin{\cup}\! a^* \neq \mathbf{1}$ and $a \mathbin{\&}\! \mathbin{\&}\! a^* \neq \mathbf{0}$ are possible. As a consequence, MV algebras permit us to describe *fuzzy* and *paraconsistent* situations;
- (iii) $a^* \oplus b = \mathbf{1}$ iff $a \preceq b$. In other words: similarly to the Boolean case, “not- a or b ” represents a *good material implication*;
- (iv) every MV-algebra is a subdirect product of totally ordered MV-algebras [Chang, 1958];
- (v) an equation holds in the class of all MV-algebras iff it holds in the concrete MV-algebra based on $[0, 1]$ [Chang, 1958].

Let us now go back to our effect-structure $\langle E(\mathcal{H}), \boxplus, \mathbf{1}, \mathbf{0} \rangle$. The partial operation \boxplus can be extended to a total operation \oplus that behaves like a truncated sum. For any $E, F \in E(\mathcal{H})$:

$$E \oplus F = \begin{cases} E + F, & \text{if } \exists (E \boxplus F); \\ \mathbf{1}, & \text{otherwise.} \end{cases}$$

Further, let us put:

$$E^* = \mathbb{I} - E.$$

The structure $\mathcal{E}(\mathcal{H}) = \langle E(\mathcal{H}), \oplus, *, \mathbf{1}, \mathbf{0} \rangle$ turns out to be “very close” to an MV-algebra. However, something is missing: $\mathcal{E}(\mathcal{H})$ satisfies the first seven axioms of our definition (MV1-MV7); at the same time one can easily check that the axiom (MV8) (usually called “Łukasiewicz axiom”) is violated. For instance, let us consider two non trivial projections P, Q such that P is not orthogonal to Q^* and Q is not orthogonal to P^* . Then, by definition of \oplus , we have that $P \oplus Q^* = \mathbb{I}$ and $Q \oplus P^* = \mathbb{I}$. Hence: $(P^* \oplus Q)^* \oplus Q = Q \neq P = (P \oplus Q^*)^* \oplus P$.

As a consequence, Łukasiewicz axiom must be conveniently weakened to obtain a representation for our concrete effect structure. This can be done by means of the notion of QMV-algebra.

DEFINITION 119. A *quantum MV-algebra* (QMV-algebra) is a structure $\mathcal{M} = (M, \oplus, *, \mathbf{1}, \mathbf{0})$ where \oplus is a binary operation, $*$ is a 1-ary operation, and $\mathbf{0}, \mathbf{1}$ are special elements of M . For any $a, b \in M$: $a \odot b := (a^* \oplus b^*)^*$, $a \pitchfork b := (a \oplus b^*) \odot a$, $a \uplus b := (a \odot b^*) \oplus b$. The following axioms are required:

- (QMV1) $a \oplus (b \oplus c) = (b \oplus a) \oplus c$,
- (QMV2) $a \oplus a^* = \mathbf{1}$,
- (QMV3) $a \oplus \mathbf{0} = a$,
- (QMV4) $a \oplus \mathbf{1} = \mathbf{1}$,
- (QMV5) $a^{**} = a$,
- (QMV6) $\mathbf{0}^* = \mathbf{1}$,
- (QMV7) $a \oplus [(a^* \pitchfork b) \pitchfork (c \pitchfork a^*)] = (a \oplus b) \pitchfork (a \oplus c)$.

The operations \pitchfork and \uplus of a QMV-algebra \mathcal{M} are generally non commutative. As a consequence, they do not represent lattice-operations. It is not difficult to prove that a QMV-algebra \mathcal{M} is an MV-algebra iff for all $a, b \in M$: $a \pitchfork b = b \pitchfork a$.

At the same time, any QMV-algebra $\mathcal{M} = (M, \oplus, *, \mathbf{1}, \mathbf{0})$ gives rise to an involutive bounded poset $\langle M, \preceq, *, \mathbf{1}, \mathbf{0} \rangle$, where the partial order relation is defined like in the MV case.

One can easily show that QMV-algebras represent a “good abstraction” from the effect-structures:

THEOREM 120. *The structure $\mathcal{E}(\mathcal{H}) = \langle E(\mathcal{H}), \oplus, *, \mathbf{1}, \mathbf{0} \rangle$ (where $\oplus, *, \mathbf{1}, \mathbf{0}$ are the operations and the special elements previously defined) is a QMV-algebra.*

The QMV-algebra $\mathcal{E}(\mathcal{H})$ cannot be linear. For, one can easily check that any linear QMV-algebra collapses into an MV-algebra.

In spite of this, our algebra of effects turns out to satisfy some weak forms of linearity.

DEFINITION 121. A QMV-algebra \mathcal{M} is called *weakly linear* iff $\forall a, b \in M$: $a \pitchfork b = b$ or $b \pitchfork a = a$.

DEFINITION 122. A QMV-algebra \mathcal{M} is called *quasi-linear* iff $\forall a, b \in M$: $a \pitchfork b = a$ or $a \pitchfork b = b$.

It is easy to see that every quasi-linear QMV-algebra is weakly linear, but not the other way around (because \pitchfork is not commutative).

A very strong relation connects the class of all effect algebras with the class of all quasi-linear QMV-algebras: every effect algebra can be uniquely transformed into a quasi-linear QMV-algebra and viceversa.

Let $\mathcal{B} = \langle B, \boxplus, \mathbf{1}, \mathbf{0} \rangle$ be an effect algebra. The operation \boxplus can be extended to a total operation

$$\overline{\boxplus} : B \times B \rightarrow B$$

in the following way:

$$a \overline{\boxplus} b := \begin{cases} a \boxplus b, & \text{if } \exists(a \boxplus b); \\ \mathbf{1}, & \text{otherwise.} \end{cases}$$

The resulting structure $\langle B, \overline{\boxplus}, ', \mathbf{1}, \mathbf{0} \rangle$ will be denoted by \mathcal{B}^{qmv} .

Viceversa, let $\mathcal{M} = \langle M, \oplus, *, \mathbf{1}, \mathbf{0} \rangle$ be a QMV-algebra. Then, one can define a partial operation $\overline{\oplus}$ on M such that

$$\begin{aligned} \text{Dom}(\overline{\oplus}) &:= \{ \langle a, b \rangle \in M \times M \mid a \preceq b^* \}. \\ \exists(a \overline{\oplus} b) &\curvearrowright a \overline{\oplus} b = a \oplus b. \end{aligned}$$

The resulting structure $\langle M, \overline{\oplus}, \mathbf{1}, \mathbf{0} \rangle$ will be denoted by \mathcal{M}^{ea} .

THEOREM 123. [Gudder, 1995; Giuntini, 1995] *Let $\mathcal{B} = \langle B, \boxplus, \mathbf{1}, \mathbf{0} \rangle$ be an effect algebra and let $\mathcal{M} = \langle M, \oplus, *, \mathbf{1}, \mathbf{0} \rangle$ be a QMV-algebra.*

- (i) \mathcal{B}^{qmv} is a quasi-linear QMV-algebra;
- (ii) \mathcal{M}^{ea} is an effect algebra;
- (iii) $(\mathcal{B}^{qmv})^{ea} = \mathcal{B}$;
- (iv) \mathcal{M} is quasi-linear iff $(\mathcal{M}^{ea})^{qmv} = \mathcal{M}$;
- (v) \mathcal{B}^{qmv} is the unique quasi-linear QMV-algebra such that $\overline{\boxplus}$ extends \boxplus and $a \preceq b$ in \mathcal{B}^{qmv} implies $a \sqsubseteq b$ in \mathcal{B} .

As a consequence, the effect algebra $\mathcal{E}(\mathcal{H})$ of all effects on a Hilbert space \mathcal{H} determines a quasi-linear QMV-algebra $\mathcal{E}(\mathcal{H})^{qmv} = \langle \mathcal{E}(\mathcal{H}), \oplus, *, \mathbf{1}, \mathbf{0} \rangle$, where

$$E \oplus F = \begin{cases} E + F, & \text{if } \exists(E \boxplus F); \\ \mathbf{1}, & \text{otherwise,} \end{cases}$$

and

$$E^* = \mathbf{1} - E = E'.$$

These different ways of inducing a structure on the set of all unsharp physical properties have suggested different logical abstractions. In the following sections, we will investigate some interesting examples of unsharp quantum logics.

13 PARACONSISTENT QUANTUM LOGIC

Paraconsistent quantum logic (**PQL**) represents the most obvious unsharp weakening of orthologic. In the algebraic semantics, this logic is characterized by the class of all realizations based on an involutive bounded lattice, where the non contradiction principle ($a \sqcap a' = \mathbf{0}$) is possibly violated.

In the Kripkean semantics, instead, **PQL** is characterized by the class of all realizations $\langle I, R, \Pi, \rho \rangle$, where the accessibility relation R is symmetric (but not necessarily reflexive), while Π behaves like in the **OL** - case. Any pair $\langle I, R \rangle$, where R is a symmetric relation on I , will be called *symmetric frame*. Differently from **OL** and **OQL**, a world i of a **PQL** realization may verify a contradiction. Since R is generally not reflexive, it may happen that $i \in \rho(\alpha)$ and $i \perp \rho(\alpha)$. Hence: $i \models \alpha \wedge \neg\alpha$.

All the other semantic definitions are given like in the case of **OL**, *mutatis mutandis*. On this basis, one can show that our algebraic and Kripkean semantics characterize the same logic.

An axiomatization of **PQL** can be obtained by dropping the *absurdity rule* and the *Duns Scotus rule* in the **OL** calculus. Similarly to **OL**, our logic **PQL** satisfies the finite model property and is consequently decidable.

Hilbert-space realizations for **PQL** can be constructed, in a natural way, both in the algebraic and in the Kripkean semantics. In the algebraic semantics, take the realizations based on the Mac Neille completion of an involutive bounded poset having the form

$$\langle E(\mathcal{H}), \sqsubseteq, ', \mathbf{1}, \mathbf{0} \rangle,$$

where \mathcal{H} is any Hilbert space. In the Kripkean semantics, consider the realizations based on the following frames

$$\langle E(\mathcal{H}) - \{\mathbf{0}\}, \not\perp \rangle,$$

where $\not\perp$ represents the non orthogonality relation between effects ($E \not\perp F$ iff $E \not\sqsubseteq F'$). Differently from the projection case, here the accessibility relation is symmetric but generally non-reflexive. For instance, the semi-transparent effect $\frac{1}{2}\mathbb{I}$ (representing the prototypical ambiguous property) is a fixed point of the generalized complement $'$; hence $\frac{1}{2}\mathbb{I} \perp \frac{1}{2}\mathbb{I}$ and $(\frac{1}{2}\mathbb{I})' \perp (\frac{1}{2}\mathbb{I})'$. From the physical point of view, possible worlds are here identified with possible pieces of information about the physical system under investigation. Any information may be either maximal (a pure state) or non maximal (a mixed state); either sharp (a projection) or unsharp (a proper effect). Violations of the non contradiction principle are determined by unsharp (ambiguous) pieces of knowledge. Interestingly enough, proper mixed states (which cannot be represented as projections) turn out to coincide with particular effects. In other words, within the unsharp approach, it is possible to represent both states and events by a unique kind of mathematical object, an effect.

PQL represents a somewhat rough logical abstraction from the class of all effect-realizations. An important condition that holds in all effect realizations is represented by the *regularity property* (which may fail in a generic **PQL**-realization).

DEFINITION 124. An algebraic **PQL** realization $\langle B, v \rangle$ is called *regular* iff the involutive bounded lattice \mathcal{B} is regular ($a \sqcap a' \sqsubseteq b \sqcup b'$).

The regularity property can be naturally formulated also in the framework of the Kripkean semantics:

DEFINITION 125. A **PQL** Kripkean realization $\langle I, R, \Pi, \rho \rangle$ is *regular* iff its frame $\langle I, R \rangle$ is *regular*. In other words, $\forall i, j \in I: i \perp i$ and $j \perp j \curvearrowright i \perp j$.

One can prove that a symmetric frame $\langle I, R \rangle$ is regular iff the involutive bounded lattice of all propositions of $\langle I, R \rangle$ is regular. As a consequence, an algebraic realization is regular iff its Kripkean transformation is regular and viceversa (where the Kripkean [algebraic] transformation of an algebraic [Kripkean] realization is defined like in **OL**).

On this basis one can introduce a proper extension of **PQL**: *regular paraconsistent quantum logic* (**RPQL**). Semantically **RPQL** is characterized by the class of all regular realizations (both in the algebraic and in the Kripkean semantics). The calculus for **RPQL** is obtained by adding to the **PQL**-calculus the following rule:

$$\alpha \wedge \neg\alpha \vdash \beta \vee \neg\beta \quad (\text{Kleene rule})$$

A completeness theorem for both **PQL** and **RPQL** can be proved, similarly to the case of **OL**. Both logics **PQL** and **RPQL** admit a natural modal translation (similarly to **OL**). The suitable modal system which **PQL** can be transformed into is the system **KB**, semantically characterized by the class of all symmetric frames. A convenient strengthening of **KB** gives rise to a regular modal system, that is suitable for **RPQL**.

An interesting question concerns the relation between **PQL** and the orthomodular property.

Let $\mathcal{B} = \langle A, \sqsubseteq, ', \mathbf{1}, \mathbf{0} \rangle$ be an ortholattice. By Lemma 19 the following three conditions (expressing possible definitions of the orthomodular property) turn out to be equivalent:

- (i) $\forall a, b \in B: a \sqsubseteq b \curvearrowright b = a \sqcup (a' \sqcap b)$;
- (ii) $\forall a, b \in B: a \sqsubseteq b$ and $a' \sqcap b = \mathbf{0} \curvearrowright a = b$;
- (iii) $\forall a, b \in B: a \sqcap (a' \sqcup (a \sqcap b)) \sqsubseteq b$.

However, this equivalence breaks down in the case of involutive bounded lattices. One can prove only:

LEMMA 126. *Let \mathcal{B} be an involutive bounded lattice. If \mathcal{B} satisfies condition (i), then \mathcal{B} satisfies conditions (ii) and (iii).*

Proof. (i) implies (ii): trivial. Suppose (i); we want to show that (iii) holds. Now, $a' \sqsubseteq a' \sqcup b' = (a \sqcap b)'$. Therefore, by (i), $(a \sqcap b)' = a' \sqcup (a \sqcap (a \sqcap b)')$. By de Morgan law: $a \sqcap b = (a \sqcap (a' \sqcup (a \sqcap b))) \sqsubseteq b$. ■

Figure 6. \mathcal{G}_{14}

LEMMA 127. *Any involutive bounded lattice \mathcal{B} that satisfies condition (iii) is an ortholattice.*

Proof. Suppose (iii). It is sufficient to prove that $\forall a, b \in B: a \sqcap a' \sqsubseteq b$. Now, $a \sqcap a' \sqsubseteq a, a'$. Moreover, $a' \sqsubseteq a' \sqcup (a \sqcap b)$. Therefore, by (iii), $a \sqcap a' \sqsubseteq a \sqcap (a' \sqcup (a \sqcap b)) \sqsubseteq b$. Thus, $\forall a \in B: a \sqcap a' = \mathbf{0}$. ■

As a consequence, we can conclude that there exists no proper orthomodular paraconsistent quantum logic when orthomodularity is understood in the sense (i) or (iii). A residual possibility for a proper paraconsistent quantum logic to be orthomodular is orthomodularity in the sense (ii). In fact, the lattice \mathcal{G}_{14} (see Figure 6) is an involutive bounded lattice which turns out to be orthomodular (ii) but not orthomodular (i).

Since $f \sqcap f' = f \neq \mathbf{0}$, \mathcal{G}_{14} cannot be an ortholattice. Hence, \mathcal{G}_{14} is neither orthomodular (i) nor orthomodular (iii). However, \mathcal{G}_{14} is trivially orthomodular (ii) since the premiss of condition (ii) is satisfied only in the trivial case where both a, b are either $\mathbf{0}$ or $\mathbf{1}$.

Hilbert space realizations for orthomodular paraconsistent quantum logic can be constructed in the algebraic semantics by taking as support the following proper subset of the set of all effects:

$$I(\mathcal{H}) := \{a\mathbb{I} \mid a \in [0, 1]\} \cup P(\mathcal{H}).$$

In other words, a possible meaning of the formula is either a sharp property (projection) or an unsharp property that can be represented as a multiple of the universal property (\mathbb{I}).

The set $I(\mathcal{H})$ determines an orthomodular involutive regular bounded lattice, where the partial order is the partial order of $\mathcal{E}(\mathcal{H})$ restricted to $I(\mathcal{H})$, while the fuzzy complement is defined like in the class of all effects ($E' := \mathbb{I} - E$).

An interesting feature of **PQL** is represented by the fact that this logic turns out to be a common sublogic in a wide class of important logics. In particular, **PQL** is a sublogic of Girard's linear logic [Girard, 1987], of Łukasiewicz' infinite many-valued logic and of some relevant logics.

As we will see in Section 17, **PQL** represents the most natural quantum logical extension of a quite weak and general logic, that has been called *basic logic*.

14 THE BROUWER–ZADEH LOGICS

The *Brouwer–Zadeh logics* (called also *fuzzy intuitionistic logics*) represent natural abstractions from the class of all **BZ**-lattices (defined in Section 12). As a consequence, a characteristic property of these logics is a splitting of the connective “not” into two forms of negation: a *fuzzy-like* negation, that gives rise to a *paraconsistent* behaviour and an *intuitionistic-like* negation. The fuzzy “not” represents a weak negation, that inverts the two extreme truth-values (truth and falsity), satisfies the double negation principle but generally violates the non-contradiction principle. The second “not” is a stronger negation, a kind of necessitation of the fuzzy “not”.

We will consider two forms of Brouwer–Zadeh logic: **BZL** (*weak Brouwer–Zadeh logic*) and **BZL**³ (*strong Brouwer–Zadeh logic*). The language of both **BZL** and **BZL**³ is an extension of the language of **QL**. The primitive connectives are: the *conjunction* (\wedge), the *fuzzy negation* (\neg), the *intuitionistic negation* (\sim).

Disjunction is metatheoretically defined in terms of conjunction and of the fuzzy negation:

$$\alpha \vee \beta := \neg(\neg\alpha \wedge \neg\beta).$$

A *necessity* operator is defined in terms of the intuitionistic and of the fuzzy negation:

$$L\alpha := \sim \neg\alpha.$$

A *possibility* operator is defined in terms of the necessity operator and of the fuzzy negation:

$$M\alpha := \neg L\neg\alpha.$$

Let us first consider our weaker logic **BZL**. Similarly to **OL** and **PQL**, also **BZL** can be characterized by an algebraic and a Kripkean semantics.

DEFINITION 128 (Algebraic realization for **BZL**). An *algebraic realization* of **BZL** is a pair $\langle \mathcal{B}, v \rangle$, consisting of a **BZ**-lattice $\langle B, \sqsubseteq, ', \sim, \mathbf{1}, \mathbf{0} \rangle$ and a valuation-function v that associates to any formula α an element in B , satisfying the following conditions:

- (i) $v(\neg\beta) = v(\beta)'$
- (ii) $v(\sim\beta) = v(\beta)\sim$
- (iii) $v(\beta \wedge \gamma) = v(\beta) \sqcap v(\gamma)$.

The definitions of truth, consequence in an algebraic realization for **BZL**, logical truth and logical consequence are given similarly to the case of **OL**.

A Kripkean semantics for **BZL** has been first proposed in [Giuntini, 1991]. A characteristic of this semantics is the use of frames with two accessibility relations.

DEFINITION 129. A *Kripkean realization* for **BZL** is a system

$\mathcal{K} = \langle I, \not\sim, \not\leq, \Pi, \rho \rangle$ where:

- (i) $\langle I, \not\sim, \not\leq \rangle$ is a frame with a non empty set I of possible worlds and two accessibility relations: $\not\sim$ (the *fuzzy accessibility* relation) and $\not\leq$ (the *intuitionistic accessibility* relation).

Two worlds i, j are called *fuzzy-accessible* iff $i \not\sim j$. They are called *intuitionistically-accessible* iff $i \not\leq j$. Instead of *not*($i \not\sim j$) and *not*($i \not\leq j$), we will write $i \perp j$ and $i \not\leq j$, respectively.

The following conditions are required for the two accessibility relations:

- (ia) $\langle I, \not\sim \rangle$ is a regular symmetric frame;
- (ib) any world is fuzzy-accessible to at least one world:

$$\forall i \exists j : i \not\sim j.$$

- (ic) $\langle I, \not\leq \rangle$ is an orthoframe;
- (id) Fuzzy accessibility implies intuitionistic accessibility:

$$i \not\sim j \rightsquigarrow i \not\leq j.$$

- (ie) Any world i has a kind of “twin-world” j such that for any world k :

- (a) $i \not\leq k$ iff $j \not\leq k$
- (b) $i \not\leq k \rightsquigarrow j \not\leq k$.

For any set X of worlds, the *fuzzy-orthogonal* set X' is defined like in **OL**:

$$X' = \{i \in I \mid \forall j \in X : i \perp j\}.$$

Similarly, the *intuitionistic orthogonal* set X^\sim is defined as follows:

$$X^\sim = \{i \in I \mid \forall j \in X : i \not\leq j\}.$$

The notion of *proposition* is defined like in **OL**. It turns out that a set of worlds X is a proposition iff $X = X''$.

One can prove that for any set of worlds X , both X' and X^\sim are propositions. Further, like in **OL**, $X \sqcap Y$ (the greatest proposition included in the propositions X and Y) is $X \cap Y$, while $X \sqcup Y$ (the smallest proposition including X and Y) is $(X \cup Y)''$.

- (ii) Π is a set of propositions that contains I , and is closed under $', \sim, \sqcap$.
- (iii) ρ associates to any formula a proposition in Π according to the following conditions:

$$\begin{aligned} \rho(\neg\beta) &= \rho(\beta)'; \\ \rho(\sim\beta) &= \rho(\beta)^\sim; \\ \rho(\beta \wedge \gamma) &= \rho(\beta) \sqcap \rho(\gamma). \end{aligned}$$

THEOREM 130. *Let $\langle I, \not\leq, \not\leq \rangle$ be a BZ-frame (i.e. a frame satisfying the conditions of Definition 129(i)) and let Π^0 be the set of all propositions of the frame. Then, the structure $\langle \Pi^0, \subseteq, ', \sim, \emptyset, I \rangle$ is a complete BZ-lattice such that for any set $\Gamma \subseteq \Pi^0$:*

$$\text{inf}(\Gamma) := \sqcap \Gamma = \bigcap \Gamma \quad \text{and} \quad \text{sup}(\Gamma) := \sqcup \Gamma = \left(\bigcup \Gamma \right)''.$$

As a consequence, the proposition-structure $\langle \Pi, \subseteq, ', \sim, \emptyset, I \rangle$ of a **BZL** realization, turns out to be a BZ-lattice.

The definitions of truth, consequence in a Kripkean realization, logical truth and logical consequence, are given similarly to the case of **OL**.

One can prove, with standard techniques, that the algebraic and the Kripkean semantics for **BZL** characterize the same logic.

We will now introduce a calculus that represents an adequate axiomatization for the logic **BZL**. The most intuitive way to formulate our calculus is to present it as a modal extension of the axiomatic version of regular paraconsistent quantum logic **RPQL**. (Recall that the modal operators of **BZL** are defined as follows: $L\alpha := \sim \neg \alpha$; $M\alpha := \neg L\neg \alpha$).

Rules of **BZL**.

The BZL-calculus includes, besides the rules of **RPQL** the following modal rules:

$$(BZ1) \quad L\alpha \vdash \alpha$$

$$(BZ2) \quad L\alpha \vdash LL\alpha$$

$$(BZ3) \quad ML\alpha \vdash L\alpha$$

$$(BZ4) \quad \frac{\alpha \vdash \beta}{L\alpha \vdash L\beta}$$

$$(BZ5) \quad L\alpha \wedge L\beta \vdash L(\alpha \wedge \beta)$$

$$(BZ6) \quad \emptyset \vdash \neg(L\alpha \wedge \neg L\alpha)$$

The rules (BZ1)-(BZ5) give rise to a \mathbf{S}_5 -like modal behaviour. The rule (BZ6) (the non-contradiction principle for necessitated formulas) is, of course, trivial in any classical modal system.

One can prove a soundness and completeness Theorem with respect to the Kripkean semantics (by an appropriate modification of the corresponding proofs for **QL**).

Characteristic logical properties of **BZL** are the following:

- (a) like in **PQL**, the distributive principles, Duns Scotus, the non-contradiction and the excluded middle principles (for the fuzzy negation) break down;
- (b) like in intuitionistic logic, we have:

$$\begin{aligned} \models_{\mathbf{BZL}} \sim(\alpha \wedge \sim \alpha); \quad \not\models_{\mathbf{BZL}} \alpha \vee \sim \alpha; \quad \alpha \models_{\mathbf{BZL}} \sim \sim \alpha; \quad \sim \sim \alpha \not\models_{\mathbf{BZL}} \alpha; \\ \sim \sim \sim \alpha \models_{\mathbf{BZL}} \sim \alpha; \quad \alpha \models_{\mathbf{BZL}} \beta \wedge \sim \beta \models_{\mathbf{BZL}} \sim \alpha; \end{aligned}$$

- (c) moreover, we have:

$$\sim \alpha \models_{\mathbf{BZL}} \neg \alpha; \quad \neg \alpha \not\models_{\mathbf{BZL}} \sim \alpha; \quad \neg \sim \alpha \models_{\mathbf{BZL}} \sim \sim \alpha;$$

One can prove that **BZL** has the finite model property; as a consequence it is decidable [Giuntini, 1992].

The ortho-pair semantics

Our stronger logic **BZL**³ has been suggested by a form of fuzzy-intuitionistic semantics, that has been first studied in [Cattaneo and Nisticò, 1986]. The intuitive idea, underlying this semantics (which has some features in common with Klaua's *partielle Mengen* and with Dunn's *polarities*) can be sketched as follows: one supposes that interpreting a language means associating to any sentence two *domains of certainty*: the domain of the situations

where our sentence certainly holds, and the domain of the situations where our sentence certainly does not hold. Similarly to Kripkean semantics, the situations we are referring to can be thought of as a kind of possible worlds. However, differently from the standard Kripkean behaviour, the positive domain of a given sentence does not generally determine the negative domain of the same sentence. As a consequence, propositions are here identified with particular *pairs* of sets of worlds, rather than with particular sets of worlds.

Let us again assume the **BZL** language. We will define the notion of *realization with positive and negative certainty domains* (shortly *ortho-pair realization*) for a **BZL** language.

DEFINITION 131. An *ortho-pair realization* is a system $\mathcal{O} = \langle I, R, \Omega, v \rangle$, where:

- (i) $\langle I, R \rangle$ is an orthoframe.
- (ii) Let Π^0 be the set of all propositions of the orthoframe $\langle I, R \rangle$. As we already know, this set gives rise to an ortholattice with respect to the operations \sqcap, \sqcup and $'$ (where \sqcap is the set-theoretic intersection).

An *orthopairproposition* of $\langle I, R \rangle$ is any pair $\langle A_1, A_0 \rangle$, where A_1, A_0 are propositions in Π^0 such that $A_1 \subseteq A'_0$. An orthopairproposition $\langle A_1, A_0 \rangle$ is called *exact* iff $A_0 = A'_1$ (in other words, A_0 is maximal). The following operations and relations can be defined on the set of all orthopairpropositions:

- (iia) The fuzzy complement:

$$\langle A_1, A_0 \rangle^{\odot} := \langle A_0, A_1 \rangle .$$

- (iib) The intuitionistic complement:

$$\langle A_1, A_0 \rangle^{\ominus} := \langle A_0, A'_0 \rangle .$$

- (iic) The orthopairpropositional conjunction:

$$\langle A_1, A_0 \rangle \bar{\sqcap} \langle B_1, B_0 \rangle := \langle A_1 \sqcap B_1, A_0 \sqcup B_0 \rangle .$$

- (iid) The orthopairpropositional disjunction:

$$\langle A_1, A_0 \rangle \underline{\sqcup} \langle B_1, B_0 \rangle := \langle A_1 \sqcup B_1, A_0 \sqcap B_0 \rangle .$$

- (iie) The infinitary conjunction:

$$\bar{\sqcap}_n \{ \langle A_1^n, A_0^n \rangle \} := \left\langle \bigcap_n \{ A_1^n \}, \underline{\sqcup}_n \{ A_0^n \} \right\rangle .$$

(iif) The infinitary disjunction:

$$\bigsqcup_n \{\langle A_1^n, A_0^n \rangle\} := \left\langle \bigsqcup_n \{A_1^n\}, \bigcap_n \{A_0^n\} \right\rangle.$$

(iig) The necessity operator:

$$\Box(\langle A_1, A_0 \rangle) := \langle A_1, A_1' \rangle.$$

(iih) The possibility operator:

$$\Diamond(\langle A_1, A_0 \rangle) := (\Box(\langle A_1, A_0 \rangle^{\circledast}))^{\circledast}.$$

(iik) The order-relation:

$$\langle A_1, A_0 \rangle \sqsubseteq \langle B_1, B_0 \rangle \text{ iff } A_1 \subseteq B_1 \text{ and } B_0 \subseteq A_0.$$

(iii) Ω is a set of orthopairpropositions, that is closed under $\circledast, \ominus, \overline{}, \sqcup$ and $\mathbf{0} := \langle \emptyset, I \rangle$.

(iv) v is a valuation-function that maps formulas into orthopairpropositions according to the following conditions:

$$\begin{aligned} v(\neg\beta) &= v(\beta)^{\circledast}; \\ v(\sim\beta) &= v(\beta)^{\ominus}; \\ v(\beta \wedge \gamma) &= v(\beta)\overline{}v(\gamma). \end{aligned}$$

The other basic semantic definitions are given like in the algebraic semantics. One can prove the following Theorem:

THEOREM 132. *Let $\langle I, R \rangle$ be an orthoframe and let Ω^0 be the set of all orthopairpropositions of $\langle I, R \rangle$. Then, the structure $\langle \Omega^0, \subseteq, \circledast, \ominus, \langle \emptyset, I \rangle, \langle I, \emptyset \rangle \rangle$ is a complete BZ-lattice with respect to the infinitary conjunction and disjunction defined above. Further, the following conditions are satisfied: for any $\langle A_1, A_0 \rangle, \langle B_1, B_0 \rangle \in \Omega^0$:*

- (i) $\Box \langle A_1, A_0 \rangle = \langle A_1, A_0 \rangle^{\circledast\circledast}$.
- (ii) $\langle A_1, A_0 \rangle^{\ominus} = \Box(\langle A_1, A_0 \rangle^{\circledast})$.
- (iii) $\Diamond \langle A_1, A_0 \rangle = \langle A_1, A_0 \rangle^{\ominus\circledast}$.
- (iv) $(\langle A_1, A_0 \rangle \overline{} \langle B_1, B_0 \rangle)^{\ominus} = \langle A_1, A_0 \rangle^{\ominus} \overline{} \langle B_1, B_0 \rangle^{\ominus}$.
(Strong de Morgan law)
- (v) $(\langle A_1, A_0 \rangle \overline{} \langle B_1, B_0 \rangle^{\ominus\circledast}) \subseteq (\langle A_1, A_0 \rangle^{\circledast\circledast} \overline{} \langle B_1, B_0 \rangle)$.

Accordingly, in any ortho-pair realization the set of all orthopairpropositions Ω^0 gives rise to a BZ-lattice. As a consequence, one can immediately

prove a soundness theorem with respect to the ortho-pair semantics. Does perhaps the ortho-pair semantics characterizes the logic **BZL**? The answer to this question is negative. As a counterexample, let us consider an instance of the fuzzy excluded middle and an instance of the intuitionistic excluded middle applied to the same formula α :

$$\alpha \vee \neg\alpha \quad \text{and} \quad \alpha \vee \sim \alpha.$$

One can easily check that they are logically equivalent in the ortho-pair semantics. For, given any ortho-pair realization \mathcal{O} , there holds:

$$\alpha \vee \neg\alpha \models_{\mathcal{O}} \alpha \vee \sim \alpha \quad \text{and} \quad \alpha \vee \sim \alpha \models_{\mathcal{O}} \alpha \vee \neg\alpha.$$

However, generally

$$\alpha \vee \neg\alpha \not\models_{\mathbf{BZL}} \alpha \vee \sim \alpha.$$

For instance, let us consider the following algebraic **BZL**-realization $\mathcal{A} = \langle \mathcal{B}, v \rangle$, where the support \mathcal{B} of is the real interval $[0, 1]$ and the algebraic structure on \mathcal{B} is defined as follows:

$$\begin{aligned} a \sqsubseteq b & \text{ iff } a \leq b; \\ a' & = 1 - a; \\ a^\sim & = \begin{cases} 1, & \text{if } a = 0; \\ 0, & \text{otherwise.} \end{cases} \\ \mathbf{1} & = 1; \quad \mathbf{0} = 0. \end{aligned}$$

Suppose for a given sentential literal p : $0 < v(p) < 1/2$. We will have $v(p \vee \sim p) = \text{Max}(v(p), 0) = v(p) < 1/2$. But $v(p \vee \neg p) = \text{Max}(v(p), 1 - v(p)) = 1 - v(p) \geq 1/2$. Hence: $v(p \vee \sim p) < v(p \vee \neg p)$.

As a consequence, the orthopair-semantics characterizes a logic stronger than **BZL**. We will call this logic **BZL**³. The name is due to the characteristic three-valued features of the ortho-pair semantics.

Our logic **BZL**³ is axiomatizable. A suitable calculus can be obtained by adding to the **BZL**-calculus the following rules.

*Rules of **BZL**³.*

$$(BZ^3_1) \quad L(\alpha \vee \beta) \vdash L\alpha \vee L\beta$$

$$(BZ^3_2) \quad \frac{L\alpha \vdash \beta, \alpha \vdash M\beta}{\alpha \vdash \beta}$$

The following rules turn out to be derivable:

$$(DR1) \quad \frac{L\alpha \vdash \beta, M\alpha \vdash M\beta}{\alpha \vdash \beta}$$

$$(DR2) \quad M\alpha \wedge M\beta \vdash M(\alpha \wedge \beta)$$

$$(DR3) \quad \sim(\alpha \wedge \beta) \vdash \sim\alpha \vee \sim\beta$$

The validity of a strong de Morgan's principle for the connective \sim (DR3) shows that this connective represents, in this logic, a kind of strong “super-intuitionistic” negation (differently from **BZL**, where the strong de Morgan law fails, like in intuitionistic logic).

One can prove a soundness and a completeness theorem of our calculus with respect to the ortho-pair semantics.

THEOREM 133 (Soundness theorem).

$$T \vdash_{\mathbf{BZL}^3} \alpha \quad \curvearrowright \quad T \models_{\mathbf{BZL}^3} \alpha.$$

Proof. By routine techniques. ■

THEOREM 134. *Completeness theorem.*

$$T \models_{\mathbf{BZL}^3} \alpha \quad \curvearrowright \quad T \vdash_{\mathbf{BZL}^3} \alpha.$$

Sketch of the proof

Instead of $T \models_{\mathbf{BZL}^3} \alpha$ and $T \vdash_{\mathbf{BZL}^3} \alpha$, we will shortly write $T \models \alpha$ and $T \vdash \alpha$. It is sufficient to construct a canonical model $\mathcal{O} = \langle I, R, \Omega, v \rangle$ such that:

$$T \models_{\mathcal{O}} \alpha \quad \curvearrowright \quad T \vdash \alpha.$$

(The other way around follows from the soundness theorem).

Definition of the canonical model

(i) I is the set of all possible sets i of formulas satisfying the following conditions:

- (ia) i is *non contradictory* with respect to the fuzzy negation \neg : for any α , if $\alpha \in i$, then $\neg\alpha \notin i$;
- (ib) i is *L-closed*: for any α , if $\alpha \in i$, then $L\alpha \in i$;
- (ic) i is *deductively closed*: for any α , if $i \vdash \alpha$, then $\alpha \in i$.

(ii) The accessibility relation R is defined as follows:

$$Rij \text{ iff for any formula } \alpha: \alpha \in i \quad \curvearrowright \quad \neg\alpha \notin j.$$

(In other words, i and j are not contradictory with respect to the fuzzy negation).

Instead of *not Rij*, we will write $i \perp j$.

(iii) Ω is the set of all orthopairpropositions of $\langle I, R \rangle$.

(iv) For any atomic formula p :

$$v(p) = \langle v_1(p), v_0(p) \rangle ,$$

where:

$$v_1(p) = \{i \mid i \vdash p\} \quad \text{and} \quad v_0(p) = \{i \mid i \vdash \neg p\} .$$

\mathcal{O} is well defined since one can prove the following Lemmas:

LEMMA 135. *R is reflexive and symmetric.*

LEMMA 136. *For any α , $\{i \mid i \vdash \alpha\}$ is a proposition of the orthoframe $\langle I, R \rangle$.*

LEMMA 137. *For any α , $\{i \mid i \vdash \alpha\} \subseteq \{i \mid i \vdash \neg \alpha\}'$.*

Further, one can prove

LEMMA 138. *For any α , $v(\alpha) = \langle v_1(\alpha), v_0(\alpha) \rangle$, where:*

$$\begin{aligned} v_1(\alpha) &= \{i \mid i \vdash \alpha\} \\ v_0(\alpha) &= \{i \mid i \vdash \neg \alpha\} \end{aligned}$$

LEMMA 139. *For any formula α :*

$$\mathbf{0} := \langle \emptyset, I \rangle = \langle \{i \mid i \vdash L\alpha \wedge \neg L\alpha\}, \{i \mid i \vdash \neg(L\alpha \wedge \neg L\alpha)\} \rangle .$$

LEMMA 140. *Let $T = \{\alpha_1, \dots, \alpha_n, \dots\}$ be a set of formulas and let α be any formula.*

$$\bigcap \{v_1(\alpha_n) \mid \alpha_n \in T\} \subseteq v_1(\alpha) \curvearrowright L\alpha_1, \dots, L\alpha_n, \dots \vdash \alpha .$$

As a consequence, one can prove:

LEMMA 141. *Lemma of the canonical model*

$$T \models_{\mathcal{O}} \alpha \curvearrowright T \vdash \alpha .$$

Suppose $T \models_{\mathcal{O}} \alpha$. Hence (by definition of consequence in a given realization): for any orthopairproposition $\langle A_1, A_0 \rangle \in \Omega$, if for all $\alpha_n \in T$, $\langle A_1, A_0 \rangle \sqsubseteq v(\alpha_n)$, then $\langle A_1, A_0 \rangle \sqsubseteq v(\alpha)$.

The propositional lattice, consisting of all orthopairpropositions of \mathcal{O} is complete (see Theorem 132). Hence: $\prod_n \{v(\alpha_n) \mid \alpha_n \in T\} \sqsubseteq v(\alpha)$. In other words, by definition of \sqsubseteq :

- (i) $\bigcap \{v_1(\alpha_n) \mid \alpha_n \in T\} \subseteq v_1(\alpha)$;
- (ii) $v_0(\alpha) \subseteq \bigsqcup \{v_0(\alpha_n) \mid \alpha_n \in T\}$.

Thus, by (i) and by Lemma 140: $L\alpha_1, \dots, L\alpha_n, \dots \vdash \alpha$. Consequently, there exists a finite subset $\{\alpha_{n_1}, \dots, \alpha_{n_k}\}$ of T such that $L\alpha_{n_1} \wedge \dots \wedge L\alpha_{n_k} \vdash \alpha$. Hence, by the rules for \wedge and L : $L(\alpha_{n_1} \wedge \dots \wedge \alpha_{n_k}) \vdash \alpha$.

At the same time, we obtain from (ii) and by Lemma 138: $v_1(\neg\alpha) \sqsubseteq \bigsqcup\{v_1(\neg\alpha_n) \mid \alpha_n \in T\}$.

Whence, by de Morgan,

$$v_1(\neg\alpha) \subseteq \left[\bigcap \{(v_1(\neg\alpha_n))' \mid \alpha_n \in T\} \right]' .$$

Now, one can easily check that in any realization: $v_1(\neg\alpha)' = v_1(M\alpha)$. As a consequence: $v_1(\neg\alpha) \subseteq [\bigcap\{v_1(M\alpha_n) \mid \alpha_n \in T\}]'$. Hence, by contraposition:

$$\bigcap\{v_1(M\alpha_n) \mid \alpha_n \in T\} \subseteq (v_1(\neg\alpha))'$$

and

$$\bigcap\{v_1(M\alpha_n) \mid \alpha_n \in T\} \subseteq v_1(M\alpha).$$

Consequently, by Lemma 140 and by the S_5 -rules:

$$LM\alpha_1, \dots, LM\alpha_n, \dots \vdash M\alpha, \quad M\alpha_1, \dots, M\alpha_n, \dots \vdash M\alpha.$$

By syntactical compactness, there exists a finite subset $\{\alpha_{m_1}, \dots, \alpha_{m_h}\}$ of T such that $M\alpha_{m_1}, \dots, M\alpha_{m_h} \vdash M\alpha$. Whence, by the rules for \wedge and M : $M(\alpha_{m_1} \wedge \dots \wedge \alpha_{m_h}) \vdash M\alpha$. Let us put $\gamma_1 = \alpha_{n_1} \wedge \dots \wedge \alpha_{n_k}$ and $\gamma_2 = \alpha_{m_1} \wedge \dots \wedge \alpha_{m_h}$. We have obtained: $L\gamma_1 \vdash \alpha$ and $M\gamma_2 \vdash M\alpha$. Whence, $L\gamma_1 \wedge L\gamma_2 \vdash \alpha$, $L(\gamma_1 \wedge \gamma_2) \vdash \alpha$, $M\gamma_1 \wedge M\gamma_2 \vdash M\alpha$, $M(\gamma_1 \wedge \gamma_2) \vdash M\alpha$. From $L(\gamma_1 \wedge \gamma_2) \vdash \alpha$, and $M(\gamma_1 \wedge \gamma_2) \vdash M\alpha$ we obtain, by the derivable rule (DR1): $\gamma_1 \wedge \gamma_2 \vdash \alpha$. Consequently: $T \vdash \alpha$. \blacksquare

Similarly to other forms of quantum logic, also \mathbf{BZL}^3 admits an algebraic semantic characterization [Giuntini, 1993] based on the notion of \mathbf{BZ}^3 -lattice.

DEFINITION 142. A \mathbf{BZ}^3 -lattice is a \mathbf{BZ} -lattice $\mathcal{B} = \langle B, \sqsubseteq, ', \sim, \mathbf{1}, \mathbf{0} \rangle$, which satisfies the following conditions:

- (i) $(a \sqcap b) \sim = a \sim \sqcup b \sim$;
- (ii) $a \sqcap b \sim \sim \sqsubseteq a' \sim \sqcup b$.

By Theorem 132, the set of all orthopairpropositions of an orthoframe determines a complete \mathbf{BZ}^3 -lattice. One can prove the following representation theorem:

THEOREM 143. *Every \mathbf{BZ}^3 -lattice is embeddable into the (complete) \mathbf{BZ}^3 -lattice of all orthopairpropositions of an orthoframe.*

A slight modification of the proof of Theorem 17 permits us to show that ortho-pair semantics and the algebraic semantics strongly characterize the same logic.

One can prove that \mathbf{BZL}^3 can be also characterized by means of a non standard version of Kripkean semantics [Giuntini, 1993].

Some problems concerning the Brouwer-Zadeh logics remain still open:

- 1) Is there any Kripkean characterization of the logic that is algebraically characterized by the class of all de Morgan **BZ**-lattices (i.e. **BZ**-lattices satisfying condition (i) of Definition 142)? In this framework, the problem can be reformulated in this way: is the (strong) de Morgan law elementary?
- 2) Is it possible to axiomatize a logic based on an infinite many-valued generalization of the ortho-pair semantics?
- 3) Find possible conditional connectives in **BZL**³.
- 4) Find an appropriate orthomodular extension of **BZL**³.

Unsharp quantum models for **BZL³**

The ortho-pair semantics has been suggested by the effect-structures in Hilbert-space QT. In this framework, natural quantum ortho-pair realizations for **BZL**³ can be constructed. Let us refer again to the language \mathcal{L}^Q (whose atoms express possible measurement reports) and let \mathcal{S} be a quantum system whose associated Hilbert space is \mathcal{H} . As usual, $E(\mathcal{H})$ will represent the set of all effects of \mathcal{H} . Now, an ortho-pair realization $\mathcal{M}^{\mathcal{S}} = \langle I, R, \Omega, v \rangle$ (for the system \mathcal{S}) can be defined as follows:

- (i) I is the set of all pure states of \mathcal{S} in \mathcal{H} .
- (ii) Rij iff for any effect $E \in E(\mathcal{H})$ the following condition holds: whenever i assigns to E probability 1, then j assigns to E a probability different from 0.
In other words, i and j are accessible iff they cannot be strongly distinguished by any physical property represented by an effect.
- (iii) The propositions of the orthoframe $\langle I, R \rangle$ are determined by the set of all closed subspaces of \mathcal{H} (sharp properties), like in **OQL**.
- (iv) Ω is the set of all orthopairpropositions of $\langle I, R \rangle$. Any effect E can be transformed into an orthopairproposition $f(E) := \langle X_1^E, X_0^E \rangle$ of Ω , where:

$$X_1^E := \{i \mid i \text{ assigns to } E \text{ probability } 1\};$$

$$X_0^E := \{i \mid i \text{ assigns to } E \text{ probability } 0\}.$$

In other words, X_1^E, X_0^E represent the positive and the negative domain of E , respectively. The map f turns out to preserve the order relation and the two complements:

$$E \sqsubseteq F \text{ iff } f(E) \sqsubseteq f(F).$$

$$f(E') = f(E)^{\odot} = \langle X_1^E, X_0^E \rangle^{\odot} = \langle X_0^E, X_1^E \rangle.$$

$$f(E^{\sim}) = f(E)^{\ominus} = \langle X_1^E, X_0^E \rangle^{\ominus} = \langle X_0^E, (X_0^E)' \rangle.$$

- (v) The valuation-function v follows the intuitive physical meaning of the atomic sentences. Let p express the assertion “the value for the observable A lies in the sharp (or fuzzy) Borel set Δ ” and let E^p be the effect that is associated to p in \mathcal{H} . We define v as follows:

$$v(p) = f(E^p) = \langle X_1^{E^p}, X_0^{E^p} \rangle.$$

It is worthwhile to notice that our map f is not injective: different effects will be transformed into one and the same orthopairproposition. As a consequence, moving from effects to orthopairpropositions clearly determines a loss of information. In fact, orthopairpropositions are only concerned with the two extreme probability value $(0,1)$, a situation that corresponds to a three-valued semantics.

15 PARTIAL QUANTUM LOGICS

In Section 12, we have considered examples of partial algebraic structures, where the basic operations are not always defined. How to give a semantic characterization for different forms of quantum logic, corresponding respectively to the class of all effect algebras, of all orthoalgebras and of all orthomodular posets? We will call these logics: *unsharp partial quantum logic* (**UPaQL**), *weak partial quantum logic* (**WPaQL**) and *strong partial quantum logic* (**SPaQL**).

Let us first consider the case of **UPaQL**, that represents the “logic of effect algebras” [Dalla Chiara and Giuntini, 1995].

The language of **UPaQL** consists of a denumerably infinite list of atomic sentences and of two primitive connectives: the *negation* \neg and the *exclusive disjunction* Ψ (aut).

The set of sentences is defined in the usual way. A *conjunction* is metalinguistically defined, via de Morgan law:

$$\alpha \wedge \beta := \neg(\neg\alpha \Psi \neg\beta).$$

The intuitive idea underlying our semantics for **UPaQL** is the following: disjunctions and conjunctions are always considered “legitimate” from a mere linguistic point of view. However, semantically, a disjunction $\alpha \Psi \beta$ will have the intended meaning only in the “well behaved cases” (where the values of α and β are orthogonal in the corresponding effect orthoalgebra). Otherwise, $\alpha \Psi \beta$ will have any meaning whatsoever (generally not connected with the meanings of α and β). As is well known, a similar semantic “trick” is used in some classical treatments of the description operator ι (“the unique individual satisfying a given property”; for instance, “the present king of Italy”).

DEFINITION 144. A *realization* for **UPaQL** is a pair $\mathcal{A} = \langle \mathcal{B}, v \rangle$, where $\mathcal{B} = \langle B, \boxplus, \mathbf{1}, \mathbf{0} \rangle$ is an effect algebra (see Definition 115); v (the valuation-function) associates to any formula α an element of B , satisfying the following conditions:

(i) $v(\neg\beta) = v(\beta)'$, where $'$ is the generalized complement (defined in \mathcal{B}).

(ii)

$$v(\beta \Psi \gamma) = \begin{cases} v(\beta) \boxplus v(\gamma), & \text{if } v(\beta) \boxplus v(\gamma) \text{ is defined in } \mathcal{B}; \\ \text{any element,} & \text{otherwise.} \end{cases}$$

The other semantic definitions (truth, consequence in a given realization, logical truth, logical consequence) are given like in the **QL**-case.

Weak partial quantum logic (**WPaQL**) and strong partial quantum logic (**SPaQL**) (formalized in the same language as **UPaQL**) will be naturally characterized *mutatis mutandis*. It will be sufficient to replace, in the definition of realization, the notion of effect algebra with the notion of orthoalgebra and of orthomodular poset (see Definition 117 and Definition 110). Of course, **UPaQL** is weaker than **WPaQL**, which is, in turn, weaker than **SPaQL**.

Partial quantum logics are axiomatizable. We will first present a calculus for **UPaQL**, which is obtained as a natural transformation of the calculus for orthologic.

Differently from **QL**, the rules of our calculus will always have the form:

$$\frac{\alpha_1 \vdash \beta_1, \dots, \alpha_n \vdash \beta_n}{\alpha \vdash \beta}$$

In other words, we will consider only inferences from single formulas.

Rules of UPaQL

(UPa1) $\alpha \vdash \alpha$ (identity)

(UPa2) $\frac{\alpha \vdash \beta \quad \beta \vdash \gamma}{\alpha \vdash \gamma}$ (transitivity)

(UPa3) $\alpha \vdash \neg\neg\alpha$ (weak double negation)

$$(UPa4) \quad \neg\neg\alpha \vdash \alpha \quad (\text{strong double negation})$$

$$(UPa5) \quad \frac{\alpha \vdash \beta}{\neg\beta \vdash \neg\alpha} \quad (\text{contraposition})$$

$$(UPa6) \quad \beta \vdash \alpha \vee \neg\alpha \quad (\text{excluded middle})$$

$$(UPa7) \quad \frac{\alpha \vdash \neg\beta \quad \alpha \vee \neg\alpha \vdash \alpha \vee \beta}{\neg\alpha \vdash \beta} \quad (\text{unicity of negation})$$

$$(UPa8) \quad \frac{\alpha \vdash \neg\beta \quad \alpha \vdash \alpha_1 \quad \alpha_1 \vdash \alpha \quad \beta \vdash \beta_1 \quad \beta_1 \vdash \beta}{\alpha \vee \beta \vdash \alpha_1 \vee \beta_1} \quad (\text{weak substitutivity})$$

$$(UPa9) \quad \frac{\alpha \vdash \neg\beta}{\alpha \vee \beta \vdash \beta \vee \alpha} \quad (\text{weak commutativity})$$

$$(UPa10) \quad \frac{\beta \vdash \neg\gamma \quad \alpha \vdash \neg(\beta \vee \gamma)}{\alpha \vdash \neg\beta} \quad (\text{weak associativity})$$

$$(UPa11) \quad \frac{\beta \vdash \neg\gamma \quad \alpha \vdash \neg(\beta \vee \gamma)}{\alpha \vee \beta \vdash \neg\gamma} \quad (\text{weak associativity})$$

$$(UPa12) \quad \frac{\beta \vdash \neg\gamma \quad \alpha \vdash \neg(\beta \vee \gamma)}{\alpha \vee (\beta \vee \gamma) \vdash (\alpha \vee \beta) \vee \gamma} \quad (\text{weak associativity})$$

$$(UPa13) \quad \frac{\beta \vdash \neg\gamma \quad \alpha \vdash \neg(\beta \vee \gamma)}{(\alpha \vee \beta) \vee \gamma \vdash \alpha \vee (\beta \vee \gamma)} \quad (\text{weak associativity})$$

The concepts of *derivation* and of *derivability* are defined in the expected way. In order to axiomatize weak partial quantum logic (**WPaQL**) it is sufficient to add a rule, which corresponds to a *Duns Scotus-principle*:

$$(WPaQL) \quad \frac{\alpha \vdash \neg\alpha}{\alpha \vdash \beta} \quad (\text{Duns Scotus})$$

Clearly, the Duns Scotus-rule corresponds to the strong consistency condition in our definition of orthoalgebra (see Definition 117). In other words, differently from **UPaQL**, the logic **WPaQL** forbids paraconsistent situations.

Finally, an axiomatization of strong partial quantum logic (**SPaQL**) can be obtained, by adding the following rule to (UPa1)-(UPa13), (WPa):

$$(SPaQL) \quad \frac{\alpha \vdash \neg\beta \quad \alpha \vdash \gamma \quad \beta \vdash \gamma}{\alpha \vee \beta \vdash \gamma}$$

In other words, (SPaQL) requires that the disjunction \vee behaves like a supremum, whenever it has the “right meaning”.

Let **PaQL** represent any instance of our three calculi. We will use the following abbreviations. Instead of $\alpha \vdash_{\text{PaQL}} \beta$ we will write $\alpha \vdash \beta$. When α and β are logically equivalent ($\alpha \vdash \beta$ and $\beta \vdash \alpha$) we will write $\alpha \equiv \beta$.

Let p represent a particular sentential literal of the language: **T** will be an abbreviation for $p \vee \neg p$; while **F** will be an abbreviation for $\neg(p \vee \neg p)$.

Some important derivable rules of all calculi are the following:

$$(D1) \quad \mathbf{F} \vdash \beta, \beta \vdash \mathbf{T} \quad (\text{Weak Duns Scotus})$$

$$(D2) \quad \frac{\alpha \vdash \neg\beta}{\alpha \vdash \alpha \vee \beta} \quad (\text{weak sup rule})$$

$$(D3) \quad \frac{\alpha \vdash \beta}{\beta \equiv \alpha \vee \neg(\alpha \vee \neg\beta)} \quad (\text{orthomodular-like rule})$$

$$(D4) \quad \frac{\alpha \vdash \neg\gamma \quad \beta \vdash \neg\gamma \quad \alpha \vee \gamma \equiv \beta \vee \gamma}{\alpha \equiv \beta} \quad (\text{cancellation})$$

As a consequence, the following syntactical lemma holds:

LEMMA 145. *For any α, β : $\alpha \vdash \beta$ iff there exists a formula γ such that*

- (i) $\alpha \vdash \neg\gamma$;
- (ii) $\beta \equiv \alpha \vee \gamma$.

In other words, the logical implication behaves similarly to the partial order relation in the effect algebras.

The following derivable rule holds for **WPaQL** and for **SPaQL**:

$$(D5) \quad \frac{\alpha \vdash \neg\beta \quad \alpha \vdash \gamma \quad \beta \vdash \gamma \quad \gamma \vdash \alpha \vee \beta}{\alpha \vee \beta \vdash \gamma}$$

Our calculi turn out to be adequate with respect to the corresponding semantic characterizations. Soundness proofs are straightforward. Let us sketch the proof of the completeness theorem for our weakest calculus (**UP-aQL**).

THEOREM 146. *Completeness.*

$$\alpha \models \beta \quad \curvearrowright \quad \alpha \vdash \beta.$$

Proof. Following the usual procedure, it is sufficient to construct a canonical model $\mathcal{A} = \langle \mathcal{B}, v \rangle$ such that for any formulas α, β :

$$\alpha \vdash \beta \quad \curvearrowright \quad \alpha \models_{\mathcal{A}} \beta.$$

Definition of the canonical model.

- (i) The algebra $\mathcal{B} = \langle B, \boxplus, \mathbf{1}, \mathbf{0} \rangle$ is determined as follows:
 - (ia) B is the class of all equivalence classes of logically equivalent formulas: $B := \{[\alpha]_{\equiv} \mid \alpha \text{ is a formula}\}$. (In the following, we will write $[\alpha]$ instead of $[\alpha]_{\equiv}$).
 - (ib) $[\alpha] \boxplus [\beta]$ is defined iff $\alpha \vdash \neg\beta$. If defined, $[\alpha] \boxplus [\beta] := [\alpha \vee \beta]$.
 - (ic) $\mathbf{1} := [\mathbf{T}]$; $\mathbf{0} := [\mathbf{F}]$.
- (ii) The valuation function v is defined as follows: $v(\alpha) = [\alpha]$.

One can easily check that \mathcal{A} is a “good” model for our logic. The operation \boxplus is well defined (by the transitivity, contraposition and weak substitutivity rules). Further, \mathcal{B} is an effect algebra: \boxplus is weakly commutative and weakly associative, because of the corresponding rules of our calculus. The strong excluded middle axiom holds by definition of \boxplus and in virtue of the following rules: excluded middle, unicity of negation, double negation. Finally, the weak consistency axiom holds by weak Duns Scotus (D1) and by definition of \boxplus .

LEMMA 147. *Lemma of the canonical model*

$$[\alpha] \sqsubseteq [\beta] \quad \text{iff} \quad \alpha \vdash \beta.$$

Sketch of the proof. By definition of \sqsubseteq (in any effect algebra) one has to prove:

$$\alpha \vdash \beta \quad \text{iff} \quad \text{for a given } \gamma \text{ such that } [\alpha] \perp [\gamma] : [\alpha] \boxplus [\gamma] = [\beta].$$

This equivalence holds by Lemma 145 and by definition of \boxplus .

Finally, let us check that v is a “good” valuation function. In other words:

- (i) $v(\neg\beta) = v(\beta)'$
- (ii) $v(\beta \vee \gamma) = v(\beta) \boxplus v(\gamma)$, if $v(\beta) \boxplus v(\gamma)$ is defined.

(i) By definition of v , we have to show that $[\neg\beta]$ is the unique $[\gamma]$ such that $[\beta] \boxplus [\gamma] = \mathbf{1} := [\mathbf{T}]$. In other words,

- (ia) $[\mathbf{T}] \sqsubseteq [\beta] \boxplus [\neg\beta]$.
- (ib) $[\mathbf{T}] \sqsubseteq [\beta] \boxplus [\gamma] \iff \neg\beta \equiv \gamma$.

This holds by definition of the canonical model, by definition of \boxplus and by the following rules: double negation, excluded middle, unicity of negation.

(ii) Suppose $v(\beta) \boxplus v(\gamma)$ is defined. Then $\beta \vdash \neg\gamma$. Hence, by definition of \boxplus and of v : $v(\beta) \boxplus v(\gamma) = [\beta] \boxplus [\gamma] = [\beta \vee \gamma] = v(\beta \vee \gamma)$.

As a consequence, we obtain:

$$\alpha \vdash \beta \iff [\alpha] \sqsubseteq [\beta] \iff v(\alpha) \sqsubseteq v(\beta) \iff \alpha \models_{\mathcal{A}} \beta$$

■

The completeness argument can be easily transformed, *mutatis mutandis* for the case of weak and strong partial quantum logic.

16 LUKASIEWICZ QUANTUM LOGIC

As we have seen in Section 12, the class $E(\mathcal{H})$ of all effects on a Hilbert space \mathcal{H} determines a quasi-linear QMV-algebra. The theory of QMV-algebras suggests, in a natural way, the semantic characterization of a new form of quantum logic (called *Lukasiewicz quantum logic* (**LQL**)), which generalizes both **OQL** and **L_N**.

The language of **LQL** contains the same primitive connectives as **WPaQL** (\vee, \neg). The conjunction (\wedge) is defined via de Morgan law (like in **WPaQL**). Further, a new pair of conjunction (\boxtimes) and disjunction (\boxvee) connectives are defined as follows:

$$\alpha \boxtimes \beta := (\alpha \vee \neg\beta) \wedge \beta$$

$$\alpha \boxvee \beta := \neg(\neg\alpha \boxtimes \neg\beta)$$

DEFINITION 148. A *realization* for **LQL** is a pair $\mathcal{A} = \langle \mathcal{M}, v \rangle$, where

- (i) $\mathcal{M} = \langle M, \oplus, *, \mathbf{1}, \mathbf{0} \rangle$ is a QMV-algebra.
- (ii) v (the valuation-function) associates to any formula α an element of M , satisfying the following conditions:

$$v(\neg\beta) = v(\beta)^*.$$

$$v(\beta \forall \gamma) = v(\beta) \oplus v(\gamma).$$

The other semantic definitions (truth, consequence in a given realization, logical truth, logical consequence) are given like in the **QL**-case.

LQL can be easily axiomatized by means of a calculus that simply mimics the axioms of QMV-algebras.

The quasi-linearity property, which is satisfied by the QMV-algebras of effects, is highly non equational. Thus, the following question naturally arises: is **LQL** characterized by the class of all quasi-linear QMV-algebras (QLQMV)? In the case of $\mathbf{L}_\mathbb{N}$, Chang has proved that $\mathbf{L}_\mathbb{N}$ is characterized by the MV-algebra determined by the real interval $[0, 1]$. This MV-algebra is clearly quasi-linear, being totally ordered.

The relation between **LQL** and QMV algebras turns out to be much more complicated. In fact one can show that **LQL** cannot be characterized even by the class of all *weakly linear* QMV-algebras (WLQMV). Since WLQMV is strictly contained in QLQMV, there follows that **LQL** is not characterized by QLQMV. To obtain these results, something stronger is proved. In particular, we can show that:

- the variety of all QMV-algebras (\mathcal{QMV}) strictly includes the variety generated by the class of all weakly linear QMV-algebras ($\mathbb{HSP}(\text{WLQMV})$).
- $\mathbb{HSP}(\text{WLQMV})$ strictly includes the variety generated by the class of all quasi-linear QMV-algebras ($\mathbb{HSP}(\text{QLQMV})$).

So far, little is known about the axiomatizability of the logic based on $\mathbb{HSP}(\text{QLQMV})$. In the case of $\mathbb{HSP}(\text{WLQMV})$, instead, one can prove that this variety is generated by the QMV-axioms together with the following axiom:

$$a = (a \oplus c \odot b^*) \text{ \textcircled{ \& } } (a \oplus c^* \odot b).$$

The problem of the axiomatizability of the logic based on $\mathbb{HSP}(\text{QLQMV})$ is complicated by the fact that not every (quasi-linear) QMV-algebra $\mathcal{M} = \langle M, \oplus, *, \mathbf{1}, \mathbf{0} \rangle$ admits of a “good polynomial conditional”, i.e., a polynomial binary operation \circ such that

$$a \circ b = 1 \text{ iff } a \preceq b.$$

Thus, it might happen that the notion of logical truth of the logic based on $\mathbb{HSP}(\text{QLQMV})$ is (finitely) axiomatizable, while the notion of “logical entailment” ($\alpha \models \beta$) is not.

We will now show that the QMV-algebra \mathcal{M}_4 (see Figure 7 below) does not admit any good polynomial conditional. The operations of \mathcal{M}_4 are

defined as follows:

		\oplus
0	0	0
0	<i>a</i>	<i>a</i>
0	<i>b</i>	<i>b</i>
0	1	1
<i>a</i>	0	<i>a</i>
<i>a</i>	<i>a</i>	1
<i>a</i>	<i>b</i>	1
<i>a</i>	1	1
<i>b</i>	0	<i>b</i>
<i>b</i>	<i>b</i>	1
<i>b</i>	<i>a</i>	1
<i>b</i>	1	1
1	0	1
1	<i>a</i>	1
1	<i>b</i>	1
1	1	1

	*
0	1
<i>a</i>	<i>a</i>
<i>b</i>	<i>b</i>
1	0

Figure 7. \mathcal{M}_4

Let us consider the three-valued MV-algebra \mathcal{M}_3 , whose operations are

Figure 8. \mathcal{M}_3

defined as follows:

		\oplus
0	0	0
0	$\frac{1}{2}$	$\frac{1}{2}$
0	1	1
$\frac{1}{2}$	0	$\frac{1}{2}$
$\frac{1}{2}$	$\frac{1}{2}$	1
$\frac{1}{2}$	1	1
1	0	1
1	$\frac{1}{2}$	1
1	1	1

	*
0	1
$\frac{1}{2}$	$\frac{1}{2}$
1	0

It is easy to see that the map $h : \mathcal{M}_4 \rightarrow \mathcal{M}_3$ such that $\forall x \in \mathcal{M}_4$

$$h(x) := \begin{cases} 0, & \text{if } x = 0; \\ \frac{1}{2}, & \text{if } x = a \text{ or } x = b; \\ 1, & \text{otherwise} \end{cases}$$

is a homomorphism of \mathcal{M}_4 into \mathcal{M}_3 .

Suppose, by contradiction, that \mathcal{M}_4 admits of a good polynomial conditional $\rightarrow_{\mathcal{M}_4}$. Since $a \not\leq b$, we have $h(a \rightarrow_{\mathcal{M}_4} b) \neq 1$. Thus,

$$1 \neq h(a \rightarrow_{\mathcal{M}_4} b) = h(a) \rightarrow_{\mathcal{M}_3} h(b) = \frac{1}{2} \rightarrow_{\mathcal{M}_3} \frac{1}{2} = 1,$$

contradiction.

17 QUANTUM LOGIC AND THE CUBE OF LOGICS
(BY GIULIA BATTILOTTI AND CLAUDIA FAGGIAN)

Different forms of quantum logic can be axiomatized as sequent calculi [Dummett, 1976; Nishimura, 1980; Cutland and Gibbins, 1982; Tamura, 1988; Nishimura, 1994]. This permits us to investigate such logics more and more deeply from the proof-theoretical point of view. A sequent calculus for orthologic can be obtained from a calculus for classical logic, by requiring a special restriction on *contexts* in the rules that would permit to derive the distributive laws. The critical rules are the following: the introduction of disjunction on the left side, the introduction of conjunction on the right side, the rules concerning implication and negation. Such a restriction, however, determines some serious proof-theoretical difficulties, because quantum logic has a sufficiently strong negation that satisfies de Morgan's laws. The shortcoming becomes apparent when we try to prove the cornerstone result, represented by a cut-elimination theorem (which, essentially depends on the formulation of the rules that appear in our proofs).

A simple and compact sequent calculus for orthologic [Faggian and Sambin, 1997; Battilotti and Sambin, 1999], which admits cut-elimination by means of a neat procedure, can be obtained by a convenient strengthening of *basic logic*. This is a new logic that has been introduced in order to investigate a general structure for the space of logics [Sambin *et al.*, 1998].

In the framework of basic logic, constraints on contexts are not considered a limitation; on the contrary, they are regarded as a positive feature, which is called *visibility*. At the same time, negation is treated by exploiting the symmetry of the calculus: the main idea is to use Girard's linear negation, which can be interpreted as an orthocomplement in a quite natural way. This approach shows that orthologic (and non-distributive logics, in general) admits a proof-theory, which turns out to be simpler than the proof-theory for classical logic. Describing quantum logic in the framework of a uniform and general setting gives many advantages, since it permits us to study various logics and their mutual relations. In particular, we obtain a whole system of quantum logics (including *linear orthologic*); and for each of these logics we have a proof of the cut-elimination theorem. All this gives rise to a new formulation of classical logic [Faggian, 1997], with respect to which orthologic and the other quantum-like logics (created by this method) turn out to be characterizable as *substructural logics*. On this basis it is easy to compare different logics, and to prove embedding results [Battilotti, 1998].

Basic logic and the cube of logics.

As we already know, quantum logic represents a weakening of classical logic, obtained by dropping the distributive laws. There are at least two other important logics that are weaker than classical logic: intuitionistic logic and linear logic [Girard, 1987]. The situation can be sketched as pictured in Figure 9.

Figure 9. The most important weakenings of classical logic

It is natural to ask whether there exists a logic that represents a kind of common denominator for **Q**, **I** and **L**, in the same way as classical logic theoretically includes all the other logics. A solution to this problem has been found in terms of a suitable sequent calculus **B**, that represents a *basic logic*.

Differently from the calculi we have considered in the previous sections, a *sequent calculus* for a given logic **L** is based on *axioms* and *rules* that govern the behaviour of *sequents*. Any sequent has the form

$$M \vdash N$$

where M, N are (possibly empty) finite multisets of formulas.¹⁴ Axioms are particular sequents. Any rule has the form

$$\frac{M_1 \vdash N_1 \quad \dots \quad M_n \vdash N_n}{M \vdash N}$$

where $M_1 \vdash N_1, \dots, M_n \vdash N_n$ are the *premisses*, while $M \vdash N$ is the *conclusion* of the rule. Rules can be *structural* or *operational*. Operational rules introduce a new connective, while structural rules deal only with the structure of the sequents (orders, repetitions, etc.).

A *derivation* is a sequence of sequents where any element is either an axiom or the conclusion of a rule whose premisses are previous elements of the sequence.

Basic logic has been introduced in [Battilotti and Sambin, 1999], and substantially reformulated in [Sambin *et al.*, 1998]. According to the sec-

¹⁴A *multiset* is a set of pairs such that the first element of every pair denotes any object, while the second element denotes the multiplicity of the occurrences of our object. Two multisets are equal if and only if all their pairs are equal, that is all their objects together with their multiplicities are equal.

ond formulation (we will follow here),¹⁵ our logic is characterized by three strictly linked principles: *reflection*, *symmetry*, *visibility*. The reflection principle states the fact that logical constants are the result of importing into a formal system metalinguistic links between assertions, considered pre-existing. There is a method that leads to the rules of the calculus, starting from metalinguistic links between assertions. Such a method analyses the following equivalences, which assert a correspondence between language and metalanguage:

$$M \vdash \alpha \cdot \beta \quad \text{if and only if} \quad M \vdash \alpha \circ_R \beta$$

$$\alpha \cdot \beta \vdash N \quad \text{if and only if} \quad \alpha \circ_L \beta \vdash N$$

Here the generic sign “.”, corresponding to a metalinguistic link between assertions, is translated respectively into the connective \circ_R , when it appears on the right of the sign \vdash , and into the connective \circ_L , when it appears on the left. In **B**, the operational rules are completely determined by such equivalences. As a consequence, the meaning of a connective turns out to be semantically determined by the correspondence with a metalinguistic link, quite independently of any link with a context. Since every metalinguistic link is translated into a connective according to two specular ways, the system of rules, obtained by this method, turns out to be strongly symmetric. In fact **B** contains, for every axiom and for every (unary or binary) rule R

$$\frac{M_i \vdash N_i}{M \vdash N} R$$

its symmetric rule R^s , given by

$$\frac{N_i^s \vdash M_i^s}{N^s \vdash M^s} R^s$$

where the map $(-)^s$ is defined by induction (on the length of formulas), by putting $\circ_R^s \equiv \circ_L$ and $\circ_L^s \equiv \circ_R$, given a suitable correspondence between propositional variables.

The third principle that **B** satisfies is the visibility property. A rule for a given connective is called *visible* when the principal formula and the corresponding *secondary formulas* appear in the rule without any context.¹⁶

¹⁵The formulation of the rules of **B** presented in [Sambin *et al.*, 1998] is based on finite lists rather than finite multisets of formulas; hence it contains in addition the structural rule of exchange. Here we prefer to use multisets, in order to obtain an easy comparison with sequent calculi for quantum logics.

¹⁶In any operational rule, the formula in the conclusion that contains the connective introduced by the rule itself is called the *principal formula*; the formulas in the premisses that are the components of the formula introduced by the rule are called the *secondary formulas*.

We shall see below the syntactical consequences of visibility; we stress here that semantically it corresponds to the fact that basic connectives have a primitive meaning, in accordance with the reflection principle.

As an example let us refer to a rule that plays an important role in the case of quantum logic. As is well known, in classical logic, disjunction is introduced on the left according to the following rule:

$$\frac{M, \alpha \vdash N \quad M, \beta \vdash N}{M, \alpha \vee \beta \vdash N}$$

In the case of **B**, instead, disjunction is introduced according to the following visible form:

$$\frac{\alpha \vdash N \quad \beta \vdash N}{\alpha \vee \beta \vdash N}$$

where the context M has disappeared.

From the intuitive point of view, one can read the difference between the two cases as follows: the rule typical of classical logic attaches a meaning to the connective \vee in presence of the link “,” with M (such a link is to be interpreted as a conjunction), whereas the visible rule is intended to explain the meaning of the connective \vee by referring only to the connective itself. In particular, the visible rule does not permit us to prove the equation that links conjunction and disjunction (the distributive law of \wedge with respect to \vee). As a consequence, any sequent calculus for a quantum logic shall adopt the visible form for the rule that concerns the introduction of disjunction on the left. As to the other rules, visibility is not strictly necessary in order to obtain an adequate sequent calculus for quantum logic. However, a more convenient strategy permits us to axiomatize quantum logic, by adding only structural rules to basic logic, without any change in the rules for the connectives. In this way, we can preserve the characteristic properties of symmetry and visibility of **B**, that turn out to be highly convenient from the proof-theoretical point of view (as we will see below).

Basic logic **B** has no structural rules. As a consequence, **B** can be regarded as “the logic of connectives” from which various stronger logics can be obtained by adding suitable structural rules.

Let us now present the sequent calculus for **B**. Similarly to linear logic, the language of **B** contains two pairs of conjunctions and disjunctions: the *additive conjunction* \wedge and the *multiplicative conjunction* \otimes ; the *additive disjunction* \vee and the *multiplicative disjunction* \wp . Further there are two conditionals (\rightarrow , \leftarrow), and two pairs of propositional literals 1 and \top , 0 and \perp .

The basic sequent calculus B
Axioms

$$\alpha \vdash \alpha$$

Operational rules

(Formation)	$\frac{\beta, \alpha \vdash N}{\beta \otimes \alpha \vdash N} \otimes L$	$\frac{M \vdash \alpha, \beta}{M \vdash \alpha \wp \beta} \wp R$
(Reflection)	$\frac{\alpha \vdash N_1 \quad \beta \vdash N_2}{\alpha \wp \beta \vdash N_1, N_2} \wp L$	$\frac{M_2 \vdash \beta \quad M_1 \vdash \alpha}{M_2, M_1 \vdash \beta \otimes \alpha} \otimes R$
(Formation)	$\frac{\vdash N}{1 \vdash N} 1L$	$\frac{M \vdash}{M \vdash \perp} \perp R$
(Reflection)	$\perp \vdash \perp L$	$\vdash 1 \quad 1R$
(Formation)	$\frac{\beta \vdash N \quad \alpha \vdash N}{\beta \vee \alpha \vdash N} \vee L$	$\frac{M \vdash \alpha \quad M \vdash \beta}{M \vdash \alpha \wedge \beta} \wedge R$
(Reflection)	$\frac{\alpha \vdash N}{\alpha \wedge \beta \vdash N} \wedge L$	$\frac{M \vdash \beta}{M \vdash \beta \vee \alpha} \vee R$
(Formation)	$0 \vdash N \quad 0L$	$M \vdash \top \quad \top R$
(Formation)	$\frac{\beta \vdash \alpha}{\beta \leftarrow \alpha \vdash} \leftarrow L$	$\frac{\alpha \vdash \beta}{\vdash \alpha \rightarrow \beta} \rightarrow R$
(Reflection)	$\frac{\vdash \alpha \quad \beta \vdash N}{\alpha \rightarrow \beta \vdash N} \rightarrow L$	$\frac{M \vdash \beta \quad \alpha \vdash}{M \vdash \beta \leftarrow \alpha} \leftarrow R$
(Order)	$\frac{\alpha \vdash \beta \quad \gamma \vdash \delta}{\beta \rightarrow \gamma \vdash \alpha \rightarrow \delta} \rightarrow U$	$\frac{\gamma \vdash \delta \quad \alpha \vdash \beta}{\gamma \leftarrow \beta \vdash \delta \leftarrow \alpha} \leftarrow U$

We will distinguish three main kinds of structural rules, labelled by the letters **L**, **R** and **S**. The extensions of **B** obtained by the addition of any combination of such rules can be organized in a cube, which is conceived as an architecture whose basis is **B** (see Figure 9).

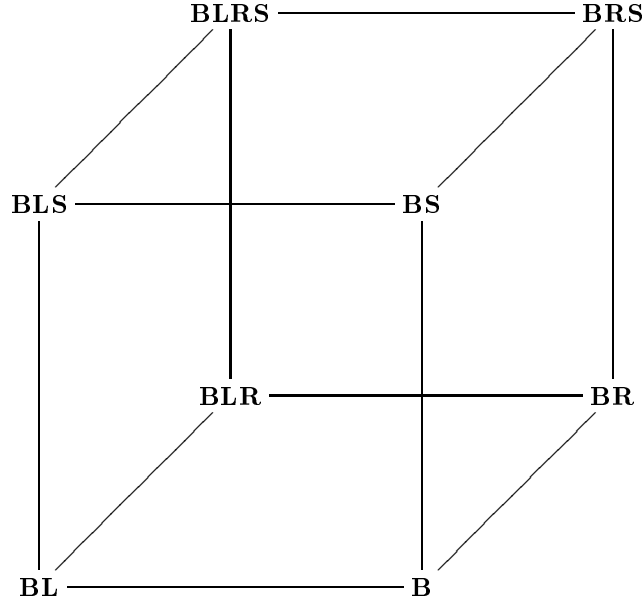

Figure 10. The cube of logics

In the cube, every logic with **S** satisfies the structural rules of weakening and contraction:¹⁷

$$\frac{M \vdash N}{M, O \vdash P, N} \textit{weakening} \quad \frac{M, O, O \vdash N, N, P}{M, O \vdash N, P} \textit{contraction}$$

Every logic with “**L**” allows left contexts in any inference rule; every logic with **R** allows right contexts in any inference rule. In particular, the cube solves our initial problem, sketched in Figure 11. In fact, vertex **BLRS**, opposed to **B** represents classical logic, vertex **BLR** and vertex **BLS** represent respectively Girard’s linear logic and intuitionistic logic; finally, vertex **BS** corresponds to paraconsistent quantum logic (see below). Moreover, since logics with **R** are simply the symmetric copy of logics with **L**, logics containing both **L** and **R** (**BLRS**, **BLR**) or logics containing neither **L** nor

¹⁷As we have seen, in **B** (as well as in linear logic) the connectives conjunction and disjunction are splitted into a *multiplicative* and an *additive* connective. Such a distinction depends on the fact that there are two ways of formulating contexts in any operational rule: this leads to a multiplicative and to an additive form for each rule. The multiplicative and additive formulation turn out to be equivalent, whenever the structural rules of weakening and contraction hold. Hence, the distinction plays an essential role in linear logic and a fortiori in basic logic (where weakening and contraction fail); at the same time, it vanishes in classical logic and in orthologic.

R (**BS**, **B**), are symmetric. The study of quantum logics finds place in the diagonal of symmetric logics, where a finer distinction of structural rules can be obtained.

Sequent calculus for Orthologic.

The logic **BS** is non-distributive. Let us consider the fragment of **BS** restricted to the connectives \wedge and \vee . If we want to obtain a quantum logic from it, what is still missing is an involutive negation, satisfying de Morgan.

This aim can be reached by extending the language and by adopting Girard's negation. The key point is to assume as primitive symbols of the language both the propositional variables and their duals. In other words, the propositional literals are assumed to be given in pairs, consisting of a positive element (written p) and of a negative one (written p^\perp). On this basis, the negation of a formula is defined as follows:

$$p^{\perp\perp} := p \quad (\alpha \wedge \beta)^\perp := \alpha^\perp \vee \beta^\perp \quad (\alpha \vee \beta)^\perp := \alpha^\perp \wedge \beta^\perp$$

By this choice, we obtain a calculus called *basic orthologic* and denoted by ${}^\perp\mathbf{BS}$ (where the symbol ${}^\perp$ reminds us that our calculus is applied to a dual language). Basic orthologic turns out to be equivalent to paraconsistent quantum logic (**PQL**). As we already know, **PQL** represents a weakening of orthologic, that is obtained by dropping the *non contradiction* and the *excluded middle* principles. Hence, in order to have a calculus for orthologic, it will be sufficient to add such principles to our ${}^\perp\mathbf{BS}$. This can be done by means of two new structural rules called *transfer*. The result is a calculus for orthologic, which will be denoted by ${}^\perp\mathbf{O}$.

The rules of ${}^\perp\mathbf{O}$ are the following (where (i) - (v) are the rules of ${}^\perp\mathbf{BS}$ ¹⁸ while (vi) express the *transfer* rules).

$$(i) \quad \alpha \vdash \alpha$$

$$(ii) \quad \frac{\alpha \vdash N \quad \beta \vdash N}{\alpha \vee \beta \vdash N} \vee L \qquad \frac{M \vdash \alpha \quad M \vdash \beta}{M \vdash \alpha \wedge \beta} \wedge R$$

$$(iii) \quad \frac{\alpha \vdash N}{\alpha \wedge \beta \vdash N} \quad \frac{\beta \vdash N}{\alpha \wedge \beta \vdash N} \wedge L \qquad \frac{M \vdash \alpha}{M \vdash \alpha \vee \beta} \quad \frac{M \vdash \beta}{M \vdash \alpha \vee \beta} \vee R$$

$$(iv) \quad \frac{M \vdash N}{M, O \vdash P, N} \textit{weakening}$$

¹⁸Note that, in ${}^\perp\mathbf{BS}$, weakening and contraction are redundant. In fact, one can show that such a calculus admits elimination of contraction. At the same time, weakening on the right and on the left can be simulated by $\wedge L$ and $\vee R$, respectively. On this basis, **PQL** turns out to admit a very simple formulation, given by (i), (ii), (iii).

$$(v) \quad \frac{M, O, O \vdash N, N, P}{M, O \vdash N, P} \text{ contraction}$$

$$(vi) \quad \frac{M \vdash N}{M, N^\perp \vdash} \text{ tr1} \qquad \frac{M \vdash N}{\vdash M^\perp, N} \text{ tr2}$$

It is not hard to prove:

THEOREM 149. $\perp\mathbf{BS}$ is a calculus for paraconsistent quantum logic.

THEOREM 150. $\perp\mathbf{O}$ is a calculus for orthologic.

As we have seen, our calculus $\perp\mathbf{O}$ contains both p, q, r, \dots and $p^\perp, q^\perp, r^\perp, \dots$. Moreover, for any rule of the calculus, the calculus shall contain also the symmetric one. As a consequence, whenever the calculus produces a derivation Π , it will also produce the dual derivation Π^\perp , obtained substituting every axiom $\alpha \vdash \alpha$ with the axiom $\alpha^\perp \vdash \alpha^\perp$ and every occurrence of a rule with an occurrence of its corresponding symmetric rule (e.g. $\wedge R$ with $\vee L$). On this basis there holds:

LEMMA 151. The following rule is derivable for $\perp\mathbf{O}$:

$$\frac{M \vdash N}{N^\perp \vdash M^\perp}$$

Sketch of the proof One can easily see that $M \vdash N$ is derivable by a derivation Π if and only if $N^\perp \vdash M^\perp$ is derivable by the symmetric derivation Π^\perp . ■

The structure of the calculus $\perp\mathbf{O}$ permits us to prove the following cut-elimination result.

THEOREM 152. $\perp\mathbf{O}$ admits the elimination of the cuts.

$$\frac{O \vdash \mu \quad M, \mu \vdash N}{M, O \vdash N} \text{ cutL} \qquad \frac{O \vdash \mu, P \quad \mu \vdash N}{O \vdash N, P} \text{ cutR}$$

Sketch of the proof Like in Gentzen, the cut-elimination procedure is obtained by induction on two parameters: the *degree* and the *rank* of the cut-formula¹⁹.

¹⁹Suppose a derivation and a sequent where a formula α occurs. Let us consider the *paths* (i.e. the sequences of consecutive sequents) connecting that point with the point where the formula α has been introduced, (by an axiom, or by weakening, or by an operational rule whose principal formula was α). The *rank* of this particular occurrence of α is the maximum among the lengths of all these paths. In other words, the rank represents the 'maximum length' between the formula-occurrence we are examining and the point where that occurrence has been introduced.

The *degree* (or *length*) of a formula α is the number of the connectives occurring in α .

The calculus $\perp\mathbf{O}$ permits us to overcome in a simple way two questions that usually make cut elimination for orthologic so complicated: (i) constraints on contexts and (ii) negation. We give a sketch of the proof, considering the two points. The first problem is solved by visibility, while the second one is solved by symmetry.

- (i) As we have seen, in any calculus for quantum logic the rule that introduces \vee on the left (here indicated with $\vee L$) must have an empty context on the left. Now consider, for a generic calculus, the derivation

$$\frac{\frac{\alpha \vdash \gamma \wedge \delta \quad \beta \vdash \gamma \wedge \delta}{\alpha \vee \beta \vdash \gamma \wedge \delta} \vee L \quad \frac{M, \gamma \vdash \Delta}{M, \gamma \wedge \delta \vdash \Delta} cutL}{M, \alpha \vee \beta \vdash \Delta} cutL$$

In this derivation, the cut-formula is principal on the right premiss; hence the right rank is 1. In such a situation, Gentzen's procedure to lower the rank must operate on the left; this would necessarily produce the two derivations

$$\frac{\alpha \vdash \gamma \wedge \delta \quad M, \gamma \wedge \delta \vdash \Delta}{M, \alpha \vdash \Delta} cutL \quad \frac{\beta \vdash \gamma \wedge \delta \quad M, \gamma \wedge \delta \vdash \Delta}{M, \beta \vdash \Delta} cutL$$

Now, one would like to conclude by applying $\vee L$, in order to obtain $M, \alpha \vee \beta \vdash \Delta$. However, this step is here not allowed, unless M is empty. Such a problem does not arise for the calculus $\perp\mathbf{O}$, because, by visibility, every principal formula has an empty context.

- (ii) In $\perp\mathbf{O}$ the only rules about negation are the structural rules of transfer. Let us consider a derivation of the form:

$$\frac{O \vdash \mu^\perp \quad \frac{\frac{\vdots \Pi}{M \vdash \mu} tr1}{M, \mu^\perp \vdash} cutL}{M, O \vdash} cutL$$

We can reduce the rank in a quick way, by exploiting symmetry. In fact, Girard's negation has the nice property that every formula α and its dual α^\perp have exactly the same degree. The same idea can be extended to derivations, and hence to the rank of a cut. As we have seen in Lemma 151, whenever we have a derivation Π for the sequent $M \vdash N$, we also have the dual derivation Π^\perp , which derives $N^\perp \vdash M^\perp$. The two derivations Π and Π^\perp have exactly the same (symmetrical) structure. Hence in particular, if μ is principal, μ^\perp is principal. If μ has rank r , then also μ^\perp will have the same rank r . In

Figure 11. The diagonal of the cube

such a situation, in order to raise the cut rule, we can substitute Π^\perp by Π (*flipping derivation*). As a consequence, the initial derivation will be simply reduced to:

$$\frac{\frac{O \vdash \mu^\perp \quad \mu^\perp \vdash M^\perp}{O \vdash M^\perp} \text{tr1} \quad \frac{\vdots \quad \Pi^\perp}{\text{cutL}}}{O, M \vdash} \text{tr1}$$

■

Quantum logics and classical logic

We will now consider the *symmetric diagonal* of the cube in the diagram in Figure 11. In our diagram, the calculus $\perp\mathbf{O}$ appears as an intermediate point between basic orthologic and classical logic. Similarly, we have another intermediate point between basic logic and linear logic: this is given by $\perp\mathbf{B} + \mathbf{tr}$, which represents the common denominator for orthologic and linear logic (we will call it “ortholinear logic” $\perp\mathbf{OL}$). In the same way, $\perp\mathbf{B}$ turns out to be the common denominator of basic orthologic and linear logic. On this basis, we obtain a whole system of quantum logics, which are all cut-free. The last of our logics, $\perp\mathbf{B} + \mathbf{tr}$, seems to be a good candidate in order to represent a *linear quantum logic* in the sense of Pratt [1993].

So far we have only dealt with a fragment of basic logic, which has no implication connective. By means of this linguistic restriction, we have easily proved the equivalence between our calculi and the usual formulations of paraconsistent quantum logic and of orthologic. However, the same methods can be naturally applied to the complete versions of our calculi, preserving cut-elimination and flipping of derivations. In this way, we will have a primitive implication connective \rightarrow (together with its dual \leftarrow) in all the logics we have considered. An interesting question to be investigated concerns the possibility of physical interpretations of such new connectives.

In the diagram above, we have still a question mark concerning the path from orthologic to classical logic. Our question can be solved as follows:

THEOREM 153. *A calculus for classical logic is obtained from a calculus for orthologic by adding a pair of structural rules, named separation:*

$$(vii) \quad \frac{M, O \vdash}{M \vdash O^\perp} \text{ sep1} \qquad \frac{\vdash N, P}{N^\perp \vdash P} \text{ sep2}$$

It is easy to see that, in the framework of $^\perp\mathbf{O}$, separation rules allow us to derive the following full cut

$$\frac{M_1 \vdash \mu, N_1 \quad M_2, \mu \vdash N_2}{M_1, M_2 \vdash N_1, N_2} \text{ cut}$$

The converse is also true: full cut allows us to derive separation (by cutting with $\vdash A, A^\perp$). In this sense, separation and cut rule are equivalent: adding either of them to orthologic gives rise to one and the same logic. Theorem 153 then expresses, with a more effective²⁰ content, the well known fact that adding a full cut rule to orthologic yields classical logic (cf. [Dummett, 1976], [Cutland and Gibbins, 1982]).

It is natural to ask what is the meaning of *sep*. In the same way as the *tr* rules are equivalent to *tertium non datur* and *non contradiction*, the *sep* rules turn out to be equivalent to *reductio ad absurdum*²¹

$$\frac{M, \alpha^\perp \vdash}{M \vdash \alpha} \text{ RAA}$$

Let us consider again our Figure 11, where the question marks have been substituted by *sep*. Given the logic \mathbf{B} as a basic calculus, which contains the fundamental rules for the connectives, several structural rules can be added: each rule permits us to reach a “superior” logic. The strongest element is represented by classical logic, which can be characterized as $^\perp\mathbf{B} + \mathbf{S} + \mathbf{tr} + \mathbf{sep}$. With respect to our formulation of classical logic (denoted by $^\perp\mathbf{C}$) all the other logics in the diagram can be described as ‘substructural logics: for, they can be obtained by dropping some structural rules. This situation holds in particular for quantum logics, which turn out to be simpler and more basic than classical logic, from the proof-theoretical point of view.

As we have seen, the examples of quantum logic (we have considered so far) are, at the same time, substructural with respect to classical logic and substructural one with respect to the other. On this basis, on can prove

²⁰For, in a sequent calculus cut should represent a *metarule*, that is should be eliminable.

²¹In [Gibbins, 1985], pag.361, Gibbins shows that dropping the rule RAA has a direct justification in terms of *quantum mechanics*, and this is the only case of direct justification, among all the rules which must be restricted in *quantum logic*.

some embedding theorems, by convenient restriction of our structural rules to suitable kinds of formulas, by means of special modalities. In the case of linear logic, *exponentials* have been introduced in order to express weakening and contraction. In the case of quantum logics, instead, we should obtain rules of separation and of transfer in a suitable way. How to express the separation rules in orthologic, in order to obtain an embedding of classical logic into orthologic? Given $\perp\mathbf{O}$, let us first assume in the language, besides the literals p and p^\perp , two new kinds of literals, $\downarrow p$ and $\downarrow p^\perp$. This permits us to obtain a new kind of formulas, that will be named “separable formulas”, formulated as follows:

$$\downarrow(p) := \downarrow p \quad \downarrow(p^\perp) := \downarrow p^\perp \quad \downarrow(\downarrow p) := \downarrow p \quad \downarrow(\downarrow p^\perp) := \downarrow p^\perp$$

for literals;

$$\downarrow(\alpha \circ \beta) := \downarrow\alpha \circ \downarrow\beta$$

for every binary connective \circ .

Separable formulas are precisely those formulas that satisfy the separation rules, which are then defined as follows:

$$(vii') \quad \frac{M, \downarrow O \vdash}{M \vdash \downarrow O^\perp} \downarrow sep1 \qquad \frac{\vdash \downarrow N, P}{\downarrow N^\perp \vdash P} \downarrow sep2$$

where formulas in M , N are any kind of formulas, while formulas in $\downarrow M$, $\downarrow N$ are separable formulas. We can now introduce the system $\downarrow\perp\mathbf{O}$, which is defined by the rules of $\perp\mathbf{O}$ and by the rules $\downarrow sep$. In this system, the sign \downarrow plays the role of a *modality* (which behaves as an unary *monotonic* connective: if $M \vdash N$, is a derivable sequent in $\downarrow\perp\mathbf{O}$, then also $\downarrow M \vdash \downarrow N$ is a derivable sequent).

Consider now the system $\perp\mathbf{C}$ for classical logic, and let us describe \downarrow as a map from formulas of the language of $\perp\mathbf{C}$ into formulas of the language of $\downarrow\perp\mathbf{O}$. It is easy to show, by induction on the depth of the derivation, that:

THEOREM 154. *For every M , N , $M \vdash N$ is derivable in $\perp\mathbf{C}$ if and only if $\downarrow M \vdash \downarrow N$ is derivable in $\downarrow\perp\mathbf{O}$.*

Sketch of the proof A proof can be obtained by a natural transformation of a similar proof, given in [Battilotti, 1998] for the case of classical logic and basic orthologic. ■

As a consequence we obtain an embedding of $\perp\mathbf{C}$ in $\downarrow\perp\mathbf{O}$. Formulas of the kind $\downarrow\alpha$ can be interpreted as “the classical part of $\downarrow\perp\mathbf{O}$ ”. Similarly to \perp , the sign \downarrow does not represent here a connective; therefore, there is no need of introduction rules. One can prove that sequents like $\downarrow\alpha \vdash \alpha$ or like $\alpha \vdash \downarrow\alpha$ are not provable (differently from the exponentials in linear logic).

In this way, the system $\downarrow^\perp \mathbf{O}$ is simply a way to represent the *coexistence* of classical and quantum logic: it does not assert that “classical” propositions are stronger or weaker than “quantum” propositions.

18 CONCLUSION

Some general questions that have been often discussed in connection with (or against) quantum logic are the following:

- (a) Why quantum logics?
- (b) Are quantum logics helpful to solve the difficulties of QT?
- (c) Are quantum logics “real logics”? And how is their use compatible with the mathematical formalism of QT, based on classical logic?
- (d) Does quantum logic confirm the thesis that “logic is empirical”?

Our answers to these questions are, in a sense, trivial, and close to a position that Gibbins (1991) has defined a “quietist view of quantum logic”. It seems to us that quantum logics are not to be regarded as a kind of “clue”, capable of solving the main physical and epistemological difficulties of QT. This was perhaps an illusion of some pioneering workers in quantum logic. Let us think of the attempts to recover a *realistic interpretation* of QT based on the properties of the quantum logical connectives²².

Why quantum logics? Simply because “quantum logics are there!” They seem to be deeply incorporated in the abstract structures generated by QT. Quantum logics are, without any doubt, *logics*. As we have seen, they satisfy all the canonical conditions that the present community of logicians require in order to call a given abstract object *a logic*. A question that has been often discussed concerns the compatibility between quantum logic and the mathematical formalism of quantum theory, based on classical logic. Is the quantum physicist bound to a kind of “logical schizophrenia”? At first sight, the compresence of different logics in one and the same theory may give a sense of uneasiness. However, the splitting of the basic logical operations (negation, conjunction, disjunction,...) into different connectives with different meanings and uses is now a well accepted logical phenomenon, that admits consistent descriptions. Classical and quantum logic turn out to apply to different sublanguages of quantum theory, that must be sharply distinguished.

Finally, does quantum logic confirm the thesis that “logic is empirical”? At the very beginning of the contemporary discussion about the *nature of logic*, the claim that the “right logic” to be used in a given theoretical situation may depend also on experimental data appeared to be a kind of

²²See for instance [Putnam, 1969]

extremistic view, in contrast with a leading philosophical tradition according to which a characteristic feature of logic should be its absolute independence from any content.

These days, an empirical position in logic is generally no longer regarded as a “daring heresy” . At the same time, as we have seen, we are facing not only a variety of logics, but even a variety of *quantum logics*. As a consequence, the original question seems to have turned to the new one : to what extent is it reasonable to look for the “right logic” of QT?

COMBINATORS, PROOFS AND IMPLICATIONAL LOGICS

1 INTRODUCTION

In this chapter we first look at operators called **combinators**. These are very simple but extremely powerful. They provide a means of doing logic and mathematics without using variables, are powerful enough to allow the definition of all recursive functions and have more recently been used as a basis for certain “functional” computer languages.

We are interested in another use here which involves the **functional character** or **type** possessed by many combinators. Each type can be interpreted as a theorem of the intuitionistic implicative logic H_{\rightarrow} and combinators possessing that type can be interpreted as Hilbert-style proofs of that theorem. Weaker sets of combinators can be used to represent proofs in sublogics of H_{\rightarrow} , these include the substructural logics, such as the relevance logics R_{\rightarrow} and T_{\rightarrow} . There is a further interpretation of combinators and types as programs and specifications which we will not discuss here.

Next we look at lambda calculus. This also allows the definition of all recursive functions and has also been used in foundations of mathematics and computer language development. Many lambda terms also have types and these again are the theorems of H_{\rightarrow} . The lambda terms represent natural deduction style proofs of these theorems.

In the third section of this chapter we look at translations from combinators to lambda terms and vice versa. For the combinators and lambda terms that represent proofs in H_{\rightarrow} these translations are well known, for those corresponding to proofs in weaker logics they are quite new.

In a fourth section we develop a new algorithm which, given an implicational formula, allows us to find lambda terms representing natural deduction style proofs of the formula or demonstrates that the formula has no proof.

Most implicational substructural logics are specified by substructural rules or by axioms and not by rules in the natural deduction form. Our translation procedure, together with the algorithm, provides us with a simple constructive means of finding Hilbert-style proofs in many of these logics. As the translation procedure tells us which lambda terms are translatable into which sets of combinators, the algorithm can be directed to look only for the lambda terms of the appropriate kind. The algorithm is inherently finite; for any given formula, and for many logics, bounds for the proof searches can be written down.

The H_{\rightarrow} algorithm has been implemented by Anthony Dekker as Brouwer 7.9.0 (see [Dekker, 1996]) and, for any implicational formula, produces a λ -term proof (or even 50 alternative proofs) or a guarantee that there is no proof, virtually instantly. The implementation has more recently been extended by Martijn Oostdijk as LambdaCal2, (see [Oostdijk, 1996]) to cover the other implicational systems in this chapter as well as certain systems with other connectives. This implementation supplies combinator and lambda calculus proofs.

2 COMBINATORY LOGIC

Combinators are operators which manipulate arbitrary expressions by cancellation, duplication, bracketing and permutation. Combinators were first defined by Schönfinkel in his 1924 paper and rediscovered by Curry in [1930].

To illustrate their use we consider the following examples:

let Axy (rather than $A(x, y)$) represent $x + y$. The commutative law for addition can then be written as

$$Axy = Ayx.$$

Given a combinator \mathbf{C} with the property:

$$\mathbf{C}xyz = xzy$$

this becomes

$$Axy = \mathbf{C}Axy$$

which could be simply written, without variables, as

$$A = \mathbf{C}A.$$

Given an identity combinator \mathbf{I} , i.e. one such that

$$\mathbf{I}x = x$$

we can write

$$0 + x = x$$

as

$$A0x = x$$

or

$$A0x = \mathbf{I}x$$

and so, without variables, as

$$A0 = \mathbf{I}.$$

$$x + 0 = x$$

would be

$$\mathbf{CA0} = \mathbf{I}.$$

Schönfinkel found that only two combinators, \mathbf{K} and \mathbf{S} , were enough to define all others.

We will now introduce these, other combinators, and our method of writing functional expressions (such as Axy rather than $A(x, y)$) more formally.

2.1 Combinators and Application

DEFINITION 1 (Combinator).

1. \mathbf{K} and \mathbf{S} are combinators.
2. If X and Y are combinators so is (XY) .

(The operation in (2) is called **application**.)

Though it is possible, it is often not convenient to work without variables; we therefore introduce terms which are made up of combinators and variables using application. Other constants could also be included in (1) below.

DEFINITION 2 (Term).

1. \mathbf{K} , \mathbf{S} , x , y , $z, \dots, x_1, x_2, \dots$ are terms
2. If X and Y are terms so is (XY) .

Notation We use association to the left for terms. This means that our Axy is short for $((Ax)y)$. A binary function over the real numbers such as A is therefore interpreted as a unary function from real numbers into the set of unary functions from real numbers to real numbers.

The process of going from \mathbf{CXYZ} to XZY or from \mathbf{IX} to X is called **reduction**. This is defined as follows:

DEFINITION 3 (Reduction). The relation $X \triangleright Y$ (X reduces weakly to Y) is defined as follows:

$$(\mathbf{K}) \quad \mathbf{KXY} \triangleright X$$

$$(\mathbf{S}) \quad \mathbf{SXYZ} \triangleright XZ(YZ)$$

$$(\rho) \quad X \triangleright X$$

$$(\mu) \quad X \triangleright Y \Rightarrow UX \triangleright UY$$

$$(\nu) \quad X \triangleright Y \Rightarrow XU \triangleright YU$$

$$(\tau) \quad X \triangleright Y \text{ and } Y \triangleright Z \Rightarrow X \triangleright Z$$

(**K**) and (**S**) are called the **reduction axioms** for **K** and **S**.

DEFINITION 4 (Weak equality). $X = Y$ if this can be derived from the axioms and rules of Definition 3 with “=” instead of “ \triangleright ”, together with

$$(\sigma) \quad X = Y \quad \Rightarrow \quad Y = X.$$

The formal system consisting of at least Definition 1 and the postulates in Definitions 3 we call **combinatory logic**. Other axioms and rules may be added.

We now show how the combinators we met earlier, and others, can be defined. We use “ \equiv ” for “equals by definition”.

DEFINITION 5.

$$\begin{aligned} \mathbf{I} &\equiv \mathbf{SKK} \\ \mathbf{B} &\equiv \mathbf{S(KS)K} \\ \mathbf{C} &\equiv \mathbf{S(BBS)(KK)} \\ \mathbf{B}' &\equiv \mathbf{CB} \\ \mathbf{W} &\equiv \mathbf{SS(KI)} \\ \mathbf{S}' &\equiv \mathbf{B(BW)(BBB')} \end{aligned}$$

Each of these defined combinators has a characteristic reduction theorem:

THEOREM 6.

1. $\mathbf{IX} \triangleright X$
2. $\mathbf{BXYZ} \triangleright X(YZ)$
3. $\mathbf{CXYZ} \triangleright XZY$
4. $\mathbf{B'XYZ} \triangleright Y(XZ)$
5. $\mathbf{WXY} \triangleright XYY$
6. $\mathbf{S'XYZ} \triangleright YZ(XZ)$

Proof.

1. $\mathbf{SKKX} \triangleright \mathbf{KX(KX)}$ by (**S**)
- so $\mathbf{SKKX} \triangleright X$ by (**K**) and (τ)
2. $\mathbf{S(KS)KXYZ} \triangleright \mathbf{KSX(KX)YZ}$ by (τ) and (ν)
- $\triangleright \mathbf{S(KX)YZ}$ by (**K**) and (ν)
- $\triangleright \mathbf{KXZ(YZ)}$ by (**S**)
- $\triangleright X(YZ)$ by (**K**) and (ν).
- so $\mathbf{S(KS)KXYZ} \triangleright X(YZ)$ by (τ) ■

If $M(X_1, \dots, X_n)$ is a term made up by application using zero or more occurrences of each of X_1, \dots, X_n , we can find a combinator Z such that $ZX_1X_2 \dots X_n \triangleright M(X_1, \dots, X_n)$.

This property is called the “**combinatory completeness**” of the combinatory logic based on **K** and **S**.

The combinator Z above is represented by

$$Z \equiv [x_1]([x_2](\dots([x_n]M(x_1, \dots, x_n)) \dots))$$

where each $[x_i](\dots)$ is called a **bracket abstraction**.

Bracket abstractions can be defined in various ways, a simple definition, involving **S** and **K**, is as follows:

DEFINITION 7 (Bracket abstraction $[x_i]$).

- (i) $[x_i] x_i \equiv \mathbf{I}$
- (k) $[x_i] Y \equiv \mathbf{K}Y$ if $x_i \notin Y$
- (η) $[x_i]Yx_i \equiv Y$ if $x_i \notin Y$
- (s) $[x_i]YZ \equiv \mathbf{S}([x_i]Y)([x_i]Z)$,

where $x_i \notin Y$ stands for x_i does not appear in Y .

The above clauses must be used in the order given i.e. $(ik\eta s)$. In the order $(iks\eta)$, we would always obtain $\mathbf{S}([x_i]Y)\mathbf{I}$ for $[x_i]Yx_i$, if $x_i \notin Y$, instead of the simpler Y .

Repeated bracket abstraction as in $[x_1]([x_2](\dots([x_n]M) \dots))$ we will write as $[x_1, x_2, \dots, x_n]M$.

EXAMPLE 8.

$$\begin{aligned} [x_1, x_2, x_3] x_3(x_1 x_3) &\equiv [x_1, x_2]\mathbf{S}([x_3]x_3)([x_3](x_1 x_3)) && \text{by (s)} \\ &\equiv [x_1, x_2]\mathbf{S}\mathbf{I}x_1 && \text{by (i) and (\eta)} \\ &\equiv [x_1]\mathbf{K}(\mathbf{S}\mathbf{I}x_1) && \text{by (k)} \\ &\equiv \mathbf{S}(\mathbf{K}\mathbf{K})(\mathbf{S}\mathbf{I}) && \text{by (k) and (\eta)}. \end{aligned}$$

$$\begin{aligned} \mathbf{S}(\mathbf{K}\mathbf{K})(\mathbf{S}\mathbf{I})x_1x_2x_3 &\triangleright \mathbf{K}\mathbf{K}x_1(\mathbf{S}\mathbf{I}x_1)x_2x_3 \\ &\triangleright \mathbf{K}(\mathbf{S}\mathbf{I}x_1)x_2x_3 \\ &\triangleright \mathbf{S}\mathbf{I}x_1x_3 \\ &\triangleright \mathbf{I}x_3(x_1x_3) \\ &\triangleright x_3(x_1x_3). \end{aligned}$$

Bracket abstraction has the following property which we call (β) for lambda abstraction in Section 3.

THEOREM 9. $[x]X)Y \triangleright [Y/x]X$ where $[Y/x]X$ is the result of substituting Y for all occurrences of x in X .

Proof. By a simple induction on the length of X . ■

From this theorem we get:

$$([x]X) x \triangleright X$$

and if $x_1, \dots, x_n \notin X_1 X_2 \dots X_n$,

$$([x_1, \dots, x_n]X) X_1 \dots X_n \triangleright [X_1/x_1, \dots, X_n/x_n]X ,$$

where $[X_1/x_1, \dots, X_n/x_n]X$ is the result of substituting simultaneously X_1 for all occurrences of x_1 in X , \dots , X_n for all occurrences of x_n in X .

2.2 Combinators, Types, Proofs and Theorems

If a term X is an element of a set α (which we write as $X \in \alpha$ or $X : \alpha$ below) we have as

$$\begin{aligned} \mathbf{K}XY &= X, \\ \mathbf{K}XY &\in \alpha. \end{aligned}$$

If $Y \in \beta$ we have that $\mathbf{K}X$ is a function from the set β into the set α , i.e. in the usual mathematical notation:

$$\mathbf{K}X : \beta \rightarrow \alpha ,$$

where $\beta \rightarrow \alpha$ represents the set of all functions from β into α .

From this it follows that \mathbf{K} is a function from α into $\beta \rightarrow \alpha$, so we can write:

$$\mathbf{K} : \alpha \rightarrow (\beta \rightarrow \alpha) .$$

Sets such as the α , β and $\alpha \rightarrow (\beta \rightarrow \alpha)$ above will be denoted by expressions called **types**. Types are defined as follows:

DEFINITION 10 (Types).

1. a, b, c, \dots are (atomic) types.
2. If α and β are types so is $(\alpha \rightarrow \beta)$.

For types we use **association to the right**, $\alpha \rightarrow (\beta \rightarrow \alpha)$ can therefore be written as $\alpha \rightarrow \beta \rightarrow \alpha$.

The type variables or atomic types can be interpreted as arbitrary sets, the compound types then represent sets of functions.

Above we arrived at $\mathbf{K} : \alpha \rightarrow \beta \rightarrow \alpha$; such a derivation we call a **type assignment**, we call $\alpha \rightarrow \beta \rightarrow \alpha$ the **type of \mathbf{K}** and \mathbf{K} an **inhabitant** of $\alpha \rightarrow \beta \rightarrow \alpha$.

Type assignments can be more formally derived from:

DEFINITION 11 (Type Assignment).

1. Variables can be assigned arbitrary types

2. If $X : \alpha \rightarrow \beta$ and $Y : \alpha$ then $(XY) : \beta$.
3. If $Xx : \alpha$, $x \notin X$ and $x : \beta$ then $X : \beta \rightarrow \alpha$.

We will illustrate this by assigning a type to \mathbf{S} .

If we let $x : \alpha \rightarrow \beta \rightarrow \gamma$, $y : \alpha \rightarrow \beta$ and $z : \alpha$ we have by (2) $xz : \beta \rightarrow \gamma$ and $yz : \beta$ and so $xz(yz) : \gamma$ which is, by (\mathbf{S}), $\mathbf{S}xyz : \gamma$.

Now by (3) $\mathbf{S}xy : \alpha \rightarrow \gamma$,
 $\mathbf{S}x : (\alpha \rightarrow \beta) \rightarrow \alpha \rightarrow \gamma$
 and $\mathbf{S} : (\alpha \rightarrow \beta \rightarrow \gamma) \rightarrow (\alpha \rightarrow \beta) \rightarrow \alpha \rightarrow \gamma$.

In particular we have

$$\mathbf{S} : (a \rightarrow b \rightarrow c) \rightarrow (a \rightarrow b) \rightarrow a \rightarrow c ,$$

and it can be seen, from the work above, that every type of \mathbf{S} has to be a substitution instance of this. A type with this property we call the **principal type scheme** (PTS).

The PTS of \mathbf{K} is given by

$$\mathbf{K} : a \rightarrow b \rightarrow a .$$

Notice that the types of \mathbf{K} and \mathbf{S} are exactly the axioms of H_{\rightarrow} , intuitionistic implicational logic, when \rightarrow is read as implication and α , β, \dots are read as well formed formulas or propositions.

Definition 11.2 and 3 can be rewritten as:

$$\rightarrow_e \frac{X : \alpha \rightarrow \beta \quad Y : \alpha}{XY : \beta}$$

and

$$\rightarrow_i \frac{\begin{array}{c} [x : \alpha] \\ \vdots \\ Xx : \beta \end{array}}{X : \alpha \rightarrow \beta} \quad (x \notin X)$$

We have, considering only the right hand sides of the $:$ s, the rules of inference of a natural deduction formulation of H_{\rightarrow} .

If we take the types of \mathbf{K} and \mathbf{S} as axiom schemes and use only the parts of \rightarrow_e to the right of the $:$ s, we have a Hilbert-style formulation of H_{\rightarrow} . What appears on the left hand side of the final step in such a proof gives us a unique representation of a proof of the theorem expressed on the right of the $:$.

EXAMPLE 12. If we abbreviate $(\beta \rightarrow \gamma \rightarrow \delta) \rightarrow (\beta \rightarrow \gamma) \rightarrow \beta \rightarrow \delta$ by α we have:

$$\begin{aligned}
\mathbf{K} &: \alpha \rightarrow (\gamma \rightarrow \delta) \rightarrow \alpha \\
\mathbf{S} &: \alpha \\
\mathbf{KS} &: (\gamma \rightarrow \delta) \rightarrow \alpha \\
\mathbf{S} &: ((\gamma \rightarrow \delta) \rightarrow \alpha) \rightarrow ((\gamma \rightarrow \delta) \rightarrow \beta \rightarrow \gamma \rightarrow \delta) \\
&\quad \rightarrow (\gamma \rightarrow \delta) \rightarrow (\beta \rightarrow \gamma) \rightarrow \beta \rightarrow \delta \\
\mathbf{S(KS)} &: ((\gamma \rightarrow \delta) \rightarrow \beta \rightarrow \gamma \rightarrow \delta) \rightarrow (\gamma \rightarrow \delta) \rightarrow (\beta \rightarrow \gamma) \rightarrow \beta \rightarrow \delta \\
\mathbf{K} &: (\gamma \rightarrow \delta) \rightarrow \beta \rightarrow \gamma \rightarrow \delta \\
\mathbf{S(KS)K} &: (\gamma \rightarrow \delta) \rightarrow (\beta \rightarrow \gamma) \rightarrow \beta \rightarrow \delta
\end{aligned}$$

We note that each \mathbf{S} or \mathbf{K} in $\mathbf{S(KS)K}$ represents the use of an axiom and each application a use of \rightarrow_e . We also note that the above represents a type for the combinator \mathbf{B} of Definition 5.

Some combinators do not have types, for example if we want to find a type for \mathbf{SSS} we would proceed as follows:

$$\begin{aligned}
\text{let } \mathbf{S} &: (\beta \rightarrow \gamma \rightarrow \delta) \rightarrow (\beta \rightarrow \gamma) \rightarrow \beta \rightarrow \delta \\
\text{and } \mathbf{S} &: (\tau \rightarrow \rho \rightarrow \sigma) \rightarrow (\tau \rightarrow \rho) \rightarrow \tau \rightarrow \sigma
\end{aligned}$$

then we have putting $\tau \rightarrow \rho \rightarrow \sigma = \beta$, $\tau \rightarrow \rho = \gamma$ and $\tau \rightarrow \sigma = \delta$:

$$\mathbf{SS} : ((\tau \rightarrow \rho \rightarrow \sigma) \rightarrow \tau \rightarrow \rho) \rightarrow (\tau \rightarrow \rho \rightarrow \sigma) \rightarrow \tau \rightarrow \sigma .$$

Now with $\mathbf{S} : (\mu \rightarrow \nu \rightarrow \xi) \rightarrow (\mu \rightarrow \nu) \rightarrow \mu \rightarrow \xi$, we would need, to assign a type to \mathbf{SSS} :

$$\begin{aligned}
\tau \rightarrow \rho \rightarrow \sigma &= \mu \rightarrow \nu \rightarrow \xi , \\
\tau &= \mu \rightarrow \nu , \\
\text{and } \rho &= \mu \rightarrow \xi .
\end{aligned}$$

However this requires both $\tau = \mu$ and $\tau = \mu \rightarrow \nu$ which is impossible.

Also there are types that have no inhabitant, for example $a \rightarrow b$ and $((a \rightarrow b) \rightarrow a) \rightarrow a$. In fact:

THEOREM 13.

1. If a type τ has a combinator inhabitant, τ is a theorem of the intuitionistic implicative logic H_{\rightarrow} .
2. If τ is a theorem of H_{\rightarrow} , then it is the type of a combinator.

Proof.

1. It can be proved by an easy induction on the length of X that

$$x_1 : \alpha_1, \dots, x_n : \alpha_n \vdash X : \tau$$

implies

$$\alpha_1, \dots, \alpha_n \vdash \tau$$

2. It can be proved by an induction on the length of the deduction leading to

$$\alpha_1, \dots, \alpha_n \vdash \tau$$

that there are variables $x_{11}, \dots, x_{1m_1}, \dots, x_{nm_n}$ and a term X such that

$$FV(X) \subseteq \{x_{11}, \dots, x_{nm_n}\}$$

and

$$x_{11} : \alpha_1, \dots, x_{1m_1} : \alpha_1, x_{21} : \alpha_2, \dots, x_{nm_n} : \alpha_n \vdash X : \alpha .$$

For more details on this see Hindley [1997, Section 6B2 and Section 6B5].

■

The isomorphism between inhabitants and types and proofs and theorems of H_{\rightarrow} , which can be extended to fit programs and specifications, is called the **Curry-Howard or Formulas-as types isomorphism**.

Curry was the first to recognise the relation between types and theorems of H_{\rightarrow} (see [Curry and Feys, 1958]). The idea was taken up and extended to other connectives and quantifiers in Lauchli [1965; 1970], Howard [1980] (but written in 1969), de Bruin [1970; 1980] and Scott [1970]. Recently it was extended to include a large amount of mathematics in Crossley and Shepherdson [1993].

2.3 Types and Weaker Logics

If we consider an arbitrary set of combinators Q , we can define the set of **Q -combinators** and **Q -terms** as follows:

DEFINITION 14 (Q -terms).

1. Elements of Q and $x, y, z, \dots, x_1, x_2, \dots$ are Q -terms
2. If X and Y are Q -terms so is (XY) .

DEFINITION 15 (Q -combinators). A Q -term containing no variables is a Q -combinator.

The formal system consisting of at least Definition 15 and the postulates of Definition 3, with the reduction axioms (**K**) and (**S**) replaced by ones appropriate to Q , is called Q -**combinatory logic**. Q -**logic** is the implicational logic whose axioms are the types of the combinators in Q and whose rule is \rightarrow_e .

Thus combinatory logic, as defined before, is $\{\mathbf{S}, \mathbf{K}\}$ - (or simply **SK**-) combinatory logic, terms are **SK**-terms and combinators are **SK**-combinators.

DEFINITION 16 (Weaker sets of combinators). A set Q_1 of combinators is said to be **weaker** than a set Q_2 , if for every Q_1 -combinator X there is a Q_2 -combinator Y with the same reduction theorem. (In that case we say X is Q_2 -**definable**.) Also there must be a Q_2 -combinator which is not Q_1 -definable.

DEFINITION 17 (Weaker combinatory logics). Q_1 -combinatory logic is **weaker than** Q_2 -combinatory logic if Q_1 is weaker than Q_2 .

BCKW-combinatory logic is just as strong as **SK**-combinatory logic as **B, C, K** and **W** are (by Definition 5) **SK**-definable and **S** is also **BCKW**-definable ($\mathbf{S} \equiv \mathbf{B}(\mathbf{B}\mathbf{W})(\mathbf{B}\mathbf{C}(\mathbf{B}\mathbf{B}))$).

BCW and **BCIW**-combinatory logics are both weaker than **SK**-combinatory logic as **S** is not definable using **B, C, I** and **W**.

It is clear that **BCK**- and **BCIW**-combinatory logics are not combinatorially complete.

The set of types of the **BCK**-combinators can easily be seen to be the set of theorems generated by \rightarrow_e using the types of **B, C** and **K**. This we call **BCK**-(implicational) logic, which is a subsystem of H_{\rightarrow} .

In general, if all the combinators of $Q_1 \cup Q_2$ have types and Q_1 is weaker than Q_2 then Q_1 -logic is weaker than Q_2 -logic.

As before, given a Q -combinator, a Q -theorem and its proof can be read off.

EXAMPLE 18. Determine the type of **BC(BK)** and the **BCK**-proof of this as a **BCK**-theorem.

$$\begin{aligned}
 \mathbf{B} &: (\alpha \rightarrow \beta) \rightarrow (\gamma \rightarrow \alpha) \rightarrow \gamma \rightarrow \beta \\
 \mathbf{C} &: (\delta \rightarrow \tau \rightarrow \sigma) \rightarrow \tau \rightarrow \delta \rightarrow \sigma \\
 \mathbf{BC} &: (\gamma \rightarrow \delta \rightarrow \tau \rightarrow \sigma) \rightarrow \gamma \rightarrow \tau \rightarrow \delta \rightarrow \sigma \\
 &\quad (\text{Here } \alpha = \delta \rightarrow \tau \rightarrow \sigma, \beta = \tau \rightarrow \delta \rightarrow \sigma.) \\
 \mathbf{K} &: \mu \rightarrow \nu \rightarrow \mu \\
 \mathbf{BK} &: (\xi \rightarrow \mu) \rightarrow \xi \rightarrow \nu \rightarrow \mu \\
 &\quad (\text{Here } \alpha = \mu, \beta = \nu \rightarrow \mu \text{ and } \gamma = \xi.) \\
 \mathbf{BC(BK)} &: (\xi \rightarrow \mu) \rightarrow \nu \rightarrow \xi \rightarrow \mu \\
 &\quad (\text{Here } \gamma = \xi \rightarrow \mu, \delta = \xi, \tau = \nu \text{ and } \sigma = \mu)
 \end{aligned}$$

2.4 Combinator Reduction and Proof Reduction

We illustrate here what happens to (part of) a proof represented by a combinator \mathbf{KXY} or \mathbf{SXYZ} when this combinator is reduced by (\mathbf{K}) or (\mathbf{S}) .

The original proof involving \mathbf{KXY} must look like:

$$\frac{\frac{\mathbf{K} : \alpha \rightarrow \beta \rightarrow \alpha \quad \overset{D_1}{X : \alpha}}{\mathbf{KX} : \beta \rightarrow \alpha} \quad \overset{D_2}{Y : \beta}}{\mathbf{KXY} : \alpha} \quad \overset{D_3}{}{}$$

with D_1 , D_2 and D_3 representing other proof steps.

With the reduction of \mathbf{KXY} to X the proof reduces (or normalises) to:

$$\overset{D_1}{X : \alpha} \quad \overset{D_3}{}{}$$

If the proof involving \mathbf{SXYZ} is:

$$\frac{\overset{D_2}{Y : \alpha \rightarrow \beta} \quad \frac{\mathbf{S} : (\alpha \rightarrow \beta \rightarrow \gamma) \rightarrow (\alpha \rightarrow \beta) \rightarrow \alpha \rightarrow \gamma \quad \overset{D_1}{X : \alpha \rightarrow \beta \rightarrow \gamma}}{\mathbf{SX} : (\alpha \rightarrow \beta) \rightarrow \alpha \rightarrow \gamma}}{\mathbf{SXY} : \alpha \rightarrow \gamma} \quad \overset{D_3}{Z : \alpha}}{\mathbf{SXYZ} : \gamma} \quad \overset{D_4}{}{}$$

With the reduction of \mathbf{SXYZ} to $XZ(YZ)$ the proof reduces (or normalises) to:

$$\frac{\frac{\overset{D_1}{X : \alpha \rightarrow \beta \rightarrow \gamma} \quad \overset{D_3}{Z : \alpha}}{XZ : \beta \rightarrow \gamma} \quad \frac{\overset{D_2}{Y : \alpha \rightarrow \beta} \quad \overset{D_3}{Z : \alpha}}{YZ : \beta}}{XZ(YZ) : \gamma} \quad \overset{D_4}{}{}$$

It may be, by the way, if D_3 is a particularly long part of the proof, that the “reduced proof” is actually longer than the original. In the same way, if Z is long, $XZ(YZ)$ may be longer than \mathbf{SXYZ} .

DEFINITION 19. If a term has no subterms of the form \mathbf{KXY} or \mathbf{SXYZ} , the term is said to be in **normal form**.

Not every combinator has a normal form, for example $\mathbf{WI(WI)}$ and $\mathbf{WW(WW)}$ do not, but every combinator that has a type also has a normal form.

A combinator in normal form will represent a normalised proof, these however are not unique. For example:

$$\mathbf{K} : a \rightarrow a \rightarrow a$$

and also

$$\mathbf{KI} : a \rightarrow a \rightarrow a.$$

3 LAMBDA CALCULUS

Lambda calculus, like combinatory logic, provides a means of representing all recursive functions. It is, these days, much used as the basis for functional computer languages. Extensions of the typed lambda calculus we introduce in Section 3.2 below, also have applications in program verification.

Lambda calculus was first developed by Church in the early 30s (see [Church, 1932; Church, 1933]) as part of a foundation of logic and mathematics. This was also the aim of Curry's "illative combinatory logic", but both Church's and Curry's extended systems proved to be inconsistent.

The use of the lambda calculus notation is best seen through an example such as the following:

If the value of the sin function at x is $\sin x$ and the value of the log function at x is $\log x$, what is the function whose value at x is x^2 ? Usually this function is also called x^2 . The lambda calculus allows us to eliminate this ambiguity by using $\lambda x.x^2$ for the name of the function.

3.1 *Lambda terms and lambda reductions*

We will now set up the system more formally:

DEFINITION 20 (Lambda terms or λ -terms).

1. Variables are λ -terms.
2. If X is a λ -term and x a variable then, the **abstraction of X with respect to x** , $(\lambda x.X)$ is a λ -term.
3. If X and Y are λ -terms then (XY) , the **application** of X to Y , is a λ -term.

$(\lambda x.X)$ is interpreted as the **function** whose value at x is X .

Given this we would expect the following to hold:

EXAMPLE 21.

$$\begin{aligned} (\lambda x. \sin x) &= \sin \\ ((\lambda x. \sin x)x) &= \sin x \\ ((\lambda x. \sin x)\pi) &= \sin \pi \\ ((\lambda x.x^2)2) &= 4 \\ ((\lambda x.2)x) &= 2 \end{aligned}$$

$(\lambda x.2)$ is the constant function whose value is 2.

For terms formed by application we use association to the left as for terms of combinatory logic. Repeated λ -abstraction as in $(\lambda x_1.(\lambda x_2 \dots (\lambda x_n.X) \dots))$ we abbreviate to $\lambda x_1.\lambda x_2 \dots \lambda x_n.X$ or to $\lambda x_1 x_2 \dots x_n.X$.

Note that while $\lambda x_1 x_2 \dots x_n.X$ represents a function of n variables, it is also a function of one variable whose value, $\lambda x_2 x_3 \dots x_n.X$ at x_1 , is also a function (if $n \geq 2$).

The process of simplifying $(\lambda x. \sin x)x$ to $\sin x$ or $(\lambda x.x^2)2$ to 2^2 is called β -reduction. To explain this we need to define free and bound variables and, using these, a substitution operator.

As in combinatory logic we use \equiv for equality by definition or identity.

DEFINITION 22 (Free and bound variables, closed terms).

1. x is a **free** variable in x .
2. If x is **free** in Y or Z then x is free in (YZ) .
3. If x is **free** in Y and $y \neq x$, x is free in $\lambda y.Y$.
4. Every x that appears in $\lambda x.Y$ is **bound** in $\lambda x.Y$.

We write $FV(X)$ for the set of free variables of X .

A **closed term** is one without free variables.

EXAMPLE 23.

1. If $X \equiv \lambda xy.xyx$, X is a closed term and x and y are bound in X .
2. If $X \equiv \lambda xy.xyzx(\lambda u.zx)w$, x , y and u are bound in X and $FV(X) = \{z, w\}$
3. If $X \equiv x(\lambda x.xy)x$, the first and last occurrences of x are **free occurrences** of x . Both the occurrences of x in $\lambda x.xy$ are **bound**.

DEFINITION 24. $[Y/x]X$ - the result of substituting Y for all free occurrences of x in X)

1. $[Y/x]x \equiv Y$
2. $[Y/x]y \equiv y$ if y is an atom, $x \neq y$
3. $[Y/x](WZ) \equiv ([Y/x]W)([Y/x]Z)$
4. $[Y/x](\lambda x.Z) \equiv \lambda x.Z$
5. $[Y/x](\lambda y.Z) \equiv \lambda y.[Y/x]Z$ if $y \neq x$
and, $y \notin FV(Y)$ or $x \notin FV(Z)$.

6. $[Y/x]\lambda y.Z \equiv \lambda z.[Y/x][z/y]Z$
 if $y \neq x$, $y \in FV(Y)$, $x \in FV(Z)$ and $z \notin FV(YZ)$.

As we saw in Example 21, a λ -term of the form $(\lambda x.X)Y$ can be simplified or “**reduced**”. This kind of reduction is specified by the following axiom:

$$(\beta) (\lambda x.X)Y \triangleright [Y/x]X .$$

A λ -term of the form $(\lambda x.X)Y$ is called a β -**redex**.

The following axiom allows a change of bound variables and is called an α -reduction.

$$(\alpha) \lambda x.X \triangleright \lambda y.[y/x]X \quad \text{if } y \notin FV(X).$$

Rules (μ) , (ν) and (τ) of Definition 3 together with:

$$(\xi) X \triangleright Y \Rightarrow \lambda x.X \triangleright \lambda x.Y ,$$

allow us to perform α - and β -reductions within a term.

DEFINITION 25 (β - and $\beta\eta$ -reduction).

The reduction \triangleright specified by (α) , (β) , (ρ) , (μ) , (ν) , (τ) and (ξ) is called β -**reduction**.

This becomes $\beta\eta$ - (or just η -) **reduction** if the following axiom is added:

$$(\eta) \lambda x.Xx \triangleright X \quad \text{if } x \notin FV(X).$$

We denote the two forms of reduction, when we wish to distinguish them, by \triangleright_β and $\triangleright_{\beta\eta}$. If in a $\beta\eta$ -reduction (β) is not used we sometimes write \triangleright_η instead of $\triangleright_{\beta\eta}$.

We will call α -, β - and η - reductions λ -reductions to distinguish them from combinator reductions.

EXAMPLE 26.

$$1. \lambda x_1.x_1((\lambda x_2.x_3x_2x_2)x_1) \triangleright_\beta \lambda x_1.x_1(x_3x_1x_1)$$

$$\begin{aligned} 2. & \lambda x_3.(\lambda x_1.x_1x_2(\lambda x_2.x_3x_1x_2))(\lambda x_1.x_1) \\ & \triangleright_\eta \lambda x_3.(\lambda x_1.x_1x_2(x_3x_1))(\lambda x_1.x_1) \\ & \triangleright_\beta \lambda x_3.(\lambda x_1.x_1)x_2(x_3(\lambda x_1.x_1)) \\ & \triangleright_\beta \lambda x_3.x_2(x_3(\lambda x_1.x_1)) \end{aligned}$$

$$\begin{aligned} \text{so } & \lambda x_3.(\lambda x_1.x_1x_2(\lambda x_2.x_3x_1x_2))(\lambda x_1.x_1) \\ & \triangleright_{\beta\eta} \lambda x_3.x_2(x_3(\lambda x_1.x_1)) \end{aligned}$$

A term of the form $\lambda x.Xx$ where $x \notin FV(X)$, is called an η -**redex**.

A term with no β -redexes is said to be in β -**normal form**. One without β - and η - redexes is in $\beta\eta$ -**normal form**. One without η -redexes is said to

be in η -normal form. β -, η - and $\beta\eta$ -normal forms are unique (see [Hindley and Seldin, 1986]).

DEFINITION 27 (α -, β - and $\beta\eta$ -equality).

The relation $=_\alpha$ is specified by (α) , (ρ) , (μ) , (ν) , (τ) and (ξ) , all with $=_\alpha$ for \triangleright and

$$(\sigma) X =_\alpha Y \Rightarrow Y =_\alpha X.$$

The relation $=_\beta$ is specified by all the above postulates, as well as (β) , with $=_\beta$ for \triangleright and $=_\alpha$.

The relation $=_{\beta\eta}$ is specified by all the $=_\beta$ postulates, as well as (η) , with $=_{\beta\eta}$ replacing $=_\beta$ and \triangleright .

Note that the weak equality of combinatory logic obeys all the above postulates (with $[.]$ for $\lambda.$) except (ξ) and (η) . It is possible to extend weak equality by means of some extra equations involving combinators to make (ξ) and/or (η) admissible (see [Curry and Feys, 1958, Section 6C4]). We will call the corresponding equalities for combinatory logic $=_\beta$ and $=_{\beta\eta}$ respectively.

3.2 Lambda Terms, Types, Proofs and Theorems

If a term X is an element of a set α and the variable y is in a set β , $\lambda y.X$ will represent a function from β into α i.e. $\lambda y.X : \beta \rightarrow \alpha$. We will denote sets such as these by the types introduced in Definition 10. We assign types to λ -terms in a similar way to the assignment to combinators.

DEFINITION 28 (Type Assignment).

1. Variables can be assigned arbitrary types.
2. If $X : \alpha \rightarrow \beta$ and $Y : \alpha$ then $(XY) : \beta$
3. If $X : \alpha$ and $y : \beta$ then $\lambda y.X : \beta \rightarrow \alpha$.

EXAMPLE 29.

1. If $x_2 : a \rightarrow a \rightarrow b$, $x_3 : a$ then $x_2 x_3 x_3 : b$ and $\lambda x_3. x_2 x_3 x_3 : a \rightarrow b$.
If $x_1 : (a \rightarrow b) \rightarrow c$ then $x_1(\lambda x_3. x_2 x_3 x_3) : c$, so $\lambda x_1 x_2. x_1(\lambda x_3. x_2 x_3 x_3) : ((a \rightarrow b) \rightarrow c) \rightarrow (a \rightarrow a \rightarrow b) \rightarrow c$.
2. If $x_1 : \alpha \rightarrow \beta$ then for $x_1 x_1$ to have a type we must have $\alpha = \alpha \rightarrow \beta$ which is impossible. Hence $x_1 x_1$ and so $\lambda x_1. x_1 x_1$ have no types.

DEFINITION 30. If X is a closed lambda term and $\vdash X : \alpha$ is derived by the type assignment rules then X is said to be an **inhabitant** of α and α a **type** of X .

Note that, as with combinatory logic, if we ignore the terms on the left of the $:$, we have in Definition 20.2 and 3 the elimination and introduction rules for \rightarrow of the natural deduction version of H_{\rightarrow} . For any $Y : \alpha$, the types of the variables free in Y constitute the uncanceled hypothesis which yield α . When Y has no free variables, α is a theorem of H_{\rightarrow} and Y represents a natural deduction proof of α . This can be best seen when the type assignment rules are written in tree form as in the example below.

EXAMPLE 31.

$$\begin{array}{c}
\begin{array}{c}
\rightarrow_e \frac{\begin{array}{c} (A) \quad (\beta) \\ x_1 : a \rightarrow b \rightarrow c \quad x_2 : a \end{array}}{x_1 x_2 : b \rightarrow c} \quad \frac{\quad}{x_3 : (b \rightarrow c) \rightarrow a \rightarrow d} \quad (\beta) \\
\rightarrow_e \frac{x_2 : a}{x_3(x_1 x_2) : a \rightarrow d}
\end{array} \\
\rightarrow_e \frac{x_3(x_1 x_2) x_2 : d}{\lambda x_2. x_3(x_1 x_2) x_2 : a \rightarrow d} \quad - (2) \quad \frac{\quad}{x_4 : (a \rightarrow d) \rightarrow e} \quad (A) \\
\rightarrow_i \frac{x_4(\lambda x_2. x_3(x_1 x_2) x_2) : e}{\lambda x_3. x_4(\lambda x_2. x_3(x_1 x_2) x_2) : ((b \rightarrow c) \rightarrow a \rightarrow d) \rightarrow e} \quad - (3) \\
\rightarrow_i \frac{\lambda x_3. x_4(\lambda x_2. x_3(x_1 x_2) x_2) : ((b \rightarrow c) \rightarrow a \rightarrow d) \rightarrow e}{\lambda x_1 x_3. x_4(\lambda x_2. x_3(x_1 x_2) x_2) : (a \rightarrow b \rightarrow c) \rightarrow ((b \rightarrow c) \rightarrow a \rightarrow d) \rightarrow e} \quad - (1) \\
\rightarrow_i \frac{\lambda x_1 x_3. x_4(\lambda x_2. x_3(x_1 x_2) x_2) : (a \rightarrow b \rightarrow c) \rightarrow ((b \rightarrow c) \rightarrow a \rightarrow d) \rightarrow e}{\lambda x_4 x_1 x_3. x_4(\lambda x_2. x_3(x_1 x_2) x_2) : ((a \rightarrow d) \rightarrow e) \rightarrow (a \rightarrow b \rightarrow c) \rightarrow ((b \rightarrow c) \rightarrow a \rightarrow d) \rightarrow e} \quad - (4)
\end{array}$$

At a \rightarrow_i step the assumption cancelled is indicated by $-(n)$. At this time the assumption is relabelled with (β) .

In the lambda term proof each application represents a use of \rightarrow_e and each λ -abstraction a use of \rightarrow_i . It follows that:

THEOREM 32.

1. Every type of a λ -term is a theorem of H_{\rightarrow} .
2. Every natural deduction style proof of a theorem of H_{\rightarrow} can be represented by a closed λ -term with that theorem as its type.

Proof.

1. We will prove the following more general result by induction on X :

If $FV(X) \subseteq \{x_1, \dots, x_n\}$ and if

$$x_1 : \alpha_1, \dots, x_n : \alpha_n \vdash X : \beta \quad - (a)$$

then

$$\alpha_1, \dots, \alpha_n \vdash \beta \quad - (b)$$

in H_{\rightarrow} .

If X is an atom, $X = x_i$ for some i , $1 \leq i \leq n$ and $\beta = \alpha_i$, so (b) holds.

If (a) is obtained from

$$x_1 : \alpha_1, \dots, x_n : \alpha_n, x_{n+1} : \alpha_{n+1} \vdash Y : \alpha,$$

where $\beta = \alpha_{n+1} \rightarrow \alpha$ and $X = \lambda x_{n+1}.Y$ then by the induction hypothesis

$$\alpha_1, \dots, \alpha_n, \alpha_{n+1} \vdash \alpha$$

is valid in H_{\rightarrow} and so also (b).

$$\begin{aligned} \text{If } X \equiv UV \text{ where} \\ x_{i_1} : \alpha_{i_1}, \dots, x_{i_k} : \alpha_{i_k} \vdash U : \alpha \rightarrow \beta, \\ x_{j_1} : \alpha_{j_1}, \dots, x_{j_m} : \alpha_{j_m} \vdash V : \alpha \\ \text{and } \{x_{i_1} : \alpha_{i_1}, \dots, x_{i_n} : \alpha_{i_n}\} \cup \{x_{j_1} : \alpha_{j_1}, \dots, x_{j_m} : \alpha_{j_m}\} \\ = \{x_1 : \alpha_1, \dots, x_n : \alpha_n\} \end{aligned}$$

we have by the induction hypothesis in H_{\rightarrow} :

$$\alpha_{i_1}, \dots, \alpha_{i_k} \vdash \alpha \rightarrow \beta$$

and

$$\alpha_{j_1}, \dots, \alpha_{j_m} \vdash \alpha$$

and so (b).

2. We show by induction on the length of a proof in H_{\rightarrow} of

$$\alpha_1, \dots, \alpha_n \vdash \beta \tag{c}$$

that there is a term X with $FV(X) \subseteq \{x_1, \dots, x_n\}$ such that

$$x_1 : \alpha_1, \dots, x_n : \alpha_n \vdash X : \beta \tag{d}$$

If β is one of the α_i s this is obvious with $X = x_i$.

If (c) is obtained by the \rightarrow_i rule from

$$\alpha_1, \dots, \alpha_n, \gamma \vdash \delta$$

where $\beta = \gamma \rightarrow \delta$, then by the induction hypothesis we have

$$x_1 : \alpha_1, \dots, x_n : \alpha_n, x_{n+1} : \gamma \vdash Y : \delta$$

where $FV(Y) \subseteq \{x_1, \dots, x_n, x_{n+1}\}$.

Then (d) follows with $X = \lambda x_{n+1}.Y$.

If (c) is obtained from

$$\begin{array}{l} \alpha_{i_1} \dots, \alpha_{i_k} \vdash \alpha \rightarrow \beta \\ \text{and } \alpha_{j_1} \dots, \alpha_{j_m} \vdash \alpha \\ \text{where } \{\alpha_{i_1}, \dots, \alpha_{i_k}\} \cup \{\alpha_{j_1}, \dots, \alpha_{j_m}\} = \{\alpha_1, \dots, \alpha_n\} \end{array}$$

We have, by the induction hypothesis:

$$\begin{array}{l} x_{i_1} : \alpha_{i_1}, \dots, x_{i_k} : \alpha_{i_k} \vdash Y : \alpha \rightarrow \beta \\ x_{j_1} : \alpha_{j_1}, \dots, x_{j_m} : \alpha_{j_m} \vdash Z : \alpha \end{array}$$

where $FV(Y) \subseteq \{x_{i_1}, \dots, x_{i_k}\}$ and $FV(Z) \subseteq \{x_{j_1}, \dots, x_{j_m}\}$.

(d) then follows with $X = YZ$. ■

3.3 Long Normal Forms

In Section 5 we will develop an algorithm, which, when given a type, will produce an inhabitant of this type if it has one. The inhabitant that is produced is in **long normal form**. This is defined below.

DEFINITION 33 (Long normal form). A typed λ -term $\lambda x_1 \dots x_n. x_i X_1 \dots X_k$ ($n \geq 0$, $k \geq 0$) is said to be in **long normal form** (lnf) if X_1, \dots, X_k are in lnf and have types τ_1, \dots, τ_k and x_i has type $\tau_1 \rightarrow \dots \rightarrow \tau_k \rightarrow a$ where a is an atom.

THEOREM 34. *If X is a λ -term such that $\vdash X : \alpha$, then there is a term Y in lnf such that $\vdash Y : \alpha$ and $Y \triangleright_\eta X$.*

Proof. By induction on the number of parts $x_i X_1 \dots X_k$ of X that are not in lnf and are not the initial part of a term $x_i X_1 \dots X_m$, with $m > k$.

Consider the shortest of these. X_1, \dots, X_k must then be in lnf and if each X_j has type τ_j , x_i must have type $\tau_1 \rightarrow \dots \rightarrow \tau_m \rightarrow a$ where $m > k$.

Let $x_{p+1}, x_{p+2}, \dots, x_{p+m-k}$ be variables not free in $x_i X_1 \dots X_k$ with types $\tau_{k+1}, \tau_{k+2}, \dots, \tau_m$ respectively.

Then $x_i X_1 \dots X_k x_{p+1} \dots x_{p+m-k}$ has type a and $\lambda x_{p+1} \dots x_{p+m-k}. x_i X_1 \dots X_k x_{p+1} \dots x_{p+m-k}$ has type $\tau_{k+1} \dots \rightarrow \tau_m \rightarrow a$, the same as $x_i X_1 \dots X_k$.

This new term with the same type as $x_i X_1, \dots, X_k$ is in lnf, so when it replaces $x_i X_1 \dots X_k$ in X , there is one fewer part not in lnf.

Hence X can be expanded to a term Y in lnf such that $Y \triangleright_\eta X$. The types of the parts of X being changed are not affected so the type of Y will be the same as the type of X . ■

3.4 Lambda Reductions and Proof Reductions

We illustrate here what happens to (a part of) a proof represented by a λ -term $(\lambda x.X)Y$ or $\lambda y.Xy$ with $y \notin FV(X)$ when this is reduced by (β) or (η) .

$$\frac{\frac{\frac{(\lambda)}{x : \alpha} D_1}{X : \beta} \text{-(1)} \quad \frac{D_2}{Y : \alpha}}{(\lambda x.X)Y : \beta} D_3$$

reduces to:

$$\frac{\frac{D_2}{Y : \alpha} [Y/x]D_1}{[Y/x]X : \beta} D_3$$

and

$$\rightarrow_e \frac{\frac{\frac{D_1}{X : \alpha \rightarrow \beta} \quad \frac{(\lambda)}{x : \alpha}}{Xx : \beta} \text{-(1)} \quad (x \notin FV(X))}{\rightarrow_i \frac{\lambda x.Xx : \alpha \rightarrow \beta} D_2} \text{-(1)}$$

reduces to

$$\frac{D_1}{X : \alpha \rightarrow \beta} [X/\lambda x.Xx] D_2$$

An expansion of a typed λ -term to Inf reverses the second reduction.

The effect of these reductions on a type assignment shown by the above is stated in the theorem below.

THEOREM 35 (Subject Reduction Theorem). *If*

$$x_1 : \tau_1, \dots, x_n : \tau_n \vdash X : \alpha$$

and

$$X \triangleright_{\beta\eta} Y \quad ,$$

then

$$x_1 : \tau_1, \dots, x_n : \tau_n \vdash Y : \alpha$$

Proof. A full proof of this is lengthy. A good outline appears in [Hindley and Seldin, 1986, Chapter 15]. ■

The converse of this is not true, for example $(\lambda uv.v)(\lambda x.xx)$ has no type but it β -reduces to $\lambda v.v$ which has type $a \rightarrow a$.

$\lambda xyz.(\lambda u.y)(xz)$ has type $(c \rightarrow d) \rightarrow b \rightarrow c \rightarrow b$, but not type $a \rightarrow b \rightarrow c \rightarrow b$, it reduces to $\lambda xyz.y$ which has type $a \rightarrow b \rightarrow c \rightarrow b$.

The η -expansion used in forming a lnf in the proof of Theorem 34, illustrates the following limited form of the Subject Expansion Theorem.

THEOREM 36. *If*

$$x_1 : \tau_1, \dots, x_n : \tau_n \vdash X : \alpha \rightarrow \beta$$

then

$$x_1 : \tau_1, \dots, x_n : \tau_n \vdash \lambda x.Xx : \alpha \rightarrow \beta$$

if $x \notin FV(X)$.

Proof. See Hindley and Seldin [1986, Chapter 15]. ■

References Much more detail on the work in this section can be found in [Hindley, 1997, Chapter 2]. The system TA_λ discussed there is effectively the system we have introduced. See also [Barendregt, 1984, Appendix A].

4 TRANSLATIONS

As λ -terms and combinators describe the same set of (recursive) functions it is not surprising that for each λ -term there is a combinator representing the same function and, in a simple case, with the same reduction theorems (as in **(K)**, **(S)** or Theorem 6) and the same types.

For every combinator there is also a similar λ -term given by:

DEFINITION 37 ((X_λ)).

$$\begin{aligned} \mathbf{S}_\lambda &\equiv \lambda xyz.xz(yz) \\ \mathbf{K}_\lambda &\equiv \lambda xy.x \\ (XY)_\lambda &\equiv X_\lambda Y_\lambda. \end{aligned}$$

Any λ -term X can be translated into a combinator by taking parts of X of the form $\lambda x_i \dots x_j.Y$ where Y contains no λx_k s and changing these to $[x_i, \dots, x_j]Y$ as defined in Definition 7, then further parts of the form $\lambda x_i \dots x_j.Y$ can be changed in the same way until there are no λx_k s left. If we call this translation $*$ we might hope to have

$$X_{\lambda*} \equiv X$$

and

$$Y_{*\lambda} \equiv Y$$

for any combinator X and λ -term Y .

The former identity holds, but the latter one does not, in general.

EXAMPLE 38.

1. $(\mathbf{SKK})_{\lambda*} \equiv (\lambda xyz.xz(yz))_*(\lambda uv.u)_*(\lambda ts.t)_*$
 $\equiv ([x, y, z].xz(yz))([u.v]u)([t, s]t)$
 $\equiv ([x, y].\mathbf{S}xy)([u].\mathbf{K}u)([t].\mathbf{K}t) \equiv \mathbf{SKK}$
2. $(z(\lambda xyz.xyyz))_{*\lambda} \equiv z([x, y, z].xyyz)_\lambda$
 $\equiv z([x, y].xyy)_\lambda \equiv z([x].\mathbf{S}x\mathbf{I})_\lambda \equiv z(\mathbf{SS}(\mathbf{KI}))_\lambda$
 $\equiv z(\lambda xyz.xz(yz))(\lambda uvw.uw(vw))((\lambda st.s)(\lambda r.r))$
 $\triangleright z(\lambda yzw.zw(yzw))(\lambda tr.r)$
 $\triangleright z(\lambda zw.zw((\lambda tr.r)zw))$
 $\triangleright z(\lambda zw.zww)$

In the second example above we have only

$$Y_{*\lambda} =_{\beta\eta} Y .$$

This turns out to be about as much as we can hope to have.

Weaker sets of combinators can be translated into λ -calculus in the same way as above with the translations of \mathbf{S} and \mathbf{K} in Definition 37 replaced by appropriate translations such as:

$$\mathbf{B}_\lambda \equiv \lambda xyz.x(yz) ,$$

for each element of the given basis set Q .

The reverse process however is not so simple. It is not clear which λ -terms can be translated, say, into \mathbf{BCIW} combinators, nor how to perform this translation.

We will resolve this problem later for several basis sets Q .

The process is important as, as was mentioned in the introduction, it provides a decision procedure and a constructive proof finding algorithm for axiomatic logics.

4.1 Q -Translation Algorithms

Trigg, Bunder and Hindley in [Trigg *et al.*, 1994] have extended the notion of abstractibility from that of Definition 7 for \mathbf{SK} -combinators to abstractibility for Q -combinators for various basis sets Q . These definitions will form part of our translation procedures.

First we will give the definition, from [Bunder, 1996], of a translation from λ -terms into Q -combinators.

DEFINITION 39. A mapping $*$ from λ -terms to Q -terms is defined by:

1. $X_* \equiv X$ (X an atom)
2. $(XY)_* \equiv X_*Y_*$
3. $(\lambda x.X)_* \equiv \lambda^*x.X_*$,

λ^*x varies with Q but is, in simple cases, like the bracket abstraction $[x]$ of Definition 7, a sequence of some of the following clauses:

- (i) $\lambda^*x.x \equiv \mathbf{I}$
- (k) $\lambda^*x.X \equiv \mathbf{K}X$ if $x \notin FV(X)$
- (η) $\lambda^*x.Xx \equiv X$ if $x \notin FV(X)$
- (s) $\lambda^*x.XY \equiv \mathbf{S}(\lambda^*x.X)(\lambda^*x.Y)$
- (b) $\lambda^*x.XY \equiv \mathbf{B}X(\lambda^*x.Y)$ if $x \notin FV(X)$
- (c) $\lambda^*x.XY \equiv \mathbf{C}(\lambda^*x.X)$ if $x \notin FV(Y)$

Note that, as before, the clauses in an algorithm $*$ are used strictly in the order in which they appear.

Note also that the mapping starts by assigning a $*$ to each λ in the term starting from the outermost ones and working inwards. Then, to the innermost terms $\lambda^*x.Z$ i.e. those for which Z contains no λ^* s, we apply the appropriate abstraction clause. Later steps now evaluate terms $\lambda^*x.Z_1$ where Z_1 is a Q -term. The Q -combinators in Z_1 arise from the evaluation of previous $\lambda^*x.Z$ s.

EXAMPLE 40.

$$\begin{aligned} \lambda^{(ik\eta s)}xy.xzy &\equiv \lambda^{(ik\eta s)}x.xz \equiv \mathbf{SI}(\mathbf{K}z) \\ \lambda^{(isk\eta)}xy.xzy &\equiv \lambda^{(isk\eta)}x.\mathbf{S}(\mathbf{S}(\mathbf{K}x)(\mathbf{K}z))\mathbf{I} \\ &\equiv \mathbf{S}(\mathbf{S}(\mathbf{K}\mathbf{S})\mathbf{S}(\mathbf{S}(\mathbf{K}\mathbf{S})\mathbf{S}(\mathbf{K}\mathbf{K})\mathbf{I}))(\mathbf{S}(\mathbf{K}\mathbf{K})(\mathbf{K}z)))(\mathbf{K}\mathbf{I}) \end{aligned}$$

DEFINITION 41. A mapping $*$ from λ -terms to Q -terms is said to be a **Q-translation algorithm** if:

- (A) For every Q -combinator X , X_{λ^*} is defined and

$$X_{\lambda^*} \equiv X .$$

- (B) If for a λ -term Y , Y_* is defined and is a Q -term, then there is a λ -term Y_1 such that:

$$Y_{*\lambda} \triangleright_Q Y_1 \triangleleft_\eta Y$$

where \triangleright_Q means that only full or partial reductions involving the λ -versions of Q -combinators are used and \triangleleft_η involves only η and α -reductions.

EXAMPLE 38.2 (again) In this example we had,

$$\begin{aligned} \text{with } * &\equiv (ik\eta s), \\ Y &\equiv z(\lambda xyz. xy yz), \\ \text{and } Y_{*\lambda} &\equiv z(\lambda zw. zww), \end{aligned}$$

so (B) holds with $Y_1 =_\alpha Y_{*\lambda}$.

EXAMPLE 42. $(\mathbf{BCC})_{\lambda*} \equiv (\lambda xyz. x(yz))_*(\lambda uvw. uvw)_*(\lambda rst. rts)_*$

If $*$ is $(i\eta bc)$ we have

$$(\mathbf{BCC})_{\lambda*} \equiv \mathbf{BCC}$$

as required by (A).

If however $*$ is (ikc) $(\lambda xyz. x(yz))_*$ is not definable so (ikc) is not a **BCI**-translation algorithm.

If $*$ is (ibc) we have

$$\begin{aligned} \mathbf{B}_{\lambda*} &\equiv (\lambda xyz. x(yz))_* \\ &\equiv \mathbf{C}(\mathbf{BB}(\mathbf{BBI}))(\mathbf{C}(\mathbf{BBI})\mathbf{I}) \neq \mathbf{B}, \end{aligned}$$

so (ibc) is also not a **BCI**-translation algorithm.

(note that we do have $\mathbf{B}_{\lambda*} =_{\beta\eta} \mathbf{B}$.)

EXAMPLE 43. When $*$ is $(i\eta bc)$

$$\begin{aligned} (\lambda yz. z(\lambda x. yx))_{*\lambda} &\equiv (\lambda^* yz. z(\lambda^* x. yx))_\lambda \\ &\equiv (\lambda^* yz. zy)_\lambda \equiv (\lambda^* z. \mathbf{CI}z)_\lambda \\ &\equiv (\mathbf{CI})_\lambda \\ &\equiv (\lambda uvw. uvw)(\lambda x. x) \\ &\triangleright_{\mathbf{BCI}} \lambda vw. (\lambda x. x)wv \\ &\triangleright_{\mathbf{BCI}} \lambda vw. wv. \end{aligned}$$

while also $\lambda yz. z(\lambda x. yx) \triangleright_\eta \lambda vw. wv$

The following theorem lists some properties that are preserved under the operations λ and $*$.

THEOREM 44.

1. If X and Y are Q -terms then

$$X \triangleright_Q Y \Rightarrow X_\lambda \triangleright_Q Y_\lambda .$$

If $*$ is a Q -translation algorithm then:

2. for every Q -term X , $X_{\lambda*}$ is defined and

$$X_{\lambda*} \equiv X$$

3. For every pair of λ -terms U and V for which U_* and V_* are defined and are Q -terms,

$$U =_{\beta\eta} V \Leftrightarrow U_* =_{\beta\eta} V_*$$

4. If Y_* is defined and is a Q -term then

$$(\lambda x.Y)_*x =_{\beta\eta} Y_*$$

Proof.

1. It suffices to prove the result for $X \equiv PX_1 \dots X_n$ where P is any Q -combinator and $Y \equiv f(X_1, \dots, X_n)$ which results by a single P -reduction step. Then

$$\begin{aligned} X_\lambda &\equiv P_\lambda X_{1\lambda} \dots X_{n\lambda} \\ &\equiv (\lambda x_1 \dots x_n. f(x_1, \dots, x_n)) X_{1\lambda} \dots X_{n\lambda} \triangleright_Q f(X_{1\lambda}, \dots, X_{n\lambda}) \\ &\equiv Y_\lambda. \end{aligned}$$

2. By an easy induction using (A) and Definition 39.2.

3. By Curry and Feys [1958, Section 6C4, Theorem 1]:

$$U_* =_{\beta\eta} V_* \iff U_{*\lambda} =_{\beta\eta} V_{*\lambda}$$

so the result follows by (B).

4. By (3) $((\lambda x.Y)x)_* =_{\beta\eta} Y_*$ so the result holds by Definition 39.2. ■

4.2 Q -definability

We now come to the important question as to which λ -terms can be translated into Q -combinators, for a given Q . We first define Q -definability.

DEFINITION 45. A λ -term Y is **Q -definable** if there is a Q -translation algorithm $*$ for which Y_* is defined and is a Q -term.

The following theorem relates the $()_\lambda$ operation to Q -definability.

THEOREM 46.

1. If Z is Q -definable there is a Q -term X such that $Z =_{\beta\eta} X_\lambda$.
2. If X is a Q -term and there is a Q -translation algorithm then X_λ is Q -definable.

Proof.

1. If Z is Q -definable there is a Q -translation algorithm $*$ so that, by (B)

$$Z_{*\lambda} =_{\beta\eta} Z.$$

thus Z_* is the required X .

2. If X is a Q -term and $*$ is a Q -translation algorithm, by Theorem 44.2 $X_{\lambda*} \equiv X$, so clearly X_λ is Q -definable. ■

The importance of Q -definability, for implicational logics is that a typed λ -term Y is Q -definable if and only if its type is a theorem of Q -logic. In all the cases we deal with below we find that, for a given Q , we can find a Q -translation algorithm which translates all Q -definable λ -terms.

We now give translations algorithms for a number of sets of combinators. First we need a lemma.

LEMMA 47. *If U is a λ -term for which U_* is defined then*

1. *if $*$ is the $(i\eta ks)$ algorithm* $(\lambda^*x.U_*)x \triangleright_{\mathbf{KS}} U_*$.
2. *if $*$ is the $(i\eta kbc)$ algorithm* $(\lambda^*x.U_*)x \triangleright_{\mathbf{BCK}} U_*$.
3. *if $*$ is the $(i\eta bc)$ algorithm* $(\lambda^*x.U_*)x \triangleright_{\mathbf{BCI}} U_*$.
4. *if $*$ is the $(i\eta bcs)$ algorithm* $(\lambda^*x.U_*)x \triangleright_{\mathbf{BCIW}} U_*$.

Proof.

1. By induction on the length of U_* . If $U_* \equiv x$

$$(\lambda^*x.U_*)x \equiv \mathbf{I}x \equiv \mathbf{SKK}x \triangleright_{\mathbf{KS}} x \equiv U_*.$$

If $U_* \equiv U_{1*}x$ where $x \notin FV(U_{1*})$,

$$(\lambda^*x.U_*)x \equiv U_{1*}x \equiv U_*.$$

If $x \notin FV(U_*)$,

$$(\lambda^*x.U_*)x \equiv \mathbf{K}U_*x \triangleright_{\mathbf{KS}} U_*$$

If $U_* \equiv U_{1*}U_{2*}$, where $x \in FV(U_{1*}U_{2*})$ and either $x \in FV(U_{1*})$ or $U_{2*} \neq x$, $(\lambda^*x.U_*)x = \mathbf{S}(\lambda^*x.U_{1*})(\lambda^*x.U_{2*})x \triangleright_{\mathbf{KS}} (\lambda^*x.U_{1*})x((\lambda^*x.U_{2*})x) \triangleright_{\mathbf{KS}} U_{1*}U_{2*} \equiv U_*$ by the induction hypothesis.

Cases 2. to 4. are similar. ■

THEOREM 48.

1. $(i\eta ks)$ is an **SK**-translation algorithm.
2. $(i\eta kbc)$ is a **BCK**-translation algorithm.
3. $(i\eta bc)$ is a **BCI**-translation algorithm.
4. $(i\eta bcs)$ is a **BCIW**-translation algorithm.

Proof.

1. It is easy to check that (A) holds for the $(i\eta ks)$ abstraction algorithm.

We prove (B) by induction on the length of the λ -term Y .

If Y is an atom $Y_{*\lambda} \equiv Y$.

If $Y \equiv UV$, $Y_{*\lambda} \equiv U_{*\lambda}V_{*\lambda}$ and by the inductive hypothesis we have a U_1 and V_1 such that $Y_{*\lambda} \equiv U_{*\lambda}V_{*\lambda} \triangleright_{\mathbf{KS}} U_1V_1 \triangleleft_{\eta} UV \equiv Y$.

If $Y \equiv \lambda x.Xx$, where $x \notin FV(X)$,

$$Y_{*\lambda} \equiv (\lambda x.Xx)_{*\lambda} \equiv X_{*\lambda}.$$

By the induction hypothesis there is an X_1 such that

$$Y_{*\lambda} \equiv X_{*\lambda} \triangleright_{\mathbf{KS}} X_1 \triangleleft_{\eta} X \triangleleft_{\eta} Y.$$

If $Y = \lambda x.UV$ where $x \in FV(U)$ or $x \neq V$, but $x \in FV(UV)$.

$$\begin{aligned} Y_{*\lambda} &\equiv \mathbf{S}_{\lambda}(\lambda x.U)_{*\lambda}(\lambda x.V)_{*\lambda} \\ &\equiv (\lambda uvx.ux(vx)) \\ &\quad (\lambda x.U)_{*\lambda}(\lambda x.V)_{*\lambda} \\ \triangleright_{\mathbf{SK}} \lambda x.((\lambda x.U)_{*\lambda}x)((\lambda x.V)_{*\lambda}x) &\equiv \lambda x.((\lambda^*x.U^*)x)_{\lambda}((\lambda^*x.V^*)x)_{\lambda} \\ &\quad \triangleright_{\mathbf{SK}} \lambda x.U_{*\lambda}V_{*\lambda} \end{aligned}$$

by Lemma 47 and Theorem 44.1.

Now by the induction hypothesis there exist U_1 and V_1 such that

$$\lambda x.U_{*\lambda}V_{*\lambda} \triangleright_{\mathbf{SK}} \lambda x.U_1V_1 \triangleleft_{\eta} \lambda x.UV \equiv Y .$$

Note that if x had not been chosen as the third bound variable in \mathbf{S}_{λ} , an extra α -reduction would have been required from $\lambda x.U_1V_1$ to reach the term obtained by the **SK**-reduction. We will use similar simplifications below.

If $Y \equiv \lambda x.x$,

$$Y_{*\lambda} \equiv \mathbf{I}_{\lambda} =_{\alpha} Y .$$

If $Y \equiv \lambda x.X$, where $x \notin FV(X)$,

$$\begin{aligned} Y_{*\lambda} &\equiv \mathbf{K}_\lambda X_{*\lambda} \\ &\equiv (\lambda y.x.y) X_{*\lambda} \triangleright_{\mathbf{SK}} \lambda x.X_{*\lambda} . \end{aligned}$$

By the induction hypothesis there exists an X_1 such that

$$X_{*\lambda} \triangleright_{\mathbf{SK}} X_1 \triangleleft_\eta X$$

so

$$Y_{*\lambda} \triangleright_{\mathbf{SK}} \lambda x.X_1 \triangleleft_\eta Y$$

2., 3. and 4. are similar. ■

EXAMPLE 49.

1. $\lambda^{i\eta kbc} x_1 x_2 . x_2 (\lambda^{i\eta kbc} x_3 . x_1 x_4) \equiv \lambda^{i\eta kbc} x_1 x_2 . x_2 (\mathbf{K}(x_1 x_4))$
 $\equiv \lambda^{i\eta kbc} x_1 . \mathbf{CI}(\mathbf{K}(x_1 x_4))$
 $\equiv \mathbf{B}(\mathbf{CI})(\mathbf{BK}(\mathbf{CI}x_4))$
2. $\lambda^{i\eta bc} x_1 x_2 . x_2 (\lambda^{i\eta bc} x_3 . x_3 x_1)$
 $\equiv \lambda^{i\eta bc} x_1 x_2 . x_2 (\mathbf{CI}x_1)$
 $\equiv \lambda^{i\eta bc} x_1 . \mathbf{CI}(\mathbf{CI}x_1)$
 $\equiv \mathbf{B}(\mathbf{CI})(\mathbf{CI})$.
3. $\lambda^{i\eta kbc s} x_1 x_2 . x_2 (\lambda^{i\eta kbc s} x_3 . x_2 (x_1 x_3))$
 $\equiv \lambda^{i\eta kbc s} x_1 x_2 . x_2 (\mathbf{B}x_2 x_1)$
 $\equiv \lambda^{i\eta kbc s} x_1 . \mathbf{SI}(\mathbf{CB}x_1)$
 $\equiv \mathbf{B}(\mathbf{SI})(\mathbf{CB})$.

4.3 SK, BCI, BCK and BKIW Definable Terms

For many sets Q we can delineate the Q -definable terms. First we need some notation.

DEFINITION 50.

1. Λ is the set of all λ -terms.
2. A λ -term is in $\text{Once}(i_1, \dots, i_n)$ if each x_{i_1}, \dots, x_{i_n} appears free exactly once in the term and if in every subterm $\lambda x_{j_1} \dots x_{j_k} . Y$ of the term, Y is in $\text{Once}(j_1, \dots, j_k)$.
3. A λ -term is in $\text{Once}^-(i_1, \dots, i_n)$ if each x_{i_1}, \dots, x_{i_n} appears free at most once in the term and if in every subterm $\lambda x_{j_1} \dots x_{j_k} . Y$ of the term, Y is in $\text{Once}^-(j_1, \dots, j_k)$.

4. A λ -term is in $\text{Once}^+(i_1, \dots, i_n)$ if each of x_{i_1}, \dots, x_{i_n} appears at least once in the term and if in every subterm $\lambda x_{j_1} \dots x_{j_k}. Y$ of the term, Y is in $\text{Once}^+(j_1, \dots, j_k)$.

THEOREM 51.

1. The set of **SK**-definable terms is Λ .
2. The set of **BCI**-definable terms is $\text{Once}(\)$.
3. The set of **BCK**-definable terms is $\text{Once}^-(\)$.
4. The set of **BCIW**-definable terms is $\text{Once}^+(\)$.

Proof.

1. is trivial.
2. If $Y \in \text{Once}(i_1, \dots, i_n)$ for some i_1, \dots, i_n we show by induction on Y that Y is **BCI**-definable using the $(i\eta bc)$ algorithm.

Case 1 Y is an atom $Y_{(i\eta bc)} \equiv Y$.

Case 2 $Y \equiv UV$, $U \in \text{Once}(j_1, \dots, j_r)$ and $V \in \text{Once}(m_1, \dots, m_s)$, where (j_1, \dots, j_r) and (m_1, \dots, m_s) are disjoint subsequences of (i_1, \dots, i_n) and $r + s = n$.

Then by the induction hypothesis U and V are **BCI**-definable using the $(i\eta bc)$ algorithm and

$$Y_{(i\eta bc)} = U_{(i\eta bc)} V_{(i\eta bc)}.$$

Case 3 $Y \equiv \lambda x_p. Zx_p$ where $x_p \notin FV(Z)$.

$$Zx_p \in \text{Once}(i_1, \dots, i_n, p)$$

and by the induction hypothesis Zx_p is **BCI**-definable as $Z_{(i\eta bc)}x_p$ and

$$Y_{(i\eta bc)} = Z_{(i\eta bc)}.$$

Case 4 $Y \equiv \lambda x_p. UV$, $UV \in \text{Once}(i_1, \dots, i_n, p)$ and so $x_p \in FV(V) - FV(U)$ or $x_p \in FV(U) - FV(V)$.

Hence, for similar disjoint sequences to the above we have $U \in \text{Once}(j_1, \dots, j_r)$ and $V \in \text{Once}(m_1, \dots, m_s, p)$ or $U \in \text{Once}(j_1, \dots, j_r, p)$ and $V \in \text{Once}(m_1, \dots, m_s)$.

In the former case U, V and $\lambda x_p. V$ are **BCI** definable and

$$Y_{(i\eta bc)} \equiv \mathbf{BU}_{(i\eta bc)}(\lambda^{(i\eta bc)} x_p. V_{(i\eta bc)}).$$

In the latter case U, V and $\lambda x_p.U$ are **BCI**-definable and

$$Y_{(i\eta bc)} \equiv \mathbf{C}(\lambda^{(i\eta bc)} x_p.U_{(i\eta bc)})V_{(i\eta bc)}.$$

3. and 4. are similar, except that in 4. (m_1, \dots, m_s) and (j_1, \dots, j_r) need not be disjoint. ■

Note that in each of the four cases above the set of definable λ -terms leads us to a natural deduction style system for the logic.

In the case of **BCIW**-logic (the relevance logic R_{\rightarrow}), the only λ -terms allowable are those in $\text{Once}^+(\cdot)$. These can be generated by allowing $\lambda x.X$ to be defined only when $x \in FV(X)$. This restriction when translated to typed terms becomes:

$$\frac{\begin{array}{c} (A) \\ x : \alpha \\ D_1 \\ X : \beta \end{array}}{\lambda x.X : \alpha \rightarrow \beta} \text{---}(1)$$

only if $x : \alpha$ is used in the proof D_1 . This therefore gives the appropriate restriction on an $R_{\rightarrow} \rightarrow$ introduction rule.

4.4 Bases Without **C**

We now look at some basis sets that do not include (as defined or primitive) the combinator **C**. Its lack causes a problem.

Previously the algorithms we used in evaluating $\lambda^* x_2.X$ did not affect the definability of $\lambda^* x_1.\lambda^* x_2.X$. When we are dealing with algorithms that do not include (c) (or (s)), this definability may fail depending on a choice of $*$.

If, for example, we define $\lambda^* x_3.x_4 x_2(x_1 x_3)$ to be $\mathbf{B}(x_4 x_2)x_1$, using clause (b), we cannot easily define $\lambda^* x_2.\mathbf{B}(x_4 x_2)x_1$. If however we defined $\lambda^* x_3.x_4 x_2(x_1 x_3)$ as $\mathbf{B}'x_1(x_4 x_2)$, using a clause (b'), we can define $\lambda^* x_2.\lambda^* x_3.x_4 x_2(x_1 x_3)$ as $\mathbf{B}(\mathbf{B}\mathbf{B}')x_1 x_4$ using (b). Clearly if (b) and (b') (and so **B** and **B'**) are both available in our translation algorithm, the choice of which to use would depend on the variables to be abstracted later.

If a subterm $\lambda x_{i_n+1}.Y$ of a λ -term X is to be translated by $*$ and is in the scope of (from left to right in X): $\lambda x_{i_1}, \dots, \lambda x_{i_n}$, we will write this translation as $\lambda_{x_{i_n+1}}^{x_{i_1}, \dots, x_{i_n}}.Y_*$, so that the variables with respect to which we need to abstract later are flagged as: x_{i_n} to be done next, then $x_{i_{n-1}}$ etc. These abstractions are of course tied to some set Q and to algorithm clauses which we still denote by $*$.

To ensure that the flagged x_{i_j} s are distinct we will assume that any λ -term X being translated has, if necessary, first been altered so that no λx_k appears more than once in X .

For Q -translation algorithms $*$, where \mathbf{C} is not in Q , such as $\mathbf{BB'I}$ and $\mathbf{BB'IW}$, we replace Definition 39 by:

DEFINITION 52. $(x_{i_1}, \dots, x_{i_n}; Y)^*$ and in particular $(; Y)^* \equiv Y_*$ are given by:

$$\begin{aligned} (x_{i_1}, \dots, x_{i_n}; P)^* &\equiv P \quad \text{if } P \text{ is an atom} \\ (x_{i_1}, \dots, x_{i_n}; PQ)^* &\equiv (x_{i_1}, \dots, x_{i_n}; P)^*(x_{i_1}, \dots, x_{i_n}; Q)^* \\ (x_{i_1}, \dots, x_{i_n}; \lambda_{x_{i_{n+1}}}.R)^* &\equiv \lambda_{x_{i_{n+1}}}^{x_{i_1}, \dots, x_{i_n}}.(x_{i_1}, \dots, x_{i_n}, x_{i_{n+1}}; R)^* \\ (; \lambda_{x_{i_1}}.R)^* &\equiv \lambda^* x_{i_1} (x_{i_1}; R)^*. \end{aligned}$$

Note that Theorem 44 still holds under this definition.

EXAMPLE 53.

$$\begin{aligned} (& ; \lambda x_4 x_1 . x_3 (\lambda x_5 x_6 . x_1 (\lambda x_7 . x_1 x_5)) (\lambda x_2 . x_2 (\lambda x_9 . x_2)))^* \equiv \\ & \lambda^* x_4 \lambda_{x_1}^{x_4} . x_3 (\lambda_{x_5}^{x_4 x_1} . (\lambda_{x_6}^{x_4 x_1 x_5} . x_1 (\lambda_{x_7}^{x_4 x_1 x_5 x_6} . x_1 x_5))) (\lambda_{x_2}^{x_4 x_1} . x_2 (\lambda_{x_9}^{x_4 x_1 x_2} . x_2)) \end{aligned}$$

Before we can write down the algorithm clauses used for logics without \mathbf{C} , we need the notion of the index of a term with respect to a set of variables.

DEFINITION 54. $(idx(M, i_1, \dots, i_n))$

$$idx(M, i_1, \dots, i_n) = \max \left\{ p \mid 1 \leq p \leq n \wedge x_{i_p} \in FV(M) \right\}$$

DEFINITION 55 $((\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . P))$. This is defined using some or all of the following clauses, depending on $*$.

- (i) $\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . x_{i_{n+1}} \equiv \mathbf{I}$
- (η) $\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . U x_{i_{n+1}} \equiv U$ if $x_{i_{n+1}} \notin FV(U)$
- (b) $\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . PQ \equiv \mathbf{BP}(\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . Q)$
if $idx(P, i_1, \dots, i_n) \leq idx(Q, i_1, \dots, i_n)$ or $x_{i_1} \dots x_{i_n}$ is replaced by $*$;
and $x_{i_{n+1}} \notin FV(P)$.
- (b') $\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . PQ \equiv \mathbf{B}'(\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . Q)P$
if $idx(P, i_1, \dots, i_n) > idx(Q, i_1, \dots, i_n)$ and $x_{i_{n+1}} \notin FV(P)$.
- (s) $\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . PQ \equiv \mathbf{S}(\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . P)(\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . Q)$
if $idx(P, i_1, \dots, i_n) \leq idx(Q, i_1, \dots, i_n)$ or if $x_{i_1} \dots x_{i_n}$ is replaced by
 $*$
- (s') $\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . PQ \equiv \mathbf{S}'(\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . Q)(\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . P)$
if $idx(Q, i_1, \dots, i_n) < idx(P, i_1, \dots, i_n)$

EXAMPLE 56.

$$\begin{aligned}
1. & \quad (; \lambda x_2 x_4 . x_2 (\lambda x_3 . (\lambda x_5 x_6 . x_5 (x_4 x_6))) x_3)^{(i\eta bb')} \\
& \equiv \lambda^* x_2 \lambda_{x_4}^{x_2} . x_2 (\lambda_{x_3}^{x_2 x_4} . (\lambda_{x_5}^{x_2 x_4 x_3} \lambda_{x_6}^{x_2 x_4 x_3 x_5} . x_5 (x_4 x_6))) x_3 \\
& \equiv \lambda^* x_2 \lambda_{x_4}^{x_2} . x_2 (\lambda_{x_3}^{x_2 x_4} . (\lambda_{x_5}^{x_2 x_4 x_3} . \mathbf{B}' x_4 x_5) x_3) \\
& \equiv \lambda^* x_2 \lambda_{x_4}^{x_2} x_2 (\lambda_{x_3}^{x_2 x_4} . \mathbf{B}' x_4 x_3) \\
& \equiv \lambda^* x_2 \lambda_{x_4}^{x_2} . x_2 (\mathbf{B}' x_4) \\
& \equiv \mathbf{B}' \mathbf{B}' \quad \text{where } * \text{ is } (i\eta bb')
\end{aligned}$$

$$\begin{aligned}

& \equiv \lambda^* x_2 . \lambda_{x_4}^{x_2} . x_2 (\lambda_{x_3}^{x_2 x_4} . x_2 x_4 (\lambda_{x_1}^{x_2 x_4 x_3} . x_3 (x_4 x_1))) \\
& \equiv \lambda^* x_2 . \lambda_{x_4}^{x_2} . x_2 (\lambda_{x_3}^{x_2 x_4} . x_2 x_4 (\mathbf{B}' x_4 x_3)) \\
& \equiv \lambda^* x_2 . \lambda_{x_4}^{x_2} . x_2 (\mathbf{B} (x_2 x_4) (\mathbf{B}' x_4)) \\
& \equiv \lambda^* x_2 . \mathbf{B} x_2 (\mathbf{S}' \mathbf{B}' (\mathbf{B} \mathbf{B} x_2)) \\
& \equiv \mathbf{S} \mathbf{B} (\mathbf{B} (\mathbf{S}' \mathbf{B}') (\mathbf{B} \mathbf{B})) \quad \text{where } * \text{ is } (\eta ikbb' ss') .
\end{aligned}$$

4.5 Translation Algorithms and Definable Terms for $\mathbf{BB}'\mathbf{I}$ and $\mathbf{BB}'\mathbf{IW}$

Before we give the algorithms we need a lemma

LEMMA 57. *If Q is (i) $\mathbf{BB}'\mathbf{I}$ or (ii) $\mathbf{BB}'\mathbf{IW}$, X is a Q -term and $\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . X$ is defined then*

$$\left(\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . X \right) x_{i_{n+1}} \triangleright_Q X .$$

Proof. By induction on the length of X .

Cases 1 to 4 apply where Q is \mathbf{BBI}' or $\mathbf{BB}'\mathbf{IW}$, Cases 5 and 6 only for $\mathbf{BB}'\mathbf{IW}$.

Case 1 $X \equiv x_{i_{n+1}}$.

$$\left(\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . X \right) x_{i_{n+1}} \equiv \mathbf{I} x_{i_{n+1}} \triangleright_Q x_{i_{n+1}} \equiv X$$

Case 2 $X \equiv U x_{i_{n+1}}$ where $x_{i_{n+1}} \notin FV(U)$

$$\left(\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . X \right) x_{i_{n+1}} \equiv U x_{i_{n+1}} \equiv X .$$

Case 3 $X \equiv UV$ where $x_{i_{n+1}} \notin FV(U)$, $x_{i_{n+1}} \neq V$, and $idx(U, i_1, \dots, i_n) \leq idx(V, i_1, \dots, i_n)$.

$$\begin{aligned} (\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . X) x_{i_{n+1}} &\equiv \mathbf{BU} (\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . V) x_{i_{n+1}} \\ &\triangleright_Q U \left((\lambda_{x_{i_{n+1}}}^{x_{i_1} \dots x_{i_n}} . V) x_{i_{n+1}} \right) \\ &\triangleright_Q UV \equiv X, \end{aligned}$$

by the induction hypothesis.

Case 4 $X \equiv UV$ where $x_{i_{n+1}} \notin FV(U)$, $x_{i_{n+1}} \not\equiv V$ and $idx(V, i_1, \dots, i_n) < idx(U, i_1, \dots, i_n)$. Similar to Case 3.

Case 5 $X \equiv UV$ where $x_{i_{n+1}} \in FV(U) \cap FV(V)$ and $idx(U, i_1, \dots, i_n) \leq idx(V, i_1, \dots, i_n)$. Similar to Case 3.

Case 6 $X \equiv UV$ where $x_{i_{n+1}} \in FV(U) \cap FV(V)$ and $idx(V, i_1, \dots, i_n) < idx(U, i_1, \dots, i_n)$. Similar to Case 3. \blacksquare

THEOREM 58. *The following are translation algorithms:*

1. $(;)^{(i\eta bb')}$, for **BB'I**
2. $(;)^{(i\eta bb' ss')}$, for **BB'IW**

Proof. In each case (A) is obvious.

We will prove, for each algorithm $*$ and each basis Q , if $((x_{i_1}, \dots, x_{i_n}; Y)^*$ is defined, that there is a Y_1 such that:

$$\left((x_{i_1}, \dots, x_{i_n}; Y)^* \right)_\lambda \triangleright_Q Y_1 \triangleleft_\eta Y.$$

This we do by induction on the number k of clauses of $*$ that are needed to evaluate $(x_{i_1}, \dots, x_{i_n}; Y)^*$.

If $k = 0$ there are no λ s in Y and so

$$((x_{i_1}, \dots, x_{i_n}; Y)^*)_\lambda \equiv Y \equiv Y_1$$

If $k > 0$ it is sufficient to consider a subterm $(x_{i_1}, \dots, x_{i_m}; \lambda x_{i_{m+1}} . Z)^*$ ($\equiv \lambda_{x_{m+1}}^{x_{i_1} \dots x_{i_m}} . Z$) of $(x_{i_1}, \dots, x_{i_n}; Y)^*$ where Z contains no λ s and to show that there is a Z_1 such that:

$$(\lambda_{x_{m+1}}^{x_{i_1} \dots x_{i_m}} . Z)_\lambda \triangleright_Q Z_1 \triangleleft_\eta \lambda x_{i_{m+1}} . Z$$

We then have, by Theorem 44.1,

$$((x_{i_1}, \dots, x_{i_n}; Y)^*)_\lambda \triangleright_Q ((x_{i_1}, \dots, x_{i_n}; Y')^*)_\lambda \triangleleft_\eta Y' \triangleleft_\eta Y$$

where Y' is Y with Z_1 for $\lambda x_{i_{m+1}} . Z$.

Now Y' needs fewer than k clauses of $*$ for its evaluation, so by the induction hypothesis we have a Y_1 such that

$$((x_{i_1}, \dots, x_{i_n}; Y')^*)_\lambda \triangleright_Q Y_1 \triangleleft_\eta Y',$$

which provides the result.

To prove the above result for $\lambda x_{i_{m+1}}.Z$ we consider 6 cases for **BB'IW**. The first 4 also apply to **BB'I**.

Note that in each case if U is Z or a subterm of Z , as this contains no λ s, we have $U_* \equiv U$.

(a) If $Z \equiv x_{i_{m+1}}$, then

$$\left(\lambda_{x_{i_{m+1}}}^{x_{i_1}, \dots, x_{i_m}}.Z \right)_\lambda \equiv \mathbf{I}_\lambda \equiv \lambda x_{i_{m+1}}.Z$$

(b) If $Z \equiv Ux_{i_{m+1}}$ where $x_{i_{m+1}} \notin FV(U)$ then

$$\left(\lambda_{x_{i_{m+1}}}^{x_{i_1}, \dots, x_{i_m}}.Z \right)_\lambda \equiv U_{*\lambda}.$$

By the induction hypothesis there is a U_1 , such that

$$(\lambda_{x_{i_{m+1}}}^{x_{i_1}, \dots, x_{i_m}}.Z)_\lambda \triangleright_Q U_{*\lambda} \triangleright_Q U_1 \triangleleft_\eta U \triangleleft_\eta \lambda x_{i_{m+1}}.Z$$

(c) If $Z \equiv UV$, where $x_{i_{m+1}} \notin FV(U)$, $V \neq x_{i_{m+1}}$ and $idx(U, i_1, \dots, i_m) \leq idx(V, i_1, \dots, i_m)$

$$\begin{aligned} \left(\lambda_{x_{i_{m+1}}}^{x_{i_1}, \dots, x_{i_m}}.Z \right)_\lambda &\equiv \left(BU \left(\lambda_{x_{i_{m+1}}}^{x_{i_1}, \dots, x_{i_m}}.V \right) \right)_\lambda \\ &\equiv B\lambda U_{*\lambda} \left(\lambda_{x_{i_{m+1}}}^{x_{i_1}, \dots, x_{i_m}}.V \right)_\lambda \\ &\triangleright_Q \lambda x_{i_{m+1}}.U_{*\lambda} \left(\left(\lambda_{x_{i_{m+1}}}^{x_{i_1}, \dots, x_{i_m}}.V \right) x_{i_{m+1}} \right)_\lambda \end{aligned}$$

so by Theorem 44.1 and Lemma 57,

$$\left(\lambda_{x_{i_{m+1}}}^{x_{i_1}, \dots, x_{i_m}}.Z \right)_\lambda \triangleright_Q \lambda x_{i_{m+1}}.U_{*\lambda} V_\lambda \equiv \lambda x_{i_{m+1}}.U_{*\lambda} V_{*\lambda}$$

Now by the induction hypothesis we have a U_1 and V_1 such that:

$$\left(\lambda_{x_{i_{m+1}}}^{x_{i_1}, \dots, x_{i_m}}.Z \right)_\lambda \triangleright_Q \lambda x_{i_{m+1}}.U_1 V_1 \triangleleft_\eta \lambda x_{i_{m+1}}.UV \equiv \lambda x_{i_{m+1}}.Z$$

(d), (e), (f) The cases $Z \equiv UV$ where $x_{i_{m+1}} \notin FV(U)$ and $idx(U, i_1, \dots, i_m) > idx(V, i_1, \dots, i_m)$ or where $x_{i_{m+1}} \in FV(U) \cap FV(V)$ are similar. \blacksquare

Our classification of the **BB'I** and **BB'IW**-definable λ -terms involves a class $HRM(i_1, \dots, i_n)$ of **hereditary right maximal terms** with respect to $x_{i_1} \dots x_{i_n}$, which we now define.

DEFINITION 59 ($(HRM(i_1, \dots, i_n))$).

1. Every variable and every basis combinator is in $HRM(i_1, \dots, i_n)$.

2. If $M, N \in HRM(i_1, \dots, i_n)$
and $idx(M, i_1, \dots, i_n) \leq idx(N, i_1, \dots, i_n)$
then $MN \in HRM(i_1, \dots, i_n)$.
3. If $M \in HRM(i_1, \dots, i_{n+1})$
then $\lambda x_{i_{n+1}}.M \in HRM(i_1, \dots, i_n)$.

Strictly we should write $HRM_Q(i_1, \dots, i_n)$, but in each case below the basis Q will be clear from the context.

$HRM_{\mathbf{BB}'\mathbf{I}}(1, \dots, n)$ is $HRM(x_1, \dots, x_n)$ of Hirokawa 1996. Our $HRM(1, \dots, n)$ is also HRM_n of Trigg *et al.* [1994] where the basis is also taken from the context.

Before obtaining the classifications we need a lemma.

LEMMA 60. *If X is a $\mathbf{BB}'\mathbf{IW}$ -term or $X \equiv Y_\lambda$ where Y is a $\mathbf{BB}'\mathbf{IW}$ -term and $X \triangleright_{\mathbf{BB}'\mathbf{IW}} Z$ or $Z \triangleright_\eta X$ then, if X is in $HRM(i_1, \dots, i_n)$, so is Z .*

Proof. If X is a $\mathbf{BB}'\mathbf{IW}$ -term this is easy to prove by induction on the length of the $\mathbf{BB}'\mathbf{IW}$ -reduction or of the η -expansion.

If $X \equiv Y_\lambda$, where Y is a $\mathbf{BB}'\mathbf{IW}$ -term more single $\mathbf{BB}'\mathbf{IW}$ -reductions are possible. For example instead of

$$\mathbf{B}'UVW \triangleright_{\mathbf{B}'} V(UW)$$

we can have $(\lambda uvw.v(uw)) U_\lambda V_\lambda W_\lambda \triangleright_{\mathbf{B}'} (\lambda vw.v(U_\lambda w)) V_\lambda W_\lambda$

$$\begin{aligned} &\triangleright_{\mathbf{B}'} (\lambda w.V_\lambda(U_\lambda w)) W_\lambda \\ &\triangleright_{\mathbf{B}'} V_\lambda(U_\lambda W_\lambda), \end{aligned}$$

however in each case the membership of $HRM(i_1, \dots, i_n)$ is preserved. Similarly for η -expansions. ■

THEOREM 61.

1. *The set of $\mathbf{BB}'\mathbf{I}$ -definable terms is $HRM(\) \cap Once(\)$.*
2. *The set of $\mathbf{BB}'\mathbf{IW}$ -definable terms is $HRM(\) \cap Once^+(\)$.*

Proof. Theorem 58 gives translation algorithms.

1. If $Y \in HRM(i_1, \dots, i_n) \cap Once(i_1, \dots, i_n)$, it is easy to show by induction on the length of Y that Y is $\mathbf{BB}'\mathbf{I}$ definable by $(x_{i_1}, \dots, x_{i_n}; Y)^{i\eta bb'}$. This holds in particular when $n = 0$.

If Y is $\mathbf{BB}'\mathbf{I}$ -definable then there is a $\mathbf{BB}'\mathbf{I}$ -translation algorithm $*$ and a λ -term Y_1 such that

$$Y_{*\lambda} \triangleright_{\mathbf{BB}'\mathbf{I}} Y_1 \triangleleft_\eta Y$$

Now Y_* is a $\mathbf{BB}'\mathbf{I}$ -term and is therefore in $HRM(\) \cap Once(\)$. It follows by Lemma 60 that Y_1 and Y are also in $HRM(\) \cap Once(\)$.

2. is similar. ■

The $(i\eta bb')$ -algorithm for **BB'I** was first used (for abstraction only) in [Helman, 1977]. It was also used by Hirokawa in his proof of the \Rightarrow half of (B) in [Hirokawa, 1996]. Hirokawa proved the result of Theorem 61.1 there.

5 THE BASES **BB'IK**, **BB'**, **BB'W** AND **BB'K**

The **BB'IK** (i_1, \dots, i_n) abstractable terms of Trigg *et al* 1994 were terms obtainable from terms of $HRM(i_1, \dots, i_n) \cap Once(i_1, \dots, i_n)$ by deleting certain variables. The **BB'IK** (i_1, \dots, i_n) -translation algorithm that we develop here has as its first stage, a “**full ordering algorithm**” which reverses the deletion process by building up elements of a subclass of $Once^-(i_1, \dots, i_n)$ to elements of $HRM(i_1, \dots, i_n) \cap Once(i_1, \dots, i_n)$. Such elements can then be translated by $(;)^{(bb' in)}$. A partial ordering algorithm, which builds up to elements of $HRM(i_1, \dots, i_n) \cap Once^-(i_1, \dots, i_n)$ could also be used and requires only simple alterations to 1. and 2. below.

THE FULL ORDERING ALGORITHM

Aim To extend, if possible, a λ -**BB'IK**-term $Y \in Once^-(i_1, \dots, i_n)$ to a λ -**BB'IK**-term $Y^o \in HRM(i_1, \dots, i_n) \cap Once(i_1, \dots, i_n)$ so that $Y^o \triangleright_{\mathbf{KI}} Y$.

1. If $Y \equiv a$, an atom not in $\{x_{i_1}, \dots, x_{i_n}\}$
 $Y^o \equiv \mathbf{K}_\lambda a (x_{i_1} x_{i_2} \dots x_{i_n})$
2. If $Y \equiv x_{i_m}$, and $1 \leq m < n$ then
 $Y^o \equiv \mathbf{K}_\lambda x_{i_m} (x_{i_1} \dots x_{i_{m-1}} x_{i_{m+1}} \dots x_{i_n})$
3. If $Y \equiv x_{i_n}$,
 $Y^o \equiv \mathbf{K}_\lambda \mathbf{I}_\lambda (x_{i_1} \dots x_{i_{n-1}}) x_{i_n}$
4. If $Y \equiv \lambda x_{i_{n+1}}.Z$, find, if possible, Z^o such that

$$Z^o \in HRM(i_1, \dots, i_{n+1}) \cap Once(i_1, \dots, i_{n+1})$$

and $Z^o \triangleright_{\mathbf{KI}} Z$
then $Y^o \equiv \lambda x_{i_{n+1}}.Z^o$.

5. If $Y \equiv Zx_{i_n}$, find, if possible, Z^o such that

$$Z^o \in HRM(i_1, \dots, i_{n-1}) \cap Once(i_1, \dots, i_{n-1})$$

and $Z^o \triangleright_{\mathbf{KI}} Z$
then $Y^o \equiv Z^o x_{i_n}$.

6. If $Y \equiv UV$, where $V \not\equiv x_{i_n}$ find, by going back to (1), a term U° and a subsequence $(x_{j_1}, \dots, x_{j_r})$ of $(x_{i_1}, \dots, x_{i_n})$ such that:

- (a) $FV(U) \cap \{x_{i_1}, \dots, x_{i_n}\} \subseteq \{x_{j_1}, \dots, x_{j_r}\}$ and $FV(V) \cap \{x_{j_1}, \dots, x_{j_r}\} = \emptyset$.
- (b) $U^\circ \in HRM(j_1, \dots, j_r) \cap Once(j_1, \dots, j_r)$
- (c) $U^\circ \triangleright_{\mathbf{KI}} U$
- (d) $j_r \neq i_n$
- (e) $\max\{p \mid x_{j_p} \in \{x_{j_1}, \dots, x_{j_r}\} - FV(U)\}$ is minimal.
- (f) Given (e), the number of variables in $\{x_{j_1}, \dots, x_{j_r}\} - FV(U)$ is minimal.

Now let $(x_{s_1}, \dots, x_{s_t})$ be the sequence obtained from $(x_{i_1}, \dots, x_{i_n})$ by removing $(x_{j_1}, \dots, x_{j_r})$.

Now if possible (i.e. by going back to (1)) find V° such that

- (g) $V^\circ \in HRM(s_1, \dots, s_t) \cap Once(s_1, \dots, s_t)$
- and
- (h) $V^\circ \triangleright_{\mathbf{KI}} V$

then $Y^\circ \equiv U^\circ V^\circ$.

Choosing the maximal p in $x_{j_p} \in FV(U^\circ) \cap \{x_{i_1}, \dots, x_{i_n}\}$ to be minimal in (e) and then using as few as possible variables new to U in (f), gives us maximal flexibility for expanding V to V° using the remaining, especially the higher subscripted, variables. These clauses also ensure that a unique Y° is produced by the algorithm. Other Y° s satisfying the above aim may exist as well.

The algorithm is applied in two examples below.

EXAMPLE 62. $Y \equiv x_3x_2x_1$ cannot be ordered relative to $(1, 2, 3)$ or even $(1, 2, 3, 4)$, but relative to $(1, 2, 3, 4, 5)$

$$Y^\circ \equiv x_3(\mathbf{K}_\lambda x_2 x_4)(\mathbf{K}_\lambda x_1 x_5)$$

EXAMPLE 63.

$$Y \equiv x_7x_0(\lambda x_9.x_5(x_4(x_3x_2)))x_1x_9$$

Relative to $(0, 1, 2, \dots, 7, 8, 10, 11)$ we have

$$\begin{aligned} Y^\circ &\equiv x_7(\mathbf{K}_\lambda x_0 x_8)(\lambda x_9.x_5(x_4(x_3(\mathbf{K}_\lambda x_2 x_6))(\mathbf{K}_\lambda x_1(x_{10}x_{11})))x_9) \\ &\in HRM(0, 1, 2, \dots, 8, 10, 11) \cap Once(0, 1, 2, \dots, 8, 10, 11) \end{aligned}$$

The λ -terms that are **BB'IK**-translatable will be represented in terms of a generalisation of the class $HRM(i_1, \dots, i_n)$. If it is not possible to extend a λ -**BB'IK**-term Y to a $Y^\circ \in HRM(i_1, \dots, i_n) \cap Once(i_1, \dots, i_n)$, it is always

possible to choose variables $x_{i_{n+1}}, \dots, x_{i_m}$ and a $Y^o \in HRM(i_1, \dots, i_m) \cap Once(i_1, \dots, i_m)$ so that $Y^o \triangleright_{\mathbf{KI}} Y$.

If $(x_{j_1}, \dots, x_{j_r})$ is $(x_{i_1}, \dots, x_{i_n})$ with the free variables of Y deleted and if we named the atom occurrences in Y from the leftmost to the rightmost a_1, \dots, a_p then Y^o could be defined as: Y with a_1 replaced by $\mathbf{K}a_1(x_{j_1} \dots x_{j_r} x_{i_{n+1}})$ and a_i ($1 < i \leq p$) replaced by $\mathbf{K}a_i x_{i_{n+i}}$. Repeatedly using the full reordering algorithm, with n increased by one each time, will produce a minimal set of extra variables that need to be added to form a Y^o .

DEFINITION 64 (Potentially Right Maximal (i_1, \dots, i_n) - λ -terms).

($PRM(i_1, \dots, i_n)$ - λ -terms)

1. If X is an atom $X \in PRM()$.
2. $x_e \in PRM(e)$.
3. If $X \in PRM(i_1, \dots, i_{n-1})$ and $x_j \notin FV(X)$ then $X \in PRM(i_1, \dots, i_k, i_j, i_{k+1}, \dots, i_n)$ for $0 \leq k \leq n$.
4. If $X \in PRM(i_1, \dots, i_{n+1})$ then $\lambda x_{i_{n+1}}.X \in PRM(i_1, \dots, i_n)$.
5. If $X \in PRM(j_1, \dots, j_p)$ and $Y \in PRM(r_1, \dots, r_q)$ where $p = q = n = 0$ or $r_q = i_n$,

$$\begin{aligned} \{j_1, \dots, j_p\} \cap \{r_1, \dots, r_q\} &= \emptyset, \\ FV(X) \cap \{x_{r_1}, \dots, x_{r_q}\} &= \emptyset, \\ FV(Y) \cap \{x_{j_1}, \dots, x_{j_p}\} &= \emptyset, \end{aligned}$$

and (i_1, \dots, i_n) is a merge of (j_1, \dots, j_p) and (r_1, \dots, r_q) (i.e. $n = p + q$ and (i_1, \dots, i_n) has the elements of the two sequences with the orders preserved) then $XY \in PRM(i_1, \dots, i_n)$.

EXAMPLE 65.

$$x_1 \in PRM(1)$$

so

$$x_1 \in PRM(1, 5)$$

Similarly

$$x_2 \in PRM(2, 4)$$

and

$$x_3 \in PRM(3)$$

so

$$x_3 x_2 \in PRM(2, 3, 4)$$

and

$$x_3x_2x_1 \in PRM(1, 2, 3, 4, 5)$$

Note:

$$x_3x_2x_1 \notin PRM(1, 2, 3) \cup PRM(1, 2, 3, 4)$$

Note that the variables in $\{x_{i_1}, \dots, x_{i_n}\} - FV(X)$ are used in the ordering of a term Y relative to (i_1, \dots, i_n) , in the same way these extra variable subscripts are needed to show $X \in PRM(i_1, \dots, i_n)$. The connection is given by the following lemmas.

LEMMA 66. *If Y , ordered relative to (i_1, \dots, i_n) by the full ordering algorithm, becomes Y° , then*

$$Y^\circ \triangleright_{\mathbf{KI}} Y$$

where each single \mathbf{K} -reduction eliminates one or more of x_{i_1}, \dots, x_{i_n} .

Proof. Obvious from the algorithm. ■

LEMMA 67. $Y \in PRM(i_1, \dots, i_n) \cap Once^-(i_1, \dots, i_n) \iff$ there is a $Y^\circ \in HRM(i_1, \dots, i_n) \cap Once(i_1, \dots, i_n)$ defined by the full ordering algorithm.

Proof. \Rightarrow By induction on Y .

The case where Y is an atom is obvious.

If $Y \equiv \lambda x_{i_{n+1}}.Z$, then as each bounded variable of Y appears at most once in Y , we have $Z \in PRM(i_1, \dots, i_{n+1}) \cap Once^-(i_1, \dots, i_{n+1})$.

By the induction hypothesis we have an appropriate

$$Z^\circ \in HRM(i_1, \dots, i_{n+1}) \cap Once(i_1, \dots, i_{n+1})$$

and so a $Y^\circ \equiv \lambda x_{i_{n+1}}.Z^\circ \in HRM(i_1, \dots, i_n) \cap Once(i_1, \dots, i_n)$.

If $Y \equiv Zx_{i_n}$, then as each bounded variable of Y appears at most once in Y , we have $Z \in PRM(i_1, \dots, i_{n-1}) \cap Once^-(i_1, \dots, i_{n-1})$.

By the induction hypothesis we have an appropriate

$$Z^\circ \in HRM(i_1, \dots, i_{n-1}) \cap Once(i_1, \dots, i_{n-1})$$

and so a $Y^\circ \equiv Z^\circ x_{i_n} \in HRM(i_1, \dots, i_n) \cap Once(i_1, \dots, i_n)$.

If $Y \equiv UV$ ($V \neq x_{i_n}$) then we have (j_1, \dots, j_p) and (r_1, \dots, r_q) such that

$$\begin{aligned} \{j_1, \dots, j_p\} \cap \{r_1, \dots, r_q\} &= \emptyset, \\ FV(U) \cap \{x_{r_1}, \dots, x_{r_q}\} &= \emptyset, r_q = i_n, \text{ or } n = p = q = 0, \\ FV(V) \cap \{x_{j_1}, \dots, x_{j_p}\} &= \emptyset \\ U &\in PRM(j_1, \dots, j_p) \cap Once^-(j_1, \dots, j_p) \end{aligned}$$

and

$$V \in PRM(r_1, \dots, r_q) \cap Once^-(r_1, \dots, r_q)$$

Also the order of (j_1, \dots, j_p) and (r_1, \dots, r_q) is preserved in (i_1, \dots, i_n) , where $\{i_1, \dots, i_n\} = \{j_1, \dots, j_p\} \cup \{r_1, \dots, r_q\}$.

Of the sequences $(j_1, \dots, j_p), (r_1, \dots, r_q)$ that satisfy these properties (and so (a), (b), (c), (d), (e) and (h) of (4) of the full ordering algorithm), choose those that also satisfy (e) and (f).

Then, as by the induction hypothesis we have:

$$U^\circ \in HRM(j_1, \dots, j_p) \cap Once(j_1, \dots, j_p)$$

and

$$V^\circ \in HRM(r_1, \dots, r_q) \cap Once(r_1, \dots, r_q),$$

we have

$$Y^\circ \equiv U^\circ V^\circ \in HRM(i_1, \dots, i_n) \cap Once(i_1, \dots, i_n).$$

\Leftarrow To prove this we only need to show, by the previous lemma, that \mathbf{K}_λ or \mathbf{I}_λ -reductions in λ -terms eliminating some of x_{i_1}, \dots, x_{i_n} , preserve membership of $PRM(i_1, \dots, i_n)$ in a reduction $T \triangleright_{\mathbf{BB}'\mathbf{IK}} R$.

We prove this by induction on T .

If T is an atom or contains an \mathbf{I}_λ redex this is obvious.

If

$$T \equiv \mathbf{K}_\lambda W x_{i_s} \in PRM(i_1, \dots, i_n)$$

then

$$\mathbf{K}_\lambda W \in PRM(j_1, \dots, j_p)$$

and

$$x_{i_s} \in PRM(r_1, \dots, r_q)$$

where $i_n = r_q$ and the other conditions apply.

From there it follows that $x_{r_1}, \dots, x_{r_p} \notin FV(W)$.

Also $W \in PRM(j_1, \dots, j_p)$

and as (j_1, \dots, j_p) is a subsequence of (i_1, \dots, i_n) , by 3,

$$W \in PRM(i_1, \dots, i_n).$$

If $T \equiv \lambda x_{i_{n+1}}.W$, $R \equiv \lambda x_{i_{n+1}}.S$ and $W \triangleright S$,

$$W \in PRM(i_1, \dots, i_{n+1})$$

and by the induction hypothesis $S \in PRM(i_1, \dots, i_{n+1})$ and so

$R \in PRM(i_1, \dots, i_n)$.

If $T \equiv UV$, where $R \equiv WS$, $U \triangleright_{\mathbf{BB}'\mathbf{IK}} W$ and $V \triangleright_{\mathbf{BB}'\mathbf{IK}} S$, we have: for some (j_1, \dots, j_p) and (r_1, \dots, r_q)

$$\begin{aligned} U &\in PRM(j_1, \dots, j_p) \\ V &\in PRM(r_1, \dots, r_q) \end{aligned}$$

with the usual conditions.

By the induction hypothesis

$$W \in PRM(j_1, \dots, j_p)$$

and

$$S \in PRM(r_1, \dots, r_q)$$

and so

$$R \equiv WS \in PRM(i_1, \dots, i_n)$$

■

LEMMA 68. *If $A \triangleright_\eta B$ and $A \triangleright_{\mathbf{KI}} C$ then there is a term D such that $B \triangleright_{\mathbf{KI}} D$ and $C \triangleright_\eta D$.*

Proof. By induction on the number of reduction steps in $A \triangleright_\eta B$ and a secondary induction on the number of steps in $A \triangleright_{\mathbf{KI}} C$ (i.e. a standard Church-Rosser theorem proof.) ■

THEOREM 69. $(; Y^o)^{(i\eta bb')}$ is a **BB'IK**-translation algorithm.

Proof. (A) holds as before. By Theorem 58.1 there is a term Y_1 such that $((; Y^o)^{(i\eta bb'))_\lambda \triangleright_{\mathbf{BB'I}} Y_1 \triangleleft_\eta Y^o$.

Now also by Lemma 66

$$Y^o \triangleright_{\mathbf{KI}} Y,$$

so by Lemma 68 there is a Y_2 such that

$$Y_1 \triangleright_{\mathbf{KI}} Y_2 \triangleleft_\eta Y$$

So $((; Y^o)^{(i\eta bb'))_\lambda \triangleright_{\mathbf{BB'IK}} Y_2 \triangleleft_\eta Y$, i.e. (B) holds. ■

Thus $(; Y^o)^{(i\eta bb')}$ is a **BB'IK**-translation algorithm.

THEOREM 70. *The set of **BB'IK**-translatable terms is $PRM() \cap Once^-()$.*

Proof. We have a **BB'IK**-translation algorithm by Theorem 69.

If $Y \in PRM() \cap Once^-()$, then by Lemma 67 $Y^o \in HRM() \cap Once^-()$ and so $(; Y^o)^{(i\eta bb')}$ is a **BB'IK**-term, so Y is **BB'IK**-definable.

If Y is **BB'IK**-definable, the proof of $Y \in PRM() \cap Once^-()$ proceeds as for Theorem 61. ■

We now consider some bases without **I**.

We define Λ^- as the set of all λ -terms whose β -normal forms do not have subterms of the form $\lambda x_{i_1} \dots x_{i_n} . x_{i_j} x_{i_{j+1}} \dots x_{i_n}$ or $\lambda x_{i_1} \dots x_{i_n} . x_{i_1} x_{i_1} x_{i_2} x_{i_3} \dots x_{i_n}$.

THEOREM 71.

1. $HRM(\) \cap \Lambda^- \cap Once$ is the set of \mathbf{BB}' -definable terms.
2. $HRM(\) \cap \Lambda^- \cap Once^+$ is the set of $\mathbf{BB}'\mathbf{W}$ -definable terms.
3. $PRM(\) \cap \Lambda^- \cap Once^-$ is the set of $\mathbf{BB}'\mathbf{K}$ -definable terms.

Proof. 3. Any $\mathbf{BB}'\mathbf{K}$ -translation algorithm $*$ must contain (η) , otherwise, for example, $\mathbf{B}_{\lambda*}$ would not be definable. If a Q -translation algorithm $*$ contains (η) it is easy to show, by induction on the length of a λQ -term Y , with η -normal form Z that $Y_* \equiv Z_*$.

The full ordering algorithm is such that the combinator \mathbf{I} is used only when it is essential (i.e. just \mathbf{K} , \mathbf{B}' and \mathbf{B} won't do) and it is clear that the only terms in η -normal form in $PRM(\) \cap \Lambda^- \cap Once^-$ that can have an \mathbf{I} in their translation are of the form: $\lambda x_{i_1} \dots x_{i_n} . x_{i_j} x_{i_{j+1}} \dots x_{i_n}$.

Hence our result follows from Theorems 69 and 70.

1. and 2. are similar but simpler. ■

Note that in a $\mathbf{BB}'\mathbf{IW}$ abstraction of a term only terms of the form $\lambda x_{i_1} \dots x_{i_n} . x_{i_1} x_{i_2} \dots x_{i_n}$ and $\lambda x_{i_1} \dots x_{i_n} . x_{i_1} x_{i_1} x_{i_2} \dots x_{i_n}$ can contain an \mathbf{I} and in $\mathbf{BB}'\mathbf{I}$ abstraction only the former.

6 THE λ PROOF FINDING ALGORITHMS

We have shown that for each theorem of a wide range of implicational logics there is a λ -term of a particular kind, depending on the logic, that has that theorem as a type. We have also shown that we can expand any such λ -term into long normal form.

If a theorem, or type, τ takes the form $\tau_1 \rightarrow \dots \rightarrow \tau_n \rightarrow a$, where a is an atom, we know that any lnf inhabitant must take the form $\lambda x_1 \dots x_n . X$, where X has type a and has $FV(X) \subseteq \{x_1, \dots, x_n\}$. This is the basis for the Ben-Yelles algorithm (see [Ben-Yelles, 1979; Hindley, 1997; Bunder, 1995]), which constructs potential inhabitants of a given type from the outside in. As there may be several potential X s with type a the process can branch several times. There is, at least for \mathbf{SK} and sets of combinators without \mathbf{S} and \mathbf{W} a simple bound to this inhabitant, or proof, finding procedure. The version of the algorithm given in [Bunder, 1995], which is very efficient, has been implemented in [Dekker, 1996].

In this section we will be looking at an alternative inhabitant building algorithm, generally even more efficient, which builds the inhabitants of a type from the inside outwards. The given type provides the building blocks we use for this. This algorithm has been implemented in [Oostdijk, 1996].

6.1 The Variables and Subterms of an Inhabitant of a Type

In order to describe the way in which a λ -term inhabitant of a type is built up we need some notation.

DEFINITION 72.

1. α is a positive subtype of a type α .
2. If β is a positive subtype of α or a negative subtype of γ then β is a negative subtype of $\alpha \rightarrow \gamma$.
3. If β is a negative subtype of α or a positive subtype of γ then β is a positive subtype of $\alpha \rightarrow \gamma$.

DEFINITION 73. An occurrence of a positive (negative) subtype β of a type τ is said to be **long** if the occurrence of β is not the right hand part of a positive (negative) subtype $\alpha \rightarrow \beta$ of τ .

All types other than atomic types are said to be **composite**.

DEFINITION 74. The rightmost atomic subtype of a type is known as its **tail**.

EXAMPLE 75. $\tau = (a \rightarrow b) \rightarrow (b \rightarrow c) \rightarrow ((a \rightarrow b) \rightarrow c) \rightarrow c$ has $b \rightarrow c, (a \rightarrow b) \rightarrow c$, the second occurrence of a and the first occurrence of $a \rightarrow b$ as long negative subtypes and τ , the first occurrence of a and the second occurrences of b and $a \rightarrow b$ as long positive subtypes of τ .

DEFINITION 76.

$dn(\tau)$ = the number of distinct long negative subtypes of τ .

$do(\tau)$ = the number of occurrences of long negative subtypes of τ .

$dcp(\tau)$ = the number of distinct long positive composite subtypes of τ .

$dapn(\tau)$ = the number of distinct atoms that are tails of both long positive and long negative subtypes of τ .

$F(\tau) = 2^{dn(\tau)}(dapn(\tau) + dcp(\tau)) + dn(\tau)$.

$G(\tau) = 2^{do(\tau)}(dapn(\tau) + dcp(\tau)) + do(\tau)$.

$|\tau|$ = the total number of subtypes of τ .

DEFINITION 77.

1. X is of λ -depth 0 in X .
2. If an occurrence of a term Y is of λ -depth d in X then Y is of λ -depth d in UX and XU , provided these are in β -normal form.
3. If an occurrence of a term Y is of λ -depth d in $\lambda x_i.U$, it is of λ -depth d in $\lambda x_j x_i.U$.

4. If an occurrence of a term Y is of λ -depth d in $V \not\equiv \lambda x_i.U$ for any x_i or U , then Y is of λ -depth $d + 1$ in $\lambda x_j.V$.

The two lemmas that now follow will help to tell us with what a long normal form inhabitant of a given type τ can be constructed and also how to restrict the search for components.

LEMMA 78. *If X is a normal form inhabitant of τ , U is a subterm of X of type α and V is a term of type α with $FV(V) \subseteq FV(U)$, then the result of replacing U by V in X is another inhabitant of τ .*

Proof. By a simple induction on the length of X . ■

EXAMPLE 79.

$$\lambda x_1 x_2. x_2(\lambda x_3. x_2(\lambda x_4. x_1 x_3 x_4)) : (a \rightarrow a \rightarrow b) \rightarrow ((a \rightarrow b) \rightarrow b) \rightarrow b$$

Here $x_1 : a \rightarrow a \rightarrow b$, $x_2 : (a \rightarrow b) \rightarrow b$, $x_3 : a$ and $x_4 : a$, so

$$\lambda x_3. x_2(\lambda x_4. x_1 x_3 x_4) : a \rightarrow b$$

and

$$\lambda x_3. x_1 x_3 x_3 : a \rightarrow b.$$

So we have by Lemma 77:

$$\lambda x_1 x_2. x_2(\lambda x_3. x_1 x_3 x_3) : (a \rightarrow a \rightarrow b) \rightarrow ((a \rightarrow b) \rightarrow b) \rightarrow b.$$

LEMMA 80. *If $\vdash Z : \tau$, then there is a term X in long normal form, in which no two distinct variables have the same type, such that:*

1. $\vdash X : \tau$
2. For every long subterm Y of X with $FV(Y) = \{x_{i_1}, \dots, x_{i_k}\}$ we have:

$$x_{i_1} : \tau_{i_1}, \dots, x_{i_k} : \tau_{i_k} \vdash Y : \beta$$

where β is either a long occurrence of a composite positive subtype of τ or an atom which is the tail of both a long positive and a long negative subtype of τ . $\tau_{i_1}, \dots, \tau_{i_k}$ are distinct long negative subtypes of τ .

Proof.

1. By Theorem 34 there is an X' in *lnf* such that $\vdash X' : \tau$.

If X' now contains two variables x_k and x_e with the same type β we can change any part $\lambda x_e.B(x_k, x_e)$ of X' to $\lambda x_k.B(x_k, x_k)$ and any part $\lambda x_e.B(x_e)$ to $\lambda x_k.B(x_k)$.

Let X be the term obtained when all possible changes of this kind have been made to X' . In X no two distinct variables will have the same type.

2. We prove this by induction on the λ -depth d of Y in X .

If X is formed by application, as it is in long normal form, it takes the form:

$$X \equiv x_i X_1 \dots X_m$$

and the type of X must be dependent on that of x_i , which does not agree with 1.

Hence X is not formed by application and if $\tau = \tau_1 \rightarrow \dots \rightarrow \tau_n \rightarrow a$ takes the form

$$X \equiv \lambda x_1 \dots x_n. x_i X_1 \dots X_m.$$

(Note: some of x_1, \dots, x_n could be identical.)

If $d = 0$ and Y is long, we must have $Y \equiv X$ and the result holds with $k = 0$ and $\beta = \tau$. If $d = 1$ and $X = \lambda x_1 \dots x_n. x_i X_1 \dots X_m$, Y will appear in $x_i X_1 \dots X_m$, not in the scope of any λx_j s. Thus it appears in a part $x_t Z_1 \dots Z_r Y Z_{r+2} \dots Z_q$ of X for some $t(1 \leq t \leq n)$.

If $\tau_t = \beta_1 \rightarrow \dots \rightarrow \beta_q \rightarrow b$ we have, $x_1 : \tau_1, \dots, x_n : \tau_n \vdash Y : \beta_{r+1}$.

β_{r+1} is a long negative subtype of τ_t and so a long positive subtype of τ . τ_1, \dots, τ_n are occurrences of long negative subtypes of τ .

If β_{r+1} is an atom, then β_{r+1} must also be the tail of a long negative subtype of τ (namely one of τ_1, \dots, τ_n).

Leaving out the variables not free in Y and variables identical to others gives the result.

If $d > 1$,

$X \equiv \lambda x_1 \dots x_n. x_i X_1 \dots X_{j-1} (\lambda x_{n+1} \dots x_k. x_s Z_1 \dots Z_p) X_{j+1} \dots X_m$, where Y is a long subterm of $x_s Z_1 \dots Z_p$.

As $x_s Z_1 \dots Z_p$ is long and only in the scope of $\lambda x_1 \dots x_n \dots x_k$, we have, if $\tau_i = \gamma_1 \rightarrow \dots \rightarrow \gamma_m \rightarrow c$ and $\gamma_j = \tau_{n+1} \rightarrow \dots \rightarrow \tau_k \rightarrow b$:

$$x_1 : \tau_1, \dots, x_n : \tau_n, \dots, x_k : \tau_k \vdash x_s Z_1 \dots Z_p : b.$$

Thus $\vdash \lambda x_1 \dots x_k. x_s Z_1 \dots Z_p : \tau_1 \rightarrow \dots \rightarrow \tau_k \rightarrow b$ where Y is a long subterm of $\lambda x_1 \dots x_k. x_s Z_1 \dots Z_p$ of λ -depth $d - 1$.

Thus 2. holds by the induction hypothesis with β a long positive subtype of $\tau_1 \rightarrow \dots \rightarrow \tau_k \rightarrow b$ and so of τ or an atom which is the tail of a long positive as well as of a long negative subtype of $\tau_1 \rightarrow \dots \rightarrow \tau_k \rightarrow b$ and so of τ .

■

Note The first inhabitant given in Example 79 is a counterexample, due to Ryo Kashima, to an earlier version of Lemma 80. This claimed property 2.

for any inhabitant X of the given type τ in long normal form, rather than just some X .

It follows from Lemmas 78 and 80 that an X in long normal form such that

$$\vdash X : \tau,$$

can be built up from subterms of the form

$$\lambda x_r \dots x_s. x_i X_1 \dots X_n,$$

where $x_i : \tau_i$, τ_i is a long negative subtype of τ , and τ_i has tail a , where a is an atom which is also the tail of a positive subtype of τ .

The compound types of these subterms in long normal form must be among the long positive subtypes of τ .

With this in mind we arrive at the following algorithm for finding inhabitants of types, i.e. proofs in intuitionistic implicative logic.

6.2 SK-logic ($H \rightarrow$)

The $H \rightarrow$ Decision Procedure or the SK Long Inhabitant Search Algorithm

Aim

Given a type τ , to find a closed X in long normal form (if any) such that

$$\vdash X : \tau$$

Step 1

To each distinct long negative subtype τ_i of τ assign a variable x_i giving a finite list:

$$x_1 : \tau_1, \dots, x_m : \tau_m$$

Step 2

For each atomic type b that is the tail of both a long negative and a long positive subtype of τ , form by application, (if possible) a lnf inhabitant Y of b if we don't already have a $Y' : b$ with $FV(Y') \subseteq FV(Y)$ in Step 1 or this or earlier Steps 2.

Step 3

For each long positive composite subtype β of τ , form, by abstraction, with respect to some of x_1, \dots, x_m , a term Y in Inf such that $Y : \beta$ if we don't already have a $Y' : \beta$ with $FV(Y') \subseteq FV(Y)$ in Step 1 or earlier Steps 3.

If one of these terms Y is closed and has type τ we stop.

If there is no such term we continue with Steps 2 and 3 until we obtain no more terms with a “new” set of free variables or a new (atomic tail or long positive) type. If there are no new terms there is no solution X .

Note

In the work below and in all examples we will select our variables in Step 1 in the following order: x_1 is assigned to the leftmost shallowest long negative subtype of τ , x_2 to the next to leftmost shallowest long negative subtype etc. until the shallowest long negative subtypes are used up. The next variable x_{n+1} is assigned to the leftmost next shallowest long negative subtype and eventually x_m to the rightmost deepest long negative subtype.

In Example 81 below, x_1 to x_4 are assigned to the shallowest subtypes and x_5 to the next shallowest (the deepest) subtype.

Because of this ordering of the variables of X any subterm Y formed by the algorithm will be in the scope of $\lambda x_1 x_2 \dots x_n x_{p_1} x_{p_1+1} \dots x_{p_2} x_{p_3} \dots x_{p_4} \dots x_{p_q}$ where $n < p_1 < p_2 < p_3 \dots < p_q$ and where each $\lambda x_{p_{2i+1}} \dots \lambda x_{p_{2i+2}}$ represents a single set of abstractions.

EXAMPLE 81.

$$\tau = [((a \rightarrow b) \rightarrow d) \rightarrow d] \rightarrow [(a \rightarrow b) \rightarrow d \rightarrow e] \rightarrow [a \rightarrow a \rightarrow b] \rightarrow a \rightarrow b$$

Step 1 $x_1 : ((a \rightarrow b) \rightarrow d) \rightarrow d$, $x_2 : (a \rightarrow b) \rightarrow d \rightarrow e$,
 $x_3 : a \rightarrow a \rightarrow b$, $x_4 : a$, $x_5 : a \rightarrow b$,

Step 2 $x_3 x_4 x_4 : b$, $x_5 x_4 : b$,

Step 3 $\lambda x_4. x_3 x_4 x_4 : a \rightarrow b$, $\lambda x_4. x_5 x_4 : a \rightarrow b$, $\lambda x_1 x_2 x_3 x_4. x_3 x_4 x_4 : \tau$.

EXAMPLE 82.

$$\tau = ((a \rightarrow b) \rightarrow a) \rightarrow a.$$

Step 1 $x_1 : (a \rightarrow b) \rightarrow a$, $x_2 : a$.

Step 2 No new terms can be formed by application.

Step 3 $\lambda x_1. x_2 : \tau$.
 No new terms can be formed. $\lambda x_1. x_2$ is not closed so τ has no inhabitants and no proof in $H \rightarrow$.

EXAMPLE 83.

$$\tau = [((a \rightarrow a) \rightarrow a) \rightarrow a] \rightarrow [(a \rightarrow a) \rightarrow a \rightarrow a] \rightarrow [a \rightarrow a \rightarrow a] \rightarrow a \rightarrow a.$$

Step 1 $x_1 : ((a \rightarrow a) \rightarrow a) \rightarrow a$, $x_2 : (a \rightarrow a) \rightarrow a \rightarrow a$,
 $x_3 : a \rightarrow a \rightarrow a$, $x_4 : a$, $x_5 : a \rightarrow a$,

Step 2 $x_3 x_4 x_4 : a$, $x_5 x_4 : a$,

Step 3 $\lambda x_4. x_4 : a \rightarrow a$, $\lambda x_5. x_5 x_4 : (a \rightarrow a) \rightarrow a$, $\lambda x_1 x_2 x_3 x_4. x_3 x_4 x_4 : \tau$.

THEOREM 84. *Given a type τ , the **SK** long inhabitant search algorithm will, in finite time, produce an inhabitant of τ or will demonstrate that τ has no inhabitants. The algorithm will produce at most $F(\tau)$ terms before terminating.*

Proof. It follows from the Weak Normalisation Theorem (see [Turing, 1942; Hindley, 1997]) that if τ has an inhabitant, this inhabitant has a normal form and this will also have type τ .

By Lemma 80, τ will have an inhabitant X of the form prescribed there. We show that our **SK**-algorithm provides such an inhabitant X of τ .

Step 1 of the **SK**-algorithm provides us with the largest set of variables x_1, \dots, x_m that, by Lemma 80, need appear in a solution for X .

Step 2 of the algorithm considers terms $U = x_i X_1 \dots X_n$ with an atomic type having a particular subset of x_1, \dots, x_m as free variables. By Lemma 78 other terms $x_j Y_1 \dots Y_k$ with the same atomic type and a superset of these free variables can at most produce alternative inhabitants and so do not need to be considered.

The total number of variables we can have is $dn(\tau)$. These are the terms generated by Step 1. The number of subsets of these is at most $2^{dn(\tau)}$, the number of atomic types we can have is at most $dapn(\tau)$ so the number of terms generated by Steps 2 is at most $2^{dn(\tau)}.dapn(\tau)$.

Step 3 forms terms in long normal form which have composite long positive subtypes of τ as types. There are $dcp(\tau)$ of these and we can form at most one of these terms for each set of variables. Hence the most terms we can form using Steps 3 is $2^{dn(\tau)}.dcp(\tau)$.

The maximal number of terms formed using the algorithm is therefore $dn(\tau) + 2^{dn(\tau)}.(dapn(\tau) + dcp(\tau)) = F(\tau)$. ■

Note

As $dapn(\tau) + dcp(\tau) \leq dp(\tau)$ where $dp(\tau)$ is the number of occurrences of distinct positive subtypes in τ , $F(\tau) < dn(\tau) + 2^{dn(\tau)}.dp(\tau) < 2^{dn(\tau)+dp(\tau)} \leq 2^{d(\tau)}$ where $d(\tau)$ is the number of long subtypes of τ so $F(\tau) < 2^{|\tau|}$.

In Example 1, $F(\tau) = 197$ while $2^{d(\tau)} = 2^{12}$ and $2^{|\tau|} = 2^{25}$. The actual number of terms formed by the algorithm was 10.

6.3 BCK Logic

We now adapt our long Inhabitant Search Algorithm to search for **BCK**- λ -terms in long normal form. By Theorem 51(3), these need to be elements of $Once^-(\cdot)$.

The BCK Logic Decision Procedure or the BCK-Long Inhabitant Search Algorithm

Aim

Given a type τ to find a closed **BCK**-definable λ -term in long normal form (if any) such that

$$\vdash X : \tau.$$

Step 1 To each occurrence of a long negative subtype τ_i of τ assign a variable x_i giving a finite list:

$$x_1 : \tau_1, \dots, x_m : \tau_m.$$

Step 2 For each atomic type b that is the tail of both a long positive and a long negative subtype of τ form (if possible), by application, from the terms we have so far, an inhabitant Y of b such that no free variables appear more than once in Y , if we don't already have a $Y' : b$ with $FV(Y') \subseteq FV(Y)$.

Step 3 For each long positive subtype β of τ , form, by abstraction, with respect to some of x_1, \dots, x_m , a term Y such that $Y : \beta$, if we don't already have a $Y' : \beta$ where $FV(Y') \subseteq FV(Y)$.

EXAMPLE 85.

$$\tau = [((a \rightarrow b) \rightarrow d) \rightarrow d] \rightarrow [(a \rightarrow b) \rightarrow d \rightarrow e] \rightarrow [a \rightarrow a \rightarrow b] \rightarrow a \rightarrow b$$

Step 1 $x_1 : ((a \rightarrow b) \rightarrow d) \rightarrow d$, $x_2 : (a \rightarrow b) \rightarrow d \rightarrow e$,
 $x_3 : a \rightarrow a \rightarrow b$, $x_4 : a$, $x_5 : a \rightarrow b$, $x_6 : a$,

Step 2 $x_5 x_4 : b$, $x_5 x_6 : b$, $x_3 x_4 x_6 : b$,

Step 3 $\lambda x_4. x_5 x_4 : a \rightarrow b$,
 $\lambda x_4. x_3 x_4 x_6 : a \rightarrow b$, $\lambda x_6. x_3 x_4 x_6 : a \rightarrow b$, $\lambda x_1 x_2 x_3 x_4. x_5 x_4 : \tau$,
 $\lambda x_1 x_2 x_3 x_6. x_3 x_4 x_6 : \tau$, $\lambda x_1 x_2 x_3 x_4. x_3 x_4 x_6 : \tau$.

No new terms are generated by further uses of steps 2 and 3 and as the terms with type τ are not closed, there is no **BCK** inhabitant of τ . Note that τ does have an **SK** inhabitant $\lambda x_1 x_2 x_3 x_4. x_3 x_4 x_4$, but this is not **BCK** because x_4 is used twice.

EXAMPLE 86.

$$\tau = ((a \rightarrow a) \rightarrow a \rightarrow a \rightarrow b) \rightarrow a \rightarrow a \rightarrow b$$

Step 1 $x_1 : (a \rightarrow a) \rightarrow a \rightarrow a \rightarrow b, x_2 : a, x_3 : a, x_4 : a,$

Step 2 No new terms are formed.

Step 3 $\lambda x_2.x_2 : a \rightarrow a,$

Step 2 $x_1(\lambda x_2.x_2)x_2x_3 : b,$
 $x_1(\lambda x_2.x_2)x_2x_4 : b, x_1(\lambda x_2.x_2)x_3x_4 : b,$

Step 3 $\lambda x_1x_2x_3.x_1(\lambda x_2.x_2)x_2x_3 : \tau.$

Notes: 1. The **SK** algorithm would have produced only $\lambda x_1x_2x_3.x_1(\lambda x_2.x_2)x_2x_3 : \tau$ which is not a **BCK**- λ -term.

2. It was essential here to have a variable for each **distinct** long negative occurrence of a in τ .

LEMMA 87. *If X is a **BCK** term which is a normal form inhabitant of τ , U a subterm of X of type α and V a **BCK** term of type α , in which no free variable appears more than once, with $FV(V) \subseteq FV(U)$, then the result of replacing U by V in X is another **BCK** inhabitant of τ .*

Proof. As for Lemma 78. ■

LEMMA 88. *If $\vdash_{\mathbf{BCK}} Z : \tau$, then there is a term X in long normal form such that:*

1. $\vdash_{\mathbf{BCK}} X : \tau$

2. For every long subterm Y of X with $FV(Y) = \{x_{i_1}, \dots, x_{i_n}\}$ we have

$$x_{i_1} : \tau_{i_1}, \dots, x_{i_n} : \tau_{i_n} \vdash_{\mathbf{BCK}} Y : \beta,$$

where β is either a long occurrence of a composite positive subtype of τ or an atom which is the tail of both a long positive and a long negative subtype of τ . $\tau_{i_1}, \dots, \tau_{i_n}$ are distinct occurrences of long negative subtypes of τ .

Proof.

1. The formation of an X in long normal form is as in the proof of Lemma 80(1) except that the extra variables x_{m+1}, \dots, x_n that are chosen must not be free in x_iX_1, \dots, X_m , (otherwise $\lambda x_{m+1} \dots x_n.x_iX_1, \dots, X_mx_{m+1}, \dots, x_n$ would not be a **BCK**-term). Also for the same reason, we don't identify distinct variables with the same type. We let X be a term obtained by the expansion of Z to long normal form.

2. As for Lemma 80(2) except that we have to show that we have at most one variable for each distinct occurrence of a long negative subtype of τ . We extend the induction proof to include this.

When $d = 1$, we clearly have one variable for every long negative subtype $\tau_1 \dots, \tau_n$ of $\tau = \tau_1 \rightarrow \dots \rightarrow \tau_n \rightarrow a$ and no others.

When $d > 1$ the subterm Y appears as Z_j in a term

$$\begin{aligned} & x_t U_1 \dots U_s \\ \text{where } & U_e = \lambda x_u \dots x_v. x_r Z_1 \dots Z_p \\ & x_t : \gamma_1 \rightarrow \dots \rightarrow \gamma_s \rightarrow c \\ \text{and } & \gamma_w = \delta_u \rightarrow \dots \rightarrow \delta_v \rightarrow d \\ \text{and } & 1 \leq j \leq p, \quad 1 \leq e \leq s \text{ and } 1 \leq w \leq s. \end{aligned}$$

The extra typed variables added at this stage are $x_u : \delta_u, \dots, x_v : \delta_v$.

By the inductive hypothesis we have that $\gamma_1 \rightarrow \dots \rightarrow \gamma_s \rightarrow c$ is an occurrence of a long negative subtype of τ and it therefore follows that the same holds for $\delta_u, \dots, \delta_v$. Note that as in **BCK** (and **BCI**) logic there can be only one free occurrence of the variable x_t in a term before we abstract with respect to x_t , so there can be no other use of x_t that might generate another set of variables with types $\delta_u, \dots, \delta_v$ i.e. one occurrence of $\gamma_1 \rightarrow \dots \rightarrow \gamma_q \rightarrow c$ in τ generates at most one occurrence of a variable for each occurrence of $\delta_u, \dots, \delta_v$ which are long negative subtypes of depth one lower than $\gamma_1 \rightarrow \dots \rightarrow \gamma_q \rightarrow c$ in τ . ■

THEOREM 89. *Given a type τ , the **BCK** long inhabitant search algorithm will in finite time produce an inhabitant or will demonstrate that τ has no **BCK**-inhabitants. The algorithm will produce at most $G(\tau)$ terms before terminating.*

Proof. As for Theorem 84, except that Lemmas 87 and 88 replace Lemmas 78 and 80. ■

It might be thought that the **BCK** algorithm might require fewer than the maximal $F(\tau)$ terms required for **SK**, in fact it requires more because there may be several variables with the same type. Even when this is not the case, both algorithms require at most one term for each given type and each set of variables. For **SK** some variables may appear several times, for **BCK** they may not. For **BCI** in addition all abstracted variables will have to appear in the term being abstracted.

The bounds $F(\tau)$ and $G(\tau)$ are not directly related to standard complexity measures. The algorithm will in fact generate some other terms but not record them because they have the same type and set of free variables to another already recorded.

6.4 BCI Logic

Again we can adapt the Long Inhabitant Search Algorithm. This time the inhabitants found must, by Theorem 51(2) be in *Once*().

The BCI-Logic Decision Procedure or the BCI Long Inhabitant Search Algorithm

Aim

Given a type τ to find a closed BCI- λ -term X in long normal form (if any) such that:

$$\vdash X : \tau.$$

Method

As for the BCK-algorithm except that Step 2 and 3 end in “ $FV(Y') = FV(Y)$ ” and in Step 3 we may only form $\lambda x_i \dots x_j. Z$ if x_i, \dots, x_j occur free in Z exactly once each.

EXAMPLE 90.

$$\tau = ((a \rightarrow b) \rightarrow c) \rightarrow b \rightarrow d \rightarrow (c \rightarrow e) \rightarrow e$$

Step 1 $x_1 : (a \rightarrow b) \rightarrow c, x_2 : b, x_3 : d, x_4 : c \rightarrow e, x_5 : a$

Step 2 No new terms are formed.

Step 3 $\lambda x_5. x_2$ is not a BCI- λ -term, so no new terms are generated and so there is no BCI-proof of τ .

EXAMPLE 91.

$$((a \rightarrow b \rightarrow c) \rightarrow d) \rightarrow (b \rightarrow a \rightarrow c) \rightarrow d.$$

Step 1 $x_1 : (a \rightarrow b \rightarrow c) \rightarrow d, x_2 : b \rightarrow a \rightarrow c, x_3 : a, x_4 : b,$

Step 2 $x_2 x_4 x_3 : c,$

Step 3 $\lambda x_3 x_4. x_2 x_4 x_3 : a \rightarrow b \rightarrow c,$

Step 2 $x_1 (\lambda x_3 x_4. x_2 x_4 x_3) : d,$

Step 3 $\lambda x_1 x_2. x_1 (\lambda x_3 x_4. x_2 x_4 x_3) : \tau.$

Example 86 also produced a BCI-term.

THEOREM 92. *Given a type τ , the BCI long inhabitant search algorithm will, in finite time, produce an inhabitant or will demonstrate that τ has no inhabitants. The algorithm will produce at most $G(\tau)$ terms before terminating.*

Proof. Lemma 87 holds provided that V is a **BCI** term such that $FV(V) = FV(U)$ and each free variable of V appears exactly once in V . If Z in Lemma 87 is a **BCI** term so is X .

The proof of the theorem now proceeds as for Theorem 89 except that in any substitution $[V/U]X$ the above restrictions apply. Hence $FV(Y') = FV(Y)$ was needed in Step 2 of the **BCI**-algorithm. In Steps 2 and 3 we must, for each subset of $\{x_1, \dots, x_m\}$, consider a term with those free variables with a particular atomic negative or long positive subtype of T . ■

6.5 **BCIW** Logic ($R \rightarrow$)

The **BCI**-search algorithm can easily be extended to **BCIW**-logic. By Theorem 51(4), the λ -terms required are from $Once^+(\cdot)$.

*The **BCIW** Long Inhabitant Search Algorithm*

Aim

Given a type τ to find a closed **BCIW**- λ -term X in long normal form (if any) such that

$$\vdash X : \tau$$

Method

As for the **BCI** algorithm except that in Steps 2 and 3 each variable must appear in Y and Z at least once.

If the algorithm that we have to this stage fails, additional variables with the same types as the ones first given in Step 1 are added and the previous algorithm is repeated.

Note that, as it is not clear as to how many times new variables might need to be added, this method, while, as shown in Theorem 96, it leads to finding an inhabitant if there is one, does not constitute a decision procedure. The need for extra variables is illustrated in Example 95 below. This logic does have a decision procedure (see [Urquhart, 1990]), but its maximum complexity is related to Ackermann's function.

EXAMPLE 93.

$$\tau = [((a \rightarrow b) \rightarrow d) \rightarrow d] \rightarrow [(a \rightarrow b) \rightarrow d \rightarrow e] \rightarrow [a \rightarrow a \rightarrow b] \rightarrow a \rightarrow b$$

Step 1 $x_1 : ((a \rightarrow b) \rightarrow d) \rightarrow d, x_2 : (a \rightarrow b) \rightarrow d \rightarrow e,$
 $x_3 : a \rightarrow a \rightarrow b, x_4 : a, x_5 : a \rightarrow b, x_6 : a$

Step 2 $x_3x_4x_4 : b, x_3x_4x_6 : b, x_3x_6x_6 : b, x_5x_4 : b, x_5x_6 : b$

Step 3 $\lambda x_4.x_3x_4x_4 : a \rightarrow b, \lambda x_4.x_3x_4x_6 : a \rightarrow b, \lambda x_6.x_3x_4x_6 : a \rightarrow b,$
 $\lambda x_4.x_5x_4 : a \rightarrow b$

We cannot form $\lambda x_1 x_2 x_3 x_4 . x_3 x_4 x_4$ as this is not a **BCIW**- λ -term.

We can form no more terms by Step 2 as we have no terms of type d or $(a \rightarrow b) \rightarrow d$ and no new terms of type a . Hence τ has no **BCIW** inhabitant.

EXAMPLE 94.

$$\tau = (c \rightarrow a \rightarrow a \rightarrow a) \rightarrow c \rightarrow a \rightarrow a$$

Step 1 $x_1 : c \rightarrow a \rightarrow a \rightarrow a, x_2 : c, x_3 : a.$

Step 2 $x_1 x_2 x_3 x_3 : a.$

Step 3 $\lambda x_1 x_2 x_3 . x_1 x_2 x_3 x_3 : \tau.$

EXAMPLE 95.

$$\tau = c \rightarrow c \rightarrow (a \rightarrow a \rightarrow b) \rightarrow (c \rightarrow (a \rightarrow b) \rightarrow b) \rightarrow b$$

Step 1 $x_1 : c, x_2 : c, x_3 : a \rightarrow a \rightarrow b, x_4 : c \rightarrow (a \rightarrow b) \rightarrow b, x_5 : a$

Step 2 $x_3 x_5 x_5 : b$

Step 3 $\lambda x_5 . x_3 x_5 x_5 : a \rightarrow b$

Step 2 $x_4 x_1 (\lambda x_5 . x_3 x_5 x_5) : b,$
 $x_4 x_2 (\lambda x_5 . x_3 x_5 x_5) : b,$

Step 3 No new terms can be formed.

(Add to) Step 1 $x_6 : a$

Step 2 $x_3 x_5 x_6 : b, x_3 x_6 x_6 : b$

Step 3 $\lambda x_6 . x_3 x_5 x_6 : a \rightarrow b, \lambda x_5 . x_3 x_5 x_6 : a \rightarrow b$

Step 2 $x_4 x_1 (\lambda x_6 . x_3 x_5 x_6) : b, x_4 x_2 (\lambda x_6 . x_3 x_5 x_6) : b,$
 $x_4 x_1 (\lambda x_5 . x_3 x_5 x_6) : b, x_4 x_2 (\lambda x_5 . x_3 x_5 x_6) : b,$

Step 3 $\lambda x_5 . x_4 x_1 (\lambda x_6 . x_3 x_5 x_6) : a \rightarrow b, \lambda x_5 . x_4 x_2 (\lambda x_6 . x_3 x_5 x_6) : a \rightarrow b,$

Step 2 $x_4 x_1 (\lambda x_5 . x_4 x_1 (\lambda x_6 . x_3 x_5 x_6)) : b,$
 $x_4 x_2 (\lambda x_5 . x_4 x_1 (\lambda x_6 . x_3 x_5 x_6)) : b,$
 $x_4 x_2 (\lambda x_5 . x_4 x_2 (\lambda x_6 . x_3 x_5 x_6)) : b,$

Step 3 $\lambda x_1 x_2 x_3 x_4 . x_4 x_2 (\lambda x_5 . x_4 x_1 (\lambda x_6 . x_3 x_5 x_6)) : \tau.$

Note that in Example 95 x_4 is used twice and so the one occurrence of a in $c \rightarrow (a \rightarrow b) \rightarrow b$, requires two variables of type a . If these were identified the resultant λ -term would no longer be **BCIW**-definable.

THEOREM 96. *Given a type τ , the **BCIW** long inhabitant search algorithm will, in finite time, produce an inhabitant.*

Proof. Lemma 87 holds for **BCIW**-terms provided that we have $FV(U) = FV(V)$.

If Z in Lemma 88 is a **BCIW**-term so is X . In the counterpart to Lemma 88 the word “distinct” must also be dropped for the reasons illustrated in Example 95 above.

The proof of the theorem now proceeds as that of Theorem 91 except that multiple copies of variables may appear in substitutions and in terms formed by the algorithm. ■

6.6 **BB'IW** Logic ($T \rightarrow$)

BB'IW search algorithm finds λ -terms of a given type that are in $HRM() \cap Once^+(\cdot)$, as required by Theorem 61.

*The **BB'IW** Long Inhabitant Search Algorithm*

Aim

Given a type τ to find a closed **BB'IW**- λ -term X in long normal form (if any) such that

$$\vdash X : \tau$$

Step 1 As for **BCIW**.

Step 2 For each atom b and for each subsequence (j_1, \dots, j_r) of $(1, \dots, m)$ find one **BB'IW**- λ -term $Y \equiv x_{j_i} X_1 \dots X_k$ ($k \geq 0, 1 \leq i \leq r$), such that $Y \in HRM(j_1, \dots, j_r)$, $Y : b$ and $FV(Y) = \{x_{j_1}, \dots, x_{j_r}\}$, if there is not already such a Y .

Step 3 For each subsequence (j_1, \dots, j_r) of $(1, \dots, m)$ and for each long positive subtype β of τ , form a **BB'IW**- λ -term Y by abstraction so that $Y : \beta$ and $FV(Y) = \{x_{j_1}, \dots, x_{j_r}\}$, if we don't already have such a Y .

Now repeat steps 2 and 3 and if needs be add extra variables as for **BCIW**.

As with the **BCIW**-algorithm this does not, in general, provide a decision procedure.

EXAMPLE 97.

$$\tau = (a \rightarrow b \rightarrow c \rightarrow d) \rightarrow a \rightarrow c \rightarrow b \rightarrow d$$

Step 1 $x_1 : a \rightarrow b \rightarrow c \rightarrow d, x_2 : a, x_3 : c, x_4 : b$

Step 2 $x_1 x_2 x_4 x_3 : d$ and $x_1 x_2 x_4 x_3 \in HRM(1, 2, 4, 3)$

Step 3 The only term with a positive subtype of τ that can be formed is $\lambda x_1 x_2 x_3 x_4. x_1 x_2 x_4 x_3 : \tau$, but this is not a **BB'IW**- λ -term. Adding extra variables with the same types only allows us to generate this same (modulo- α conversion) inhabitant of τ .

EXAMPLE 98.

$$\tau = (c \rightarrow a \rightarrow a \rightarrow a) \rightarrow c \rightarrow a \rightarrow a$$

The only **BCIW** definable- λ -term inhabitant of τ was $\lambda x_1 x_2 x_3. x_1 x_2 x_3 x_3$, this is also a **BB'IW** definable λ -term.

THEOREM 99. *Given a type τ , the **BB'IW** long inhabitant search algorithm will, in finite time, produce an inhabitant.*

Proof. As for Theorem 96, except that we can replace subterms only by subterms belonging to the same class $HRM(j_1, \dots, j_r)$ ($1 \leq j_1 < \dots < j_r \leq m$). ■

6.7 **BB'I** Logic (*T-W, P-W*)

The search algorithm for this logic finds elements of the appropriate type in $HRM(\) \cap Once(\)$, as required by Theorem 61(1).

*The **BB'I** Logic or T-W(P-W) Decision Procedure or the **BB'I** Long Inhabitant Search Algorithm*

Aim

Given a type τ to find a closed **BB'I**- λ -term X in long normal form (if any) such that

$$\vdash X : \tau$$

Method

As for **BB'IW** logic except that in the terms formed in **Step 2** no free variable may appear twice and that no extra variables need be added.

EXAMPLE 100.

$$\tau = (c \rightarrow a \rightarrow a \rightarrow a) \rightarrow c \rightarrow a \rightarrow a$$

The only **BB'IW** inhabitant of τ is $\lambda x_1 x_2 x_3. x_1 x_2 x_3 x_3$ and this is not a **BB'I**-definable λ -term. Thus τ has no **BB'I** inhabitants.

EXAMPLE 101.

$$\tau = [(a \rightarrow a) \rightarrow a] \rightarrow (a \rightarrow a) \rightarrow a$$

Step 1 $x_1 : (a \rightarrow a) \rightarrow a, x_2 : a \rightarrow a, x_3 : a$

Step 2 $x_2 x_3 : a$

Step 3 $\lambda x_3. x_3 : a \rightarrow a \quad \lambda x_3. x_2 x_3 : a \rightarrow a$

Step 2 $x_1(\lambda x_3. x_2 x_3) : a, x_1(\lambda x_3. x_3) : a$

Step 3 $\lambda x_1 x_2. x_1(\lambda x_3. x_2 x_3) : \tau$

THEOREM 102. *Given a type τ the **BB'I** long inhabitant search algorithm will, in finite time, produce an inhabitant or will demonstrate that τ has no inhabitants. The algorithm will produce at most $G(\tau)$ terms before terminating.*

Proof. As for Theorem 99, except that each variable x_i must appear exactly once in Y in any $\lambda x_i. Y$ as with **BCI** logic. Also as in Theorem 89 and 92 the procedure can be bounded. Note that the number of subsequences of a sequence is the same as the number of subsets of the corresponding set. ■

6.8 **BB'IK** Logic

The search algorithm for this logic finds λ -terms of the appropriate type in $PRM(\cdot) \cap Once^-(\cdot)$.

*The **BB'IK** Logic Decision Procedure or the **BB'IK** Long Inhabitant Search Algorithm*

Aim

Given a type τ to find a closed **BB'IK**- λ term X in long normal form (if any) such that

$$\vdash X : \tau.$$

Method

As for **BB'I** logic except that in Step 2 *HRM* is replaced by *PRM*.

EXAMPLE 103.

$$\tau = b \rightarrow (b \rightarrow c) \rightarrow a \rightarrow c$$

Step 1 $x_1 : b, x_2 : b \rightarrow c, x_3 : a$

Step 2 $x_2 x_1 : c \quad (x_2 x_1 \in PRM(1, 2, 3))$

Step 3 $\lambda x_1 x_2 x_3. x_2 x_1 \in \tau.$

THEOREM 104. *Given a type τ the **BB'IK** long inhabitant search algorithm will, in finite time, produce an inhabitant or will demonstrate that τ has no inhabitant. The algorithm will produce at most $G(\tau)$ terms before terminating.*

Proof. As for Theorem 99. ■

6.9 Some Other Logics

Bunder [1996] also gives the λ -terms definable in terms of the combinators **BB'**, **BT**, **BB'K**, **BIT**, **BITK**, **BITW**, **BTK**, and **BTW**. Those for **BCW** and **BB'W** can easily be found.

Inhabitant finding algorithms for these logics can easily be obtained as above. Decision procedures can be obtained for those without **W**.

GRAHAM PRIEST

PARACONSISTENT LOGIC

Indeed, even at this stage, I predict a time when there will be mathematical investigations of calculi containing contradictions, and people will actually be proud of having emancipated themselves from ‘consistency’. Ludwig Wittgenstein, 1930.¹

1 INTRODUCTION

Paraconsistent logics are those which permit inference from inconsistent information in a non-trivial fashion. Their articulation and investigation is a relatively recent phenomenon, even by the standards of modern logic. (For example, there was no article on them in the first edition of the *Handbook*.) The area has grown so rapidly, though, that a comprehensive survey is already impossible. The aim of this article is to spell out the basic ideas and some applications. Paraconsistent logic has interest for philosophers, mathematicians and computer scientists. As befits the *Handbook*, I will concentrate on those aspects of the subject that are likely to be of more interest to philosopher-logicians. The subject also raises many important philosophical issues. However, here I shall tread over these very lightly—except in the last section, where I shall tread over them lightly.

I will start in part 2 by explaining the nature of, and motivation for, the subject. Part 3 gives a brief history of it. The next three parts explain the standard systems of paraconsistent logic; part 4 explains the basic ideas, and how, in particular, negation is treated; parts 5 and 6 discuss how this basic apparatus is extended to handle conditionals and quantifiers, respectively. In part 7 we look at how a paraconsistent logic may handle various other sorts of machinery, including modal operators and probability. The next two parts discuss the applications of paraconsistent logic to some important theories; part 8 concerns set theory and semantics; part 9, arithmetic. The final part of the essay, 10, provides a brief discussion of some central philosophical aspects of paraconsistency.

In writing an essay of this nature, there is a decision to be made as to how much detail to include concerning proofs. It is certainly necessary to include many proofs, since an understanding of them is essential for anything other than a relatively modest grasp of the subject. On the other hand, to prove everything in full would not only make the essay extremely long, but distract from more important issues. I hope that I have struck a happy *via media*.

¹Wittgenstein [1975], p. 332.

Where proofs are given, the basic definitions and constructions are spelled out, and the harder parts of the proof worked. Routine details are usually left to the reader to check, even where this leaves a considerable amount of work to be done. In many places, particularly where the material is a dead end for the purposes of this essay, and is easily available elsewhere, I have not given proofs at all, but simply references. Those for whom a modest grasp of the subject is sufficient may, I think, skip all proofs entirely.

Paraconsistent logic is strongly connected with many other branches of logic. I have tried, in this essay, not to duplicate material to be found in other chapters of this *Handbook*, and especially, the chapter on Relevant Logic. At several points I therefore defer to these. There is no section of this essay entitled ‘Further Reading’. I have preferred to indicate in the text where further reading appropriate to any particular topic may be found.²

2 DEFINITION AND MOTIVATION

2.1 Definition

The major motivation behind paraconsistent logic has always been the thought that in certain circumstances we may be in a situation where our information or theory is inconsistent, and yet where we are required to draw inferences in a sensible fashion. Let \vdash be any relationship of logical consequence. Call it *explosive* if it satisfies the condition that for all α and β , $\{\alpha, \neg\alpha\} \vdash \beta$, *ex contradictione quodlibet* (ECQ). (In future I will omit set braces in this context.) Both classical and intuitionist logics are explosive. Clearly, if \vdash is explosive it is not a sensible inference relation in an inconsistent context, for applying it gives rise to *triviality*: everything. Thus, a minimal condition for a suitable inference relation in this context is that it not be explosive. Such inference relationships (and the logics that have them) have come to be called *paraconsistent*.³

Paraconsistency, so defined, is something of a minimal condition for a logic to be used as envisaged; and there are logics that are paraconsistent but not really appropriate for the use. For example, Johansson’s minimal logic is paraconsistent, but satisfies $\alpha, \neg\alpha \vdash \neg\beta$. One might therefore attempt a stronger constraint on the definition of ‘paraconsistent’, such as: for no syntactically definable class of sentences (e.g., negated sentences), Σ , do

²The most useful general reference is Priest *et al.* [1989] (though this is already a little dated). That book also contains a bibliography of paraconsistency up to about the mid-1980s.

³The word was coined by Miró Quesada at the Third Latin American Symposium on Mathematical Logic, in 1976. Note that a paraconsistent logic need not itself have an inconsistent set of logical truths: most do not. But there are some that do, e.g., any logic produced by adding the connexivist principle $\neg(\alpha \rightarrow \neg\alpha)$ to a relevant logic at least as strong as *B*. See Mortensen [1984].

we have $\alpha, \neg\alpha \vdash \sigma$, for all $\sigma \in \Sigma$. This seems too strong, however. In many logics, $\alpha, \neg\alpha \vdash \beta$, for every logical truth, β . If the logic is decidable, then there is a clear sense in which the set of logical truths is syntactically characterisable. Yet such logics would still be acceptable for many paraconsistent purposes. Hence, this definition would seem to be too strong.⁴

In his [1974], da Costa suggests another couple of natural constraints on a paraconsistent logic, of a rather different nature. One is to the effect that the logic should not contain $\neg(\alpha \wedge \neg\alpha)$ as a logical truth. The rationale for this is not spelled out. However, I take it that the idea is that if one has information that contains α and $\neg\alpha$ one does not want to have a logical truth that contradicts this. Why not though? Since one is not ruling out inconsistency *a priori*, there would seem to be nothing *a priori* against this (though maybe for particular applications one would not want the situation to arise). As a general condition, then, it seems too strong. And certainly a number of the logics that we will consider have $\neg(\alpha \wedge \neg\alpha)$ as a logical truth.

Another of the constraints that da Costa suggests is to the effect that the logic should contain as much of classical—or at least intuitionist—logic, as does not interfere with its paraconsistent nature. The condition is somewhat vague, though its intent is clear enough; and again, it is too strong. It assumes that a paraconsistent logician must have no objection to other aspects of classical or intuitionist logic, and this is clearly not true. For example, a relevant logician might well object to paradoxes of implication, such as $\alpha \rightarrow (\beta \rightarrow \alpha)$.⁵

As an aside, let me clarify the relationship between relevant logics and paraconsistent logics. The motivating concern of relevant logic is somewhat different from that of paraconsistency, namely to avoid paradoxes of the conditional. Thus, one may take a relevant (propositional) logic to be one such that if $\alpha \rightarrow \beta$ is a logical truth then α and β share a propositional parameter. The interests of relevant and paraconsistent logics clearly converge at many points. Relevant logics and paraconsistent logics are not coextensive, however. There are many paraconsistent logics that are not relevant, as we shall see. The relationship the other way is more complex, since there are different ways of using a relevant logic to define a consequence relation. A natural way is to say that $\alpha \vdash \beta$ iff $\alpha \rightarrow \beta$ is a logical truth. Such a consequence relation is clearly paraconsistent. Another is to define logical consequence as deducibility, defined in the standard way, using some set of axioms and rules for the relevant logic. Such a consequence relation may, but need not, be relevant. For example, Ackermann's original formulation of E contained the rule γ : if $\vdash \alpha$ and $\vdash \neg\alpha \vee \beta$ then $\vdash \beta$. This gives explo-

⁴Further attempts to tighten up the definition of paraconsistency along these lines can be found in Batens [1980] (in the definition of 'A-destructive', p. 201, clause (i) should read $\not\vdash_L A$), and Urbas [1990].

⁵Indeed, it is just this principle that ruins minimal logic for serious paraconsistent purposes. For α and $\alpha \rightarrow \perp$ (i.e., $\neg\alpha$) give \perp , and the principle then gives $\beta \rightarrow \perp$.

sion by an argument often called the ‘Lewis Independent Argument’, that we will meet in a moment.

Anyway, and to return from the digression: the definition of paraconsistency given here is weaker than sufficient to *guarantee* sensible application in inconsistent contexts; but an elegant stronger definition is not at hand, and since the one in question has become standard, I will use it to define the contents of this essay.

2.2 *Inconsistency and Dialetheism*

Numerous examples of inconsistent information/theories from which one might want to draw inferences in a controlled way have been offered by paraconsistent logicians. For example:

1. information in a computer data base;
2. various scientific theories;
3. constitutions and other legal documents;
4. descriptions of fictional (and other non-existent) objects;
5. descriptions of counterfactual situations.

The first of these is fairly obvious. As an example of the second, consider, e.g., Bohr’s theory of the atom, which required bound electrons both to radiate energy (by Maxwell’s equations) and not to (since they do not spiral inwards towards the nucleus). As an example of the third, just consider a constitution that gives persons of kind *A* the right to do something, *x*, and forbids persons of kind *B* from doing *x*. Suppose, then, that a person in both categories turns up. (We may assume that it had never occurred to the legislators that there might be such a person.) In the fourth case, the information (in, say, a novel or a myth) characterises an object, and turns out—deliberately or otherwise—to be inconsistent. To illustrate the fifth, suppose, for example, that we need to compute the truth of the conditional: if you were to square the circle, I would give you all my money. Applying the Ramsey-test, we see what follows from the antecedent (which is logically impossible), together with appropriate background assumptions. (And I would *not* give you all my money!)⁶

There is no suggestion here that in every case one must remain content with the inconsistent information in question. One might well like to remove

⁶Many of these examples are discussed further in Priest *et al.* [1989], ch. 18. The Bohr case is discussed in Brown [1993]. Another kind of example that is sometimes cited is the information provided by witnesses at a trial. I find this less persuasive. It seems to me that the relevant information here is all of the form: witness *x* says so and so. (That a witness is lying, or making an honest mistake, is always a possibility to be taken into account.) And any collection of statements of this form is quite consistent.

some of the inconsistent information in the data base; reject or revise the scientific theory; change the law to eliminate the inconsistency. But this is not possible in all of the cases given, e.g., for counterfactual conditionals with impossible antecedents. And even where it is, this not only may take time; it is often not clear how to do so satisfactorily. (The matter is certainly not algorithmic.) While we figure out how to do it, we may still be in a situation where inference is necessary, perhaps for practical ends, e.g., so that we can act on the information in the data base; or manipulate some piece of scientific technology; or make decisions of law (on other than an obviously inconsistent case). Moreover, since there is no decision procedure for consistency, there is no guarantee that any revision will achieve consistency. We cannot, therefore, be sure that we have succeeded. (This is particularly important in the case of the data base, where the deductions go on “behind our back”, and the need to revise may never become apparent.)

In cases of this kind, then, even though we may not, ideally, be satisfied with the inconsistent information, it may be desirable—indeed, practically necessary—to use a paraconsistent logic. Moreover, we know that many scientific theories are false; they may still be important because they make correct predications in most, or even all, cases; they may be good *approximations* to the truth, and so on. These points remain in force, even if the theories in question contain contradictions, and so are (thought to be) false for logical reasons. Of course, this is not so if the theories are trivial; but that’s the whole point of using a paraconsistent logic.

One can thus subscribe to the use of paraconsistent logics for some purposes without believing that inconsistent information or theories may be *true*. The view that some *are* true has come to be called *dialetheism*, a dialetheia being a true contradiction.⁷ If the truth about some subject is dialethic then, clearly, a paraconsistent logic needs to be employed in reasoning about that subject. (I take it to be uncontentious that the set of truths is not trivial. Why this is so, especially once one has accepted dialetheism is, however, a substantial question.)

Examples of situations that may give rise to dialetheias, and that have been proposed, are of several kinds, including:

1. certain kinds of moral and legal dilemmas;
2. borderline cases of vague predicates;
3. states of change.

Thus, one may suppose, in the legal example mentioned before, that a person who is *A* and *B* both has and has not the right to do *x*; or that in

⁷The term was coined by Priest and Routley in 1981. See Priest *et al.* [1989], p. xx. Note that some writers prefer ‘dialethism’.

a case of light drizzle it both is and is not raining; or that at the instant a moving object comes to rest, it both is and is not in motion.⁸

The most frequent and, arguably, most persuasive examples of dialetheias that have been given are the paradoxes of self-reference, such as the Liar Paradox and Russell's Paradox. What we have in such cases, are apparently sound arguments resulting in contradictions. There are many suggestions as to what is wrong with such arguments, but none of them is entirely happy. Indeed, in the case of the semantic paradoxes there is not (even after 2,000 years) any consensus concerning the most plausible way to go. This gives the thought that the arguments are, after all, sound, its appeal.⁹

Naturally, all the examples cited in this section are contestable. I will return to the issue of possible objections in the last part of this essay.

3 A BRIEF HISTORY OF PARACONSISTENT LOGIC

3.1 *The Law of Non-contradiction and Paraconsistency*

During the history of Western Philosophy, there have been a number of figures who deliberately endorsed inconsistent views.¹⁰ The earliest were some Presocratics, including Heraklitus. In the middle ages, some Neo-Platonists, such as Nicholas of Cusa, endorsed contradictory views. In the modern period, the most notable advocate of inconsistent views was Hegel.¹¹ These figures are relatively isolated, however. It is something of an understatement to say that the dominant orthodoxy in Western Philosophy has been strongly hostile to inconsistency.¹² Consistency has been taken to be pivotal to a number of fundamental notions, such as truth and rational belief. This antipathy to contradiction is, historically, due in large part to Aristo-

⁸Many of these examples are discussed further in Priest *et al.* [1989], ch. 18, 2.2. A discussion of transition states and legal dialetheias can be found in chs. 11 and 13 of Priest [1987]. Moral dilemmas are also discussed in Routley and Routley [1989]. The dialethic nature of vagueness is advocated in Peña [1989]. It has also been suggested that some contradictions in the Hegel/Marx tradition are dialethic. For a discussion of this, see Priest [1989a].

⁹For further discussion, see Routley [1979] and Priest [1987], chs. 1-3.

¹⁰And nearly every great philosopher has unwittingly endorsed inconsistent views.

¹¹In each case, there is, of course, some—though, I would argue, misguided—possibility for exegetical attempts to render the views consistent. Other modern philosophers whose thought also appears to endorse inconsistency are Meinong and the later Wittgenstein. In their cases there is more scope for exegetical evasion. For further discussion on all these matters, see Priest *et al.* [1989], chs. 1, 2.

¹²Eastern philosophy has been notably less so—though there is, again, room for exegetical debate. The most natural interpretation of Jaina philosophy has them endorsing inconsistent positions. And major Buddhist logicians of the stature of Nāgārjuna held that it was quite possible for statements to be both true and false. Significant elements of inconsistency can also be found in Chinese philosophy. For further discussion of all this, see Priest *et al.* [1989], ch. 1, sect. 2.

tle's defense of the Law of Non-contradiction in the *Metaphysics*.¹³ Given this situation, it may therefore be surprising that the orthodoxy against paraconsistency is a relatively recent phenomenon.

3.2 Paraconsistency Before the Twentieth Century

The major account of validity until this century was, of course, Aristotelian Syllogistic. Now, consider any sentences of the Syllogistic *E* and *I* forms; for example, 'No women are white' and 'Some women are white'. These are contradictories. But the inference from them to, e.g., 'All cows are black', is not a valid syllogism. Syllogistic is not, therefore, explosive: it is paraconsistent.

It might be suggested that it is more appropriate to look for explosion in accounts of propositional inference. Here the story is more complex, but the conclusion is similar. Aristotle had no elaborated account of propositional inference. However, there are comments that bear on the matter scattered through the *Organon*, and they have a distinctly paraconsistent flavour. For example, in the *Prior Analytics* (57^b3), Aristotle states that contradictories cannot both entail the same thing. It would seem to follow that Aristotle did not endorse at least one of (in modern notation) $\alpha \wedge \neg\alpha \vdash \alpha$ and $\alpha \wedge \neg\alpha \vdash \neg\alpha$. For contraposing (a move that Aristotle endorses immediately before), we obtain $\alpha \vdash \neg(\alpha \wedge \neg\alpha)$ and $\neg\alpha \vdash \neg(\alpha \wedge \neg\alpha)$. Hence, not everything can follow from a contradiction. In fact, there are reasons to suppose that Aristotle held a view of negation according to which the negation of any claim cancels that claim out. A contradiction has, therefore, no content, and entails nothing. This view of negation (which would now be called 'connexivist') was endorsed by a number of subsequent logicians (notably Abelard) well into the late middle ages.¹⁴

A theory of propositional inference was worked out much more thoroughly by Stoic logicians, and the explosive nature of their theories is more plausible for the following reason. There is a famous argument for ECQ, often called the Lewis (independent) argument, after C. I. Lewis. This goes (in natural deduction form) as follows:

$$\frac{\alpha \quad \frac{\neg\alpha}{\neg\alpha \vee \beta}}{\beta}$$

¹³Book Γ , ch 4. The historical success of this defence is, however, out of all proportion to its intellectual weight. See Priest [1998e].

¹⁴Much of this and the rest of the material in this subsection is documented in Sylvan [2000], ch. 4. The discussion there is carried out in terms of the conditional, though it is equally applicable to the consequence relation.

The argument uses just two principles (three if you include the transitivity of deducibility): Addition ($\alpha \vdash \alpha \vee \beta$) and the Disjunctive Syllogism ($\alpha, \neg\alpha \vee \beta \vdash \beta$). As we shall see in due course, the Disjunctive Syllogism (DS) has, unsurprisingly, been rejected by most paraconsistent logicians. Now Stoic logicians endorsed just this principle. The explosive nature of their logic would therefore seem a good bet. Despite this, it probably was not: there is reason to suppose that their disjunction was an intensional one that required some kind of connection between α and β for the truth of $\alpha \vee \beta$. If this is the case, Addition fails in general, as does the Lewis argument.

It is not known who discovered the Lewis argument. Martin [1985] conjectures that it was William of Soissons in the 12th Century. (It was certainly known to, and endorsed by, some later logicians, such as Scotus and Buridan.) At any rate, William was a member of a group of logicians called the Parvipontanians, who were known not only for living by a small bridge, but for defending ECQ. This group may therefore herald the arrival of explosion on the philosophical stage. Whether or not this is so, after this time, some logicians endorsed explosion, some rejected it, different orthodoxies ruling at different times and different places (though, possibly, the explosive view was more common). One group of logicians who rejected it is notable, since they very much prefigure modern paraconsistent logicians. This is the Cologne School of the late 15th Century, who argued against the DS on the ground that if you start by *assuming* that α and $\neg\alpha$, then you cannot appeal to α to rule out $\neg\alpha$ as the DS manifestly does.

Notoriously, logic made little progress between the end of the Middle Ages and the start of the third great period in logic, towards the end of the 19th Century. With the work of logicians such as Boole and Frege, we see the mathematical articulation of an explosive logical theory that has come to be known, entirely inappropriately, as ‘classical logic’. Though, in its early years, many objected to its explosive features, it has achieved a hegemony (though never a universality) in the logical community, in a (historically) very brief space of time. Whether this is because the truth was definitively and transparently revealed, or because at the time it was the only game in town, history will tell.

3.3 *The Twentieth Century*

A feature of paraconsistent logic this century is that the idea appears to have occurred independently to many different people, at different times and places, working in ignorance of each other, and often motivated by somewhat different considerations. Some, notably, for example, da Costa, have been motivated by the idea that inconsistent theories might be of intrinsic importance. Others, notably the early relevant logicians, were motivated simply by the idea that explosion, as a property of entailment, is

just too counter-intuitive.¹⁵

The earliest paraconsistent logics (that I am aware of) were given by two Russians. The first of these was Vasil'ev. Starting about 1910, Vasil'ev proposed a modified Aristotelian syllogistic, according to which there is a new form: S is both P and not P . How, exactly, this form was to be interpreted is contentious, though, a problem exacerbated by the fact that he was not in a position to employ the techniques of modern logic. This is not true of the second logician, Orlov, who, in 1929, gave the first axiomatisation of the relevant logic R . Sadly, the work of neither Vasil'ev nor Orlov made any impact at the time.¹⁶

An important figure who did have a good deal of influence was the Polish logician and philosopher Lukasiewicz. Partly influenced by Meinong's account of impossible objects, Lukasiewicz clearly envisaged the construction of paraconsistent logics in his seminal 1910 critique of Aristotle on the Law of Non-contradiction.¹⁷ And it was his erstwhile student, Jaškowski, who, in 1948, produced the first non-adjunctive paraconsistent logic.¹⁸

Paraconsistent logics were again, independently, proposed in South America in doctoral dissertations by Asenjo (1954, Argentina) and da Costa (1963, Brazil). Asenjo proposed the first many-valued paraconsistent logic. Da Costa gave axiom systems for a certain family of paraconsistent logics (the C systems), and produced the first quantified paraconsistent logic. Many co-workers, such as Arruda and Loparić, joined da Costa in the next 20 years, to produce an active school of paraconsistent logicians at Campinas (and later São Paulo). They developed non-truth-functional semantics for the C systems, and articulated the subject in various other ways; this included "rediscovering" Vasil'ev, taking up the work of Jaškowski, and formulating various other paraconsistent systems.¹⁹

Guided by considerations of relevance, an entirely different approach to paraconsistency was proposed in England by Smiley in [1959], who articulated the first filter logic. Starting at about the same time, and drawing on the earlier work of Ackermann and Church, Anderson and Belnap in the USA proposed a number of relevant paraconsistent logics of a different kind. A research school quickly grew up around them in Pittsburgh, which included co-workers such as Meyer and Dunn.²⁰ The algebraic semantics

¹⁵The later Wittgenstein was also sympathetic to paraconsistency for various reasons, though he never articulated a paraconsistent logic. See, e.g., Marconi [1984].

¹⁶On Vasil'ev see Priest *et al.* [1989], ch. 3, 2.2 and Arruda [1977]. On Orlov, see Anderson *et al.* [1992], p. xvii.

¹⁷A synopsis of this is published in English in Lukasiewicz [1971].

¹⁸For a discussion of Lukasiewicz and Jaškowski, see Priest *et al.* [1989], ch. 3, 2.1, 2.3. Jaškowski's work is translated into English in his [1969].

¹⁹Discussion and bibliography can be found in Priest *et al.* [1989], 5.6. The most accessible introduction to Asenjo's work is his [1966], and to da Costa's is his [1974]. Da Costa and Marconi [1989] reports much of the work of da Costa and his co-workers.

²⁰The work of this school is recorded in Anderson and Belnap [1975], and Anderson *et*

for relevant logics, in particular, was inaugurated largely by Dunn's 1966 doctoral thesis.²¹

Investigation of things paraconsistent in Australia took off in the early 1970s with the discovery of world (intensional) semantics for negation by R. Routley (now Sylvan) and V. Routley (now Plumwood). This was developed into an intensional semantics for the Anderson/Belnap logics—and many others—by Routley,²² Meyer (now in Australia), and a school that developed around them in Canberra, which included workers such as Brady and Mortensen. These semantics made the paraconsistent aspects of relevant logics plain.²³ Later in the 1970s the cudgel for dialetheism was taken up by Priest (now Priest) and Routley.²⁴

By the mid-1970s the paraconsistent movement was a fully international one, with workers in all countries cooperating (though not necessarily agreeing!), and with logicians working in numerous countries other than the ones already mentioned, including Belgium, Bulgaria, Canada and Italy. Some feel for the state of the subject at the end of the 70s can be obtained from Priest *et al.* [1989].²⁵ The rest, as they say, is not history.

4 BASIC TECHNIQUES OF PARACONSISTENT LOGICS

An understanding of most paraconsistent logics can be obtained by looking at the strategies employed in virtue of which ECQ fails. There are many techniques for achieving this end. In this part, I will describe the most fundamental. In the process, we will meet dozens of different systems of paraconsistent logic, often constructed along very different lines. It is therefore necessary to have some common medium for comparison. I have chosen to make this semantics, and will specify systems in terms of these. (I would warn straight away though, that many of the systems we will meet appeared first in proof theoretic terms. Indeed, some of the authors of these systems—e.g. Tennant—would privilege proof theory over semantics.) When I give details of corresponding proof theories, I will use the sort of proof theory (natural deduction, sequent calculus, or axiomatic) that seems most natural for the logic.

Because paraconsistency concerns only negation essentially, we can see the essentials of paraconsistent logics in languages with very little logical

al. [1992].

²¹See Anderson and Belnap [1975], and also the article on Relevant Logic in this volume of the *Handbook*.

²²Whenever the name 'Routley' is used without initial in this essay, it refers to Sylvan.

²³The work of this group is most accessible in Routley *et al.* [1982].

²⁴See, e.g., Routley [1979]. Priest's early work on the area is most accessible in Priest [1987].

²⁵Despite the date, all the work in the collection was finished by 1980. A number of papers produced at the same time, that were not included in this, were published in a special issue of *Studia Logica* on paraconsistent logics (**43** (1984), nos. 1 & 2).

apparatus. In this part, we will be concerned with a propositional language whose only connectives are negation, \neg , conjunction, \wedge , and disjunction, \vee . I will use lower case Roman letters, starting with p , for propositional parameters, lower case Greeks, starting with α , for arbitrary formulas, and upper case Greeks for sets of formulas. I will use \models_C , \models_I , and \models_{S5} for the consequence relations of classical logic, intuitionist logic and $S5$, respectively, and \models for the semantic consequence relation of whichever paraconsistent logic happens to be the topic of discussion. If a proof theory is involved, I will use \vdash for the corresponding notion of deducibility.

4.1 Filtration

One of the simplest ways to prevent explosion is to filter it, and any other undesirables, out. Consider, for simplicity, the one-premise case. (Finite sets of premises can always be reduced to this by conjoining.) Let $F(\alpha, \beta)$ be any relationship between formulas. Define an inference from α to β to be *prevalid* iff $\alpha \models_C \beta$ and $F(\alpha, \beta)$. The thought here is that for an inference to be correct, something more than classical truth-preservation is required, e.g., some *connection* between premise and conclusion. This is expressed by F . Usually, prevalidity is too weak as a notion of validity, since, in general, it is not closed under uniform substitution, and this is normally taken to be a desideratum for any notion of validity. However, closure can be ensured if we define an inference to be valid iff it is a uniform substitution instance of a prevalid inference.

What inferences are valid depends, of course, entirely on the filter, F . One that naturally and obviously gives rise to a paraconsistent logic is: $F(\alpha, \beta)$ iff α and β share a propositional parameter. (This collapses the notions of validity and prevalidity, since if α and β share a propositional parameter, so do uniform substitution instances thereof.) This logic is not a very interesting paraconsistent one, however, since, as is clear, $p \wedge \neg p \models \alpha$ where α is any formula containing the parameter p .²⁶

A different filter, proposed by Smiley [1959] is: $F(\alpha, \beta)$ iff α is not a (classical) contradiction and β is not a (classical) tautology.²⁷ (Note that, according to this definition, $\alpha \wedge \neg \alpha / \alpha$ is not prevalid, but it is valid, since it is an instance of $p \wedge q / p$.) It is easy to see that on this account $p \wedge \neg p$ does not entail q . The major notable feature of filter logics is that, in general, transitivity of deducibility breaks down.²⁸ For example, using

²⁶A stronger filter is one to the effect that *all* the variables of the premise occur in the conclusion. This gives rise to a logic in the family of analytic implications. On this family, see Anderson and Belnap [1975], sect. 29.6.

²⁷Filters of a related kind were also suggested by Geach and von Wright. See Anderson and Belnap [1975], sect. 20.1.

²⁸Though it need not. First Degree Entailment, where transitivity holds, can be seen as a filter logic. See Dunn [1980].

Smiley's filter, it is easy to see that $p \wedge \neg p \models p \wedge (\neg p \vee q)$, $p \wedge (\neg p \vee q) \models q$, but $p \wedge \neg p \not\models q$.

One of the most interesting filter logics, given by Tennant [1984], is obtained by generalising Smiley's approach. Let Π and Σ be sets of sentences, and let ' $\Pi \models_C \Sigma$ ' be understood in the natural way (every classical evaluation that makes every member of Π true makes some member of Σ true). Define the inference from Π to Σ to be prevalid iff: $\Pi \models_C \Sigma$ and for no proper subsets of Π and Σ , Π' and Σ' , respectively, do we have $\Pi' \models_C \Sigma'$. Validity is then defined by closing under substitution as before. In this account, a valid inference is one which is classically valid, and minimally so: there is no "noise" amongst premise and conclusion set.²⁹

Tennant's \models is obviously non-monotonic (that is, adding extra premises may invalidate an inference). It also has the following property: if $\Pi \models_C \Sigma$, then there are subsets of Π and Σ , Π' and Σ' , respectively, such that $\Pi' \models \Sigma'$. For if $\Pi \models_C \Sigma$, we can simply throw out premises and/or conclusions until this is no longer true; the result is a prevalid, and so valid, inference. In particular, if $\Pi \models_C \alpha$ then for some $\Pi' \subseteq \Pi$, $\Pi' \models \alpha$ or $\Pi' \models \phi$. In the first case, α follows validly from *part* of Π ; in the second, part of Π can be shown to be inconsistent by valid reasoning.

Filtration can also be applied proof theoretically: we start with classical proofs and throw out those that do not satisfy some specific criteria. Tennant's logic can be characterised proof-theoretically in just this way. For finite premises and conclusions, the valid inferences are exactly those that are provable in the Gentzen sequent calculus for classical logic, but which do not use the structural rules of dilution (thinning) and cut. Specifically, consider the sequent calculus whose basic sequents are of the form $\alpha : \alpha$, and whose rules are as follows. (Π_1, Π_2 means $\Pi_1 \cup \Pi_2$; similarly, Π, α means $\Pi \cup \{\alpha\}$, and if something of this form occurs as a premise of a rule, it is to be understood that $\alpha \notin \Pi$).

$$\frac{\Pi, \alpha : \Delta}{\Pi : \Delta, \neg \alpha} \qquad \frac{\Pi : \Delta, \alpha}{\Pi, \neg \alpha : \Delta}$$

$$\frac{\Pi, \alpha : \Delta}{\Pi, \alpha \wedge \beta : \Delta} \qquad \frac{\Pi, \beta : \Delta}{\Pi, \alpha \wedge \beta : \Delta} \qquad \frac{\Pi_1 : \Delta_1, \alpha \quad \Pi_2 : \Delta_2, \beta}{\Pi_1, \Pi_2 : \Delta_1, \Delta_2, \alpha \wedge \beta}$$

$$\frac{\Pi : \Delta, \alpha}{\Pi : \Delta, \alpha \vee \beta} \qquad \frac{\Pi : \Delta, \beta}{\Pi : \Delta, \alpha \vee \beta} \qquad \frac{\Pi_1, \alpha : \Delta_1 \quad \Pi_2, \beta : \Delta_2}{\Pi_1, \Pi_2, \alpha \vee \beta : \Delta_1, \Delta_2}$$

²⁹The restriction of Tennant's approach to the one-premise, one-conclusion, case obviously gives Smiley's account. Smiley himself, handles the multiple-premise case, simply by conjoining. As Tennant points out ([1984], p. 199), this generates a different account from his. It is not difficult to check that $p \vee q, \neg(p \vee q) \not\models p \wedge q$ for Smiley. (The conjoined antecedent is a contradiction; and any inference of which the conjoined form is a substitution instance is not classically valid.) But it is valid for Tennant, since it is a substitution instance of $p \vee q, r \vee s, \neg(t \vee q), \neg(r \vee u) \models p \wedge s$.

Then we have $\Pi \models \Sigma$ iff the sequent $\Pi : \Sigma$ is provable. For the proof see Tennant [1984].³⁰

Tennant's account of inference seems to capture very nicely what one might call the 'essential core' of classical inference. As an inference engine to be applied to inconsistent information/theories, it could not be applied in the obvious way, however. This is because information is often heavily redundant. For example, for Tennant's \models , we do not have $p, \neg p \vee q, q \models q$. Yet given the information in the premises, it would certainly seem that we are entitled to infer q . Presumably, then, we would take α to follow from Σ iff for some $\Sigma' \subseteq \Sigma$, $\Sigma' \models \alpha$.³¹ If we do this then more than transitivity fails; so does Adjunction. For $\neg p, p \vee q \models q$ and $\neg q, p \vee q \models p$, hence both p and q follow from $\{\neg p, p \vee q, \neg q\} = \Sigma$. But for no subset of Σ , Σ' , do we have $\Sigma' \models p \wedge q$. ($\Sigma \models \phi$, and if Σ' is a proper subset of Σ , $\Sigma' \not\models_C p \wedge q$.) In this respect, Tennant's approach is similar to the next one that we will look at.

4.2 Non-adjunction

All the other approaches that we will consider, except the last (algebraic logics) accept validity as defined simply in terms of model-preservation. Thus, given some notion of interpretation, call it a *model* of a sentence if the sentence holds in the interpretation; an interpretation is a model of a set of sentences if it is a model of every member of the set; and an inference is valid iff every model of the premises is a model of the conclusion. In particular, then, if explosion is to be avoided, it must be possible to have models for contradictions, which are not models of everything. Where the differences in the following approaches lie is in what counts as an interpretation, and what counts as holding in it.

For the next approach, an interpretation, I , is a Kripke interpretation of some modal logic, say $S5$, employing the usual truth conditions. Each world in an interpretation may be thought of as the world according to some party in a debate or discussion. This gives the approach its common name, *discussive* (or *discursive*) logic. I is a (discursive) model of sentence α iff α holds at some world in I , i.e., $\diamond\alpha$ holds in the model. Thus, $\Sigma \models \alpha$ iff α holds, discursively, in every discursive model of Σ , i.e., iff $\diamond\Sigma \models_{S5} \diamond\alpha$, where $\diamond\Sigma$ is $\{\diamond\alpha; \alpha \in \Sigma\}$. This approach is that of Jaškowski [1969].³² It is clear that discussive logic is paraconsistent, since we may have $\diamond\alpha$ and $\diamond\neg\alpha$

³⁰The proof theory can be given a filtered natural deduction form too. Essentially, classical deductions that have a certain "normal form" pass through the filter. See Tennant [1980].

³¹Though if we do this, symmetry suggests that we should take Π to follow from Σ iff for some $\Sigma' \subseteq \Sigma$ and $\Pi' \subseteq \Pi$, $\Sigma' \vdash \Pi'$; in this case paraconsistency is lost since $\alpha, \neg\alpha \vdash \phi$.

³²Popper also seems to have had a similar idea in 1948. See his [1963], p. 321.

in an $S5$ interpretation, without having $\diamond\beta$. For similar reasons, Adjunction ($\alpha, \beta \models \alpha \wedge \beta$) fails. It should be noted, however, that $\alpha \wedge \neg\alpha \models \beta$, so the logic is not paraconsistent for conjoined contradictions.

A closely related approach can be found in Rescher and Brandom [1979]. They define validity as truth preservation in all worlds, but they augment the worlds of standard modal logic by inconsistent and complete worlds, constructed using operators $\dot{\cup}$ and $\dot{\cap}$. Specifically, worlds are constructed recursively from standard worlds as follows. If W is a set of worlds, $\dot{\cup}W$ is a world such that α is true in $\dot{\cup}W$ iff for some w in W , α is true in w ; and $\dot{\cap}W$ is a world such that α is true in $\dot{\cap}W$ iff for all w in W , α is true in w . As is intuitively clear, inconsistent worlds just provide another way of expressing what holds in a Jaśkowski interpretation. Incomplete worlds appear more novel, but, in fact, add nothing. For if truth fails to be preserved in one of these, it fails to be preserved in one of the ordinary worlds which go into making it up. These ideas can be recast to show that the semantics of Rescher and Brandom, and of Jaśkowski are inter-translatable, and deliver the same notion of validity.³³

A notable feature of discussive logic is that $\Sigma \models \alpha$ iff for some $\beta \in \Sigma$, $\beta \models_C \alpha$. (The proof from right to left is obvious. From left to right, suppose that for every $\beta \in \Sigma$, $\beta \not\models_C \alpha$. Let w_β be a classical world where β holds but α does not. If we take the interpretation whose worlds are $\{w_\beta; \beta \in \Sigma\}$ this is a counter-model for $\Sigma \models \alpha$.) Thus, single-premise discussive inference is classical, and there is no essentially multiple-premise inference. One way to avoid the second of these features is to add an appropriate conditional connective. We will look at this later. Another way is to allow a certain amount of conjoining of premises. The question is how to do this in a controlled way so that explosion does not arise.

One suggestion, made by Rescher and Manor, is, in effect, to allow conjoining up to maximal consistency.³⁴ Given a set of premises, Σ , a maximally consistent subset (mcs) is any consistent subset, Σ' , such that if

³³Proof: Suppose that, discursively, $\Sigma \not\models \alpha$. Then there is an interpretation such that for each $\sigma \in \Sigma$, there is some world, w_σ , such that σ is true in w_σ , but α is not true in w_σ . Let $w = \dot{\cup}\{w_\sigma; \sigma \in \Sigma\}$, then w is a Rescher/Brandom counter-model. Conversely, suppose that $\Sigma \not\models \alpha$ for Rescher and Brandom. Then there is some world such that for every $\sigma \in \Sigma$, σ is true at w , but α is not. We show that there is a Jaśkowski counter-model. The result is proved by recursion on the construction of Rescher/Brandom worlds. If w is a standard world, the result is clear. So suppose that $w = \dot{\cap}W$, where the result holds for all members of W . By definition, for every $z \in W$, and every $\sigma \in \Sigma$, σ is true in z , but for some z , α is not true in z . Consider that z . This is a Rescher/Brandom counter-model to the inference. Hence, the result holds by recursion hypothesis. Alternatively, suppose that $w = \dot{\cup}W$, where the result holds for all members of W . By definition, for every $\sigma \in \Sigma$, there is some $w_\sigma \in W$, such that σ is true in w_σ , but α is not. By recursion, there must be a Jaśkowski countermodel for the inference σ/α . σ is true at some world in this, but α is not. If we form the collection of worlds for all such σ , this then gives us a Jaśkowski counter-model to the original inference.

³⁴Rescher and Manor [1970-1]. This takes off from the earlier work of Rescher [1964].

$\alpha \in \Sigma - \Sigma'$, $\Sigma' \cup \{\alpha\}$ is inconsistent. We can now say that α follows from Σ iff for some mcs Σ' , $\Sigma' \models_C \alpha$. In possible world terms, we can rephrase this as follows. Let us say that an interpretation, I , *respects* Σ iff for every mcs Σ' , there is a world, w , in I such that Σ' is true in w . Then it is not difficult to see that this policy is a variant of discussive logic: $\Sigma \models \alpha$ iff α holds discussively in every interpretation that respects Σ . (If α follows classically from some Σ' , then it holds in every discussive interpretation that respects Σ . Conversely, suppose that it follows from no Σ' . Then for each Σ' choose a world $w_{\Sigma'}$ where Σ' is true, but α is not. The interpretation containing all such $w_{\Sigma'}$ is a countermodel.)

This policy is certainly stronger than simple discussive consequence. For example, it gives: $p, q \models p \wedge q$. In fact, if Σ is (classically) consistent then every classical consequence of α is a consequence. But it is still non-adjunctive: $p, \neg p \not\models p \wedge \neg p$.³⁵

A slightly different way of proceeding is provided by Schotch and Jennings.³⁶ Given a finite set, Σ , a *partition* is any family of disjoint sets, each of which is classically consistent, and whose union is Σ . The *level* of Σ , $l(\Sigma)$, is the least n such that Σ can be partitioned into n sets (or, conventionally, ∞ if there is no such n). $\Sigma \models \alpha$ iff $l(\Sigma) = \infty$ or, $l(\Sigma) = n$ and for any partition of Σ of size n , $\{\Sigma_i; 1 \leq i \leq n\}$, there is an i such that $\Sigma_i \models_C \alpha$. As with the previous approach, this definition can be converted into discussive terms, by taking our models to be those that respect the premise set. But this time, an interpretation respects Σ iff for some partition of the level of Σ , $\{\Sigma_i; 1 \leq i \leq n\}$, and every i , there is a world in the interpretation where Σ_i is true.

Leaving aside the fact that Schotch and Jennings consider only finite premise sets, one difference between their approach and the previous one concerns the consequences of sets, Σ , with single inconsistent members. Such sets have no partitions, and so explode for Schotch and Jennings. They still have mcscs though (e.g., ϕ), and so do not explode for Rescher and Manor. If Σ has no single inconsistent member then Schotch and Jennings' consequence relation is included in that of Rescher and Manor. For if $\{\Sigma_i; i \in n\}$ is a partition of the premises, Σ , and for some i , $\Sigma_i \models_C \alpha$, then Σ_i can be extended to an mcs of Σ , and this classically entails α . The converse is not true, however. Let $\Sigma = \{p, \neg p, q, r\}$. This has two mcscs, $\{p, q, r\}$ and $\{\neg p, q, r\}$. Hence, for Rescher and Manor, $q \wedge r$ follows. But Σ has level 2, and one partition is $\{\{p, q\}, \{\neg p, r\}\}$. Neither of these classically entails $q \wedge r$, so this does not follow for Schotch and Jennings (which seems wrong, intuitively).³⁷

³⁵ Rescher and Manor also formulate a weaker policy of inference. α follows from Σ iff for *all* mcs Σ' , $\Sigma' \models_C \alpha$. This logic is clearly adjunctive.

³⁶ See their [1980], where they also discuss appropriate proof theories and modal connections.

³⁷ The same example shows that Schotch and Jennings' \models , unlike Rescher and Manor's,

Despite the differences, Schotch and Jennings' approach shares with that of Rescher and Manor the following features: for consistent sets, consequence coincides with classical consequence; Adjunction fails. For Schotch and Jennings, like Jaśkowski, $\alpha \wedge \neg\alpha$ explodes. For Rescher and Manor, it has no consequences (other than tautologies). The logics that we will look at in subsequent sections are more discriminating concerning conjoined contradictions.

4.3 Interlude: Henkin Constructions

Before we move on to look at the other basic approaches to paraconsistent logic, I want to isolate a construction that we will have many occasions to use. In a standard Henkin proof for the completeness of an explosive logic, we construct a maximally consistent set of sentences, and use this to define an evaluation. In the construction of the set, we keep something out of it by putting its negation in. As might be expected, these techniques do not work in paraconsistent logic; but they can be generalised to do so. What plays the role of a maximally consistent set in a paraconsistent logic is a *prime theory*, where a set of sentences, Σ , is a theory iff it is closed under deducibility; and it is prime iff $\alpha \vee \beta \in \Sigma \Rightarrow (\alpha \in \Sigma \text{ or } \beta \in \Sigma)$. To keep something out in the construction of a prime theory, we have to exclude it explicitly. I now show how.

Assume that the proof theory is to be given in natural deduction terms. For definiteness I adopt the notational conventions of Prawitz [1965].³⁸ Consider the following rules for conjunction and disjunction:

$$\begin{array}{l} \vee I \quad \frac{\alpha \quad \beta}{\alpha \wedge \beta} \\ \\ \wedge E \quad \frac{\alpha \wedge \beta}{\alpha} \quad \frac{\alpha \wedge \beta}{\beta} \\ \\ \vee I \quad \frac{\alpha}{\alpha \vee \beta} \quad \frac{\beta}{\alpha \vee \beta} \end{array}$$

is non-monotonic, since we have $q, r \models q \wedge r$.

³⁸In particular, something of the form:

$$\begin{array}{c} \alpha \\ \vdots \\ \beta \end{array}$$

in a rule indicates a subproof with α as one assumption—though there may be others—and conclusion β . If α is overlined, this means that the application of the rule discharges it.

$$\vee E \quad \frac{\alpha \vee \beta \quad \begin{array}{c} \bar{\alpha} \\ \vdots \\ \gamma \end{array} \quad \begin{array}{c} \bar{\beta} \\ \vdots \\ \gamma \end{array}}{\gamma}$$

Let \vdash be any proof theory that includes these rules. Write $\Sigma \vdash \Pi$ to mean that there are members of Π , π_1, \dots, π_n , such that $\Sigma \vdash \pi_1 \vee \dots \vee \pi_n$. Then if $\Sigma \not\vdash \Pi$, there are sets $\Delta \supseteq \Sigma$ and $\Gamma \supseteq \Pi$, such that $\Delta \not\vdash \Gamma$, and Δ is a prime theory. To prove this, we enumerate the formulas of the language: $\beta_0, \beta_1, \beta_2, \dots$, and define a sequence of sets Σ_n, Π_n ($n \in \omega$) as follows. $\Sigma_0 = \Sigma$; $\Pi_0 = \Pi$. If $\Sigma_n \cup \{\beta_n\} \not\vdash \Pi_n$, then $\Sigma_{n+1} = \Sigma_n \cup \{\beta_n\}$ and $\Pi_{n+1} = \Pi_n$. Otherwise $\Sigma_{n+1} = \Sigma_n$ and $\Pi_{n+1} = \Pi_n \cup \{\beta_n\}$. $\Delta = \bigcup_{n \in \omega} \Sigma_n$; $\Gamma = \bigcup_{n \in \omega} \Pi_n$.

It is not difficult to check by induction that for all n , $\Sigma_n \not\vdash \Pi_n$. (Suppose this holds for n ; if $\Sigma_n \cup \{\beta_n\} \not\vdash \Pi_n$, the result for $n + 1$ is immediate. So suppose that $\Sigma_n \cup \{\beta_n\} \vdash \Pi_n$ and $\Sigma_{n+1} \vdash \Pi_{n+1}$. Then $\Sigma_n \vdash \{\beta_n\} \cup \Pi_n$. By a sequence of moves that amount to “cut”, $\Sigma_n \vdash \Pi_n$, contrary to induction hypothesis.) By compactness, it follows that $\Delta \not\vdash \Gamma$.

It is also easy to check that Δ is a prime theory. Suppose that $\Delta \vdash \alpha$, but $\alpha \notin \Delta$. Then for some n , $\Sigma_n \cup \{\alpha\} \vdash \Pi_n$. Hence, $\Delta \vdash \Gamma$. Next, suppose that $\alpha \vee \beta \in \Delta$, but $\alpha \notin \Delta$ and $\beta \notin \Delta$. Then for some m and n , $\Sigma_n \cup \{\alpha\} \vdash \Pi_n$ and $\Sigma_m \cup \{\beta\} \vdash \Pi_m$. Hence $\Delta \cup \{\alpha \vee \beta\} \vdash \Gamma$, and so $\Delta \vdash \Gamma$.

4.4 Non-truth-functionality

Let us now return to the other basic approaches to paraconsistent logics. On the first of these, explosion is invalidated by employing a non-truth-functional account of negation. Typically, this account of negation is imposed on top of an orthodox account of positive logic. Thus, let an interpretation be a map, ν , from the set of formulas to $\{1, 0\}$, satisfying just the following conditions:

$$\begin{aligned} \nu(\alpha \wedge \beta) &= 1 \text{ iff } \nu(\alpha) = 1 \text{ and } \nu(\beta) = 1 \\ \nu(\alpha \vee \beta) &= 1 \text{ iff } \nu(\alpha) = 1 \text{ or } \nu(\beta) = 1 \end{aligned}$$

In particular, the truth value of $\neg\alpha$ is independent of that of α . Validity is defined as truth preservation over all interpretations. It is obvious that explosion fails, since we may choose an evaluation that assigns both p and $\neg p$ (and their conjunction) the value 1, whilst assigning q the value 0.

These semantics can be characterised very simply in natural deduction terms by just the rules $\vee I$, $\vee E$, $\wedge I$ and $\wedge E$. Soundness is easy to check. For completeness, suppose that $\Sigma \not\vdash \alpha$. Then put $\Pi = \{\alpha\}$, and extend Σ

to a prime theory, Δ , with the same property, as in 4.3. Define a map, ν , as follows:

$$\begin{aligned}\nu(\alpha) &= 1 \text{ if } \alpha \in \Delta \\ \nu(\alpha) &= 0 \text{ if } \alpha \notin \Delta\end{aligned}$$

It is easy to check that ν is an interpretation. Hence, we have the result.

This system contains no inferences that involve negation essentially. For this reason, \neg can hardly be thought of as a negation functor. Stronger paraconsistent systems, where this is more plausibly the case, can be obtained by adding conditions on the semantics. The following are some examples:³⁹

- (i) if $\nu(\alpha) = 0$, $\nu(\neg\alpha) = 1$
- (ii) if $\nu(\neg\neg\alpha) = 1$, $\nu(\alpha) = 1$
- (iii) if $\nu(\alpha) = 1$, $\nu(\neg\neg\alpha) = 1$
- (iv) $\nu(\neg(\alpha \wedge \beta)) = \nu(\neg\alpha \vee \neg\beta)$
- (v) $\nu(\neg(\alpha \vee \beta)) = \nu(\neg\alpha \wedge \neg\beta)$

Sound and complete rule systems can be obtained by adding the corresponding rules, which are, respectively:

- (i) $\frac{}{\overline{\alpha \vee \neg\alpha}}$
- (ii) $\frac{\neg\neg\alpha}{\alpha}$
- (iii) $\frac{\alpha}{\neg\neg\alpha}$
- (iv) $\frac{\neg(\alpha \wedge \beta)}{\neg\alpha \vee \neg\beta}$
- (v) $\frac{\neg(\alpha \vee \beta)}{\neg\alpha \wedge \neg\beta}$

(Double underlining indicates a two-way rule of inference, and a zero premise rule, as in (i), can be thought of as an assumption that discharges itself.) The corresponding soundness and completeness proofs are simple extensions of the basic arguments.

These additions give the \wedge, \vee, \neg -fragments of various systems in the literature. (i) gives that of Batens' *PI* [1980]; (i) and (ii) that of da Costa's C_ω ; ⁴⁰ (i)-(v) that of Batens' PI^S . In PI^S every sentence is logically equivalent to one in Conjunctive Normal Form. This can be used to show that PI^S

³⁹Some others can be found in Loparić and da Costa [1984], and Beziau [1990].

⁴⁰Semantics of the present kind for the da Costa systems were first proposed in da Costa and Alves [1977].

is a maximal paraconsistent logic, in the sense that any logic that extends it is not paraconsistent. (For details, see Batens [1980].)

Observe, for future reference, that if we add to PI or an extension thereof the condition:

$$\text{if } \nu(\alpha) = 1, \nu(\neg\alpha) = 0$$

then all interpretations are classical, and so we have classical logic. As may easily be checked, adding this is sound and complete with respect to the rule of inference:

$$\frac{\alpha \wedge \neg\alpha}{\beta}$$

Another major da Costa system, C_1 , extends C_ω in accordance with the following idea. It should be possible to express in the language the idea that a sentence, α , behaves consistently; and for consistent sentences classical logic should apply. Let us write $\neg(\alpha \wedge \neg\alpha)$ as α^0 . Then it is natural enough to suppose that α^0 expresses the consistency of α . It does not, in any of the above systems, since we may have $\alpha \wedge \neg\alpha \wedge \alpha^0$ true in an interpretation. This is exactly what is ruled out by the condition:

$$\text{(vi) } \nu(\alpha) = \nu(\neg\alpha) \text{ then } \nu(\alpha^0) = 0^{41}$$

($\nu(\alpha) = \nu(\neg\alpha)$ iff both are 1, by semantic condition (i). Note that (i) also guarantees the converse of (vi): $\nu(\alpha) \neq \nu(\neg\alpha)$ then $\nu(\alpha^0) = 1$.)

C_1 is obtained by adding (vi) to C_ω , together with the following condition, which requires consistency to be preserved under syntactic constructions:

$$\text{(vii) if } \nu(\alpha^0) = \nu(\beta^0) = 1 \text{ then } \nu((\neg\alpha)^0) = \nu((\alpha \wedge \beta)^0) = \nu((\alpha \vee \beta)^0) = 1$$

The deduction rules that correspond to (vi) and (vii) are, respectively:

$$\text{(vi) } \frac{\alpha \wedge \neg\alpha \wedge \alpha^0}{\beta}$$

$$\text{(vii) } \frac{\alpha^0}{(\neg\alpha)^0} \quad \frac{\alpha^0 \quad \beta^0}{(\alpha \wedge \beta)^0} \quad \frac{\alpha^0 \quad \beta^0}{(\alpha \vee \beta)^0}$$

Soundness and completeness of the extensions are easily checked.

Now suppose that we have a piece of valid classical reasoning concerning formulas composed of parameters p_1, \dots, p_n . If we *assume* p_1^0, \dots, p_n^0 then for

⁴¹Da Costa's actual condition is: if $\nu(\alpha^0) = \nu(\beta \supset (\alpha \wedge \neg\alpha)) = 1$ then $\nu(\beta) = 0$. This is equivalent, given his account of the conditional.

every such formula, α , α^0 follows by the appropriate applications of the rules of (vii). Hence, whenever we have established $\alpha \wedge \neg\alpha$ we may apply rule (vi) to give β . But the addition of this inference is sufficient to give classical logic, as I have already observed. Hence any valid classical reasoning may be recaptured formally by adding the appropriate consistency assumptions.⁴²

One final comment on treating negation non-truth-functionally. It is a consequence of this that the substitutivity of provable equivalents breaks down in general. For example, even though α is logically equivalent to $\alpha \wedge \alpha$ there is no guarantee that the negations of these formulas have the same truth value in an interpretation.⁴³

4.5 Many Values

The previous approach sticks with the traditional two truth values, and obtains a paraconsistent logic by making negation non-truth-functional. The next approach retains truth functionality, but drops the idea that there are exactly two truth values. That is, such logics are many-valued.⁴⁴ A many-valued logic will be paraconsistent if it is possible for a formula and its negation both to take designated values (whilst not everything does). A natural way of obtaining this is to have a designated value that is a fixed point for negation. The simplest such logic is a three valued one with values, t , b , and f , where t and b are designated, and the matrices are:

\neg	
t	f
b	b
f	t

\wedge	t	b	f
t	t	b	f
b	b	b	f
f	f	f	f

\vee	t	b	f
t	t	t	t
b	t	b	b
f	t	b	f

It will be noted that these are just the matrices of Lukasiewicz and Kleene's 3-valued logics, where the middle value is normally thought of as *undecidable*, or *neither true nor false*, and so not designated. It was the thought that this value might be read as *both true and false*—a natural enough thought, given dialetheism—and so be designated, that marks the start of many-valued paraconsistent logic. This was the approach proposed by Asenjo (see his [1966]), and others, e.g. Priest [1979], where the logic is called *LP*, a nomenclature that I will stick with here.

⁴²It might be suggested that one ought not to take α^0 as expressing consistency unless it, itself, behaves consistently. This thought motivates the weaker da Costa system C_2 , which is the same as C_1 , except that α^0 is replaced everywhere by $\alpha^0 \wedge \alpha^{00}$. Of course, there is no reason to suppose that this expresses the consistency of α unless it, itself, behaves consistently. This thought motivates the da Costa system C_3 where α^0 is replaced everywhere by $\alpha^0 \wedge \alpha^{00} \wedge \alpha^{000}$. And so on for all the da Costa Systems C_i , for finite non-zero i .

⁴³For a discussion of this in the context of da Costa's logics, see Urbas [1989].

⁴⁴For a general discussion of many-valued logics, see the articles on the topic in this *Handbook*. See also, Rescher [1969].

LP may be generalised in various different ways. One is as follows. If we let $t = +1$, $b = 0$ and $f = -1$ then the truth conditions of LP are:

$$\begin{aligned}\nu(\neg\alpha) &= -\nu(\alpha) \\ \nu(\alpha \wedge \beta) &= \min\{\nu(a), \nu(\beta)\} \\ \nu(\alpha \vee \beta) &= \max\{\nu(a), \nu(\beta)\}\end{aligned}$$

The same conditions can be used for any set of integers, X , containing 0 and closed under $-$. The designated values are the non-negative values. Let us call this a *Sugihara generalisation*, after the person who, in effect, first proposed a matrix of this kind, where X was the set of all integers.⁴⁵

Any Sugihara generalisation, though semantically different from LP , is essentially equivalent to it. Any LP countermodel is a Sugihara countermodel. But conversely, if we have a Sugihara countermodel, we can obtain an LP countermodel by mapping all positive values to $+1$, 0 to 0, and all negative values to -1 . A little thought is sufficient to establish that the mapping respects the matrices and preserves designated values, as required.

A different way of generalising LP is as follows. If we let $t = 1$, $b = 0.5$ and $f = 0$ then the truth conditions of LP are:

$$\begin{aligned}\nu(\neg\alpha) &= 1 - \nu(\alpha) \\ \nu(\alpha \wedge \beta) &= \min\{\nu(a), \nu(\beta)\} \\ \nu(\alpha \vee \beta) &= \max\{\nu(a), \nu(\beta)\}\end{aligned}$$

The same conditions can be used for any set of reals $\{0, 0.5, 1\} \subseteq X \subseteq [0, 1]$, which is closed under subtraction (of a greater by a lesser). For suitable choices of X , these are the matrices of the odd-numbered finite Łukasiewicz many-valued logics, and for $X = [0, 1]$ they are the matrices of Łukasiewicz' continuum-valued logic. In Łukasiewicz' logics proper, the only designated value is 1, which does not give a paraconsistent logic. But if one takes the designated values to be $\{x; a < x \leq 1\}$ (or $\{x; a \leq x \leq 1\}$) then the logic will be paraconsistent provided that $0 < a < 0.5$ (or $0 < a \leq 0.5$). Let us call such logics *Łukasiewicz generalisations*. In a Łukasiewicz generalisation where the set of truth values is $[0, 1]$, these may naturally be thought of as degrees of truth. Hence, such a logic is a natural candidate for a paraconsistent fuzzy logic (logic of vagueness).⁴⁶

It is not difficult to see that any Łukasiewicz generalisation is, in fact, equivalent to LP . As with the Sugihara generalisations, any LP countermodel is a Łukasiewicz countermodel; and conversely, any Łukasiewicz

⁴⁵See Anderson and Belnap [1975], sect. 26.9.

⁴⁶A variation on this theme is given by Peña in a number of papers. (See, e.g., Peña [1984].) Peña takes truth values to be an ordered set of more complex entities defined in terms of the interval $[0, 1]$.

countermodel can be collapsed into an LP countermodel by the mapping, f , defined thus:

$$\begin{aligned} f(x) &= 1 && \text{if } 1 - a \leq x \leq 1 \\ &= 0.5 && \text{if } a < x < 1 - a \\ &= 0 && \text{if } 0 \leq x \leq a \end{aligned}$$

or for the case where a is a designated value:

$$\begin{aligned} f(x) &= 1 && \text{if } 1 - a < x \leq 1 \\ &= 0.5 && \text{if } a \leq x \leq 1 - a \\ &= 0 && \text{if } 0 \leq x < a \end{aligned}$$

The generalisations of LP that we have considered in this section all, therefore, generate the same logic. What its proof theory is, we will see in the next.

4.6 Relational Valuations

Standardly, semantic evaluations are thought of as functions from formulas to truth values, say, 0 and 1. Another way of invalidating explosion is to take them to be, not functions, but relations. A formula may then relate to both 0 and 1, another way of expressing the thought that a sentence is both true and false. Assuming that negation behaves as usual, this means that both p and $\neg p$ may relate to 1, whilst an arbitrary formula may not. A natural way of spelling out this idea is as follows.

If P is the set of propositional parameters, an evaluation, ρ , is a subset of $P \times \{0, 1\}$. The evaluation is extended to a relation for all formulas by the familiar looking recursive clauses:

$$\begin{aligned} \neg\alpha\rho 1 &\text{ iff } \alpha\rho 0 \\ \neg\alpha\rho 0 &\text{ iff } \alpha\rho 1 \end{aligned}$$

$$\begin{aligned} \alpha \wedge \beta\rho 1 &\text{ iff } \alpha\rho 1 \text{ and } \beta\rho 1 \\ \alpha \wedge \beta\rho 0 &\text{ iff } \alpha\rho 0 \text{ or } \beta\rho 0 \end{aligned}$$

$$\begin{aligned} \alpha \vee \beta\rho 1 &\text{ iff } \alpha\rho 1 \text{ or } \beta\rho 1 \\ \alpha \vee \beta\rho 0 &\text{ iff } \alpha\rho 0 \text{ and } \beta\rho 0 \end{aligned}$$

Let us say that a formula, α , is true in an interpretation, ρ , iff $\alpha\rho 1$, and false iff $\alpha\rho 0$; then validity may be defined as truth preservation in all interpretations. According to this account, classical logic is just the special case where multi-valued relations have been forgotten.

These semantics are the Dunn semantics for the logic of First Degree Entailment, *FDE*.⁴⁷ In natural deduction terms, *FDE* can be characterised by the rules $\wedge I$, $\wedge E$, $\vee I$ and $\vee E$, together with the rules:

$$\frac{\neg(\alpha \wedge \beta)}{\neg\alpha \vee \neg\beta} \quad \frac{\neg\alpha \wedge \neg\beta}{\neg(\alpha \vee \beta)} \quad \frac{\alpha}{\neg\neg\alpha}$$

Soundness is easily checked. For completeness, suppose that $\Sigma \not\vdash \alpha$. Extend Σ to a prime theory, Δ , with the same property, as in 4.3. Now define an interpretation, ρ , thus:

$$\begin{aligned} p\rho 1 &\text{ iff } p \in \Delta \\ p\rho 0 &\text{ iff } \neg p \in \Delta \end{aligned}$$

A straightforward (joint) induction shows that this characterisation extends to all formulas. Completeness follows.

There are two natural restrictions that one may place upon Dunn evaluations:

- #1 for every p , there is at most one x such that $p\rho x$
- #2 for every p there is at least one x such that $p\rho x$

Both conditions extend from propositional parameters to all formulas, by a simple induction. Thus, the first condition ensures that the relation is *functional*; the second that it is *total*. A relation that satisfies both conditions is just a classical evaluation.

These extra conditions are sound and complete with respect to the extra rules:

$$\frac{\alpha \wedge \neg\alpha}{\beta} \quad \frac{}{\alpha \vee \neg\alpha}$$

respectively, as simple extensions of the completeness proofs demonstrate.

We can express the relational semantics in functional terms by taking an evaluation to be a function from formulas to *subsets* of $\{1, 0\}$, since there is an obvious isomorphism between relations, ρ , and functions, ν , given by the condition:

$$\alpha\rho x \text{ iff } x \in \nu(\alpha)$$

⁴⁷Published in Dunn [1976], though he discovered them somewhat earlier than this. In the present context, it might be better to call the system ‘Zero Degree Entailment’ since the language does not contain a conditional connective.

In this way, *FDE* can be seen as a many- (in fact, four-) valued logic.⁴⁸

Restriction #2, which ensures that no formula takes the value ϕ , gives a three-valued logic that is identical with *LP*. It is easy enough to check that the values $\{1\}$, $\{1, 0\}$, and $\{0\}$ work the same way as *t*, *b*, and *f*, respectively. I will make this identification in the rest of this essay. Restriction #1, which ensures that no formula takes the value $\{1, 0\}$, obviously gives an explosive logic, which is, in fact, the strong Kleene three-valued logic. This is therefore a logic dual to *LP*.⁴⁹

A feature of these semantics for *LP* and *FDE* is that they are monotonic in the following sense. Let ν_1 and ν_2 be functional evaluations. If for all propositional parameters, p , $\nu_1(p) \subseteq \nu_2(p)$ then for all α , $\nu_1(\alpha) \subseteq \nu_2(\alpha)$. The proof of this is by a simple induction. One consequence of this for *LP* is worth remarking on. *LP* is clearly a sub-logic of classical logic, since it has the classical matrices as sub-matrices. The consequence relation of *LP* is weaker than that of classical logic, since it is paraconsistent. But the set of logical truths of *LP* is identical with that of classical logic. For suppose that α is not valid in *LP*. Let ν be an evaluation such that $1 \notin \nu(\alpha)$. Let ν' be the interpretation that is the same as ν , except that for every parameter, p , if $\nu(p) = \{0, 1\}$, $\nu'(p) = \{0\}$. This is a classical evaluation; and by monotonicity, $1 \notin \nu'(\alpha)$, as required.

Another feature of these semantics is the evaluation that assigns every propositional parameter the value $\{1, 0\}$, $v_{\{1,0\}}$; and, in the four-valued case, the evaluation that gives every parameter the value ϕ , v_ϕ . A simple induction shows that these properties extend to all formulas. Thus, $v_{\{1,0\}}$ makes all formulas true—and false—and v_ϕ makes every formula neither. In particular, then, *FDE* has no logical truths.⁵⁰

4.7 Possible Worlds

Yet another, closely connected, way of invalidating explosion is to treat negation as an intensional operator. This way was proposed by the Routleys in [1972]. A *Routley interpretation* is a structure, $\langle W, *, \nu \rangle$, where W is a set (of worlds), $*$ is a map from W to W , and ν maps sets of pairs comprising a world and propositional parameter to $\{1, 0\}$. (I will write $\nu(w, \alpha)$ as $\nu_w(\alpha)$.) The truth conditions for conjunction and disjunction are the standard:

$$\nu_w(\alpha \wedge \beta) = 1 \text{ iff } \nu_w(\alpha) = 1 \text{ and } \nu_w(\beta) = 1$$

⁴⁸In fact, the straight truth tables with values 1, 2, 3 and 4 were enunciated by Smiley. See Anderson and Belnap [1975], p. 161.

⁴⁹I will usually use the functional semantic representation for *FDE* and *LP* in the rest of this essay. A word of warning, though: in the context of a dialethic metatheory, the functional approach may have consequences that the relational approach, proper, does not have. See Priest and Smiley [1993], p. 49ff.

⁵⁰Further interesting properties of *LP* and *FDE* are established in Pynko [1995a] and [1995b].

$$\nu_w(\alpha \vee \beta) = 1 \text{ iff } \nu_w(\alpha) = 1 \text{ or } \nu_w(\beta) = 1$$

The truth conditions for negation are:

$$\nu_w(\neg\alpha) = 1 \text{ iff } \nu_{w^*}(\alpha) = 0$$

Note that if $w^* = w$, these conditions just reduce to the classical ones. A natural understanding of the $*$ operator is a moot point.⁵¹ I will return to the issue in a moment. Validity is defined in terms of truth preservation at all worlds of all interpretations.

In natural deduction terms, this system can be characterised by modifying that for *FDE* by dropping the rule for double negation, and replacing it with:

$$\frac{\begin{array}{c} \bar{\alpha} \\ \vdots \\ \beta \quad \neg\beta \end{array}}{\neg\alpha}$$

where, in the subproof, there are no undischarged assumptions other than α . Soundness is easily checked. For completeness, suppose that $\Sigma \not\vdash \alpha$. Extend Σ to a prime theory, Δ , with the same property, as in 4.3. Now define an interpretation, $\langle W, *, \nu \rangle$, where W is the set of all prime theories, $*$ is defined by the condition:

$$\alpha \in \Delta^* \text{ iff } \neg\alpha \notin \Delta$$

and ν is defined by:

$$\nu_\Delta(p) = 1 \text{ iff } p \in \Delta \quad (\#)$$

It is not difficult to check that if Δ is a prime theory, so is Δ^* and hence that $*$ is well defined. First, suppose that $\alpha \notin \Delta^*$ and $\beta \notin \Delta^*$. Then $\neg\alpha$ and $\neg\beta$ are in Δ . Since Δ is a theory, $\neg\alpha \wedge \neg\beta \in \Delta$, and so $\neg(\alpha \vee \beta) \in \Delta$. Hence, $\alpha \vee \beta \notin \Delta^*$. Next, suppose that $\Delta^* \vdash \alpha$, but $\alpha \notin \Delta^*$. Then for some $\beta_1, \dots, \beta_n \in \Delta^*$, $\beta_1 \wedge \dots \wedge \beta_n \vdash \alpha$. Hence, by contraposition and De Morgan $\neg\alpha \vdash \neg\beta_1 \vee \dots \vee \neg\beta_n$. But $\neg\alpha \in \Delta$; hence $\neg\beta_1 \vee \dots \vee \neg\beta_n \in \Delta$. Since Δ is prime, for some $1 \leq i \leq n$, $\neg\beta_i \in \Delta$, i.e., $\beta_i \notin \Delta^*$. Contradiction.

An easy recursion shows that $(\#)$ extends to all formulas. The result follows.

⁵¹ For some discussion and references, see the article on Relevance Logic and Entailment in this *Handbook*.

The logic can be made stronger without (necessarily) ruining its paraconsistency by adding further conditions on $*$. The most notable is: $w^{**} = w$. This is sound and complete with respect to the additional rule:

$$\frac{\alpha}{\neg\neg\alpha}$$

as a simple extension of the completeness argument demonstrates.

These semantics are, in fact, very closely related to the those for *FDE* of the previous section. Given an *FDE* interpretation, ν , define a Routley evaluation on the worlds w and w^* , as follows:

$$\begin{aligned}\nu_w(p) &= 1 \text{ iff } 1 \in \nu(p) \\ \nu_{w^*}(p) &= 1 \text{ iff } 0 \notin \nu(p)\end{aligned}$$

A simple induction shows that these conditions follow for all formulas. Conversely, we can turn the conditions into reverse. Given any Routley evaluation on a pair of worlds, w, w^* , define a Dunn evaluation by the conditions:

$$\begin{aligned}1 \in \nu(p) &\text{ iff } \nu_w(p) = 1 \\ 0 \in \nu(p) &\text{ iff } \nu_{w^*}(p) \neq 1\end{aligned}$$

Essentially the same induction shows that these conditions hold for all formulas. Hence, the two semantics are inter-translatable, and validate the same proof theories.⁵² The translation also suggests a natural interpretation of the $*$ operator. w^* is that world characterised by the set of untruths of w . (This is, of course, in general, distinct from the set of truths in a four-valued context.)

Under the above translation, the condition: $1 \in \nu(p)$ or $0 \in \nu(p)$, which gives an *LP* interpretation, is equivalent to: $\nu_w(p) = 1$ or $\nu_{w^*}(p) \neq 1$; imposing which condition on an intensional interpretation therefore gives an intensional semantics for *LP*.

4.8 Algebraic Semantics

Let us now turn to the final approach to paraconsistent logics that we will consider, an algebraic one. In algebraic logic, an interpretation is a homomorphism, ν , from sentences into some algebraic structure, $\mathcal{A} = \langle A, \wedge, \vee, \neg \rangle$; i.e., $\nu(\neg\alpha) = \neg\nu(\alpha)$, $\nu(\alpha \wedge \beta) = \nu(\alpha) \wedge \nu(\beta)$, etc. (I will use the same signs for the connectives and the algebraic operations. Context, and the style of variable, will serve to disambiguate.) If the algebra is a lattice—as it usually

⁵²Which shows that the contraposition rule is admissible in *FDE*, something that is not at all obvious.

is, and will be in all the cases we consider—the consequence relation of the logic is represented by the lattice order relation, defined in the usual way: $a \leq b$ iff $a \wedge b = a$. Thus, a logic will be paraconsistent if it is possible in the algebra to have an a and b such that $a \wedge \neg a \not\leq b$.

Several of the logics that we have looked at can be algebraicised. Consider, for example, *FDE*. If we take the four-valued semantics for this, we can think of the values as a lattice whose Hasse diagram is as follows:

(\wedge is lattice-meet; \vee is lattice join; $\neg\{1,0\} = \{1,0\}$, and $\neg\phi = \phi$.) This generalises to a *De Morgan algebra*. A De Morgan algebra is a structure $\mathcal{A} = \langle A, \wedge, \vee \rangle$, where $\langle A, \wedge, \vee, \neg \rangle$ is a distributive lattice, and \neg is an involution of period 2, i.e.:

$$\neg\neg a = a$$

$$a \leq b \Rightarrow \neg b \leq \neg a$$

The structures take their name from the fact that in every such algebra $\neg(a \wedge b) = \neg a \vee \neg b$ holds, as do the other De Morgan laws.

Define an inference $\alpha_1, \dots, \alpha_n / \beta$ to be algebraically valid iff for every homomorphism, ν , into a De Morgan algebra, \mathcal{A} , $\nu(\alpha_1) \wedge \dots \wedge \nu(\alpha_n) \leq \nu(\beta)$. Then the algebraically valid inferences are exactly those of *FDE*. It is easy to check that the rule system for *FDE* is sound with respect to these semantics. Completeness follows from completeness in the four-valued case. Alternatively, we can give a direct argument as follows.

Consider the relation $\alpha \sim \beta$, defined by: $\alpha \vdash \beta$ and $\beta \vdash \alpha$. One can check that this is an equivalence relation, and a congruence on the logical operators (i.e., if $\alpha_1 \sim \beta_1$ and $\alpha_2 \sim \beta_2$ then $\alpha_1 \wedge \alpha_2 \sim \beta_1 \wedge \beta_2$, etc.).⁵³ If F is the set of formulas, define the quotient algebra, $\mathcal{A} = \langle F / \sim, \wedge, \vee, \neg \rangle$, where, if $[\alpha]$ is the equivalence class of α , $\neg[\alpha] = [\neg\alpha]$, $[\alpha] \wedge [\beta] = [\alpha \wedge \beta]$, etc. One can check that \mathcal{A} is a De Morgan lattice. Now, let ν be the homomorphism that maps every α to $[\alpha]$. If $\nu(\alpha_1) \wedge \dots \wedge \nu(\alpha_n) \leq \nu(\beta)$. Then $[\alpha_1 \wedge \dots \wedge \alpha_n] \leq [\beta]$, i.e., $[\alpha_1 \wedge \dots \wedge \alpha_n \wedge \beta] = [\alpha_1 \wedge \dots \wedge \alpha_n]$. Hence, $\alpha_1 \wedge \dots \wedge \alpha_n \vdash \alpha_1 \wedge \dots \wedge \alpha_n \wedge \beta$ and so $\alpha_1 \wedge \dots \wedge \alpha_n \vdash \beta$. Conversely, then, if $\alpha_1 \wedge \dots \wedge \alpha_n \not\vdash \beta$ then $\nu(\alpha_1) \wedge \dots \wedge \nu(\alpha_n) \not\leq \nu(\beta)$, as required.

⁵³The only tricky point concerns negation. For this, we need to appeal to the fact, which we have already noted, that if $\alpha \vdash \beta$ then $\neg\beta \vdash \neg\alpha$. This can be established directly, by an induction on proofs.

It should be noted that not all the logics we have considered in previous sections algebraicise. In particular, the non-truth-functional logics resist this treatment in general. This is for the same reason that the substitutivity of provable equivalents breaks down: the semantic value of $\neg\alpha$ is *entirely independent* of that of α . It cannot, therefore, correspond to any well-defined algebraic operation.

The point can be made more precise in many cases. Suppose that \mathcal{A} is some algebraic structure for a logic, and consider any interpretation, ν , with values in the algebra, such that for some p, q and r , $\nu(p) = \nu(q) \neq \nu(r)$. Then the condition $\nu(\alpha) = \nu(\beta)$ is a congruence relation on the set of formulas, and collapse by it gives a non-degenerate quotient algebra (i.e., an algebra that is neither a single-element algebra, nor the algebra of formulas). But many non-truth-functional logics can be shown to have no such thing. (See, e.g., Mortensen [1980].)

One final algebraic paraconsistent logic is worth noting. This is that of Goodman [1981]. A Heyting algebra can be thought of as a distributive lattice, with a bottom element, \perp , and an operator, \rightarrow , satisfying the condition:

$$a \wedge b \leq c \text{ iff } a \leq b \rightarrow c$$

(which makes $\perp \rightarrow \perp$ the top element). We may define $\neg a$ as $a \rightarrow \perp$.

Let \mathcal{T} be a topological space. Then a standard example of a Heyting algebra is the topological Heyting algebra $\langle X, \wedge, \vee, \rightarrow, \perp \rangle$, where X is the set of open sets in \mathcal{T} , \wedge and \vee are intersection and union, respectively, \perp is ϕ , and $a \rightarrow b$ is $(\overline{a} \vee b)^{\circ}$ —overlining denotes complementation and $^{\circ}$ is the interior operator of the topology. $\neg a$ is clearly \overline{a}° .

It is well known that for finite sets of premises, Intuitionistic logic is sound and complete with respect to the class of Heyting algebras, in fact, with respect to the topological Heyting algebras. That is, $\alpha_1, \dots, \alpha_n \models_I \beta$ iff for every homomorphism, ν , into such an algebra, $\nu(\alpha_1 \wedge \dots \wedge \alpha_n) \leq \nu(\beta)$.⁵⁴

The whole construction can be dualised in a natural way to give a paraconsistent logic. A dual Heyting algebra is a distributive lattice, with a top element, \top , and an operator, \leftarrow , satisfying the condition:

$$a \leq b \vee c \text{ iff } a \leftarrow b \leq c$$

(which makes $\top \leftarrow \top$ the bottom element). We may define $\neg a$ as $\top \leftarrow a$. As may be checked, if \mathcal{T} is a topological space, then the structure $\langle X, \wedge, \vee, \leftarrow, \top \rangle$ is a dual Heyting algebra, where X is the set of *closed* sets of \mathcal{T} , \wedge and \vee are intersection and union, respectively, \top is the whole space,

⁵⁴See, e.g., Dummett [1977], 5.3.

and $a \leftarrow b$ is $(a \wedge \bar{b})^c$ —where c is the closure operator of the topology. $\neg b$ is clearly \bar{b}^c .

The logic generated by dual Heyting algebras is dual to Intuitionistic logic. In particular, in Intuitionistic logic we have $\alpha \wedge \neg\alpha \models \beta$, but not $\alpha \models \beta \vee \neg\beta$; and $\alpha \models \neg\neg\alpha$, but not $\neg\neg\alpha \models \alpha$. Thus in dual Intuitionist logic, we have $\alpha \models \beta \vee \neg\beta$ but not $\alpha \wedge \neg\alpha \models \beta$; and $\neg\neg\alpha \models \alpha$ but not $\alpha \models \neg\neg\alpha$. For a topological counter-model to the first, consider the real line with its usual topology, and an interpretation, ν , that maps p to $[-1, +1]$, and q to ϕ . Then $\nu(p \wedge \neg p) = \{-1, +1\} \not\subseteq \phi = \nu(q)$. (This illustrates how the points in the set represented by $p \wedge \neg p$ may be thought of as the points on the topological boundary between the set of points represented by p and the set of points represented by $\neg p$.) For a counter-model to the second, let $\nu(p) = \{0\}$. Then $\nu(\neg\neg p) = \phi \not\subseteq \nu(p)$.

If $\models \alpha$ in dual Intuitionist logic, then $\models_C \alpha$, since the two-element Boolean algebra is a dual Heyting algebra. Conversely, if α is any classical tautology, its dual, α' , is a contradiction. Hence, $\models_C \neg\alpha'$. But then by a result of Glivenko, $\models_I \neg\alpha'$, and so $\alpha' \models_I$. Thus by duality, in dual Intuitionist logic $\models \alpha$. The logical truths of dual Intuitionist logic are therefore the same as those of classical logic.

It is worth noting that just as Intuitionist logic can be given an intensional semantics, namely Kripke semantics, so can dual Intuitionist logic; we simply dualise the Kripke construction. For further details of all the above, see Goodman [1981].⁵⁵

5 CONDITIONAL CONNECTIVES

We have now looked at most of the basic techniques of paraconsistent logic, applied to languages containing only negation, conjunction and disjunction.⁵⁶ I will call this language the *basic* language. Next, we will look at some important extensions of these techniques (which do not ruin paraconsistency). In this part, we will start with the conditional, by which I mean some con-

⁵⁵It is well known that in a certain well defined sense, Intuitionist logic can be seen as the “internal logic” of the category-theoretic structures called topoi. It is possible to dualise the construction involved there to show that dual Intuitionist logic has an equally good claim to that title. For details, see Mortensen [1995], who calls the \wedge, \vee, \neg -fragment of a dual Heyting algebra a ‘paraconsistent algebra’.

⁵⁶There are others, such as the use of the techniques of combinatorial logic, but I will not go into these here. For details, one can consult, e.g., Bunder [1984]. There *ought* to be yet more. The discussion of connexivism in 3.2 suggests that there ought to be a distinctive connexivist approach to paraconsistency. To date, this has not emerged. The most articulated modern connexivist logic is due to McCall (see sect. 29.8 of Anderson and Belnap [1975], which can also be consulted for references to other discussions). Although this provides a connexivist treatment of the connective \rightarrow , the logic of the basic language is classical, and so explosive. Alternatively, one can formulate versions of relevant logic that contain connexivist principles. See Routley [1978] and Mortensen [1984].

nective, \rightarrow (if necessary, added to the basic language), satisfying, at least, *modus ponens*: $\alpha, \alpha \rightarrow \beta \models \beta$.

Although paraconsistency does not concern the conditional as such, many of the paraconsistent logics that we have looked at have distinctive approaches to the conditional. And this is no accident. If one identifies $\alpha \rightarrow \beta$ with the material conditional, $\alpha \supset \beta$, defined in the usual way as $\neg\alpha \vee \beta$, then *modus ponens* reduces to the disjunctive syllogism. But in any logic where disjunction behaves normally and deducibility is transitive, the disjunctive syllogism must fail, or explosion would arise, due to the ‘‘Lewis independent argument’’. Specifically, in all the logics we have looked at except filter logics and some of the non-adjunctive logics, the syllogism fails. In such logics, therefore, a distinct account of the conditional is required. For completeness’ sake, we will start by considering the others.

5.1 \rightarrow as \supset

In filter logics, we may simply identify \rightarrow with \supset . Things then proceed as before. A one-premise inference in this language, α/β , is prevalid iff it is classically valid and $F(\alpha, \beta)$. It is valid iff it is a substitution instance of a prevalid inference.⁵⁷

In the natural extension of Tennant’s semantic approach, an inference from Π to Σ is prevalid iff $\Pi \models_C \Sigma$ and for no proper subsets of Π and Σ , Π' and Σ' , respectively, $\Pi' \models_C \Sigma'$. The natural extension of the proof theory is to add the conditional rules:

$$\frac{\Pi, \alpha : \beta, \Delta}{\Pi : \alpha \rightarrow \beta, \Delta} \quad \frac{\Pi_1, \alpha : \Delta_1 \quad \beta, \Pi_2 : \Delta_2}{\Pi_1, \Pi_2, \alpha \rightarrow \beta : \Delta_1, \Delta_2}$$

Unfortunately, the equivalence between these two approaches now fails. For, semantically, $p \models \neg p \rightarrow q$ (though the system is still paraconsistent); but without dilution there is no proof of the sequent $p : \neg p \rightarrow q$. At this point, Tennant prefers to go with the proof theory rather than the semantics. He also prefers the intuitionist version, which allows at most one formula on the right-hand side of a sequent. For further details, including natural deduction versions of the proof theory, see Tennant [1987], ch. 23.

In [1992] Tennant suggests modifying the rule for the introduction of \rightarrow on the right.⁵⁸ The α in the premise sequent is made optional, and the following rule is added.

⁵⁷One can modify this approach, invoking the filter in the truth conditions of the conditional itself, to give logics of a more relevant variety. This is pursued in a number of the essays in *Philosophical Studies* 26 (1979), no. 2, a special issue on relatedness logics.

⁵⁸In fact, he gives the natural deduction rules. The sequent rules described are the obvious equivalents.

$$\frac{\Pi, \alpha : \Delta}{\Pi : \alpha \rightarrow \beta, \Delta}$$

The exact relationship between these rules and the above semantics is as yet unresolved.

In the non-adjunctive logics of Rescher and Manor, and Schotch and Jennings: \rightarrow may again be identified with \supset , producing no novelties. The machinery of maximally consistent subsets and partitions carries straight over.

5.2 Discursive Implication

The situation is otherwise with discursive logic. Here a distinct approach is required, since, as we have already seen, the disjunctive syllogism fails discursively.

Given an $S5$ interpretation, Jaśkowski adds a conditional, \rightarrow (often written as \supset_d , and called discursive implication), and defines $\alpha \rightarrow \beta$ as $\diamond\alpha \supset \beta$.⁵⁹ It is easy to check that in discursive logic $\alpha, \alpha \rightarrow \beta \models \beta$, since $\diamond\alpha, \diamond(\diamond\alpha \supset \beta) \models_{S5} \diamond\beta$ (and so there are essentially multi-premise inferences).

In fact, the logical truths of the pure \rightarrow fragment of discursive logic are the same as those of the pure \supset fragment of classical logic. For let α_{\supset} be any sentence containing only \supset s, and let α_{\rightarrow} be the corresponding sentence containing only \rightarrow s. In an $S5$ interpretation with only one world, α_{\supset} and $\diamond\alpha_{\rightarrow}$ are equivalent. So if α_{\supset} is not a classical logical truth, $\diamond\alpha_{\rightarrow}$ is not a discursive one. Conversely, suppose that α_{\supset} is a classical logical truth. We need to show that $\diamond\alpha_{\rightarrow}$ is valid in every $S5$ model. As may easily be checked, in $S5$, $\diamond(\diamond\alpha \supset \beta)$ is logically equivalent to $\diamond\alpha \supset \diamond\beta$. Hence, given $\diamond\alpha_{\rightarrow}$, we may “drive the \diamond s inwards” to obtain a logically equivalent sentence where the modal operator applies only to propositional parameters. But this is a substitution instance of α_{\supset} , and hence valid in $S5$. This result does not carry over to the full language. For example, $\not\models \alpha \rightarrow (\neg\alpha \rightarrow \beta)$, since, as may be checked, $\not\models_{S5} \diamond(\diamond\alpha \supset (\diamond\neg\alpha \supset \beta))$.⁶⁰

Full discursive logic can naturally be generalised in two obvious ways. The first is by using some modal logic other than $S5$. The second is by changing the definition of what it is for a sentence, α , to hold discursively in an interpretation. We change this from $\diamond\alpha$ holding to $M\alpha$ holding, where M is some other modality (i.e., string of \diamond s and \Box s). For references and discussion, see Błaszczuk [1984] and Kotas and da Costa [1989].

⁵⁹ Given what amounts to Jaśkowski’s identification of truth with truth in some possible world, it might be more natural to define $\alpha \rightarrow \beta$ as $\diamond\alpha \rightarrow \diamond\beta$. This would have just the same consequences.

⁶⁰ The natural definition of the biconditional, $\alpha \leftrightarrow \beta$, is $(\alpha \rightarrow \beta) \wedge (\beta \rightarrow \alpha)$. For reasons not explained, Jaśkowski defines it as $(\alpha \rightarrow \beta) \wedge (\beta \rightarrow \diamond\alpha)$. This asymmetric and counter-intuitive definition would seem to have no significant advantages.

5.3 Da Costa's C -systems

The natural way of extending the non-truth functional semantics of 4.4 to include a conditional connective, in keeping with the idea that such logics are just the addition of a non-truth-functional negation to a standard positive logic, is to give \rightarrow the classical truth conditions:

$$\nu(\alpha \rightarrow \beta) = 1 \text{ iff } \nu(\alpha) = 0 \text{ or } \nu(\beta) = 1$$

(Note that \rightarrow , so defined, is distinct from \supset .) Adding this condition to the logics of 4.4 (except, C_ω , which we will come to in a moment) gives the full (propositional) versions of the logics mentioned there; in particular it gives the da Costa logic C_1 (and the other C_i for finite non-zero i). In each case, a natural deduction system can be obtained by adding the rules:

$$\rightarrow E \quad \frac{\alpha \quad \alpha \rightarrow \beta}{\beta}$$

$$(a) \quad \frac{\beta}{\alpha \rightarrow \beta}$$

$$(b) \quad \frac{}{\alpha \vee (\alpha \rightarrow \beta)}$$

Soundness is proved as usual. The extension to the completeness proof amounts to checking that for a prime theory, Σ , $\alpha \rightarrow \beta \in \Sigma$ iff $\alpha \notin \Sigma$ or $\beta \in \Sigma$. From left to right, the result follows by $(\rightarrow E)$. From right to left: if $\beta \in \Sigma$ then the result follows from (a); if $\alpha \notin \Sigma$ then $(\alpha \rightarrow \beta) \in \Sigma$ by (b) and primeness.

If instead of (a) and (b), we add to any of these systems—except the ones with a consistency operator; I will come to these in a second—the rule:

$$\rightarrow I \quad \frac{\begin{array}{c} \bar{\alpha} \\ \vdots \\ \beta \end{array}}{\alpha \rightarrow \beta}$$

we obtain, not classical positive logic, but intuitionist positive logic. (These rules are well known to be complete with respect to this logic.) In particular, if we add $\rightarrow I$ and $\rightarrow E$ to the rule system for the basic language fragment of C_ω we obtain da Costa's C_ω .

The intuitionist conditional is not, of course, truth functional, but a valuational semantics for C_ω can be obtained as follows. A *semi-valuation* is any function that satisfies the conditions for conjunction, disjunction and negation, plus:

if $\nu(\alpha \rightarrow \beta) = 1$ then $\nu(\alpha) = 0$ or $\nu(\beta) = 1$
 if $\nu(\alpha \rightarrow \beta) = 0$ then $\nu(\beta) = 0$

A valuation is any semi-valuation, ν , satisfying the following condition. Let α be of the form $\alpha_1 \rightarrow (\alpha_2 \rightarrow (\alpha_3 \dots \rightarrow \alpha_n) \dots)$, where α_n is not itself of the form $\beta \rightarrow \gamma$. Then if $\nu(\alpha) = 0$ there is a semi-valuation, ν' , such that for all $1 \leq i < n$, $\nu'(\alpha_i) = 1$, and $\nu'(\alpha_n) = 0$. C_ω is sound and complete with respect to this notion of valuation. For details, see Loparić [1986].⁶¹

Changing the deduction rules for \rightarrow to the intuitionist ones, makes no difference for those logics that contain a consistency operator, and in particular, the da Costa logics C_i for finite i .⁶² The reason, *in nuce*, is that the consistency operator allows us to define a negation with the properties of classical negation. As is well known, the addition of such a negation to positive intuitionist logic is not conservative, but produces classical logic. In more detail, the argument for C_1 is as follows.⁶³

Define $\neg^* \alpha$ as $\neg \alpha \wedge \alpha^\circ$. Then it is easy to check that:

$$\nu(\neg^* \alpha) = 1 \text{ iff } \nu(\alpha) = 0$$

In particular, then, $\neg^* \alpha$ satisfies the rules for classical negation:

$$\frac{}{\alpha \vee \neg^* \alpha} \qquad \frac{\alpha \wedge \neg^* \alpha}{\beta}$$

Given these, it is easy to show that $\alpha \rightarrow \beta \dashv\vdash \neg^* \alpha \vee \beta$. (Hint: from left to right, assume $\alpha \vee \neg^* \alpha$ and argue by cases. From right to left, assume α and $\neg^* \alpha \vee \beta$, and argue to β by cases.) Hence, \rightarrow has the classical truth conditions.

5.4 Many-valued Conditionals

There are numerous ways to define a many-valued conditional operator. We will just look at two of the more systematic.⁶⁴

Given a Sugihara generalisation of LP , one can define a conditional with the following truth conditions:

⁶¹ A Kripke-style semantics for C_ω can be found in Baaz [1986].

⁶² This was first observed, in effect, by da Costa and Guillaume [1965].

⁶³ The argument for the other C_i s is similar.

⁶⁴ In the three-valued case, other definitions give the system of Asenjo and Tamburino [1975], and the J systems of D'Ottaviano and da Costa [1970]. A natural many-valued conditional, given the four-valued semantics of FDE , produces the system $BN4$ of Brady [1982].

$$\begin{aligned} \nu(\alpha \rightarrow \beta) &= \nu(\neg\alpha \vee \beta) && \text{if } \nu(\alpha) \leq \nu(\beta) \\ &= \nu(\neg\alpha \wedge \beta) && \text{if } \nu(\alpha) > \nu(\beta) \end{aligned}$$

This definition gives rise to “semi-relevant” logics, i.e., logics that avoid the standard paradoxes of relevance, but are still not relevant.

In the case where the set of truth values is the set of all integers, this gives the Anderson/Belnap logic *RM*. Proof-theoretically, *RM* is obtained from the relevant logic *R*, which we will come to in the next section, by adding the “mingle” axiom:

$$\vdash \alpha \rightarrow (\alpha \rightarrow \alpha)$$

For details of proofs, see Anderson and Belnap [1975], sect. 29.3.

In the 3-valued case, where the set of truth values is $\{-1, 0, +1\}$, the conditions for \rightarrow give the matrix:

\rightarrow	+1	0	-1
+1	+1	-1	-1
0	+1	0	-1
-1	+1	+1	+1

and the stronger logic called *RM3*. This is sound and complete with respect to the axiomatic system obtained by augmenting the system *R* with the axioms:

$$\begin{aligned} &\vdash (\neg\alpha \wedge \beta) \rightarrow (\alpha \rightarrow \beta) \\ &\vdash \alpha \vee (\alpha \rightarrow \beta) \end{aligned}$$

For the proof, see Brady [1982].

Turning to the second systematic approach, consider any Łukasiewicz generalisation of *LP*. Łukasiewicz’ truth conditions for his conditional, \mapsto , are as follows:

$$\begin{aligned} \nu(\alpha \mapsto \beta) &= 1 && \text{if } \nu(\alpha) \leq \nu(\beta) \\ &= 1 - (\nu(\alpha) - \nu(\beta)) && \text{if } \nu(\alpha) > \nu(\beta) \end{aligned}$$

In the three-valued case, this gives the well known matrix:

\mapsto	1	0.5	0
1	1	0.5	0
0.5	1	1	0.5
0	1	1	1

Now the most notable feature of the Łukasiewicz definition, given that 0.5 is designated, is that *modus ponens* fails. For example, consider a valuation, ν , where $\nu(p) = 0.5$ and $\nu(q) = 0$. Then $\nu(p \mapsto q) = 0.5$. Hence $p, p \mapsto q \not\models q$. (*Modus ponens* is valid provided that the only designated value is 1, but then the logic is not paraconsistent.)

Kotas and da Costa [1978] get around this problem by adding to the language a new operator, Δ , with the truth conditions:

$$\begin{aligned} \nu(\Delta\alpha) &= 1 && \text{if } \nu(\alpha) \text{ is designated} \\ &= 0 && \text{otherwise} \end{aligned}$$

and then define a conditional, $\alpha \rightarrow \beta$, as $\Delta\alpha \mapsto \beta$.⁶⁵ They point out the similarity of this definition to Jaśkowski's definition of discursive implication. (In fact, they use the symbol \diamond instead of Δ because of this.)⁶⁶

It is not difficult to check that *modus ponens* for \rightarrow holds. In fact, as Kotas and da Costa point out, the $\wedge, \vee, \rightarrow$ -fragment of the logic is exactly positive classical logic. The easiest way to see this is just to collapse the designated values to 1, and the others to 0, to obtain classical truth tables.

5.5 Relevant \rightarrow s

Given a Routley interpretation (say one for *FDE*, though the other cases will be similar), it is natural to treat \rightarrow intensionally. The simplest way is to give it the *S5* truth conditions:

$$\nu_w(\alpha \rightarrow \beta) = 1 \text{ iff for all } w' \in W (\nu_{w'}(\alpha) = 1 \Rightarrow \nu_{w'}(\beta) = 1)$$

Clearly, given an interpretation either $\alpha \rightarrow \beta$ is true at all worlds, or at none. With the Routley $*$ giving the semantics for negation, it follows that the same is true of negated conditionals. It also follows that $\nu_w(\alpha \rightarrow \beta) = 1$ iff $\nu_{w*}(\alpha \rightarrow \beta) = 1$ iff $\nu_w\neg(\alpha \rightarrow \beta) \neq 1$. Thus, the semantics validate the rules:

$$\text{LEM}_{\rightarrow} \quad \overline{(\alpha \rightarrow \beta) \vee \neg(\alpha \rightarrow \beta)}$$

$$\text{EFQ}_{\rightarrow} \quad \frac{\alpha \rightarrow \beta \quad \neg(\alpha \rightarrow \beta)}{\gamma}$$

and so are unsuitable for serious paraconsistent purposes. Moreover, even though there may be worlds where $\alpha \wedge \neg\alpha$ is true, or where $\alpha \vee \neg\alpha$ is false,

⁶⁵In fact, their treatment is more general, since they consider the case in which the extension of Δ may be other than the set of designated values.

⁶⁶Peña [1984] defines an operator, F , on real numbers such that the value $F\alpha$ is 0 if that of α is greater than 0, and 1 otherwise; and then defines a conditional operator, $\alpha C\beta$, as $F\alpha \vee \beta$. The result is similar.

and so neither $(\alpha \wedge \neg\alpha) \rightarrow \beta$ nor $\alpha \rightarrow (\alpha \vee \neg\alpha)$ is valid, the system is not a relevant one since, e.g., $\models p \rightarrow (q \rightarrow q)$.

These facts may both be changed by modifying the semantics, by adding a class of non-normal worlds. Thus, an interpretation is a structure $\langle W, N, *, \nu \rangle$. The worlds in N are called *normal*; the worlds in $W - N$ (NN) are called *non-normal*. Truth conditions are the same as before, except that at non-normal worlds, the truth value of a conditional is arbitrary. Technically, ν assigns to every pair of world and propositional parameter a truth value, as before, but for every $w \in NN$ and every conditional $\alpha \rightarrow \beta$, it now also assigns $\alpha \rightarrow \beta$ a value at w . This provides the value of $\alpha \rightarrow \beta$ at non-normal worlds (non-recursively). Validity is defined as truth preservation at all *normal* worlds of all interpretations.

If one thinks of the conditionals as entailments, then the non-normal worlds are those where the facts of logic may be different. Thus, one may think of non-normal worlds as logically impossible situations.⁶⁷

The system described is called *H* in Routley and Loparić [1978].⁶⁸ It is sound and weakly complete (i.e., theorem-complete) with respect to the following axiom system.

$$\begin{aligned} &\vdash \alpha \rightarrow \alpha \\ &\vdash (\alpha \wedge \beta) \rightarrow \alpha \quad \vdash (\alpha \wedge \beta) \rightarrow \beta \\ &\vdash \beta \rightarrow (\alpha \vee \beta) \quad \vdash \beta \rightarrow (\alpha \vee \beta) \\ &\vdash \alpha \leftrightarrow \neg\neg\alpha \\ &\vdash (\neg\alpha \vee \neg\beta) \leftrightarrow \neg(\alpha \wedge \beta) \\ &\vdash (\neg\alpha \wedge \neg\beta) \leftrightarrow \neg(\alpha \vee \beta) \\ &\vdash (\alpha \wedge (\beta \vee \gamma)) \rightarrow ((\alpha \wedge \beta) \vee (\alpha \wedge \gamma)) \end{aligned}$$

$$\begin{aligned} &\text{If } \vdash \alpha \text{ and } \vdash \alpha \rightarrow \beta \text{ then } \vdash \beta \\ &\text{If } \vdash \alpha \text{ and } \vdash \beta \text{ then } \vdash \alpha \wedge \beta \\ &\text{If } \vdash \alpha \rightarrow \beta \text{ and } \vdash \beta \rightarrow \gamma \text{ then } \vdash \alpha \rightarrow \gamma \\ &\text{If } \vdash \alpha \rightarrow \beta \text{ then } \vdash \neg\beta \rightarrow \neg\alpha \\ &\text{If } \vdash \alpha \rightarrow \beta \text{ and } \vdash \alpha \rightarrow \gamma \text{ then } \vdash \alpha \rightarrow (\beta \wedge \gamma) \\ &\text{If } \vdash \alpha \rightarrow \gamma \text{ and } \vdash \beta \rightarrow \gamma \text{ then } \vdash (\alpha \vee \beta) \rightarrow \gamma \end{aligned}$$

Strong (i.e., deducibility-) completeness requires also the rules in disjunctive form.⁶⁹ The disjunctive form of the first is: $\vdash \alpha \vee \gamma$ and $\vdash (\alpha \rightarrow \beta) \vee \gamma$ then $\vdash \beta \vee \gamma$. The others are similar.⁷⁰

⁶⁷For a further discussion of non-normality, see Priest [1992].

⁶⁸There are several other systems in the vicinity here. Some are obtained by varying the conditions on $*$. Others, sometimes called the Arruda - da Costa *P* systems, are obtained by retaining the positive logic and adding a non-truth-functional negation. For details, see Routley and Loparić [1978].

⁶⁹Which are known to be admissible anyway.

⁷⁰A sound and complete natural deduction system is an open question.

Soundness is proved as usual. The (strong) completeness proof is as follows. We first show by induction on proofs that if $\alpha \vdash \beta$ then $\alpha \vee \gamma \vdash \beta \vee \gamma$. It quickly follows that if $\alpha \vdash \gamma$ and $\beta \vdash \gamma$ then $\alpha \vee \beta \vdash \gamma$. Now suppose that $\Gamma \not\vdash \alpha$. Extend Γ to a prime theory, Θ , with the same property, as in 4.3. Call a set Δ a Θ -theory if it is prime, closed under adjunction, and $\beta \rightarrow \gamma \in \Theta \Rightarrow (\beta \in \Delta \Rightarrow \gamma \in \Delta)$. Note that Θ is a Θ -theory. Define the interpretation $\langle W, N, *, \nu \rangle$, where W is the set of Θ -theories; $N = \{\Theta\}$, $\beta \in \Delta^*$ iff $\neg\beta \notin \Delta$ (which is well-defined). If $\Delta \in NN$ then $\nu_\Delta(\beta \rightarrow \gamma) = 1$ iff $\beta \rightarrow \gamma \in \Delta$; and for all Δ :

$$\nu_\Delta(p) = 1 \text{ iff } p \in \Delta$$

Once it can be shown that this condition carries over to all formulas, the result follows as usual. This is proved by induction. The only difficult case concerns \rightarrow when $\Delta = \Theta$. From right to left, the result follows from the definition of W . From left to right, the result follows from the following lemma. If $\beta \rightarrow \gamma \notin \Theta$ then there is a Θ -theory, Δ , such that $\beta \in \Delta$ and $\gamma \notin \Delta$. To prove this, we proceed essentially as in 4.3, except that $\Sigma \vdash \Pi$ is redefined. Let Θ_\rightarrow be the set of conditionals in Θ ; then $\Sigma \vdash \Pi$ is now taken to mean that there are $\sigma_1, \dots, \sigma_n \in \Sigma$ and $\pi_1, \dots, \pi_m \in \Pi$ such that $\Theta_\rightarrow \vdash (\sigma_1 \wedge \dots \wedge \sigma_n) \rightarrow (\pi_1 \vee \dots \vee \pi_m)$. Now set $\Sigma = \{\beta\}$, and $\Pi = \{\gamma\}$, and proceed as in 4.3. The rest of the details are left as a (lengthy) exercise.⁷¹

If we add the Law of Excluded Middle to the axiom system:

$$\vdash \alpha \vee \neg\alpha$$

we obtain a logic that we will call HX . In virtue of the discussion in 4.7, one might suppose that this would be sound and complete if we add the condition: for all w , and parameters, p , $1 = \nu_w(p)$ or $0 = \nu_w^*(p)$. This condition indeed makes $\alpha \vee \neg\alpha$ true in all worlds; but for just that reason, it also verifies the irrelevant $\beta \rightarrow (\alpha \vee \neg\alpha)$. To obtain HX , we place this constraint on just normal worlds. The semantics are then just right, as may be checked. For further details, see Routley and Loparić [1978]. Since normal worlds are now, in effect, LP interpretations, HX verifies all the logical truths of LP and so of classical logic.

A feature of this system is that substitutivity of equivalents breaks down. For example, as is easy to check, $p \leftrightarrow q \not\vdash (r \rightarrow p) \leftrightarrow (r \rightarrow q)$. This can be changed by taking the valuation function to work on propositions (i.e., set of worlds), rather than formulas.⁷² The most significant feature of semantics of this kind is that there are no principles of inference that employ nested

⁷¹Details can be found in Priest and Sylvan [1992].

⁷²For details see Priest [1992].

conditionals in an essential way. This is due entirely to the anarchic nature of non-normal worlds. In effect, *any* breakdown of logic is countenanced.

One way of putting a little order into the anarchy without destroying relevance, proposed by Routley and Meyer,⁷³ is by employing a ternary relation, R , to give the truth conditions of conditionals at non-normal worlds. An interpretation is now of the form $\langle W, N, R, *, \nu \rangle$. All is as before, except that ν no longer gives the truth values of conditionals at non-normal worlds. Rather, for any $w \in NN$, the truth conditions are:

$$\nu_w(\alpha \rightarrow \beta) = 1 \text{ iff for all } x, y \in W, Rwx y \Rightarrow (\nu_x(\alpha) = 1 \Rightarrow \nu_y(\beta) = 1)$$

Note that this is just the standard condition for strict implication, except that the worlds of the antecedent (x) and the consequent (y) have become distinguished. What, exactly, the ternary relation, R , means, is still a matter for philosophical deliberation. Validity is again defined as truth preservation at all normal worlds.

These semantics give the basic system of affixing relevant logic, B . An axiom system therefor can be obtained by replacing the last two rules for H by the corresponding axioms:

$$\begin{aligned} &\vdash ((\alpha \rightarrow \beta) \wedge (\alpha \rightarrow \gamma)) \rightarrow (\alpha \rightarrow (\beta \wedge \gamma)) \\ &\vdash ((\alpha \rightarrow \gamma) \wedge (\beta \rightarrow \gamma)) \rightarrow ((\alpha \vee \beta) \rightarrow \gamma) \end{aligned}$$

and adding a rule that ensures replacement of equivalents:

$$\text{If } \vdash \alpha \rightarrow \beta \text{ and } \vdash \gamma \rightarrow \delta \text{ then } \vdash (\beta \rightarrow \gamma) \rightarrow (\alpha \rightarrow \delta)$$

The soundness and completeness proofs generalise those for H . Details can be found in Priest and Sylvan [1992].

We may form the system BX proof theoretically by adding the Law of Excluded Middle. Semantically, we proceed as with H , placing the appropriate condition on normal worlds.

As with modal logics, stronger logics can be obtained by placing conditions on the accessibility relation, R . In this way, most of the logics in the Anderson/Belnap family can be generated. Details can be found in Restall [1993]. The strongest of these is the logic R , an axiom system for which is as follows:

$$\begin{aligned} &\vdash \alpha \rightarrow \alpha \\ &\vdash (\alpha \rightarrow \beta) \rightarrow ((\beta \rightarrow \gamma) \rightarrow (\alpha \rightarrow \gamma)) \\ &\vdash \alpha \rightarrow ((\alpha \rightarrow \beta) \rightarrow \beta) \end{aligned}$$

⁷³Initially, this was in Routley and Meyer [1973]. For further discussion of all the following, see the article on Relevant Logic in this volume of the *Handbook*.

$$\begin{aligned}
&\vdash (\alpha \rightarrow (\alpha \rightarrow \beta)) \rightarrow (\alpha \rightarrow \beta) \\
&\vdash (\alpha \wedge \beta) \rightarrow \beta, \quad \vdash (\alpha \wedge \beta) \rightarrow \alpha \\
&\vdash ((\alpha \rightarrow \beta) \wedge (\alpha \rightarrow \gamma)) \rightarrow (\alpha \rightarrow (\beta \wedge \gamma)) \\
&\vdash \beta \rightarrow (\alpha \vee \beta), \quad \vdash \alpha \rightarrow (\alpha \vee \beta) \\
&\vdash ((\alpha \rightarrow \gamma) \wedge (\beta \rightarrow \gamma)) \rightarrow ((\alpha \vee \beta) \rightarrow \gamma) \\
&\vdash (\alpha \wedge (\beta \vee \gamma)) \rightarrow ((\alpha \wedge \beta) \vee \gamma) \\
&\vdash (\alpha \rightarrow \neg\beta) \rightarrow (\beta \rightarrow \neg\alpha) \\
&\vdash \neg\neg\alpha \rightarrow \alpha
\end{aligned}$$

with the rules of adjunction and *modus ponens*.

The equivalence between the Dunn 4-valued semantics and the Routley * operation that we noted in 4.7 suggests another way of obtaining an intensional conditional connective. In the simplest case, an interpretation is a structure $\langle W, \nu \rangle$ where W is a set of worlds and ν is an evaluation of the parameters at worlds, but this time it is a Dunn 4-valued interpretation. The truth conditions for the basic language are as in 4.6, except that they are relativised to worlds. Thus, using the functional notation:

$$\begin{aligned}
1 \in \nu_w(\neg\alpha) &\text{ iff } 0 \in \nu_w(\alpha) \\
0 \in \nu_w(\neg\alpha) &\text{ iff } 1 \in \nu_w(\alpha)
\end{aligned}$$

$$\begin{aligned}
1 \in \nu_w(\alpha \wedge \beta) &\text{ iff } 1 \in \nu_w(\alpha) \text{ and } 1 \in \nu_w(\beta) \\
0 \in \nu_w(\alpha \wedge \beta) &\text{ iff } 0 \in \nu_w(\alpha) \text{ or } 0 \in \nu_w(\beta)
\end{aligned}$$

$$\begin{aligned}
1 \in \nu_w(\alpha \vee \beta) &\text{ iff } 1 \in \nu_w(\alpha) \text{ or } 1 \in \nu_w(\beta) \\
0 \in \nu_w(\alpha \vee \beta) &\text{ iff } 0 \in \nu_w(\alpha) \text{ and } 0 \in \nu_w(\beta)
\end{aligned}$$

The natural truth and falsity conditions for \rightarrow are:

$$\begin{aligned}
1 \in \nu_w(\alpha \rightarrow \beta) &\text{ iff for all } w' \in W, (1 \in \nu_{w'}(\alpha) \Rightarrow 1 \in \nu_{w'}(\beta)) \\
0 \in \nu_w(\alpha \rightarrow \beta) &\text{ iff for some } w' \in W, 1 \in \nu_{w'}(\alpha) \text{ and } 0 \in \nu_{w'}(\beta)
\end{aligned}$$

These semantics do not validate the undesirable:

$$\frac{\alpha \rightarrow \beta \quad \neg(\alpha \rightarrow \beta)}{\gamma}$$

as their * counterparts do. But they are still not relevant. Relevant logics can be obtained by adding a class of non-normal worlds. The semantic values of conditionals at these may either be arbitrary, as with H , or, as with B , we may employ a ternary relation and give the conditions as follows:

$$\begin{aligned}
1 \in \nu_w(\alpha \rightarrow \beta) & \text{ iff for all } x, y \in W, Rwx y \Rightarrow (1 \in \nu_x(\alpha) \Rightarrow 1 \in \nu_y(\beta)) \\
0 \in \nu_w(\alpha \rightarrow \beta) & \text{ iff for some } x, y \in W, Rwx y, 1 \in \nu_x(\alpha) \text{ and } 0 \in \nu_y(\beta)
\end{aligned}$$

As usual, extra conditions may be imposed on R . This construction produces a family of relevant logics distinct from the usual ones, and one that has not been studied in great detail. One way in which it differs from the more usual ones is that contraposition of the conditional fails, though this can be rectified by modifying the truth conditions for \rightarrow by adding the clause: ‘and $0 \in \nu_{w'}(\beta) \Rightarrow 0 \in \nu_{w'}(\alpha)$ ’ (or in the case of non-normal worlds employing a ternary relation: ‘and $0 \in \nu_x(\beta) \Rightarrow 0 \in \nu_x(\alpha)$ ’). A more substantial difference concerns negated conditionals. Because of the falsity conditions of the conditional, all logics of this family validate $\alpha \wedge \neg\beta \models \neg(\alpha \rightarrow \beta)$. This is a natural enough principle, but absent from many of the logics obtained using the Routley $*$.

The more usual relevant logics can be obtained with the 4-valued semantics, but only by using some *ad hoc* device or other, such as an extra accessibility relation, or allowing only certain classes of worlds. For details, see Routley [1984] and Restall [1995].

5.6 \rightarrow as \leq

There is a very natural way of employing any algebra which has an ordering relation to give a semantics for conditionals. One may think of the members of the algebra as propositions, or as Fregean senses. The relation \leq on the algebra can be thought of as an entailment relation, and it is then natural to take $\alpha \rightarrow \beta$ to hold in some interpretation, ν , iff $\nu(\alpha) \leq \nu(\beta)$. The problem, then, is to express the thought that $\alpha \rightarrow \beta$ holds in algebraic terms. We obviously need an algebraic operator, \rightarrow , corresponding to the connective; but how is one to express the idea that $a \rightarrow b$ holds when the algebra may have no maximal element?

A way to solve this problem for De Morgan algebras is to employ a designated member of the lattice, e , and take the things that hold in the algebra to be those whose values are $\geq e$.⁷⁴ While we are introducing new machinery, it is also useful algebraically to introduce another binary (groupoid) operator, \circ , often called ‘fusion’, whose significance we will come back to in a moment. We may also enrich the basic language to one containing a constant, e , and an operator, \circ , expressing the new algebraic features.

Thus, following Meyer and Routley [1972], let us call the structure $\mathcal{A} = \langle \mathcal{D}, e, \rightarrow, \circ \rangle$ a *De Morgan groupoid* iff \mathcal{D} is a De Morgan algebra, $\langle \mathcal{A}, \wedge, \vee, \neg \rangle$, and for any $a, b, c \in \mathcal{A}$:

⁷⁴A different way is to let T be a prime filter on the lattice, thought of as the set of all true propositions. We can then require that $a \rightarrow b \in T$ iff $a \leq b$. For details, see Priest [1980].

$$\begin{aligned}
 e \circ a &= a \\
 a \circ b \leq c &\text{ iff } a \leq b \rightarrow c \\
 \text{if } a \leq b &\text{ then } a \circ c \leq b \circ c \text{ and } c \circ a \leq c \circ b \\
 a \circ (b \vee c) &= (a \circ b) \vee (a \circ c) \text{ and } (b \vee c) \circ a = (b \circ a) \vee (c \circ a)
 \end{aligned}$$

The first of these conditions ensures that e is a left identity on the groupoid. (Note that the groupoid may not be commutative.) And it, together with the second, ensure that $a \leq b$ iff $e \leq a \rightarrow b$. The third and fourth ensure that \circ respects the lattice operations in a certain sense. The sense is question in that of a sort of conjunction, and this makes it possible to think of fusion as a kind of intensional conjunction.

An inference, $\alpha_1, \dots, \alpha_n / \beta$, is algebraically valid iff for every homomorphism, ν , into a De Morgan groupoid, $\nu(\alpha_1 \wedge \dots \wedge \alpha_n) \leq \nu(\beta)$, i.e., $e \leq \nu((\alpha_1 \wedge \dots \wedge \alpha_n) \rightarrow \beta)$.⁷⁵

These semantics are sound and complete with respect to the relevant logic B of 5.5. Soundness is shown in the usual way, and completeness can be proved, as in 4.8, by constructing the Lindenbaum algebra, and showing that it is a De Morgan groupoid.

Stronger logics can be obtained, as usual, by adding further constraints. The condition: $e \leq a \vee \neg a$ gives the law of excluded middle (and all classical tautologies). Additional constraints on \circ give the stronger logics in the usual relevant family, including R . Details of all the above can be found in Meyer and Routley [1972] (who also show how to translate between algebraic and world semantics).⁷⁶

Before leaving the topic of conditionals in algebraic paraconsistent logics, a final comment on dual intuitionist logic. Goodman [1981] proves that in this logic there is no conditional operator (i.e., operator satisfying *modus ponens*) that can be defined in terms of \vee, \wedge and \neg ; and draws somewhat pessimistic conclusions from this concerning the usefulness of the logic. Such pessimism is not warranted, however. Exactly the same is true in relevant logic; this does not mean that a conditional operator cannot be added to the basic language. And as Mortensen notes,⁷⁷ given any algebraic structure with top (\top) and bottom (\perp) elements, the following conditions can always be used to define a conditional operator:

$$\begin{aligned}
 \nu(\alpha \rightarrow \beta) &= \top && \text{if } \nu(\alpha) \leq \nu(\beta) \\
 &= \perp && \text{otherwise}
 \end{aligned}$$

⁷⁵A different notion of validity can be formulated using fusion thus: $\nu(\alpha_1 \circ \dots \circ \alpha_n) \leq \nu(\beta)$, i.e., $e \leq \nu((\alpha_1 \rightarrow (\dots \rightarrow (\alpha_n \rightarrow \beta)\dots))$.

⁷⁶See also Brink [1988]. A rather different algebraic approach which produces a relevant logic is given in Avro'n [1990]. This maintains an ordered structure, but dispenses with the lattice. The result is a logic closely related to the intensional fragment of RM .

⁷⁷Mortensen [1995], p. 95.

Though this particular conditional is not suitable for robust paraconsistent purposes since it satisfies: $\alpha \rightarrow \beta, \neg(\alpha \rightarrow \beta) \models \gamma$.

5.7 Decidability

Before we leave the topic of propositional logics, let me review, briefly, the question of decidability for the logics that we have looked at. Unsurprisingly, most (though not all) are decidable, as the following decision procedures indicate. As will be clear, in many cases the procedures actually given could be greatly optimised.

Any filter logic is decidable if the filter is. Given any inference, we can effectively find the set of all inferences of which it is a uniform substitution instance. Provided that the filter is decidable, we can test each of these for prevalidity. If any of them is valid, the original inference is valid; otherwise not.

Smiley's filter is clearly decidable. So is Tennant's semantic filter. Given an inference with finite sets of premises and conclusions, Σ and Π , respectively, we can test the inference for classical validity. We may then test the inferences for all subsets of Σ and Π . (There is only a finite number of these.) If the original inference is valid, but its subinferences are not, it passes the test; otherwise not. Tennant's proof theory of 5.1 is also decidable. Anything provable has a Cut-free proof (since Cut is not a rule of proof). Decidability then follows as it does in the case of classical logic.

Turning to non-adjunctive logics: Jaśkowski's discursive logic is decidable; we may simply translate an inference into the corresponding one concerning $S5$, and use the $S5$ decision procedure for this. The same obviously goes for any generalisation, provided only that the underlying modal logic is decidable.

Rescher and Manor's logic is decidable in the obvious way. Given any finite set of premises, we can compute all its subsets, the classical consistency of each of these, and hence determine which of the sets are maximally consistent. Once we have these, we can determine if any of them classically entails the conclusion. Similar comments apply to Schotch and Jennings' logic. Given any premise set, we can compute all its partitions, and so determine its level. For every partition of that size, we can test to see if one of its members classically entails the conclusion.

Non-truth-functional logics are also decidable by a simple procedure. Given an inference, we consider the set of all subformulas of the sentences involved (which is finite). We then consider all mappings from these to $\{0, 1\}$, the set of which is also finite. For each of these we go through and test whether it satisfies the appropriate constraints in the obvious way. Throwing away all those that do not, we see whether the conclusion holds

in all that remain.⁷⁸

All finite many-valued logics are decidable by truth-tables. The infinite valued Lukasiewicz logics (and so their Kotas and da Costa augmentations) are not, in general, even axiomatisable, let alone decidable. (See Chang [1963].) This leaves *RM*. If there is a counter-model for an *RM* inference, there must be a number of maximum absolute value employed. Ignoring all the numbers in the model whose absolute size is greater than this gives a finite counter-model. Hence, *RM* has the finite model property. As is well known, any axiomatisable theory with this property is decidable. (Enumerate the theorems and the finite models simultaneously. Eventually we must find either a proof of a countermodel.)

Dual intuitionist logic is decidable since intuitionist logic is. We just compute the dual inference and test it with the intuitionist procedure.

This just leaves the logics of the relevant family. As we saw, the semantics of these can take either a world form or an algebraic form. The question of decidability here is the hardest and most sensitive. The weaker logics in the family are decidable, and can be shown to be so by semantic methods (such as filtration arguments) and/or proof theoretic ones (such as Gentzenisation plus Cut elimination).⁷⁹ The stronger ones, such as *R*, are not. Urquhart's [1984] proof of this fact contains one of the few applications of geometry to logic. A crucial principle in this context would seem to be contraction: $(\alpha \rightarrow (\alpha \rightarrow \beta)) \rightarrow (\alpha \rightarrow \beta)$ (or various equivalent forms, such as $(\alpha \wedge (\alpha \rightarrow \beta)) \rightarrow \beta$). Speaking very generally, systems without this principle are decidable; systems with it are not.

6 QUANTIFIERS

The novelty of paraconsistent logic lies, it is fair to say, almost entirely at the propositional level. However, if a logic is to be applied in any serious way, it must be quantificational. Most of the paraconsistent logics that we have considered extend in straightforward ways to quantified logics. In this section I will indicate how. Let us suppose that the propositional language is now augmented to a language, *L*, with predicates, constants, variables and the quantifiers \forall and \exists in the usual way. I will let the adicity of a predicate be shown by the context. Propositional parameters can be identified with predicates of adicity 0. I will write $\alpha(x/t)$ to mean the result of substituting the term *t* for all free occurrences of *x*, any bound variables in α having been relabelled, if necessary, to avoid clashes.

I will reserve the word 'sentence' for formulas without free variables. I will always define validity for inferences containing only sentences, though the accounts could always be extended to ones employing all formulas, in

⁷⁸For the method applied to the da Costa systems, see da Costa and Alves [1977].

⁷⁹See, respectively, Routley *et al.* [1982], sect. 5.9, and Brady [1991].

standard ways. Where quantifiers have an objectual interpretation, and the set of objects is D , I will assume—for the rest of this essay—that the language has been augmented by a set of constants in such a way that each member of the domain has a name. In particular, I will always assume that the names are the members of D themselves, and that each object names itself. This assumption is never essential, but it simplifies the notation.

6.1 Filter and Non-adjunctive Logics

In filter logics, we may simply take the filter to be a relation on the extended language. Smiley's filter works equally well, for example, when the notion of classical logical truth employed is that for first order, not propositional, logic. Similarly for Tennant's. In his case (without the conditional operator), the semantics are sound and complete with respect to the sequent calculus of 4.1 for the basic language, together with the usual rules for the quantifiers:

$$\frac{\Gamma : \alpha(x/c), \Delta}{\Gamma : \forall x\alpha, \Delta} \qquad \frac{\Gamma, \alpha : \Delta}{\Gamma, \forall x\alpha : \Delta}$$

$$\frac{\Gamma : \alpha, \Delta}{\Gamma : \exists x\alpha, \Delta} \qquad \frac{\Gamma, \alpha(x/c) : \Delta}{\Gamma, \exists x\alpha : \Delta}$$

where in the first and last of these, c does not occur in any formula in Γ or Δ . For proofs, see Tennant [1984]. (With the conditional operator added, the situation is different, as we saw in 5.1.)

Non-adjunctive logic accommodates quantifiers in an obvious way. Consider discursive logic. An inference in the quantified language is discursively valid iff $\diamond\Sigma \models_{CS5} \diamond\alpha$, where $CS5$ is constant-domain quantified $S5$. Clearly, any other quantified modal logic could be used to generalise this notion.⁸⁰

Rescher and Manor's approach and Schotch and Jennings' also generalise in the obvious way, the classical notion of propositional consequence involved being replaced by the classical first-order notion. In the quantificational case, the usefulness of these logics is moot, since the computation of classically maximally consistent sets of premises, or partitions, is highly non-effective.

In all these logics, except Smiley's, the set of logical truths (in the appropriate vocabulary) coincides with that of classical quantifier logic; hence these logics are undecidable.⁸¹

⁸⁰ For details of quantified modal logic, see the article on that topic in this *Handbook*.

⁸¹ I do not know whether Smiley's logic is decidable, though I assume that it is not.

6.2 Positive-plus Logics

Let us turn now to the logics that augment classical or intuitionist positive logic with a non-truth-functional negation. Since the semantics of these are not truth functional, the most natural quantifier semantics are not objectual, but substitutional. Let me illustrate this with the simplest non-truth-functional logic, with a classical conditional operator, but no semantic constraints on negation. Extensions of this to other cases are left as an exercise.

An interpretation is a pair $\langle C, \nu \rangle$. C is a set of constants, and L_C is the language L augmented by the constants C . ν is a map from the sentences of L_C to $\{1, 0\}$ satisfying the same conditions as in the propositional case, together with:

$$\begin{aligned} \nu(\forall x\alpha) &= 1 \text{ iff for every constant of } L_C, c, \nu(\alpha(x/c)) = 1 \\ \nu(\exists x\alpha) &= 1 \text{ iff for some constant of } L_C, c, \nu(\alpha(x/c)) = 1 \end{aligned}$$

An inference is valid iff it is truth-preserving in all interpretations.

The semantics are sound and complete with respect to the quantifier rules:

$$\forall I \quad \frac{\beta \vee \alpha(x/c)}{\beta \vee \forall x\alpha}$$

provided that c does not occur in β , or in any undischarged assumption on which the premise depends.

$$\forall E \quad \frac{\forall x\alpha}{\alpha(x/c)}$$

$$\exists I \quad \frac{\alpha(x/c)}{\exists x\alpha}$$

$$\exists E \quad \frac{\exists x\alpha \quad \begin{array}{c} \overline{\alpha(x/c)} \\ \vdots \\ \beta \end{array}}{\beta}$$

provided that c does not occur in β or in any undischarged assumption in the subproof.

Soundness is proved by a standard recursive argument. For completeness, call a theory, Σ , *saturated* in a set of constants, C , iff:

$$\exists x\alpha \in \Sigma \text{ iff for some } c \in C, \alpha(x/c) \in \Sigma$$

$$\forall x \alpha \in \Sigma \text{ iff for every } c \in C, \alpha(x/c) \in \Sigma$$

It is easy to check that if Δ is a prime theory, saturated in C , then $\langle C, \nu \rangle$ is an interpretation, where ν is defined by: $\nu(\alpha) = 1$ iff $\alpha \in \Delta$.

It remains to show that if $\Sigma \not\vdash \alpha$ then Σ can be extended to a prime theory, Δ , saturated in some set of constants, C , with the same property; and the result follows as in the propositional case, using Δ to define the interpretation.

To show this, we augment the language with an infinite set of new constants, C , and then extend the proof of 4.3 as follows. Enumerate the formulas of L_C : β_0, β_1, \dots . If $\forall x\beta$ or $\exists x\beta$ occurs in the enumeration, and the constant c does not occur in any preceding formula, we will call $\beta(x/c)$ a *witness*. Now, we run through the enumeration, as before, but this time, if we throw $\exists x\beta$ into the Σ side, we also throw in a witness; and if we throw $\forall x\beta$ into the Π side, we also throw in a witness. In proving that $\Sigma_n \not\vdash \Pi_n$, the only novelty is when a witness is present; and these can be ignored, by $\exists E$ on the left, and $\forall I$ on the right. The rest of the proof is as in 4.3. The saturation of Δ in C follows from deductive closure and construction.

I observe that all the logics in this family contain positive classical quantifier logic, and so are undecidable.

6.3 Many-valued Logics

Most of the many-valued logics with numerical values that we considered in 4.5 and 5.4 had two particular properties. First, the truth value of a conjunction [disjunction] is the minimum [maximum] of the values of the conjuncts [disjuncts]. Second, the set of truth values is closed under greatest lower bounds (glbs) and least upper bounds (lubs), i.e., if $Y \subseteq X$ then $\text{glb}(Y) \in X$ and $\text{lub}(Y) \in X$. Any such logic can be extended to a quantified logic in a very natural way, merely by treating \forall and \exists as the “infinitary” generalisations of conjunction and disjunction, respectively.

Specifically, a quantifier interpretation adds to the propositional machinery, the pair $\langle D, d \rangle$ where D is a non-empty domain of objects, d maps every constant into D , and if P is an n -place predicate, d maps P to a function from n -tuples of the domain into the set of truth-values. Every sentence, α , can now be assigned a truth value, $\nu(\alpha)$, in the natural way. For atomic sentences, $Pc_1 \dots c_n$:

$$\nu(Pc_1 \dots c_n) = d(P) \langle d(c_1) \dots d(c_n) \rangle$$

The truth conditions for propositional connectives are as in the propositional logic. The truth conditions for the quantifiers are:

$$\begin{aligned} \nu(\forall x\alpha) &= \text{glb}\{\alpha(x/c); c \in D\} \\ \nu(\exists x\alpha) &= \text{lub}\{\alpha(x/c); c \in D\} \end{aligned}$$

Validity is defined in terms of preservation of designated values, as in the propositional case.

I will make just a few comments about what happens when these definitions are applied to the many-valued logics we have looked at. The quantified finite-valued logics of 4.5 all collapse into quantified *LP* (which we will come to in the next section), as extensions of the arguments given there, show. For a general theory of quantified finitely-many-valued logics, see Rosser and Turquette [1952]. Quantified *RM* we will come to in a later section. Infinite-valued Łukasiewicz logics are proof-theoretically problematic. For a start, standard quantifier rules may break down. In particular, $\forall x\alpha$ may be undesignated, even though each substitution instance is designated. Thus, $\forall I$ may fail. (Similarly for existential quantification.) Worse, as for their propositional counterparts, such logics are not even axiomatisable in general.⁸²

6.4 *LP and FDE*

The technique of extending a many-valued logic to a quantified one can be put in a slightly different, and possibly more illuminating, way for the logics with relational semantics, *LP* and *FDE*. An interpretation, \mathcal{I} , is a pair, $\langle D, d \rangle$, where D is the usual domain of quantification, d is a function that maps every constant into the domain, and every n -place predicate into a pair, $\langle E_P, A_P \rangle$, each member of which is a subset of the set of n -tuples of D, D^n . E_P is the *extension* of P ; A_P is the *anti-extension*. For *LP* interpretations, we require, in addition, that $E_P \cup A_P = D^n$. Truth values are now assigned to sentences in accord with the following conditions. For atomic sentences:

$$\begin{aligned} 1 \in \nu(Pc_1 \dots c_n) &\text{ iff } \langle d(c_1), \dots, d(c_n) \rangle \in E_P \\ 0 \in \nu(Pc_1 \dots c_n) &\text{ iff } \langle d(c_1), \dots, d(c_n) \rangle \in A_P \end{aligned}$$

Truth/falsity conditions for connectives are as in the propositional case; and for the quantifiers:

$$\begin{aligned} 1 \in \nu(\forall x\alpha) &\text{ iff for every } c \in D, 1 \in \nu(\alpha(x/c)) \\ 0 \in \nu(\forall x\alpha) &\text{ iff for some } c \in D, 0 \in \nu(\alpha(x/c)) \end{aligned}$$

$$1 \in \nu(\exists x\alpha) \text{ iff for some } c \in D, 1 \in \nu(\alpha(x/c))$$

⁸²See Chang [1963] for details.

$0 \in \nu(\exists x\alpha)$ iff for every $c \in D$, $0 \in \nu(\alpha(x/c))$

An inference is valid iff it is truth-preserving in all interpretations. It should be noted that if for every predicate, P , E_P and A_P are exclusive and exhaustive, we have an interpretation of classical first order logic. All classical interpretations are therefore *FDE* (and *LP*) interpretations.

These semantics are sound and complete if we add to the rules for *LP* or *FDE*, the rules $\forall I$, $\forall E$, $\exists I$ and $\exists E$, plus:

$$\frac{\forall x\neg\alpha}{\neg\exists x\alpha} \quad \frac{\exists x\neg\alpha}{\neg\forall x\alpha}$$

Soundness is established by the usual argument. For completeness, suppose that $\Sigma \not\vdash \alpha$. Extend Σ to a set Δ , which is prime, deductively closed and saturated in a set of new constants, such that $\Delta \not\vdash \alpha$, as in 6.2. Then define an interpretation $\langle D, d \rangle$ where D is the set of constants of the extended language, d maps any constant to itself, and for any predicate, P , its extension and anti-extension are defined as follows:

$$\begin{aligned} \langle c_1, \dots, c_n \rangle \in E_P &\text{ iff } Pc_1\dots c_n \in \Delta \\ \langle c_1, \dots, c_n \rangle \in A_P &\text{ iff } \neg Pc_1\dots c_n \in \Delta \end{aligned}$$

We now establish that for all formulas, α :

$$\begin{aligned} 1 \in \nu(\alpha) &\text{ iff } \alpha \in \Delta \\ 0 \in \nu(\alpha) &\text{ iff } \neg\alpha \in \Delta \end{aligned}$$

The argument is a routine induction. Here are the cases for \forall .

$$\begin{aligned} \forall x\alpha \in \Delta &\Leftrightarrow \text{for all } c, \alpha(x/c) \in \Delta && \text{saturation} \\ &\Leftrightarrow \text{for all } c, 1 \in \nu(\alpha(x/c)) && \text{induction hypothesis} \\ &\Leftrightarrow 1 \in \nu(\forall x\alpha) && \text{truth conditions of } \forall \\ \neg\forall x\alpha \in \Delta &\Leftrightarrow \exists x\neg\alpha \in \Delta && \text{quantifier rules} \\ &\Leftrightarrow \text{for some } c, \neg\alpha(x/c) \in \Delta && \text{saturation} \\ &\Leftrightarrow \text{for some } c, 0 \in \nu(\alpha(x/c)) && \text{induction hypothesis} \\ &\Leftrightarrow 0 \in \nu(\forall x\alpha) && \text{truth conditions of } \forall \\ &\Leftrightarrow 1 \in \nu(\neg\forall x\alpha) && \text{truth conditions of } \neg \end{aligned}$$

The monotonicity property of the propositional logics *LP* and *FDE* carries over to the quantified case. If \mathcal{I}_1 and \mathcal{I}_2 are any interpretations, with truth value assignments ν_1 and ν_2 , define $\mathcal{I}_1 \leq \mathcal{I}_2$ to mean that \mathcal{I}_1 and \mathcal{I}_2 have the same domain, and for every predicate, P , the extension (anti-extension) of P in \mathcal{I}_1 is a subset of the extension (anti-extension) of P in

\mathcal{I}_2 . A simple induction shows that if $\mathcal{I}_1 \leq \mathcal{I}_2$ then for all formulas, α (in a language with a name for every member of the domain), $\nu_1(\alpha) \subseteq \nu_2(\alpha)$. As in 4.6, it follows that the set of logical truths of LP is exactly the same as that of classical first order logic. And FDE has no logical truths (just consider an interpretation that makes the extension and anti-extension of every predicate empty).

Since classical quantifier logic is not decidable, neither is quantified LP . If P is any n -place predicate, let P_{LEM} be the sentence: $\forall x_1 \dots \forall x_n (Px_1 \dots x_n \vee \neg Px_1 \dots x_n)$. If P_{LEM} is true in an interpretation, then the extension and anti-extension of P , exhaust the n -tuples of the domain. If α is any formula, let α_{LEM} be the conjunction of all formulas of the form P_{LEM} , where P occurs in α . It follows that $\alpha_{LEM} \models \alpha$ in FDE iff $\models \alpha$ in LP . Hence, quantified FDE is undecidable too.

6.5 Relevant Logics

Turning to relevant logics, the issues are more complex. This is due to the fact that there are various approaches to these logics, the variety of the logics themselves, and the intrinsic complexities of the stronger logics.

Let us start with the world semantics. As we saw in 5.5, a world semantics for a relevant logic with the Routley operator is a structure $\langle W, N, *, \nu, R \rangle$, where W is a set of worlds, N is a subclass of normal worlds (the complement being NN), $*$ is the Routley operation (such that $w = w^{**}$), and ν assigns truth values to all propositional parameters at worlds. In the logic H , it also assigns values to conditionals at non-normal worlds. In stronger logics, the ternary relation R is present, and is used to specify the values of conditionals at non-normal worlds. When no constraints are placed on R , we have the logic B .

The simplest way of extending such semantics to those of a quantified language is by removing ν from the structure and adding a domain of quantification, D , and a denotation function d . d specifies a denotation for each constant (same at each world) and an extension for each n -place predicate at each world, $d_w(P) \subseteq D^n$. Truth conditions are given in the standard way. In particular, for the quantifiers:

$$\begin{aligned} \nu(\forall x \alpha) &= 1 \text{ iff for every } c \in D, \nu(\alpha(x/c)) = 1 \\ \nu(\exists x \alpha) &= 1 \text{ iff for some } c \in D, \nu(\alpha(x/c)) = 1 \end{aligned}$$

An inference is valid iff it is truth-preserving in all *normal* worlds of all interpretations.⁸³

⁸³More complex semantics can be employed in the usual variety of ways employed in modal logic. (See the article on Quantified Modal Logic in this *Handbook*.) In particular, we might employ variable-domain semantics. This makes matters more complex.

Consider the following quantifier axioms and rules (where \vdash is now taken to indicate universal closure):

$$\begin{aligned} &\vdash \forall x\alpha \rightarrow \alpha(x/c) \\ &\vdash \alpha(x/c) \rightarrow \exists x\alpha \\ &\vdash \alpha \wedge \exists x\beta \rightarrow \exists x(\alpha \wedge \beta) \quad x \text{ not free in } \alpha \\ &\vdash \forall x(\alpha \vee \beta) \rightarrow (\alpha \vee \forall x\beta) \quad x \text{ not free in } \beta \end{aligned}$$

$$\begin{aligned} &\text{If } \vdash \forall x(\alpha \rightarrow \beta) \text{ then } \vdash \exists x\alpha \rightarrow \beta \quad x \text{ not free in } \beta \\ &\text{If } \vdash \forall x(\alpha \rightarrow \beta) \text{ then } \vdash \alpha \rightarrow \forall x\beta \quad x \text{ not free in } \alpha \end{aligned}$$

It is easy to check that these axioms/rules are valid/truth-preserving for H . If they are added to the propositional axioms/rules for H , they are also complete. For the proof, see Routley and Loparić [1980].⁸⁴

If we strengthen the two rules to conditionals (so that the first of these becomes $\vdash \forall x(\alpha \rightarrow \beta) \rightarrow (\exists x\alpha \rightarrow \beta)$, etc.) and add them to the rules for B , they are also sound and complete. The same is true for a number of the extensions of B , including BX . (For details, see Routley [1980a].) A notable exception to this fact is the system R . Though the system is sound, it is, perhaps surprisingly, not complete.⁸⁵ In fact, a proof-theoretic characterisation of constant domain quantified R is still an open problem. The axioms and rules are complete for the stronger semi-relevant system RM of 5.4.⁸⁶

Since every relevant logic in the above family contains FDE , and this is undecidable, it follows that all the logics in this family are also undecidable.

6.6 Algebraic Logics

Given any algebraic logic, for which the appropriate algebraic structures are lattices, and in which conjunction and disjunction behave as lattice meet and join, there is, as with many-valued logics, a natural way to extend the machinery to quantifiers. An algebra is *complete* iff it is closed under least upper bounds (\bigvee) and greatest lower bounds (\bigwedge), i.e., if the domain of the algebra is A and $B \subseteq A$ then $\bigvee B \in A$ and $\bigwedge B \in A$. If \mathcal{A} is any algebraic structure of the required kind, with domain A , then an interpretation is a triple $\langle \mathcal{A}, D, d \rangle$, where D is the domain of quantification, d maps every constant into D and every n -place predicate into a function from D^n into

(The philosophical gain, however, is dubious: world relativised quantifiers can always be defined in constant-domain semantics, provided we have an Existence predicate.)

⁸⁴If one works with a free-variable notion of deducibility, as Routley and Loparić do, one also has to add the rule of universal generalisation: if $\vdash \alpha$ then $\vdash \forall x\alpha$.

⁸⁵As Fine showed. Fine also produced a rather different semantics with respect to which it is complete. See Anderson *et al.* [1992], sects. 52 and 53.

⁸⁶See Anderson *et al.* [1992], sect. 49.2.

A. Algebraic values are then assigned to all formulas in the usual way. In particular, for quantified sentences the conditions are:

$$\begin{aligned}\nu(\forall x\alpha) &= \bigwedge\{\nu(\alpha(x/c)); c \in D\} \\ \nu(\exists x\alpha) &= \bigvee\{\nu(\alpha(x/c)); c \in D\}\end{aligned}$$

I will comment on this construction for only two kinds of algebras. The first is when \mathcal{A} is a De Morgan groupoid, or strengthening thereof. In this case, the above semantics clearly give quantified relevant logics. Their relation to quantified relevant logics based on the intensional semantics has not, as far as I am aware, been investigated.

The second is where \mathcal{A} is a dual intuitionist algebra. In this case, the semantics give a quantified logic that is dual to quantified intuitionist logic. For details, see Goodman [1981].⁸⁷

6.7 A Brief Look Back

Now that we have surveyed a large number of paraconsistent logics up to a quantified level—some very briefly—it would seem appropriate to look back for a moment and put the systems into some sort of perspective.

The logics we have looked at fall roughly and inexactly into four categories: non-transitive logics, non-adjunctive logics, non-truth-functional logics and relevant logics. (The most interesting many-valued systems are zero degree relevant logic, *FDE*, or closely related to it, like *LP*, and so may be classed in this family.) The non-transitive logics seem to be good for extracting the essential juice out of classical inferences, but do not really take inconsistent semantic structures seriously. Non-adjunctive logics may be just what one needs for certain applications (e.g., inferences in a data base, where one would not necessarily want to infer $\alpha \wedge \neg\alpha$ from α and $\neg\alpha$); they also take inconsistent structure seriously, though conjoined contradictions are handled indiscriminately, which makes them unsuitable for many applications. Non-truth-functional logics contain the whole of classical (or at least intuitionist) positive logic, and so are useful when strong canons of positive reasoning are required. However, this very strength is a weakness when it comes to some important applications, as we shall see in connection with set theory. Undoubtedly the simplest and most robust paraconsistent logic is the logic *LP*. When conditional operators are required, the relevant logic *BX* is a good all-purpose paraconsistent logic. Its conditional operator is satisfactory for many purposes, but may be considered relatively weak. It may be strengthened to give stronger relevant logics; but this, too, may cause a problem for some applications, as we shall see.

⁸⁷There is also a topos-theoretic account of quantification for dual intuitionistic logic. See Mortensen [1995], ch. 11.

7 OTHER EXTENSIONS OF THE BASIC APPARATUS

I now want to look at other extensions of the basic paraconsistent apparatus. One way or another, all the paraconsistent logics we have looked at can be extended appropriately. However, it is tedious to run through every case, especially when details are often obvious. Hence, I shall illustrate the extensions mainly with respect to just one logic. Since *LP* is simple and natural, it recommends itself for this purpose. I will comment on other logics occasionally, when there is a point to doing so.

7.1 Identity and Function Symbols

LP—and all the other logics with objectual semantics that we have looked at—can be extended to include function symbols and identity in the usual way. The denotation function, d , maps each n -place function symbol, f , to an n -place function on the domain. A denotation for every (closed) term, t , is then obtained by the usual recursive condition:

$$d(ft_1\dots t_n) = d(f)(d(t_1), \dots, d(t_n))$$

With functional terms present, the quantifier rules of proof are extended to arbitrary (closed) terms in the usual way.

If we require the extension of the identity predicate to be $\{\langle x, x \rangle ; x \in D\}$ then this is sufficient to validate the usual laws of identity:

$$\frac{}{\overline{t = t}} \quad \frac{t_1 = t_2 \quad \alpha(x/t_1)}{\alpha(x/t_2)}$$

This does not require identity statements to be consistent. In *LP* the anti-extension of identity is any set whose union with the extension exhausts D^2 , and so a pair can be in both the extension and the anti-extension of the identity predicate. In other logics, negated identities can be taken care of by whatever mechanism is used for negation. The completeness proof for quantified *LP* can be extended to include function symbols and identity in the usual Henkin fashion.

I note that description operators can be added in the obvious ways, with the same panoply of options as in the classical case.⁸⁸

7.2 Second-order Logic

Paraconsistent logics can also be extended to second order in the obvious ways. Consider *LP*. We add (monadic) second order variables, X, Y, \dots to

⁸⁸See the article of Free Logics in this *Handbook*.

the first-order language. Then, given an interpretation, $\langle D, d \rangle$, we extend the language to one, L_D , such that every member of the domain has a name, and for every pair E, A such that $E \cup A = D$ there is a predicate, P , with E and A as extension and anti-extension, respectively.⁸⁹ The truth/falsity conditions for the second order universal quantifier are then:

$$\begin{aligned} 1 \in \nu(\forall X\alpha) & \text{ iff for every } P \text{ in } L_D, 1 \in \nu(\alpha(X/P)) \\ 0 \in \nu(\forall X\alpha) & \text{ iff for some } P \text{ in } L_D, 0 \in \nu(\alpha(X/P)) \end{aligned}$$

The truth/falsity conditions for the existential quantifier are the dual ones.

Appropriate monotonicity carries over to second order LP . Recall from 6.4 that if \mathcal{I}_1 and \mathcal{I}_2 are any interpretations, with truth value assignments ν_1 and ν_2 , $\mathcal{I}_1 \leq \mathcal{I}_2$ means that \mathcal{I}_1 and \mathcal{I}_2 have the same domain, and for every predicate, P , the extension (anti-extension) of P in \mathcal{I}_1 is a subset of the extension (anti-extension) of P in \mathcal{I}_2 . The same sort of induction as in the first-order case shows that if $\mathcal{I}_1 \leq \mathcal{I}_2$ then for all formulas, α , in L_D , $\nu_1(\alpha) \subseteq \nu_2(\alpha)$. (The predicates added in forming L_D have the same extension/anti-extension in both interpretations; and thus atomic sentences containing them satisfy the condition.)

In the second order case, and unlike the first order case, the logical truths of LP are distinct from their classical counterparts. For example, as is easy to check, in LP , $\models \exists X(Xa \wedge \neg Xa)$ (just consider the predicate which has D as both extension and anti-extension).⁹⁰ In fact, the logical truths of second order LP are inconsistent, since it is also a logical truth that $\forall X(Xa \vee \neg Xa)$, which is equivalent by quantifier rules and De Morgan to $\neg \exists X(Xa \wedge \neg Xa)$.

7.3 Modal Operators

All the logics may have modal operators added to them in one way or another. In the case of discursive logics, indeed, the semantics already provide for the possibility of alethic modal operators.

Adding modal operators to intensional logics where negation is handled by the Routley $*$ operator is very natural, but suffers problems similar to those we witnessed at the start of 5.5 in connection with the conditional. Suppose we take an intensional interpretation and give the modal operators the natural $S5$ conditions:

$$\nu_w(\Box\alpha) = 1 \text{ iff for every } w' \in W, \nu_{w'}(\alpha) = 1$$

⁸⁹This is the natural policy, since properties are characterised semantically by an extension/anti-extension pair. As in the classical case, there are other policies, e.g., where only predicates corresponding to some restricted class of properties are added.

⁹⁰Second order FDE is constructed in the obvious way. The same sentence is a logical truth of this, showing that, unlike the first order case, it has logical truths.

$$\nu_w(\diamond\alpha) = 1 \text{ iff for some } w' \in W, \nu_{w'}(\alpha) = 1$$

(or even N instead of W). Then the truth values of modalised statements are the same at all worlds. Hence, $\nu_w(\Box\alpha) = 1 \Leftrightarrow \nu_{w^*}(\Box\alpha) = 1 \Leftrightarrow \nu_w(\neg\Box\alpha) = 0$. Hence $\Box\alpha, \neg\Box\alpha \models \beta$, and so the logic is not suitable for serious paraconsistent purposes. The problem does not arise if we attempt a modal logic weaker than $S5$, for then the truth conditions of modal operators are given employing a binary accessibility relation in the usual way, and the truth values of modal statements will vary across worlds. But, at least for some purposes, an $S5$ modality is desirable.

These problems are avoided if we use the Dunn semantics for negation. The values of modalised formulas will still be the same at all worlds (in the $S5$ case), but we may now have both $\Box\alpha$ and $\neg\Box\alpha$ true at a world. I will illustrate, again, with respect to LP . Let us start with the case where the binary accessibility relation is arbitrary, the three-valued analogue of the modal system K .

An interpretation is now a structure $\langle W, R, \nu \rangle$, where W is a set of worlds; R is a binary relation on W ; and for each parameter, p , $\nu_w(p) \in \{\{1\}, \{1, 0\}, \{0\}\}$. Truth/falsity conditions for the propositional connectives are as in 5.5. The conditions for \Box are:

$$\begin{aligned} 1 \in \nu_w(\Box\alpha) & \text{ iff for every } w' \text{ such that } wRw', 1 \in \nu_{w'}(\alpha) \\ 0 \in \nu_w(\Box\alpha) & \text{ iff for some } w' \text{ such that } wRw', 0 \in \nu_{w'}(\alpha) \end{aligned}$$

and dually for \diamond .⁹¹

It is easy to check that at every world of an interpretation $\Box\neg\alpha$ has the same truth value as $\neg\diamond\alpha$, and dually. In fact, we can simply define $\diamond\alpha$ as $\neg\Box\neg\alpha$, and will do this in what follows.

To obtain a proof-theoretic characterisation for the logic, we add to the rules for LP the following (chosen to make the completeness proof simple):

$$\frac{\begin{array}{c} \bar{\gamma} \\ \vdots \\ \beta \end{array} \quad \Box\gamma}{\Box\beta} \quad \frac{\begin{array}{c} \bar{\beta} \\ \vdots \\ \delta \end{array} \quad \diamond\beta}{\diamond\delta}$$

where there are no other undischarged assumptions in the sub-proofs.

$$\frac{\frac{\Box(\beta \vee \delta)}{\Box\beta \vee \diamond\delta} \quad \frac{\Box\gamma \wedge \diamond\beta}{\diamond(\gamma \wedge \beta)}}{\Box\beta \vee \diamond\delta \quad \diamond(\gamma \wedge \beta)}$$

⁹¹ If a conditional operator is required, we may add a class of non-normal worlds—and maybe a ternary accessibility relation—and proceed as in 5.5.

$$\frac{\Box\gamma_1 \wedge \dots \wedge \Box\gamma_n}{\Box(\gamma_1 \wedge \dots \wedge \gamma_n)} \quad \frac{\Diamond(\delta_1 \vee \dots \vee \delta_n)}{\Diamond\delta_1 \vee \dots \vee \Diamond\delta_n}$$

Soundness is easily checked. For completeness, suppose that $\Sigma \not\vdash \alpha$. Extend Σ to a prime, deductively closed theory, Π , with the same property, as in 4.3. Define an interpretation, $\langle W, R, \nu \rangle$, where W is the set of prime deductively closed theories; $\Gamma R \Delta$ iff for all β :

$$\begin{aligned} \Box\beta \in \Gamma &\Rightarrow \beta \in \Delta \\ \beta \in \Delta &\Rightarrow \Diamond\beta \in \Gamma \end{aligned}$$

and ν is defined by:

$$\begin{aligned} 1 \in \nu_\Gamma(p) &\text{ iff } p \in \Gamma \\ 0 \in \nu_\Gamma(p) &\text{ iff } \neg p \in \Gamma \end{aligned}$$

All that remains is to show that these conditions extend to all formulas. Completeness then follows as usual. This is established by induction. The only difficult case is that for \Box , which requires the following two-part lemma.

If $\Box\beta \notin \Gamma$ then there is a $\Delta \in W$ such that $\Gamma R \Delta$ and $\beta \notin \Delta$. Proof: Let $\Gamma_\Box = \{\gamma; \Box\gamma \in \Gamma\}$ and $\Gamma_\Diamond = \{\delta; \Diamond\delta \notin \Gamma\}$. Then $\Gamma_\Box \not\vdash \beta, \Gamma_\Diamond$, by the first and second pair of rules, and a bit of fiddling with the third. Extend Γ_\Box to a prime, deductively closed set, Δ , with the same property, as in 4.3. The result follows.

If $\Diamond\beta \in \Gamma$ then there is a $\Delta \in W$ such that $\Gamma R \Delta$ and $\beta \in \Delta$. Proof: Let Γ_\Box and Γ_\Diamond be as before. Then $\Gamma_\Box, \beta \not\vdash \Gamma_\Diamond$, by the first and second pair of rules, and a bit of fiddling with the third. Extend Γ_\Box, β to a prime, deductively closed set, Δ , with the same property, as in 4.3. The result follows.

We can now prove the induction step for \Box :

$$\begin{aligned} \Box\beta \in \Gamma &\Leftrightarrow \forall \Delta \text{ s.t. } \Gamma R \Delta, \beta \in \Delta && \text{lemma in one direction} \\ &\Leftrightarrow \forall \Delta \text{ s.t. } \Gamma R \Delta, 1 \in \nu_\Delta(\beta) && \text{definition of } R \text{ in the other} \\ &\Leftrightarrow 1 \in \nu_\Gamma(\Box\beta) && \text{induction hypothesis} \\ \\ \neg\Box\beta \in \Gamma &\Leftrightarrow \Diamond\neg\beta \in \Gamma && \text{definition of } \Diamond \\ &\Leftrightarrow \exists \Delta(\Gamma R \Delta \text{ and } \neg\beta \in \Delta) && \text{lemma in one direction} \\ &\Leftrightarrow \exists \Delta(\Gamma R \Delta \text{ and } 0 \in \nu_\Delta(\beta)) && \text{definition of } R \text{ in the other} \\ &\Leftrightarrow 0 \in \nu_\Gamma(\Box\beta) && \text{induction hypothesis} \end{aligned}$$

Stronger modal logics can be obtained by placing conditions on R , and corresponding conditions on the proof theory. But even if we make R universal (so that for all x and y , xRy), and obtain the analogue of $S5$, we still do not get $\Box\alpha, \neg\Box\alpha \models \beta$. To see this, merely consider the interpretation with one world, w , which accesses itself; and where $\nu_w(p) = \{1, 0\}$ and $\nu_w(q) = \{0\}$. It is easy to check that $\nu_w(\Box p) = \nu_w(\neg\Box p) = \{1, 0\}$. Hence, $\Box p, \neg\Box p \not\models q$.

The same treatment can be given to temporal operators. If we take these, as usual, to be F and G for the future, and P and H for the past, then (three-valued) tense logic gives F and G the same truth conditions as \Diamond and \Box , respectively; and P and H are the same, except that R is replaced by its converse, \check{R} (where $x\check{R}y$ iff yRx). Appropriate soundness and completeness proofs for the case where R is arbitrary are obtained by modifying the alethic modal argument,⁹² and stronger tense logics are obtained by adding conditions on R , in the usual way.⁹³

Let me also mention conditional operators, $>$, of the Lewis/Stalnaker variety. These are modal (binary) operators, and can be given LP (or FDE) semantics in the same way that they are given a more usual semantics. For example, for the Stalnaker version, one extends interpretations with a selection function, $f(w, \alpha)$, thought of as selecting the nearest world to w where α is true. $\alpha > \beta$ is then true at w iff β is true at $f(w, \alpha)$. Details are left as a very non-trivial exercise.⁹⁴

7.4 The Paraconsistent Importance of Modal Operators

Let me digress from the technical details to say a little about why modal operators are important in the context of paraconsistency. The reason is simply that so many of the natural areas where one might want to apply a paraconsistent logic involve them.

Take alethic modalities first. Even though one might not think that there are any true contradictions, one might still take them to be possible, in the sense of holding in some situations, such as fictional or counterfactual ones. Thus, one might hold that for some p , $\Diamond(p \wedge \neg p)$. This has a simple and obvious model in the above semantics. In this context, let me mention again the importance for counterfactual conditionals of worlds where the impossible holds; “impossible worlds” are just what one needs to evaluate such conditionals, according to the Lewis/Stalnaker semantics in whose direction I have just gestured.

Some have been tempted not just by the view that some contradictions

⁹²See Priest [1982].

⁹³See the article on Tense Logic in this *Handbook*.

⁹⁴For a paraconsistent theory of conditionals of this kind, and of many other modal operators, that employs the Routley $*$ to handle negation, see Routley [1989].

are possible, but by the view that *everything* is possible.⁹⁵ The valuation $\nu_{\{1,0\}}$ assigns every formula the value $\{1,0\}$. (See 4.6). Hence, any interpretation that contains $\nu_{\{1,0\}}$ as one world will verify $\diamond\alpha$, for all α , at any world that accesses it.⁹⁶ If we interpret the modal operators \square and \diamond as the deontic operators O (it is obligatory that) and P (it is permissible that), respectively, then the thesis that everything is possible becomes the nihilistic thesis that everything is permissible—what, according to Dostoevski, would be the case if there is no God.

Less exotically, standard deontic logic suffers badly from explosion.⁹⁷ Since in classical logic $\alpha, \neg\alpha \models \beta$ it follows that $O\alpha, O\neg\alpha \models O\beta$: if you have inconsistent obligations then you are obliged to do everything. This is surely absurd. People incur inconsistent obligations; this may give rise to legal or moral dilemmas, but hardly to legal or moral anarchy.⁹⁸ And one does not have to believe in dialetheism to accept this. Unsurprisingly, deontic explosion fails, given the semantics of the previous section: just consider the interpretation where there is a single world, w ; R is universal; $\nu_w(p) = \{1,0\}$ and $\nu_w(q) = \{0\}$. It is not difficult to check that $\nu_w(Op) = \nu_w(O\neg p) = \{1,0\}$, whilst $\nu_w(Oq) = \{0\}$.

What is often taken to be the basic possible-worlds deontic logic (called *KD* by Chellas [1980], p. 131) makes matters even worse, by requiring that in an interpretation the accessibility relation be serial: for all x , there is a y such that xRy . This validates the inference $O\alpha/P\alpha$. It also validates the inference $O\neg\alpha/\neg O\alpha$. Hence we have, classically, $O\alpha, O\neg\alpha \models O\alpha \wedge \neg O\alpha \models \beta$; one who incurs inconsistent obligations renders the world trivial. Someone who believes that there are deontic dilemmas may just have to jettison the view that obligation entails permission, and so give up seriality. But on the above account one can retain seriality, and so both the above inferences; for $O\alpha \wedge \neg O\alpha \not\models \beta$, as the countermodel of the last paragraph shows.⁹⁹

Another standard way of interpreting the modal operator \square is as an epistemic operator, K (it is known that), or a doxastic operator B (it is believed that). In these cases, classically, one would almost certainly want to put extra constraints on the accessibility relation, though what these should be might be contentious: all can accept reflexivity (xRx) for K (but not for B) since this validates $K\alpha \models \alpha$. Whether one would want transitivity ($(xRy \& yRz) \Rightarrow xRz$) is much more dubious for B and K , since this gives the

⁹⁵E.g., Mortensen [1989].

⁹⁶A similar, but slightly more complex, construction can be employed to the same effect if the logic has a conditional operator.

⁹⁷See the article on Deontic Logic in this *Handbook* for details of Deontic Logic, including the possible-worlds approach.

⁹⁸For further discussion, see Priest [1987], ch. 13.

⁹⁹We have just been dealing with some of the “paradoxes of deontic logic”. There are many of these. Arguably, all of them—or at least all the serious ones—are avoided by using a paraconsistent logic with a relevant conditional. See Routley and Routley [1989].

highly suspect $K\alpha \models KK\alpha$ and $B\alpha \models BB\alpha$. All this applies equally to the semantics of the previous section. Moreover, the paraconsistent semantics solve problems for doxastic logic of the same kind as for deontic logic. It is clear that people sometimes have inconsistent beliefs (if not knowledge). Standard semantics give $B\alpha, B\neg\alpha \models B\beta$. Yet patently someone may have inconsistent beliefs without believing everything.¹⁰⁰

Observations such as this are particularly apt in the branch of *AI* known as knowledge representation, where it is common to use epistemic operators to model the information available to a computer. (See, e.g., a number of the essays in Halpern [1986].) Such information may well be inconsistent.

Finally, to tense operators. Whilst one does not have to be a dialetheist to hold that inconsistencies may be believed, obligatory, or true in some counterfactual situation, one does have to be, to believe that they were or will be true. Such views have certainly been held, however. Following Zeno, the whole dialectical tradition holds that contradictions arise in a state of change. To see one of the more plausible examples of this, just consider a state described by p which changes instantaneously at time t_0 to a state described by $\neg p$. What is the state of affairs at t_0 ? One answer is that at t_0 , $p \wedge \neg p$ is true. Indeed, the contradictory state *is* the state of change.¹⁰¹

This can be modeled by the paraconsistent interpretation $\langle W, R, \nu \rangle$, where W is the set of real numbers (thought of as times); R is the standard ordering on the reals; and ν is defined by the condition:

$$\begin{aligned} \nu_t(p) &= \{1\} && \text{if } t < t_0 \\ &= \{1, 0\} && \text{if } t = t_0 \\ &= \{0\} && \text{if } t > t_0 \end{aligned}$$

It is easy to check that this interpretation verifies the inference: $p \wedge F\neg p / (p \wedge \neg p) \vee F(p \wedge \neg p)$, which we might call ‘Zeno’s Principle’: change implies contradiction.

7.5 Probability

Probability is not a modal notion. But it, too, has paraconsistent significance. One of the most natural ways of constructing a paraconsistent probability theory is to extract one from a class of paraconsistent interpretations, in the manner of Carnap.¹⁰²

¹⁰⁰If you believe classical logic, then you might suppose that they are *rationally committed* to everything, but that is quite different. Even here, however, an explosive logic would seem to go astray. Dialetheism aside, situations such as the paradox of the preface, as well as more mundane things, would seem to show that one can be rationally committed to inconsistent propositions without being rationally committed to everything. See Priest [1987], sect. 7.4.

¹⁰¹See Priest [1982] and Priest [1987], ch. 11.

¹⁰²See Carnap [1950].

A probabilistic interpretation is a pair, $\langle I, \mu \rangle$, where I is a class of interpretations for LP^{103} and μ a finitely additive measure on I , that is, a function from subsets of I to non-negative real numbers such that:

$$\begin{aligned} \mu(\phi) &= 0 \\ \mu(X \cup Y) &= \mu(X) + \mu(Y) \quad \text{if } X \cap Y = \phi \end{aligned}$$

If α is any sentence, let $[\alpha] = \{\nu \in I; 1 \in \nu(\alpha)\}$. For reasons that we will come to, we also require that for all α , $\mu([\alpha]) \neq 0$. There certainly are such interpretations and measures. For example, let I be any finite class that contains the trivial interpretation, $\nu_{\{1,0\}}$, where all sentences are true, and let $\mu(X)$ be the cardinality of X . Then this condition is satisfied.

Given a probabilistic interpretation, we define a probability function, p , by:

$$p(\alpha) = \mu([\alpha]) / \mu(I)$$

It is easy to see that p satisfies all the standard conditions for a probability function, such as:

$$\begin{aligned} 0 &\leq p(\alpha) \leq 1 \\ \text{if } \alpha \models \beta &\text{ then } p(\alpha) \leq p(\beta) \\ \text{if } \models \alpha &\text{ then } p(\alpha) = 1 \\ p(\alpha \vee \beta) &= p(\alpha) + p(\beta) - p(\alpha \wedge \beta) \end{aligned}$$

except, of course: $p(\neg\alpha) + p(\alpha) = 1$. Since we have $p(\alpha \wedge \neg\alpha) > 0$, and $p(\alpha \vee \neg\alpha) = 1$, it follows that $p(\alpha) + p(\neg\alpha) > 1$.

By the construction, we have, in fact, $p(\alpha) > 0$ for all α . It might be suggested that a person whose personal probability function gives nothing the value zero would have to be very stupid—or at least credulous. But since $p(\alpha)$ may be as small as one wishes, this hardly seems to follow. Moreover, giving nothing a zero probability signals an open-minded and undogmatic policy of belief. Arguably, this is the most rational policy.

Given a probability function, conditional probability can be defined in the usual way:

$$p(\alpha/\beta) = p(\alpha \wedge \beta) / p(\beta)$$

A singular advantage of this paraconsistent probability theory over standard accounts is that conditional probability is *always* defined, since the denominator is always non-zero.

¹⁰³ Again, many other paraconsistent logics could be used instead.

Perhaps the major application of probability theory is in framing an account of non-deductive inference. How, exactly, to do this is a moot question. But however one does it, a paraconsistent account of non-deductive inference can be framed in the same way, employing paraconsistent probability theory. For example, we may define the degree of (non-deductive) validity of the inference α/β to be $p(\beta/(\alpha \wedge \eta))$, where η is our background evidence. As one would expect, deductively valid inferences come out as having maximal degree of inductive validity.

To compute the degree of validity of an inference, so defined, we would often need to employ Bayes' Theorem. Let us look at the paraconsistent two-hypothesis version of this. Suppose that we have two hypotheses, h_1 and h_2 , that are exclusive and exhaustive, in the sense that $\models h_1 \vee h_2$ and $\models \neg(h_1 \wedge h_2)$, and that we wish to compute the probability of h_1 on evidence, e , given the inverse probabilities of these hypotheses on the evidence (all relative to some background evidence, η , which we will ignore).

Note first that $p(h_1/e) = p(h_1 \wedge e)/p(e) = p(e/h_1).p(h_1)/p(e)$. It remains to compute $p(e)$. Since $h_1 \vee h_2$ entails $e \vee h_1 \vee h_2$ we have :

$$\begin{aligned} 1 &= p(e \vee h_1 \vee h_2) &= p(e) + p(h_1 \vee h_2) - p(e \wedge (h_1 \vee h_2)) \\ & &= p(e) + 1 - p(e \wedge (h_1 \vee h_2)) \end{aligned}$$

Hence:

$$\begin{aligned} p(e) &= p(e \wedge (h_1 \vee h_2)) \\ &= p((e \wedge h_1) \vee (e \wedge h_2)) \\ &= p(e \wedge h_1) + p(e \wedge h_2) - p(e \wedge h_1 \wedge h_2) \\ &= p(h_1).p(e/h_1) + p(h_2).p(e/h_2) - p(h_1 \wedge h_2).p(e/(h_1 \wedge h_2)) \end{aligned}$$

Thus:

$$p(h_1/e) = \frac{p(e/h_1).p(h_1)}{p(h_1).p(e/h_1) + p(h_2).p(e/h_2) - p(h_1 \wedge h_2).p(e/(h_1 \wedge h_2))}$$

This is the paraconsistent version of Bayes' Theorem. In the classical case, the last term of the denominator is zero, since $\models \neg(h_1 \wedge h_2)$; but this is not so in the paraconsistent case. The theorem illustrates a general fact about paraconsistent probability theory: everything works as normal, except that we have to carry round some extra terms concerning the probabilities of certain contradictions which may be neglected in the classical case.

The extra complication may actually be a gain in some contexts. Let me mention one possible one; this concerns quantum mechanics. Quantum mechanics is known to suffer from various phenomena often called 'causal anomalies', a famous one of which is the two-slit experiment.¹⁰⁴ In this, a

¹⁰⁴See, e.g., Haack [1974], ch. 8.

light is shone onto a screen through a mask with two slits. The intensity of light on any point on the screen is proportional to the probability that a photon hits it, σ , given that it goes through one slit, α , or goes through the other, β . Let us write $p(\alpha \vee \beta)$ as q . Then:

$$\begin{aligned} p(\sigma/(\alpha \vee \beta)) &= p(\sigma \wedge (\alpha \vee \beta))/p(\alpha \vee \beta) \\ &= p((\sigma \wedge \alpha) \vee (\sigma \wedge \beta))/q \\ &= p(\sigma \wedge \alpha)/q + p(\sigma \wedge \beta)/q - p(\sigma \wedge \alpha \wedge \beta)/q \end{aligned}$$

Classically, we know that $\neg(\alpha \wedge \beta)$, and so the last term may be ignored. For similar reasons, $q = p(\alpha \vee \beta) = p(\alpha) + p(\beta)$, and by symmetry we can arrange for $p(\alpha)$ and $p(\beta)$ to be equal. Hence:

$$\begin{aligned} p(\sigma/(\alpha \vee \beta)) &= p(\sigma \wedge \alpha)/2p(\alpha) + p(\sigma \wedge \beta)/2p(\beta) \\ &= \frac{1}{2}(p(\sigma/\alpha) + p(\sigma/\beta)) \end{aligned}$$

Thus, the intensity of light on the screen should be the average of the intensities of light going each slit independently (which can be determined by closing off the other). Exactly this is what is *not* found.

Standard quantum logic¹⁰⁵ avoids the result by rejecting the inference of distribution (i.e., the equivalence between $\sigma \wedge (\alpha \vee \beta)$ and $(\sigma \wedge \alpha) \vee (\sigma \wedge \beta)$), and so faulting the second line of the above proof. A paraconsistent solution is just to note that we cannot ignore the third term in the computation of $p(\sigma/(\alpha \vee \beta))$, even though we know that $\neg(\alpha \wedge \beta)$. In qualitative terms, what this means is that the photon has a non-zero probability of doing the impossible, and going through both slits simultaneously!

This application of paraconsistent probability theory to quantum mechanics is *highly* speculative. Whether it could be employed to resolve the other causal anomalies of quantum theory, let alone to predict the observations that are actually made, has not been investigated.¹⁰⁶

7.6 The Classical Recapture

Most paraconsistent logicians have supposed that reasoning in accordance with classical logic is sometimes legitimate. Most, for example, have taken it that classical logic is perfectly acceptable in consistent situations. They have therefore proposed ways in which classical logic can be “recaptured” from a paraconsistent perspective.

The simplest such recapture occurs in non-adjunctive logics. As we noted in 4.2, single premise non-adjunctive reasoning is classical. Hence, classical

¹⁰⁵See the article on this in the *Handbook*.

¹⁰⁶For more on the above issues, including the effects of paraconsistent probability theory on confirmation theory, see Priest [1987], sect. 7.6, and Priest *et al.* [1989], pp. 376-9, 385-8.

reasoning can be regained simply by conjoining all premises. A different strategy is to employ a consistency operator, as is done in the da Costa logics C_i , for finite non-zero i . As we saw in 5.3, this can be employed to define a negation which behaves classically; hence classical reasoning can simply be interpreted within the system. This approach has problems for some applications, as we shall see when we come to look at set theory.

Yet another way to recapture classical reasoning, provided that a conditional operator is available, is to employ an absurdity constant, \perp , satisfying the condition $\models \perp \rightarrow \alpha$, for all α . Such a constant makes perfectly good sense paraconsistently. Algebraically, it corresponds to the minimal value of an algebra (which can usually be added if it is not present already). In truth-preservation terms, there are two ways of handling its semantics. One is to require that \perp be untrue at every (world of every) evaluation. Its characteristic principle then holds vacuously. The other way (which may be preferable if one objects to vacuous reasoning) is simply to assign \perp (at a world) the value of the (infinitary) conjunction of all other formulas (at that world). A bit of juggling then usually verifies the characteristic principle. (The definition itself guarantees it only when α does not contain \perp .)

Now let C be the set of all formulas of the form $(\alpha \wedge \neg\alpha) \rightarrow \perp$. Then an inference is classically valid iff it is enthymematically valid with C as the set of suppressed premises, in most paraconsistent logics. For if every member of C holds at (a world of) an interpretation, then the (world of the) interpretation is a classical one—or at least the trivial one—and hence if the premises of a classically valid inference are true at it, so is the conclusion. Thus, we have an enthymematic recapture.

Let us write $\neg\alpha$ for $\alpha \rightarrow \perp$. In classical (and intuitionist) logic, $\neg\alpha$ just is $\neg\alpha$. It might therefore be thought that provided a logic possesses \perp , we could simply interpret classical logic in it by identifying $\neg\alpha$ with $\alpha \rightarrow \perp$. This thought would be incorrect, though. In many paraconsistent logics, $\neg\alpha$ behaves quite differently from classical (and intuitionist) negation. What properties it has depends, of course, on the properties of \rightarrow . While it will always be the case that $\alpha, \neg\alpha \models \beta$, it will certainly not be true in general that $\models \alpha \vee \neg\alpha$, that $\neg\neg\alpha \models \alpha$, or even that $\alpha \models \neg\neg\alpha$. As an example of the last, consider an intensional interpretation for the logic H . (See 5.5.) Suppose that p is true at some normal world, w , but that at some non-normal world $p \rightarrow \perp$ is true (and \perp is not). Then $(p \rightarrow \perp) \rightarrow \perp$ fails at w .¹⁰⁷

A final, and much less brute-force, way of recapturing classical logic starts from the idea that consistency is the norm. It is implicit in the paraconsistent enterprise that inconsistency can be contained. Instead of spreading everywhere, inconsistencies can exist isolated, as do singularities in a field

¹⁰⁷It might be thought that the existence of the explosive connective ‘ \perp ’ would cause problems for certain paraconsistent applications; notably, for example, for set theory. This is not the case, however, as we will see.

(of the kind found in physics, not agriculture). This metaphor suggests that even if inconsistencies are present they will be relatively rare. If it is *true* inconsistencies we are talking about, these will be even rarer—something that the classical logician can readily agree with!¹⁰⁸

This suggests that consistency should be a default assumption, in the sense of non-monotonic logic. Many non-monotonic logics can be formulated by defining validity over some class of models, minimal with respect to violation of the default condition. In effect, we consider only those interpretations that are no more profligate in the relevant way than the information necessitates. In the case where it is consistency that is the default condition, we may define validity over models that are minimally inconsistent in some sense. I will illustrate, as usual, with respect to LP .¹⁰⁹

Let $\mathcal{I} = \langle D, d \rangle$ be an LP interpretation. Let $\alpha \in \mathcal{I}!$ iff α is $Pd_1\dots d_n$, where P is an n -place predicate and $\langle d_1, \dots, d_n \rangle \in E_P \cap A_P$ in \mathcal{I} . (Recall that I am using members of the domain as names for themselves.) $\mathcal{I}!$ is a measure of the inconsistency of \mathcal{I} . In particular, \mathcal{I} is a classical interpretation iff $\mathcal{I}! = \phi$. If \mathcal{I}_1 and \mathcal{I}_2 are LP interpretations, I will write $\mathcal{I}_1 < \mathcal{I}_2$, and say that \mathcal{I}_1 is *more consistent than* \mathcal{I}_2 , iff $\mathcal{I}_1! \subset \mathcal{I}_2!$. (The containment here is proper.) \mathcal{I} is a *minimally inconsistent (mi) model* of Σ iff \mathcal{I} is a model of Σ iff \mathcal{I} is a model of Σ and if $\mathcal{J} < \mathcal{I}$, \mathcal{J} is not a model of Σ . Finally, α is an *mi consequence* of Σ ($\Sigma \models_m \alpha$) iff every mi model of Σ is a model of α .

As is to be expected, \models_m is non-monotonic. For if p and q are atomic sentences, it is easy to check that $\{p, \neg p \vee q\} \models_m q$, but $\{\neg p, p, \neg p \vee q\} \not\models_m q$. Moreover, since all classical models (if there are any) are mi models, and all mi models are models, it follows that $\Sigma \models \alpha \Rightarrow \Sigma \models_m \alpha \Rightarrow \Sigma \models_C \alpha$. The implications are, in general, not reversible. For the first, note that $\{p, \neg p \vee q\} \not\models q$; for the second, note that $\{p, \neg p\} \not\models_m q$. But if Σ is classically consistent, its mi models are exactly its classical models, and hence we have $\Sigma \models_m \alpha \Leftrightarrow \Sigma \models_C \alpha$: classical recapture.

\models_m has various other interesting properties. For example, it can be shown that if the LP consequences of some set is non-trivial, so are its mi consequences *Reassurance*. For details, see Priest [1991a].¹¹⁰

¹⁰⁸Though this is not so obvious once one accepts dialetheism. For a defence of the view given dialetheism, see Priest [1987], sect. 8.4.

¹⁰⁹Though the first paraconsistent logician to employ this strategy was Batens [1989], who employs a non-truth-functional logic. Batens also considers the dynamical aspects of such default reasoning.

¹¹⁰In that paper, in the definition of $<$, a clause stating that the domains of \mathcal{I}_∞ and \mathcal{I}_ϵ are the same is added. With this clause, the result concerning classical recapture is false (and that paper is mistaken). For example, if α is $\exists x Px \wedge \exists x \neg Px$, then $\langle D, d \rangle$ is an mi model, where $D = \{a\}$, $E_P = A_P = \{a\}$, though this is not a classical model. (This was first noted by Diderik Batens, in correspondence.) As $<$ is defined here, $\{\forall x(Px \wedge \neg Px)\} \models_m \exists x \forall yx = y$, which may be thought to be counter-intuitive. But if $\forall x(Px \wedge \neg Px)$ is *all* the information we have, and inconsistencies are to be minimised, perhaps it is correct to infer that there is just one thing. Note that $\{\forall x(Px \wedge \neg Px), \exists x Qx \wedge \exists x \neg Qx\} \not\models_m \exists x \forall yx = y$. For $\langle d, d \rangle$ is an mi model of the premises, where $D = \{a, b\}$, $E_P = A_P =$

8 SEMANTICS AND SET THEORY

The previous part gestured in the direction of various applications of paraconsistent logic. I want, in the next two parts, to look at some other applications in greater detail. These concern theories of particular mathematical significance. In this part I will deal with semantics and set theory.

Semantic and set-theoretic notions appear to be governed by simple and apparently obvious principles. In semantics, these concern truth, T , satisfaction, S , and denotation, D , and are:

$$\begin{aligned} T\text{-schema: } & T \langle \alpha \rangle \leftrightarrow \alpha \\ S\text{-schema: } & Sx \langle \beta \rangle \leftrightarrow \beta(y/x) \\ D\text{-schema: } & D \langle t \rangle x \leftrightarrow x = t \end{aligned}$$

where α is any sentence, β is any formula with one free variable, y , and t is any closed term. Angle brackets indicate a name-forming device. In set theory the principle is the schema of set existence:

$$\text{Comprehension Schema: } \exists x \forall y (y \in x \leftrightarrow \beta)$$

where β is *any* formula not containing x . What the connective \leftrightarrow is in the above schemas, we will have to come back to.

Despite the fact that these schemas appear to be obvious, they all give rise to contradictions, as is well known: the paradoxes of self-reference, such as (respectively) the Liar Paradox, the Heterological Paradox, Berry's Paradox and Russell's Paradox. The usual approaches to set theory and semantics restrict the principles in some way. Such approaches are all unsatisfactory in one way or another, though I shall not discuss this here.¹¹¹

A paraconsistent approach can simply leave the principles as they are, and allow the contradictions to arise. They need do no damage, because the logic is not explosive. Even so, not all paraconsistent logics are suitable as the underlying logics of these theories. For a start, if the above schemas are formulated with the material \equiv they give rise to a conjoined contradiction, so using a non-adjunctive logic (except Rescher and Manor's) explodes the theory.¹¹² And in the da Costa systems, C_i , for finite i , an operator behaving like classical negation, \neg^* can be defined (see 5.3). The usual arguments establish contradictions of the form $\alpha \wedge \neg^* \alpha$, and so again

$\{a, b\}, E_Q = \{a\}, A_Q = \{b\}$. With the present definition, the proof of Reassurance for the first-order case, appropriately modified, still goes through.

¹¹¹See, for example, Priest [1987], chs. 1, 2.

¹¹²Rescher and Brandom, [1980], p. 164, suggest splitting the biconditionals up into two non-conjoined conditionals.

the theories explode. Fortunately, there are other paraconsistent logics that will do the job.¹¹³

8.1 Truth Theory in LP

Let us start with the semantic case. I will deal with truth; similar remarks and constructions hold for the other semantic notions, but I will leave readers to ponder these for themselves. The first question we need to address is what connective it is that occurs in the biconditional of the T -schema. The first possibility is that it is a material biconditional, \equiv .¹¹⁴

Let us, then, suppose that we are dealing with the logic LP . We will need some machinery to handle self reference; a straightforward option is to let this be arithmetic. Hence, we suppose the language, L , to be that of first order arithmetic augmented by a one place predicate, T . To make things easy, we will assume that L has a function symbol for each primitive recursive function (and only those function symbols). Let T_0 be the LP theory in this language which comprises the truths of first order arithmetic plus the T -schema.

The assumption that T_0 contains all of arithmetic is obviously a very strong one, and means that the theory is not axiomatic. We could, instead, consider an axiomatic theory with some suitable fragment of arithmetic, but since a major part of our concern will be with what *cannot* be proved, it is useful to have the arithmetic part as strong as possible.

The first thing to note is that T_0 is inconsistent. Given the resources of arithmetic, for any formula, α , of one free variable, x , one can find, by the usual Gödel construction, a fixed-point formula, β , of the form $\alpha(x/\langle\beta\rangle)$.¹¹⁵ Now, let α be $\neg Tx$ and let β be its fixed point. Then the T -schema gives us: $T\langle\beta\rangle \equiv \beta$, i.e., $T\langle\beta\rangle \equiv \neg T\langle\beta\rangle$. Unpacking the definition of \equiv , in terms of \wedge , \vee , and \neg and fiddling, gives exactly $T\langle\beta\rangle \wedge \neg T\langle\beta\rangle$.¹¹⁶

Despite being inconsistent, T_0 is non-trivial. An easy way to see this is to observe, first of all, that if in any interpretation $\nu(\alpha) = \{1, 0\}$ then $\nu(\alpha \equiv \beta) = \{1, 0\}$. Hence, an LP model for T_0 can be obtained by letting the denotations of the arithmetic language be that of the standard interpretation of arithmetic—so that, in particular, the domain is N , the natural numbers; recall that classical interpretations are just special cases of LP

¹¹³There are paraconsistent set theories based on da Costa's C systems. (See, e.g., Arruda [1980], da Costa [1986].) In these theories, the schemas have to be constrained, as they are classically. This takes away much of the appeal of a paraconsistent approach.

¹¹⁴It is natural to suppose that it ought to be a detachable conditional. Goodship [1996] argues that it is only a material conditional. Whether or not this is the case, it is certainly interesting to explore the two possibilities.

¹¹⁵See, e.g., Priest [1987], sect. 3.5.

¹¹⁶It is worth noting that for the S -schema, the fixed point machinery is unnecessary for the demonstration of inconsistency. For let α be $\neg Sxx$. Then an instance of the S -schema is: $S\langle\alpha\rangle\langle\alpha\rangle \equiv \neg S\langle\alpha\rangle\langle\alpha\rangle$, and we can then proceed as before.

interpretations—and setting E_T and A_T , the extension and anti-extension of T , both to N . Call this interpretation \mathcal{I}_0 . In \mathcal{I}_0 every sentence of the form $T \langle \alpha \rangle$ takes the value $\{1, 0\}$, and so by the observation concerning \equiv , \mathcal{I}_0 is a model for the T -schema, and so of all of T_0 . The same interpretation shows that if α is any arithmetic formula false in the standard model, $T_0 \not\models \alpha$.

T_0 is a relatively weak theory. In particular, it does not legitimate the two way rule of inference:

$$\frac{\alpha}{T \langle \alpha \rangle}$$

(just consider the south-north inference in \mathcal{I}_0 , where α is an arithmetic sentence false in the standard model).¹¹⁷

Let the theory obtained by replacing the material T -schema of T_0 with this rule be called T_1 . T_1 is inconsistent. For choose an α of the form $\neg T \langle \alpha \rangle$. The law of excluded middle gives $T \langle \alpha \rangle \vee \neg T \langle \alpha \rangle$, i.e., $T \langle \alpha \rangle \vee \alpha$, which, applying the rule, gives $T \langle \alpha \rangle$ and α , i.e., $\neg T \langle \alpha \rangle$.

We can construct a model for T_1 as follows. If an interpretation assigns the standard denotations to all arithmetical language let us call it *arithmetical*. Any arithmetical interpretation is a model all of T_1 except, perhaps, the T -schema. Let \mathcal{I}_1 and \mathcal{I}_2 be two arithmetical interpretations, with assignment functions ν_1 and ν_2 . Define $\nu_1 \preceq \nu_2$ to mean that for all atomic sentences in the language, α :

$$\begin{aligned} \nu_1(\alpha) = t &\Rightarrow \nu_2(\alpha) = t \\ \nu_1(\alpha) = f &\Rightarrow \nu_2(\alpha) = f \end{aligned}$$

If $\nu_1 \preceq \nu_2$ then this condition extends to all formulas of L . For suppose that $\nu_1 \preceq \nu_2$. If n is in the extension of T in \mathcal{I}_2 but not \mathcal{I}_1 ; then $\nu_2(Tn) = t$ or b , but $\nu_1(Tn) = f$, violating the condition. Similarly for anti-extensions. Hence, $\mathcal{I}_2 \preceq \mathcal{I}_1$. By monotonicity, for all α , $\nu_2(\alpha) \subseteq \nu_1(\alpha)$. The conclusion follows. For suppose that $\nu_2(\alpha) \neq t$. Then α is false (i.e., b or f) in \mathcal{I}_2 ; hence α is false in \mathcal{I}_1 , i.e., $\nu_1(\alpha) \neq t$. The argument for f is similar.

This result is, in fact, just another version of monotonicity; I will call it the *Monotonicity Lemma*.

Let \mathcal{I}_0 be any arithmetical interpretation, with evaluation function ν_0 . We now define a transfinite sequence of arithmetical interpretations,

¹¹⁷Whether or not more follows with minimally inconsistent *LP* (see 7.6) is presently unknown. Another non-monotonic notion of inference also suggests itself here. According to this, the things that follow are the things that hold in all minimally inconsistent models where the arithmetic part is the standard model. Employing this would be appropriate if there were good reasons to believe that the only inconsistencies involve the truth predicate.

$\langle \mathcal{J}_i; i \in On \rangle$ (On is the class of ordinals). I will make the construction slightly more complex than necessary, for the benefits of the next section. It suffices to define the evaluation function ν_i of each interpretation. If $i > 0$ and n is not the code of a sentence, then $\nu_i(Tn) = \nu_0(Tn)$. We therefore need to consider only atomic formulas of the form $T \langle \alpha \rangle$. Let us say that α is *eventually t by k* iff $\exists i > 0 \forall j (i \leq j < k, \nu_j(\alpha) = t)$. Similarly for f . Then for $k \neq 0$:

$$\begin{aligned} \nu_k(T \langle \alpha \rangle) &= t && \text{if } \alpha \text{ is eventually } t \text{ by } k \\ &= f && \text{if } \alpha \text{ is eventually } f \text{ by } k \\ &= b && \text{otherwise} \end{aligned}$$

We can now establish that if $0 < i \leq k$ then $\nu_i \preceq \nu_k$. The proof is by transfinite induction. Suppose that the result holds for all $j < k$. We show it for k . Since the truth values of atomic formulas other than ones of the form $T \langle \alpha \rangle$ are constant, we need consider only these. So suppose that $\nu_i(T \langle \alpha \rangle) = t$. Then α is eventually t by i . In particular, for some $0 < j < i$, $\nu_j(\alpha) = t$. By induction hypothesis, for all l such that $j < l < k$, $\nu_j \preceq \nu_l$. Hence, by monotonicity $\nu_l(\alpha) = t$. Hence, α is eventually t by k , i.e., $\nu_k(T \langle \alpha \rangle) = t$. The case for f is similar.

What this lemma shows is that once $i > 0$, and increases, sentences of the form $T \langle \alpha \rangle$ can change their truth value at most once. If they ever attain a classical value, they keep it. Since there is only a countable number of sentences of this form, there must be an ordinal, l , by which all the formulas that change value have done so. Hence $\nu_l = \nu_{l+1}$. Call $\mathcal{J}_l, \mathcal{J}_*$; and its corresponding evaluation function ν^* . Then if $\nu^*(\alpha) = t$, $\nu^*(T \langle \alpha \rangle) = t$. Similarly for f and b . Hence $\nu^*(\alpha) = \nu^*(T \langle \alpha \rangle)$, and so \mathcal{J}_* is a model of T_1 . For the same reason, \mathcal{J}_* also verifies the two-way rule:

$$\frac{\neg \alpha}{\neg T \langle \alpha \rangle}$$

Yet the theory is not trivial: anything false in the standard model of arithmetic is untrue in \mathcal{J}_* , and so $T_1 \not\models \alpha$.

It is not difficult to see that the construction used to define \mathcal{J}_* is, in fact, just a dualised form of Kripke's fixed point construction for a logic with truth value gaps using the strong Kleene three-valued logic.¹¹⁸ (Provided we start with a suitable ground model, monotonicity is guaranteed from the beginning, and so we can just set $\nu_k(T \langle \alpha \rangle)$ to t (or f) if α takes the value t (or f) at some $i < k$.) Hence, if any sentence is *grounded* in Kripke's sense, it takes a classical value in \mathcal{J}_* . In particular, if α is any false grounded sentence, $T_1 \not\models \alpha$.

¹¹⁸See the article on Semantics and the Liar Paradox in this *Handbook*. One of the first people to realise that the construction could be dualised for this end was Dowden [1984].

8.2 Adding a Conditional

Although T_1 validates the two-way inferential T -schema, it does not validate the T -schema as formulated with a detachable conditional. This is for the simple reason that LP does not contain such a conditional. A natural thought is to augment the language with one to make this possible. Let the resulting language be L_{\rightarrow} . Not all conditionals are suitable here, however. This is due to Curry paradoxes. If the conditional satisfies the inference of contraction: $\alpha \rightarrow (\alpha \rightarrow \beta) \models \alpha \rightarrow \beta$, then the theory collapses into triviality. For consider the fixed-point formula, γ , of the form $T\langle\gamma\rangle \rightarrow \perp$ (or if \perp is not present, just an arbitrary β). The T -schema gives: $T\langle\gamma\rangle \leftrightarrow (T\langle\gamma\rangle \rightarrow \perp)$. Contraction gives us: $T\langle\gamma\rangle \rightarrow \perp$ and then a couple of applications of *modus ponens* give \perp .¹¹⁹

This fact rules out the use of all the non-transitive logics we looked at (since they validate $\alpha \leftrightarrow (\alpha \rightarrow \beta) \models \beta$), all the da Costa logics and discussive logic (using discussive implication for the T -schema), since these validate contraction, and those relevance logics that validate contraction, such as R .¹²⁰ A relevant logic without contraction can be used for the purpose.

Let T_2 be as for T_0 , except that the T -schema is formulated with \rightarrow , and the underlying logic is BX (see 5.5, 6.5). T_2 is inconsistent, since it is obviously stronger than T_1 . But it can be shown to be non-trivial. If we try to generalise the proof for T_1 in simple ways, attempts are stymied by the failure of anything like monotonicity once \rightarrow is involved. However, there is a way of building on the proof.¹²¹ This requires us to move from objectual semantics to simple evaluational semantics. For the purpose of this section (and this one only), an atomic formula will be any of the usual kind *or* any one of the form $\alpha \rightarrow \beta$. Clearly, any sentence of the language can be built up from atomic formulas using \wedge , \vee , \neg , \exists and \forall . Call an evaluation of atomic formulas, ν , *arithmetical* if it assigns to every identity its value in the standard model of arithmetic. Given an arithmetical evaluation, it is extended to an evaluation of all sentences by LP truth conditions, using substitutional quantification.

A quick induction shows that any arithmetical evaluation assigns t to all the arithmetic truths of the standard model (which do not contain \rightarrow or T), and f to all the falsehoods. Moreover, for this notion of valuation, we do have the Monotonicity Lemma. Finally, given any such evaluation, we

¹¹⁹An argument of this kind first appeared in Curry [1942]. Different versions that employ close relatives of contraction, such as $\vdash (\alpha \wedge (\alpha \rightarrow \beta)) \rightarrow \beta$ (but *not* $\alpha \wedge (\alpha \rightarrow \beta) \vdash \beta$) can also be found in the literature. See, e.g., Meyer *et al.* [1979].

¹²⁰For good measure, it also rules out using Rescher and Manor's non-adjunctive approach. Using this, every consistent sentence would follow, since if β is consistent, so is $\alpha \leftrightarrow (\alpha \rightarrow \beta)$.

¹²¹The following is taken from Priest [1991b], which simply modifies Brady's proof for set theory in [1989].

can construct a fixed point, ν^* , such that $\nu^*(\alpha) = \nu^*(T \langle \alpha \rangle)$, as in 8.1. The construction is the same, except that in the definition of ν_k , we set Ts to t if s is a (closed) term that evaluates to the code of α , and α is eventually t by k . Similarly for f . (The values of atoms of the form $\alpha \rightarrow \beta$ do not change in the process.)

An induction shows that if $\mu \preceq \nu$ then for all i , $\mu_i \preceq \nu_i$. Suppose the result for all $i < k$. We show it for k . We need consider only those atomic formulas of the form Ts where s evaluates to the code of sentence α . $\mu_k(Ts) = t$ iff α is eventually t by k , for μ . By induction hypothesis, this implies that α is eventually t by k for ν . Hence, $\nu_k(Ts) = t$, as required. The case for f is similar. From this result it obviously follows that if $\mu \preceq \nu$ then $\mu^* \preceq \nu^*$.

Let \Rightarrow be the conditional connective of *RM3* (see 5.4, identifying $+1$, 0 , and -1 with t , b , and f , respectively). This also plays a role in the proof. Its relevant property is that if $\mu \preceq \nu$ then if α and β are formulas of L_{\rightarrow} and $\mu(\alpha \Rightarrow \beta) = t$, $\nu(\alpha \Rightarrow \beta) = t$. For if $\mu(\alpha \Rightarrow \beta) = t$ then $\mu(\alpha) = f$ or $\mu(\beta) = t$. By monotonicity $\nu(\alpha) = f$ or $\nu(\beta) = t$. Hence, $\nu(\alpha \Rightarrow \beta) = t$.

Let ν_0 be the arithmetical interpretation that assigns every sentence of the form Ts the value b . We now define a transfinite sequence of arithmetic valuations, $\langle \nu_i; i \in On \rangle$, as follows. (I write $(\nu_j)^*$ as ν_j^* .) For $k \neq 0$:

$$\begin{aligned} \nu_k(\alpha \rightarrow \beta) &= t && \text{if } \forall j < k, \nu_j^*(\alpha \Rightarrow \beta) = t \\ &= f && \text{if } \exists j < k, \nu_j^*(\alpha \Rightarrow \beta) = f \\ &= b && \text{otherwise} \end{aligned}$$

And where α is of the form Ts , where s is any closed term which evaluates to the code of a sentence:

$$\begin{aligned} \nu_k(\alpha) &= t && \text{if } \exists i \forall j (i \leq j < k, \nu_j^*(\alpha) = t) \\ &= f && \text{if } \exists i \forall j (i \leq j < k, \nu_j^*(\alpha) = f) \\ &= b && \text{otherwise} \end{aligned}$$

We can now establish that if $i \leq k$ then $\nu_i \preceq \nu_k$. The proof is by transfinite induction. Suppose that the result holds for all $j < k$. We need to consider cases where a formula is of the form $\alpha \rightarrow \beta$ or Ts , where s is a term that evaluates to the code of a sentence. Take them in that order.

Suppose that $\nu_i(\alpha \rightarrow \beta) = t$. Then $\nu_0^*(\alpha \Rightarrow \beta) = t$. By induction hypothesis, for $0 < j < k$, $\nu_0 \preceq \nu_j$. Thus, $\nu_0^* \preceq \nu_j^*$. Hence, $\nu_j^*(\alpha \Rightarrow \beta) = t$, by the observation concerning \Rightarrow . Thus, $\nu_k(\alpha \rightarrow \beta) = t$, as required. The case for f is trivial.

For the other case, suppose that $\nu_i(\alpha) = t$. Then $\exists j < i$, $\nu_j^*(\alpha) = t$. By induction hypothesis, if $j \leq l < k$, $\nu_j \preceq \nu_l$, and hence $\nu_j^* \preceq \nu_l^*$. By monotonicity, $\nu_l^*(\alpha) = t$. Thus, $\nu_k(\alpha) = t$. The case for f is similar.

What this lemma shows, as before, is that we must eventually reach an l such that $\nu_l = \nu_{l+1}$. Let this evaluation be $\vec{\nu}$. Then $\vec{\nu}$ is a model of all the extensional arithmetic apparatus. It also models the T -schema. For if $i < l$, $\nu_i^*(\alpha) = \nu_i^*(T \langle \alpha \rangle)$, and so $\nu_i^*(\alpha \leftrightarrow T \langle \alpha \rangle) = t$ or b , and $\vec{\nu}(\alpha \leftrightarrow T \langle \alpha \rangle) = t$ or b . (For the same reason, $\vec{\nu}$ models the contraposed form: $\neg\alpha \leftrightarrow \neg T \langle \alpha \rangle$. Since $T \langle \neg\alpha \rangle \leftrightarrow \neg\alpha$ is an instance of the T -schema, it also models $T \langle \neg\alpha \rangle \leftrightarrow \neg T \langle \alpha \rangle$.)

It remains to check that $\vec{\nu}$ models the axioms and respects the rules of inference of BX . This requires no little checking. Most of it is routine. Here, for example, is one of the harder propositional axioms: $((\alpha \rightarrow \beta) \wedge (\alpha \rightarrow \gamma)) \rightarrow (\alpha \rightarrow ((\beta \wedge \gamma)))$. Let the antecedent be φ , and the consequent be ψ . Then $\vec{\nu}(\varphi \rightarrow \psi) = t$ or b iff for no $i < l$, $\nu_i^*(\varphi \Rightarrow \psi) = f$. Now, suppose that $\nu_i^*(\varphi \Rightarrow \psi) = f$. Then one of:

$$\begin{aligned} \nu_i^*(\varphi) = t \text{ and } (\nu_i^*(\psi) = b \text{ or } \nu_i^*(\psi) = f) \\ \nu_i^*(\varphi) = b \text{ and } \nu_i^*(\psi) = f \end{aligned}$$

In the first case, $\nu_i(\alpha \rightarrow \beta) = \nu_i(\alpha \rightarrow \gamma) = t$. But then for all $j < i$, $\nu_j^*(\alpha \Rightarrow \beta) = \nu_j^*(\alpha \Rightarrow \gamma) = t$, in which case $\nu_j^*(\alpha \Rightarrow (\beta \wedge \gamma)) = t$, and so $\nu_i(\alpha \rightarrow (\beta \wedge \gamma)) = t$, which is impossible. In the second case, $\nu_i(\alpha \rightarrow \beta) = t$ or b , and $\nu_i(\alpha \rightarrow \gamma) = t$ or b . But then for all $j < i$, $\nu_j^*(\alpha \Rightarrow \beta) = t$ or b , and $\nu_j^*(\alpha \Rightarrow \gamma) = t$ or b , in which case $\nu_j^*(\alpha \Rightarrow (\beta \wedge \gamma)) = t$ or b , and so $\nu_i(\alpha \rightarrow ((\beta \wedge \gamma))) = t$ or b , which is also impossible.

For further details, see Brady [1989].¹²² The construction shows that T_1 is non-trivial, since if α is any arithmetic sentence false in the standard model $\vec{\nu}(\alpha) = f$. (Indeed, as with the previous construction, which is incorporated in this, if α is any false grounded sentence, the same is true.)

8.3 Advantages of a Paraconsistent Approach

What we have seen is that it is possible to have a theory containing all the machinery of arithmetic, plus a truth predicate which satisfies the T -schema for every sentence of the language—whether this is formulated as a material biconditional, a two-way rule of inference, or a detachable bi-conditional. It is inconsistent, but non-trivial; in fact, the inconsistencies do not spread

¹²²Brady shows that the construction verifies propositional logics that are a good deal stronger than BX . His treatment of identity is different, though. To verify the substitutivity rule of 7.1, it suffices to show that if $t_1 = t_2$ holds in an interpretation then $\alpha(x/t_1)$ and $\alpha(x/t_2)$ have the same truth value. A quick induction shows that if this is true for atomic α it is true for all α . Hence, we need consider only these. Next, show by induction that if this holds for ν it holds for all evaluations in the construction of ν^* , and so of ν^* itself. Finally, we show by induction that it holds for every ν_i in the hierarchy, and hence for $\vec{\nu}$.

into the arithmetic machinery.¹²³ Thus, it is possible to have a workable, if inconsistent, theory which respects the central intuition about truth.

It is not my aim here to discuss the shortcomings of other standard approaches to the theory of truth,¹²⁴ but none can match this. All restrict the T -schema in one way or another. The one that comes closest to having the full T -schema is Kripke's account of truth, which at least has it in the form of a two way rule of inference. However, this account has the singular misfortune of being self-referentially inconsistent. According to this account, if α is the Liar sentence it is *neither* true nor false, and so not true, but the theory pronounces $\neg T \langle \alpha \rangle$ itself neither true nor false. According to T_2 , α is *both* true and false (i.e., has a true negation), and this is exactly what it proves: $T \langle \alpha \rangle \wedge \neg T \langle \alpha \rangle$ entails $T \langle \alpha \rangle \wedge T \langle \neg \alpha \rangle$. It might also show that α is *not* true (and so not both true and false). But paraconsistency shows you exactly how to live with this kind of contradiction.

This is not unconnected with the matter of "strengthened" paradoxes. If someone holds the Liar sentence to be neither true nor false, one can invite them to consider the sentence, β , 'This sentence is not true' (as opposed to false). Whether β is true, false or neither, a contradiction arises. It is sometimes suggested that a paraconsistent account of truth falls to the same problem, since β can have no consistent truth-value on this account either. It should be clear that this argument is just an *ignoratio*. A paraconsistent account does not *require* it to have a consistent truth-value. In fact, according to T_2 , $T \langle \neg \alpha \rangle \leftrightarrow \neg T \langle \alpha \rangle$; if this is right, there is no distinction between the standard Liar and the "strengthened Liar" at all.¹²⁵

Let me finish with a word of caution. We can construct non-trivial theories which incorporate the S -schema of satisfaction and the D -schema of denotation, in exactly the same way as we did the T -schema. If, however, we try to add descriptions to a theory with self-reference and the D -schema, trouble does arise.

Suppose that we have a description operator, ε , satisfying the Hilbertian principle: $\exists x \alpha \vdash \alpha(x/\varepsilon x \alpha)$. If t is any closed term, $t = t$, and so by the D -schema $D \langle t \rangle t$, and $\exists x D \langle t \rangle x$. Thus, by the description principle, $D \langle t \rangle \varepsilon x D \langle t \rangle x$, whence, by the D -schema again:

$$t = \varepsilon x D \langle t \rangle x$$

¹²³Nor does the T -schema have to be taken as axiomatic. One can give truth conditions for atomic sentences and then prove the T -schema in the usual Tarskian fashion. See Priest [1987], ch. 7.

¹²⁴For this, see Priest [1987], ch. 2.

¹²⁵The advantages of a paraconsistent account of truth rub off onto any account of modal (deontic, doxastic, etc.) operators that treats them as predicates. For all such theories are just sub-theories of the theory of truth. See Priest [1991b]. We will have an application of this concerning provability in 9.6.

Now in arithmetic, just as for any formula, α , with one free variable, x , we can find a sentence, β , of the form $\alpha(x/\langle\beta\rangle)$, so, for any term, t , with one free variable, x , we can find a closed term, s , such that s is $t(x/\langle s\rangle)$. If f is any one place function symbol, apply this fact to the term $f\varepsilon yDxy$, to obtain an s such that:

$$s = f\varepsilon yD\langle s\rangle y$$

Since $s = \varepsilon yD\langle s\rangle y$, it follows that $s = fs$: any function has a fixed point. This shows that the semantic machinery does have purely arithmetic consequences. In particular, for example, $\exists x x = x + 1$. Arithmetic statements like this can be kept under control, as we will see later in the next part, but worse is to come.

Let f be the parity function, i.e.:

$$\begin{aligned} fx &= 0 && \text{if } x \text{ is odd} \\ &= 1 && \text{if } x \text{ is even} \end{aligned}$$

We have $fs = 0 \vee fs = 1$. In the first case $s = fs = 0$, which is even, and so $fs = 1$. Thus, $0 = 1$. Similarly in the second case. This is unacceptable, even for someone who supposes that there are *some* inconsistent numbers.

Where to point the finger of suspicion is obvious enough. As we saw, the D -schema entails $\exists xD\langle t\rangle x$, for any closed term, t ; and there is no reason why someone who subscribes to a paraconsistent account of semantic notions must believe that every term has a denotation: in particular, in the vernacular, ‘ s ’ is ‘a number that is 1 if it is even and 0 if it is odd’, which would certainly seem to have no denotation. This suggests that the D -schema should be subjected to the condition that $\exists xD\langle t\rangle x$ in some suitable way. The behaviour of resulting theories is a particularly interesting unsolved problem.¹²⁶

8.4 Set Theory in LP

Let us now turn to the second theory that we will look at, set theory. This is a theory of sets governed by the full Comprehension schema. This schema is structurally very similar to the T -schema, and many of the considerations of previous subsections carry over to set theory in a straightforward manner. The major element of novelty concerns the other axiom, the Extensionality axiom.

Let us start with set theory in LP . The language here contains just the predicates $=$ and \in , and the axioms are:

¹²⁶For a further discussion of all of these issues, see Priest [1997a].

$$\begin{aligned} &\exists x \forall y (y \in x \equiv \alpha) \\ &\forall x (x \in y \equiv x \in z) \supset y = z \end{aligned}$$

where x does not occur free in α . Call this theory S_0 . S_0 is inconsistent. For putting $y \notin y$ for α , and instantiating the quantifier we get: $\forall y (y \in r \equiv y \notin y)$, whence $r \in r \equiv r \notin r$. Cashing out \supset in terms of \neg and \vee gives $r \in r \wedge r \notin r$.

In constructing models of S_0 , the following observation (due to Restall [1992]) is a useful one. First some definitions. Given two vectors of LP values, $(g_m; m \in D)$, $(h_m; m \in D)$, the first *subsumes* the second iff for all $m \in D$, $g_m \supseteq h_m$. Now consider a matrix of such values $(e_{m,n}; m, n \in D)$. This is said to *cover* the vector $(g_m; m \in D)$ iff for some $n \in D$, the vector $(e_{m,n}; m \in D)$ subsumes it. A vector indexed by D is *classical* iff all its members are t or f . (Recall that we are writing $\{1\}$, $\{1, 0\}$, $\{0\}$ as t , b , f , respectively.)

Now the observation. Consider an LP interpretation, $\langle D, d \rangle$, and the matrix $(e_{m,n}; m, n \in D)$, where $e_{m,n} = \nu(m \in n)$. If this covers every classical vector indexed by D it verifies the Comprehension principle. For let α be any formula not containing x , and consider the vector $(\nu(\alpha(y/m)); m \in D)$. This certainly subsumes some classical vector; choose one such, and let this be subsumed by $(e_{m,n}; m \in D)$. Now consider any formula of the form $m \in n \equiv \alpha(y/m)$. Where the two sides differ in value, one of them has the value b . Hence, the value of the biconditional is either t or b . Thus the same is true of $\forall y (y \in n \equiv \alpha)$, and $\exists x \forall y (y \in x \equiv \alpha)$.

Using this fact, it is easy to construct models for S_0 . Consider an LP interpretation, $\langle D, d \rangle$, where $D = \{m, n\}$, and $e_{m,n}$ is given by the following matrix:

\in	m	n
m	b	t
n	b	t

Each column is the membership vector of the appropriate member of D ; and since that of m subsumes every classical vector indexed by D , this verifies the Comprehension axiom. In the Extensionality axiom, if y and z are the same, the axiom is obviously true. If they are distinct, one is n and the other is m , and for each x , the value of $x \in n \equiv x \in m$ is b . Hence, $\forall x (x \in n \equiv x \in m)$ has the value b and Extensionality is verified. In this model, $m \notin n$ and $n \notin n$ have the value f , as, therefore do $\exists y y \notin n$ and $\forall x \exists y y \notin x$. Hence, S_0 is non-trivial.

A characterisation of what can be proved in S_0 (and of what its minimally inconsistent consequences are) is still an open question. There are, however, certainly theorems of Zermelo Fraenkel set theory, ZF , that are not provable

in S_0 . For example, in ZF there is provably no universal set: $ZF \vdash \forall x \exists y y \notin x$. But this is not a consequence of S_0 , as we have just seen.¹²⁷

The simple model of S_0 that we have just used to prove non-triviality is obviously pathological in some sense. An interesting question is what the “intended” interpretations of S_0 are like. Whilst unable to give an answer to this, I note that for any classical model of ZF , $\mathcal{M} = \langle D, d \rangle$, there is a model of S_0 which has \mathcal{M} as a substructure. Let a be some new object, let $\mathcal{M}^+ = \langle D^+, d^+ \rangle$, where $D^+ = D \cup \{a\}$, d^+ is the same as d , except that for every $c \in D^+$, the value of $c \in a$ is b ; for every $c \in D$, the value of $a \in c$ is f ; the value of $a = a$ is t ; and for every $c \in D$, the value of $a = c$ is f . \mathcal{M} is clearly a substructure of \mathcal{M}^+ . The membership vector of a subsumes every classical vector, and hence \mathcal{M} is a model of Comprehension.

It remains to verify Extensionality: $\forall x(x \in m \equiv x \in n) \supset m = n$. If m and n are the same in \mathcal{M}^+ , then the consequent is true, as is the conditional. So suppose that they are distinct. If they are both in D , then, by extensionality in \mathcal{M} , there is some $c \in D$ such that $c \in m$ is t and $c \in n$ is f , or vice versa. Whichever of these is the case, $c \in m \equiv c \in n$ is f , as is $\forall x(x \in m \equiv x \in n)$. Hence the conditional is t . Finally, suppose that $m \in D$ and n is a (or vice versa, which is similar). Then if $c \in D^+$, every sentence of the form $c \in n$ is b . Hence, every sentence of the form $c \in m \equiv c \in n$ is b , as therefore is $\forall x(x \in n \equiv x \in m)$. Hence, the conditional is true.

8.5 Brady’s Non-triviality Proof

As a working set theory, S_0 is rather weak. Since the Comprehension axiom is only a material one, we cannot infer that something is in a set from the fact that it satisfies its defining condition, and vice versa. This suggests strengthening the principle to a two-way rule of inference, as we did for truth theory. This, in turn, requires the addition of set abstracts to the language. So let us enrich the language with terms of the form $\{x; \alpha\}$ for any variable, x , and formula, α ; and trade in the Comprehension principle of S_0 for the two-way rule:

$$\frac{x \in \{y; \alpha\}}{\alpha(y/x)}$$

Call this theory S_1 . S_1 is inconsistent. For let r be $\{x; x \notin x\}$. Then:

$$\frac{r \in r}{r \notin r}$$

The law of excluded middle then quickly gives us $r \in r \wedge r \notin r$.

¹²⁷For this, and some further observations in this direction, see Restall [1992].

The non-triviality of S_1 is presently an open question. But even though it is probably non-trivial, as a working set theory, it is still rather weak. This is because we have no useful way of establishing that two sets are identical. Even if we can show that $\forall x(\alpha \equiv \beta)$, and so that $\forall x(x \in \{x; \alpha\} \equiv x \in \{x; \beta\})$, we cannot infer that $\{x; \alpha\} = \{x; \beta\}$ since Extensionality does not support a detachable inference.

We might hope to circumvent this problem by trading in the Extensionality principle for the corresponding rule:

$$\frac{\forall x(\alpha \equiv \beta)}{\{x; \alpha\} = \{x; \beta\}}$$

But if we do this, trouble arises.¹²⁸ For let r be as before. Then since $r \in r$ must take the value b in any interpretation, we have, for any α , $\forall x(\alpha \equiv r \in r)$, and so $\{x; \alpha\} = \{x; r \in r\}$. Thus, for any α and β , $\{x; \alpha\} = \{x; \beta\}$; which is rather too much.

The problem arises because the Extensionality rule of inference allows us to move from an equivalence that does not guarantee substitution ($\alpha \equiv \beta, \beta \equiv \gamma \not\vdash_{LP} \alpha \equiv \gamma$) to one that does (identity). This suggests formulating Extensionality itself with a connective that legitimises substitution. So let us add a detachable connective to the language, \leftrightarrow , and formulate Extensionality as:

$$\frac{\forall x(\alpha \leftrightarrow \beta)}{\{x; \alpha\} = \{x; \beta\}}$$

The trouble then disappears.

And now that we have a detachable conditional connective at our disposal, it is natural to formulate the Comprehension principle as a detachable biconditional, as follows:

$$\forall y(y \in \{x; \alpha\} \leftrightarrow \alpha(x/y))$$

We have to be careful about the conditional connective here. As with truth, any conditional connective that satisfies contraction would give rise to triviality. For let c be $\{x \in x \rightarrow \perp\}$. Then an instance of Comprehension is $y \in c \leftrightarrow (y \in y \rightarrow \perp)$. Instantiating with c , we get $c \in c \leftrightarrow (c \in c \rightarrow \perp)$, and we can then proceed, as with truth, to obtain \perp . Even if the logic does not contain contraction, Curry-style paradoxes may still be forthcoming. For example, if we drop the contraction axiom from the relevant logic R

¹²⁸There are other cases where the full Comprehension principle by itself is alright, but throwing in extensionality causes problems; for example, set theory based on Łukasiewicz' continuum-valued logic. See White [1979].

and add the law of excluded middle, the Comprehension principle still gives triviality.¹²⁹ Again however, a relevant logic without contraction will do the job.

Consider the set theory with Extensionality and Comprehension formulated as just described, and based on the underlying logic BX (with free variables, so that these may occur in the schematic letters of Extensionality and Comprehension). Call this S_2 . The first thing to note about S_2 is that identity can be defined in it, in Russellian fashion. Writing $x = y$ for $\forall z(x \in z \leftrightarrow y \in z)$, $x = x$ follows. Substituting $\{w; \alpha\}$ for z , and using the Comprehension principle gives $\alpha(w/x) \leftrightarrow \alpha(w/y)$. Hence, we need no longer assume that $=$ is part of the language.

Since the Comprehension principle of S_2 gives the two-way deduction version of S_1 , S_2 is inconsistent. It is also demonstrably non-trivial, as shown by Brady [1989].¹³⁰ To prove this, we repeat the proof for T_2 of 8.2 with three modifications. The first, a minor one, is that we add two propositional constants t and f to the language; their truth values are always what the letters suggest. (This is necessary to kick-start the generation of the fixed point into motion. In the case of truth, this was done by the arithmetic sentences.) More substantially, in constructing ν^* we replace the clause for T by:

$$\begin{aligned} \nu_k(s \in \{x; \alpha\}) &= t && \text{if } \alpha(x/s) \text{ is eventually } t \text{ by } k \\ &= f && \text{if } \alpha(x/s) \text{ is eventually } f \text{ by } k \\ &= b && \text{otherwise} \end{aligned}$$

where s is any closed term, and α contains at most x free. The final modification is that in extending evaluations to all formulas, we use substitutional quantification with respect to the closed set abstracts.

Now, $\vec{\nu}$ verifies all the theorems of S_2 , in the sense that if α is any closed substitution instance of a theorem, it receives the value t or b in $\vec{\nu}$. This is shown by an induction on the length of proofs. That the logical axioms have this property, and the logical rules of inference preserve this property, is shown as in 8.2. This leaves the set theoretic ones.

Given the construction of $\vec{\nu}$, it is not difficult to see that it verifies the Comprehension principle. It is not at all obvious that Extensionality preserves verification. What needs to be shown is that if $\forall x(\alpha \leftrightarrow \beta)$ is verified, so is anything of the form $a \in c \leftrightarrow b \in c$, where a is $\{x; \alpha\}$ and b is $\{x; \beta\}$. Let c be $\{y; \gamma\}$. Then, given Comprehension, what needs to be shown is that $\gamma(y/a) \leftrightarrow \gamma(y/b)$ is verified. If this can be shown for atomic γ , the result will follow by induction. Given the premise of the inference and Comprehension, it is true if γ is of the form $d \in y$. If it is of the form $y \in d$, where

¹²⁹See Slaney [1989]. Other classical principles are also known to give rise to triviality in conjunction with the Comprehension schema. See Bunder [1986].

¹³⁰A modification of the proof shows that the theory based on the logic B is, in fact, consistent. See Brady [1983].

d is $\{z; \delta\}$, we need to show that $\delta(z/a) \leftrightarrow \delta(z/b)$ is verified. We obviously have a regress. In fact, the regression grounds out in a suitable way in the construction of \vec{v} . For details, see Brady [1989].¹³¹

The non-triviality of S_2 is established since there are many sentences that are not verified by \vec{v} . It is easy to check, for example, that any sentence of the form $c \in \{x; f\}$ takes the value f , as, therefore, does the formula $\forall x \exists y y \in x$.

A notable feature of Brady's proof is the following. As formulated, the Comprehension principle entails: $\exists y \forall x (x \in y \leftrightarrow \alpha)$, where y does not occur in α . (The y in question is $\{x; \alpha\}$ and so cannot be a subformula of α .) If we relax the restriction, we get an absolutely unrestricted version of the principle. Brady's proof can be extended to verify this version too, by adding a fixed point operator to the language, and treating it suitably. Again, for details, see Brady [1989].

Finally, it is worth observing that the T -schema is interpretable in S_2 . If α is any closed formula, let us write $\langle \alpha \rangle$ for $\{z; \alpha\}$, where z is some fixed variable. Define Tx to be $a \in x$, where a is any fixed term. Then $T \langle \alpha \rangle = a \in \{z; \alpha\} \leftrightarrow \alpha$. Moreover, the absolutely unrestricted Comprehension principle gives us fixed points of the kind required for self-reference. Let α be any formula of one free variable, x . By the principle, there is a set, s , such that $\forall x (x \in s \leftrightarrow \alpha(x/\{z; a \in s\}))$. It follows that $a \in s \leftrightarrow \alpha(x/\{z; a \in s\})$. Thus, if β is $a \in s$, we have $\beta \leftrightarrow \alpha(x/\langle \beta \rangle)$. S_2 (with the absolutely unrestricted Comprehension principle) therefore gives us a demonstrably non-trivial *joint* theory of truth, sethood and self-reference.

8.6 Paraconsistent Set Theory

Despite the strong structural similarities between semantics and set theory, there is an important historical difference. Set theory is a well developed mathematical theory in a way that semantics is not. In the case of set theory, it is therefore natural to ask how a paraconsistent theory such as S_2 relates to this development.

To answer this question (at least to the extent that the answer is known), it will be useful to divide set theory into three parts. The first comprises that basic set-theory which all branches of mathematics use as a tool. The second is transfinite set theory, as it can be established in ZF . The third

¹³¹ Brady's treatment of identity is slightly different from the one given here. He defines $x = y$ as $\forall z (z \in x \leftrightarrow z \in y)$. Given Comprehension, this delivers the version of Extensionality used here straight away. What is lost is the substitution principle $x = y, \alpha(w/x) \vdash \alpha(w/y)$. Given the Comprehension principle, this can be reduced to $x = y, x \in z \vdash y \in z$ (which follows from our definition of identity). Brady takes something stronger than this as his substitutivity axiom: $\vdash (x = y \wedge z = z) \rightarrow (x \in z \leftrightarrow y \in z)$. Hence, his construction certainly verifies the weaker principle. It is worth noting that the construction does not validate the simpler $\vdash x = y \rightarrow (x \in z \leftrightarrow y \in z)$, which, in any case, is known to be a Destroyer of Relevance. See Routley [1980b], sect. 7.

concerns results about sets, like Russell's set and the universal set, that do not exist in ZF . Let us take these matters in turn.

S_2 is able to provide for virtually all of bread-and-butter set theory (Boolean operations on sets, power sets, products, functions, operations on functions, etc.), and so provide for the needs of working mathematics.¹³² For example, if we define the Boolean operators, $x \cap y$, $x \cup y$ and \bar{x} as $\{z; z \in x \wedge z \in y\}$, $\{z; z \in x \vee z \in y\}$ and $\{z; z \notin x\}$, respectively, and $x \subseteq y$ as $\forall z(z \in x \rightarrow z \in y)$, then we can establish the usual facts concerning these notions. Some care needs to be taken over defining a universal set, U , and empty set, ϕ , though. If we define ϕ , as $\{x; x \neq x\}$, we cannot show that for all y , $\phi \subseteq y$, since the underlying logic is relevant and cannot prove $x \neq x \rightarrow \alpha$ for arbitrary α . (Dually for U .) If we define ϕ as $\{x; \forall z x \in z\}$, this problem is solved, since $\forall z x \in z \rightarrow x \in y$. (Dually for U .)

The reason for the qualification 'virtually' in the first sentence of the last paragraph, is as follows. The sets, as structured by union, intersection and complementation, are not a Boolean algebra, but a De Morgan algebra with maximum and minimum elements. Though we can show that $\forall y y \notin x \cap \bar{x}$, we cannot show that $x \cap \bar{x} \subseteq \phi$, since, relevantly, $(\alpha \wedge \neg\alpha) \rightarrow \beta$ fails. (Dually for U .) There are, in a sense, more than one universal and empty sets. Moreover, this is essential. If we had $x \cap \bar{x} \subseteq \phi$ then, taking $\{z; \alpha\}$ for x , we get $(\alpha \wedge \neg\alpha) \rightarrow \forall y z \in y$. Now take $\{z; \beta\}$ for y , and we get $(\alpha \wedge \neg\alpha) \rightarrow \beta$; paraconsistency fails. In fact, Dunn [1988] shows that if the principles that there is a unique universal set, and a unique empty set, are added to any set theory such as S_2 , full classical logic falls out.

Turning to the second area, the question of how much of the usual transfinite set theory can be established in S_2 is one to which the answer is currently unknown. What can be said is that the *standard* proofs of a number of results break down. This is particularly the case for results that are proved by *reductio*, such as Cantor's Theorem. Where α is an assumption made for the purpose of *reductio*, we may well be able to establish that $(\alpha \wedge \beta) \rightarrow (\gamma \wedge \neg\gamma)$, for some γ , where β is the conjunction of other facts appealed to in deducing the contradiction (such as instances of the Comprehension principle). But contraposing and detaching will give us only $\neg\alpha \vee \neg\beta$, and we can get no further.¹³³

Lastly, the third area: reasoning in S_2 , one can prove various results about sets that are impossible in ZF . For example, as usual, let $\{x\}$ be $\{y; y = x\}$, $\{x, y\}$ be $\{x\} \cup \{y\}$ and $\bigcup x$ be $\{z; \exists y \in x, z \in y\}$. $r = \{x; x \notin x\}$, and we know that $r \in r$ and $r \notin r$. Then:¹³⁴

- (1) If $x \in r$ then $\{x\} \in r$. For $\{x\} \in \{x\}$ or $\{x\} \notin \{x\}$. In the first case,

¹³²Much of this is spelled out in Routley [1980b], sect. 8.

¹³³Interesting enough, however, it is possible to prove a version of the Axiom of Choice using the completely unrestricted version of the Comprehension principle. See Routley [1980b], sect. 8.

¹³⁴The following is taken from Arruda and Batens [1982].

$\{x\} = x$, and so $\{x\} \in r$. In the second case, $\{x\} \in r$ by definition.

(2) If $x, y \in r$ then $\{x, y\} \in r$. For $\{x, y\} \in \{x, y\}$ or $\{x, y\} \notin \{x, y\}$. In the first case, $\{x, y\} = x$ or $\{x, y\} = y$, and so $\{x, y\} \in r$. In the second case, $\{x, y\} \in r$ by definition.

(3) $\{\{x, r\}\} \in r$. For $\{\{x, r\}\} \in \{\{x, r\}\}$ or $\{\{x, r\}\} \notin \{\{x, r\}\}$. In the first case, $\{\{x, r\}\} = \{x, r\}$, hence, $x = \{x, r\} = r$. But then $x, r \in r$ so $\{x, r\} \in r$, by (2), and, $\{\{x, r\}\} \in r$, by (1). In the second case, $\{\{x, r\}\} \in r$ by definition.

(4) $\forall x x \in \bigcup r$. For suppose that $\{x, r\} \in \{x, r\}$. Then $\{x, r\} = x$ or $\{x, r\} = r$. In the first case, $\{x\} = \{\{x, r\}\}$, so $\{x\} \in r$, by (3). In the second, $\{x, r\} \in r$. In either case $x \in \bigcup r$. Suppose, on the other hand, that $\{x, r\} \notin \{x, r\}$. Then $\{x, r\} \in r$, by definition, and so $x \in \bigcup r$.

That $\bigcup r$ is universal, is hardly a profound result. But it at least illustrates the fact that there are possibilities which transcend ZF .

Let me end this section with a speculative comment on what all this shows. The discussion of this section, and especially the part concerning the non-Boolean properties of sets in S_2 , shows that it is impossible to recapture standard set theory in its entirety in this theory. Sets are extensional entities *par excellence*; using an intensional connective in their identity conditions is bound to gum up the works. In fact, it seems to me that the most plausible way of viewing S_2 is as a theory of properties, where intensional identity conditions are entirely appropriate. But what you call these entities does not really matter here. The important fact is that they are not the sets of standard modern mathematical practice.

If we want a theory of such entities, the appropriate identity conditions must employ \equiv , and this means that we are back with the proof-theoretically weak S_0 (or S_1). Since this does not contain ZF , how should someone who subscribes to a paraconsistent theory of such sets view modern mathematical practice?

One answer is as follows. The standard model of ZF is the cumulative hierarchy. As we saw in 8.2, there are models of S_0 which contain this hierarchy. We may thus take it that the intended interpretation of S_0 is a model of this kind (or if there are more than one, that they are all models of this kind). The cumulative hierarchy is therefore a (consistent) fragment of the set-theoretic universe, and modern set theory provides a description of it. There is, however, more to the universe than this fragment. A classical logician may well agree with that claim. For example, they may think that there are also non-well-founded sets. The paraconsistent logician agrees with this: after all, r is not well-founded; but they will think that sets outside the hierarchy may have even more remarkable properties: some of them are inconsistent.

9 ARITHMETIC AND ITS METATHEORY

In this part I want to look at the application of paraconsistent logic to another important mathematical theory: arithmetic. The situation concerning arithmetic is rather different from that concerning set theory and semantics. There are no apparently obvious and intrinsically arithmetical principles that give rise to contradiction, in the way that the Comprehension principle and the T -schema do—or if there are, this fact has not yet been discovered. In the first instance, the paraconsistent interest in arithmetic arises because there is a class of inconsistent models of arithmetic. (It might be more accurate to say ‘models of inconsistent arithmetic’.) It may be supposed that these models are pathological in some sense.¹³⁵ I will come back to this matter later. But even if it is so, the models nevertheless have an interesting and important *mathematical* structure, as do the classical non-standard models of arithmetic—which are, in fact, just a special case, as we will see. And just as one does not have to be an intuitionist to find intuitionistic structures of intrinsic mathematical interest, so one does not have to be a dialetheist for the same to be true of inconsistent structures. One thing this part illustrates, therefore, is the existence of a new branch of mathematics which concerns the investigation of just such structures.¹³⁶

The existence of inconsistent models of arithmetic bears, as might be expected, on the limitative theorems of Metamathematics. And whatever the status of the inconsistent models themselves, many have held that these theorems have important philosophical implications. This part will also look at the connection between the inconsistent models and the limitative theorems, and I will comment on the significance of this for the philosophical implications of Gödel’s incompleteness theorem.

9.1 *The Collapsing Lemma*

Let us start with a theorem about LP on which much of the following depends: the Collapsing Lemma.¹³⁷

Let $\mathcal{I} = \langle D, d \rangle$ be any interpretation for LP . Let \sim be any equivalence relation on D , that is also a congruence relation on the denotations of the function symbols in the language (i.e., if g is such a denotation, and $d_i \sim e_i$ for all $1 \leq i \leq n$, then $g(d_1, \dots, d_n) \sim g(e_1, \dots, e_n)$). If $d \in D$ let $[d]$ be the

¹³⁵Though this claim has certainly been queried. See Priest [1994].

¹³⁶On this, see further, Mortensen [1995]. Perhaps surprisingly, the first person to investigate an inconsistent arithmetic was Nelson [1959], who gave a realisability-style semantics for the language of arithmetic, according to which the set of formulas realised was inconsistent (and closed under a logic somewhat weaker than intuitionist logic).

¹³⁷The theorem works equally well for FDE , but we will be concerned primarily with models of theories that contain the law of excluded middle, and so where there are no truth-value gaps.

equivalence class of d under \sim . Define an interpretation, $\mathcal{I}_\sim = \langle D_\sim, d_\sim \rangle$, to be called the *collapsed interpretation*, where $D_\sim = \{[d]; d \in D\}$; if c is a constant, $d_\sim(c) = [d(c)]$; if f is an n -place function symbol:

$$d_\sim(f)([d_1], \dots, [d_n]) = [d(f)(d_1, \dots, d_n)]$$

(this is well defined, since \sim is a congruence relation); and if P is an n -place predicate, its extension and anti-extension in \mathcal{I}_\sim , E_P^\sim and A_P^\sim , are defined by:

$$\begin{aligned} \langle [d_1], \dots, [d_n] \rangle \in E_P^\sim &\text{ iff for all } 1 \leq i \leq n, \exists e_i \sim d_i, \langle e_1, \dots, e_n \rangle \in E_P \\ \langle [d_1], \dots, [d_n] \rangle \in A_P^\sim &\text{ iff for all } 1 \leq i \leq n, \exists e_i \sim d_i, \langle e_1, \dots, e_n \rangle \in A_P \end{aligned}$$

where E_P and A_P are the extension and anti-extension of P in \mathcal{I} . It is easy to check that E_\sim^\sim is $\{\langle [d], [d] \rangle; d \in D\}$, as required for an LP interpretation.

The collapsed interpretation, in effect, identifies all members of an equivalence class to produce a composite individual that has the properties of all of its members. It may, of course, be inconsistent, even if its members are not.

A swift induction confirms that for any closed term, t , $d_\sim(t) = [d(t)]$. Hence:

$$\begin{aligned} 1 \in \nu(Pt_1 \dots t_n) &\Rightarrow \langle d(t_1), \dots, d(t_n) \rangle \in E_P \\ &\Rightarrow \langle [d(t_1)], \dots, [d(t_n)] \rangle \in E_P^\sim \\ &\Rightarrow \langle d_\sim(t_1), \dots, d_\sim(t_n) \rangle \in E_P^\sim \\ &\Rightarrow 1 \in \nu_\sim(Pt_1 \dots t_n) \end{aligned}$$

Similarly for 0 and anti-extensions. Monotonicity then entails that for any formula, α , $\nu(\alpha) \subseteq \nu_\sim(\alpha)$. This is the *Collapsing Lemma*.¹³⁸

The Collapsing Lemma assures us that if an interpretation is a model of some set of sentences, then any interpretation obtained by collapsing it will also be a model. This gives us an important way of constructing inconsistent models. In particular, if the language contains no function symbols, and \mathcal{I} is a model of some set of sentences, then, by appropriate choice of equivalence relation, we can collapse it down to a model of *any* smaller size. Thus we have a very strong downward Löwenheim-Skolem Theorem: If a theory in a language without function symbols has a model, it has a model of all smaller cardinalities.

I note that, since monotonicity holds for second order LP (section 7.2), the Collapsing Lemma extends to second order LP . Details are left as an exercise.

¹³⁸The result is proved in Priest [1991a]. A similar result was proved by Dunn [1979].

9.2 Collapsed Models of Arithmetic

From now on, let L be the standard language of first-order arithmetic: one constant, $\mathbf{0}$, function symbols for successor, addition and multiplication, $'$, $+$, and \times , respectively, and one predicate symbol, $=$. If \mathcal{I} is any interpretation, let $Th(\mathcal{I})$ (the *theory* of \mathcal{I}) be the set of all sentences true in \mathcal{I} . Let \mathcal{N} be the standard model of arithmetic, and $A = Th(\mathcal{N})$. Let $\mathcal{M} = \langle M, d \rangle$ be any classical model of A —which is just special cases of an *LP* model. (As is well known, there are many of these other than \mathcal{N} .¹³⁹) I will refer to the denotations of $'$, $+$, and \times as the arithmetic operations of \mathcal{M} , and since no confusion is likely, use the same signs for them.¹⁴⁰

Let \sim be an equivalence relation on M , that is also a congruence relation with respect to the interpretations of the function symbols. Then we may construct the collapsed interpretation, \mathcal{M}_\sim . By the Collapsing Lemma, \mathcal{M}_\sim is a model of A . Provided that \sim is not the trivial equivalence relation, that relates each thing only to itself, then \mathcal{M}_\sim will model inconsistencies. For suppose that \sim , relates the distinct members of M , n and m , then in \mathcal{M}_\sim , $[n] = [m]$ and so $\langle [n], [m] \rangle$ is in the extension of $=$. But since $n \neq m$ in \mathcal{M} , $\langle [n], [m] \rangle$ is in the anti-extension too. Thus, $\exists x(x = x \wedge x \neq x)$ holds in \mathcal{M}_\sim .

As an illustration of constructing an inconsistent model of A using the Collapsing Lemma, suppose that we partition M into $n+1$ successive blocks, C_0, \dots, C_{n+1} , such that if $x, z \in C_i$ and $x < y < z$ then $y \in C_i$. And suppose that for $0 < i \leq n+1$, C_i is closed under the arithmetic operations of \mathcal{M} . (The existence of such a partition follows from a standard result in the study of classical models of arithmetic. See Kaye [1991], sect. 6.1.) Let $1 \leq k \in C_0 \cup C_1$ and define $x \sim y$ as:

$$(x, y \in C_0 \text{ and } x = y) \text{ or} \\ \text{for some } 0 < i \leq n+1, x, y \in C_i \text{ and } x = y \text{ mod } k$$

where ' $x = y \text{ mod } k$ ' means that for some $j \in M$, $x + j \times k = y$, in \mathcal{M} .

It is not difficult to check that \sim is an equivalence relation on M , and, moreover, that it is a congruence relation on the arithmetic operations of \mathcal{M} . Hence, we may use it to give a collapsed model. In this, C_0 collapses into an initial tail of numbers, and each C_i ($0 < i \leq n+1$) collapses into a block of period k . For example, if \mathcal{M} is the standard model, $n = 1$ and $C_0 = \phi$, the collapsed model is a simple cycle of period k . The successor function in the model may be depicted as follows:

¹³⁹See, e.g., Kaye [1991].

¹⁴⁰For a more detailed discussion of the material in this section, see Priest [1997a].

$$\begin{array}{ccccccc}
 0 & \rightarrow & 1 & \rightarrow & \dots & \rightarrow & i \\
 \uparrow & & & & & & \downarrow \\
 k-1 & \leftarrow & & \dots & & \leftarrow & i+1
 \end{array}$$

I will call such models *cycle models*. They were, in fact, the first inconsistent models to be discovered.¹⁴¹ If \mathcal{M} is any model, $n = 1$, and $k = 1$, we have a tail isomorphic to C_0 , and then a degenerate single-point cycle. In particular, if \mathcal{M} is a non-standard model and C_0 comprises the standard numbers, we have the natural numbers with a “point at infinity”, Ω :

$$0 \rightarrow 1 \rightarrow \dots \rightarrow \Omega \leftarrow$$

9.3 Inconsistent Models of Arithmetic

Now that we have seen the existence of inconsistent models of arithmetic, let us look at their general structure.

Take any *LP* model of arithmetic, $\mathcal{M} = \langle M, d \rangle$. I will call the denotations of the numerals *regular* numbers. Let $x \leq y$ be defined in the usual way, as $\exists z \ x + z = y$. It is easy to check that \leq is transitive. For if $i \leq j \leq k$ then for some $x, y, i + x = j$ and $j + y = k$. Hence $(i + x) + y = k$. But $(i + x) + y = i + (x + y)$ (since it is a model of arithmetic). The result follows.

If $i \in M$, let $N(i)$ (the *nucleus* of i) be $\{x \in M; i \leq x \leq i\}$. In a classical model, $N(i) = \{i\}$, but this need not be the case in an inconsistent model. For example, in a cycle model the members of the cycle constitute a nucleus. If $j \in N(i)$ then $N(i) = N(j)$. For if $x \in N(j)$ then $i \leq j \leq x \leq j \leq i$, so $x \in N(i)$, and similarly in the other direction. Thus, every member of a nucleus defines the same nucleus.

Now, if N_1 and N_2 are nuclei, define $N_1 \preceq N_2$ to mean that for some (or all, it makes no difference) $i \in N_1$ and $j \in N_2, i \leq j$. It is not difficult to check that \preceq is a partial ordering. Moreover, since for any i and $j, i \leq j$ or $j \leq i$, it is a linear ordering. The least member of the ordering is $N(0)$. If $N(1)$ is distinct from this, it is the next (since for any $x, x \leq 0 \vee x \geq 1$), and so on for all regular numbers.

Say that $i \in M$ has period $p \in M$ iff $i + p = i$. In a classical model every number has period 0 and only 0. But again, this need not be the case in an inconsistent model, as the cycle models demonstrate. If $i \leq j$ and i has period p so does j . For $j = i + x$, so $p + j = p + i + x = i + x = j$. In particular, if p is a period of some member of a nucleus, it is a period of

¹⁴¹This was by Meyer [1978]. Things are spelled out in Meyer and Mortensen [1984]. The idea of collapsing non-standard classical models is to be found in Mortensen [1987]. Different structures can be collapsed to provide inconsistent models of other kinds of number, e.g., real numbers. See Mortensen [1995].

every member. We may thus say that p is a period of the nucleus itself. It also follows that if $N_1 \preceq N_2$ and p is a period of N_1 it is a period of N_2 .

If a nucleus has a regular non-zero period, m , then it must have a minimum (in the usual sense) non-zero period, since the sequence $0, 1, 2, \dots, m$ is finite. If $N_1 \preceq N_2$ and N_1 has minimum regular non-zero period, p , then p is a period of N_2 . Moreover, the minimum non-zero period of N_2 , q , must be a divisor (in the usual sense) of p . For suppose that $q < p$, and that q is not a divisor of p . For some $0 < k < q$, p is some finite multiple of q plus k . So if $x \in N_2$, $x = x + q = x + p + \dots + p + k$. Hence $x = x + k$, i.e., k is a period of N_2 , which is impossible.

If a nucleus has period $p \geq 1$, I will call it *proper*. Every proper nucleus is closed under successors. For suppose that $j \in N$ with period p . Then $j \leq j' \leq j + p = j$. Hence, $j' \in N$. In an inconsistent model, a number may have more than one predecessor, i.e., there may be more than one x such that $x' = j$. (Although $x' = y' \supset x = y$ holds in the model, we cannot necessarily detach to obtain $x = y$.)¹⁴² But if j is in a proper nucleus, N , it has a unique predecessor in N . For let the period of N be q' . Then $(j + q)' = j + q' = j$. Hence, $j + q$ is a predecessor of j ; and $j \leq j + q' = j$. Hence, $j + q \in N$. Next, suppose that x and y are in the nucleus, and that $x' = y' = j$. We have that $x \leq y \vee y \leq x$. Suppose, without loss of generality, the first disjunct. Then for some z , $x + z = y$; so $j + z = j$, and z is a period of the nucleus. But then $x = x + z = y$. I will write the unique predecessor of j in the nucleus as $'j$.

Now let N be any proper nucleus, and $i \in N$. Consider the sequence $\dots, ''i, 'i, i, i, 'i, i'' \dots$. Call this the *chromosome* of i . Note that if $i, j \in N$, the chromosomes of i and j are identical or disjoint. For if they have a common member, z , then all the finite successors of z are identical, as are all its finite predecessors (in N). Thus they are identical. Now consider the chromosome of i , and suppose that two members are identical. There must be members where the successor distance between them is a minimum. Let these be j and $j' \dots'$ where there are n primes. Then $j = j + n$, and n is a period of the nucleus—in fact, its minimum non-zero period—and the chromosome of every member of the nucleus is a successor cycle of period n .

Hence, any proper nucleus is a collection of chromosomes, all of which are either successor cycles of the same finite period, or are sequences isomorphic to the integers (positive and negative). Both sorts are possible in an inconsistent model. Just consider the collapse of a non-standard model, of the kind given in the last section, by an equivalence relation which leaves all the standard numbers alone and identifies all the others modulo p . If p is standard, the non-standard numbers collapse into a successor cycle; if it

¹⁴²In fact, it is not difficult to show that there is at most one number with multiple predecessors; and this can have only two.

is non-standard, the nucleus generated is of the other kind.

To summarise so far, the general structure of a model is a linear sequence of nuclei. There are three segments (any of which may be empty). The first contains only improper nuclei. The second contains proper nuclei with linear chromosomes. The final segment contains proper nuclei with cyclical chromosomes of finite period. A period of any nucleus is a period of any subsequent nucleus; and in particular, if a nucleus in the third segment has minimum non-zero period, p , the minimum non-zero period of any subsequent nucleus is a divisor of p . Thus, we might depict the general structure of a model as follows (where $m + 1$ is a multiple of $n + 1$):

Another obvious question is what possible orderings the proper nuclei can have. For a start, they can have the order-type of any ordinal. To prove this, one establishes by transfinite induction that for any ordinal, α , there is a classical model of arithmetic in which the non-standard numbers can be partitioned into a collection of disjoint blocks with order-type α , closed under arithmetic operations. One then collapses this interpretation in such a way that each block collapses into a nucleus.

The proper nuclei need not be discretely ordered. They can also have the order-type of the rationals. To prove this, one considers a classical non-standard model of arithmetic, where the order-type of the non-standard numbers is that of the rationals. It is possible to show that these can be partitioned into a collection of disjoint blocks, closed under arithmetic operations, which themselves have the order-type of the rationals. One can then collapse this model in such a way that each of the blocks collapses into a proper nucleus, giving the result. This proof can be extended to show that any order-type that can be embedded in the rationals in a certain way, can also be the order-type of the proper nuclei. This includes ω^* (the reverse of ω) and $\omega^* + \omega$, but *not* $\omega + \omega^*$. For details of all this, see Priest [1997b].

What other linear order-types proper nuclei may or may not have, is still an open question.

9.4 Finite Models of Arithmetic

First-order arithmetic has many classical nonstandard models, but none of these is finite. One of the intriguing features of *LP* is that it permits

finite models of arithmetic, e.g., the cycle models. For these, a complete characterisation is known.

Placing the constraint of finitude on the results of the previous section, we can infer as follows. The sequence of improper nuclei is either empty or is composed of the singletons of $0, 1, \dots, n$, for some finite n . There must be a finite collection of proper nuclei, $N_1 \preceq \dots \preceq N_m$; each N_i must comprise a finite collection of successor cycles of some minimum non-zero finite period, p_i . And if $1 \leq i \leq j \leq m$, p_j must be a divisor of p_i .¹⁴³

Moreover, there are models of any structure of this form. To show this, we can generalise the construction of 9.2. Take any non-standard classical model of arithmetic. This can be partitioned into the finite collection of blocks:

$$C_0, C_{1_0}, \dots, C_{1_{k(1)}}, \dots, C_{i_0}, \dots, C_{i_{k(i)}}, \dots, C_{m_0}, \dots, C_{m_{k(m)}}$$

where C_0 is either empty or is of the form $\{0, \dots, n\}$, each subsequent block is closed under arithmetic operations, and there are $k(i)$ successor cycles in N_i . We now define a relation, $x \sim y$, as follows:

$$\begin{aligned} &(x, y \in C_0 \text{ and } x = y) \text{ or} \\ &\text{for some } 1 \leq i \leq m: \\ &\quad (\text{for some } 0 < j < k(i), x, y \in C_{i_j}, \text{ and } x = y \bmod p_i) \text{ or} \\ &\quad (x, y \in C_{i_0} \cup C_{i_{k(i)}} \text{ and } x = y \bmod p_i) \end{aligned}$$

One can check that \sim is an equivalence relation, and also that it is a congruence relation on the arithmetic operations. Hence we can construct the collapsed model. \sim leaves all members of C_0 alone. For every i it collapses every C_{i_j} into a successor cycle of period p_i , and it identifies the blocks C_{i_0} and $C_{i_{k(i)}}$. Thus, the sequence $C_{i_0}, \dots, C_{i_{k(i)}}$ collapses into a nucleus of size $k(i)$. The collapsed model therefore has exactly the required structure.¹⁴⁴

There are many interesting questions about inconsistent models, even the finite ones, whose answer is not known. For example: how many models of each structure are there? (The behaviour of the successor function in a model does not determine the behavior of addition and multiplication, except in the tail.) Perhaps the most important question is as follows. Not all inconsistent model of arithmetic are collapses of classical models. Let \mathcal{M} be any model of arithmetic; if \mathcal{M}' is obtained from \mathcal{M} by adding extra pairs to the anti-extension of $=$, call \mathcal{M}' an *extension* in \mathcal{M} . If \mathcal{M}' is an extension of \mathcal{M} , monotonicity ensures that it is a model of arithmetic. Now, consider the extension of the standard model obtained by adding $\langle 0, 0 \rangle$ to the anti-extension of $=$. This is not a collapsed model, since, if it were, 0 would have to have been identified with some $x > 0$. But then 1 would have

¹⁴³It is also possible to show that each nucleus is closed under addition and multiplication.

¹⁴⁴For further details, see Priest [1997a].

been identified with $x' > 1$. Hence, $\mathbf{0}' \neq \mathbf{0}'$ would also be true in the model, which it is not. Maybe, however, each inconsistent model is the extension of a collapsed classical model. If this conjecture is correct, collapsed models can be investigated via an analysis of the classical models of arithmetic and their congruence relations.

9.5 The Limitative Theorems of Metamathematics

Let us now turn to the limitative theorems of Metamathematics in the context of LP . These are the theorems of Löwenheim-Skolem, Church, Tarski and Gödel. I will take them in that order.¹⁴⁵ In what follows, let P be the set of theorems of classical Peano Arithmetic, and let Q be any non-trivial theory that contains P .

According to the classical Löwenheim-Skolem, Q has models of every infinite cardinality but has no finite models. Moving to LP changes the situation somewhat. Q still has a model of every infinite cardinality.¹⁴⁶ But it has models of finite size too: any inconsistent model may be collapsed to a finite model merely by identifying all numbers greater than some cut-off.¹⁴⁷

The situation with second order P is again different in LP . Classically, this is known to be categorical, having the standard model as its only interpretation. But as I noted in 9.1, the Collapsing Lemma holds for second order LP . Hence, second order P is not categorical in LP . For example, it has finite models.

Turning to Church's theorem, this says, classically, that Q is undecidable. In LP , extensions of Q may be decidable. For example, let \mathcal{M} be any finite model of A ($= Th(\mathcal{N})$), and let Q be $Th(\mathcal{M})$. Then Q is a theory that contains P . Yet Q is decidable, as is the theory of any finite interpretation. In the language of \mathcal{M} there is only a finite number of atomic sentences; their truth values can be listed. The truth values of truth functions of these can be computed according to (LP) truth tables, and the truth values of quantified sentences can be computed, since $\exists x\alpha$ has the same truth value

¹⁴⁵For a statement of these in the classical context, see Boolos and Jeffrey [1974]. This section expands on the appendix of Priest [1994].

¹⁴⁶The standard classical proof of this adds a new set of constants, $\{c_i, i \in I\}$, to the language, and all sentences of the form $c_i \neq c_j, i \neq j$, to Q . It then uses the compactness theorem. Things are more complex in LP , since the fact that $c_i \neq c_j$ holds in an interpretation does not mean that the denotations of these constants are distinct. After extending the language, we observe that $c_i = c_j$ cannot be proved. We then construct a prime theory in the manner of 4.3, keeping things of this form *out*. This is then used to define an appropriate interpretation.

¹⁴⁷Let us say that M is an *exact model* of a theory iff the truths of M are exactly the members of the theory. Classically, for complete theories, there is no difference between modelling and exact modelling. The situation for LP is more complex. It can be shown that if Q has an infinite exact model it has exact models of every greater cardinality. On the other hand, if Q has a finite model, \mathcal{M} , in which every number is denoted by a numeral, \mathcal{M} can be shown to be the only exact model of Q (up to isomorphism).

as the disjunction of all formulas of the form $\alpha(x/a)$, where a is in the domain of \mathcal{M} ; dually for \forall .

Tarski's Theorem: this says that Q cannot contain its own truth predicate, in the sense that even if Q is a theory in an extended language, there is no formula, β , of one free variable, x , such that $\beta(x/\langle\alpha\rangle) \equiv \alpha \in Q$, for all closed formulas, α , of the language. This, too, fails for LP . Let \mathcal{M} be any (classical) model of P , let \mathcal{M}' be any finite collapse of \mathcal{M} , and let Q be $Th(\mathcal{M}')$. By the Collapsing Lemma, Q contains P . Since Q is decidable, it is representable in (classical) P by a formula, β , of one free variable, x . That is, we have :

$$\begin{aligned} \text{If } \alpha \in Q \text{ then } \beta(x/\langle\alpha\rangle) \in P \\ \text{If } \alpha \notin Q \text{ then } \neg\beta(x/\langle\alpha\rangle) \in P \end{aligned}$$

By the Collapsing Lemma, ' P ' may be replaced by ' Q '. If $\alpha \in Q$, $\beta(x/\langle\alpha\rangle) \in Q$, and so $\beta(x/\langle\alpha\rangle) \equiv \alpha \in Q$ (since $\gamma, \delta \models_{LP} \gamma \equiv \delta$); and if $\alpha \notin Q$, $\neg\beta(x/\langle\alpha\rangle) \in Q$, and so $\beta(x/\langle\alpha\rangle) \equiv \alpha \in Q$ (since $\neg\alpha \in Q$ and $\neg\gamma, \neg\delta \models_{LP} \gamma \equiv \delta$).

There is no guarantee that α and $\beta(x/\langle\alpha\rangle)$ have the same truth value in \mathcal{M}' . In particular, then, β may not satisfy the T -schema in the form of a two-way rule of inference. So it might be said that β is not really a truth predicate. Whether or not this is so, we have already seen that there are Q s where there is a predicate satisfying this condition (though this has to be added to the language of arithmetic): the theory T_1 of section 8.1.¹⁴⁸ Finally, let us turn to Gödel's undecidability theorems. A statement of the first of these is that if Q is axiomatisable then there are sentences true in the standard model that are not in Q . It is clear that this may fail in LP . Let \mathcal{M} be any finite model of arithmetic. Then if Q is $Th(\mathcal{M})$, Q contains all of the sentences true in the standard model of arithmetic, but is decidable, as we have noted, and hence axiomatisable (by Craig's Theorem).

It is worth asking what happens to the "undecidable" Gödel sentence in such a theory. Let β be any formula that represents Q in Q . (There are such formulas, as we just saw.) Then a Gödel sentence is one, α , of the form $\neg\beta(x/\langle\alpha\rangle)$. If $\alpha \in Q$ then $\neg\beta(x/\langle\alpha\rangle) \in Q$, but $\beta(x/\langle\alpha\rangle) \in Q$ by representability. If $\alpha \notin Q$ then $\neg\beta(x/\langle\alpha\rangle) \in Q$ by representability, i.e., $\alpha \in Q$, so $\beta(x/\langle\alpha\rangle) \in Q$ by representability. In either case, then,

¹⁴⁸The construction of 8.1 can be applied to any model of arithmetic—not just the standard model—as the ground model. However, if we apply it to a finite model care needs to be exercised. The construction will not work as given, since different formulas may be coded by the same number in the model, which renders the definition of the sequence of interpretations illicit. We can switch to evaluational semantics, as in 8.2, though the construction then no longer validates the substitutivity of identicals. Alternatively, we can refrain from using numbers as names, but just augment the language with names for all sentences.

$\alpha \wedge \neg\alpha \in Q$.

Gödel's second undecidability theorem says that the statement that canonically asserts the consistency of Q is not in Q ; this statement is usually taken to be $\neg\beta(x/\langle\alpha_0\rangle)$, where α_0 is $\mathbf{0} = \mathbf{0}'$, and β is the canonical proof predicate of Q . This also fails in LP .¹⁴⁹ Let Q be as in the previous two paragraphs. Then Q is not consistent. However, it is still the case that $\alpha_0 \notin Q$ (provided that the collapse is not the trivial one). Consider the relationship: n is (the code of) a proof of formula (with code) m in Q . Since this is recursive, it is represented in A by a formula $Prov(x, y)$. If α is provable in Q then for some n , $Prov(\mathbf{n}, \langle\alpha\rangle) \in A$ (where \mathbf{n} is the numeral for n); thus, $\exists xProv(x, \langle\alpha\rangle) \in A$ and so Q . If α is not provable in Q then for all n , $\neg Prov(\mathbf{n}, \langle\alpha\rangle) \in A$; thus, $\forall x\neg Prov(x, \langle\alpha\rangle) \in A$ (since A is ω -complete) and $\neg\exists xProv(x, \langle\alpha\rangle) \in A$ and so Q . Thus, $\exists xProv(x, y)$ represents Q in Q . In particular, since $\alpha_0 \notin Q$, $\neg\exists xProv(x, \langle\alpha_0\rangle) \in Q$, as required.

9.6 The Philosophical Significance of Gödel's Theorem

People have tried to make all sorts of philosophical capital out of the negative results provided by the limitative theorems of classical Metamathematics. As we have seen, all of these, save the Löwenheim-Skolem Theorem, fail for arithmetic based on a paraconsistent logic. Setting this theorem aside, then, nothing can be inferred from these negative results unless one has reason to rule out paraconsistent theories. At the very least, this adds a whole new dimension to the debates in question.

This is not the place to discuss all the philosophical issues that arise in this context, but let me say a little more about one of the theorems by way of illustration. Doubtless, the incompleteness result that has provoked most philosophical rumination is Gödel's first incompleteness theorem: usually in a form such as: for any axiomatic theory of arithmetic (with sufficient strength, etc.), which we can recognise to be sound, there will be an arithmetic truth—viz., its Gödel sentence—not provable in it, but which we can establish as true.¹⁵⁰ This is just false, paraconsistently. If the theory is inconsistent, the Gödel sentence may well be provable in the theory, as we have seen.

An obvious thought at this point is that if we can recognise the theory to be sound then it can hardly be inconsistent. But unless one closes the question prematurely, by a refusal to consider the paraconsistent possibility, this is by no means obvious. What *is* obvious to anyone familiar with the subject, is that at the heart of Gödel's theorem, is a paradox. The paradox concerns the sentence, γ , 'This sentence is not provable', where 'provable'

¹⁴⁹It is worth noting that there are *consistent* arithmetics based on some relevant logics, notably R , for which the statement of consistency is in the theory. See Meyer [1978].

¹⁵⁰For example, the theorem is stated in this form in Dummett [1963]; it also drives Lucas' notorious [1961], though it is less clearly stated there.

is not to be understood to mean being the theorem of some axiom system or other, but as meaning ‘demonstrated to be true’. If γ is provable, then it is true and so not provable. Thus we have proved γ . It is therefore true, and so unprovable. Contradiction. The argument can be formalised with one predicate, B , satisfying the conditions:

$$\begin{aligned} &\vdash B \langle \alpha \rangle \rightarrow \alpha \\ &\text{If } \vdash \alpha \text{ then } \vdash B \langle \alpha \rangle \end{aligned}$$

for all closed α —including sentences containing B . For if γ is of the form $\neg B \langle \gamma \rangle$, then, by the first, $\vdash B \langle \gamma \rangle \rightarrow \neg B \langle \gamma \rangle$, and so $\vdash \neg B \langle \gamma \rangle$, i.e., $\vdash \gamma$. Hence, $\vdash B \langle \gamma \rangle$, by the second.

And we *do* recognise these principles to be sound. Whatever is provable is true, by definition; and demonstrating α shows that α is provable, and so counts as a demonstration of this fact.¹⁵¹

B is a predicate of numbers, but we do not have to assume that B is definable in terms of $'$, $+$ and \times using truth functions and quantifiers. The argument could be formalised in a language with B as primitive. As we saw in the previous part in connection with truth, it is quite possible to have an inconsistent theory with a predicate of this kind, where the sentences definable in terms of $'$, $+$ and \times using truth functions and quantifiers behave quite consistently.

Of course, if B is so definable, which it will be if the set of things we can prove is axiomatic, then the set of things that hold in this language *is* inconsistent. And there are reasons for supposing that this is indeed the case.¹⁵² Even this does not necessarily mean that the familiar natural numbers behave strangely, however. As the model with the “point at infinity” of 9.2 showed, it is quite possible for inconsistent models to have the ordinary natural numbers as a substructure.¹⁵³ There are just more possibilities in Heaven and Earth than are dreamt of in a consistent philosophy.

10 PHILOSOPHICAL REMARKS

In previous parts I have touched occasionally on the philosophical aspects of paraconsistency. In this section I want to take up a few of the philosophical implications of paraconsistency at slightly greater length. Its major

¹⁵¹The paradox is structurally the same as a paradox often called the ‘Knower paradox’. In this, B is interpreted as ‘It is known that’. For references and discussion of this paradox and others of its kind, see Priest [1991b].

¹⁵²See Priest [1987], ch. 3. This chapter discusses the connection between Gödel’s theorem, the paradoxes of self-reference and dialetheism at greater length.

¹⁵³Though whether the theory of that particular model is axiomatisable is currently unknown.

implication is very simple. As I noted in 3.1, the absolute unacceptability of inconsistency has been deeply entrenched in Western philosophy. It is an assumption that has hardly been questioned since Aristotle. Whilst the law of non-contradiction is a traditional statement of this fact, it is *ECQ* which expresses the real *horror contradictionis*: contradictions explode into triviality. Paraconsistency challenges exactly this, and so questions any philosophical claim based on this supposed unacceptability. This does not mean that consistency cannot play a regulative function: it may still be an expected norm, departure from which requires a justification; but it can no longer provide a constraint of absolute nature. Given the centrality of consistency to Western thought, the philosophical ramifications of paraconsistency are bound to be profound, and this is hardly the place to take them all—or even some—up at great length. What I will do here is consider various objections to employing a paraconsistent logic, and explore a little some of the philosophical issues that arise in this context. In the process we will need to consider not only the purposes of logic, but also the natures of negation, denial, rational belief and belief revision.¹⁵⁴

10.1 *Instrumentalism and Information*

Why, then, might one object to paraconsistent logic? Logic has many uses, and any objection to the use of a paraconsistent logic must depend on what it is supposedly being used for. One thing one may want a logic for is to draw out consequences of some information in a purely instrumental way. In such circumstances one may use any logic one likes provided that it gives appropriate results. And if the information is inconsistent, an explosive logic is hardly likely to do this.

Referring back to the list of motivations for the use of a paraconsistent logic in 2.2, drawing inferences from a scientific theory would fall into this category if one is a scientific instrumentalist. Drawing inferences from the information in a computer data base could also fall into this category. If the logic gives the right results—or at least, does not give the wrong results—use it.

The only objection that there is likely to be to the use of a paraconsistent logic in this context is that it is too weak to be of any serious use. One might note, for example, that most paraconsistent logics invalidate the disjunctive syllogism, a special case of resolution, on the basis of which many theorem-provers work.¹⁵⁵ This objection carries little weight, however. Theorem-

¹⁵⁴Other philosophical aspects of paraconsistency are discussed in numerous places, e.g., da Costa [1982], Priest [1987], Priest *et al.* [1989], ch. 18.

¹⁵⁵It is worth noting, however, that some theorem-provers that use resolution are not complete with respect to classical semantics. For example, to determine whether α follows from the information in a data base, some theorem-provers employ a heuristic that requires them resolve $\neg\alpha$ with something on the data base, and so on recursively. Em-

provers can certainly be based on other mechanisms.¹⁵⁶ Moreover, the inferential moves of the standard programming language PROLOG can all be interpreted validly in many paraconsistent logics (when ‘:-’ is interpreted as ‘-’).

One will often require a logic for something other than merely instrumental use. This does not mean that one is necessarily interested in truth-preservation, however. One might, for example, require a logic whose valid inferences preserve, not truth, but information. The computer case could also be an example of this. Other natural examples of this in the list of 2.2 are the fictional and counterfactual situations. By definition, truth is not at issue here.¹⁵⁷

Information-preservation implies truth preservation, presumably, but the converse is not at all obvious, and not even terribly plausible. The information that the next flight to Sydney leaves at 3.45 and does not leave at 3.45 would hardly seem to contain the information that there is life on Mars. A paraconsistent logic is therefore a plausible one in this context.

What information, and so information-preservation, are, is an issue that is currently much discussed. One popular approach is based on the situation semantics of Barwise and Perry [1983].¹⁵⁸ This takes a unit of information (an *infor*) to be something of the form $\langle R, a_1, \dots, a_n, s \rangle$, where R is an n -place relation, the a_i 's are objects, and s is a sign-bit (0 or 1). A situation is a set of infons. The situations in question do not have to be veridical in any sense. In particular, they may be both inconsistent and incomplete. In fact, it is easy to see that a situation, so characterised, is just a relational *FDE* evaluation. This approach to information therefore naturally incorporates a paraconsistent logic, which may be thought of as a logic of information preservation.¹⁵⁹

10.2 Negation

Another major use of logic (perhaps the one that many think of first) is in contexts where we want inference to be truth-preserving; for example,

employing this procedure when the data base is $\{p, \neg p\}$ and the query is q will result in a negative answer. Such inference engines are therefore paraconsistent, though they do not answer to any principled semantics that I am aware of.

¹⁵⁶For details of some automated paraconsistent logics, see, e.g., Blair and Subrahmanian [1988], Thistlewaite *et al.* [1988].

¹⁵⁷One might also take the other example on that list, constitutions and other legal documents, to be an example of this. Such documents certainly contain information. And one might doubt that this information is the sort of thing that is true or false: it can, after all, be brought into effect by fiat—and may be inconsistent. However, if it is that sort of thing, legal reasoning concerning it would seem to require truth-preservation.

¹⁵⁸See, e.g., Devlin [1991].

¹⁵⁹It is worth noting that North American relevant logicians have very often—if not usually—thought of the *FDE* valuations information-theoretically, as *told* true and *told* false. See, e.g., Anderson *et al.* [1992], sect. 81.

where we are investigating the veridicality of some theory or other. And here, it is very natural to object to the use of a paraconsistent logic. Since truth is never inconsistent a paraconsistent logic is not appropriate.

A paraconsistent logician who thinks that truth is consistent may agree with this, in a sense. We have already seen in 7.6 how a paraconsistent logic, applied to a consistent situation, may give classical reasoning. However, a dialetheist *will* object; not to the need for truth preservation, but to the claim that truth is consistent: some contradictions are true: dialetheias.

This is likely to provoke the fiercest objections. Let me start by dividing these into two kinds: local and global. Global objections attack the possibility of dialetheias on completely general grounds. Local objections, by contrast, attack the claim that some particular claims are dialethic on grounds specific to the situation concerned.

Let us take the global objections first. Why might one think that dialetheias can be ruled out quite generally, independently of the considerations of any particular case? A first argument is to the effect that a contradiction cannot be true, since contradictions entail everything, and not everything is true. It is clear that in the context where the use of a paraconsistent logic is being defended, this simply begs the question.

Of more substance is the following objection. The truth of contradictions is ruled out by the (classical) account of negation, which is manifestly correct. The amount of substance is only slightly greater here, though: the claim that the classical account of negation is manifestly correct is just plain false.

An account of negation is a *theory* concerning the behaviour of something or other. It is sometimes suggested that it is an account of how the particle ‘not’, and similar particles in other languages, behaves. This is somewhat naive. Inserting a ‘not’ does not necessarily negate a sentence. (The negation of ‘All logicians do believe the classical account of negation’ is not ‘All logicians do not believe the classical account of negation’.) And ‘not’ may function in ways that have nothing to do with negation at all. Consider, e.g.: ‘I’m not a Pom; I’m English’, where it is connotations of what is said that are being rejected, not the literal truth.

It seems to me that the most satisfactory understanding of an account of negation is to regard it as a theory of the relationship between statements that are contradictory. Note that this by no means rules out a paraconsistent account of negation.¹⁶⁰ Even supposing that we characterise contradictories as pairs of formulas such that at least one must be true and at most one can be true—with which an intuitionist would certainly disagree—it is quite possible to have both $\Box(\alpha \vee \neg\alpha)$ and $\neg\Diamond(\alpha \wedge \neg\alpha)$ valid in a paraconsistent logic, as we saw in 7.3.

Anyway, whatever we take a theory of negation to be a theory *of*, it is but

¹⁶⁰ As Slater [1995] claims.

a *theory*. And different theories are possible. As we have already observed, Aristotle gave an account of this relationship that was quite different from the classical account as it developed after Boole and Frege. And modern intuitionists, too, give a quite different account. Which account is correct is to be determined by the usual criteria for the rational acceptability of theories. (I will say a little more about this later.) The matter is not at all obvious.

Quine is well known for his objection to non-classical logic in general, and paraconsistent logic in particular, on the ground that changing the logic (from the classical one) is ‘changing the subject’, i.e., succeeds only in giving an account of something else ([1970], p. 81). This just confuses logic, *qua* theory, with logic, *qua* object of theory. Changing one’s theory of logic no more changes what it is one is theorising about—in this case, relationships grounding valid reasoning—than changing one’s theoretical geometry changes the geometry of the cosmos. Nor does it help to suppose that logic, unlike geometry, is analytic (i.e., true solely in virtue of meanings). Whether or not, e.g., ‘There will be a sea battle tomorrow or there will not’ is analytic in this sense, is no more obvious than is the geometry of the cosmos. And changing from one theory, according to which it is analytic, to another, according to which it is not, does not change the facts of meaning.¹⁶¹

How plausible a paraconsistent account of negation is depends, of course, on which paraconsistent account of negation is given. As we saw in part 4, there are many. One of the simplest and most natural is provided by the relational semantics of 4.5. This is just the classical account, except that classical logic makes the *extra* assumption that all statements have *exactly* one truth value. And logicians as far back as Aristotle have questioned that assumption.¹⁶²

10.3 Denial

Another global objection to dialetheism goes by way of a supposed connection between negation and denial. It is important to be clear about the distinction between these two things for a start. Negation is a syntactic and/or semantic feature of language. Denial is a feature of language use: it is one particular kind of force that an utterance can have, one kind of illocutionary act, as Austin put it. Specifically, it is to be contrasted with assertion.¹⁶³ Typically, to assert something is to express one’s belief in, or acceptance of, it (or some Gricean sophistication thereof). Typically, to deny something is to express one’s rejection of it, that is, one’s refusal to ac-

¹⁶¹ The analogy between logic and geometry is discussed further in Priest [1997a].

¹⁶² The topics of this section and the next are discussed at greater length in Priest [1999].

¹⁶³ Traditional logic usually drew the distinction, not in terms of saying, but in terms of judging. It can be found in these terms, for example, in the *Port-Royal Logic* of Arnauld and Nicole.

cept it (or some Gricean sophistication thereof). Clearly, if one is uncertain about a claim, one may wish neither to assert nor to deny it.

Although assertion and denial are clearly different kinds of speech act, Frege argued, and many now suppose, that denial may be reduced to the assertion of negation.¹⁶⁴ If this is correct, then dialetheism faces an obvious problem. Even if some contradictions were true, no one could ever endorse a contradiction, since they could not express an acceptance of one of the contradictories without expressing a rejection of the other.¹⁶⁵

Frege's reduction has no appeal if we take the negation of a statement simply to be its contradictory. In asserting 'Some men are not mortal', I am not denying 'All men are mortal'. I might not even realise that these are contradictories, and neither might anyone else. And if this does not seem plausible in this simple case, just make the example more complex, and recall that there is no decision procedure for contradictories.

The reduction takes on more plausibility if we identify the negation of a sentence as that sentence prefixed by 'It is not the case that'. But even in this case, the claim that to assert a negation is invariably to deny the sentence negated appears to be false. Dialetheists who asserts both, e.g., 'The Liar sentence is true' and 'It is not the case that the Liar sentence is true', are not expressing the rejection of the former with the latter: they are simply expressing their acceptance of a certain negated sentence.¹⁶⁶ It may well be retorted that this reply just begs the question, since what is at issue is whether a dialetheist *can* do just this. This may be so; but it may now be fairly pointed out that the original objection just begs the question against the dialetheist too.

In any case, there would appear to be plenty of other examples where to assert a negation is not to deny. For example, we may be brought to see that our views are inconsistent by being questioned in Socratic fashion and thus made to assert an explicit contradiction. When this happens, we are not expressing the rejection of any view. What the questioning exposes is exactly our *acceptance* of contradictory views. We may, in the light of the questioning, come to reject one of the contradictories, and so revise our views, but that is another matter.¹⁶⁷

To assert a negated sentence is not, then, *ipso facto* to deny the sentence negated. Some, having taken this point to heart, object on the other side of the street: dialetheists have no way of expressing some of their views, specifically their rejection of certain claims: we need take nothing a dialetheist

¹⁶⁴See Frege [1919].

¹⁶⁵For an objection along these lines, see Smiley in Priest and Smiley [1993].

¹⁶⁶And even those who take negation to express denial must hold that there is more to the meaning of negation than this. It cannot, for example, perform that function when it occurs attached to *part* of a sentence.

¹⁶⁷Some non-dialetheists have even argued that it may not even be rational to revise our views in some contexts. See, e.g., Prior on the paradox of the preface [1971], pp. 84f.

says as a denial.¹⁶⁸

This objection is equally flawed. For a start, even if to assert a negated sentence is to deny it, it is certainly not the only way to deny it. One can do so by a certain shake of the head, or by the use of some other body language. A dialetheist may deny in this way. Moreover, just because the assertion of a negated sentence by a dialetheist (or even a non-dialetheist, as we have seen) may not be a denial, it does not follow that it is not. In denial, a person aims to communicate to a listener a certain mental state, that of rejection; and asserting a negated sentence with the right intonation, and in the right context, may well do exactly that—even if the person is a dialetheist.¹⁶⁹

10.4 *The Rational Acceptability of Contradictions*

This does not exhaust the possible global objections to dialetheism,¹⁷⁰ but let us move on to the local ones. These do not object to the possibility of dialetheism in general, but to particular (supposed) cases of it. We noted in 2.2 that a number of these have been proposed, which include legal dialetheias, descriptions of states of change, borderline cases of vague predications and the paradoxes of self-reference. Though the detailed reasons for endorsing dialetheism in each case are different, their general form is the same: a dialethic account of the phenomenon in question provides the most satisfactory way of handling the problems it poses. A local objection may therefore be provided by producing a consistent account of the phenomenon, and arguing this is rationally preferable. The precise issues involved here will, again, depend on the topic in question; but let us examine one issue in more detail. This will allow the illustration of a number of more general points.

The case we will look at is that of the semantic paradoxes. The background to this needs no long explanation, since a logician or philosopher who does not know it may fairly be asked where they have been this century. Certain arguments such as the Liar paradox, and many others discovered in the middle ages and around the turn of this century, appear to be sound arguments to the effect that certain contradictions employing self-reference and semantic notions are true. A dialethic account simply endorses the semantic principles in question, and thus the contradictions to which these give rise. A consistent account must find some way of rejecting the reasoning, notably by giving a different account of how the semantic apparatus

¹⁶⁸Objections along these lines can be found in Batens [1990], and Parsons [1990]. A reply can be found in Priest [1995].

¹⁶⁹That the same sentence may have different forces in different contexts is hardly a novel observation. For example, an utterance of 'Is the door closed', can be a question, a request or a command, depending on context, intonation, power-relationships, etc.

¹⁷⁰Some others, together with appropriate discussion, can be found in Sainsbury [1995], ch. 6.

functions. This account must both do justice to the data, and avoid the contradictions.

Many such accounts have, of course, been offered. But they are all well known to suffer from various serious problems. For example, they may provide no independent justification for the restrictions on the semantic principles involved, and so fail to explain why we should be so drawn to the general and contradiction-producing principles. They are often manifestly contrived and/or fly in the face of other well established views. Perhaps most seriously, none of them seems to avoid the paradoxes: all seem to be subject to extended paradoxes of one variety or another.¹⁷¹ If the global objections to dialetheism have no force, then, the dialethic position here seems manifestly superior.¹⁷²

It might be said that the inconsistency of the theory is at least a *prima facie* black mark against it. This may indeed be so; but even if one of the consistent theories could find plausible replies to its problems, as long as the theory is complex and fighting a rearguard action, the dialethic account may still have a simplicity, boldness and mathematical elegance that makes it preferable.

As orthodox philosophy of science realised a long time ago, there are many criteria which are good-making for theories: simplicity, adequacy to the data, preservation of established problem-solutions, etc.; and many which are bad-making: being contrived, handling the data in an *ad hoc* way, and, let us grant, being inconsistent, amongst others.¹⁷³ These criteria are usually orthogonal, and may even pull in opposite directions. But when applied to rival theories, the combined effect may well be to render an inconsistent theory rationally preferable to its consistent rival.

General conclusion: a theory in some area is to be rationally preferred to its rivals if it best satisfies the standard criteria of theory choice, familiar from the philosophy of science. An inconsistent theory may be the only viable theory; and even if it is not, it may still, on the whole, be rationally preferable.¹⁷⁴

¹⁷¹ All this is documented in Priest [1987], ch. 2.

¹⁷² One strategy that may be employed at this point is to argue that a dialethic theory is trivial, and hence that any other theory, even one with problems, is better. As we have seen, dialethic truth-theory is non-trivial, but one might nonetheless hope to prove that it is trivial when conjoined with other unobjectionable apparatus. Such arguments have been put forward by Denyer [1989], Smiley, in Priest and Smiley [1993], and Everett [1995] and elsewhere. Replies can be found in, respectively, Priest [1989b], Priest and Smiley [1993], and Priest [1996]. Since my aim here is to illustrate general features of the situation, I will not discuss these arguments.

¹⁷³ Though one might well challenge the last of these as a universal rule. There might be nothing wrong with *some* contradictions at all. See Priest [1987], sect. 13.6, and Sylvan [1992], sect. 2.

¹⁷⁴ For a longer discussion of the relationship between paraconsistency and rationality, see Priest [1987], ch. 7.

10.5 Boolean Negation

Another sort of local objection to some dialethic theories is based on the claim that, whatever one says about negation, there is certainly an operator that behaves in the way that Boolean negation does—call it what you like. Some paraconsistent logicians may even agree with this. (As we saw in 5.3, such an operator is definable in some of the da Costa systems.) And if the point is correct, it suffices to dispose of any dialethic account of the semantic paradoxes which endorses the *T*-schema; similarly, any account of set theory that endorses the Comprehension schema. For as I observed in the introduction to part 8, these schemas will then generate Boolean contradictions, and so entail triviality.

Someone who endorses such an account of semantics or set theory must therefore object to the claim that there is an operator that behaves as does Boolean negation. Why, after all, should we suppose this?¹⁷⁵ It might be suggested that we can simply define an operator, $-$, satisfying the proof theoretic principles of Boolean negation, and in particular: $\alpha, -\alpha \vdash \beta$. Such a suggestion would fail: the reason is simply that there is no guarantee that a connective, so characterised, has any determinate sense. The point was made by Prior [1960], who illustrated it with the operator “tonk”, $*$, supposedly characterised by the rules $\alpha \vdash \alpha * \beta$, $\alpha * \beta \vdash \beta$. Such an operator induces triviality and can make no sense. Similarly, a paraconsistent logician who endorses the *T*-schema may fairly point out that the supposition that there is an operator satisfying the proof-theoretic conditions of Boolean negation induces triviality, and so makes no sense.¹⁷⁶

The claim is theory laden, in the sense that it presupposes that the *T*-schema is correct. (The addition of such an operator need not produce triviality if only more limited machinery is present.) But any claim about what makes sense is bound to be theory-laden in a similar way. Prior’s argument, for example, presupposes the transitivity of deducibility, which may be questioned, as we have seen. The thought that Boolean negation is meaningless may initially be somewhat shocking. But the point has been argued by intuitionist logicians for many years. And though the grounds are quite different,¹⁷⁷ the paraconsistent logician sides with the intuitionist against the classical logician on this occasion.

Can we not, though, characterise Boolean negation semantically, and so show that it is a meaningful connective? The answer is, again, no; not without begging the question. How one attempts to characterise Boolean negation semantically will depend, of course, on one’s preferred sort of se-

¹⁷⁵The following material is covered in more detail in Priest [1990].

¹⁷⁶There may, of course, be operators that behave like Boolean negation in a limited domain. That is another matter.

¹⁷⁷The intuitionist reason is that meaningful logical operators cannot generate statements with recognition-transcendent truth conditions, which Boolean negation does. See, e.g., Dummett [1975].

mantics. Let me illustrate the matter with the Dunn semantics. Similar considerations apply to others. With these semantics, the natural attempt to characterise Boolean negation is:

$-\alpha\rho 1$ iff it is not the case that $\alpha\rho 1$
 $-\alpha\rho 0$ iff $\alpha\rho 1$

And such a characterisation makes perfectly good semantic sense. However, it does not entail that $-$ satisfies the Boolean proof-theoretic principles. Why should one suppose, crucially, that it validates $\alpha, -\alpha \models \beta$? From the characterisation, it certainly follows that for all ρ , it is not the case that $\alpha\rho 1$ and $-\alpha\rho 1$; but to infer from this that for all ρ , if $\alpha\rho 1$ and $-\alpha\rho 1$ then $\beta\rho 1$ (which states that the inference is valid), just employs the principle of inference that a conditional is true if the negation of its antecedent is. And no sensible paraconsistent conditional validates this.

In other words, to insist that $-$, so characterised, is explosive, just begs the question against the paraconsistentist. And if it is claimed that the negation in the statement of the truth conditions is itself Boolean, and so the inference is acceptable, this again begs the question: whether there is a connective satisfying the Boolean proof-theoretic conditions is exactly what is at issue.¹⁷⁸

10.6 *Logic as an Organon of Criticism*

We have now noted three reasons why one might employ a logic: as a purely instrumental means of generating consequences, as an organon of information preservation, and as an organon of truth preservation. This does not exhaust the uses for which one might employ a logic. Another very traditional one is as an organon of criticism, to force others to revise their views. One may object to the use of a paraconsistent logic in this context as follows. If one subscribes to a paraconsistent logic, then there is nothing to stop a person from accepting any inconsistency to which their views lead. Hence, paraconsistency renders logic useless in this context.¹⁷⁹

The move from the premise that contradictions do not entail everything to the claim that there is nothing to stop a person subscribing to a contradiction is a blatant *non-sequitur*. The threat of triviality may be a reason

¹⁷⁸ I have sometimes heard it said that the logic of a metatheory must be classical. This is just false, as the existence of intuitionist metatheories serves to remind. For certain purposes a dialetheist may, in any case, use a classical metatheory. If, for example, we are trying to show a certain theory to be non-trivial, it suffices to show all the theorems have some property which not all sentences have. This might well be shown using *ZF*. As we saw in 8.6, *ZF* makes perfectly good dialetheic sense.

¹⁷⁹ An objection of this kind is to be found in Popper [1963], pp. 316-7. The following is discussed at greater length in Priest [1987], ch. 7.

for revision; it is not the only reason. This is quite obvious in the case of non-dialethic paraconsistency. If a contradiction is entailed by one's views, then even though they do not explode into triviality, they are still not true. One will still, therefore, wish to revise. One may not, as in the classical case, have to revise immediately. It may not be at all clear how to revise; and in the meantime, an inconsistent but non-trivial belief set is better than no belief set at all. But the pressure will still be there to revise in due course.

The situation may be thought to change if one brings dialetheism into the picture. For the contradiction may then be true, and the pressure to revise is removed. Again, however, the conclusion is too swift. It is certainly true that showing that a person's views are inconsistent may not necessarily force a dialetheist to revise, but other things may well do so. For example, if a person is committed to something of the form $\alpha \rightarrow \perp$, and their views are shown to entail α , there will be pressure to revise, for exactly the classical reason.¹⁸⁰

Even if a dialetheist's views do not collapse into triviality, the inference to the claim that there is no pressure to revise is still too fast. The fact that there is no *logical* objection to holding on to a contradiction does not show there are no other kinds of objection. There is a lot more to rationality than consistency. Even those who hold consistency to be a constraint on rationality hold that there are many other such constraints. In fact, consistency is a rather weak constraint. That the earth is flat, that Elvis is alive and living in Melbourne, or, indeed, that one is Kermit the Frog, are all views that can be held consistently if one is prepared to make the right kinds of move elsewhere; but these views are manifestly irrational. For a start, there is no evidence for them; moreover, to make things work elsewhere one has to make all kinds of *ad hoc* adjustments to other well-supported views. And whatever constraints there are on rational belief—other than consistency—these work just as much on a dialetheist, and may provide pressure to revise. Not, perhaps, pressure of the *stand 'em up - knock 'em down* kind. But such would appear to be illusory in any case. As the history of ideas has shown, rational debates may be a long and drawn out business. There is no magic strategy that will always win the debate—other than employing (or at least showing) the instruments of torture.¹⁸¹

¹⁸⁰ Provided that one is not a person who believes that everything is true, then asserting $\alpha \rightarrow \perp$ is a way of denying α . A dialetheist might do this for a whole class of sentences, and so rule out contradictions occurring in certain areas, wholesale.

¹⁸¹ Avicenna, apparently, realised this. According to Scotus, he wrote that those who deny the law of non-contradiction 'should be flogged or burned until they admit that it is not the same thing to be burned and not burned, or whipped and not whipped'. (*The Oxford Commentary on the Four Books of the Sentences*, Bk. I, Dist. 39. Thanks to Vann McGee for the reference.)

11 CONCLUSION

Let me conclude this essay by trying to put a little perspective into the development of paraconsistent logic. Paraconsistent and explosive accounts of validity are both to be found in the history of logic. The revolution in logic that started around the turn of the century, and which was constituted by the development and application of novel and powerful mathematical techniques, entrenched explosion on the philosophical scene. The application of the same techniques to give paraconsistent logics had to wait until after the second world war.

The period from then until about the late 1970s saw the development of many paraconsistent logics, their proof theories and semantics, and an initial exploration of their possible applications. Though there are still many open problems in these areas, as I have indicated in this essay, the subject was well enough developed by that time to permit the beginning of a second phase: the investigation of inconsistent mathematical theories and structures in their own rights. Whereas the first period was dominated by a negative metaphor of paraconsistency as damage control, the second has been dominated by a more positive attitude: let us investigate inconsistent mathematical structures, both for their intrinsic interest and to see what problems—philosophical, mathematical, or even empirical—they can be used to solve.¹⁸²

Where this stage will lead is as yet anyone's guess. But let me speculate. Traditional wisdom has it that there have been three foundational crises in the history of mathematics. The first arose around the Fourth Century BC, with the discovery of irrational numbers, such as $\sqrt{2}$. It resulted in the overthrow of the Pythagorean doctrine that mathematical truths are exhausted by the domain of the whole numbers (and the rational numbers, which are reducible to these); and eventually, in the development of an appropriate mathematics. The second started in the Seventeenth Century with the discovery of the infinitesimal calculus. The appropriate mathematics came a little faster this time; and the result was the overthrow of the Aristotelian doctrine that truth is exhausted by the domain of the finite (or at least the potential infinite, which is a species of the finite). The third crisis started around the turn of this century, with the discovery of apparently inconsistent entities (such as the Russell set and the Liar sentence) in the foundations of logic and set theory—or at least, with the realisation that such entities could not be regarded as mere curiosities. This provided a major—perhaps the major—impetus for the development of paraconsistent logic and mathematics (as far as it has got). And the philosophical result may be the overthrow of another Aristotelian doctrine: that truth is

¹⁸²It must be said that both stages have been pursued in the face of an attitude sometimes bordering on hostility from certain sections of the establishment logico-philosophical, though things are slowly changing.

exhausted by the domain of the consistent.¹⁸³

PREFACE TO THE SECOND EDITION

It is with great pleasure that we are presenting to the community the second edition of this extraordinary handbook. It has been over 15 years since the publication of the first edition and there have been great changes in the landscape of philosophical logic since then.

The first edition has proved invaluable to generations of students and researchers in formal philosophy and language, as well as to consumers of logic in many applied areas. The main logic article in the Encyclopaedia Britannica 1999 has described the first edition as ‘the best starting point for exploring any of the topics in logic’. We are confident that the second edition will prove to be just as good!

The first edition was the second handbook published for the logic community. It followed the North Holland one volume *Handbook of Mathematical Logic*, published in 1977, edited by the late Jon Barwise. The four volume *Handbook of Philosophical Logic*, published 1983–1989 came at a fortunate temporal junction at the evolution of logic. This was the time when logic was gaining ground in computer science and artificial intelligence circles.

These areas were under increasing commercial pressure to provide devices which help and/or replace the human in his daily activity. This pressure required the use of logic in the modelling of human activity and organisation on the one hand and to provide the theoretical basis for the computer program constructs on the other. The result was that the *Handbook of Philosophical Logic*, which covered most of the areas needed from logic for these active communities, became their bible.

The increased demand for philosophical logic from computer science and artificial intelligence and computational linguistics accelerated the development of the subject directly and indirectly. It directly pushed research forward, stimulated by the needs of applications. New logic areas became established and old areas were enriched and expanded. At the same time, it socially provided employment for generations of logicians residing in computer science, linguistics and electrical engineering departments which of course helped keep the logic community thriving. In addition to that, it so happens (perhaps not by accident) that many of the Handbook contributors became active in these application areas and took their place as time passed on, among the most famous leading figures of applied philosophical logic of our times. Today we have a handbook with a most extraordinary collection of famous people as authors!

The table below will give our readers an idea of the landscape of logic and its relation to computer science and formal language and artificial intelligence. It shows that the first edition is very close to the mark of what was needed. Two topics were not included in the first edition, even though

they were extensively discussed by all authors in a 3-day Handbook meeting. These are:

- a chapter on non-monotonic logic
- a chapter on combinatory logic and λ -calculus

We felt at the time (1979) that non-monotonic logic was not ready for a chapter yet and that combinatory logic and λ -calculus was too far removed.¹ Non-monotonic logic is now a very major area of philosophical logic, alongside default logics, labelled deductive systems, fibring logics, multi-dimensional, multimodal and substructural logics. Intensive re-examinations of fragments of classical logic have produced fresh insights, including at time decision procedures and equivalence with non-classical systems.

Perhaps the most impressive achievement of philosophical logic as arising in the past decade has been the effective negotiation of research partnerships with fallacy theory, informal logic and argumentation theory, attested to by the Amsterdam Conference in Logic and Argumentation in 1995, and the two Bonn Conferences in Practical Reasoning in 1996 and 1997.

These subjects are becoming more and more useful in agent theory and intelligent and reactive databases.

Finally, fifteen years after the start of the Handbook project, I would like to take this opportunity to put forward my current views about logic in computer science, computational linguistics and artificial intelligence. In the early 1980s the perception of the role of logic in computer science was that of a specification and reasoning tool and that of a basis for possibly neat computer languages. The computer scientist was manipulating data structures and the use of logic was one of his options.

My own view at the time was that there was an opportunity for logic to play a key role in computer science and to exchange benefits with this rich and important application area and thus enhance its own evolution. The relationship between logic and computer science was perceived as very much like the relationship of applied mathematics to physics and engineering. Applied mathematics evolves through its use as an essential tool, and so we hoped for logic. Today my view has changed. As computer science and artificial intelligence deal more and more with distributed and interactive systems, processes, concurrency, agents, causes, transitions, communication and control (to name a few), the researcher in this area is having more and more in common with the traditional philosopher who has been analysing

¹I am really sorry, in hindsight, about the omission of the non-monotonic logic chapter. I wonder how the subject would have developed, if the AI research community had had a theoretical model, in the form of a chapter, to look at. Perhaps the area would have developed in a more streamlined way!

such questions for centuries (unrestricted by the capabilities of any hardware).

The principles governing the interaction of several processes, for example, are abstract and similar to principles governing the cooperation of two large organisations. A detailed rule based effective but rigid bureaucracy is very much similar to a complex computer program handling and manipulating data. My guess is that the principles underlying one are very much the same as those underlying the other.

I believe the day is not far away in the future when the computer scientist will wake up one morning with the realisation that he is actually a kind of formal philosopher!

The projected number of volumes for this Handbook is about 18. The subject has evolved and its areas have become interrelated to such an extent that it no longer makes sense to dedicate volumes to topics. However, the volumes do follow some natural groupings of chapters.

I would like to thank our authors and readers for their contributions and their commitment in making this Handbook a success. Thanks also to our publication administrator Mrs J. Spurr for her usual dedication and excellence and to Kluwer Academic Publishers for their continuing support for the Handbook.

Dov Gabbay
King's College London

Logic	IT			
	Natural language processing	Program control specification, verification, concurrency	Artificial intelligence	Logic programming
Temporal logic	Expressive power of tense operators. Temporal indices. Separation of past from future	Expressive power for recurrent events. Specification of temporal control. Decision problems. Model checking.	Planning. Time dependent data. Event calculus. Persistence through time—the Frame Problem. Temporal query language. temporal transactions.	Extension of Horn clause with time capability. Event calculus. Temporal logic programming.
Modal logic. Multi-modal logics	generalised quantifiers	Action logic	Belief revision. Inferential databases	Negation by failure and modality
Algorithmic proof	Discourse representation. Direct computation on linguistic input	New logics. Generic theorem provers	General theory of reasoning. Non-monotonic systems	Procedural approach to logic
Non-monotonic reasoning	Resolving ambiguities. Machine translation. Document classification. Relevance theory	Loop checking. Non-monotonic decisions about loops. Faults in systems.	Intrinsic logical discipline for AI. Evolving and communicating databases	Negation by failure. Deductive databases
Probabilistic and fuzzy logic	logical analysis of language	Real time systems	Expert systems. Machine learning	Semantics for logic programs
Intuitionistic logic	Quantifiers in logic	Constructive reasoning and proof theory about specification design	Intuitionistic logic is a better logical basis than classical logic	Horn clause logic is really intuitionistic. Extension of logic programming languages
Set theory, higher-order logic, λ-calculus, types	Montague semantics. Situation semantics	Non-well-founded sets	Hereditary finite predicates	λ -calculus extension to logic programs

Imperative vs. declarative languages	Database theory	Complexity theory	Agent theory	Special comments: A look to the future
Temporal logic as a declarative programming language. The changing past in databases. The imperative future	Temporal databases and temporal transactions	Complexity questions of decision procedures of the logics involved	An essential component	Temporal systems are becoming more and more sophisticated and extensively applied
Dynamic logic	Database updates and action logic	Ditto	Possible actions	Multimodal logics are on the rise. Quantification and context becoming very active
Types. Term rewrite systems. Abstract interpretation	Abduction, relevance	Ditto	Agent's implementation rely on proof theory.	
	Inferential databases. Non-monotonic coding of databases	Ditto	Agent's reasoning is non-monotonic	A major area now. Important for formalising practical reasoning
	Fuzzy and probabilistic data	Ditto	Connection with decision theory	Major area now
Semantics for programming languages. Martin-Löf theories	Database transactions. Inductive learning	Ditto	Agents constructive reasoning	Still a major central alternative to classical logic
Semantics for programming languages. Abstract interpretation. Domain recursion theory.		Ditto		More central than ever!

Classical logic. Classical frag- ments	Basic back- ground lan- guage	Program syn- thesis	A basic tool	
Labelled deductive systems	Extremely use- ful in modelling		A unifying framework. Context theory.	Annotated logic programs
Resource and substructural logics	Lambek calcu- lus		Truth maintenance systems	
Fibring and combining logics	Dynamic syn- tax	Modules. Combining languages	Logics of space and time	Combining fea- tures
Fallacy theory				
Logical Dynamics	Widely applied here			
Argumentation theory games		Game seman- tics gaining ground		
Object level/ metalevel			Extensively used in AI	
Mechanisms: Abduction, default relevance			ditto	
Connection with neural nets				
Time-action- revision mod- els			ditto	

	Relational databases	Logical complexity classes	The workhorse of logic	The study of fragments is very active and promising.
	Labelling allows for context and control.		Essential tool.	The new unifying framework for logics
Linear logic			Agents have limited resources	
	Linked databases. Reactive databases		Agents are built up of various fibred mechanisms	The notion of self-fibring allows for self-reference
				Fallacies are really valid modes of reasoning in the right context.
			Potentially applicable	A dynamic view of logic
				On the rise in all areas of applied logic. Promises a great future
			Important feature of agents	Always central in all areas
			Very important for agents	Becoming part of the notion of a logic
				Of great importance to the future. Just starting
			A new theory of logical agent	A new kind of model

BASIC TENSE LOGIC

1 WHAT IS TENSE LOGIC?

We approach this question through an example:

- (1) *Smith*: Have you heard? Jones is going to Albania!
Smythe: He won't get in without an extra-special visa.
 Has he remembered to apply for one?
Smith: Not yet, so far as I know.
Smythe: Then he'll have to do so soon.

In this bit of dialogue the argument, such as it is, turns on issues of temporal order. In English, as in all Indo-European and many other languages, such order is expressed in part through changes in verb-form, or tenses. How should the logician treat such tensed arguments?

A solution that comes naturally to mathematical logicians, and that has been forcefully advocated in [Quine, 1960], is to regiment ordinary tensed language to make it fit the patterns of classical logic. Thus Equation 1 might be reduced to the quasi-English Equation 1 below, and thence to the 'canonical notation' of Equation 3:

- (2) Jones/visits/Albania at some time later than the present.

At any time later than the present, if Jones/visits/Albania then, then at some earlier time Jones/applies/for a visa.

At no time earlier than or equal to the present it is the case that Jones/applies/for a visa.

Therefore, Jones/applies/for a visa at some time later than the present.

- (3) $\exists t(c < t \wedge P(t))$
 $\forall t(c < t \wedge P(t) \rightarrow \exists u(u < t \wedge Q(u)))$
 $\neg \exists t((t < c \vee t = c) \wedge Q(t))$
 $\therefore \exists t(c < t \wedge Q(t)).$

Regimentation involves introducing quantification over instants t, u, \dots of time, plus symbols of the present instant c and the earlier-later relation $<$. Above all, it involves treating such a linguistic item as 'Jones is visiting Albania' *not* as a complete sentence expressing a proposition and having a truth-value, to be symbolised by a sentential variable p, q, \dots , but rather as a predicate expressing a property on instants, to be symbolised by a one-place predicate variable P, Q, \dots . Regimentation has been called *detensing*

since the verb in, say, ‘Jones/visits/Albania at time t ’, written here in the grammatical present tense, ought really to be regarded as *tenseless*; for it states not a present fact but a timeless or ‘eternal’ property of the instant t . Bracketing is one convention for indicating such tenselessness. The knack for regimenting or detensing, for reducing something like Equation 1 to something like Equation 3, is easily acquired. The analysis, however, cannot stop there. For a tensed argument like that above must surely be regarded as an *enthymeme*, having as unstated premises certain assumptions about the structure of Time. Smith and Smythe, for instance, probably take it for granted that of any two distinct instants, one is earlier than the other. And if this assumption is formalised and added as an extra premise, then Equation 3, invalid as it stands, becomes valid.

Of course, it is the job of the cosmologist, not the logician, to judge whether such an assumption is physically or metaphysically correct. What *is* the logician’s job is to formalise such assumptions, correct or not, in logical symbolism. Fortunately, most assumptions people make about the structure of Time go over readily into first- or, at worst, second-order formulas.

1.1 Postulates for Earlier-Later

(B0)	Antisymmetry	$\forall x \forall y \neg(x < y \wedge y < x)$
(B1)	Transitivity	$\forall x \forall y \forall z (x < y \wedge y < z \rightarrow x < z)$
(B2)	Comparability	$\forall x \forall y (x < y \vee x = y \vee y < x)$
(B3)	(a) Maximum	$\exists x \forall y (y < x \vee y = x)$
	(b) Minimum	$\exists x \forall y (x < y \vee x = y)$
(B4)	(a) No Maximals	$\forall x \exists y (x < y)$
	(b) No Minimals	$\forall x \exists y (y < x)$
(B5)	Density	$\forall x \forall y (x < y \rightarrow \exists z (x < z \wedge z < y))$
(B6)	(a) Successors	$\forall x \exists y (x < y \wedge \neg \exists z (x < z \wedge z < y))$
	(b) Predecessors	$\forall x \exists y (y < x \wedge \neg \exists z (y < z \wedge z < x))$
(B7)	Completeness	$\forall U ((\exists x U(x) \wedge \exists x \neg U(x) \wedge$ $\forall x \forall y (U(x) \wedge$ $\wedge \neg U(y) \rightarrow x < y)) \rightarrow$ $(\exists x (U(x) \wedge$ $\wedge \forall y (x < y \rightarrow \neg U(y))) \vee$ $\exists x (\neg U(x) \wedge$ $\wedge \forall y (y < x \rightarrow U(y))))$
(B8)	Wellfoundedness	$\forall U (\exists x U(x) \rightarrow \exists x (U(x) \rightarrow$ $\wedge \forall y (y < x \rightarrow \neg U(y)))$
(B9)	(a) Upper Bounds	$\forall x \forall y \exists z (x < z \wedge y < z)$
	(b) Lower Bounds	$\forall x \forall y \exists z (z < x \wedge z < y)$.

For more on the development of the logic of time as a branch of applied first- and second-order logic, see [van Benthem, 1978].

The alternative to regimentation is the development of an autonomous *tense logic* (also called *temporal logic* or *chronological logic*), first undertaken in [Prior, 1957] (though several precursors are cited in [Prior, 1967]). Tense logic takes seriously the idea that items like ‘Jones is visiting Albania’ are already complete sentences expressing propositions and having truth-values, and that they should therefore be symbolised by sentential variables p, q, \dots . Of course, the truth-value of a sentence in the present tense may well differ from that of the corresponding sentence in the past or future tense. Hence, tense logic will need some way of symbolising the relations between sentences that differ only in the tense of the main verb. At its simplest, tense logic adds for this purpose to classical truth-functional sentential logic just two one-place connectives: the future-tense or ‘will’ operator F and the past-tense or ‘was’ operator P . Thus, if p symbolises ‘Jones is visiting Albania’, then Fp and Pp respectively symbolise something like ‘Jones is sooner or later going to visit Albania’ and ‘Jones has at least once visited Albania’. In reading tense-logical symbolism aloud. F and P may be read respectively as ‘it will be the case that’ and ‘it was the case that’. Then $\neg F\neg$, usually abbreviated G , and $\neg P\neg$, usually abbreviated H , may be read respectively as ‘it is always going to be the case that’ and ‘it has always been the case that’. Actually, for many purposes it is preferable to take G and H as primitive, defining F and P as $\neg G\neg$ and $\neg H\neg$ respectively. Armed with this notation, the tense-logician will reduce Equation 1 above to the stylised Equation 1.1 and then to the tense-logical Equation 5:

(4) Future-tense (Jones visits Albania)

Not future-tense (Jones visits Albania and not past-tense (Jones applies for a visa)).

Not past-tense (Jones applies for a visa) and not Jones applies for a visa.

Therefore, future-tense (Jones applies for a visa)

(5) Fp
 $\neg F(p \wedge \neg Pq)$
 $\neg Pq \wedge \neg q$
 $\therefore Fq.$

Of course, we will want some axioms and rules for the new temporal operators F, P, G, H . All the axiomatic systems considered in this survey will share the same standard format.

1.2 Standard Format

We start from a stock of sentential *variables* p_0, p_2, p_2, \dots , usually writing p for p_0 and q for p_1 . The (well-formed) *formulas* of tense logic are built

up from the variables using negation (\neg), and conjunction (\wedge), and the strong future (G) and strong past (H) operators. The *mirror image* of a formula is the result of replacing each occurrence of G by H and vice versa. Disjunction (\vee), material conditional (\rightarrow), material biconditional (\leftrightarrow), constant true (\top), constant false (\perp), weak future (F), and weak past (P) can be introduced as abbreviations.

As *axioms* we take all substitution instances of truth-functional tautologies. In addition, each particular system will take as axioms all substitution instances of some finite list of extra axioms, called the *characteristic* axioms of the system. As *rules* of inference we take Modus Ponens (MP) plus the specifically tense-logical:

Temporal Generalisation(TG): From α to infer $G\alpha$ and $H\alpha$

The *theses* of a system are the formulas obtainable from its axioms by these rules. A formula is *consistent* if its negation is not a thesis; a set of formulas is *consistent* if the conjunction of any finite subset is. These notions are, of course, relative to a given system.

The systems considered in this survey will have characteristic axioms drawn from the following list:

1.3 Postulates for a Past-Present-Future

- | | | | |
|------|--|-----|--|
| (A0) | (a) $G(p \rightarrow q) \rightarrow (Gp \rightarrow Gq)$ | (b) | $H(p \rightarrow q) \rightarrow (Hp \rightarrow Hq)$ |
| | (c) $p \rightarrow Gpp$ | (d) | $p \rightarrow HFp$ |
| (A1) | (a) $Gp \rightarrow GGp$ | (b) | $Hp \rightarrow HHp$ |
| (A2) | (a) $Pp \wedge Fq \rightarrow F(p \wedge Fq) \vee F(p \wedge q) \vee F(Fp \wedge q)$ | | |
| | (b) $Pp \wedge Pq \rightarrow P(p \wedge Pq) \vee P(p \wedge q) \vee P(Pp \wedge q)$ | | |
| (A3) | (a) $G\perp \vee FG\perp$ | (b) | $H\perp \vee PH\perp$ |
| (A4) | (a) $Gp \rightarrow Fp$ | (b) | $Hp \rightarrow Pp$ |
| (A5) | (a) $Fp \rightarrow FFp$ | (b) | $Pp \rightarrow PPp$ |
| (A6) | (a) $p \wedge Hp \rightarrow FHp$ | (b) | $p \wedge Gp \rightarrow PGp$ |
| (A7) | (a) $Fp \wedge FG\neg p \rightarrow F(HFp \wedge G\neg p)$ | | |
| | (b) $Pp \wedge PH\neg p \rightarrow P(GPp \wedge H\neg p)$ | | |
| (A8) | $H(Hp \rightarrow p) \rightarrow Hp$ | | |
| (A9) | (a) $FGp \rightarrow GFp$ | (b) | $PHp \rightarrow HPp$ |

A few definitions are needed before we can state precisely the basic problem of tense logic, that of finding characteristic axioms that ‘correspond’ to various assumptions about Time.

1.4 Formal Semantics

A *frame* is a nonempty set C equipped with a binary relation R . A *valuation* in a frame (X, R) is a function V assigning each variable p_i a subset of X . Intuitively, X can be thought of as representing the set of instants of time, R

the earlier-later relation, V the function telling us *when* each p_i is the case. We extend V to a function defined on *all* formulas, by abuse of notation still called V , inductively as follows:

$$\begin{aligned} V(\neg\alpha) &= X - V(\alpha) \\ V(\alpha \wedge \beta) &= V(\alpha) \cap V(\beta) \\ V(G\alpha) &= \{x \in X : \forall y \in X(xRy \rightarrow y \in V(\alpha))\} \\ V(H\alpha) &= \{x \in X : \forall y \in X(yRx \rightarrow y \in V(\alpha))\}. \end{aligned}$$

(Some writers prefer a different notion. Thus, what we have expressed as $x \in V(\alpha)$ may appear as $\|\alpha\|_x^V = \text{TRUE}$ or as $(X, R, V) \models \alpha[x]$.) A formula α is *valid* in a frame (X, R) if $V(\alpha) = X$ for every valuation V in (X, R) , and is *satisfiable* in (X, R) if $V(\alpha) \neq \emptyset$ for some valuation V in (X, R) , or equivalently if $\neg\alpha$ is not valid in (X, R) . Further, α is *valid* over a class \mathcal{K} of frames if it is valid in every $(X, R) \in \mathcal{K}$, and is *satisfiable* over \mathcal{K} if it is satisfiable in some $(X, R) \in \mathcal{K}$, or equivalently if $\neg\alpha$ is not valid over \mathcal{K} . A system \mathbf{L} in standard format is *sound* for \mathcal{K} if every thesis of \mathbf{L} is valid over \mathcal{K} , and a sound system \mathbf{L} is *complete* for \mathcal{K} if conversely every formula valid over \mathcal{K} is a thesis of \mathbf{L} , or equivalently, if every formula consistent with \mathbf{L} is satisfiable over \mathcal{K} . Any set (let us say, finite) Φ of first- or second-order axioms about the earlier-later relation $<$ determines a class $\mathcal{K}(\Phi)$ of frames, the class of its *models*. The basic correspondence problem of tense logic is, given Φ to find characteristic axioms for a system \mathbf{L} that will be sound and complete for $\mathcal{K}(\Phi)$. The next two sections of this survey will be devoted to representing the solution to this problem for many important Φ .

1.5 Motivation

But first it may be well to ask, why bother? Several classes of motives for developing an autonomous tense logic may be cited:

(a) *Philosophical* motives were behind much of the pioneering work of A. N. Prior, to whom the following point seemed most important: whereas our ordinary language is tensed, the language of physics is mathematical and so untensed. Thus, there arise opportunities for confusions between different ‘terms of ideas’. Now working in tense logic, what we learn is precisely how to avoid confusing the tensed and the tenseless, and how to clarify their relations (e.g. we learn that essentially the same thought can be formulated tenselessly as, ‘Of any two distinct instants, one /is/ earlier and the other /is/ later’, and tensedly as, ‘Whatever is going to have been the case either already has been or now is or is sometime going to be the case’). Thus, the study of tense logic can have at least a ‘therapeutic’ value. Later writers have stressed other philosophical applications, and some of these are treated elsewhere in this *Handbook*.

(b) *Exegetical* applications again interested Prior (see his [Prior, 1967, Chapter 7]). Much was written about the logic of time (especially about future contingents) by such ancient writers as Aristotle and Diodoros Kronos (whose works are unfortunately lost) and by such mediaeval ones as William of Ockham or Peter Auriolo. It is tempting to try to bring to bear insights from modern logic to the interpretation of their thought. But to pepper the text of an Aristotle or an Ockham with such regimenters' phrases as 'at time t ' is an almost certain guarantee of misunderstanding. For these earlier writers thought of such an item as 'Socrates is running' as being already complete as it stands, *not* as requiring supplementation before it could express a proposition or have a truth-value. Their standpoint, in other words, was like that of modern tense logic, whose notions and notations are likely to be of most use in interpreting their work, if any modern developments are.

(c) *Linguistic* motivations are behind much recent work in tense logic. A certain amount of controversy surrounds the application of tense logic to natural language. See, e.g. van Benthem [1978; 1981] for a critic's views. To avoid pointless disputes it should be emphasised from the beginning that tense logic does not attempt the faithful replication of every feature of the deep semantic structure (and still less of the surface syntax) of English or any other language; rather, it provides an idealised model giving the sympathetic linguist food for thought. an example: in tense logic, P and F can be iterated indefinitely to form, e.g. $PPPFp$ or $FPFPp$. In English, there are four types of verbal modifications indicating temporal reference, each applicable at most *once* to the main verb of a sentence: Progressive (be + ing), Perfect (have + en), Past (+ ed), and Modal auxiliaries (including will, would). Tense logic, by allowing unlimited iteration of its operators, departs from English, to be sure. But by doing so, it enables us to raise the question of whether the multiple compounds formable by such iteration are really all distinct in meaning; and a theorem of tense logic (see Section 3.5 below) tells us that on reasonable assumptions they are not, e.g. $PPPFp$ and $FPFPp$ both collapse to PFp (which is equivalent to PPp). and this may suggest *why* English does not *need* to allow unlimited iteration of its temporal verb modifications.

(d) *Computer Science*: Both tense logic itself and, even more so, the closely related so-called *dynamic logic* have recently been the objects of much investigation by theorists interested in program verification. temporal operators have been used to express such properties of programs as termination, correctness, safety, deadlock freedom, clean behaviour, data integrity, accessibility, responsiveness, and fair scheduling. These studies are mainly concerned only with *future* temporal operators, and so fall technically within the province of *modal* logic. See Harel *et al.*'s chapter on dynamic logic in Volume 4 of this *Handbook*, Pratt [1980] among other items in our bibliog-

raphy.

(e) *Mathematics*: Some taste of the purely mathematical interest of tense logic will, it is hoped, be apparent from the survey to follow. Moreover, tense logic is not an isolated subject within logic, but rather has important links with modal logic, intuitionistic logic, and (monadic) second-order logic.

Thus, the motives for investigating tense logic are many and varied.

2 FIRST STEPS IN TENSE LOGIC

Let \mathbf{L}_0 be the system in standard format with characteristic axioms (A0a, b, c, d). Let \mathcal{K}_0 be the class of *all* frames. We will show that \mathbf{L}_0 is (sound and) complete for \mathcal{L}_0 , and thus deserves the title of *minimal* tense logic. The method of proof will be applied to other systems in the next section. Throughout this section, thesishood and consistency are understood relative to \mathbf{L}_0 , validity and satisfiability relative to \mathcal{K}_0 .

THEOREM 1 (Soundness Theorem). \mathbf{L}_0 is sound for \mathcal{K}_0 .

Proof. We must show that any thesis (of \mathbf{L}_0) is valid (over \mathcal{K}_0). for this it suffices to show that each axiom is valid, and that each rule preserves validity. the verification that tautologies are valid, and that substitution and MP preserves validity is a bit tedious, but entirely routine.

To check that (A0a) is valid, we must show that for all relevant X, R, V and x , if $x \in V(G(p \rightarrow q))$ and $x \in V(Gp)$, then $x \in V(Gq)$. Well, the hypotheses here mean, first that whenever xRy and $y \in V(p)$, then $y \in V(q)$; and second that whenever xRy , then $y \in V(p)$. The desired conclusion is that whenever xRy , then $y \in V(q)$; which follows immediately. Intuitively, (A0a) says that if q is going to be the case whenever p is, and p is always going to be the case, then q is always going to be the case. The treatment of (A0b) is similar.

To check that (A0c) is valid, we must show that for all relevant X, R, V , and x , if $x \in V(p)$, then $x \in V(GPp)$. Well, the desired conclusion here is that for every y with xRy there is a z with zRy and $z \in V(p)$. It suffices to take $z = x$. Intuitively, (A0c) says that whatever is now the case is always going to have been the case. The treatment of (A0d) is similar.

To check that TG preserves validity, we must show that if for all relevant X, R, V , and x we have $x \in V(\alpha)$, then for all relevant X, R, V , and x we have $x \in V(H\alpha)$ and $x \in V(G\alpha)$, in other words, that whenever yRx we have $y \in V(\alpha)$ and whenever xRy we have $y \in V(\alpha)$. But this is immediate. Intuitively, TG says that if something is now the case *for logical reasons alone*, then for logical reasons alone it always has been and is always going to be the case: logical truth is eternal. ■

In future, verifications of soundness will be left as exercises for the reader. Our proof of the completeness of \mathbf{L}_0 for \mathcal{K}_0 will use the method of maximal

consistent sets, first developed for first-order logic by L. Henkin, systematically applied to tense logic by E. J. Lemmon and D. Scott (in notes eventually published as [Lemmon and Scott, 1977]), and refined [Gabbay, 1975].

The completeness of \mathbf{L}_0 for \mathcal{K}_0 is due to Lemmon. We need a number of preliminaries.

THEOREM 2 (Derived rules). *The following rules of inference preserve thesishood:*

1. from $\alpha_1, \alpha_2, \dots, \alpha_n$ to infer any truth-functional consequence β
2. from $\alpha \rightarrow \beta$ to infer $G\alpha \rightarrow G\beta$ and $H\alpha \rightarrow H\beta$
3. from $\alpha \leftrightarrow \beta$ and $\theta(\alpha/p)$ to infer $\theta(\beta/p)$
4. from α to infer its mirror image.

Proof.

1. To say that β is a truth-functional consequence of $\alpha_1, \alpha_2, \dots, \alpha_n$ is to say that $(\alpha_1 \wedge \alpha_2 \wedge \dots \wedge \alpha_n \rightarrow \beta)$ or equivalently $\alpha_1 \rightarrow (\alpha_2 \rightarrow (\dots (\alpha_n \rightarrow \beta) \dots))$ is an instance of a tautology, and hence is an axiom. We then apply MP.
2. From $\alpha \rightarrow \beta$ we first obtain $G(\alpha \rightarrow \beta)$ by TG, and then $G\alpha \rightarrow G\beta$ by A0a and MP. Similarly for H .
3. Here (α/p) denotes substitution of α for the variable p . It suffices to prove that if $\alpha \rightarrow \beta$ and $\beta \rightarrow \alpha$ are theses, then so are $\theta(\alpha/p) \rightarrow \theta(\beta/p)$ and $\theta(\beta/p) \rightarrow \theta(\alpha/p)$. This is proved by induction on the complexity of θ , using part (2) for the cases $\theta = G\chi$ and $\theta = H\chi$. In particular, part (3) allows us to insert and remove double negations freely. We write $\alpha \approx \beta$ to indicate that $\alpha \leftrightarrow \beta$ is a thesis.
4. This follows from the fact that the tense-logical axioms of \mathbf{L}_0 come in mirror-image pairs, (A0a, b) and (A0c, d). Unlike parts (1)–(3), part (4) will *not* necessarily hold for every extension of \mathbf{L}_0 . ■

THEOREM 3 (Theses). *Items (a)–(h) below are theses of \mathbf{L}_0 .*

Proof. We present a deduction, labelling some of the lines as theses for future reference:

- | | | |
|----------|--|--------------------------|
| (1) | $G(p \rightarrow q) \rightarrow G(\neg q \rightarrow \neg p)$ | from a tautology by 1.2b |
| (2) | $G(\neg q \rightarrow \neg p) \rightarrow (G\neg q \rightarrow G\neg p)$ | (A0a) |
| (a) (3) | $G(p \rightarrow q) \rightarrow (Fp \rightarrow Fq)$ | from 1,2 by 1.2a |
| (4) | $Gp \rightarrow G(q \rightarrow p \wedge q)$ | from a tautology by 1.2b |
| (5) | $G(q \rightarrow p \wedge q) \rightarrow (Fq \rightarrow F(p \wedge q))$ | 3 |
| (b) (6) | $Gp \wedge Fq \rightarrow F(p \wedge q)$ | from 4, 5 by 1.2a |
| (7) | $p \rightarrow GPP$ | (A0c) |
| (8) | $GPP \wedge Fq \rightarrow F(Pp \wedge q)$ | 6 |
| (c) (9) | $p \wedge Fq \rightarrow F(Pp \wedge q)$ | from 7, 8 by 1.2a |
| (10) | $G(p \wedge q) \rightarrow Gp$ | |
| | $G(p \wedge q) \rightarrow Gq$ | from tautologies by 1.2b |
| (11) | $G(q \rightarrow p \wedge q) \rightarrow (Gq \rightarrow G(p \wedge q))$ | (A0a) |
| (d) (12) | $Gp \wedge Gq \leftrightarrow G(p \wedge q)$ | 12 |
| (14) | $G\neg p \wedge G\neg q \rightarrow G\neg(p \vee q)$ | from 13 by 1.3c |
| (e) (15) | $Fp \vee Fq \leftrightarrow F(p \vee q)$ | from 14 by 1.2a |
| (16) | $Gp \rightarrow G(p \vee q)$ | |
| | $Gq \rightarrow G(p \vee q)$ | from tautologies by 1.2b |
| (f) (17) | $Gp \vee Gq \rightarrow G(p \vee q)$ | from 16 by 1.2a |
| (18) | $G\neg q \vee G\neg q \rightarrow G(\neg p \vee \neg q)$ | 17 |
| (19) | $G\neg p \vee G\neg q \rightarrow G\neg(p \wedge q)$ | from 18 by 1.2c |
| (g) (20) | $F(p \wedge q) \rightarrow Fp \wedge Fq$ | from 19 by 1.2a |
| (21) | $\neg p \rightarrow HF\neg p$ | (A0d) |
| (22) | $\neg p \rightarrow H\neg Gp$ | from 21 by 1.2c |
| (h) (23) | $PGp \rightarrow p$ | from 22 by 1.2a |

Also the mirror images of 1.3a–h are theses by 1.2d. ■

We assume familiarity with the following:

LEMMA 4 (Lindenbaum's Lemma). *Any consistent set of formulas can be extended to a maximal consistent set.*

LEMMA 5. *Let Q be a maximal consistent set of formulas. For all formulas we have:*

1. *If $\alpha_1, \dots, \alpha_n \in A$ and $\alpha_1 \wedge \dots \wedge \alpha_n \rightarrow \beta$ is a thesis, then $\beta \in A$.*
2. *$\neg\alpha \in A$ iff $\alpha \notin A$*
3. *$(\alpha \wedge \beta) \in A$ iff $\alpha \in A$ and $\beta \in A$*
4. *$(\alpha \vee \beta) \in A$ iff $\alpha \in A$ or $\beta \in A$.*

They will be used tacitly below.

Intuitively, a maximal consistent set—henceforth abbreviated MCS—represents a full description of a possible state of affairs. For MCSs A, B we say that A is *potentially followed* by B , and write $A \dashv\vdash B$, if the conditions

of Lemma 6 below are met. Intuitively, this means that a situation of the sort described by A could be followed by one of the sort described by B .

LEMMA 6. *For any MCSs A, B , the following are equivalent:*

1. *whenever $\alpha \in A$, we have $P\alpha \in B$,*
2. *whenever $\beta \in B$, we have $F\beta \in A$,*
3. *whenever $G\gamma \in A$, we have $\gamma \in B$,*
4. *whenever $H\delta \in B$, we have $\delta \in A$.*

Proof. To show (1) implies (3): assume (1) and let $G\gamma \in A$. Then $PG\gamma \in B$, so by Thesis 3(h) we have $\gamma \in B$ as required by (3).

To show (3) implies (2): assume (3) and let $\beta \in B$. then $\neg\beta \notin B$, so $G\neg\beta \notin A$, and $F\beta = \neg G\neg\beta \in A$ as required by (2).

Similarly (2) implies (4) and (4) implies (1). ■

LEMMA 7. *Let C be an MCS, γ any formula:*

1. *if $F\gamma \in C$, then there exists an MCS B with $C \rightarrow B$ and $\gamma \in B$,*
2. *if $P\gamma \in C$, then there exists an MCS A with $A \rightarrow C$ and $\gamma \in A$.*

Proof. We treat (1): it suffices (by the criterion of Lemma 6(a)) to obtain an MCS B containing $B_0 = \{P\alpha : \alpha \in C\} \cup \{\gamma\}$. For this it suffices (by Lindenbaum's Lemma) to show that B_0 is consistent. For this it suffices (by the closure of C under conjunction plus the mirror image of Theorem 3(g)) to show that for any $\alpha \in C$, $P\alpha \wedge \gamma$ is consistent. For this it suffices (since TG guarantees that $\neg F\delta$ is a thesis whenever $\neg\delta$ is) to show that $F(P\alpha \wedge \gamma)$ is consistent. And for this it suffices to show that $F(P\alpha \wedge \gamma)$ belongs to C —as it must by 3(c). ■

DEFINITION 8. A *chronicle* on a frame (X, R) is a function T assigning each $x \in X$ an MCS $T(x)$. Intuitively, if X is thought of as representing the set of instants, and R the earlier-later relation, T should be thought of as providing a complete description of what goes on at each instant. T is *coherent* if we have $T(x) \rightarrow T(y)$ whenever xRy . T is *prophetic* (resp. *historic*) if it is coherent and satisfies the first (resp. second) condition below:

1. *whenever $F\gamma \in T(x)$ there is a y with xRy and $\gamma \in T(y)$,*
2. *whenever $P\gamma \in T(x)$ there is a y with yRx and $\gamma \in T(y)$.*

T is *perfect* if it is both prophetic and historic. Note that T is coherent iff it satisfies the two following conditions:

3. whenever $\gamma \in T(x)$ and xRy , then $\gamma \in T(y)$,
4. whenever $H\gamma \in T(x)$, and yRx , then $\gamma \in T(y)$.

If V is a valuation in (X, R) , the *induced* chronicle T_V is defined by $T_V(x) = \{\gamma : x \in V(\gamma)\}$; T_V is always perfect. If T is a perfect chronicle on (X, R) , the *induced* valuation V_T is defined by $V_T(p_i) = \{x : p_i \in T(x)\}$. We have:

LEMMA 9 (Chronicle Lemma). *Let T be a perfect chronicle on a frame (X, R) . If $V = V_T$ is the valuation induced by T , then $T = T_V$ the chronicle induced by V . In other words, for all formulas γ we have:*

$$(+) \quad V(\gamma) = \{x : \gamma \in T(x)\}$$

In particular, any member of any $T(x)$ is satisfiable in (X, R) .

Proof. (+) is proved by induction on the complexity of γ . As a sample, we treat the induction step for G : assume (+) for γ , to prove it for $G\gamma$:

On the one hand, if $G\gamma \in T(x)$, then by Definition 8(3), whenever xRy we have $\gamma \in T(y)$ and by induction hypothesis $y \in V(\gamma)$. This shows $x \in V(G\gamma)$.

On the other hand, if $G\gamma \notin T(x)$, then $F\neg\gamma \approx \neg G\gamma \in T(x)$, so by Definition 8(1) for some y with xRy we have $\neg\gamma \in T(y)$ and $\gamma \notin T(y)$, whence by induction hypothesis, $y \notin V(\gamma)$. This shows $x \notin V(G\gamma)$. ■

To prove the completeness of \mathbf{L}_0 for \mathcal{K}_0 we must show that every consistent formula γ_0 is satisfiable. Now Lemma 9 suggests an obvious strategy for proving γ_0 satisfiable, namely to construct a perfect chronicle T on some frame (X, R) containing an x_0 with $\gamma_0 \in T(x_0)$. We will construct X, R , and T piecemeal.

DEFINITION 10. Fix a denumerably infinite set W . Let M be the set of all triples (X, R, T) such that :

1. X is a nonempty finite subset of W ,
2. R is an antisymmetric binary relation on X ,
3. T is a coherent chronicle on (X, R) .

For $\mu = (X, R, T)$ and $\mu' = (X', R', T')$ in M we say μ' *extends* μ if (when relations and functions are identified with sets of ordered pairs) we have:

- 1'. $X \subseteq X'$
- 2'. $R = R' \cap (X \times X)$
- 3'. $T \subseteq T'$.

A conditional requirement of form 8(1) or (2) will be called *unborn* for $\mu = (X, R, T) \in M$ if its antecedent is not fulfilled; that is, if $x \notin X$ or if $x \in X$ but $F\gamma$ or $P\gamma$ a the case may be does not belong to $T(x)$. It will be called *alive* for μ if its antecedent is fulfilled but its consequent is not; in other words, there is no $y \in X$ with xRy or yRx as the case may be and $\gamma \in T(y)$. It will be called *dead* for μ if its consequent is fulfilled.

Perhaps no member of M is perfect; but any imperfect member of M can be improved:

LEMMA 11 (Killing Lemma). *Let $\mu = (X, R, T) \in M$. For any requirement of form 8(1) or (2) which is alive for μ , there exists an extension $\mu' = (X', R', T') \in M$ of μ for which that requirement is dead.*

Proof. We treat a requirement of form 8(1). If $x \in X$ and $F\gamma \in T(x)$, by 7(1) there is an MCS B with $T(x) \rightarrow B$ and $\gamma \in B$. It therefore suffices to fix $y \in W - X$ and set

1. $X' = X \cup \{y\}$
2. $R' = R \cup \{(x, y)\}$
3. $T' = T \cup \{(y, B)\}$. ■

THEOREM 12 (Completeness Theorem). \mathbf{L}_0 is complete for \mathcal{K}_0 .

Proof. Given a consistent formula γ_0 , we wish to construct a frame (X, R) and a perfect chronicle T on it, with $\gamma_0 \in t(x_0)$ for some x_0 . To this end we fix an enumeration x_0, x_1, x_2, \dots of W , and an enumeration $\gamma_0, \gamma_1, \gamma_2, \dots$ of all formulas. To the requirement of form 8(1) (resp. 8(2)) for $x = x_i$ and $\gamma = \gamma_j$ we assign the *code number* $2 \cdot 5^i \cdot 7^j$ (resp. $3 \cdot 5^i \cdot 7^j$). Fix an MCS C_0 with $\gamma_0 \in C_0$, and let $\mu_0 = (X_0, R_0, T_0)$ where $X_0 = \{x_0\}$, $R_0 = \emptyset$, and $T_0 = \{(x_0, C_0)\}$. If μ_n is defined, consider the requirement, which among all those which are alive for μ_n , has the least code number. Let μ_{n+1} be an extension of μ_n for which that requirement is dead, as provided by the Killing Lemma. Let (X, R, T) be the union of the $\mu_n = (X_n, R_n, T_n)$; more precisely, let X be the union of the X_n , R of the R_n , and T of the T_n . It is readily verified that T is a perfect chronicle on (X, R) , as required. ■

The observant reader may be wondering why in Definition 10(2) the relation R was required to be antisymmetric. the reason was to enable us to make the following remark: our proof actually shows that every thesis of \mathbf{L}_0 is valid over the class \mathcal{K}_0 of all frames, and that every formula consistent with \mathbf{L}_0 is satisfiable over the class $\mathcal{K}_{\text{anti}}$ of antisymmetric frames. Thus, \mathcal{K}_0 and $\mathcal{K}_{\text{anti}}$ give rise to the same tense logic; or to put the matter differently, there is no characteristic axiom for tense logic which ‘corresponds’ to the assumption that the earlier-later relation on instants of time is antisymmetric.

In this connection a remark is in order: suppose we let X be the set of all MCSs, R the relation \rightarrow , V the valuation $V(p_i) = \{x : p_i \in x\}$. Then using Lemmas 6 and 7 it can be checked that $V(\gamma) = \{x : \gamma \in x\}$ for all γ . In this way we get a quick proof of the completeness of \mathbf{L}_0 for \mathcal{K}_0 . However, this (X, R) is not antisymmetric. Two MCSs A and B may be *clustered* in the sense that $A \rightarrow B$ and $B \rightarrow A$. There is a trick, known as ‘bulldozing’, though, for converting nonantisymmetric frames to antisymmetric ones, which can be used here to give an alternative proof of the completeness of \mathbf{L}_0 for $\mathcal{K}_{\text{anti}}$. See Bull and Segerberg’s chapter in Volume 3 of this *Handbook* and [Segerberg, 1970].

3 A QUICK TRIP THROUGH TENSE LOGIC

The material to be presented in this section was developed piecemeal in the late 1960s. In addition to persons already mentioned, R. Bull, N. Cocchiarella and S. Kripke should be cited as important contributors to this development. Since little was published at the time, it is now hard to assign credits.

3.1 Partial Orders

Let \mathbf{L}_1 be the extension for \mathbf{L}_0 obtained by adding (A1a) as an extra axiom. Let \mathcal{K}_1 be the class of *partial orders*, that is, of antisymmetric, transitive frames. We claim \mathbf{L}_1 is (sound and) complete for \mathcal{K}_1 . Leaving the verification of soundness as an exercise for the reader, we sketch the modifications in the work of the preceding section needed to establish completeness.

First of all, we must now understand the notions of thesishood and consistency and, hence, of MCS and chronicle, as relative to \mathbf{L}_0 . Next, we must revise clause 10(2) in the definition of \mathbf{M} to read:

2₁. R is a partial order on X .

This necessitates a revision in clause 11(2) in the proof of the Killing Lemma. Namely, in order to guarantee that R' will be a partial order on X' , that clause must now read:

2₁. $R' = R \cup \{(x, y)\} \cup \{(v, y) : vRx\}$.

But now it must be checked that T' , as defined by clause 11(3), remains a coherent chronicle under the revised definition of R' . Namely, it must be checked that if vRx , then $T(v) \rightarrow B$. To show this (and so complete the proof) the following suffices:

LEMMA *Let A, C, B be MCSs. If $A \rightarrow C$ and $C \rightarrow B$, then $A \rightarrow B$.*

Proof. We use criterion 6(3) for $\neg\exists$: assume $G\gamma \in A$, to prove $\gamma \in B$. Well, by the new axiom (A1a) we have $GG\gamma \in A$. Then since $A \neg\exists C$, we have $G\gamma \in C$, and since $C \neg\exists B$, we have $\gamma \in B$. ■

It is worth remarking that the mirror image (A1b) of (A1a) is equally valid over partial orders, and must thus by the completeness theorem be a thesis of \mathbf{L}_0 . To find a deduction of it is a nontrivial exercise.

3.2 Total Orders

Let \mathbf{L}_2 be the extension of \mathbf{L}_1 obtained by adding (A2a, b) as extra axioms. Let \mathcal{K}_1 be the class of *total orders*, or frames satisfying antisymmetry, transitivity, and comparability. Leaving the verification of soundness to the reader, we sketch the modifications in the work of Section 3.1 above, beyond simply understanding thesishood and related notions as relative to \mathbf{L}_2 , needed to show \mathbf{L}_2 complete for \mathcal{K}_2 .

To begin with, we must revise clause 10(2) in the definition of M to read:

2₂. R is a partial order on X .

This necessitates revisions in the proof of the Killing Lemma, for which the following will be useful:

LEMMA *Let A, B, C be MCSs. If $A \neg\exists B$ and $A \neg\exists C$, then either $B = C$ or $B \neg\exists C$ or $C \neg\exists B$.*

Proof. Suppose for contradiction that the two hypotheses hold but none of the three alternatives in the conclusion holds. Using criterion 6(2) for $\neg\exists$, we see that there must exist a $\gamma_0 \in C$ with $F\gamma_0 \notin b$ (else $B \neg\exists C$) and a $\beta_0 \in B$ with $F\beta_0 \notin C$ (else $C \neg\exists B$). Also there must exist a δ with $\delta \in B, \delta \notin C$ (else $B = C$). Let $\beta = \beta_0 \wedge \neg F\gamma_0 \wedge \delta \in B, \gamma = \gamma_0 \wedge \neg F\beta_0 \wedge \neg\delta \in C$. We have $F\beta \in A$ (since $A \neg\exists B$) and $F\gamma \in A$ (since $A \neg\exists C$). hence, by A2a, one of $F(\beta \wedge F\gamma), F(F\beta \wedge \gamma), F(\beta \wedge \gamma)$ must belong to A . But this is impossible since all three are easily seen (using 3(7)) to be inconsistent. ■

Turning now to the Killing Lemma, consider a requirement of form 8(1) which is alive for a certain $\mu = (X, R, T) \in M$. We claim there is an extension $\mu' = (X', R', T')$ for which it is dead. This is proved by induction on the number n of successors which x has in (X, R) . We fix an MCS B with $T(x) \neg\exists B$ and $\gamma \in B$. If $n = 0$, it suffices to define μ' as was done in Section 3.1 above.

If $n > 0$, let x' be the immediate successor of x in (X, R) . We cannot have $\gamma \in T(x')$ or else our requirement would already be dead for μ . If $F\gamma \in T(x')$, we can reduce to the case $n - 1$ by replacing x by x' . So suppose $F\gamma \notin T(x')$. Then we have neither $B = T(x')$ nor $T(x') \neg\exists B$.

Hence, by the Lemma, we must have $B \rightarrow \neg T(x')$. Therefore it suffices to fix $y \in W - X$ and set:

$$\begin{aligned} X' &= X \cup \{y\} \\ R' &= R \upharpoonright \text{cup}\{(x, y), (y, x')\} \cup \{(v, y) : vRx\} \cup \{(y, v) : (x'Rv)\} \\ I' &= T \cup \{(y, B)\}. \end{aligned}$$

In other words, we insert a point between x and x' , assigning it the set B . Requirements of form 8(2) are handled similarly, using a mirror image of the Lemma, proved using (A2b). No further modifications in the work of Section 3.1 above are called for.

The foregoing argument also establishes the following: let \mathbf{L}_{tree} be the extension of \mathbf{L}_1 obtained by adding (A2b) as an extra axiom. Let $\mathcal{K}_{\text{tree}}$ be the class of *trees*, defined for present purposes as those partial orders in which the predecessors of any element are totally ordered. Then \mathbf{L}_{tree} is complete for $\mathcal{K}_{\text{tree}}$.

It is worth remarking that the following are valid over total orders:

$$FPp \rightarrow Pp \vee p \vee Fp, \quad PFP \rightarrow Pp \vee p \vee Fp.$$

To find deductions of them in \mathbf{L}_2 is a nontrivial exercise. As a matter of fact, these two items could have been used instead of (A2a, b) as axioms for total orders. One could equally well have used their contrapositives:

$$Hp \wedge p \wedge Gp \rightarrow GHp, \quad Hp \wedge p \wedge Gp \rightarrow HGP.$$

The converses of these four items are valid over partial orders.

3.3 No Extremals (No Maximals, No Minimals)

Let \mathbf{L}_3 (resp. \mathbf{L}_4) be the extension of \mathbf{L}_2 obtained by adding (A3a, b) (resp. (A4a, b)) as extra axioms. Let \mathcal{K}_3 (resp. \mathcal{K}_4) be the class of total orders having (resp. not having) a maximum and a minimum. Beyond understanding the notions of consistency and MCS relative to \mathbf{L}_3 or \mathbf{L}_4 as the case may be, no modification in the work of Section 3.2 above is needed to prove \mathbf{L}_3 complete for \mathcal{K}_3 and \mathbf{L}_4 for \mathcal{K}_4 . The following observations suffice:

On the one hand, understanding consistency and MCS relative to \mathbf{L}_3 , if (X, R) is any total order and T any perfect chronicle on it, then for any $x \in X$, either $G\perp \in T(x)$ itself, or $FG\perp \in T(x)$ and so $G\perp \in t(y)$ for some y with xRy —this by (A3a). But if $G\perp \in T(z)$, then with w with zRw would have to have $\perp \in T(w)$, which is impossible so z must be the maximum of (X, R) . Similarly, A3b guarantees the existence of a minimum in (X, R) .

On the other hand, understanding consistency and MCS relative to \mathbf{L}_4 , if (X, R) is any total order and T any perfect chronicle on it, then for any

$x \in X$ we have $G\top \rightarrow F\top \in T(x)$, and hence $F\top \in T(x)$, so there must be a y with $(\top \in T(y))$ and xRy — this by (A4a). Similarly, (A4b) guarantees that for any x there is a y with yRx .

The foregoing argument also establishes that the extension of \mathbf{L}_1 obtained by adding (A4a, b) is complete for the class of partial orders having nonmaximal or minimal elements.

It hardly needs saying that one can axiomatise the view (characteristic of Western religious cosmologies) that Time had a beginning, but will have no end, by adding (A3b) and (A4a) to \mathbf{L}_2 .

3.4 Density

The extension \mathbf{L}_5 of \mathbf{L}_2 obtained by adding (A5a) (or equivalently (A5b)) is complete for the class \mathcal{K}_5 of dense total orders. The main modification in the work of Section 3.2 above needed to show this is that in addition to requirements of forms 8(1,2) we need to consider requirements of the form:

- 5. if xRy , then there exists a z with xRz and zRy .

To ‘kill’ such a requirement, given a coherent chronicle T on a finite total order $(X, R$ and $x, y \in X$ with y immediately succeeding x , we need to be able to insert a point z between x and y , and find a suitable MCS to assign to z . For this the following suffices:

LEMMA *Let A, B be MCSs with $A \dashv\vdash B$. Then there exists an MCS C with $A \dashv\vdash C$ and $C \dashv\vdash B$.*

Proof. The problem quickly reduces to showing $\{P\alpha : \alpha \in A\} \cup \{F\beta : \beta \in B\}$ consistent. For this it suffices to show that if $\alpha \in A$ and $\beta \in b$, then $F(P\alpha \wedge F\beta) \in A$. Now if $\beta \in B$, then since $A \dashv\vdash B, F\beta \in A$, and by (A5a), $FF\beta \in A$. An appeal to 3(3) completes the proof. ■

Figure 1.

Table 1.

$GGHp \approx GHp$	$FGHp \approx GHp$
$GFHp \approx GHp$	$FFHp \approx FHp$
$GPGp \approx Gp$	$FPGp \approx FGp$
$GPHp \approx PHp$	$FPHp \approx PHp$
$GFGp \approx FGp$	$FFGp \approx FGp$
$GHPp \approx HPp$	$FHPp \approx HPp$
$GGFp \approx GFp$	$FGFp \approx GFp$
$GGPp \approx GPp$	$FGPp \approx FPp$
$GHFp \approx GFp$	$FHFp \approx Fp$
$GFPp \approx FPp$	$FFPp \approx FPp$

Similarly, the extension \mathbf{L}_Q of \mathbf{L}_2 obtained by adding (A4a, b) and (A5a) is complete for the class of dense total orders without maximum or minimum. A famous theorem tells us that any *countable* order of this class is isomorphic to the rational numbers in their usual order. Since our method of proof always produces a *countable* frame, we can conclude that \mathbf{L}_Q is the tense logic of the rationals. The accompanying diagram (1) indicates some implications that are valid over dense total orders without maximum or minimum, and hence theses of \mathbf{L}_Q ; no further implications among the formulas considered are valid. A theorem of C. L. Hamblin tells us that in \mathbf{L}_Q any sequence of *G*s, *H*s, *F*s and *P*s prefixed to the variable *p* is provably equivalent to one of the 15 formulas in our diagram. It obviously suffices to prove this for sequences of length three. The reductions listed in the accompanying Table 1 together with their mirror images, suffice to prove this. It is a pleasant exercise to verify all the details.

3.5 Discreteness

The extension \mathbf{L}_6 of \mathbf{L}_2 obtained by adding (A6a, b) is complete for the class \mathcal{K}_6 of total orders in which every element has an immediate successor and an immediate predecessor. The proof involves quite a few modifications in the work of Section 3.2 above, beginning with:

LEMMA *For any MCS A there exists an MCS B such that:*

1. *whenever $F\gamma \in A$ then $\gamma \vee F\gamma \in B$.*

Moreover, any such MCS further satisfies:

2. *whenever $P\delta \in B$, then $\delta \vee P\delta \in A$,*

3. whenever $A \rightarrow C$, then either $B = C$ or $B \rightarrow C$,
4. whenever $C \rightarrow B$, then either $A = C$ or $C \rightarrow A$.

Proof.

1. The problem quickly reduces to proving the consistency of any finite set of formulas of the forms $P\alpha$ for $\alpha \in A$ and $\gamma \vee F\gamma$ for $F\gamma \in A$. To establish this, one notes that the following is valid over total orders, hence a thesis of \mathbf{L}_2 and *a fortiori* of \mathbf{L}_6 :

$$Fp_0 \wedge Fp_1 \wedge \dots \wedge Fp_n \rightarrow \\ F((p_0 \vee Fp_0) \wedge (p_1 \vee Fp_1) \wedge \dots \wedge (p_n \vee Fp_n))$$

2. We prove the contrapositive. Suppose $\delta \vee P\delta \notin A$. By (A6a), $FH\neg\delta \in A$. by part (1), $H\neg\delta \vee FH\neg\delta \in B$. But $FHp \rightarrow Hp$ is valid over total orders, hence a thesis of \mathbf{L}_2 and *a fortiori* of \mathbf{L}_6 . So $H\neg\delta \in B$ and $P\delta \notin B$ as required.
3. Assume for contradiction that $A \rightarrow C$ but neither $B = C$ nor $B \rightarrow C$. Then there exist a $\gamma_0 \in C$ with $\gamma_0 \notin B$ and a $\gamma_1 \in C$ with $F\gamma_1 \notin B$. Let $\gamma = \gamma_0 \wedge \gamma_1$. Then $\gamma \in C$ and since $A \rightarrow C$, $F\gamma \in A$. but $\gamma \vee F\gamma \notin B$, contrary to (1).
4. Similarly follows from (2). ■

We write $A \rightarrow' B$ to indicate that A, B are related as in the above Lemma. Intuitively this means that a situation of the sort described by A could be *immediately* followed by one of the sort described by B .

We now take M to be the set of *quadruples* (X, R, S, T) where on the one hand, as always X is a nonempty finite subset of W , R a total order on X , and T a coherent chronicle on (X, R) ; while on the other hand, we have:

4. whenever xSy , then y immediately succeeds x in (X, R) ,
5. whenever xSy , then $T(x) \rightarrow' T(y)$,

Intuitively xSy means that no points are ever to be added between x and y . We say (X', R', S', T') *extends* (X, R, S, T) if on the one hand, as always, Definition 10(1', 2', 3') hold; while on the other hand, $S \subseteq S'$. In addition to requirements of the form 8(1, 2) we need to consider requirements of the form:

5. there exists a y with xSy ,
4. there exists a y with ySx .

To ‘kill’ a requirement of form (5), take an MCS B with $T(x) \rightarrow 3' B$. If x is the maximum of (X, R) it suffices to fix $z \in W - X$ and set:

$$\begin{aligned} X' &= X \cup \{z\}, & R' &= R \cup \{(x, z)\} \cup \{(v, z) : vRx\}, \\ S' &= S \cup \{(x, z)\}, & T' &= T \cup \{(z, B)\} \end{aligned}$$

Otherwise, let y immediately succeed x in (X, R) . If $B = T(y)$ set:

$$\begin{aligned} X' &= X, & R' &= R, \\ S' &= S \cup \{(x, y)\} & T' &= T. \end{aligned}$$

Otherwise, we have $B \rightarrow 3T(y)$, and it suffices to fix $z \in W - X$ and set:

$$\begin{aligned} X' &= X, & R' &= R \cup \{(x, z), (z, y)\} \cup \\ & & & \cup \{(v, z) : vRx\} \cup \{(z, v) : yRv\}, \\ S' &= S \cup \{(x, z)\}, & T' &= T \cup \{(z, B)\} \end{aligned}$$

Similarly, to kill a requirement of form (6) we use the mirror image of the Lemma above, proved using (A6b).

It is also necessary to check that when xSy we never need to insert a point between x and y in order to kill a requirement of form 8(1) or (2). Reviewing the construction of Section 3.2 above, this follows from parts (3), (4) of the Lemma above. The remaining details are left to the reader.

A total order is *discrete* if every element but the maximum (if any) has an immediate successor, and every element but the minimum (if any) has an immediate predecessor. The foregoing argument establishes that we get a complete axiomatisation for the tense logic of discrete total orders by adding to \mathbf{L}_2 the following weakened versions of (A6a, b):

$$p \wedge Hp \rightarrow G \perp \vee FHp, \quad p \wedge Gp \rightarrow H \perp \vee PGp.$$

A total order is *homogeneous* if for any two of its points x, y there exists an automorphism carrying x to y . Such an order cannot have a maximum or minimum and must be either dense or discrete. In Burgess [1979] it is indicated that a complete axiomatisation of the tense logic is homogeneous orders is obtainable by adding to \mathbf{L}_4 the following which should be compared with (A5a) and (A6a, b):

$$(Fp \rightarrow FFp) \vee [(q \wedge Hq \rightarrow FHq) \wedge (q \wedge Gq \rightarrow PGq)].$$

3.6 Continuity

A *cut* in a total order (X, R) is a partition (Y, Z) of X into two nonempty pieces, such that whenever $y \in Y$ and $z \in Z$ we have yRz . A *gap* is a cut (Y, Z) such that Y has no maximum and Z no minimum. (X, R) is complete if it has no gaps. The *completion* (X^+, R^+) of a total order (X, R) is the complete total order obtained by inserting, for each gap (Y, Z) in (X, R) ,

an element $w(Y, Z)$ after all elements of Y and before all elements of Z . For example, the completion of the rational numbers in their usual order is the real numbers in their usual order. The extension \mathbf{L}_7 of \mathbf{L}_2 obtained by adding (A7a, b) is complete for the class \mathcal{K}_7 of complete total orders. The proof requires a couple of Lemmas:

LEMMA *Let T be a perfect chronicle on a total order (X, R) , and (Y, Z) a gap in (X, R) . Then if $G\alpha \in T(z)$ for all $z \in Z$, then $G\alpha \in T(y)$ for some $y \in Y$.*

Proof. Suppose for contradiction that $G\alpha \in T(z)$ for all $z \in Z$ but $F\neg\alpha \approx \neg G\alpha \in T(y)$ for all $y \in Y$. For any $y_0 \in Y$ we have $F\neg\alpha \wedge FG\alpha \in T(y_0)$. Hence, by A7a, $F(G\alpha \wedge HF\neg\alpha) \in T(y_0)$, and there is an x with y_0Rx and $G\alpha \in HF\neg\alpha \in T(x)$. But this is impossible, since if $x \in Y$ then $G\alpha \notin T(x)$, while if $x \in Z$ then $HF\neg\alpha \notin T(x)$. ■

LEMMA *Let T be a perfect chronicle on a total order (X, R) . Then T can be extended to a perfect chronicle T^+ on its completion (X^+, R^+) .*

Proof. For each gap (Y, Z) in (X, R) , the set:

$$C(Y, Z) = \{P\alpha : \exists y \in Y(\alpha \in T(y))\} \cup \{F\alpha : \exists z \in Z(\alpha \in T(z))\}$$

is consistent. This is because any finite subset, involving only y_1, \dots, y_m from Y and z_1, \dots, z_n from Z will be contained in $T(x)$ where x is any element of Y after all the y_i or any element of Z before all the z_j . Hence, we can define a coherent chronicle T^+ on (X^+, R^+) by taking $T^+(w(Y, Z))$ to be some MCS extending $C(Y, Z)$. Now if $F\alpha \in T^+(w(Y, Z))$, we claim that $F\alpha \in T(z)$ for some $z \in Z$. For if not, then $G\neg\alpha \in T(z)$ for all $z \in Z$, and by the previous Lemma, $G\neg\alpha \in T(y)$ for some $y \in Y$. But then $PG\neg\alpha$, which implies $\neg F\alpha$, would belong to $C(Y, Z) \subseteq T^+(w(Y, Z))$, a contradiction. It hardly needs saying that if $F\alpha \in T(z)$, then there is some x with zRx and *a fortiori* $w(Y, Z)R^+x$ having $\alpha \in T(x)$. This shows T^+ is prophetic. Axiom (A7b) gives us a mirror image to the previous Lemma, which can be used to show T^+ historic. ■

To prove the completeness of \mathbf{L}_7 for \mathcal{K}_7 , given a consistent γ_0 use the work of Section 2.2 above to construct a perfect chronicle T on a frame (X, R) such that $\gamma_0 \in T(x_0)$ for some x_0 . Then use the foregoing Lemma to extend to a perfect chronicle on a complete total order, as required to prove satisfiability. ■

Similarly, \mathbf{L}_R , the extension of \mathbf{L}_2 obtained by adding (A4a, b) and (A5a) and (A7a, b) is complete for the class of complete dense total orders without maximum or minimum, sometimes called *continuous* orders. As a matter of fact, our construction shows that any formula consistent with this theory is satisfiable in the completion of the rationals, that is, in the reals. Thus \mathbf{L}_R is the tense logic of real time and, hence, of the time of classical physics.

3.7 Well-Orders

The extension \mathbf{L}_8 of \mathbf{L}_2 obtained by adding (A8) is complete for the class \mathcal{K}_8 of all well-orders. For the proof it is convenient to introduce the abbreviations Ip for $Pp \vee p \vee Fp$ or ‘ p sometime’, and Bp for $p \wedge \neg Pp$ or ‘ p for the first time’. an easy consequence of (A8) is $Ip \rightarrow IBp$: if something *ever* happens, then there is a *first* time when it happens the reader can check that the following are valid over total orders; hence, theses of $(\mathbf{L}_2$ and *a fortiori* of \mathbf{L}_9):

1. $Ip \wedge Iq \rightarrow I(Pp \wedge q) \vee I(p \wedge q) \vee I(p \wedge Pq)$,
2. $I(q \wedge Fr) \wedge I(PBp \wedge Bq) \rightarrow I(p \wedge Fr)$.

Now, understanding consistency, MCS, and related notions relative to \mathbf{L}_8 , let δ_0 be any consistent formula and D_0 any MCS containing it. Let $\delta_1, \dots, \delta_k$ be all the proper subformulas of δ_0 . Let Γ be the set of formulas of form

$$(\neg)\delta_0 \wedge (\neg)\delta_1 \wedge \dots \wedge (\neg)\delta_k$$

where each δ_i appears once, plain or negated. Note that distinct elements of Γ are truth-functionally inconsistent. Let $\Gamma' = \{\gamma \in \Gamma : I\gamma \in D_0\}$. Note that for each $\gamma \in \Gamma'$ we have $IB\gamma \in D_0$, and that for distinct $\gamma, \gamma' \in \Gamma'$ we must by (1) have either $I(PB\gamma \wedge B\gamma')$ or $I(PB\gamma' \wedge B\gamma)$ in D_0 . Enumerate the elements of Γ' as $\gamma_0, \gamma_1, \dots, \gamma_n$ so that $I(PB\gamma_i \wedge B\gamma_j) \in D_0$ iff $i < j$. We write $i \triangleleft j$ if $I(\gamma_i \wedge F\gamma_j) \in D_0$. This clearly holds whenever $i < j$, but may also hold in other cases. A crucial observation is:

$$(+) \quad \text{If } i < j \leq k \text{ and } k \triangleleft i, \text{ then } j \triangleleft i$$

This follows from (2). These tedious preliminaries out of the way, we will now define a set X of ordinals and a function t from X to Γ' . Let a, b, c, \dots range over *positive* integers:

- We put $0 \in X$ and set $t(0) = \gamma_0$.
- If $0 \triangleleft 0$ we also put each $a \in X$ and set $t(a) = \gamma_0$.
- We put $\omega \in X$ and set $t(\omega) = \gamma_1$.
- If $1 \triangleleft 1$ we also put each $\xi = \omega \cdot b \in X$ and set $t(\xi) = \gamma_1$.
- If $1 \triangleleft 0$ we also put each $\xi = \omega \cdot b + a \in X$ and set $t(\xi) = \gamma_0$.
- We put $\omega^2 \in X$ and set $t(\omega^2) = \gamma_2$.
- If $2 \triangleleft 2$ we also put each $\xi = \omega^2 \cdot c \in X$ and set $t(\xi) = \gamma_2$.
- If $2 \triangleleft 1$ we also put each $\xi = \omega^2 \cdot c + \omega \cdot b \in X$, and set $t(\xi) = \gamma_1$.
- If $2 \triangleleft 0$ we also put each $\xi = \omega^2 \cdot c + \omega \cdot b + a \in X$ and set $t(\xi) = \gamma_0$.
- and so on.

Using (+) one sees that whenever $\xi, \eta \in X$ and $\xi < \eta$, then $i \triangleleft j$ where $t(\xi) = \gamma_i$ and $t(\eta) = \gamma_j$. Conversely, inspection of the construction shows that:

1. whenever $\xi \in X$ and $t(\xi) = \gamma_j$ and $j \triangleleft k$, then there is an $\eta \in X$ with $\xi < \eta$ and $t(\eta) = \gamma_k$
2. whenever $\xi \in X$ and $t(\xi) = \gamma_j$ and $i < j$, then there is an $\eta \in X$ with $\eta < \xi$ and $t(\eta) = \gamma_i$.

For $\xi \in X$ let $T(\xi)$ be the set of conjuncts of $t(\xi)$. Using (1) and (2) one sees that T satisfies all the requirements 8(1,2,3,4) for a perfect chronicle, *so far as these pertain to subformulas of δ_0* . Inspection of the proof of Lemma 9 then shows that this suffices to prove δ_0 satisfiable in the well-order $(X, <)$. ■

Without entering into details here, we remark that variants of \mathbf{L}_8 provide axiomatisations of the tense logics of the integers, the natural numbers, and of finite total orders. In particular, for the natural numbers one uses \mathbf{L}_ω , the extension of \mathbf{L}_2 obtained by adding (A8) and $p \wedge Gp \rightarrow H\perp \vee PGp$. \mathbf{L}_ω is the tense logic of the notion of time appropriate for discussing the working of a digital computer, or of the mental mathematical constructions of Brouwer's 'creative subject'.

3.8 Lattices

The extension \mathbf{L}_9 of \mathbf{L}_1 obtained by adding (A4a, b) and (A9a, b) is complete for the class \mathcal{K}_9 of partial orders without maximal or minimal elements in which any two elements have an upper and a lower bound. We sketch the modifications in the work of Section 3.2 above needed to prove this:

To begin with, we must revise clause 10(2) in the definition of M to read:

- 2g. R is a partial order on X having a maximum and a minimum.

This necessitates revisions in the proof of the Killing Lemma, for which the following will be useful:

LEMMA *Let A, B, C be MCSs. If $A \rightarrow B$ and $A \rightarrow C$, then there exists an MCS D such that $B \rightarrow D$ and $C \rightarrow D$.*

Proof. The problem quickly reduces to showing $\{\beta : G\beta \in B\} \cup \{\gamma : G\gamma \in C\}$ consistent. For this it suffices (using 3(4)) to show that $\beta \wedge \gamma$ is consistent whenever $G\beta \in B, G\gamma \in C$. Now in that case we have $FG\beta, FG\gamma \in A$, since $A \rightarrow B, C$. By A9a, we then have $GF\beta \in A$, and by 3(2) we then have $F(F\beta \wedge G\gamma) \in A$ and $FF(\beta \wedge \gamma) \in A$, which suffices to prove $\beta \wedge \gamma$ consistent as required. ■

Turning now to the Killing Lemma, trouble arises when for a given $(X, R, T) \in M$ a requirement of form Definition 8(1) is said to be 'killed' for some x other than the maximum y of (X, R) and some $F\gamma \in T(x)$.

Fixing an MCS B with $T(x) \rightarrow B$ and $\gamma \in B$, and $az \in W - X$, we would like to add z to x placing it after x and assigning it the MCS B . But we cannot simply do this, else the resulting partial order would have no maximum. (For y and z would be incomparable.) So we apply the Lemma (with $A = T(x), C = T(y)$) to obtain an MCS D with $B \rightarrow D$ and $T(y) \rightarrow D$. We fix a $w \in W - X$ distinct from z , and set:

$$\begin{aligned} X' &= X \cup \{z, w\}, \\ R' &= R \cup \{(x, z), (z, w)\} \cup \{(v, z) : vRx\} \cup \{(v, w) : v \in X\}. \\ T' &= T \cup \{(z, B), (w, D)\}. \end{aligned}$$

Similarly, a requirement of form 8(2) involving an element other than the minimum is treated using the mirror image of the Lemma above, proved using (A9b).

Now given a formula γ_0 consistent with \mathbf{L}_9 , the construction of Definition 10 above produces a perfect chronicle T on a partial order (X, R) with $\gamma_0 \in T(x_0)$ for some x_0 . The work of Section 2.4 above shows that (X, R) will have no maximal or minimal elements. Moreover, (X, R) will be a union of partial orders (X_n, R_n) satisfying (2g). Then any $x, y \in X$ will have an R -upper bound and an R -lower bound, namely the R_n -maximum and R_n -minimum elements of any X_n containing them both. Thus, $(X, R) \in \mathcal{K}_9$ and γ_0 is satisfiable over \mathcal{K}_9 . ■

A *lattice* is a partial order in which any two elements have a *least* upper bound and a *greatest* lower bound. Actually, our proof shows that \mathbf{L}_9 is complete for the class of lattices without maximum or minimum. It is worth mentioning that (A9a, b) could have been replaced by:

$$Fp \wedge Fq \rightarrow F(Pp \wedge Pq), \quad Pp \wedge Pq \rightarrow P(Fp \wedge Fq).$$

Weakened versions of these axioms can be used to give an axiomatisation for the tense logic of arbitrary lattices.

4 THE DECIDABILITY OF TENSE LOGICS

All the systems of tense logic we have considered so far are recursively decidable. Rather than give an exhaustive (and exhausting) survey, we treat here two examples, illustrating the two basic methods of proving decidability: one method, borrowed from modal logic, is that of using so-called *filtrations* to establish what is known as the *finite model property*. The other, borrowed from model theory, is that of using so-called *interpretations* in order to be able to exploit a powerful theorem of [Rabin, 1966].

THEOREM 13. \mathbf{L}_9 is decidable.

Proof. Let \mathcal{K} be the class of models of (B1) and (B9a, b); thus \mathcal{K} is like \mathcal{K}_9 except that we do *not* require antisymmetry. Let \mathcal{K}' be the class of finite

elements of \mathcal{K} . It is readily verified that \mathbf{L}_9 is sound for \mathcal{K} and *a fortiori* for \mathcal{K}' . We claim that \mathbf{L}_9 is complete for \mathcal{K}' . This provides an effective procedure for testing whether a given formula α is a thesis of \mathbf{L}_9 or not, as follows: search simultaneously through all deductions in the system \mathbf{L}_9 and through all members of \mathcal{K}' —or more precisely, of some nice countable subclass of \mathcal{K}' containing at least one representative of each isomorphism-type. Eventually one either finds a deduction of α , in which case α is a thesis, or one finds an element of \mathcal{K}' in which $\neg\alpha$ is satisfiable, in which case by our completeness claim, α is not a thesis.

To prove our completeness claim, let γ_0 be consistent with \mathbf{L}_9 . We showed in Section 2.9 above how to construct a perfect chronicle T on a frame $(X, R) \in \mathcal{K}_9 \subseteq \mathcal{K}$ having $\gamma_0 \in T(x_0)$ for some x_0 . For $x \in X$, let $t(x)$ be the set of subformulas of γ_0 in $T(x)$. Define an equivalence relation on X by:

$$x \leftrightarrow y \text{ iff } t(x) = t(y).$$

Let $[x]$ denote the equivalence class of x , X' the set of all $[x]$. Note that X' is finite, having no more than 2^k elements, where k is the number of subformulas of γ_0 . Consider the relations on X' defined by:

$$\begin{aligned} aR^+b & \text{ iff } xRy \text{ for some } x \in a \text{ and } y \in b, \\ aR'b & \text{ iff for some finite sequence } a = c_0, c_1, \dots, c_{n-1}, c_n = b \\ & \text{ we have } c_iR^+c_{i+1} \text{ for all } i < n. \end{aligned}$$

Clearly R' is transitive, while R^+ and, hence, R' inherit from R the properties expressed by B9a, b. Thus $(X', R') \in \mathcal{K}'$. Define a function t' on X' by letting $t'(a)$ be the common value of $t(x)$ for all $x \in a$. In particular for $a_0 = [x_0]$ we have $\gamma_0 \in t'(a_0)$. We claim that t' satisfies clauses 8(1, 2, 3, 4) of the definition of a perfect chronicle *so far as these pertain to subformulas of γ_0* . As remarked in Section 3.8 above, this suffices to show γ_0 satisfiable in (X', R') and, hence, satisfiable over \mathcal{K}' as required.

In connection with Definition 8(1), what we must show is:

$$1. \text{ whenever } F\gamma \in t(a) \text{ there is a } b \text{ with } aR'b \text{ and } \gamma \in t(b)$$

Well, let $a = [x]$, so $F\gamma \in t(x) \subseteq T(x)$. There is a y with xRy and $\gamma \in t(y)$ since T is prophetic. Letting $b = [y]$ we have aR^+b and so $aR'b$.

In connection with Definition 8(3) what we must show is:

$$3'. \text{ whenever } G\gamma \in t(a) \text{ and } aR'b, \text{ then } \gamma \in t(b).$$

For this it clearly suffices to show:

$$3^+ \text{ whenever } G\gamma \in t(a) \text{ and } aR^+b, \text{ then } \gamma \in t(b) \text{ and } G\gamma \in t(b).$$

To show this, assuming the two hypotheses, fix $x \in a$ and $y \in b$ with xRy . We have $G\gamma \in t(x) \subseteq T(x)$, so by (A1a), $GG\gamma \in T(x)$. Hence, $\gamma \in t(y)$ and $G\gamma \in t(y)$, since T is coherent—which completes the proof.

Definitions 8(2, 4) are treated similarly. ■

THEOREM 14. \mathbf{L}_R is decidable.

Proof. We introduce an alternative definition of *validity* which is useful in other contexts. To each tense-logical formula α we associate a first-order formula $\hat{\alpha}$ as follows: for a sentential variable p_i we set $\hat{p}_i = P_i(x)$ where P_i is a one-place predicate variable. We then proceed inductively:

$$\begin{aligned} (\neg\alpha)^\wedge &= \neg\hat{\alpha}, \\ (\alpha \wedge \beta)^\wedge &= \hat{\alpha} \wedge \hat{\beta} \\ (G\alpha)^\wedge &= \forall y(x < y \rightarrow \hat{\alpha}(y/x)), \\ (H\alpha)^\wedge &= \forall y(y < x \rightarrow \hat{\alpha}(y/x)). \end{aligned}$$

Here (y/x) represents the result of substituting for x the alphabetically first variable y not occurring yet. Given a valuation V in a frame (X, R) we have an interpretation in the sense of first-order model theory, in which R interprets the symbol $<$ and $V(p_i)$ the symbol P_i . Unpacking the definitions it is entirely trivial that we always have:

$$(*) \quad a \in V(\alpha) \text{ iff } (X, R, V(p_0), V(p_1), V(p_2), \dots) \models \hat{\alpha}(x),$$

where \models is the usual satisfaction relation of model theory. We now further define:

$$a^+ = \forall P_0 \forall P_1, \dots, \forall P_k \forall x \hat{\alpha}(x),$$

where p_0, p_1, \dots, p_k include all the variables occurring in α . Note that α^+ is a second-order formula of the simplest kind: it is *monadic* (all its second-order variables are *one-* place predicate variables) and *universal* (consisting of a string of universally-quantified second-order variables prefixed to a first-order formula). It is entirely trivial that:

$$(+)$$

$$\alpha \text{ is valid in } (X, R) \text{ iff } (X, R) \models \alpha^+$$

It follows that to prove the decidability of the tense logic of a given class \mathcal{K} of frames it will suffice to prove the decidability of the set of universal monadic (second-order) formulas true in all members of \mathcal{K} .

Let $2^{<\omega}$ be the set of all finite 0,1-sequences. Let $*0$ be the function assigning the argument $s = (i_0, i_1, \dots, i_n) \in 2^{<\omega}$ the value $s * 0 = (i_0, i_1, \dots, i_n, 0)$, and similarly for $*1$. Rabin proves the decidability of the set $S2S$ of monadic (second order) formulas true in the structure $(2^{<\omega}, *0, *1)$. He deduces as an easy corollary the decidability of the set of monadic formulas true in the frame $(\mathbb{Q}, <)$ consisting of the rational numbers with their usual order. This immediately yields the decidability of the system \mathbf{L}_Q of Section 2.5 above. Further corollaries relevant to tense logic are the decidability of the set of monadic formulas true in all countable total orders, and similarly for countable well-orders.

It only remains to reduce the decision problem for \mathbf{L}_R to that for \mathbf{L}_Q . The work of 2.7 above shows that a formula α is satisfiable in the frame $(\mathbb{R}, <)$ consisting of the real numbers with their usual order, iff it is satisfiable in the frame $(\mathbb{Q}, <)$ by a valuation V with the property:

1. $V(\alpha) = \mathbb{Q}$ for every substitution instance α of (A7a or b).

Inspection of the proof actually shows that it suffices to have:

2. $V(\alpha') = \mathbb{Q}$ where α' is the conjunction of all instances of (A7a or b) obtainable by substituting subformulas of α for variables.

A little thought shows that this amounts to demanding:

3. $V(\alpha \wedge GH\alpha') \neq \emptyset$.

In other words, α is satisfiable in $(\mathbb{R}, <)$ iff $\alpha \wedge GH\alpha'$ is satisfiable in $(\mathbb{R}, <)$, which effects the desired reduction. For the lengthy original proof see [Bull, 1968]. Other applications of Rabin's theorem are in [Gabbay, 1975]. Rabin's proof uses automata-theoretic methods of Büchi; these are avoided by [Shelah, 1975]. ■

5 TEMPORAL CONJUNCTIONS AND ADVERBS

5.1 *Since, Until, Uninterruptedly, Recently, Soon*

All the systems discussed so far have been based on the primitives \neg, \wedge, G, H . It is well-known that any truth function can be defined in terms of \neg, \wedge . Can we say something comparable about temporal operators and G, H ? When this question is formulated precisely, the answer is a resounding NO.

DEFINITION 15. Let φ be a first-order formula having one free variable x and no nonlogical symbols but the two-place predicate $<$ and the one-place predicates P_1, \dots, P_n . corresponding to φ we introduce a new n -place connective, the (first-order, one-dimensional) temporal operator $O(\varphi)$. We describe the formal semantics of $O(\varphi)$ in terms of the alternative approach of Theorem 14 above: we add to the definition of $\hat{}$ the clause:

$$(O(\varphi)(\alpha_1, \dots, \alpha_n))^\wedge = \varphi(\hat{\alpha}_1/P_1, \dots, \hat{\alpha}_n/P_n).$$

Here $\hat{\alpha}/P$ denotes substitution of the formula $\hat{\alpha}$ for the predicate variable P . We then let formula (*) of Theorem 14 above *define* $V(\alpha)$ for formulas α involving $O(\varphi)$. Examples 16 below illustrate this rather involved definition. If $\mathcal{O} = \{O(\varphi_1), \dots, O(\varphi_k)\}$ is a set of temporal operators, an \mathcal{O} -*formula* is one built up from sentential variables using \neg, \wedge , and elements of \mathcal{O} . A temporal operator $O(\varphi)$ is \mathcal{O} -*definable* over a class \mathcal{K} of frames if there is an \mathcal{O} -formula α such that $O(\varphi)(p_1, \dots, p_n) \leftrightarrow \alpha$ is valid over \mathcal{K} . \mathcal{O} is

temporally complete over \mathcal{K} if every temporal operator is \mathcal{O} -definable over \mathcal{K} . Note that the smaller \mathcal{K} is—it may consist of a single frame—the easier it is to be temporally complete over it.

EXAMPLES 16.

1. $\forall y(x < y \rightarrow P_1(y))$
2. $\forall y(y < x \rightarrow P_1(y))$
3. $\exists y(x < y \wedge \forall z(x < z \wedge z < y \rightarrow P_1(z)))$
4. $\exists y(y < x \wedge \forall z(y < z \wedge z < x \rightarrow P_1(z)))$
5. $\exists y(x < y \wedge P_1(y) \wedge \forall z(y < z \wedge z < x \rightarrow P_1(z)))$

For (1), $O(\varphi)$ is just G . For (2), $O(\varphi)$ is just H . For (3), $O(\varphi)$ will be written G' , and may be read ‘ p is going to be uninterruptedly the case for some time’. For (4), $O(\varphi)$ will be written H' , and may be read ‘ p has been uninterruptedly the case for some time. For (5), $O(\varphi)$ will be written U , and $U(p, q)$ may be read ‘until p, q ’; it predicts a future occasion of p ’s being the case, up until which q is going to be uninterruptedly the case. For (6), $O(\varphi)$ will be written S , and $S(p, q)$ may be read ‘since p, q ’. In terms of G' we define $F' = \neg G; \neg$, read ‘ p is going to be the case arbitrarily soon’. In terms of H' we define $P' = \neg H' \neg$, read ‘ p has been the case arbitrarily recently’. Over all frames, Gp is definable as $\neg U(\neg p, \top)$, and G' as $U(\top, p)$. Similarly, H and H' are definable in terms of S . The following examples are due to H. Kamp:

PROPOSITION 17. G' is not G, H -definable over the frame $(\mathbb{R}, <)$.

Sketch of Proof. Define two valuations over that frame by:

$$V(p) = \{0, \pm 1, \pm 2, \pm 3, \dots\} \quad W(p) = V(p) \cup \{\pm \frac{1}{2}, \pm \frac{1}{4}, \pm \frac{1}{8}, \dots\}$$

Then intuitively it is plausible, and formally it can be proved that for any G, H -formula α we have $0 \in V(\alpha)$ iff $0 \in W(\alpha)$. But $0 \in V(G'p) - W(G'p)$. ■

PROPOSITION 18. U is not G, H, G', H' -definable over the frame $(\mathbb{R}, <)$.

Sketch of Proof. Define two valuations by:

$$\begin{aligned} V(p) &= \{\pm 1, \pm 2, \pm 3, \pm 4, \dots\} & W(p) &= \{\pm 2, \pm 3, \pm 4, \dots\} \\ V(q) &= W(q) = \text{the union of the open intervals} \\ &\dots, (-5, -4), (-3, -2), (-1, +1), \\ &(+2, +3), (+4, +5), \dots \end{aligned}$$

Then intuitively it is plausible, and formally it can be proved that for any G, H, G', H' -formula α we have $0 \in V(\alpha)$ iff $0 \in W(\alpha)$. But $0 \in V(U(p, q) - W(U(p, q)))$. ■

Such examples might inspire pessimism, but [Kamp, 1968] proves:

THEOREM 19. *The set $\{U, S\}$ is temporally complete over continuous orders.*

We will do no more than outline the difficult proof (in an improved version due to Gabbay): Let \mathcal{O} be a set of temporal operators, \mathcal{K} a class of frames. An \mathcal{O} -formula α is *purely past* over \mathcal{K} if whenever $(X, R) \in \mathcal{K}$ and $x \in K$ and V, W are valuations in (X, R) agreeing before x (so that for all i , $V(p_i) \cap \{y : yRx\} = W(p_i) \cap \{y : yRx\}$) then $x \in V(\alpha)$ iff $x \in W(\alpha)$. Similarly, one defines *purely present* and *purely future*, and one defines *pure* to mean purely past, or present, or future. Note that $Hp, H'p, S(p, q)$, are purely past, their mirror images purely future, and any truth-functional compound of variables purely present. \mathcal{O} has the *separation property* over \mathcal{K} if for every \mathcal{O} -formula α there exists a truth-functional compound β of \mathcal{O} -formulas pure over \mathcal{K} such that $\alpha \leftrightarrow \beta$ is valid over \mathcal{K} . \mathcal{O} is *strong* over \mathcal{K} if G, H are \mathcal{O} -definable over \mathcal{K} . Gabbay [1981a] proves:

Criterion 20. *Over any given class \mathcal{K} of total orders, if \mathcal{O} is strong and has the separation property, then it is temporally complete.*

A full proof being beyond the scope of this survey (see, however, the next chapter ‘Advanced Tense Logic’), we offer a sketch: we wish to find for any first-order formula $\varphi(x, <, P_1, \dots, P_n)$ an \mathcal{O} -formula $\alpha(p_1, \dots, p_n)$ *representing* it in the sense that for any $(X, R) \in \mathcal{K}$ and any valuation V and any $a \in X$ we have:

$$a \in V(\alpha) \text{ iff } (X, R, V(p_1), \dots, V(p_n)) \models \varphi(a/x).$$

The proof proceeds by induction on the depth of nesting of quantifiers in φ , the key step being $\varphi(x) = \exists y \psi(x, y)$. In this case, the atomic subformulas of ψ are of the forms $P_i(x), P_i(z), z < x, z = x, x < z, z = w, z < w$, where z and w are variables other than x . Actually, we may assume there are no subformulas of the form $P_i(x)$ since these can be brought outside the quantifier $\exists y$. We introduce new singulary predicates Q^-, Q^0, Q^+ and replace the subformulas of ψ of forms $z < x, z = x, x < z$ by $Q^-(z), Q^0(z), Q^+(z)$, to obtain a formula $\vartheta(y, <, P_1, \dots, P_n, Q^-, Q^0, Q^+)$ to which we can apply our induction hypothesis, obtaining an \mathcal{O} -formula $\delta(p_1, \dots, p_n, q^-, q^0, q^+)$ representing it. Let $\gamma(p_1, \dots, sp_n) = \delta(p-1, \dots, p_n, Fq, q, Pq)$, and $\beta = P\gamma \vee \gamma \vee F\gamma$. It is readily verified that for any $(X, R) \in \mathcal{K}$ and any $a, b \in X$ and any valuation V with $V(q) = \{a\}$ that we have:

$$\begin{aligned} b \in V(\gamma) & \text{ iff } (X, R, V(p_1), \dots, V(p_n)) \models \psi(a/x, b/y), \\ a \in V(\beta) & \text{ iff } (X, R, V(p_1), \dots, V(p_n)) \models \varphi(a/x). \end{aligned}$$

By hypothesis, β is equivalent over \mathcal{K} to a truth-functional compound of purely past formulas β_i^- , purely present ones β_j^0 , and purely future ones

β_k^+ . In each β_i^- (resp. β_j^0) (resp. β_k^+) replace q by \perp (resp. \top) (resp. \perp) to obtain an \mathcal{O} -formula α . It is readily verified that α represents φ .

It ‘only’ remains to show:

LEMMA 21. *The set $\{U, S\}$ has the separation property over complete orders.*

Though a full proof is beyond the scope of this survey, we sketch the method for achieving the separation for a formula α in which there is a single occurrence of an S within the scope of a U . This case (and its mirror image) is the first and most important in a general inductive proof.

To begin with, using conjunctive and disjunctive normal forms and such easy equivalences as:

$$\begin{aligned} U(p \vee q, t) &\leftrightarrow U(p, t) \vee U(q, t), \\ U(p, q \wedge r) &\leftrightarrow U(p, q) \wedge U(p, r), \\ \neg S(q, r) &\leftrightarrow S(\neg r, \neg q) \vee P'\neg r, \end{aligned}$$

we can achieve a reduction to the case where α has one of the forms:

1. $U(p \wedge S(q, r), t)$
2. $U(p, q \wedge S(r, t))$

For (1), an equivalent which is a truth-functional compound of pure formulas is provided by :

$$1'. \quad [(S(q, r) \vee q) \wedge U(p, r \wedge t)] \vee U(q \wedge U(p, r \wedge t), t)$$

For (2) we have:

$$2'. \quad \{[(S(r, t) \wedge t) \vee r] \wedge [U(p, t) \vee U(\beta, t)]\} \vee \beta$$

where β is: $F'\neg t \wedge U(p, q \vee S(r, t))$. This, despite its complexity, is purely future. The observant reader should be able to see how completeness is needed for the equivalence of (2) and w' .

Unfortunately, U and S take us no further, for Kamp proves:

PROPOSITION 22. *The set $\{U, S\}$ is not temporally complete over $(\mathbb{Q}, <)$.*

Without entering into details, we note that one undefinable operator is $O(\varphi)$ where φ says:

$$\begin{aligned} \exists y(x < y \wedge \forall z(x < z \wedge z < y \rightarrow \\ (\forall w(x < w \wedge w < z \rightarrow P_1((w))) \vee \forall w(z < w \wedge w < y \rightarrow P_2(w)))) \end{aligned}$$

Over complete orders $O(\varphi)(p, q)$ amounts to $U(G'q \wedge (p \vee q), p)$.

J. Stavi has found two new operators U', S' and proved:

THEOREM 23. *The set $\{U, S, U', S'\}$ is temporally complete over total orders.*

Gabbay has greatly simplified the proof: the idea is to try to prove the separation property over arbitrary total orders, and see what operators one needs. One quickly hits on the right U', S' . The combinatorial details cannot detain us here.

What about axiomatisability for U, S -tense logic? Some years ago Kamp announced (but never published) finite axiomatisability for various classes of total orders. Some are treated in [Burgess, 1982], where the system for dense orders takes a particularly simple form: we depart from standard format only to the extent of taking U, S as our primitives. As characteristic axioms, it suffices to take the following and their mirror images:

$$\begin{aligned} G(p \rightarrow q) &\rightarrow (U(p, r) \rightarrow U(q, r)) \wedge ((U(r, p) \rightarrow U(r, q)) \\ p \wedge U(q, r) &\rightarrow U(q \wedge S(p, r), r), \\ U(p, q) &\leftrightarrow U(p, q \wedge U(p, q)) \leftrightarrow U(q \wedge U(p, q), q), \\ U(, q) \wedge \neg U(p, r) &\rightarrow U(q \wedge \neg r, q), \\ U(p, q) \wedge U(r, s) &\rightarrow U(p \wedge r, q \wedge s \vee U(p \wedge s, q \wedge s) \vee U(q \wedge r, q \wedge s). \end{aligned}$$

A particularly important axiomatisability result is in [Gabbay *et al.*, 1980].

What about decidability? Rabin's theorem applies in most cases, the notable exceptions being complete orders, continuous orders, and $(\mathbb{R}, <)$. Here techniques of monadic second-order logic are useful. Decidability for the cases of complete and continuous orders is established in [Gurevich, 1977, Appendix]; and for $(\mathbb{R}, <)$ in [Burgess and Gurevich, 1985]. A fact (due to Gurevich) from the latter paper worth emphasising is that the U, S -tense logics of $(\mathbb{R}, <)$ and of arbitrary continuous orders are *not* the same.

5.2 *Now, Then*

We have seen that simple G, H -tense logic is inadequate to express certain temporal operators expressible in English. Indeed it turns out to be inadequate to express even the shortest item in the English temporal vocabulary, the word 'now'. Just what role this word plays is unclear—some incautious writers have even claimed it is semantically redundant—but [Kamp, 1971] gives a thorough analysis. Let us consider some examples:

0. The seismologist predicted that there would be an earthquake.
1. The seismologist predicted that there would be an earthquake *now*.
2. The seismologist predicted that there would already have been an earthquake *before now*.
3. The seismologist predicted that there would be an earthquake, but not till *after now*.

As Kamp says:

The function of the word ‘now’ in (1) is to make the clause to which it applies—i.e. ‘there would be an earthquake’—refer to the moment of utterance of (1) and not to the moment of moments (indicated by other temporal modifiers that occur in the sentence) to which the clause would refer (as it does in (0)) if the word ‘now’ were absent.

5.3 Formal Semantics

To formalise this observation, we introduce a new one-place connective J (for *jetzt*). We define a *pointed frame* to be a frame with a designated element. A *valuation* in a pointed frame (X, R, x_0) is just a valuation in $(X < R)$. We extend the definition of 0.4 above to G, H, J -formulas by adding the clause:

$$V(J\alpha) = X \text{ if } x_0 \in V(\alpha), \emptyset \text{ if } x_0 \notin V(\alpha)$$

is *valid* in (X, R, x_0) if $x_0 \in V(\alpha)$ for all valuations V .

An alternative approach is to define a *2-valuation* in a frame (X, R) to be a function assigning each p_i a subset of the Cartesian product X^2 . Parallel to 1.4 above we have the following inductive definition:

$$\begin{aligned} V(\neg\alpha) &= X^2 - V(\alpha), \\ V(\alpha \wedge \beta) &= V(\alpha) \cap V(\beta), \\ V(G\alpha) &= \{(x, y) : \forall x'(xRx' \rightarrow (x', y) \in V(\alpha))\}, \\ V(H\alpha), & \text{ similarly,} \\ V(J\alpha) &= \{(x, y) : (y, y) \in V(\alpha)\} \end{aligned}$$

α is *valid* in (X, R) if $\{(y, y) : y \in X\} \subseteq V(\alpha)$ for all 2-valuations V .

The two alternatives are related as follows: Given a 2-valuation V in the frame (X, R) , for each $y \in X$ consider the valuation V_y in the pointed frame $(X < R, y)$ given by $V_y(p_i) = \{x : (x, y) \in V(p_i)\}$. Then we always have $(y, y) \in V(\alpha)$ iff $y \in V_y(\alpha)$.

The second approach has the virtue of making it clear that though J is not a temporal operator in the sense of the preceding section, it is in a sense that can be made precise a *two-dimensional* tense operator. This suggests the project of investigating two- and multi-dimensional operators generally. Some such operators, for instance the ‘then’ of [Vlach, 1973], have a natural reading in English. Among other items in our bibliography, [Gabbay, 1976] and [Gabbay and Guenther, 1982] contain much information on this topic.

Using J we can express (0)–(3) as follows:

- 0'. P (seismologist says: F (earthquake occurs)),
- 1'. P (seismologist says: J (earthquake occurs)),

- 2'. P (seismologist says: JP (earthquake occurs)),
 3'. P (seismologist says: JF (earthquake occurs)).

The observant reader will have noted that (0')–(3') are not really representable by G, H, J -formulas since they involve the notion of 'saying' or 'predicting'), a *propositional attitude*. Gabbay, too, gives many examples of uses of 'now' and related operators, and on inspection these, too, turn out to involve propositional attitudes. That this is no accident is shown by the following result of Kamp:

THEOREM 24 (Eliminability theorem). *For any G, H, J -formula α there is a G, H -formula α^* equivalent over all pointed frames.*

Proof. Call a formula *reduced* if it contains no occurrence of a J within the scope of a G or an H . Our first step is to find for each formula α an equivalent reduced formula α_R . This is done by induction on the complexity of α , only the cases $\alpha = G\beta$ or $\alpha = H\beta$ being nontrivial. In, for instance, the latter case, we use the fact that any truth-function can be put into disjunctive normal form, plus the following valid equivalence:

$$(R) \quad {}_H((Jp \wedge q) \wedge r) \leftrightarrow ((Jp \wedge H(q \vee r)) \vee (\neg Jp \wedge Hr))$$

Details are left to the reader. Our second step is to observe that if β is reduced, then it is equivalent to the result β^- of dropping all its occurrences of J . It thus suffices to set $\alpha^* = (\alpha_R)^-$. ■

The foregoing theorem says that in the presence of truth-functions and G and H , the operator J is, in a sense, redundant. By contrast, examples (0)–(3) suggest that in contexts with propositional attitudes, J is *not* redundant; the lack of a generally-accepted formalisation of the logic of propositional attitudes makes it impossible to turn this suggestion into a rigorous theorem. But in contexts with *quantifiers*, Kamp *does* prove rigorously that J is irredundant. Consider:

4. The Academy of Arts rejected an applicant who was to become a terrible dictator and start a great war.
5. The Academy of arts has rejected an applicant who is to become a terrible dictator and start a great war.

The following formalisations suggest themselves:

- 4'. $P(\exists x(R(x) \wedge FD(x)))$
 5'. $P(\exists x(R(x) \wedge JFD(x))),$

the difference between (4) and (5) lying precisely in the fact that the latter, unlike the former, definitely places the dictatorship and war in the hearer's future. What Kamp proves is that (5') cannot be expressed by a G, H -formula with quantifiers.

Returning to sentential tense logic, Theorem 24 obviously reduces the *decision* problem for G, H, J -tense logic to that for G, H -tense logic. As for *axiomatisability*, obviously we cannot adopt the standard format of G, H -tense logic, since the rule TG does not preserve validity for G, H, J -formulas. For instance:

$$(D0) \quad p \leftrightarrow Jp$$

is valid, but $G(p \leftrightarrow Jp)$ and $H(p \leftrightarrow Jp)$ are not. Kamp overcomes this difficulty, and shows how, in very general contexts, to obtain from a complete axiomatisation of a logic without J , a complete axiomatisation of the same logic with J . For the sentential G, H, J -tense logic of total orders, the axiomatisation takes a particularly simple form: take as sole rule MP. Let Lp abbreviate $Hp \wedge p \wedge Gp$. Take as axioms all substitution instances of tautologies, of (D0) above, and of $L\alpha$, where α may be any item on the lists (D1), (D2) below, or the mirror image of such an item:

$$(D1) \quad \begin{aligned} &G(p \rightarrow q) \rightarrow (Gp \rightarrow Gq) \\ &p \rightarrow Gp \\ &Gp \leftrightarrow GGp \\ &Lp \leftrightarrow GHp \end{aligned}$$

$$(D2) \quad \begin{aligned} &J\neg p \leftrightarrow \neg Jp \\ &J(p \wedge q) \leftrightarrow Jp \wedge Jq \\ &\neg L\neg Jp \leftrightarrow LJp \\ &Lp \rightarrow Jp. \end{aligned}$$

(In outline, the proof of completeness runs thus: using (D1) one deduces $Lp \rightarrow LLp$. It follows that the class of theses deducible without use of (D0) is closed under TG. Our work in Section 3.2 shows that we then get the complete G, H -tense logic of total orders. We then use (D2) to prove the equivalence (R) in the proof of Theorem 24 above. More generally, for any α , $\alpha \leftrightarrow \alpha_R$ is deducible without using (D0). Moreover, using D0, $\beta \leftrightarrow \beta^-$ is deducible for any reduced formula β . Thus in general $\alpha \leftrightarrow \alpha^*$ is a thesis, completing the proof.)

6 TIME PERIODS

The geometry of Space can be axiomatised taking unextended *points* as basic entities, but it can equally well be axiomatised by taking as basic certain regular open solid regions such as *spheres*. Likewise, the order of

Time can be described either (as in Section 1.1) in terms of *instants* in terms of *periods* of non zero duration. Recently it has become fashionable to try to redo tense logic, taking periods rather than instants as basic. Humberstone [1979] seems to be the first to have come out in print with such a proposal. This approach has become so popular that we must give at least a brief account of it; further discussion can be found in [van Benthem, 1991]. (See also Kuhn's discussion in the last chapter of this Volume of the *Handbook*.)

In part, the switch from instants to periods is motivated by a desire to model certain features of natural language. One of these is *aspect*, the verbal feature which indicates whether we are thinking of an occurrence as an *event* whose temporal stages (if any) do not concern us, or as a protracted *process*, forming, perhaps the backdrop for other occurrences. These two ways of looking at death (a popular, if morbid, example) are illustrated by:

When Queen Anne died, the Whigs brought in George.

While Queen Anne was dying, the Jacobites hatched treasonable plots.

Another feature of linguistic interest is the peculiar nature of *accomplishment* verbs, illustrated by:

1. The Amalgamated Conglomerate Building was built during the period March–August 1972.
- 1'. The ACB was built during the period April–July, 1972.
2. The ACB was being built (i.e. was under construction) during the period March–August, 1972.
- 2'. The ACB was under construction during the period April– July, 1972.

Note that (1) and (1') are inconsistent, whereas (2) implies (2')!

In part, the switch is motivated by a philosophical belief that periods are somehow more basic than instants. This motivation would be more convincing were 'periods' not assumed (as they are in too many recent works) to have sharply-defined (i.e. *instantaneous*) beginnings and ends. It may also be remarked that at the level of *experience* some occurrences do *appear* to be instantaneous (i.e. we don't *discern* stages in them). Thus 'bubbles when they burst' *seem* to do so 'all at once and nothing first'. While at the level of *reality*, some occurrences of the sort studied in quantum physics may well take place instantaneously, just as some elementary particles may well be pointlike. Thus the philosophical belief that every occurrence takes some time (period) to occur is not *obviously* true on any level.

Now for the mechanics of the switch: for any frame (X, R) we consider the set $I(X, R)$ of nonempty bounded open intervals of form $\{z : xRz \wedge zRy\}$.

Among the many relations on this set that could be defined in terms of R we single out two:

$$\begin{aligned} \text{Inclusion: } a \subseteq b & \text{ iff } \forall x(x \in a \rightarrow x \in b), \\ \text{Order: } a \triangleleft b & \text{ iff } \forall x \forall y(x \in a \wedge y \in b \rightarrow xRy). \end{aligned}$$

To any class \mathcal{K} of frames we associate the class \mathcal{K}' of those structures of form $(I(X, R), \subseteq, \triangleleft)$ with $(X, R) \in \mathcal{K}$, and the class \mathcal{K}^+ of those structures (Y, S, T) that are isomorphic to elements of \mathcal{K}' .

A first problem in switching from instants to periods as the basis for the logic of time is to find each important class \mathcal{K} of frames a set of postulates whose models will be precisely the structures in \mathcal{K}^+ . For the case of dense total orders without extrema, and for some other cases, suitable postulate sets are known, though none is very elegant. Of course this first problem is not yet a problem of *tense* logic; it belongs rather to applied first- and second-order logic.

To develop a period-based *tense* logic we define a *valuation* in a structure (Y, S, T) —where S, T are binary relations on Y —to be a function V assigning each p_i a subset of Y . Then from among all possible connectives that could be defined in terms of S and T , we single out the following:

$$\begin{aligned} V(\neg\alpha) &= Y - V(\alpha) \\ V(\alpha \wedge \beta) &= V(\alpha) \cap V(\beta) \\ V(\nabla\alpha) &= \{a : \forall b(bSa \rightarrow b \in V(\alpha))\} \\ V(\Delta\alpha) &= \{a : \forall b(aSb \rightarrow b \in V(\alpha))\} \\ V(F\alpha) &= \{a : \exists b(aTb \wedge b \in V(\alpha))\} \\ V(P\alpha) &= \{a : \exists b(bTa \wedge b \in V(\alpha))\}. \end{aligned}$$

The main *technical* problem now is, given a class \mathbf{L} of structures (Y, S, T) —for instance, one of form $\mathbf{L} = \mathcal{K}^+$ for some class \mathcal{K} of frames—to find a sound and complete axiomatisation for the tense logic of \mathbf{L} based on the above connectives. Some results along these lines have been obtained, but none as definitive as those of instant-based tense logic reported in Section 3. Indeed, the choice of relations (\subseteq and \triangleleft), and of admissible classes \mathbf{L} (should we only consider classes of form \mathcal{K}^+ ?), and of connectives ($\neg, \wedge, \Delta, \nabla, F, P$), and of admissible valuations (should we impose restrictions, such as requiring $b \in V(p_i)$ whenever $a \in V(p_i)$ and $b \subseteq a$?) are all matters of controversy.

The main problem of *interpretation*—one to which advocates of period-based tense logic have perhaps not devoted sufficient attention—is how to make intuitive sense of the notion $a \in V(p)$ of a sentence p being true *with respect to* a time-period a . One proposal is to take this as meaning that p is true *throughout* a . Now given a valuation W in a frame (X, R) , we can define a valuation $I(W)$ in $I(X, R)$ by $I(W)(p_i) = \{a : a \subseteq W(p_i)\}$. When and *only* when V has the form $I(W)$ is ‘ p is true throughout a ’ a tenable reading of $a \in V(p)$. It is not, however, easy to characterise intrinsically

those V that admit a representation in the form $V = I(W)$. Note that even in this case, $a \in V(\neg p)$ does not express ‘ $(\neg p)$ is true throughout a ’ (but rather ‘ $\neg(p)$ is true throughout a ’). Nor does $a \in V(p \vee q)$ express ‘ $(p \vee q)$ is true throughout a ’.

Another proposal, originating in [Burgess, 1982] is to read $a \in V(p)$ as ‘ $+$ is *almost* always true during a ’. This reading is tenable when V has the form $J(W)$ for some valuation W in (X, R) , where $J(W)(p_i)$ is by definition $\{a : a - W(p_i) \text{ is nowhere dense in the order topology on } (XR)\}$. In this case, ‘ $(\neg p)$ is almost always true during a ’ is expressible by $a \in V(\nabla \neg p)$, and ‘ $(p \vee q)$ is almost always true during a ; by $a \in V(\nabla \neg \nabla \neg (p \vee q))$. But the whole problem of interpretation for period-based tense logic deserves more careful thought.

There have been several proposals to redo tense logic on the basis of 3- or 4- of multi-valued truth-functional logic. It is tempting, of instance, to introduce a truth-value ‘unstatable’ to apply to, say, ‘Bertrand Russell is smiling’ in 1789. In connection with the switch from instants to periods, some have proposed introducing new truth-values ‘changing from true to false’ and ‘changing from false to true’ to apply to, say, ‘the rocket is at rest’ at take-off and landing times. Such proposals, along with proposals to combine, say, tense logic and intuitionistic logic, lie beyond the scope of this survey.

7 GLIMPSES AROUND

7.1 Metric Tense Logic

In *metric* tense logic we assume Time has the structure of an ordered Abelian group. We introduce variables x, y, z, \dots ranging over group elements, and simples $0, +, <$ for the group identity, addition, and order. We introduce operators \mathcal{F}, \mathcal{P} joining terms for group elements with formulas. Here, for instance, $\mathcal{F}(x + y)(p \wedge q)$ means that it will be the case $(x + y)$ time-units hence that p and q . Metric tense logic is intended to reflect such ordinary-language *quantitative* expressions as ‘10 years from now’ or ‘tomorrow about this time’ or ‘in less than five minutes’. The *qualitative* F, P of nonmetric tense logic can be recovered by the definitions $Fp \leftrightarrow \exists x > 0 \mathcal{F}xp, Pp \leftrightarrow \exists x > 0 \mathcal{P}xp$. Actually, the ‘ago’ operator \mathcal{P} is definable in terms of the ‘hence’ operator \mathcal{F} since $\mathcal{P}xp$ is equivalent to $\mathcal{F} - xp$. It is not hard to write down axioms for metric tense logic whose completeness can be proved by a Henkin-style argument.

But decidability is lost: the decision problem for metric tense logic is easily seen to be equivalent to that for the set of all universal monadic (second- order) formulas true in all ordered Abelian groups. We will show that the decision problem for the validity of first-order formulas involving

a single two-place predicate \in —which is well known to be unsolvable—is reducible to the latter: given a first-order \in -formula φ , fix two one-place predicate variables U, V . Let φ_0 be the result of restricting all quantifiers in φ to U (i.e. $\forall x$ is replaced $\forall x(U(x) \rightarrow \dots)$ and $\exists x$ by $\exists x(U(x) \wedge \dots)$.) Let φ_1 be the result of replacing each atomic subformula $x \in y$ of φ_0 by $\exists z(V(z) \wedge V(z+x) \wedge V(z+x+y))$. Let φ_2 be the universal monadic formula $\forall U \forall V (\exists x U(x) \rightarrow \varphi_2)$. Clearly if φ is logically valid, then so is φ_2 and, in particular, the latter is true in all ordered Abelian groups. If φ is not logically valid, it has a countermodel consisting of the positive integers equipped with a binary relation E . Consider the product $\mathbb{Z} \times \mathbb{Z}$ where \mathbb{Z} is the additive group of integers; addition in this group is defined by $(x, y) + (x', y') = (x+x', y+y')$; the group is orderable by $(x, y) < (x', y')$ iff $x < x'$ or $(x = x'$ and $y < y')$. Interpret U in this group as $\{(n, 0) : n > 0\}$; interpret V as the set consisting of the $(2^m 3^n, 0)$, $(2^m 3^n, m)$ and $(2^m 3^n, m+n)$ for those pairs (m, n) with mEn . This gives a countermodel to the truth of φ_2 in $\mathbb{Z} \times \mathbb{Z}$. Thus the desired reduction of decision problems has been effected.

Metric tense logic is, in a sense, a hybrid between the ‘regimentation’ and ‘autonomous tense logic’ approaches to the logic of time. Other hybrids of a different sort—not easy to describe briefly—are treated in an interesting paper of [Bull, 1978].

7.2 Time and Modality

As mentioned in the introduction, Prior attempted to apply tense logic to the exegesis of the writings of ancient and mediaeval philosophers and logicians (and for that matter of modern ones such as C. S. Peirce and J. Łukasiewicz) on future contingents. The relations between tense and mode or modality is properly the topic of Richmond H. Thomason’s chapter in this volume.

We can, however, briefly consider here the topic of so-called *Diodorean* and *Aristotelian* modal fragments of a tense logic L . The former is the set of modal formulas that become theses of L when $\Box p$ is defined as $p \wedge Gp$; the latter is the set of modal formulas that becomes theses of L when $\Box p$ is defined as $Hp \wedge p \wedge Gp$. Though these seem far-fetched definitions of ‘necessity’, the attempt to isolate the modal fragments of various tense logics undeniable was an important stimulus for the earlier development of our subject. Briefly the results obtained can be tabulated as follows. It will be seen that the modal fragments are usually well-known C. I. Lewis systems.

Class of frames	Tense logic	Diodorean fragment	Aristotelian fragment
All frames	\mathbf{L}_0	$\mathbf{T}(=\mathbf{M})$	\mathbf{B}
Partial orders	\mathbf{L}_1	$\mathbf{S4}$	\mathbf{B}
Lattices	\mathbf{L}_0	$\mathbf{S4.2}$	\mathbf{B}
Total orders	$\mathbf{L}_2, \mathbf{L}_5$	$\mathbf{S4.3}$	$\mathbf{S5}$
Dense orders			

The Diodorean fragment of the tense logic \mathbf{L}_6 of discrete orders has been determined by M. Dummett; the Aristotelian fragment of the tense logic of trees has been determined by G. Kessler. See also our comments below on R. Goldblatt's work.

7.3 *Relativistic Tense Logic*

The *cosmic* frame is the set of all point-events of space-time equipped with the relation of *causal accessibility*, which holds between u and v if a signal (material or electromagnetic) could be sent from u to v . The $(n+1)$ -dimensional *Minkowski* frame is the set of $(n+1)$ -tuples of real numbers equipped with the relation which holds between $(a_{0,1}, \dots, a_n)$ and (b_0, b_1, \dots, b_n) iff:

$$\sum_{i=1}^n (b_i - a_i)^2 - (b_0 - a_0)^2 > 0 \text{ and } b_0 > a_0.$$

For present purposes, the content of the *special theory of relativity* is that the cosmic frame is isomorphic to the 4-dimensional Minkowski frame.

A little calculating shows that any Minkowski frame is a lattice without maximum or minimum, hence the tense logic of special relativity should at least include \mathbf{L}_0 . Actually we will also want some axioms to express the density and continuity of a Minkowski frame. A surprising discovery of Goldblatt [1980] is that the *dimension* of a Minkowski frame influences its tense logic. Indeed, he shows that for each n there is a formula γ_{n+1} which is valid in the $(m+1)$ -dimensional Minkowski frame iff $m < n$. For example, writing Ep for $p \wedge Fp$, γ_2 is:

$$Ep \wedge Eq \wedge Er \wedge \neg E(p \wedge q) \wedge \neg E(p \wedge r) \wedge \neg E(q \wedge r) \rightarrow E((Ep \wedge Eq) \vee (Ep \wedge Er) \vee (Eq \wedge Er)).$$

On the other hand, he also shows that the dimension of a Minkowski frame does *not* influence the diodorean modal fragment of its tense logic: the Diodorean modal logic of special relativity is the same as that of arbitrary lattices, namely $\mathbf{S4.2}$. Combining Goldblatt's argument with the 'trousers world' construction in general relativity, should produce a proof that the Diodorean modal fragment of the latter is the same as that of arbitrary partial orders, namely $\mathbf{S4}$.

Despite recent advances, the tense logic of special relativity has not yet been completely worked out; that of general relativity is even less well understood. Burgess [1979] contains a few additional philosophical remarks.

7.4 *Thermodynamic Time*

One of the oldest metaphysical concepts (found in Hindu theology and pre-Socratic philosophy, and in modern psychological dress in Nietzsche and celestial mechanical dress in Poincaré) is that everything that has ever happened is destined to be repeated over and over again. This leads to a degenerate tense logic containing the principles $Gp \rightarrow Hp$ and $Gp \rightarrow p$ among others.

An antithetical view is that traditionally associated with the Second Law of Thermodynamics, according to which irreversible change are taking place that will eventually drive the Universe to a state of ‘heat-death’, after which no further change on a macroscopically observable level will take place. The tense logic of this view, which raises several interesting technical points, has been investigated by S. K. Thomason [1972]. The first thing to note is that the principle:

$$(A10) \quad GFp \rightarrow FGp$$

is acceptable for p expressing propositions about macroscopically observable states of affairs provided these do not contain hidden time references; e.g. p could be ‘there is now no life on Earth’, but not ‘particle κ currently has a momentum of precisely k gram- meters/second’ or ‘it is now an even number of days since the Heat Death occurred’. For the antecedent of (A20) says that arbitrarily far in the future there will be times when p is the case. But for the p that concern us, the truth-value of p is never supposed to change after the Heat Death. So in that case, there will come a time after which p is always going to be true, in accordance with the consequent of (A10).

The question now arises, how can we *formalise* the restriction of p to a special class of sentences? In general, propositions are represented in the formal semantics of tense logic by subsets of X in a frame (X, R) . A restricted class of propositions could thus be represented by a distinguished family \mathcal{B} of subsets of X . This motivates the following definition: an *augmented* frame is a triple (X, R, \mathcal{B}) where (X, R) is a frame, \mathcal{B} a subset of the lower set $\mathcal{B}(X)$ of X closed under complementation, finite intersection, and the operations:

$$\begin{aligned} gA &= \{x \in X : \forall y \in X (xRy \rightarrow y \in A)\} \\ hA &= \{x \in X : \forall y \in X (yRx \rightarrow y \in A)\}. \end{aligned}$$

A *valuation* in (X, R, \mathcal{B}) is a function V assigning each variable p_i an element of \mathcal{B} . The closure conditions on \mathcal{B} guarantee that we will then have $V(\alpha) \in \mathcal{B}$

for *all* formulas α . It is now clear how to define validity. Note that if $\mathcal{B} = \mathcal{P}(X)$, then the validity in (X, R, \mathcal{B}) reduces to validity in (X, R) ; otherwise more formulas may be valid in the former than the latter.

It turns out that the extension \mathbf{L}_{10} of $\mathbf{L}_{\mathbf{Q}}$ obtained by adding (A10) is (sound and) complete for the class of augmented frames (X, R, \mathcal{B}) in which (X, R) is a dense total order without maximum or minimum and:

$$\forall B \in \mathcal{B} \exists x (\forall y (xRy \rightarrow y \in B) \vee \forall y (xRy \rightarrow y \notin B)).$$

We have given complete axiomatisations for many intuitively important classes of frames. We have not yet broached the questions: when does the tense logic of a given class of frames admit a complete axiomatisation? When does a given axiomatic system of tense logic correspond to some class of frames in the sense of being complete for that class? For information on these large questions, and for bibliographical references, we refer the reader to Johan van Benthem's chapter in Volume 3 of this edition of the *Handbook* on so-called 'Correspondence Theory'. Suffice it to say here that positive general theorems are few, counterexamples many. The thermodynamic tense logic \mathbf{L}_{10} exemplifies one sort of pathology. Though it is not inconsistent, there is *no* (unaugmented) frame in which all its theses are valid!

7.5 Quantified Tense Logic

The interaction of temporal operators with universal and existential quantifiers raises many difficult issues, both philosophical (over identity through changes, continuity, motion and change, reference to what no longer exists or does not exist, essence, and many, many more) and technical (over undecidability, nonaxiomatisability, undefinability or multi-dimensional operators, and so forth) that it is pointless to attempt even a survey of the subject in a paragraph or two. We therefore refer the reader to Nino Cocchiarella's chapter in this volume and James W. Garson's chapter in Volume 3 of this edition of the *Handbook*, both on this subject.

ADVANCED TENSE LOGIC

1 INTRODUCTION

In this chapter we consider the tense (or temporal) logic with until and since connectives over general linear time. We will call this logic US/LT . This logic is an extension of Prior's original temporal logic of F and P over linear time [Prior, 1957], via the introduction of the more expressive connectives of Kamp's U for "until" and S for "since" [Kamp, 1968b]. U closely mimics the natural language construct "until" with $U(A, B)$ holding when A is constantly true from now up until a future time at which B holds. S is similar with respect to the past. We will see that U and S do indeed extend the expressiveness of the temporal language.

In the chapter we will also be looking at other related temporal logics. The logics differ from each other in two respects. Logics may differ in the kinds of structures which they are used to describe. Structures vary in terms of their underlying model of time (or frame): this can be like the natural numbers, or like the rationals or like the reals or some other linear order or some non-linear branching or multi-dimensional shape. Logics are defined with respect to a class of structures. Considering a logic defined by the class of all linear structures is a good base from which to begin our exploration. Temporal logics also vary in their language. For various purposes, until and since may be not expressive enough. For example, if we want to be able to reason about alternative avenues of development then we may want to allow branches in the flow of time and, in order to represent directly the fact of alternative possibilities, we may need to add appropriate branching connectives. Equally, until and since may be too strong: for simple reasoning about the forward development of a mechanical system, using since may not only be unnecessary, but may require additional axioms and complexity of a decision procedure.

In this chapter we will not be looking at temporal logics based on branching. See the handbook chapter by Thomason for these matters. We will also avoid consideration of temporal logics incorporating quantification. Instead, see the handbook chapter by Garson for a discussion of predicate temporal and modal logics and see the reference [Gabbay *et al.*, 1994] for a discussion of temporal logics incorporating quantification over propositional atoms.

So we will begin with a tour of the many interesting results concerning US/LT including axiom systems, related logics, decidability and complexity. In section 3 we sketch a proof of the expressive completeness of the logic.

Then, in section 4 we investigate combinations of logics with a temporal element. In section 5, we develop the proof theory for temporal logic within the framework of labelled deductive systems. In section 6, we show how temporal reasoning can be handled within logic programming. In section 7, we survey the much studied temporal logic of the natural numbers and consider the powerful automata technique for reasoning about it. Finally, in section 8, we consider the possibility of treating temporal logic in an imperative way.

2 U, S LOGIC OVER GENERAL LINEAR TIME

Here we have a close look at the US logic over arbitrary linear orders.

2.1 *The logic*

Frames for our logic are linear. Thus we have a non-empty set T and a binary relation $< \subseteq T \times T$ which is:

1. *irreflexive*, i.e. $\forall t \in T$, we do not have $t < t$;
2. *total*, i.e. $\forall s, t \in T$, either $s < t$, $s = t$ or $t < s$;
3. *transitive*, i.e. $\forall s, t, u \in T$, if $s < t$ and $t < u$ then $s < u$.

The underlying model of time for a temporal logic is captured by the frame $(T, <)$.

Any use of a temporal logic will involve something happening over time. The simplest method of trying to capture this formally is to use a propositional temporal logic. So we fix a countable set \mathcal{L} of atoms. The truth of a particular atom will vary in time. For example, points of time (i.e. $t \in T$) may correspond to days and the truth of the atom r on a particular day may correspond to the event of rain on that day.

A structure is a particular history of the truth of all the atoms over the full extent of time. Structures $(T, <, h)$ are linear so we have a linear frame $(T, <)$ and we have a valuation h for the atoms, i.e. for each atom $p \in \mathcal{L}$, $h(p) \subseteq T$. The set $h(p)$ is the set of all time points at which p is true.

The language $L(U, S)$ is generated by the 2-place connectives U, S along with classical \neg and \wedge . That is, we define the set of formulas recursively to contain the atoms and \top (i.e. truth) and for formulas A and B we include $\neg A$, $A \wedge B$, $U(A, B)$ and $S(A, B)$. We read $U(A, B)$ as “until A, B ” corresponding to B being true until A is. Similarly S is read as “since”.

Formulas are evaluated at points in structures. We write $\mathcal{T}, x \models A$ when A is true at the point $x \in T$. This is defined recursively as follows. Suppose that we have defined the truth of formulas A and B at all points of \mathcal{T} . Then for all points x :

$\mathcal{T}, x \models p$	iff	$x \in h(p)$, for p atomic;
$\mathcal{T}, x \models \top$;		
$\mathcal{T}, x \models \neg A$	iff	$\mathcal{T}, x \not\models A$;
$\mathcal{T}, x \models A \wedge B$	iff	both $\mathcal{T}, x \models A$ and $\mathcal{T}, x \models B$;
$\mathcal{T}, x \models U(A, B)$	iff	there is a point $y > x$ in T such that $\mathcal{T}, y \models A$ and for all $z \in T$ such that $x < z < y$ we have $\mathcal{T}, z \models B$;
$\mathcal{T}, x \models S(A, B)$	iff	there is a point $y < x$ in T such that $\mathcal{T}, y \models A$ and for all $z \in T$ such that $y < z < x$ we have $\mathcal{T}, z \models B$;

Often definitions and results involving S can be given by simply exchanging U and S and swapping $<$ and $>$. In that situation we just mention that a *mirror image* case exists and do not go into details.

There are many abbreviations that are commonly used in the language. As well as the classical \perp (i.e. $\neg\top$ for falsity), \vee , \rightarrow and \leftrightarrow , we have the following temporal abbreviations:

FA	$= U(A, \top)$	A will happen (sometime);
GA	$= \neg F\neg A$	A will always hold;
PA	$= S(A, \top)$	A was true (sometime);
HA	$= \neg P\neg A$	A was always true;
$K^+(A)$	$= \neg U(\top, \neg A)$	A will be true arbitrarily soon;
$K^-(A)$	$= \neg S(\top, \neg A)$	A was true arbitrarily recently.

Notice that Prior's original connectives F and P appear as abbreviations in this logic. The reader should check that their original semantics (see [Burgess, 2001]) are not compromised.

A formula ϕ is *satisfiable* if it has a model: i.e. there is a structure $\mathcal{T} = (T, <, h)$ and $x \in T$ such that $\mathcal{T}, x \models \phi$. A formula is *valid* iff it is true at all points of all structures. We write $\models A$ iff A is a validity. Of course, a formula is valid iff its negation is not satisfiable.

We can also define (semantic) consequence in the logic. Suppose that Γ is a set of formulas and A a formula. We say that A is a consequence of Γ and write $\Gamma \models A$ iff whenever we have $\mathcal{T}, t \models C$ for all $C \in \Gamma$, for some point t from some structure \mathcal{T} , then we also have $\mathcal{T}, t \models A$.

First-Order Monadic Logic of Order

For many purposes such as assessing the expressiveness of temporal languages or establishing their decidability, it is useful to be able to move from the internal tensed view of the world to an external untensed view. In doing

so we can also make use of logics with more familiar syntax. In the case of our linear temporal logics we find it convenient to move to the first-order monadic logic of linear order which is a sub-logic of the full second-order monadic logic of linear order.

The language of the full second-order monadic logic of linear order has formulas built from $<$, $=$, quantification over individual variable symbols and quantification over monadic (i.e. 1-ary) predicate symbols. To be more formal, suppose that $X = \{x_0, x_1, \dots\}$ is our set of individual variable symbols and $Q = \{P_0, P_1, \dots\}$ is our set of monadic predicates. The formulas of the language are $x_i < x_j$, $x_i = x_j$, $P_i(x_j)$, $\neg\alpha$, $\alpha \wedge \beta$, $\exists x_i\alpha$, and $\exists P_j\alpha$ for any $i, j < \omega$ and any formula α . We use the usual abbreviations $x_i > x_j$, $x_i \leq x_j$, $x_i < x_j < x_k$, $\forall x_i\alpha$ and $\forall P_i\alpha$ etc.

As usual we define the concept of a free individual variable symbol in a formula. We similarly define the set of free monadic variables of a formula. Write $\phi(x_1, \dots, x_m, P_1, \dots, P_n)$ to indicate that all the free variables (of both sorts) in the formula ϕ are contained in the lists x_1, \dots, x_m and P_1, \dots, P_n .

The language is used to describe linear orders. Suppose that $(T, <)$ is a linear order. As individual variable symbols we will often use t, s, r, u etc, instead of x_1, x_2, \dots

An individual variable assignment V is a mapping from X into T . A predicate variable assignment W is a mapping from Q into $\wp(T)$ (the set of subsets of T). For an individual variable assignment V , an individual variable symbol $x \in X$ and an element $t \in T$, we define the individual variable assignment $V[x \mapsto t]$ by:

$$V[x \mapsto t](y) = \begin{cases} V(y) & y \neq x \\ t & y = x. \end{cases}$$

Similarly for predicate variable assignments and subsets of T .

For a formula ϕ , variable assignments V (individual) and W (predicate), we define whether (or not resp.) ϕ under V and W is true in $(T, <)$, written $(T, <), V, W \models \phi$ by induction on the quantifier depths of ϕ .

Given some ϕ , suppose that for all its subformulas ψ , for all variable assignments V and W , we have defined whether or not $(T, <), V, W \models \psi$. For variable assignments V and W we define:

$$\begin{aligned}
 (T, <), V, W \models x_i < x_j & \text{ iff } V(x_i) < V(x_j); \\
 (T, <), V, W \models x_i = x_j & \text{ iff } V(x_i) = V(x_j); \\
 (T, <), V, W \models P_i(x_j) & \text{ iff } V(x_j) \in W(P_i); \\
 (T, <), V, W \models \neg\alpha & \text{ iff } (T, <), V, W \not\models \alpha; \\
 (T, <), V, W \models \alpha \wedge \beta & \text{ iff } (T, <), V, W \models \alpha \text{ and } (T, <), V, W \models \beta; \\
 (T, <), V, W \models \exists x_i \alpha & \text{ iff there exists some } t \in T \text{ such that} \\
 & (T, <), V[x_i \mapsto t], W \models \alpha. \\
 (T, <), V, W \models \exists P_j \alpha & \text{ iff there is some } S \subseteq T \text{ such that} \\
 & (T, <), V, W[P_j \mapsto S] \models \alpha.
 \end{aligned}$$

This is standard second-order semantics. Note that it is easy to show that the truth of a formula does not depend on the assignment to variables which do not appear free in the formula.

Mostly we will be interested in fragments of the full second-order monadic logic. In particular, we refer to the first-order monadic logic of linear order which contains just those formulas with no quantification of predicate variables. We will also mention the universal second-order monadic logic of linear order which contains just those formulas which consist of a first-order monadic formula nested under zero or more universal quantifications of predicate variables.

The important correspondence for us is that between temporal logics such as *US/LT* and the first-order monadic logic. Most of the temporal logics which we will consider allow a certain equivalence between their formulas and first-order monadic formulas. To define this we need to use a fixed one-to-one correspondence between the propositional atoms of the temporal language and monadic predicate variables. Let us suppose that $p_i \in \mathcal{L}$ corresponds to $P_i \in \mathcal{Q}$.

The translation will propagate upwards through the full temporal language provided that each of the connectives have a first-order translation. In particular we require for any n -ary temporal connective C some first-order monadic formula $\phi_C(t, P_1, \dots, P_n)$ which corresponds to $C(p_1, \dots, p_n)$. We say that ϕ_C is the (*first-order*) *table* of C iff for every linear order $(T, <)$, for all $h : \mathcal{L} \rightarrow \wp(T)$, for all $t_0 \in T$, for all variable assignments V and W ,

$$\begin{aligned}
 (T, <, h), t_0 \models C(p_1, \dots, p_n) \\
 \text{iff } (T, <), V[t \mapsto t_0], W[P_1 \mapsto h(p_1), \dots, P_n \mapsto h(p_n)] \models \phi_C.
 \end{aligned}$$

U and S have first-order tables as follows: the table of U is $\phi_U = \exists s((t < s) \wedge P_1(s) \wedge \forall r((t < r \wedge r < s) \rightarrow P_2(r)))$.

The table of S is the mirror image.

If we have a temporal logic with first-order tables for its connectives then it is straightforward to define a meaning-preserving translation (to the first-order monadic language) of all formulas in the language. The translation is

as follows:

$$\begin{aligned}
*p_i &= P_i(t) \\
*\top &= (t = t) \\
*\neg A &= \neg *A \\
*(A \wedge B) &= *A \wedge *B \\
*U(A, B) &= \phi_U[*A/P_1][*B/P_2] \\
*S(A, B) &= \phi_S[*A/P_1][*B/P_2]
\end{aligned}$$

Here, if α is a first-order monadic formula with one free individual variable t , we use the notation $\phi[\alpha/P]$ to mean the result of replacing every (free) occurrence of the predicate variable symbol P in the first-order monadic formula ϕ by the monadic formula α : i.e. $P(x_i)$ gets replaced by $\alpha[x_i/t]$. This is a little complex as we must take care to avoid clashes of variable symbols. We will not go into details here.

For any temporal formula A , $*A$ is a first-order monadic formula with t being the only free individual variable symbol. If atom p_i appears in A then $*A$ will also have a free predicate symbol P_i . There are no other predicate symbols in $*A$.

We then have:

LEMMA 1. *For each linear order $(T, <)$, for any $t_0 \in T$, for any temporal A , if A uses atoms from p_1, \dots, p_n then for all variable assignments V and W ,*

$$\begin{aligned}
(T, <, h), t_0 \models A \text{ iff } (T, <), V[t \mapsto t_0], W[P_1 \mapsto h(p_1)] \dots \\
[P_n \mapsto h(p_n)] \models *A.
\end{aligned}$$

Proof. By induction on the construction of A . ■

Below, when we discuss expressive power in section 3, we will consider whether there is a reverse translation from the first-order monadic language to the temporal language.

Uses of US/LT

In the previous chapter [Burgess, 2001], we saw a brief survey of the motivations for developing a tense logic. There are particular reasons for concentrating on the logic *US/LT*. It is a basis for reasoning about events and states in general linear time or particularly dense or continuous time.

For example, it is certainly the case that most use of tense and aspect in natural language occur in the context of an assumed dense linear flow of time. Any kind of reasoning about the same sorts of situations, as in many branches of AI or cognitive science, also requires a formalism based on dense, continuous or general linear time.

In computer science the most widely used temporal logic (PTL which we will meet later) is based on a discrete natural numbers model of time. However, there has been much recent work on developing logics based on more general models for many applications. Particular applications include refinement, analogue devices, open systems, and asynchronous distributed or concurrent systems.

Refinement here concerns the process of making something more concrete or more specific. This can include making a specification for a system (or machine, or software system) less ambiguous, or more detailed, or less nondeterministic. This can also include making an algorithm, or program, or implementation, or design, more detailed, or more low level. There are several different ways of producing a refinement but one involves breaking up one step of a process into several smaller steps which accomplish the same overall effect. If a formal description of a less refined process assumes discrete steps of time then it is easy to see that it may be hard to relate it to a description of a more refined process. Extra points of time may have to be introduced in between the assumed ones. Using a dense model of time from the outset will be seen to avoid this problem. Comparing the formal descriptions of more and less refined processes is essential for checking the correctness of any refinement procedure.

It can also be seen that a general linear model of time will be useful in describing analogue devices (which might vary in state in a continuous way), open systems (which might be affected by an unbounded number of different environmental events happening at all sorts of times) and asynchronous and distributed systems (which may have processes going through changes in state at all sorts of times).

In general the logics are used to describe or specify, to verify, to model-check, to synthesize, or to execute. A useful description of these activities can be found in [Emerson, 1990]. Specification is the task of giving a complete, precise and unambiguous description of the behaviour expected of a system (or device). Verification is the task of checking, or proving, that a system does conform to a specification and this includes the more specific task of model-checking, or determining whether a given system conforms to a particular property. Synthesis is the act of more or less automatically producing a correct system from a specification (so this avoids the need for verification). Finally execution is the process of directly implementing a specification, treating the specification language as an implementation (or programming) language.

In many of these applications it is crucial to determine whether a formula is a consequence of a set of formulas. For example, we may have a large and detailed set of formulas exactly describing the behaviour of the system and we have a small and very interesting formula describing a crucial desired property of the system (e.g., “it will fly”) and we want to determine whether the latter follows from the former. We turn to this question now.

2.2 An Axiomatization for the Logic

We have seen the importance of the consequence relation in applications of temporal logic. Because of this there are good reasons to consider syntactical ways of determining this relation between sets of formulas and a single formula. One of the most widely used and widely investigated such approaches is via a Hilbert system. Here we look in detail at a Hilbert style axiom system for our US/LT logic.

The system, which we will call $Ax(U, S)$, was first presented in [Burgess, 1982] but was later simplified slightly in [Xu, 1988]. It has what are the usual inference rules for a temporal logic: i.e. modus ponens and two generalizations, temporal generalization towards the future and temporal generalization towards the past:

$$\frac{A, A \rightarrow B}{B} \quad \frac{A}{GA} \quad \frac{A}{HA}$$

Each rule has a list of formulas (or just one formula) as antecedents shown above the horizontal line and a single formula, the consequent below the line. An *instance* of a rule is got by choosing any particular $L(U, S)$ formulas for the A and B . We describe the role of a rule below.

The axioms of $Ax(U, S)$ are all substitution instances of truth-functional tautologies and the following temporal schemas:

- (1) $G(A \rightarrow B) \rightarrow (U(A, D) \rightarrow U(B, D))$,
- (2) $G(A \rightarrow B) \rightarrow (U(D, A) \rightarrow U(D, B))$,
- (3) $A \wedge U(B, D) \rightarrow U(B \wedge S(A, D), D)$,
- (4) $U(A, B) \rightarrow U(A, B \wedge U(A, B))$,
- (5) $U(B \wedge U(A, B), B) \rightarrow U(A, B)$,
- (6) $U(A, B) \wedge U(D, E) \rightarrow$
 $(U(A \wedge D, B \wedge E) \vee U(A \wedge E, B \wedge E) \vee U(B \wedge D, B \wedge E))$.

along with the mirror images of (1) to (6). Notice that (1) and (2) are closely related to the usual axioms for the modal logic K , (3) relates the mirror image connectives, (4) and (5) have something to do with transitivity and (6) captures an aspect of linearity.

We say that a formula B follows from a list A_1, \dots, A_n of formulas by one of the rules of inference iff there is an instance of the rule with A_1, \dots, A_n as the antecedents and B as the consequent. A deduction in $Ax(U, S)$ is a finite sequence of formulas with each being either an instance of one of the axioms or following from a list of previous formulas in the sequence by one of the rules of inference. Any formula which appears as the last element in a derivation is called a *thesis* of the system. If A is a thesis then we write $\vdash A$.

We say that a formula D is a (*syntactic*) *consequence* of a set Γ of formulas iff there are $C_1, \dots, C_n \in \Gamma$ such that $\vdash (\bigwedge_{i=1}^n C_i) \rightarrow D$. In that case we write $\Gamma \vdash D$. Note that in some other logics it is possible to use a Hilbert system to define consequence via the idea of a deduction from hypotheses. In general in temporal logic, we do not do so because of problems with the generalization rules.

Note that alternative presentations of such a system may use what is known as the substitution rule:

$$\frac{A}{A[B/q]}$$

We have a whole collection of instances of the substitution rule: one for each (formula, atom , formula) triple. If B is a formula and q is an atom then we define the substitution $A[B/q]$ of q by B in a formula A by induction on the construction of A . We simply have $q[B/q] = B$ and $p[B/q] = p$ for any atom p other than q . The induction then respects every other logical operator, e.g., $(A_1 \wedge A_2)[B/q] = (A_1[B/q]) \wedge (A_2[B/q])$. If we include the substitution rule in an axiom system then axioms can be given in terms of particular atoms. For example, we could have an axiom $G(p \rightarrow q) \rightarrow (U(p, r) \rightarrow U(q, r))$.

Soundness of The System

We will now consider the relation between syntactic consequence and semantic consequence.

We say that an axiom system is *sound* (with respect to a semantically defined logic) iff any syntactic consequence (of the axiom system) is also a semantic consequence. This can readily be seen to be equivalent to the property of every thesis being valid.

We can show that:

LEMMA 2. *The system $Ax(U, S)$ is sound for US/LT .*

Proof. Via a simple induction it is enough to show that every axiom is valid and that each rule of inference preserves validity, i.e. that the consequent is valid if all the antecedents are.

The axioms are straightforward to check individually using obvious semantic arguments.

The inference rules are equally straightforward to check. For example, let us look at temporal generalization towards the future. Suppose that A is valid. We are required to show that GA is valid. So suppose that $(T, <, g)$ is a linear structure and $t \in T$. Consider any $s > t$. By the validity of A we have $(T, <, g), s \models A$. This establishes that $(T, <, g), t \models GA$ as required. ■

Completeness of the System

An axiom system is said to be (sound and) *complete* for a logic iff syntactic consequence exactly captures semantic consequence.

In fact, this is sometimes called *strong completeness* because there is a weaker notion of completeness which is still useful. We say that an axiom system is *weakly complete* for a logic iff it is sound and every validity is a thesis. Clearly weak completeness follows strong completeness. As we will see, there are temporal logics for which we can only obtain weakly complete axiom systems.

However,

THEOREM 3. *$Ax(U, S)$ is strongly complete for US/LT .*

Proof. We sketch the proof from [Burgess, 1982].

We need some common definitions in order to proceed. We say that a set of formulas is *consistent* (in the context of an axiom system) iff it is not the case that $\Gamma \vdash \perp$. If Γ is maximal in being consistent, i.e. the addition to Γ of any other formula in the language would result in inconsistency, then we say that Γ is a maximal consistent set (MCS). A useful result, due to Lindenbaum (see [Burgess, 2001]), gives us,

LEMMA 4. *If Δ is a consistent set then there is an MCS $\Gamma \supseteq \Delta$.*

There are many useful properties of MCSs, e.g.,

LEMMA 5. *If Γ is an MCS then $A \in \Gamma$ iff $\neg A \notin \Gamma$.*

In order to show the completeness of the axiom system we need only show that each MCS is satisfiable. To see this suppose that $\Gamma \models A$. Thus $\Gamma \cup \{\neg A\}$ is unsatisfiable. It can not be consistent as then by lemma 4 it could be extended to an MCS which we know would be satisfiable. Thus we must be able to derive \perp from $\Gamma \cup \{\neg A\}$, say $\bigwedge_{i=1}^n C_i \wedge \neg A \vdash \perp$. It is a simple matter to show that then we have $\vdash \bigwedge_{i=1}^n C_i \rightarrow A$, i.e. that A is a syntactic consequence of Γ .

So suppose that Γ_0 is an MCS: we want to show that it is satisfiable. We use the rationals as a base board on which we successively place whole maximal consistent sets of formulas as points which will eventually make up a flow of time. So, at each stage, we will have a subset $T \subseteq \mathbb{Q}$ and an MCS $\Gamma(t)$ for each $t \in T$.

Starting with our given maximal consistent set placed at zero, say, we look for counter-examples to either of the following rules:

1. if $U(A, B) \in \Gamma(t)$ then there should be some $\Gamma(s)$ placed at $s > t$ with $A \in \Gamma(s)$ and so that theories placed in between t and s all contain B and
2. if $\neg U(A, B) \in \Gamma(t)$ and $A \in \Gamma(s)$ placed at $s > t$ then there should be $\Gamma(r)$ placed somewhere in between with $\neg B \in \Gamma(r)$.

By carefully choosing a single maximal consistent set to right the counter-example and satisfy some other stringent conditions kept holding throughout the construction, we can ensure that the particular tuple $(t, U(A, B))$ or $(t, s, \neg U(A, B))$ never again forms a counter-example. In order to do so we need to record, for each interval between adjacent sets, which formulas must belong to any set subsequently placed in that interval. Because there are only countable numbers of points and formulas involved, in the limit we can effect that we end up with a counter-example-free arrangements of sets. This is so nice that if we define a valuation h on the final $T \subseteq \mathbb{Q}$ via $t \in h(p)$ iff $p \in \Gamma(t)$, then for all $t \in T$, for all $A \in L(U, S)$,

$$(T, <, h), t \models A \text{ iff } A \in \Gamma(t).$$

This is thus our model. ■

The IRR rule

Here we will examine a powerful alternative approach to developing Hilbert systems for temporal logics like US/LT . It is based on the use of rules such as the IRR (or irreflexivity) rule of [Gabbay, 1981]. Recall that a binary relation $<$ on a set T is irreflexive if we do not have $t < t$ for any $t \in T$. The IRR rule allows

$$\frac{q \wedge H(\neg q) \rightarrow A}{A} \quad \text{provided that the atom } q \text{ does not appear in the formula } A.$$

A short proof (see for example [Gabbay and Hodkinson, 1990], Proposition 2.2.1) establishes that,

LEMMA 6. *if \mathcal{I} is a class of (irreflexive) linear orders, then IRR is a valid rule in the class of all structures whose underlying flow of time comes from \mathcal{I} .*

Proof. Suppose that $q \wedge H(\neg q) \rightarrow A$ is valid. Consider any structure $(T, <, h)$ with $(T, <)$ from \mathcal{I} and any $t \in T$. Let g be a valuation of the atoms on T which is like h but differs only in that $g(q) = \{t\}$, i.e. $g = h[q \mapsto \{t\}]$. By the assumed validity, $(T, <, g) \models q \wedge H(\neg q) \rightarrow A$. But notice that also $(T, <, g) \models q \wedge H(\neg q)$. Thus $(T, <, g) \models A$. Clearly, since q does not appear in A , $(T, <, h) \models A$. Thus A is valid in the logic. ■

The original motivation for the use of this rule concerned the impossibility of writing an axiom to enforce irreflexivity of flows (see for example [van Benthem, 1991]). The usual technique in a completeness proof is to construct some model of a consistent formula and then turn it into an irreflexive model. IRR allows immediate construction of an irreflexive model. This is because it is always consistent to posit the truth of $q \wedge H(\neg q)$ (for some ‘new’ atom q) at any point as we do the construction.

The benefits of this rule for doing a completeness proof are enormous. Much use of it is made in [Gabbay *et al.*, 1994]. Venema [Venema, 1993] gives a long list of results proved using IRR or similar rules: examples include branching time logics [Zanardo, 1991] and two-dimensional modal logics [Kuhn, 1989]. In fact, the major benefit of IRR is a side-effect of its purpose. Not only can we construct a model which is irreflexive but we can construct a model in which each point has a unique name (as the first point where a certain atom holds).

As an example, consider our logic US/LT . We can, in fact mostly just use the standard axiomatization for F and P over the class of all linear orders. This is because if you have a unique name of the form $r \wedge H(\neg r)$ for each point then their axiom

$$(UU) \quad r \wedge H(\neg r) \rightarrow [U(p, q) \leftrightarrow F(p \wedge H[Pr \rightarrow q])]$$

and its mirror image (SS) essentially define U and S in terms of F and P .

So here is an axiom system for US/LT similar to those seen in [Gabbay and Hodkinson, 1990] and [Gabbay *et al.*, 1994]. Call it Z . The rules are modus ponens, two generalizations, substitution:

$$\frac{A, A \rightarrow B}{B} \quad \frac{A}{GA} \quad \frac{A}{HA} \quad \frac{A}{A[B/q]}$$

and the IRR:

$$\frac{q \wedge H(\neg q) \rightarrow A}{A} \quad \text{provided that the atom } q \text{ does not appear in the formula } A.$$

The axioms are:

1. all truth functional tautologies,
2. $G(p \rightarrow q) \rightarrow (Gp \rightarrow Gq)$,
3. $Gp \rightarrow GGp$,
4. $G(p \wedge Gp \rightarrow q) \vee G(q \wedge Gq \rightarrow p)$,
5. $r \wedge H\neg r \rightarrow (U(p, q) \leftrightarrow F(p \wedge H(Pr \rightarrow q)))$,

And mirror images of the above.

THEOREM 7. *The axiom system is sound and (weakly) complete for US/LT .*

Soundness is the usual induction on the lengths of proofs.

For completeness we have to do quite a bit of extra work. However this extra work is quite general and can form the basis of many and varied completeness proofs. The general idea is along the lines of the usual Henkin-style completeness proof for Prior's logic over linear time (see [Burgess, 2001]) but there is no need of bulldozing of clusters. It is as follows.

Say that a set is Z -consistent iff there is no conjunction A of its formulas such that Z derives $A \rightarrow \perp$. We are interested in maximal consistent sets of a particular sort which we call IRR theories. They contain a ‘name’ of the form $\neg q \wedge Hq$ and also similarly name any other time referred to by some zig-zagging sequence of F s and P s.

DEFINITION 8. A theory Δ is said to be an IRR-theory if (a) and (b) hold:

- (a) For some q , $\neg q \wedge Hq \in \Delta$.
- (b) Whenever $X = \diamond_1(A_1 \wedge \diamond_2(A_2 \wedge \dots \wedge \diamond_n A_n)) \dots \in \Delta$,
then for some new atom q ,
 $X(q) = \diamond_1(A_1 \wedge \diamond_2(A_2 \wedge \dots \wedge \diamond_n(A_n \wedge \neg q \wedge Hq))) \dots \in \Delta$,
where \diamond_i is either P or F .

We say that a theory Δ is complete iff for all formulas A , $A \in \Delta$ iff $\neg A \notin \Delta$. The following lemma plays the part of the Lindenbaum lemma in allowing us to work with maximal consistent IRR-theories.

LEMMA 9. *Let A be any Z -consistent formula. Then there exists a complete, Z -consistent IRR-theory, Δ , such that $A \in \Delta$. In fact, if Δ_0 is any Z -consistent theory such that an infinite number of atomic propositions q_i do not appear in Δ_0 , then there exists an IRR Z -consistent and complete theory $\Delta \supseteq \Delta_0$.*

Note that we are only proving a weak completeness result as we need to have a large number of spare atoms.

The main work of the truth lemma of the completeness proof is done by the following lemma in which we say that $\Delta < \Gamma$ iff for all $GA \in \Delta$, $A \in \Gamma$.

LEMMA 10. *Let Δ be a Z -consistent complete IRR-theory. Let $FA \in \Delta$ ($PA \in \Delta$ respectively). Then there exists a Z -consistent complete IRR-theory Γ such that $A \in \Gamma$ and $\Delta < \Gamma$ ($\Delta > \Gamma$ respectively).*

We can finish the completeness proof by then constructing a model from the consistent complete IRR-theories in the usual way: i.e. as worlds in our structure we use all those theories which are connected by some finite amount of $<$ zig-zagging with Δ_0 which contains our formula of interest. The frame of such sets under $<$ is made a structure by making an atom p true at the point Δ iff $p \in \Delta$. So far this is the usual Henkin construction as seen in [Burgess, 2001] for example. The frame will automatically be irreflexive because every set contains an atom which is true there for the first time. So there is no need for bulldozing. Transitivity and linearity follow from the appropriate axioms.

Now the IRR rule, as well as making the completeness proof easier, also arguably makes proving from a set of axioms easier. This is because, being able to consistently introduce names for points into an axiomatic proof

makes the temporal system more like the perhaps more intuitive first-order one. There are none of the problems such as with losing track of “now”.

So given all these recommendations one is brought back to the question of why is it useful to do away with IRR. The growing body of theoretical work (see for example Venema [1991; 1993]) trying to formalize conditions under which the orthodox (to use Venema’s term) system of rules needs to be augmented by something like IRR can be justified as follows:

- adding a new rule of inference to the usual temporal ones is arguably a much more drastic step than adding axioms and it is always important to question whether such additions are necessary;
- in making an unorthodox derivation one may need to go beyond the original language in order to prove a theorem, which makes such axiomatizations less attractive from the point of view of ‘resource awareness’;
- (as argued in [Venema, 1991]), using an atom to perform the naming task of an individual variable in predicate logic is not really in the spirit of temporal/modal logic;

and

- (also as mentioned in [Venema, 1991]), unorthodox axiomatizations do not have some of the nice mathematical properties that orthodox systems have.

2.3 Decidability of US/LT

We have seen that it is often useful to be able to approach the question of consequence in temporal logics in a syntactic way. For many purposes it is enough to be able to determine validity as this is equivalent to determining consequence between finite sets of formulas. A *decision procedure* for a logic is an algorithm for determining whether any given formula is valid or not. The procedure must give correct “yes” or “no” answers for each formula of the language. A logic is said to be *decidable* iff there exists such a decision procedure for its validities.

Notice that a decision procedure is able to tell us more about validities than a complete axiom system. The decision procedure can tell us when a formula is not a validity while an axiom system can only allow us to derive the validities. This is important for many applications.

For many of the most basic temporal logics some general results allow us to show decidability. The logic US/LT is such a logic.

A traditional way of showing decidability for temporal logics is via the so-called *finite model property*. We say that a logic has a finite model property iff any satisfiable formula is satisfiable in a finite model, a model with a

finite number of time points. A systematic search through all finite models coupled with a systematic search through all validities from a complete axiom system gives us a decision procedure. See [Burgess, 2001] for further details of the finite model approach to decidability: this can not be used with US/LT as there are formulas, such as $U(\top, \perp) \wedge GU(\top, \perp)$ which are satisfiable in infinite models only.

The logic US/LT can be shown to be decidable using the translation $*$ of section 2.1 into the first-order monadic logic of order. In [Ehrenfeucht, 1961] it was shown that the first-order logic of linear order is decidable. Other proofs in [Gurevich, 1964] and [Läuchli and Leonard, 1966] show that this also applies to the first-order monadic logic of linear order. The decidability of US/LT follows immediately via lemma 1 and the effectiveness of $*$.

An alternative proof uses the famous result in [Rabin, 1969] showing the decidability of a second-order monadic logic. The logic is $S2S$, the second-order logic of two successors. The language has two unary function symbols l and r as well as a countably infinite number of monadic predicate symbols P_1, P_2, \dots . The formulas are interpreted in the binary tree structure (T, l, r) of all finite sequences of zeros and ones with:

$$l(a) = a^{\wedge}0, r(a) = a^{\wedge}1 \text{ for all } a \in T.$$

As usual a sentence of the language is a formula with no free variables. Rabin shows that $S2S$ is decidable: i.e. there is an algorithm which given a sentence of $S2S$, correctly decides whether or not the sentence is true of the binary tree structure. Proofs of Rabin's difficult result use tree automata.

Rabin's is a very powerful decidability result and much used in establishing the decidability of other logics. For example, Rabin uses it to show that the full monadic second-order theory of the rational order is decidable. That is, there is an algorithm to determine whether a formula in the full monadic second-order language of order (as defined in section 2.1) is true of the order $(\mathbb{Q}, <)$. A short argument via the downward Löwenheim-Skolem theorem (see [Gurevich, 1964] or [Gabbay *et al.*, 1994]) then establishes that the universal monadic second-order theory of the class of all linear flows of time is decidable. Thus US/LT is too.

Once a decision procedure is known to exist for a useful logic it becomes an interesting problem to develop an efficient decision procedure for it. That is an algorithm which gives the "yes" or "no" answers to formulas. We might want to know about the fastest possible such algorithms, i.e. the complexity of the decision problem. To be more precise we need to turn the decision problem for a logic into a question for a Turing machine. There is a particular question about the symbolic representation of atomic propositions since we allow them to be chosen from an infinite set of atoms. A careful approach (seen in a similar example in [Hopcroft and Ullman, 1979]) is to suppose (by renaming) that the propositions actually used in a particular formula are p_1, \dots, p_n and to code p_i as the symbol p followed by i written

in binary. Of course this means that the input to the machine might be a little longer than the length of the formula. In fact a formula of length n may correspond to an input of length about $n \log_2 n$. There is no problem with output: we either want a “1” for, “yes, the formula is a validity” or a “0” for, “no, the formula is not a validity”.

Once we have a rigorously defined task for a Turing machine then we can ask all the usual questions about which complexity classes e.g., P, NP, PSPACE, EXPTIME, etc the problem belongs to. A further, very practical question then arises in the matter of actually describing and implementing efficient decision procedures for the logic. We return briefly to such questions later in the chapter.

For US/LT the complexity is an open problem. A result in [Reynolds, 1999] shows that it is PSPACE-hard. Essentially we can encode the running of a polynomially space-bounded Turing Machine in the logic. It is also believed that the decision problem for the logic is in PSPACE but, so far, this is just conjecture. The procedures which are contained within the decidability proofs above are little help as the method in [Läuchli and Leonard, 1966] relies on an enumeration of the validities in the first-order logic (with no clear guide to its complexity) and the complexity of Rabin’s original procedure is non-elementary.

2.4 Other flows of time

We have had a close look at the logic US/LT . There are many other temporal logics. We can produce other logics by varying our language and its semantics (as we will see in subsection 2.5 below) and we can produce other logics by varying the class of structures which we use to define validity. Let \mathcal{K} be some class of linear orders. We define the $L(U, S)$ (or Kamp) logic over \mathcal{K} to have validities exactly those formulas A of $L(U, S)$ which are true at all points t from any structure $(T, <, h)$ where $(T, <) \in \mathcal{K}$.

For example, the formula $\neg U(\top, \perp)$ is a validity of the $L(U, S)$ logic over the class of all dense linear orders. Let us have a closer look at this logic. In fact we can completely axiomatize this logic by adding the following two axioms to our complete axiomatization of US/LT :

$$\begin{aligned} &\neg U(\top, \perp), \\ &\neg S(\top, \perp), \end{aligned}$$

Soundness is clear. To show completeness, strong completeness, assume that Γ is a maximally consistent set of formulas, and here, this means consistent with the new axioms system. However, Γ will also be consistent with $Ax(U, S)$ and so will have a linear model by theorem 1. Say that $(T, <)$ is linear, $t_0 \in T$, and for all $C \in \Gamma$, $(T, <, h), t_0 \models C$. Now $G\neg U(\top, \perp) \in \Gamma$ because it this formula is a theorem derivable by generalization from one

of the new axioms. Thus, it is clear that no point in the future of t_0 has a discrete successor. Similarly there are no such discrete jumps in the past or immediately on either side of t_0 . Thus $(T, <, h)$ was a dense model all along.

Decidability of the $L(U, S)$ logic over dense time follows almost directly from the decidability of $L(U, S)$ over linear time: to decide A over dense time just decide

$$A \wedge \neg U(\top, \perp) \wedge G\neg U(\top, \perp) \wedge \neg S(\top, \perp) \wedge H\neg S(\top, \perp).$$

A more specific logic still is the $L(U, S)$ logic of rational (numbers) time. Here we define validity via truth at all points in any structure $(\mathbb{Q}, <, g)$ (where $<$ is the usual irreflexive ordering on the rationals). Such a logic has uses in reasoning about events and states when it might be inconvenient to assume that time is Dedekind complete. For example, a well situated gap in time could save arguments about whether there is a last moment when a light is on or a first moment when it is off. To axiomatize this logic it is enough to add to the system for dense time axioms asserting that there is neither an end of time nor a beginning:

$$GF\top, HPT.$$

The system is clearly sound. There are two ways to see that it is complete, both using the fact that any countable dense ordering without end points is (isomorphic to) the rationals. One way is to notice that Burgess' construction for a model of a set of formulas consistent with $Ax(U, S)$ does construct a countable one. The other way is to use the downward Löwenheim-Skolem theorem on the monadic translations of the temporal formulas.

The same sorts of moves give us decidability of the $L(U, S)$ logic of the rationals via the decidability over general linear time.

Another useful specific dense logic is the $L(U, S)$ logic over real (numbers) time, sometimes loosely called continuous time temporal logic. This is used in many applications as the real numbers seem to be the right model of time for many situations. Unfortunately the real numbers are not straightforward to describe with temporal axioms. The logic was first axiomatized in [Gabbay and Hodkinson, 1990] using a combination of techniques from [Läuchli and Leonard, 1966], [Burgess and Gurevich, 1985] and [Doets, 1989] to do with definable equivalence classes, the IRR approach to axiomatizing the $L(U, S)$ logics over linear time and expressive completeness ideas which we will see in section 3 below.

The axiomatization in [Gabbay and Hodkinson, 1990] consists of the basic axiom system for $L(U, S)$ logic over general linear time using the IRR rule (see above) plus:

$P\top \wedge F\top$	no end points,
$Fp \rightarrow FFp$	density,
$FGq \wedge F\neg q \rightarrow F(Gq \wedge \neg PGq)$	future Dedekind completeness,
$PHq \wedge P\neg q \rightarrow P(Hq \wedge \neg FHq)$	past Dedekind completeness,

and a new axiom,

$$\begin{aligned} & F(q \wedge F(q \wedge r \wedge H\neg r)) \wedge U(r, q \rightarrow \neg U(q, \neg q)) \\ \rightarrow & F(K^+q \wedge K^-q \wedge F(r \wedge H\neg r)) \end{aligned}$$

called the SEP rule.

The Dedekind completeness axioms are due to Prior and, as we will see, can be used with F and P logics to capture Dedekind completeness, the property of there being no gaps in the flow of time. In fact, these axioms just ensure definable Dedekind completeness, i.e. that there are no gaps in time in a structure which can be noticed by looking at the truth values of formulas.

The axiom SEP is interesting. Nothing like it is needed to axiomatize continuous temporal logic with only Prior's connectives as the property it captures is not expressible without U or S and hence without K^+ or K^- . SEP is associated with the separability of \mathbb{R} , i.e. the fact that it has a dense countable suborder (e.g., the rationals). It says roughly that if a formula is densely true in an interval then there is a point at which the formula is true both arbitrarily soon before and afterwards. That SEP is necessary in the axiom system is shown in [Gabbay and Hodkinson, 1990] when a structure is built in which all substitution instances of the other axioms including the Prior ones are valid while SEP is not. Such structures also show that the $L(U, S)$ logic over the reals is distinct from the amp logic over arbitrary continuous flows of time i.e. those that are dense, Dedekind complete and without end points.

The completeness proof only gives a weak completeness result: i.e. the axiom system allows derivation of all validities but it does not give us the general consequence relation between a possibly infinite set of formulas and a formula. In fact it is impossible to give a strongly complete axiom system for this logic because it is not *compact*: there is an infinite set of formulas which is inconsistent but every finite subset of it is consistent. Here is one example:

$$\Gamma = \{FG\neg p, G\neg K^-p, A_0, A_1, \dots\}$$

where $A_0 = Fp$ and for each n , $A_{n+1} = FA_n$.

The proof relies on building a not necessarily real flowed model M of a given satisfiable formula A , say, and then showing that for each n , there is a real flowed structure which satisfies the same monadic sentences to

quantifier depth n as M does. By choosing n to be one more than the depth of quantifiers in $*A$ one can see that we have a model of A by reasoning about the satisfiability of the monadic sentence $\exists x * A(x)$.

The later axiom system in [Reynolds, 1992] is complete for the $L(U, S)$ logic over the reals and does not use the IRR rule. Instead it adds the following axioms to $Ax(U, S)$:

$$\begin{array}{ll}
 K^+ \top, K^- \top, F \top, P \top & \text{as before,} \\
 U(\top, p) \wedge F \neg p \rightarrow U(\neg p \vee K^+ \neg p, p) & \text{Prior-U,} \\
 S(\top, p) \wedge P \neg p \rightarrow S(\neg p \vee K^- \neg p, p) & \text{Prior-S, and} \\
 K^+ p \wedge \neg K^+(p \wedge U(p, \neg p)) \rightarrow K^+(K^+ p \wedge K^- p) & \text{SEP2}
 \end{array}$$

Prior-U and its mirror image are just versions of the Dedekind completeness axioms and SEP2 is a neater version of SEP also developed by Ian Hodkinson. The proof of completeness is similar to that in [Gabbay and Hodkinson, 1990] but requires quite a bit more work as the “names” produced by the IRR rule during construction are not available to help reason about definable equivalence classes.

The decidability of the $L(U, S)$ logic over real time is also not straightforward to establish. It was proven by two different methods in [Burgess and Gurevich, 1985]. One method uses a variant of a traditional approach: show that a formula that is satisfiable over the reals is also satisfiable over the rationals under a valuation which conforms to a certain definition of “niceness”, show that a formula satisfiable under a “nice” valuation on the rationals is satisfiable over the reals, and show that deciding satisfiability under nice valuations over the rationals is decidable. The other method uses arguments about definable equivalence relations as in the axiomatization above. Both methods use Rabin’s decidability result for $S2S$ and Kamp’s expressive completeness result which we will see in a later section.

The complexity of the decision problem for the $L(U, S)$ logic over the reals is an open problem.

Now let us consider the $L(U, S)$ logics over discrete time. To axiomatize the $L(U, S)$ logic over the integers it is not enough to add the following discreteness and non-endedness axioms to the Burgess system $Ax(U, S)$:

$$U(\top, \perp) \text{ and } S(\top, \perp).$$

In fact, we must add these and Prior-style Dedekind completeness axioms such as:

$$Fp \rightarrow U(p, \neg p)$$

and its mirror image. To prove weak completeness (–it is clear that this logic is not compact–) requires a watered down version of the mechanisms for real numbers time or other ways of finding an integer-flowed model from a model with a definably Dedekind complete valuation over some other countable,

discrete flow without end points. There is a proof in [Reynolds, 1994]. An alternative axiom system in the usual IRR style is probably straightforward to construct. The decidability of this logic follows from the decidability of the full monadic second-order theory of the integers which was proved in [Büchi, 1962]. Again the complexity of the problem is open.

When we turn to natural numbers time we find the most heavily studied temporal logics. This is because of the wide-ranging computer science applications of such logics. However, it is not the $L(U, S)$ logic which is studied here but rather logics like PTL which concentrate on the future and which we will meet in section 7 below. The S connective can be shown to be unnecessary in expressing properties: to see this is a straightforward use of the separation property of the $L(U, S)$ logic over the natural numbers (see section 3 below). Despite this it has been argued (e.g., in [Lichtenstein *et al.*, 1985]) that S can help in allowing natural expression of certain useful properties: it is not necessarily easy or efficient to re-express the property without using S . Thus, axiom systems for the $L(U, S)$ logic over the natural numbers have been presented. In [Lichtenstein *et al.*, 1985], such a complete system is given which is in the style of the axiom systems for the logic PTL which we will meet in section 7 below (and so we will not describe it here). In [Venema, 1991] a different but still complete axiom system is given along with others for $L(U, S)$ logics over general classes of well-orderings. This system is simply $Ax(U, S)$ with axioms for discreteness, Dedekind completeness beginning and no end. Again the completeness proof is subtle because the logic is not compact and there are many different countable, discrete, Dedekind complete orderings with a beginning and no end. The $L(U, S)$ logic over the natural numbers is known to be decidable via monadic logic arguments (via [Büchi, 1962]) and, in [Lichtenstein *et al.*, 1985], a PSPACE decision procedure is given and the problem is shown to be PSPACE-complete.

2.5 Other linear time logics

We have met a variety of temporal logics based on using Kamp's U and S connectives (on top of propositional logic) over various classes of linear orders. Basing a logic on other classes of not necessarily linear orders can also give us useful or interesting logics as we will see in section 4 below. However, there is another way of constructing other temporal logics. For various reasons it might be interesting to build a language using other temporal connectives. We may want the temporal language to more closely mimic a particular natural language with its own ways of representing tense or aspect. We may think that U and S do not allow us to express some important properties. Or we may think that U and S allow us to express too much and so the $L(U, S)$ language is unnecessarily complex to reason with for our particular application.

In the next few sections we will consider temporal logics for reasoning about certain classes of linear flows of time based on a variety of temporal languages. By a temporal language here we will mean a language built on top of propositional logic via the recursive use of one or more temporal connectives. By a temporal connective we will mean a logical connective symbol with a first order table as defined above.

Some of the common connectives include, as well as U and S ,:

- Fp $\exists s > tP(s)$,
it will sometime be the case that p ;
- Pp $\exists s < tP(s)$,
it was sometime the case that p ;
- Xp $\exists s > tP(s) \wedge \neg \exists r(t < r < s)$,
there is a next instant and p will hold then;
- Yp $\exists s < tP(s) \wedge \neg \exists r(s < r < t)$,
there was a previous instant and p held then.

Note that some (all) of these connectives can be defined in terms of U and S .

A traditional temporal (or modal) logic is that with just the connective F over the class of all linear flows of time. This logic (often with the symbol \diamond used for F) is traditionally known as K4.3 because it can be completely axiomatized by axioms from the basic modal system K along with an axiom known as 4 (for transitivity) and an axiom for linearity which is not called 3 but usually L . The system includes modus ponens substitution and (future) temporal generalization and the axioms:

$$\begin{aligned} G(p \rightarrow q) &\rightarrow (Gp \rightarrow Gq) \\ Gp &\rightarrow GGp \\ G(p \wedge Gp \rightarrow q) &\vee G(q \wedge Gq \rightarrow p) \end{aligned}$$

where GA is the abbreviation $\neg F\neg A$ in terms of F in this language. The proof of (strong) completeness involves a little bit of rearranging of maximal consistent sets as can be seen in [Burgess, 2001] or [Bull and Segerberg, in this handbook]. The decidability and NP-completeness of the decision problem can be deduced from the result of [Ono and Nakamura, 1980] mentioned shortly.

Adding Prior's past connective P to the language, but still defining consequence over the class of all linear orders results in the basic linear $L(F, P)$ logic which is well described in [Burgess, 2001]. A strongly complete axiom system can be obtained by adding mirror images of the rules and axioms in K4.3.

To see that the linear $L(F, P)$ logic is decidable one could simply call on the decidability of the $L(U, S)$ logic over linear time (as seen above). It is a trivial matter to see that a formula in the $L(F, P)$ language can be translated

directly into an equivalent formula in the $L(U, S)$ language. An alternative approach is to show that the $L(F, P)$ logic has a finite model property: if A is satisfiable (in a linear structure) then A is satisfiable in a finite structure (of some type). As described in [Burgess, 2001], in combination with the complete axiom system, this gives an effective procedure for deciding the validity of any formula.

A third alternative is to use the result in [Ono and Nakamura, 1980] that if a $L(F, P)$ formula of length n is satisfiable in a linear model then it is satisfiable in a finite connected, transitive, totally ordered but not necessarily anti-symmetric or irreflexive model containing at most n points. This immediately gives us a non-deterministic polynomial time decision procedure. Since propositional logic is NP-complete we conclude that the linear $L(F, P)$ logic is too.

Another linear time logic has recently been studied in [Reynolds, 1999]. This is the linear time logic with just the connective U . It was studied because, despite the emerging applications of reasoning over general linear time, as we saw above, it is not known how computationally complex it is to decide validity in the linear $L(U, S)$ logic. As a first step to solving this problem the result in this paper shows that the problem of deciding formulas with just U is PSPACE-complete. The proof uses new techniques based on the “mosaics” of [Németi, 1995]. A mosaic-based decision procedure consists in trying to establish satisfiability by guessing and checking a set of model pieces to see if they can be put together to form a model. Mosaics were first used in deciding a temporal logic in [Reynolds, 1998]. It is conjectured that similar methods may be used to show that deciding the $L(U, S)$ logic is also PSPACE-complete.

The logics above have all been obviously not more expressive than the $L(U, S)$ logic of linear time. Are there linear time temporal logics which are more expressive than the $L(U, S)$ logic? We will see later that the answer is yes and that a completely expressive language (in a manner to be defined precisely) contains two more connectives along with Kamp’s. These are the Stavi connectives which were defined in [Gabbay *et al.*, 1980]. $U'(A, B)$ holds if B is true from now until a gap in time after which B is arbitrarily soon false but after which A is true for a while: $U'(A, B)$ is as pictured

S' is defined via the mirror image. Despite involving a gap, U' is in fact a first-order connective. Here is the first-order table for U' :

$$\begin{aligned}
 U'(p, q) \equiv & \\
 \exists s \quad & t < s \\
 \wedge \quad & \forall u \quad (\\
 & \quad \quad \quad t < u < s \rightarrow \\
 & \quad \quad \quad ([\quad \exists v(u < v \wedge \forall w(t < w < v \rightarrow q(w)) \quad] \\
 & \quad \quad \quad \vee \quad [\quad \forall v(u < v < s \rightarrow p(v)) \\
 & \quad \quad \quad \quad \wedge \quad \exists v(t < v < u \wedge \neg q(v)) \quad])) \\
 \wedge \quad & \exists u[t < u < s \wedge \neg q(u)] \\
 \wedge \quad & \exists u[t < u < s \wedge \forall v(t < v < u \rightarrow q(v))]
 \end{aligned}$$

Of course, S' has the mirror image table.

We will see in section 3 below that the logic with U , S , U' and S' is expressively complete for the class of structures with linear flow of time. There is no known complete axiom system for the logic with this rather complicated set of connectives. The decidability of the logic follows from the decidability of first-order monadic logic. However, the complexity of the decision problem is also open. If it was shown to be PSPACE-complete for example, then we would have the very interesting result that this temporal logic is far far easier to reason with than the equally expressive monadic logic (with one free variable).

Probably the most useful dense linear time temporal logics are those based on the real-numbers flow of time. Because it is expressively complete (as we will see), the $L(U, S)$ logic over the reals is the most important such logic. The Stavi connectives are useless over the reals. We have seen that this logic can be axiomatized in several ways, and is decidable. However, the complexity of the decision procedure is not known. Other, less expressive, real-flowed temporal logics can be defined. Logics built with any combination of connectives from $\{F, P, U, S\}$ will clearly be decidable. There is an axiomatization of the $L(F, P)$ logic over the reals in [Burgess, 2001].

Various authors have studied a real-flowed temporal logic with a slightly unusual semantics. We say that a structure $(\mathbb{R}, <, h)$ has *finite variability* iff in any bound interval of time, there are only finitely many points of time between which the truth values of all atoms are constant. A logic can be defined by evaluating U and S only on finitely variable structures. This allows the logic to be useful for reasoning about many situations but makes it amenable to the sorts of techniques which are used to reason about sequences of states and natural numbers time temporal logics. See [Kesten *et al.*, 1994] and [Rabinovich, 1998] for more details.

3 THE EXPRESSIVE POWER OF TEMPORAL CONNECTIVES

The expressivity of a language is always measured with respect to some other language. That is, when talking about expressivity, we are always comparing two or more languages. When measuring the expressivity of a large number of languages, it is usually more convenient to have a single

language with respect to which all other languages can be compared, if such a language is known to exist.

In the case of propositional one-dimensional temporal languages defined by the presence of a fixed number of *temporal connectives* (also called *temporal modalities*), the expressivity of those languages can be all measured against a fragment of first-order logic, namely the *monadic first-order language*. This is the fragment that contains a binary $<$ (to represent the underlying temporal order), $=$ (which we assume is always in the language) and a set of unary predicates $Q_1(x), Q_2(x), \dots$ (which account for the interpretation of the propositional letters, that are interpreted as a subset of the temporal domain T). Indeed, any one-dimensional temporal connective can be defined as a well-formed formula in such a fragment, known as the connective's *truth table*; one-dimensionality forces such truth tables to have a single free variable.

In the case of comparing the expressivity of temporal connectives, another parameter must be taken into account, namely the underlying flow of time. Two temporal languages may have the same expressivity over one flow of time (say, the integers) but may differ in expressivity over another (e.g. the rationals); see the discussion on the expressivity of the US connectives below.

Let us exemplify what we mean by those terms. Consider the connectives *since*(S), *until*(U), *future*(F), and *past*(P). Given a flow of time $(T, <, h)$, the truth value of each of the above connectives at a point $t \in T$ is determined as follows:

$$\begin{aligned}
(T, <, h), t \models Fp & \quad \text{iff} \quad (\exists s > t)(T, <, h), s \models p, \\
(T, <, h), t \models Pp & \quad \text{iff} \quad (\exists s < t)(T, <, h), s \models p, \\
(T, <, h), t \models U(p, q) & \quad \text{iff} \quad (\exists s > t)((T, <, h), s \models p \wedge \\
& \quad \forall y(t < y < s \rightarrow (T, <, h), y \models q)), \\
(T, <, h), t \models S(p, q) & \quad \text{iff} \quad (\exists s < t)((T, <, h), s \models p \wedge \\
& \quad \forall y(s < y < t \rightarrow (T, <, h), y \models q))
\end{aligned}$$

If we assume that $h(p)$ represents a first-order unary predicate that is interpreted as $h(p) \subseteq T$, then these truth values above can be expressed as first-order formulas. Thus:

- (a) $(T, <, h), t \models Fq$ iff $\chi_F(t, h(q))$ holds in $(T, <)$,
- (b) $(T, <, h), t \models Pq$ iff $\chi_P(t, h(q))$ holds in $(T, <)$,
- (c) $(T, <, h), t \models U(q_1, q_2)$ iff $\chi_U(t, h(q_1), h(q_2))$ holds in $(T, <)$, and
- (d) $(T, <, h), t \models S(q_1, q_2)$ iff $\chi_S(t, h(q_1), h(q_2))$ holds in $(T, <)$.

where

- (a) $\chi_F(t, Q) = (\exists s > t)Q(s)$,
- (b) $\chi_P(t, Q) = (\exists s < t)Q(s)$,
- (c) $\chi_U(t, Q_1, Q_2) = (\exists s > t)(Q_1(s) \wedge \forall y(t < y < s \rightarrow Q_2(y)))$,
- (d) $\chi_S(t, Q_1, Q_2) = (\exists s < t)(Q_1(s) \wedge \forall y(s < y < t \rightarrow Q_2(y)))$.

$\chi_{\#}(t, Q_1, \dots, Q_n)$ is called the *truth table* for the connective $\#$. The number n of parameters in the truth table will be the number of places in the connective, e.g. F and P are one place connective, and their truth tables have a single parameter; S and U are two-place connectives, with truth tables having two parameters.

It is clear that in such a way, we start defining any number of connectives. For example consider $\chi(t, Q) = \exists xy(t < x < y \wedge \forall s(x < s < y \rightarrow Q(s))$; then $\chi(t, Q)$ means ‘There is an interval in the future of t inside which P is true.’ This is a table for a connective F_{int} : $(T, <, h), t \models F_{\text{int}}(p)$ iff $\chi(t, h(p))$ holds in $(T, <)$.

We are in condition of presenting a general definition of what a temporal connective is:

DEFINITION 11.

1. Any formula $\chi(t, Q_1, \dots, Q_m)$ with one free variable t , in the monadic first-order language with predicate variable symbols Q_i , is called an m -place truth table (in one dimension).
2. Given a syntactic symbol $\#$ for an m -place connective, we say it has a truth table $\chi(t, Q_1, \dots, Q_m)$ iff for any T, h and t , $(*)$ holds:

$$(*) : (T, <, h), t \models \#(q_1, \dots, q_m) \text{ iff } (T, <) \models \chi(t, h(q_1), \dots, h(q_m)).$$

This way we can define as many connectives as we want. Usually, some connectives are definable using other connectives. For example, it is well known that F is definable using U as $Fp \equiv U(p, \top)$. As another example, consider a connective that states the existence of a “next” time point: $\delta \equiv U(\top, \perp)$.

The connective δ is a nice example on how the definability of a connective by others depends on the class of flows of time being considered. For example, in a dense flow of time, δ can be defined in terms of F and P — actually, since there are no “next” time points anywhere, $\delta \equiv \perp$. Similarly, in an integer-like flow of time, δ is equivalent to \top .

On the other hand, consider the flow $(T, <)$ of time with a single point without a “next time”: $T = \{\dots - 2, -1, 0, 1, 2, \dots\} \cup \{(1/n) \mid n = 1, 2, 3, \dots\}$, with $<$ being the usual order; then δ is not definable using P and F . To see that, suppose for contradiction that δ is equivalent to A where A is written with P and F and, maybe, atoms. Replace all appearances of atoms by \perp

to obtain A' . Since $\delta \leftrightarrow A$ holds in the structure $(T, <, h')$ with all atoms always false, in this structure $\delta \leftrightarrow A'$ holds. As neither δ nor A' contain atoms, $\delta \leftrightarrow A'$ holds in all other $(T, <, h)$ as well. Now A' contains only P and F , \top , and \perp and the classical connectives. Since $F\top \equiv P\top \equiv \top$ and $F\perp \equiv P\perp \equiv \perp$, at every point, A' must be equivalent (in $(T, <)$) to either \top or \perp and so cannot equal δ which is true at 1 and false at 0. As a consequence, δ is not definable using P and F over linear time.

In general, given a family of connectives, e.g. $\{F, P\}$ or $\{U, S\}$, we can build new connectives using the given ones. That these new connectives are connectives in the sense of Definition 11 follows from the following.

LEMMA 12. *Let $\#_1(q_1, \dots, q_{m_1}), \dots, \#_n(q_1, \dots, q_{m_n})$ be n temporal connectives with tables χ_1, \dots, χ_n . Let A be any formula built up from atoms q_1, \dots, q_m , the classical connectives, and these connectives. Then there exists a monadic $\psi_A(t, Q_1, \dots, Q_m)$ such that for all T and h ,*

$$(T, <, h), t \models A \text{ iff } (T, <) \models \psi_A(t, h(q_1), \dots, h(q_m)).$$

Proof. We construct ψ_A by induction on A . The simple cases are: $\psi_{q_j} = Q_j(t)$, $\psi_{\neg A} = \neg\psi_A$ and $\psi_{A \wedge B} = \psi_A \wedge \psi_B$.

For the temporal connective case, we construct the formula $\psi_{\#_i(A_1, \dots, A_{m_i})} = \chi_i(t, \psi_{A_1}, \dots, \psi_{A_{m_i}})$; the right-hand side is a notation for the formula obtained by substituting $\psi_{A_j}(x)$ in χ_i wherever $Q_j(x)$ appears, with the appropriate renaming of bound variables to avoid clashes. The induction hypothesis is applied over $\psi_{A_1}, \dots, \psi_{A_{m_i}}$ and the result is simply obtained by truth table of the connective $\#_i$. ■

The formula ψ_A built above is called the *first-order translation* of a temporal formula A . An m -place connective $\#$ with truth table $\chi(t, Q_1, \dots, Q_m)$ is said to be *definable* from connectives $\#_1, \dots, \#_n$ in a flow of time $(T, <)$ if there exists a temporal formula A built from those connectives whose first order translation is ψ_A such that

$$(T, <) \models \psi_A \leftrightarrow \chi.$$

The *expressive power* of a family of connectives over a flow of time is measured by how many connectives it can express over the flow of time. If it can express any conceivable connective (given by a monadic formula), then that family of connectives is *expressively complete*.

DEFINITION 13. A temporal language with one-dimensional connectives is said to be *expressively complete* or, equivalently, *functionally complete*, in one dimension over a class \mathcal{T} of partial orders iff for any monadic formula $\psi(t, Q_1, \dots, Q_m)$, there exists an A of the language such that for any $(T, <)$ in \mathcal{T} , for any interpretation h for q_1, \dots, q_m ,

$$(T, <) \models \forall t(\psi \leftrightarrow \psi_A)(t, h(q_1), \dots, h(q_m)).$$

In the cases where $\mathcal{T} = \{(T, <)\}$ we talk of expressive completeness over $(T, <)$. For example, the language of Since and Until is expressively complete over integer time and real number flow of time, as we are going to see in Section 3.2; but they are not expressively complete over rational numbers time [Gabbay *et al.*, 1980].

DEFINITION 14. A flow of time $(T, <)$ is said to be expressively complete (or functionally complete) (in one dimension) iff there exists a *finite* set of (one-dimensional) connectives which is expressively complete over $(T, <)$, in one dimension.

The qualification of one-dimensionality in the definitions above will be explained when we introduce the notion of H-dimension below.

These notions parallel the definability and expressive completeness of classical logic. We know that in classical logic $\{\neg, \rightarrow\}$ is sufficient to define all other connectives. Furthermore, for any n -place truth table $\psi : 2^n \rightarrow 2$ there exists an $A(q_1, \dots, q_n)$ of classical logic such that for any h ,

$$h(A) = \psi(h(q_1), \dots, h(q_n)).$$

This is the expressive completeness of $\{\neg, \rightarrow\}$ in classical logic.

The notion of expressive completeness leads us to formulate two questions:

- (a) Given a finite set of connectives and a class of flows of time, are these connectives expressively complete?
- (b) In case the answer to (a) is no, we would like to ask: given a class of flows, does there exist a finite set of one-dimensional connectives that is expressively complete?

These questions occupy us to the rest of this section. We show that the notion of expressive completeness is intimately related to the *separation property*.

The answer to question (b) is related to the notion of H-dimension, discussed in Section 3.3.

3.1 Separation and Expressive Completeness

The notion of separation involves partitioning a flow of time in disjoint parts (typically: present, past and future). A formula is separable if it is equivalent to another formula whose temporal connectives refer only to one of the partitions.

If every formula in a language is separable, that means that we have at least one connective that has enough expressivity over each of the partitions. So we might expect that that set of connectives is expressively complete over

a class of flows that admits such partitioning, provided the partitioning is also expressible by the connectives.

The notion of separation was initially analysed in terms of linear flows, where the notion of present, past and future most naturally applies. So we start our discussion with separation over linear time. We later extend separation to generic flows.

Separation over linear time

Consider a linear flow of time $(T, <)$. Let h, h' be two assignments and $t \in T$. We say that h, h' *agree on the past of t* , $h =_{<t} h'$, iff for any atom q and any $s < t$,

$$s \in h(q) \text{ iff } s \in h'(q).$$

We define $h' =_{=t} h$ for *agreement of the present*, iff for any atom q

$$t \in h(q) \text{ iff } t \in h'(q).$$

and $h' =_{>t} h$, for *agreement on the future*, iff for any atom q and any $s > t$,

$$s \in h(q) \text{ iff } s \in h'(q).$$

Let \mathcal{T} be a class of linear flows of time and A be a formula in a temporal language over $(T, <)$. We say that A is a *pure past formula over \mathcal{T}* , iff for all $(T, <)$ in \mathcal{T} , for all $t \in T$,

$$\forall h, h', (h =_{<t} h') \text{ implies that } (T, <, h), t \models A \text{ iff } (T, <, h'), t \models A.$$

Similarly, we define *pure future* and *pure present* formulas.

Such a definition of purity is a semantic one. In a temporal language containing only S and U there is also have a notion of syntactic purity as follows. A formula is a *Boolean combination* of ϕ_1, \dots, ϕ_n if it is built from ϕ_1, \dots, ϕ_n using only Boolean connectives. A *syntactically pure present* formula is a Boolean combination of atoms only. A *syntactically pure past* formula is a Boolean combination of formulas of the form $S(A, B)$ where A and B are either pure present or pure past. Similarly, a *syntactically pure future* formula is a Boolean combination of formulas of the form $U(A, B)$ where A and B are either pure present or pure future.

It is clear that if A is a syntactically pure past formula, then A is a pure past formula; similarly for pure present and pure future formulas. The converse, however, is not true. For example, from the semantical definition, all temporal temporally valid formulas are pure future (and pure past, and pure present), including those involving S .

We are now in a position to define the separation property.

DEFINITION 15. Let \mathcal{T} be a class of linear flows of time and A be a formula in a temporal language \mathbf{L} . We say A is *separable* in \mathbf{L} over \mathcal{T} iff there exists

a formula in \mathbf{L} which is a Boolean combination of pure past, pure future, and atomic formulas and is equivalent to A everywhere in any $(T, <)$ from \mathcal{T} .

A set of temporal connectives is said to have the separation property over \mathcal{T} iff every formula in the temporal language of these connectives is separable in the language (over \mathcal{T}).

We now show that separation implies expressive completeness.

THEOREM 16. *Let \mathbf{L} be a temporal language built from any number (finite or infinite) of connectives in which P and F are definable over a class \mathcal{T} of linear flows of time. If \mathbf{L} has the separation property over \mathcal{T} then \mathbf{L} is expressively complete over \mathcal{T} .*

Proof. If \mathcal{T} is empty, \mathbf{L} is trivially expressively complete, so suppose not. We have to show that for any $\varphi(t, \overline{Q})$ in the monadic theory of linear order with predicate variable symbols $\overline{Q} = (Q_1, \dots, Q_n)$, there exists a formula $A = A(q_1, \dots, q_n)$ in the temporal language such that for all flows of time $(T, <)$ from \mathcal{T} , for all h, t , $(T, <, h), t \models A$ iff $(T, <) \models \varphi(t, h(q_1), \dots, h(q_n))$.

We denote this formula by $A[\varphi]$ and proceed by induction on the depth m of nested quantifiers in φ . For $m = 0$, $\varphi(t)$ is quantifier free. Just replace each appearance of $t = t$ by \top , $t < t$ by \perp , and each $Q_j(t)$ by q_j to obtain $A[\varphi]$.

For $m > 0$, we can assume $\varphi = \exists x \psi(t, x, \overline{Q})$ where ψ has quantifier depth $\leq m$ (the \forall quantifier is treated as derived).

Assuming that we do not use t as a bound variable symbol in ψ and that we have replaced all appearances of $t = t$ by \top and $t < t$ by \perp then the atomic formulas in ψ which involve t have one of the following forms: $Q_i(t)$, $t < y$, $t = y$, or $y < t$, where y could be x or any other variable letter occurring in ψ .

If we regard t as fixed, the relations $t < y$, $t = y$, $t > y$ become unary and can be rewritten, respectively, as $R_{<}(y)$, $R_{=}(y)$ and $R_{>}(y)$, where $R_{<}$, $R_{=}$ and $R_{>}$ are new unary predicate symbols.

Then ψ can be rewritten equivalently as

$$\psi_0^t(x, \overline{Q}, R_{=}, R_{>}, R_{<}),$$

in which t appears only in the form $Q_i(t)$. Since t is free in ψ , we can go further and prove (by induction on the quantifier depth of ψ) that ψ_0^t can be equivalently rewritten as

$$\psi^t = \bigvee_j [\alpha_j(t) \wedge \psi_j^t(x, \overline{Q}, R_{=}, R_{>}, R_{<})],$$

where

- $\alpha_j(t)$ is quantifier free,

- $Q_i(t)$ appear only in $\alpha_j(t)$ and not at all in ψ_j^t ,
- and each ψ_j^t has quantifier depth $\leq m$.

By the induction hypothesis, there is a formula $A_j = A_j(\bar{q}, r_=:, r_>, r_<)$ in the temporal language such that, for any h, x ,

$$(T, <, h), x \models A_j \text{ iff} \\ (T, <) \models \psi_j^t(x, h(q_1), \dots, h(q_n), h(r_=), h(r_>), h(r_<)).$$

Now let $\diamond q$ be an abbreviation for a temporal formula equivalent (over \mathcal{T}) to $Pq \vee q \vee Fq$ whose existence in \mathbf{L} is guaranteed by hypothesis. Then let $B(\bar{q}, r_=:, r_>, r_<) = \bigvee_j (A[\alpha_j] \wedge \diamond A_j)$. $A[\alpha_j]$ can be obtained from the quantifier free case.

In any structure $(T, <)$ from \mathcal{T} for any h interpreting the atoms $\bar{q}, r_=:, r_>$ and $r_<$, the following are straightforward equivalences

$$\begin{aligned} (T, <, h), t \models B \\ (T, <, h), t \models \bigvee_j (A[\alpha_j] \wedge \diamond A_j) \\ \bigvee_j ((T, <, h), t \models A[\alpha_j] \wedge (T, <, h), t \models \diamond A_j) \\ \bigvee_j (\alpha_j(t) \wedge \exists x ((T, <, h), x \models A_j)) \\ \bigvee_j (\alpha_j(t) \wedge \exists x \psi_j^t(x, h(q_1), \dots, h(q_n), h(r_=), h(r_>), h(r_<))) \\ \exists x \bigvee_j (\alpha_j(t) \wedge \psi_j^t(x, h(q_1), \dots, h(q_n), h(r_=), h(r_>), h(r_<))) \\ \exists x \psi_0^t(x, h(q_1), \dots, h(q_n), h(r_=), h(r_>), h(r_<)). \end{aligned}$$

Now provided we interpret the r atoms as the appropriate R predicates, i.e.:

- $h^*(r_=) = \{t\}$,
- $h^*(r_<) = \{s \mid t < s\}$, and
- $h^*(r_>) = \{s \mid s < t\}$,

we obtain

$$(T, <, h^*), t \models B \text{ iff } \exists x \psi(t, x, h^*(q_1), \dots, h^*(q_n)) \text{ iff} \\ \varphi(t, h^*(q_1), \dots, h^*(q_n)).$$

B is almost the $A[\varphi]$ we need except for one problem. B contains, besides the q_i , also three other atoms, $r_=:, r_>$, and $r_<$, and equation (*) from Definition 9.1.1 above is valid for any h^* which is arbitrary on the q_i but very special on $r_=:, r_>, r_<$. We are now ready to use the separation property (which we haven't used so far in the proof). We use separation to eliminate $r_=:, r_>, r_<$ from B . Since we have separation B is equivalent to a Boolean combination of atoms, pure past formulas, and pure future formulas.

So there is a Boolean combination $\beta = \beta(\overline{p}_+, \overline{p}_-, p_0)$ such that

$$B \leftrightarrow \beta(\overline{B}_+, \overline{B}_-, B_0),$$

where $B_0(\overline{q}, r_>, r_=:, r_<)$ is a combination of atoms, $B_+(\overline{q}, r_>, r_=:, r_<)$ are pure future, and $B_-(\overline{q}, r_>, r_=:, r_<)$ are pure past formulas.

Finally, $B^* = \beta(B_+^*, B_-^*, B_0^*)$ where

- $B_0^* = B_0(\overline{q}, \perp, \top, \perp)$;
- $B_+^* = B_+(\overline{q}, \top, \perp, \perp)$;
- $B_-^* = B_-(\overline{q}, \perp, \perp, \top)$.

Then we obtain for any h^* ,

$$\begin{aligned} (T, <, h^*), t \models B & \text{ iff } (T, <, h^*), t \models \beta(B_+, B_-, B_0) \\ & \text{ iff } (T, <, h^*), t \models \beta(B_+^*, B_-^*, B_0^*) \\ & \text{ iff } (T, <, h^*), t \models B^*. \end{aligned}$$

Hence

$$(T, <, h^*), t \models B^* \text{ iff } (T, <) \models \varphi(t, h^*(\overline{q})).$$

This equation holds for any h^* arbitrary on \overline{q} , but restricted on $r_<, r_>, r_=:$. But $r_<, r_>, r_=:$ do not appear in it at all and hence we obtain that for any h , $(T, <, h), t \models B^*$ iff $(T, <) \models \varphi(t, h^*(\overline{q}))$. So make $A[\varphi] = B^*$ and we are done. \blacksquare

The converse is also true: expressive completeness implies separation over linear time. The proof involves using the first-order theory of linear time to first separate a first-order formula over linear time; a temporal formula is translated into the first-order language, where it is separated; expressive completeness is needed then to translate each separated first-order subformula into a temporal formula. Details are omitted, but can be found in [Gabbay *et al.*, 1994].

Generalized Separation

The separation property is not restricted to linear flows of time. In this section we generalize the separation property over any class of flows of time and see that Theorem 16 has a generalised version.

The basic idea is to have some relations that will partition every flow of time in \mathcal{T} , playing the role of $<$, $>$ and $=$ in the linear case.

DEFINITION 17. Let $\varphi_i(x, y)$, $i = 1, \dots, n$ be n given formulas in the monadic language with $<$ and let \mathcal{T} be a class of flows of time. Suppose $\varphi_i(x, y)$ partition \mathcal{T} , that is, for every t in each $(T, <)$ in \mathcal{T} the sets $T(i, t) = \{s \in T \mid \varphi_i(s, t)\}$ for $i = 1, \dots, n$ are mutually exclusive and $\bigcup_i T(i, t) = T$.

In analogy to the way that F and P represented $<$ and $>$, we assume that for each i there is a formula $\beta_i(t, x)$ such that $\varphi_i(t, x)$ and $\beta_i(t, x)$ are equivalent over \mathcal{T} and β_i is a Boolean combination of some $\varphi_j(x, t)$. Also assume that $<$ and $=$ can be expressed (over \mathcal{T}) as Boolean combinations of the φ_i .

Then we have the following series of definitions:

- For any t from any $(T, <)$ in \mathcal{T} , for any $i = 1, \dots, n$, we say that truth functions h and h' agree on $T(i, t)$ if and only if $h(q)(s) = h'(q)(s)$ for all s in $T(i, t)$ and all atoms q .
- We say that a formula A is *pure* φ_i over \mathcal{T} if for any $(T, <)$ in \mathcal{T} , any $t \in T$ and any two truth functions h and h' which agree on $T(i, t)$, we have

$$(T, <, h), t \models A \text{ iff } (T, <, h'), t \models A.$$

- The logic \mathbf{L} has the *generalized separation property* over \mathcal{T} iff every formula A of \mathbf{L} is equivalent over \mathcal{T} to a Boolean combination of pure formula.

THEOREM 18 (generalized separation theorem). *Suppose the language \mathbf{L} can express over \mathcal{T} the 1-place connectives $\#_i$, $i = 1, \dots, n$, defined by:*

$$(T, <, h), t \models \#_i(p) \quad \text{iff} \quad \exists s \quad \varphi_i(s, t) \text{ holds in } (T, <) \\ \text{and } (T, <, h), s \models p.$$

If has the generalized separation property over a class \mathcal{T} of flows of time then \mathbf{L} is expressively complete over \mathcal{T} .

A proof of this result appears in [Amir, 1985]. See also [Gabbay *et al.*, 1994].

The converse does not always hold in the general case, for it depends on the theory of the underlying class \mathcal{T} .

A simple application of the generalised separation theorem is the following. Suppose we have a first order language with the binary order predicates $<$, $>$, $=$ with their usual interpretation, and suppose it also contains a *parallel* operator $|$ defined by:

$$x|y =_{def} \neg[(x = y) \vee (x < y) \vee (y < x)].$$

Suppose we have a new temporal connective D , defined by

$$(T, <, h), t \models Dq \text{ iff } \exists x|t \text{ such that } (T, <, h), x \models q.$$

Finally, A is said to be *pure parallel* over a class \mathcal{T} of flows of time iff for all t from any $(T, <)$ from \mathcal{T} , for all $h =|_t h'$,

$$(T, <, h), t \models A \text{ iff } (T, <, h'), t \models A,$$

where $h =_{|t} h'$ iff $\forall x|t\forall q(x \in h(q) \leftrightarrow x \in h'(q))$.

It is clear what separation means in the context of pure present, past, future, and parallel. It is simple to check that the $<, >, =, |$ satisfy the general separation property and other preconditions for using the generalized separation theorem. Thus that theorem gives immediately the following.

COROLLARY 19. *Let \mathbf{L} be a language with F, P, D over any class of flows of time. If \mathbf{L} has a separation then \mathbf{L} is expressively complete.*

3.2 Expressive Completeness of Since and Until over Integer Time

As an example of the applications of separation to the expressive completeness of temporal language, we are going to sketch the proof of separation of the Since and Until-temporal logic containing over linear time. The full proof can be found in [Gabbay, 1989; Gabbay *et al.*, 1994]. With separation and Theorem 16 we immediately obtain that the connectives S and U are expressively complete over the integers; the original proof of the expressive completeness of S and U over the integers is due to Kamp [Kamp, 1968b].

The basic idea of the separation process is to start with a formula in which S and U may be nested inside each other and through several transformation steps we are going to systematically remove U from inside S and vice-versa. This gives us a syntactical separation which, obviously, implies separation.

As we shall see there are eight cases of nested occurrences of U within an S to worry about. It should be noted that all the results in the rest of this section have dual results for the *mirror images* of the formulas. The *mirror image* of a formula is the formula obtained by interchanging U and S ; for example, the mirror image of $U(p \wedge S(q, r), u)$ is $S(p \wedge U(q, r), u)$.

We start dealing with Boolean connectives inside the scope of temporal operators, with some equivalences over integer flows of time. We say that a formula A is *valid* over a flow of time $(T, <)$ if it is true at all $t \in T$; notation: $(T, <) \models A$

LEMMA 20. *The following formulas (and their mirror images) are valid over integer time:*

- $U(A \vee B, C) \leftrightarrow U(A, C) \vee U(B, C);$
- $U(A, B \wedge C) \leftrightarrow U(A, B) \wedge U(A, C);$
- $\neg U(A, B) \leftrightarrow G(\neg A) \vee U(\neg A \wedge \neg B, \neg A);$
- $\neg U(A, B) \leftrightarrow G(\neg A) \vee U(\neg A \wedge \neg B, B \wedge \neg A).$

Proof. Simply apply the semantical definitions. ■

We now show the eight separation cases involving simple nesting and atomic formulas only.

LEMMA 21. *Let p, q, A , and B be atoms. Then each of the formulas below is equivalent, over integer time, to another formula in which the only appearances of the until connective are as the formula $U(A, B)$ and no appearance of that formula is in the scope of an S :*

1. $S(p \wedge U(A, B), q)$,
2. $S(p \wedge \neg U(A, B), q)$,
3. $S(p, q \vee U(A, B))$,
4. $S(p, q \vee \neg U(A, B))$,
5. $S(p \wedge U(A, B), q \vee U(A, B))$,
6. $S(p \wedge \neg U(A, B), q \vee U(A, B))$,
7. $S(p \wedge U(A, B), q \vee \neg U(A, B))$, and
8. $S(p \wedge \neg U(A, B), q \vee \neg U(A, B))$.

Proof. We prove the first case only; omitting the others. Note that $S(p \wedge U(A, B), q)$ is equivalent to

$$\begin{aligned} & S(p, q) \wedge S(p, B) \wedge B \wedge U(A, B) \\ \vee & [A \wedge S(p, B) \wedge S(p, q)] \\ \vee & S(A \wedge q \wedge S(p, B) \wedge S(p, q), q). \end{aligned}$$

Indeed, the original formula holds at t iff there is $s < t$ and $u > s$ such that p holds at s , A at u , B everywhere between s and u , and q everywhere between s and t . The three disjuncts correspond to the cases $u > t, u = t$, and $u < t$ respectively. Note that we make essential use of the linearity of time. ■

We now know the basic steps in our proof of separation. We simply keep pulling out U s from under the scopes of S s and vice versa until there are no more. Given a formula A , this process will eventually leave us with a *syntactically separated* formula, i.e. a formula B which is a Boolean combination of atoms, formulas $U(E, F)$ with E and F built without using S and formulas $S(E, F)$ with E and F built without using U . Clearly, such a B is separated.

We start dealing with more than one U inside an S . In this context, we call a formula in which U and S do not appear *pure*.

LEMMA 22. *Suppose that A and B are pure formulas and that C and D are such that any appearance of U is as $U(A, B)$ and is not nested under any S s. Then $S(C, D)$ is equivalent to a syntactically separated formula in which U only appears as the formula $U(A, B)$.*

Proof. If $U(A, B)$ does not appear then we are done. Otherwise, by rearrangement of C and D into disjunctive and conjunctive normal form, respectively, and repeated use of Lemma 20 we can rewrite $S(C, D)$ equivalently as a Boolean combination of formulas $S(C_i, D_i)$ with no U appearing. Then the preceding lemma shows that each such Boolean constituent is equivalent to a Boolean combination of separated formulas. Thus we have a separated equivalent. ■

Next let us begin the inductive process of removing U s from more than one S . We present the separation in a crescendo. Each step introduces extra complexity in the formula being separated and uses the previous case as a starting point.

LEMMA 23. *Suppose that A, B , possibly subscripted, are pure formulas. Suppose C, D , possibly subscripted, contain no S . Then E has a syntactically separated equivalent if:*

- *the only appearance of U in E is as $U(A, B)$;*
- *the only appearances of U in E are as $U(A_i, B_i)$;*
- *the only appearances of U in E are as $U(C_i, D_i)$;*
- *E is any U, S formula.*

We omit the proof, referring to [Gabbay *et al.*, 1994, Chapter 10] for a detailed account. But note that since each case above uses the previous one as an induction basis, this process of separation tends to be highly exponential. Indeed, the separated version of a formula can be many times larger than the initial one. We finally have the main results.

THEOREM 24 (separation theorem). *Over the integer flow of time, any formula in the $\{U, S\}$ -language is equivalent to a separated formula.*

Proof. This follows directly from the preceding lemma because, as we have already noted, syntactic separation implies separation. ■

THEOREM 25. *The language $\{U, S\}$ is expressively complete over integer time.*

Proof. This follows from the separation theorem and Theorem 16. ■

Other known separation and expressive completeness results over linear time are [Gabbay *et al.*, 1994]:

- The language $\{U, S\}$ is separable over real time. Indeed, it is separable over any Dedekind complete linear flow of time. As a consequence, it is also expressively complete over such flows.
- The language $\{U, S\}$ is *not* separable over the rationals; as a result, it is not separable over the class of linear flows of time, nor is it expressively complete over such flows.

The problem of $\{U, S\}$ over generic linear flows of time is that they may contain *gaps*. It is possible to define a first order formula that makes a proposition true up until a gap and false afterwards. Such formula, however, cannot be expressed in terms of $\{U, S\}$. So is there an extra set of connectives that is expressively complete over the rationals? The answer in this case is yes, and they are called the Stavi connectives. These are connectives whose truth value depends on the existence of gaps in the flow of time, and therefore are always false over integers or reals. For a detailed discussion on separation in the presence of gaps, please refer to [Gabbay *et al.*, 1994, Chapters 11 and 12].

We remain with the following generic question: given a flow of time, can we find a set of connectives that is expressively complete over it? This is the question that we investigate next.

3.3 *H-dimension*

The notion of *Henkin-* or H-dimension involves limiting the number of bound variables employed in first-order formulas. We will see that a *necessary* condition for there to exist a finite set of connectives which is expressively complete over a flow of time is that such flow of time have a finite H-dimension.

As for a *sufficient* condition for a finite expressively complete set of connectives, we will see that if *many-dimensional connectives* are allowed, than finite H-dimension implies the existence of such finite set of connectives. However, when we consider *one-dimensional connectives* such as Since and Until, finite H-dimension is no longer a sufficient condition.

In fact our approach in this discussion will be based on a *weak many-dimensional logic*. It is *many dimensional* because the truth value of a formula is evaluated at more than one time-point. It is *weak* because atomic formulas are evaluated only at a single time point (called the *evaluation point*), while all the other points are the *reference points*). Such weak many dimensionality allows us to define the truth table of many dimensional systems as formulas in the monadic first-order language, as opposed to a full m -dimensional system (in which atoms are evaluated at m time points) which would require an m -adic language.

An *m -dimensional table for an n -place connective* is a formula of the form $\chi(x_1, \dots, x_m; R_1, \dots, R_n)$, where χ is a formula of the first-order predicate

language, written with symbols from $\{<\} \cup \{R_1, \dots, R_n\}$, where R_1, \dots, R_n are special m -place relation symbols. Without loss of expressivity, we will further assume that each term y_j occurring in $R_i(y_1, \dots, y_m)$ is always a variable.

Fix a temporal system \mathcal{T} whose language contains atoms q_1, q_2, \dots , the classical connectives, and the special symbols $\#_1, \dots, \#_j$, standing for n_1, \dots, n_j -place connectives respectively. Let χ_1, \dots, χ_j be their m -dimensional n_1, \dots, n_j -place tables respectively.

REMARK 26. Since there are finitely many χ_i to consider, we can further assume that there is $b \geq m$ such that each χ_i is written with variables x_1, \dots, x_b only.

The semantics of m -dimensional formulas is given by:

DEFINITION 27. Let $(T, <)$ be a flow of time. Let h be an assignment into T , i.e. for any atom q , $h(q) \subseteq T$. We define the truth value of each formula A of the language of \mathcal{T} at m indices $a_1, \dots, a_{m-1}, t \in T$ under h , as follows:

1. $(T, <, h), a_1, \dots, a_{m-1}, t \models q$ iff $t \in h(q)$, q atomic.
2. $(T, <, h), a_1, \dots, a_{m-1}, t \models A \wedge B$ iff $(T, <, h), a_1, \dots, a_{m-1}, t \models A$ and $(T, <, h), a_1, \dots, a_{m-1}, t \models B$.
3. $(T, <, h), a_1, \dots, a_{m-1}, t \models \neg A$ iff $(T, <, h), a_1, \dots, a_{m-1}, t \not\models A$.
4. For each i ($1 \leq i \leq j$), $(T, <, h), a_1, \dots, a_{m-1}, t \models \#_i(A_1, \dots, A_{n_i})$ iff $T \models \chi_i(a_1, \dots, a_{m-1}, t, h(A_1), \dots, h(A_{n_i}))$, where

$$h(A_k) =_{\text{def.}} \{(t_1, \dots, t_m) \in T^m \mid (T, <, h), t_1, \dots, t_m \models A_k\}.$$

Let L^M denote the monadic language with $<$, first-order quantifiers over elements, and an arbitrary number of monadic predicate symbols Q_i for subsets of T . We will regard the Q_i as predicate (subset) variables, implicitly associated with the atoms q_i . We define the translation of an m -dimensional temporal formula A into a monadic formula δA :

1. If A is an atom q_i , we set $\delta A = (x_1 = x_1) \wedge \dots \wedge (x_{m-1} = x_{m-1}) \wedge Q_i(x_m)$.
2. $\delta(A \wedge B) = \delta A \wedge \delta B$, and $\delta(\neg A) = \neg \delta A$.
3. Let $A = \#_i(A_1, \dots, A_{n_i})$, where $\chi_i(x_1, \dots, x_m; R_1, \dots, R_{n_i})$ is the table of $\#_i$. Since we can always rewrite χ such that all occurrences of $R_k(y_1, \dots, y_m)$ in χ are such that the terms y_i are variables, after a

suitable variable replacement we can write δA using only the variables x_1, \dots, x_b as:

$$\delta A = \chi_i(x_1, \dots, x_m, \delta A_1, \dots, \delta A_{n_i}).$$

Clearly, a simple induction gives us that:

$$(T, <, h), a_1, \dots, a_m \models B \text{ iff } T \models \delta B(a_1, \dots, a_m, h(q_1), \dots, h(q_k)).$$

such that $\delta B(a_1, \dots, a_m, h(q_1), \dots, h(q_k))$ uses only the variables x_1, \dots, x_b .

Suppose that \mathcal{K} is a class of flows of time, $\bar{x} = x_1, \dots, x_m$ are variables, and $\bar{Q} = Q_1, \dots, Q_r$ are monadic predicates. If $\alpha(\bar{x}, \bar{Q}), \beta(\bar{x}, \bar{Q})$ are formulas in L^M with free variables \bar{x} and free monadic predicates \bar{Q} , we say that α and β are \mathcal{K} -equivalent if for all $T \in \mathcal{K}$ and all subsets $S_1, \dots, S_r \subseteq T$,

$$T \models \forall \bar{x} \left(\alpha(\bar{x}, S_1, \dots, S_r) \leftrightarrow \beta(\bar{x}, S_1, \dots, S_r) \right).$$

We say the temporal system \mathcal{T} is *expressively complete over \mathcal{K} in n dimensions* ($1 \leq n \leq m$) if for any $\alpha(x_1, \dots, x_n, \bar{Q})$ of L^M with free variables x_1, \dots, x_n , there exists a temporal formula $B(\bar{q})$ of \mathcal{T} built up from the atoms $\bar{q} = q_1, \dots, q_r$, such that $\alpha \wedge \bigwedge_{n < i \leq m} x_i = x_i$ and δB are equivalent in \mathcal{K} . In this case, \mathcal{K} is said to be *m -functionally complete in n dimensions* (symbolically, FC_n^m); \mathcal{K} is *functionally complete* if it is FC_1^m for some m .

Finally, we define the *Henkin or H-dimension d* of a class \mathcal{K} of flows as the smallest d such that:

- For any monadic formula $\alpha(x_1, \dots, x_n, Q_1, \dots, Q_r)$ in L^M with free variables among x_1, \dots, x_n and monadic predicates Q_1, \dots, Q_r (with n, r arbitrary), there exists an L^M -formula $\alpha'(x_1, \dots, x_n, Q_1, \dots, Q_r)$ that is \mathcal{K} -equivalent to α and uses no more than d different bound variable letters.

We now show that for any class of flows, finite Henkin dimension is equivalent to functional completeness (FC_1^m for some m).

THEOREM 28. *For any class \mathcal{K} of flows of time, if \mathcal{K} is functionally complete then \mathcal{K} has finite H-dimension.*

Proof. Let $\sigma(\bar{Q})$ be any sentence of L^M . By functional completeness, there exists a $B(\bar{q})$ of \mathcal{T} such that the formulas $x_1 = x_1 \wedge \dots \wedge x_m = x_m \wedge \sigma(\bar{Q})$ and $\delta B(x_1, \dots, x_m, \bar{Q})$ are \mathcal{K} -equivalent. We know that δB is written using variables x_1, \dots, x_b only. Hence the sentence $\sigma^* = \exists x_1 \dots \exists x_m \delta B(x_1, \dots, x_m, \bar{Q})$ has at most b variables, and is clearly \mathcal{K} -equivalent to σ . So every sentence of L^M is \mathcal{K} -equivalent to one with at most b variables. This means that \mathcal{K} has H-dimension at most b , so it is finite. \blacksquare

We now show the converse. That is, we assume that the class \mathcal{K} of flows of time has finite H-dimension m . Then we are going to construct a temporal logic that is expressively complete over \mathcal{K} and that is weakly $m+1$ -dimensional (and that is why such proof does not work for 1-dimensional systems: it always constructs a logic of dimension at least 2).

Let us call this logic system \mathbf{d} . Besides atomic propositions q_1, q_2, \dots and the usual Boolean operators, this system has a set of constants (0-place operators) $C_{i,j}^<$ and $C_{i,j}^=$ and unary temporal connectives Π_i and \Box_i , for $0 \leq i, j \leq m$. If h is an assignment such that $(h(q) \subseteq T$ for atomic q , the semantics of \mathbf{d} -formulas is given by:

1. $(T, <, h), x_0, \dots, x_m \models q$ iff $x_0 \in h(q)$ for q atomic.
2. The tables for \neg, \wedge are the usual ones.
3. $(T, <, h), x_0, \dots, x_m \models C_{i,j}^<$ iff $x_i < x_j$. Similarly we define the semantics of $C_{i,j}^=$. $C_{i,j}^=$ are thus called *diagonal constants*.
4. $(T, <, h), x_0, \dots, x_m \models \Pi_i A$ iff $(T, <, h), x_i, \dots, x_i \models A$. So Π_i “projects” the truth value on the i -th dimension.
5. $(T, <, h), x_0, \dots, x_m \models \Box_i A$ iff $(T, <, h), x_0, \dots, x_{i-1}, y, x_{i+1}, \dots, x_m \models A$ for all $y \in T$. So \Box_i is an “always” operator for the i -th dimension.

LEMMA 29. *Let β be a formula of L^M written only using the variable letters u_0, \dots, u_m , and having u_{i_1}, \dots, u_{i_k} free for arbitrary $k \leq m$. Then there exists a temporal formula A of \mathbf{d} such that for all $h, t_0, \dots, t_m \in T$,*

$$(T, <, h), t_0, \dots, t_m \models A \text{ iff } \mathcal{K}, h \models \beta(t_{i_1}, \dots, t_{i_k}).$$

Proof. By induction on β . Assume first that β is atomic. If β is $u_i < u_j$ let $A = C_{i,j}^<$ if $i \neq j$, and \perp otherwise. Similarly for $u_i = u_j$. If β is $Q(u_i)$, let A be $\Pi_i(q)$.

The classical connectives present no difficulties. We turn to the case where β is $\forall u_i \alpha(u_{i_1}, \dots, u_{i_k})$. By induction hypothesis, let A be the formula corresponding α ; then $\Box_i A$ is the formula suitable for β . ■

We are now in a position to prove the converse of Theorem 28.

THEOREM 30. *For any class \mathcal{K} of flows of time, if \mathcal{K} has finite H-dimension then \mathcal{K} is functionally complete.*

Proof. Let $\beta(u_0)$ be any formula of L^M with one free variable u_0 . As \mathcal{K} has H-dimension m , we can suppose that β is written with variables u_0, \dots, u_m . By Lemma 29 there exists an A of \mathcal{T} such that for any $T \in \mathcal{K}$, $t \in T$, and assignment h into T , $(T, <, h), t, \dots, t \models A$ iff $\mathcal{K}, h \models \beta(t)$. ■

As an application of the results above, we show that the class of partial orders is not functionally complete. For consider the formula corresponding to the statement *there are at least n elements in the order*:

$$\sigma_n = \exists x_1, \dots, x_n \bigwedge_{i \neq j} [(x_i \neq x_j) \wedge \neg(x_i < x_j)].$$

It can be shown that such formula cannot be written with less than n variables (e.g. [Gabbay *et al.*, 1994]). Since we are able to say that there are at least n elements in the order for any finite n , the class partial orders have infinite H-dimension and by Theorem 28 it is not functionally complete.

On the other hand, the reals and the integers must have finite H-dimension, for the $\{U, S\}$ temporal logic is expressively complete over both. Indeed, [Gabbay *et al.*, 1994] shows that it has H-dimension at most 3, and so does the theory of linear order.

4 COMBINING TEMPORAL LOGICS

There is a profusion of logics proposed in the literature for the modelling of a variety of phenomena, and many more will surely be proposed in the future. A great part of those logics deal only with “static” aspects, and the temporal evolution is left out. But eventually, the need to deal with the temporal evolution of a model appears. What we want to avoid is the so called *reinvention of the wheel*, that is, reworking from scratch the whole logic, its language, inference system and models, and reproving all its basic properties, when the temporal dimension is added.

We therefore show here several methods for combining logic systems and we study if the properties of the component systems are *transferred* to their combination. We understand a logic system \mathcal{L}_L as composed of three elements:

- (a) a language \mathcal{L}_L , normally given by a set of formation rules generating well formed formulas over a signature and a set of logical connectives.
- (b) An inference system, i.e. a relation, \vdash_L , between sets of formulas, represented by $\Delta \vdash_L A$. As usual, $\vdash_L A$ indicates that $\emptyset \vdash_L A$.
- (c) The semantics of formulas over a class \mathcal{K} of model structures. The fact that a formulas A is true of or holds at a model $\mathcal{M} \in \mathcal{K}$ is indicated by $\mathcal{M} \models A$.

Each method for combining logic systems proposes a way of generating the language, inference system and model structures from those of the component system.

The first method presented here adds a temporal dimension \mathbb{T} to a logic system L , called the *temporalisation* of a logic system $\mathbb{T}(L)$, with an automatic way of constructing:

- the language of $\mathbb{T}(\mathbb{L})$;
- the inference system of $\mathbb{T}(\mathbb{L})$; and
- the class of temporal models of $\mathbb{T}(\mathbb{L})$.

We do that in a way that the basic properties of soundness, completeness and decidability are *transferred* from the component logics \mathbb{T} and \mathbb{L} to the combined system $\mathbb{T}(\mathbb{L})$.

If the temporalised logic is itself a temporal logic, we have a two dimensional temporal logic $\mathbb{T}(\mathbb{T}')$. Such a logic is too weak, however, because, by construction, the temporal logic \mathbb{T}' cannot refer to the the logic system \mathbb{T} . We therefore present the *independent combination* $\mathbb{T} \oplus \mathbb{T}'$ in which two temporal logics are symmetrically combined. As before, the language, inference systems and models of $\mathbb{T} \oplus \mathbb{T}'$, and show that the properties of soundness, completeness and decidability are transferred form \mathbb{T} and \mathbb{T}' to $\mathbb{T} \oplus \mathbb{T}'$.

The independent combination is not the strongest way to combine logics; in particular, the independent combination of two linear temporal logic does not necessarily produce a two-dimensional grid model. So we show how to produce the *full join* of two linear temporal logics $\mathbb{T} \times \mathbb{T}'$, such that all models will be two-dimensional grids. However, in this case we cannot guarantee that the basic properties of \mathbb{T} and \mathbb{T}' are transferred to $\mathbb{T} \times \mathbb{T}'$. In this sense, the independent combination $\mathbb{T} \oplus \mathbb{T}'$ is a *minimal symmetrical combination* of logics that automatically transfers the basic properties. Any further interaction between the logics has to be separately investigated.

As a final way of combining logics, we present methods of combination that are motivated by the study of Labelled Deductive Systems (LDS) [Gabbay, 1996].

All temporal logics considered for combination here are assumed to be linear.

4.1 Temporalising a Logic

The first of the combination methods, known as “adding a temporal dimension to a logic system” or simply “temporalising a logic system”, has been initially presented in [Finger and Gabbay, 1992].

Temporalisation is a methodology whereby an arbitrary logic system \mathbb{L} can be enriched with temporal features from a linear temporal logic \mathbb{T} to create a new, *temporalised* system $\mathbb{T}(\mathbb{L})$.

We assume that the language of temporal system \mathbb{T} is the *US* language and its inference system is an extensions of that of *US*/ \mathcal{K}_{lin} , with its corresponding class of temporal linear models $\mathcal{K} \subseteq \mathcal{K}_{lin}$.

With respect to the logic \mathbb{L} we assume it is an extension of classical logic, that is, all propositional tautologies are valid in it. The set $\mathcal{L}_{\mathbb{L}}$ is partitioned in two sets, $BC_{\mathbb{L}}$ and $ML_{\mathbb{L}}$. A formula $A \in \mathcal{L}_{\mathbb{L}}$ belongs to the set of *Boolean*

combinations, BC_L , iff it is built up from other formulas by the use of one of the Boolean connectives \neg or \wedge or any other connective defined only in terms of those; it belongs to the set of *monolithic formula* ML_L otherwise.

If L is not an extension of classical logic, we can simply “encapsulate” it in L' with a one-place symbol $\#$ not occurring in either L or T , such that for each formula $A \in \mathcal{L}_L$, $\#A \in \mathcal{L}_{L'}$, $\vdash_L A$ iff $\vdash_{L'} \#A$ and the model structures of $\#A$ are those of A . Note that $ML_{L'} = \mathcal{L}_{L'}$, $BC_{L'} = \emptyset$.

The alphabet of the temporalised language uses the alphabet of L plus the two-place operators S and U , if they are not part of the alphabet of L ; otherwise, we use \bar{S} and \bar{U} or any other proper renaming.

DEFINITION 31. Temporalised formulas The set $\mathcal{L}_{T(L)}$ of formulas of the logic system L is the smallest set such that:

1. If $A \in ML_L$, then $A \in \mathcal{L}_{T(L)}$;
2. If $A, B \in \mathcal{L}_{T(L)}$ then $\neg A \in \mathcal{L}_{T(L)}$ and $(A \wedge B) \in \mathcal{L}_{T(L)}$;
3. If $A, B \in \mathcal{L}_{T(L)}$ then $S(A, B) \in \mathcal{L}_{T(L)}$ and $U(A, B) \in \mathcal{L}_{T(L)}$.

Note that, for instance, if \Box is an operator of the alphabet of L and A and B are two formulas in \mathcal{L}_L , the formula $\Box U(A, B)$ is *not* in $\mathcal{L}_{T(L)}$. The language of $T(L)$ is independent of the underlying flow of time, but not its semantics and inference system, so we must fix a class \mathcal{K} of flows of time over which the temporalisation is defined; if \mathcal{M}_L is a model in the class of models of L , \mathcal{K}_L , for every formula $A \in \mathcal{L}_L$ we must have either $\mathcal{M}_L \models A$ or $\mathcal{M}_L \models \neg A$. In the case that L is a temporal logic we must consider a “current time” o as part of its model to achieve that condition.

DEFINITION 32. *Semantics of the temporalised logic.*¹ Let $(T, <) \in \mathcal{K}$ be a flow of time and let $g : T \rightarrow \mathcal{K}_L$ be a function mapping every time point in T to a model in the class of models of L . A model of $T(L)$ is a triple $\mathcal{M}_{T(L)} = (T, <, g)$ and the fact that A is true in $\mathcal{M}_{T(L)}$ at time t is written as $\mathcal{M}_{T(L)}, t \models A$ and defined as:

$$\begin{aligned} \mathcal{M}_{T(L)}, t \models A, A \in ML_L & \text{ iff } g(t) = \mathcal{M}_L \text{ and } \mathcal{M}_L \models A. \\ \mathcal{M}_{T(L)}, t \models \neg A & \text{ iff it is not the case that } \mathcal{M}_{T(L)}, t \models A. \\ \mathcal{M}_{T(L)}, t \models (A \wedge B) & \text{ iff } \mathcal{M}_{T(L)}, t \models A \text{ and } \mathcal{M}_{T(L)}, t \models B. \\ \mathcal{M}_{T(L)}, t \models S(A, B) & \text{ iff there exists } s \in T \text{ such that } s < t \text{ and} \\ & \mathcal{M}_{T(L)}, s \models A \text{ and for every } u \in T, \text{ if} \\ & s < u < t \text{ then } \mathcal{M}_{T(L)}, u \models B. \end{aligned}$$

¹We assume that the a model of T is given by $(T, <, h)$ where h maps time points into sets of propositions (instead of the more common, but equivalent, mapping of propositions into sets of time points); such notation highlights that in the temporalised model each time point is associated to a model of L .

$\mathcal{M}_{\mathbb{T}(\mathbb{L})}, t \models U(A, B)$ iff there exists $s \in T$ such that $t < s$ and
 $\mathcal{M}_{\mathbb{T}(\mathbb{L})}, s \models A$ and for every $u \in T$, if
 $t < u < s$ then $\mathcal{M}_{\mathbb{T}(\mathbb{L})}, u \models B$.

The inference system of $\mathbb{T}(\mathbb{L})/\mathcal{K}$ is given by the following:

DEFINITION 33. Axiomatisation for $\mathbb{T}(\mathbb{L})$ An axiomatisation for the temporalised logic $\mathbb{T}(\mathbb{L})$ is composed of:

- The axioms of \mathbb{T}/\mathcal{K} ;
- The inference rules of \mathbb{T}/\mathcal{K} ;
- For every formula A in $\mathcal{L}_{\mathbb{L}}$, if $\vdash_{\mathbb{L}} A$ then $\vdash_{\mathbb{T}(\mathbb{L})} A$, i.e. all theorems of \mathbb{L} are theorems of $\mathbb{T}(\mathbb{L})$. This inference rule is called **Persist**.

EXAMPLE 34. Consider classical propositional logic $\mathbb{PL} = \langle \mathcal{L}_{\mathbb{PL}}, \vdash_{\mathbb{PL}}, \models_{\mathbb{PL}} \rangle$. Its temporalisation generates the logic system $\mathbb{T}(\mathbb{PL}) = \langle \mathcal{L}_{\mathbb{T}(\mathbb{PL})}, \vdash_{\mathbb{T}(\mathbb{PL})}, \models_{\mathbb{T}(\mathbb{PL})} \rangle$. It is not difficult to see that the temporalised version of \mathbb{PL} over any \mathcal{K} is actually the temporal logic $\mathbb{T} = \mathbb{US}/\mathcal{K}$.

If we temporalise over \mathcal{K} the one-dimensional logic system \mathbb{US}/\mathcal{K} we obtain the two-dimensional logic system $\mathbb{T}(\mathbb{US}) = \langle \mathcal{L}_{\mathbb{T}(\mathbb{US})}, \vdash_{\mathbb{T}(\mathbb{US})}, \models_{\mathbb{T}(\mathbb{US})} \rangle = \mathbb{T}^2(\mathbb{PL})/\mathcal{K}$. In this case we have to rename the two-place operators S and U of the temporalised alphabet to, say, \bar{S} and \bar{U} . Note, however, how weak this logic is, for \bar{S} and \bar{U} cannot occur within the scope of U and S .

In order to obtain a model for $\mathbb{T}(\mathbb{US})$, we must fix a “current time”, o_1 , in $\mathcal{M}_{\mathbb{US}} = (T_1, <_1, g_1)$, so that we can construct the model $\mathcal{M}_{\mathbb{T}(\mathbb{US})} = (T_2, <_2, g_2)$ as previously described. Note that, in this case, the flows of time $(T_1, <_1)$ and $(T_2, <_2)$ need not to be the same. $(T_2, <_2)$ is the flow of time of the upper-level temporal system whereas $(T_1, <_1)$ is the flow of time of the underlying logic which, in this case, happens to be a temporal logic. The satisfiability of a formula in a model of $\mathbb{T}(\mathbb{US})$ needs two evaluation points, o_1 and o_2 ; therefore it is a *two-dimensional temporal logic*.

The logic system we obtain by temporalising US -temporal logic is the two-dimensional temporal logic described in [Finger, 1992].

This temporalisation process can be repeated n times, generating an n dimensional temporal logic with connectives U_i, S_i , $1 \leq i \leq n$, such that for $i < j$ U_j, S_j cannot occur within the scope of U_i, S_i .

We analyse now the transfer of soundness, completeness and decidability from \mathbb{T} and \mathbb{L} to $\mathbb{T}(\mathbb{L})$; that is, we are assuming the logics \mathbb{T} and \mathbb{L} have sound, complete and decidable axiomatisations with respect to their semantics, and we will analyse how such properties transfer to the combined system $\mathbb{T}(\mathbb{L})$. It is a routine task to analyse that if the inference systems of \mathbb{T} and \mathbb{L} are sound, so is $\mathbb{T}(\mathbb{L})$. So we concentrate on the proof of transference of completeness.

Completeness

We prove the completeness of $\mathbb{T}(\mathbb{L})/\mathcal{K}$ indirectly by transforming a consistent formula A of $\mathbb{T}(\mathbb{L})$ into $\varepsilon(A)$ and then mapping it into a consistent formula of \mathbb{T} . Completeness of \mathbb{T}/\mathcal{K} is used to find a \mathbb{T} -model for A^* that is used to construct a model for the original $\mathbb{T}(\mathbb{L})$ formula A .

We first define the transformation and mapping. Given a formula $A \in \mathcal{L}_{\mathbb{T}(\mathbb{L})}$, consider the following sets:

$$\begin{aligned} Lit(A) &= Mon(A) \cup \{\neg B \mid B \in Mon(A)\} \\ Inc(A) &= \{\bigwedge \Gamma \mid \Gamma \subseteq Lit(A) \text{ and } \Gamma \vdash_{\mathbb{L}} \perp\} \end{aligned}$$

where $Mon(A)$ is the set of maximal monolithic subformulae of A . $Lit(A)$ is the set of literals occurring in A and $Inc(A)$ is the set of inconsistent formulas that can be built with those. We transform A into A as: $\varepsilon(A)$:

$$\varepsilon(A) = A \wedge \bigwedge_{B \in Inc(A)} (\neg B \wedge G\neg B \wedge H\neg B)$$

The big conjunction $in\varepsilon(A)$ is a theorem of $\mathbb{T}(\mathbb{L})$, so we have the following lemma.

LEMMA 35. $\vdash_{\mathbb{T}(\mathbb{L})} \varepsilon(A) \leftrightarrow A$

If \mathbb{K} is a subclass of linear flows of time, we also have the following property (this is where linearity is used in the proof).

LEMMA 36. *Let $\mathcal{M}_{\mathbb{T}}$ be a temporal model over $\mathcal{K} \subseteq \mathcal{K}_{lin}$ such that for some $o \in T$, $\mathcal{M}_{\mathbb{T}}, o \models \sigma(\Box A)$. Then, for every $t \in T$, $\mathcal{M}_{\mathbb{T}}, t \models \sigma(\Box A)$.*

Therefore, if some subset of $Lit(A)$ is inconsistent, the transformed formula $\varepsilon(A)$ puts that fact in evidence so that, when it is mapped into \mathbb{T} , inconsistent subformulae will be mapped into falsity.

Now we want to map a $\mathbb{T}(\mathbb{L})$ -formula into a \mathbb{T} -formula. For that, consider an enumeration p_1, p_2, \dots , of elements of \mathcal{P} and consider an enumeration A_1, A_2, \dots , of formulae in $ML_{\mathbb{L}}$. The *correspondence mapping* $\sigma : \mathcal{L}_{\mathbb{T}(\mathbb{L})} \rightarrow \mathcal{L}_{\mathbb{T}}$ is given by:

$$\begin{aligned} \sigma(A_i) &= p_i \text{ for every } A_i \in ML_{\mathbb{L}}, i = 1, 2, \dots \\ \sigma(\neg A) &= \neg\sigma(A) \\ \sigma(A \wedge B) &= \sigma(A) \wedge \sigma(B) \\ \sigma(S(A, B)) &= S(\sigma(A), \sigma(B)) \\ \sigma(U(A, B)) &= U(\sigma(A), \sigma(B)) \end{aligned}$$

The following is the *correspondence lemma*.

LEMMA 37. *The correspondence mapping is a bijection. Furthermore if A is $\mathbb{T}(\mathbb{L})$ -consistent then $\sigma(A)$ is \mathbb{T} -consistent.*

LEMMA 38. *If A is $\mathsf{T}(\mathsf{L})$ -consistent, then for every $t \in T$, $G_A(t) = \{B \in \mathit{Lit}(A) \mid \mathcal{M}_{\mathsf{T}}, t \models \sigma(B)\}$ is finite and L -consistent.*

Proof. Since $\mathit{Lit}(A)$ is finite, $G_A(t)$ is finite for every t . Suppose $G_A(t)$ is inconsistent for some t , then there exist $\{B_1, \dots, B_n\} \subseteq G_A(t)$ such that $\vdash_{\mathsf{L}} \bigwedge B_i \rightarrow \perp$. So $\bigwedge B_i \in \mathit{Inc}(A)$ and $\Box \neg(\bigwedge B_i)$ is one of the conjuncts of $\varepsilon(A)$. Applying Lemma 36 to $\mathcal{M}_{\mathsf{T}}, o \models \sigma(\varepsilon(A))$ we get that for every $t \in T$, $\mathcal{M}_{\mathsf{T}}, t \models \neg(\bigwedge \sigma(B_i))$ but by, the definition of G_A , $\mathcal{M}_{\mathsf{T}}, t \models \bigwedge \sigma(B_i)$, which is a contradiction. ■

We are finally ready to prove the completeness of $\mathsf{T}(\mathsf{L})/\mathcal{K}$.

THEOREM 39 (Completeness transfer for $\mathsf{T}(\mathsf{L})$). *If the logical system L is complete and T is complete over a subclass of linear flows of time $\mathcal{K} \subseteq \mathcal{K}_{lin}$, then the logical system $\mathsf{T}(\mathsf{L})$ is complete over \mathcal{K} .*

Proof. Assume that A is $\mathsf{T}(\mathsf{L})$ -consistent. By Lemma 38, we have $(T, <) \in \mathcal{K}$ and associated to every time point in T we have a finite and L -consistent set $G_A(t)$. By (weak) completeness of L , every $G_A(t)$ has a model, so we define the temporalised valuation function g :

$$g(t) = \{\mathcal{M}_{\mathsf{L}}^t \mid \mathcal{M}_{\mathsf{L}}^t \text{ is a model of } G_A(t)\}$$

Consider the model $\mathcal{M}_{\mathsf{T}(\mathsf{L})} = (T, <, g)$ over K . By structural induction over B , we show that for every B that is a subformula of A and for every time point t ,

$$\mathcal{M}_{\mathsf{T}}, t \models \sigma(B) \text{ iff } \mathcal{M}_{\mathsf{T}(\mathsf{L})}, t \models B$$

We show only the basic case, $B \in \mathit{Mon}(A)$. Suppose $\mathcal{M}_{\mathsf{T}}, t \models \sigma(B)$; then $B \in G_A(t)$ and $\mathcal{M}_{\mathsf{L}}^t \models B$, and hence $\mathcal{M}_{\mathsf{T}(\mathsf{L})}, t \models B$. Suppose $\mathcal{M}_{\mathsf{T}(\mathsf{L})}, t \models B$ and assume $\mathcal{M}_{\mathsf{T}}, t \models \neg\sigma(B)$; then $\neg B \in G_A(t)$ and $\mathcal{M}_{\mathsf{L}}^t \models \neg B$, which contradicts $\mathcal{M}_{\mathsf{T}(\mathsf{L})}, t \models B$; hence $\mathcal{M}_{\mathsf{T}}, t \models \sigma(B)$. The inductive cases are straightforward and omitted.

So, $\mathcal{M}_{\mathsf{T}(\mathsf{L})}$ is a model for A over K and the proof is finished. ■

Theorem 39 gives us sound and complete axiomatisations for $\mathsf{T}(\mathsf{L})$ over many interesting classes of flows of time, such as the class of all linear flows of time, \mathcal{K}_{lin} , the integers, \mathbb{Z} , and the reals, \mathbb{R} . These classes are, in their T versions, decidable and the corresponding decidability of $\mathsf{T}(\mathsf{L})$ is dealt next.

Note that the construction above is finitistic, and therefore does not itself guarantee that compactness is transferred. However, an important corollary of the construction above is that the temporalised system is a *conservative extension* of both original systems, that is, no new theorem in the language of an original system is provable in the combined system. Formally, L_1 is a *conservative extension* of L_2 if it is an extension of L_2 such that if $A \in \mathcal{L}_{\mathsf{L}_2}$, then $\vdash_{\mathsf{L}_1} A$ only if $\vdash_{\mathsf{L}_2} A$.

COROLLARY 40. *Let L be a sound and complete logic system and T be sound and complete over $\mathcal{K} \subseteq \mathcal{K}_{lin}$. The logic system $\mathsf{T}(\mathsf{L})$ is a conservative extension of both L and T .*

Proof. Let $A \in \mathcal{L}_{\mathsf{L}}$ such that $\vdash_{\mathsf{T}(\mathsf{L})} A$. Suppose by contradiction that $\not\vdash_{\mathsf{L}} A$, so by completeness of L , there exists a model \mathcal{M}_{L} such that $\mathcal{M}_{\mathsf{L}} \models \neg A$. We construct a temporalised model $\mathcal{M}_{\mathsf{T}(\mathsf{L})} = (T, <, g)$ by making $g(t) = \mathcal{M}_{\mathsf{L}}$ for all $t \in T$. $\mathcal{M}_{\mathsf{T}(\mathsf{L})}$ clearly contradicts the soundness of $\mathsf{T}(\mathsf{L})$ and therefore that of T , so $\vdash_{\mathsf{L}} A$. This shows that $\mathsf{T}(\mathsf{L})$ is a conservative extension of L ; the proof of extension of T is similar. ■

Decidability

The transfer of decidability is also done using the correspondence mapping σ and the transformation η . Such a transformation is actually computable, as the following two lemmas state.

LEMMA 41. *For any $A \in \mathcal{L}_{\mathsf{T}(\mathsf{L})}$, if the logic system L is decidable then there exists an algorithm for constructing $\varepsilon(A)$.*

LEMMA 42. *Over a linear flow of time, for every $A \in \mathcal{L}_{\mathsf{T}(\mathsf{L})}$,*

$$\vdash_{\mathsf{T}(\mathsf{L})} A \text{ iff } \vdash_{\mathsf{T}} \sigma(\varepsilon(A)).$$

Decidability is a direct consequence of these two lemmas.

THEOREM 43. *If L is a decidable logic system, and T is decidable over $\mathcal{K} \subseteq \mathcal{K}_{lin}$, then the logic system $\mathsf{T}(\mathsf{L})$ is also decidable over \mathcal{K} .*

Proof. Consider $A \in \mathcal{L}_{\mathsf{T}(\mathsf{L})}$. Since L is decidable, by Lemma 41 there is an algorithmic procedure to build $\varepsilon(A)$. Since σ is a recursive function, we have an algorithm to construct $\sigma(\varepsilon(A))$, and due to the decidability of T over \mathcal{K} , we have an effective procedure to decide if it is a theorem or not. Since \mathcal{K} is linear, by Lemma 42 this is also a procedure for deciding whether A is a theorem or not. ■

4.2 Independent Combination

We now deal with the combination of two temporal logic systems. One of them will be called the *horizontal* temporal logic US , while the other will be the *vertical* temporal logic $\bar{\mathsf{U}}\bar{\mathsf{S}}$. If we temporalise the horizontal logic with the vertical logic, we obtain a very weakly expressive system; if US is the internal (horizontal) temporal logic in the temporalisation process (F is derived in US), and $\bar{\mathsf{U}}\bar{\mathsf{S}}$ is the external (vertical) one (\bar{F} is defined in $\bar{\mathsf{U}}\bar{\mathsf{S}}$), we cannot express that vertical and horizontal future operators commute,

$$F\bar{F}A \leftrightarrow \bar{F}FA.$$

In fact, the subformula $F\bar{F}A$ is not even in the temporalised language of $\bar{U}\bar{S}(US)$, nor is the whole formula. In other words, the interplay between the two-dimensions is not expressible in the language of the temporalised $\bar{U}\bar{S}(US)$.

The idea is then to define a method for combining temporal logics that is symmetrical. As usual, we combine the languages, inference systems and classes of models.

DEFINITION 44. Let $Op(L)$ be the set of non-Boolean operators of a generic logic L . Let \bar{T} and T be logic systems such that $Op(T) \cap Op(\bar{T}) = \emptyset$. The *fully combined language* of logic systems \bar{T} and T over the set of atomic propositions \mathcal{P} , is obtained by the union of the respective set of connectives and the union of the formation rules of the languages of both logic systems.

Let the operators U and S be in the language of US and \bar{U} and \bar{S} be in that of $\bar{U}\bar{S}$. Their fully combined language over a set of atomic propositions \mathcal{P} is given by

- every atomic proposition is in it;
- if A, B are in it, so are $\neg A$ and $A \wedge B$;
- if A, B are in it, so are $U(A, B)$ and $S(A, B)$.
- if A, B are in it, so are $\bar{U}(A, B)$ and $\bar{S}(A, B)$.

Not only are the two languages taken to be independent of each other, but the set of axioms of the two systems are supposed to be disjoint; so we call the following combination method the *independent combination* of two temporal logics.

DEFINITION 45. Let US and $\bar{U}\bar{S}$ be two US -temporal logic systems defined over the same set \mathcal{P} of propositional atoms such that their languages are independent. The *independent combination* $US \oplus \bar{U}\bar{S}$ is given by the following:

- The fully combined language of US and $\bar{U}\bar{S}$.
- If (Σ, \mathcal{I}) is an axiomatisation for US and $(\bar{\Sigma}, \bar{\mathcal{I}})$ is an axiomatisation for $\bar{U}\bar{S}$, then $(\Sigma \cup \bar{\Sigma}, \mathcal{I} \cup \bar{\mathcal{I}})$ is an axiomatisation for $US \oplus \bar{U}\bar{S}$. Note that, apart from the classical tautologies, the set of axioms Σ and $\bar{\Sigma}$ are supposed to be disjoint, but not the inference rules.
- The class of independently combined flows of time is $\mathcal{K} \oplus \bar{\mathcal{K}}$ composed of biordered flows of the form $(\tilde{T}, <, \bar{<})$ where the connected components of $(\tilde{T}, <)$ are in \mathcal{K} and the connected components of $(\tilde{T}, \bar{<})$ are in $\bar{\mathcal{K}}$, and \tilde{T} is the (not necessarily disjoint) union of the sets of time points T and \bar{T} that constitute each connected component.

A model structure for $US \oplus \bar{U}\bar{S}$ over $\mathcal{K} \oplus \bar{\mathcal{K}}$ is a 4-tuple $(\tilde{T}, <, \bar{<}, g)$, where $(\tilde{T}, <, \bar{<}) \in \mathcal{K} \oplus \bar{\mathcal{K}}$ and g is an assignment function $g: \tilde{T} \rightarrow 2^{\mathcal{P}}$.

The semantics of a formula A in a model $\mathcal{M} = (\tilde{T}, <, \bar{<}, g)$ is defined as the union of the rules defining the semantics of US/\mathcal{K} and $\bar{U}\bar{S}/\bar{\mathcal{K}}$. The expression $\mathcal{M}, t \models A$ reads that the formula A is true in the (combined) model \mathcal{M} at the point $t \in \tilde{T}$. The semantics of formulas is given by induction in the standard way:

$$\begin{aligned} \mathcal{M}, t \models p & \quad \text{iff } p \in g(t) \text{ and } p \in \mathcal{P}. \\ \mathcal{M}, t \models \neg A & \quad \text{iff it is not the case that } \mathcal{M}, t \models A. \\ \mathcal{M}, t \models A \wedge B & \quad \text{iff } \mathcal{M}, t \models A \text{ and } \mathcal{M}, t \models B. \\ \mathcal{M}, t \models S(A, B) & \quad \text{iff there exists an } s \in \tilde{T} \text{ with } s < t \text{ and } \mathcal{M}, s \models A \\ & \quad \text{and for every } u \in \tilde{T}, \text{ if } s < u < t \text{ then } \mathcal{M}, u \models B. \\ \mathcal{M}, t \models U(A, B) & \quad \text{iff there exists an } s \in \tilde{T} \text{ with } t < s \text{ and } \mathcal{M}, s \models A \\ & \quad \text{and for every } u \in \tilde{T}, \text{ if } t < u < s \text{ then } \mathcal{M}, u \models B. \\ \mathcal{M}, t \models \bar{S}(A, B) & \quad \text{iff there exists an } s \in \tilde{T} \text{ with } s \bar{<} t \text{ and } \mathcal{M}, s \models A \\ & \quad \text{and for every } u \in \tilde{T}, \text{ if } s \bar{<} u \bar{<} t \text{ then } \mathcal{M}, u \models B. \\ \mathcal{M}, t \models \bar{U}(A, B) & \quad \text{iff there exists an } s \in \tilde{T} \text{ with } t \bar{<} s \text{ and } \mathcal{M}, s \models A \\ & \quad \text{and for every } u \in \tilde{T}, \text{ if } t \bar{<} u \bar{<} s \text{ then } \mathcal{M}, u \models B. \end{aligned}$$

The also independent combination of two logics appears in the literature under the names of *fusion* or *join*.

As usual, we will assume that $\mathcal{K}, \bar{\mathcal{K}} \subseteq \mathcal{K}_{lin}$, so $<$ and $\bar{<}$ are transitive, irreflexive and total orders; similarly, we assume that the axiomatisations are extensions of US/\mathcal{K}_{lin} .

The temporalisation process will be used as an inductive step to prove the transference of soundness, completeness and decidability for $US \oplus \bar{U}\bar{S}$ over $\mathcal{K} \oplus \bar{\mathcal{K}}$. We define the *degree alternation* of a $(US \oplus \bar{U}\bar{S})$ -formula A for US , $dg(A)$:

$$\begin{aligned} dg(p) &= 0 \\ dg(\neg A) &= dg(A) \\ dg(A \wedge B) &= dg(S(A, B)) = dg(U(A, B)) = \max\{dg(A), dg(B)\} \\ dg(\bar{U}(A, B)) &= dg(\bar{S}(A, B)) = 1 + \max\{\bar{dg}(A), \bar{dg}(B)\} \end{aligned}$$

and similarly define $\bar{dg}(A)$ for $\bar{U}\bar{S}$.

Any formula of the fully combined language can be seen as a formula of some finite number of alternating temporalisations of the form

$US(\bar{U}\bar{S}(US(\dots)))$; more precisely, A can be seen as a formula of $US(L_n)$, where $dg(A) = n$, $US(L_0) = US$, $\bar{U}\bar{S}(L_0) = \bar{U}\bar{S}$, and $L_{n-2i} = \bar{U}\bar{S}(L_{n-2i-1})$, $L_{n-2i-1} = US(L_{n-2i-2})$, for $i = 0, 1, \dots, \lceil \frac{n}{2} \rceil - 1$.

Indeed, not only the language of $US \oplus \bar{U}\bar{S}$ is decomposable in a finite number of temporalisation, but also its inferences, as the following important lemma indicates.

LEMMA 46. *Let US and $\bar{U}\bar{S}$ be two complete logic systems. Then, A is a theorem of $US \oplus \bar{U}\bar{S}$ iff it is a theorem of $US(L_n)$, where $dg(A) = n$.*

Proof. If A is a theorem of $US(L_n)$, all the inferences in its deduction can be repeated in $US \oplus \bar{U}\bar{S}$, so it is a theorem of $US \oplus \bar{U}\bar{S}$.

Suppose A is a theorem of $US \oplus \bar{U}\bar{S}$; let $B_1, \dots, B_m = A$ be a deduction of A in $US \oplus \bar{U}\bar{S}$ and let $n' = \max\{dg(B_i)\}$, $n' \geq n$. We claim that each B_i is a theorem of $US(L_{n'})$. In fact, by induction on m , if B_i is obtained in the deduction by substituting into an axiom, the same substitution can be done in $US(L_{n'})$; if B_i is obtained by Temporal Generalisation from B_j , $j < i$, then by the induction hypothesis, B_j is a theorem of $US(L_{n'})$ and so is B_i ; if B_i is obtained by Modus Ponens from B_j and B_k , $j, k < i$, then by the induction hypothesis, B_j and B_k are theorems of $US(L_{n'})$ and so is B_i .

So A is a theorem of $US(L_{n'})$ and, since US and $\bar{U}\bar{S}$ are two complete logic systems, by Theorem 39, each of the alternating temporalisations in $US(L_{n'})$ is a conservative extension of the underlying logic; it follows that A is a theorem of $US(L_n)$, as desired. ■

Note that the proof above gives conservativeness as a corollary. The transference of soundness, completeness and decidability also follows directly from this result.

THEOREM 47 (Independent Combination). *Let US and $\bar{U}\bar{S}$ be two sound and complete logic systems over the classes \mathcal{K} and $\bar{\mathcal{K}}$, respectively. Then their independent combination $US \oplus \bar{U}\bar{S}$ is sound and complete over the class $\mathcal{K} \oplus \bar{\mathcal{K}}$. If US and $\bar{U}\bar{S}$ are complete and decidable, so is $US \oplus \bar{U}\bar{S}$.*

Proof. Soundness follows immediately from the validity of axioms and inference rules.

We only sketch the proof of completeness here. Given a $US \oplus \bar{U}\bar{S}$ -consistent formula A , Lemma 46 is used to see that it is also consistent in $US(L_n)$, so a temporalised $US(L_n)$ -model is built for it. Then, by induction on the degree of alternation of A , this $US(L_n)$ is used to construct a $US \oplus \bar{U}\bar{S}$ -model; each step of such construction preserves the satisfiability of formulas of a limited degree of alternation, so in the final model, A , is satisfiable; and completeness is proved. For details, see [Finger and Gabbay, 1996].

For decidability, suppose we want to decide whether a formula $A \in US \oplus \bar{U}\bar{S}$ is a theorem. By Lemma 46, this is equivalent to deciding whether $A \in US(L_n)$ is a theorem, where $n = dg(A)$. Since US/\mathcal{K} and $\bar{U}\bar{S}/\bar{\mathcal{K}}$ are both

complete and decidable, by successive applications of Theorems 39 and 43, it follows that the following logics are decidable: $US(\bar{U}\bar{S})$, $\bar{U}\bar{S}(US(\bar{U}\bar{S})) = \bar{U}\bar{S}(L_2)$, \dots , $\bar{U}\bar{S}(L_{n-1}) = L_n$; so a the last application of Theorems 39 and 43 yields that $US(L_n)$ is decidable. \blacksquare

The minimality of the independent combination

The logic $US \oplus \bar{U}\bar{S}$ is the minimal logic that conservatively extends both US and $\bar{U}\bar{S}$. This result was first shown for the independent combination of monomodal logics independently by [Kracht and Wolter, 1991] and [Fine and Schurz, 1991].

Indeed, suppose there is another logic T_1 that conservatively extends both US and $\bar{U}\bar{S}$ but some theorem A of $US \oplus \bar{U}\bar{S}$ is not a theorem of T_1 . But A can be obtained by a finite number of inferences $A_1, \dots, A_n = A$ using only the axioms of US and $\bar{U}\bar{S}$. But any conservative extension of US and $\bar{U}\bar{S}$ must be able to derive A_i , $1 \leq i \leq n$, from A_1, \dots, A_{i-1} , and therefore it must be able to derive A ; contradiction.

Once we have this minimal combination between two logic systems, any other interaction between the logics must be considered on its own. As an example, consider the following formulas expressing the commutativity of future and past operators between the two dimensions are not generally valid over a model of $US \oplus \bar{U}\bar{S}$:

$$\begin{aligned} l_1 \quad & F\bar{F}A \leftrightarrow \bar{F}FA \\ l_2 \quad & F\bar{P}A \leftrightarrow \bar{P}FA \\ l_3 \quad & P\bar{F}A \leftrightarrow \bar{F}PA \\ l_4 \quad & P\bar{P}A \leftrightarrow \bar{P}PA \end{aligned}$$

Now consider the *product* of two linear temporal models, given as follows.

DEFINITION 48. Let $(T, <) \in \mathcal{K}$ and $(\bar{T}, \bar{<}) \in \bar{\mathcal{K}}$ be two linear flows of time. The *product* of those flows of time is $(T \times \bar{T}, <, \bar{<})$. A *product model* over $\mathcal{K} \times \bar{\mathcal{K}}$ is a 4-tuple $\mathcal{M} = (T \times \bar{T}, <, \bar{<}, g)$, where $g : T \times \bar{T} \rightarrow 2^{\mathfrak{A}}$ is a two-dimensional assignment. The semantics of the horizontal and vertical operators are independent of each other:

$$\begin{aligned} \mathcal{M}, t, x \models S(A, B) \quad & \text{iff} \quad \text{there exists } s < t \text{ such that } \mathcal{M}, s, x \models A \\ & \text{and for all } u, s < u < t, \mathcal{M}, u, x \models B. \\ \mathcal{M}, t, x \models \bar{S}(A, B) \quad & \text{iff} \quad \text{there exists } y \bar{<} x \text{ such that } \mathcal{M}, t, y \models A \\ & \text{and for all } z, y \bar{<} z \bar{<} x, \mathcal{M}, t, z \models B. \end{aligned}$$

Similarly for U and \bar{U} , the semantics of atoms and Boolean connectives remaining the standard one. A formula A is valid over $\mathcal{K} \times \bar{\mathcal{K}}$ if for all models $\mathcal{M} = (T, <, \bar{T}, \bar{<}, g)$, for all $t \in T$ and $x \in \bar{T}$ we have $\mathcal{M}, t, x \models A$.

It is easy to verify that the formulas l_1 – l_4 are valid over product models. We wonder if such product of logics transfers the properties we have investigated for the previous logics. The answer is: it depends. We have the following results.

PROPOSITION 49.

- (a) *There is a sound and complete axiomatisation for $US \times \bar{U}\bar{S}$ over the classes of product models $\mathcal{K}_{lin} \times \mathcal{K}_{lin}$, $\mathcal{K}_{dis} \times \mathcal{K}_{dis}$, $\mathbb{Q} \times \mathbb{Q}$, $\mathcal{K}_{lin} \times \mathcal{K}_{dis}$, $\mathcal{K}_{lin} \times \mathbb{Q}$ and $\mathbb{Q} \times \mathcal{K}_{dis}$ [Finger, 1994].*
- (b) *There are no finite axiomatisations for the valid two-dimensional formulas over the classes $\mathbb{Z} \times \mathbb{Z}$, $\mathbb{N} \times \mathbb{N}$ and $\mathbb{R} \times \mathbb{R}$ [Venema, 1990].*

Note that the all the component one-dimensional mentioned above logic systems are complete and decidable, but their product sometimes is complete, sometimes not. Also, the logics in (a) are all decidable and those in (b) are undecidable.

This is to illustrate the following idea: given an independent combination of two temporal logics, the addition of extra axioms, inference rules or an extra condition on its models has to be studied on its own, just as adding a new axiom to a modal logic or imposing a new property on its accessibility relation has to be analysed on its own.

Combinations of logics in the literature

The work on combining temporal logics presented here has first appeared in the literature in [Finger and Gabbay, 1992; Finger and Gabbay, 1996].

General combinations of logics have been addressed in the literature in various forms. Combinations of tense and modality were discussed in the next chapter in this volume, (which reproduces [Thomason, 1984]), without explicitly providing a general methodology for doing so. A methodology for constructing logics of belief based on existing deductive systems is the *deductive model* of Konolige [Konolige, 1986]; in this case, the language of the original system was the base for the construction of a new modal language, and the modal logic system thus generated had its semantics defined in terms of the inferences of the original system. This is a methodology quite different from the one adopted here, in which we separately combine language, inference systems and class of models.

Combination of two monomodal logics and the transference of properties have been studied by Kracht and Wolter [1991] and Fine and Schurz [1991]; the latter even considers the transference of properties through the combination of n -monomodal logics. These works differ from the combination of temporal logics in several ways: their modalities have no interaction whatsoever (unlike S and U , which actually interact with each other); they only

consider one-place modalities (\Box); and their constructions are not a recursive application of the temporalisation (or any similar external application of one logic to another).

A stronger combination of logics have been investigated by Gabbay and Shehtman [Gabbay and Shehtman, 1998], where the starting point is the product of two Kripke frames, generating the *product* of the two monomodal logics. It shows that the transference of completeness and decidability can either succeed or fail for the product, depending on the properties of the component logics. The failure of transference of decidability for temporal products in $FP/\mathcal{K}_{lin} \times FP/\mathcal{K}_{lin}$ has been shown in [Marx and Reynolds, 1999], and fresh results on the products of logics can be found in [Reynolds and Zakharyashev, 2001].

The transference of soundness, completeness and decidability are by no means the only properties to study. Kracht and Wolter [Kracht and Wolter, 1991] study the transference of interpolation between two monomodal logics. The complexity of the combination of two monomodal logics is studied in [Spaan, 1993]; the complexity of products are studied in [Marx, 1999]. Gabbay and Shehtman [Gabbay and Shehtman, 1998] report the failure of transference of the finite model property for their product of modal logics. With respect to specific temporal properties, the transference of the separation property is studied in [Finger and Gabbay, 1992].

For a general combining methodology, see [Gabbay, 1998].

5 LABELLED DEDUCTION PRESENTATION OF TEMPORAL LOGICS

5.1 Introducing LDS

This section develops proof theory for temporal logic within the framework of labelled deductive systems [Gabbay, 1996].

To motivate our approach consider a temporal formula $\alpha = FA \wedge PB \wedge C$. This formula says that we want A to hold in the future (of now), B to hold in the past and C to hold now. It represents the following temporal configuration:

- $t < d < s, t \vDash B, d \vDash C$ and $s \vDash A$

where d is now and t, s are temporal points.

Suppose we want to be very explicit about the temporal configuration and say that we want another instance of B to hold in the past of s but not in the past or future of d , i.e. we want an additional point r such that:

- $r < s, \sim (r = d \vee r < d \vee d < r)$ and $r \vDash B$.

The above cannot be expressed by a formula. The obvious formula $\beta = F(A \wedge PB) \wedge PB \wedge C$ will not do. We need extra expressive power. We can, for example, use an additional atom q and write

$$\gamma = q \wedge Hq \wedge Gq \wedge F(A \wedge P(B \wedge \sim q)) \wedge PB \wedge C.$$

This will do the job.

However, by far the simplest approach is to allow names of points in the language and write $s : A$ to mean that we want $s \models A$ to hold. Then we can write a theory Δ as

$$\Delta = \{t < d < s, t : A, d : C, s : B, r : A, \sim (r < d \vee r = d \vee d < r)\}.$$

Δ is satisfied if we find a model (S, R, a, h) in which d can be identified with $g(d) = a$ and t, s, r can be identified with some points $g(t), g(s), g(r)$ such that the above ordering relations hold and the respective formulae are satisfied in the appropriate points.

The above language has turned temporal logic into a labelled deductive system (LDS). It has brought some of the semantics into the syntax.

But how about proof theory?

Consider $t : FFPB$. This formula does hold at t (because B holds at r). Thus we must have rules that allow us to show that

$$\Delta \vdash FFPB.$$

It is convenient to write Δ as:

Assumptions	Configuration
$t : B$	$t < d < s$
$d : C$	$\sim (r < d \vee d = r \vee d < r)$
$s : A$	$r < s$
$r : B$	

and give rules to manipulate the configuration until we get $t : FFPB$.

Thus formally a temporal database is a set of labelled formulae $\{t_i : A_i\}$ together with a configuration on $\{t_i\}$, given in the form of an earlier–later relation $<$. A query is a labelled formula $t : Q$. The proof rules have the form

$$\frac{t_1 : A_1; \dots; t_n : A_n, \text{ configuration}}{s : B \text{ configuration}'}$$

where the configuration is a set of conditions on the ordering of $\{t_i\}$.

The use of labels is best illustrated via examples:

EXAMPLE 50. This example shows the LDS in the case of modal logic. Modal logic has to do with possible worlds. Thus we think of our basic database (or assumptions) as a finite set of information about possible

worlds. This consists of two parts. The configuration part, the finite configuration of possible worlds for the database, and the assumptions part which tells us what formulae hold in each world. The following is an example of a database:

Assumptions	Configuration
(1) $t : \Box\Box B$	$t < s$
(2) $s : \Diamond(B \rightarrow C)$	

The conclusion to show (or query) is

$$t : \Diamond\Diamond C.$$

The derivation is as follows:

- (3) From (2) create a new point r with $s < r$ and get $r : B \rightarrow C$.

We thus have

Assumptions	Configuration
(1), (2), (3)	$t < s < r$

- (4) From (1), since $t < s$ get $s : \Box B$.
 (5) From (4) since $s < r$ get $r : B$.
 (6) From (5) and (3) we get $r : C$.
 (7) From (6) since $s < r$ get $s : \Diamond C$.
 (8) From (7) using $t < s$ we get $t : \Diamond\Diamond C$.

Discussion The object rules involved are:

$\Box E$ rule:

$$\frac{t < s; t : \Box A}{s : A}$$

$\Diamond I$ rule:

$$\frac{t < s, s : B}{t : \Diamond B}$$

$\Diamond E$ rule:

$$\frac{t : \Diamond A}{\text{create a new point } s \text{ with } t < s \text{ and deduce } s : A}$$

Note that the above rules are not complete. We do not have rules for deriving, for example, $\Box A$. Also, the rules are all for intuitionistic modal logic.

The metalevel considerations which determine which logic we are working in, may be properties of $<$, e.g. $t < s \wedge s < r \rightarrow t < r$, or linearity, e.g. $t < s \vee t = s \vee s < t$ etc.

There are two serious problems in modal and temporal theorem proving. One is that Skolem functions for $\exists x \Diamond A(x)$ and $\Diamond \exists x A(x)$ are not logically the same. If we ‘Skolemize’ we get $\Diamond A(c)$. Unfortunately it is not clear where c exists, in the current world ($\exists x = c \Diamond A(x)$) or the possible world ($\Diamond \exists x = c A(x)$).

If we use labelled assumptions then $t : \exists x \Diamond A(x)$ becomes $t : \Diamond A(c)$ and it is clear that c is introduced at t .

On the other hand, the assumption $t : \Diamond \exists x A(x)$ will be used by the $\Diamond E$ rule to introduce a new point $s, t < s$ and conclude $s : \exists x A(x)$. We can further ‘Skolemize’ at s and get $s : A(c)$, with c introduced at s . We thus need the mechanism of remembering or labelling constants as well, to indicate where they were first introduced.

EXAMPLE 51. Another example has to do with the Barcan formula

Assumption	Configuration
(1) $t : \forall x \Box A(x)$	$t < s$

We show

(2) $s : \forall x A(x)$.

We proceed intuitively

(3) $t : \Box A(x)$ (stripping $\forall x$, remembering x is arbitrary).

(4) Since the configuration contains $s, t < s$ we get

$$s : A(x).$$

(5) Since x is arbitrary we get

$$s : \forall x A(x).$$

The above intuitive proof can be restricted.

The rule

$$\frac{t : \Box A(x), t < s}{s : A(x)}$$

is allowed only if x is instantiated.

To allow the above rule for arbitrary x is equivalent to adopting the Barcan formula axiom

$$\forall x \Box A(x) \rightarrow \Box \forall x A(x).$$

EXAMPLE 52. To show $\forall x \Box A(x) \rightarrow \Box \forall x A(x)$ in the modal logic where it is indeed true.

(1) Assume $t : \forall x \Box A(x)$.

We show $\Box \forall x A(x)$ by the use of the metabox:

create α ,	$t < \alpha$
(2) $t : \Box A(x)$	from (1)
(3) $\alpha : A(x)$	from (2) using a rule which allows this with x a variable.
(4) $\alpha : \forall x A(x)$	universal generalization.

(5) Exit: $t : \Box \forall x A(x)$.

This rule has the form

Create α ,	$t < \alpha$
Argue to get	$\alpha : B$
Exit with	$t : \Box B$

5.2 LDS semantics

We can now formally define a simplified version of LDS, sufficient for our temporal logics. The reader is referred to [Gabbay, 1996] for full details.

An algebraic LDS is built up from two components: an algebra \mathcal{A} and a logic \mathbf{L} . To make things specific, let us assume that we are dealing with a particular algebraic model $\mathcal{A} = (S, <, f_1, \dots, f_k)$, where S is the domain of the algebra, $<$ is a strict order, i.e. irreflexive and transitive, relation on S and f_1, \dots, f_k are function symbols on S of arities r_1, \dots, r_k respectively. The sequence $\Sigma = (<, f_1, \dots, f_k)$ is called the signature of \mathcal{A} . It is really the language of \mathcal{A} in logical terms but we use Σ to separate it from \mathbf{L} . We assume the functions are *isotonic*, i.e. they are either monotonic up or monotonic down in each variable, namely for each coordinate x in f we have that either

$$\forall x, y (x < y \rightarrow f(\dots, x, \dots) < f(\dots, y, \dots))$$

or

$$\forall x, y (x < y \rightarrow f(\dots, y, \dots) < f(\dots, x, \dots))$$

holds.

A typical algebra is a binary tree algebra where each point x in the tree has two immediate successor points $r_1(x)$ and $r_2(x)$ and one predecessor point $p(x)$. $<$ is the (branching) earlier–later relation and we have $p(x) < x < r_i(x)$, $i = 1, 2$.

The general theory of LDS (see [Gabbay, 1996, Section 3.2]) requires a source of labels and a source of formulae. These together are used to form the declarative units of the form $t : A$, where t is a label and A is a formula.

The labels can be syntactical terms in some algebraic theory. The algebraic theory itself can be characterized either syntactically by giving axioms which the terms must satisfy or semantically by giving a class of models (algebras) for the language.

The formulae part of an LDS declarative unit is defined in the traditional way in some language \mathbf{L} .

An LDS database (theory) Δ is a set of terms and their formulae (i.e. a set of declarative units) with some relationships between the terms. In a general LDS, the terms themselves are syntactical and one always has to worry whether the required relations between the terms of Δ are possible (i.e. are consistent).

If, however, we have a semantic theory for the labels characterized by one single model (algebra), then we can take the labels to be elements of this model and consistency and relationships among the labels (elements) of Δ will always be clear—they are as dictated by the model. This represents a temporal logic with a concrete specific flow of time (e.g. integers, rationals, reals, etc.).

We therefore present for the purpose of this chapter, a concrete definition of LDS based on a single model as an algebra of labels.

DEFINITION 53 (Concrete algebraic LDS).

1. A concrete algebraic LDS has the form $(\mathcal{A}, \mathbf{L})$ where:
 - (a) $\mathcal{A} = (S, <, f_1, \dots, f_k)$ is a concrete algebraic model. The elements of S are called labels.
 - (b) \mathbf{L} is a predicate language with connectives $\#_1, \dots, \#_m$ with arities r_1, \dots, r_m , and quantifiers $(Q_1x), \dots, (Q_m'x)$. The connectives can be some well-known modalities, binary conditional, etc., and the quantifiers can be some known generalized or traditional quantifiers. We assume that the traditional syntactical notions for \mathbf{L} are defined. We also assume that \mathbf{L} has only constants, no function symbols and the constants of \mathbf{L} are indexed by elements of the algebra \mathcal{A} , i.e. have the form c_i^t , $t \in S$, $i = 1, 2, 3, \dots$
2. A declarative unit has the form $t : A$, where A is a wff and $t \in S$, or it has the form $t : c_i^s$. The unit $t : A$ intuitively means ‘ A holds at label t ’ and the unit $t : c_i^s$ means ‘the element c_i which was created at label s does exist in the domain of label t ’.

3. A database has the form $\Delta = (D, \mathbf{f}, d, U)$ where $D \subseteq S$ is non-empty and \mathbf{f} is a function associating with each $t \in D$ a set of wffs $\mathbf{f}(t) = \Delta_t$. U is a function associating with each $t \in D$ a set of terms U_t . $d \in D$ is a distinguished point in D . The theory Δ can be displayed by writing $\{t : A_1, t : A_2, s : B, r : c_3^s, \dots\}$, where $t : A$ indicates $A \in \mathbf{f}(t)$ and $r : c^s$ indicates $c^s \in U_r$.

DEFINITION 54 (Semantics for LDS). Let $(\mathcal{A}, \mathbf{L})$ be a concrete algebraic LDS, with algebra \mathcal{A} and language \mathbf{L} with connectives $\{\#_1, \dots, \#_m\}$ and quantifiers $\{Q_1, \dots, Q_{m'}\}$ where $\#_i$ is r_i place.

1. A semantical interpretation for the LDS has the form $\mathcal{I} = (\Psi_0(x, X), \Psi_1, \dots, \Psi_i(x, X_1, \dots, X_{r_i}), \dots, \Psi_m, \Psi'_1(x, Z), \dots, \Psi'_{m'}(x, Z))$ where Ψ_i is a formula of the language of \mathcal{A} , possibly second order, with the single free element variable x and the free set variables X as indicated, and Ψ'_i have a single free element variable x and free binary relation variable Z . We need to assume that Ψ_i and Ψ'_j have the property that if we substitute in them for the set variables closed under \leq then the element variable coordinate is monotonic up under \leq . In symbols:

$$\bullet \bigwedge_j \forall x, y (x \in X_j \wedge x \leq y \rightarrow y \in X_j) \rightarrow [x \leq y \rightarrow \Psi(x, X_j) \rightarrow \Psi(y, X_j)].$$

2. A model for the LDS has the form $\mathbf{m} = (V, h, g, d)$ where $d \in S$ is the distinguished world, V is a function associating a domain V_t with each $t \in S$, h is a function associating with each n -place atomic predicate P a subset $h(t, P) \subseteq V_t^n$.

g is an assignment giving each variable x an element $g(x) \in V_d$ and for each constant c_i^s an element $g(c_i^s) \in V_s$.

3. Satisfaction is defined by structural induction as follows:

- $t \models P(b_1, \dots, b_n)$ iff $(b_1, \dots, b_n) \in h(t, P)$;
- $t \models \exists x A(x)$ iff for some $b \in V_t$, $t \models A(b)$;
- $t \models A \wedge B$ iff $t \models A$ and $t \models B$;
- $t \models \sim A$ iff $t \not\models A$;
- $t \models \#_i(A_1, \dots, A_{r_i})$ iff $\mathcal{A} \models \Psi_i(t, \hat{A}_1, \dots, \hat{A}_{r_i})$, where $\hat{A} = \{s \in S \mid s \models A\}$;
- $t \models (Q_i y)A(y)$ iff $\mathcal{A} \models \Psi'_i(t, \widehat{\lambda y A(y)})$, where $\widehat{\lambda y A(y)} = \{(t, y) \mid t \models A(y)\}$.

4. We say A holds in \mathbf{m} iff $\mathcal{A} \models \Psi_0(d, \hat{A})$.

5. The interpretation \mathcal{I} induces a translation $*$ of \mathbf{L} into a two-sorted language \mathbf{L}^* based on the two domains S (of the algebra \mathcal{A}) and $U = \bigcup_t V_t$ (of the predicates of \mathbf{L}) as follows:

- each atomic predicate $P(x_1, \dots, x_n)$ (interpreted over the domain U) is translated into

$$[P(x_1, \dots, x_n)]_t^* = P^*(t, x_1, \dots, x_n),$$

where P^* is a two-sorted predicate with one more variable t ranging over S and x_1, \dots, x_n ranging over U ;

- $[A \wedge B]_t^* = [A]_t^* \wedge [B]_t^*$;
- $[\sim A]_t^* = \sim [A]_t^*$;
- $[\sharp_i(A_1, \dots, A_{r_i})]_t^* = \Psi_i(t, \lambda_s[A_1]_s^*, \dots, \lambda_s[A_{r_i}]_s^*)$;
- $[(Q_i y)A(y)]_t^* = \Psi'_i(t, \lambda_y \lambda_s[A(y)]_s^*)$;
- Let $\|A\|_t^* = \Psi_0(d, \lambda_t[A]_t^*)$.

6. It is easy to show by induction that:

- $t \vDash A$ iff $[A]_t^*$ holds in the naturally defined two-sorted model.

The reader should compare this definition with [Gabbay, 1996, Definition 3.2.6] and with Chapter 5 of [Gabbay *et al.*, 1994].

Gabbay's book on LDS contains plenty of examples of such systems.

In the particular case of temporal logic, the algebra has the form $(D, <, d)$, where D is the flow of time and $<$ is the earlier-later relation. $d \in D$ is the present moment (actual world).

5.3 Sample temporal completeness proof

The previous section presented the LDS semantics. This section will choose a sample temporal logical system and present *LDS* proof rules and a completeness theorem for it. We choose the modal logic \mathbf{K}_t (See Section 3.2 of [Gabbay *et al.*, 1994]). This is the propositional logic with H and G complete for all Kripke frames (S, R, a) , $a \in S$, such that R is transitive and irreflexive. A wff A is a theorem of \mathbf{K}_t iff for all models (S, R, a, h) with assignment h , we have $a \vDash A$.

We want to turn \mathbf{K}_t into a quantified logic $Q\mathbf{K}_t$. We take as semantics the class of all models of the form (S, R, a, V, h) such that V_t for $t \in S$ is the domain of world t . The following is assumed to hold:

- $tRs \wedge sRs'$ and $a \in V_{s'}$ and $a \in V_t$ imply $a \in V_s$ (i.e. elements are born, exist for a while and then possibly die).

DEFINITION 55 (Traditional semantics for $Q\mathbf{K}_t$).

1. A $Q\mathbf{K}_t$ Kripke structure has the form (S, R, a, V, h) , where S is a non-empty set of possible worlds, $R \subseteq S^2$ is the irreflexive and transitive accessibility relation and $a \in S$ is the actual world. V is a function giving for each $t \in S$ a non-empty domain V_t .

- Let $V_S = \bigcup_{t \in S} V_t$.

h is the assignment function assigning for each t and each n -place atomic predicate P its extension $h(t, P) \subseteq V_t^n$, and for each constant c of the language its extension $h(c) \in V_S$.

Each n -place function symbol of the language of the form $f(x_1, \dots, x_n)$ and t is assigned a function $h(f) : V_S^n \mapsto V_S$.

Note that function symbols are rigid, i.e. the assignment to a constant c is a fixed rigid element which may or may not exist at a world t .²

2. Satisfaction \models is defined in the traditional manner.

- (a) h can be extended to arbitrary terms by the inductive clause $h(f(x_1, \dots, x_n)) = h(f)(h(x_1), \dots, h(x_n))$.

- (b) We define for atomic P and terms x_1, \dots, x_n

$$t \models_h P(x_1, \dots, x_n) \text{ iff } (h(x_1), \dots, h(x_n)) \in h(t, P).$$

- (c) The cases of the classical connectives are the traditional ones.

- (d) $t \models_h \exists x A(x)$ iff for some $a \in V_t$, $t \models_h A(a)$.

- (e) $t \models_h \forall x A(x)$ iff for all $a \in V_t$, $t \models_h A(a)$.

3. $t \models_h GA(a_1, \dots, a_n)$ (resp. $t \models HA$) iff for all s , such that tRs (resp. sRt) and $a_1, \dots, a_n \in V_s$, $s \models A$.

4. $t \models U(A(a_1, \dots, a_n), B(b_1, \dots, b_k))$ iff for some s , tRs and $a_i \in V_s$, $i = 1, \dots, n$, we have $s \models A$ and for all s' , tRs' and $s'Rt$ and $b_j \in V_{s'}$, $j = 1, \dots, k$, imply $s' \models B$. (The mirror image holds for $S(A, B)$.)

5. Satisfaction in the model is defined as satisfaction in the actual world.

²Had we wanted non-rigid semantics we would have stipulated that the extension of a function symbol is $h(t, f) : V_t^n \mapsto V_t$. There is no technical reason for this restriction and our methods still apply. We are just choosing a simpler case to show how LDS works. Note that by taking $h(t, P) \subseteq V_t^n$ as opposed to $h(t, P) \subseteq V_S^n$, we are introducing peculiarities in the semantic evaluation. $t \models P(a_1, \dots, a_n)$ becomes false if not all a_i are in V_t . We can insist that we give values to $t \models A(a_1, \dots, a_n)$ only if all elements are in V_t , but then what value do we give to $t \models GA$? One option is to let $t \models GA(a_1, \dots, a_n)$ iff for all s such that tRs and such that all $a_i \in V_s$ we have $s \models A$.

Anyway, there are many options here and a suitable system can probably be chosen for any application area.

Note that the logic $Q\mathbf{K}_t$ is not easy to axiomatize traditionally.

We now define an LDS corresponding to the system $Q\mathbf{K}_t$.

DEFINITION 56 (The algebra of labels).

1. Consider the first-order theory of one binary relation $<$ and a single constant d . Consider the axiom $\partial = \forall x \sim (x < x) \wedge \forall xyz(x < y \wedge y < z \rightarrow x < z)$. Any classical model of this theory has the form $\mathbf{m} = (S, R, a, g)$, where S is the domain, R is a binary relation on S giving the extension of the syntactical ' $<$ ' and g gives the extension of the variables and of d . $g(d)$ equals a and is the interpretation of the constant ' d '. Since $(S, R, a, g) \models \partial$, we have that R is irreflexive and transitive.
2. Let $U = \{t_1, t_2, \dots\}$ be a set of additional constants in the predicate language of $<$ and d . Let \mathcal{A} be the set of all terms of the language. By a diagram $\Delta = (D, <, d)$, with $D = (D_1, D_2)$, we mean a set $D_1 \subseteq \mathcal{A}$, $d \in D_1$ of constants and variables and a set D_2 of formulae $\varphi(t, s)$ of the form $t < s, \sim (t < s), t = s, t \neq s$, with constants and variables from D_1 .
3. A structure $\mathbf{m} = (S, R, a, g)$ is a model of Δ iff the following hold:
 - (a) $g : D_1 \mapsto S$, with $g(d) = a$;
 - (b) R is irreflexive and transitive (i.e. it is a model of ∂);
 - (c) whenever $\varphi(t, s) \in D_2$ then $\varphi(g(t), g(s))$ holds in the model.
4. Note that g assigns elements of S also to the variables of D_1 . Let x be a constant or a variable. Denote by $g =_x g'$ iff for all variables and constants $y \neq x$ we have $g(y) = g'(y)$.

DEFINITION 57 (LDS language for $Q\mathbf{K}_t$).

1. Let \mathbf{L} be the predicate modal language with the following:
 - (a) Its connectives and quantifiers are $\wedge, \vee, \rightarrow, \perp, \top, \forall, \exists, G, F, H, P$.
 - (b) Its variables are $\{x_1, x_2, \dots\}$.
 - (c) It has atomic predicates of different arities.
 - (d) It has function symbols e_1, e_2, \dots , of different arities.
 - (e) Let \mathcal{A} be the language of the algebra of labels of Definition 56. We assume that \mathcal{A} may share variables with \mathbf{L} but its constants are distinct from the constants of \mathbf{L} . For each constant $t \in U$ of \mathcal{A} and each natural number n , we assume we have in \mathbf{L} a sequence of n -place function symbols

$$c_{n,1}^t(x_1, \dots, x_n), c_{n,2}^t(x_1, \dots, x_n) \dots$$

parameterized by t .

Figure 1.

Thus in essence we want an infinite number of Skolem functions of any arity parameterized by any $t \in U$. The elements of \mathcal{A} are our labels.

The LDS language is presented as $(\mathcal{A}, \mathbf{L})$.

2. A declarative unit is a pair $t : A$, where t is a constant from \mathcal{A} and A is a wff of \mathbf{L} .

Note that because some of the function symbols of \mathbf{L} are parameterized from U , we can get labels in \mathcal{A} as well. For example,

$$t : P(x, c_{1,1}^t(x))$$

is a declarative unit.

3. A configuration has the form $(D, <, \mathbf{f}, d, U)$, where $(D, <, d)$ is a diagram as defined in Definition 56 and \mathbf{f} and U are functions associating with each $t \in D_1$ a set $\mathbf{f}(t)$ of wffs of \mathbf{L} and a set U_t of terms of \mathbf{L} .

We also write:

$t : A$ to indicate that $A \in \mathbf{f}(t)$;

$t : c$ to indicate that $c \in U_t$.

Configurations can also be presented graphically. See for example Fig. 1.

DEFINITION 58 (LDS semantics for $Q\mathbf{K}_t$).

1. A model for an LDS language $(\mathcal{A}, \mathbf{L})$ has the form $\mathbf{n} = (S, R, a, V, h, g)$ where (S, R, a, V, h) is a traditional $Q\mathbf{K}_t$ model for the language \mathbf{L} and g is an assignment from the labelling language \mathcal{A} into S , giving values in S to each label and each variable. The following must hold:
 - (a) for a variable or a constant x common to both \mathcal{A} and \mathbf{L} , $g(x) = h(x)$;
 - (b) for any $c = c_{n,k}^t(x_1, \dots, x_n)$ we have $h(x) \in V_{g(t)}$;
 - (c) let $t_1(x), t_2(y)$ be two terms of \mathbf{L} containing the subterms x and y . Assume that ∂ (when augmented with the function symbols of \mathbf{L} and equality axioms) satisfies

$$\partial \vdash_{\mathcal{A}} (x = y) \rightarrow (t_1 = t_2);$$
 then if $g(x) = g(y)$ then $h(t_1) = h(t_2)$.
 - (d) $g(d) = a$.
2. Let $\Delta = (D, <, \mathbf{f}, d, U)$ be a modal configuration in a language \mathbf{L} . We define the notion of $\mathbf{n} \models \Delta$ to mean that the following hold:
 - (a) for every $t \in D$ and $A \in \mathbf{f}(t)$ we have $g(t) \models_h A$ in (S, R, a, V, h) , according to Definition 55;
 - (b) $(S, R, a, g) \models (D, <, d)$ according to Definition 56;
 - (c) if $x \in D_1$ is a variable then for all $g' =_x g$ we have $\mathbf{n}' = (S, R, a, V, h, g') \models \Delta$, provided \mathbf{n}' is an acceptable model (satisfying the restrictions in 1). This means that the free variables occurring in D are interpreted universally.
3. Let $\mathbf{n} = (S, R, a, V, h, g)$ be a model in a language $(\mathcal{A}, \mathbf{L})$. Let $(\mathcal{A}', \mathbf{L}')$ be an extension of the language. Then \mathbf{n}' is said to be an extension of \mathbf{n} to $(\mathcal{A}', \mathbf{L}')$ if the restriction of V', h', g' to $(\mathcal{A}, \mathbf{L})$ equals V, h, g respectively.
4. Let Δ be a temporal configuration in $(\mathcal{A}, \mathbf{L})$ and Δ' in $(\mathcal{A}', \mathbf{L}')$. We write $\Delta \models \Delta'$ iff any model \mathbf{n} of Δ can be extended to a model \mathbf{n}' of Δ' .
5. We write $\emptyset \models \Delta$ or equivalently $\models \Delta$ iff for any model \mathbf{n} , $\mathbf{n} \models \Delta$.

DEFINITION 59 (LDS proof rules for $Q\mathbf{K}_t$). Let $\Delta = (D, <, \mathbf{f}, d, U)$ and $\Delta' = (D', <', \mathbf{f}', d, U')$ be two temporal configurations. We say that Δ' is obtained from Δ by the application of a single forward proof rule if one of the following cases hold (let $\diamond \in \{P, F\}$, and $\square \in \{G, H\}$).

1. \diamond **introduction case**

For some $t, s \in D_1, t < s \in D_2, A \in \mathbf{f}(s)$ and Δ' is the same as Δ except that $\mathbf{f}'(t) = \mathbf{f}(t) \cup \{\diamond A\}$.

Symbolically we can write $\Delta' = \Delta_{[t < s; s:A]}$ for F and $\Delta_{[s < t, s:A]}$ for P .

2. \diamond **elimination case**

For some $t \in D_1$ and some $A, \diamond A \in \mathbf{f}(t)$ and for some new atomic $s \in U$, that does not appear in Δ , we have that Δ' is the same as Δ except that $D'_1 = D_1 \cup \{s\}$. $D'_2 = D_2 \cup \{t < s\}$ for $\diamond = fF$ (resp. $s < t$ for $\diamond = P$). $\mathbf{f}'(s) = \{A\}$.

Symbolically we can write $\Delta' = \Delta_{[t:\diamond A; s]}$.

3. \square **elimination case**

For some $t, s \in D_1$ such that $t < s \in D_2$ for $\square = G$ (resp. $s < t$ for $\square = H$) we have $\square A \in \mathbf{f}(t)$ and Δ' is like Δ except that $\mathbf{f}'(s) = \mathbf{f}(s) \cup \{A\}$.

Symbolically we can write $\Delta' = \Delta_{[t < s; t:GA]}$, and $\Delta' = \Delta_{[s < t; t:HA]}$.

4. **Local classical case**

Δ' is like Δ except that for $t \in D_1$ we have $\mathbf{f}'(t) = \mathbf{f}(t) \cup \{A\}$, where A follows from $\mathbf{f}(t)$ using classical logic inference only.³

Symbolically we can write $\Delta' = \Delta_{[t-A]}$.

5. **Local \forall elimination**

For some $t \in D_1$ we have $\forall x A(x) \in \mathbf{f}(t)$ and $c \in U_t$, Δ' is like Δ except $\mathbf{f}'(t) = \mathbf{f}(t) \cup \{A(c)\}$.

Symbolically we can write $\Delta' = \Delta_{[t:\forall x A(x); x/c]}$.

6. **Local \exists elimination**

For some $t \in D_1$ and $\forall x_1, \dots, x_n \exists y A(x_1, \dots, x_n, y) \in \mathbf{f}(t)$ and some *new* function symbol $c^t(x_1, \dots, x_n)$ we have

$$\mathbf{f}'(t) = \mathbf{f}(t) \cup \{\forall x_1, \dots, x_n A(x_1, \dots, x_n, c^t(x_1, \dots, x_n))\}.$$

Otherwise Δ' is like Δ .

Symbolically we can write $\Delta' = \Delta_{[t:\forall x_1, \dots, x_n \exists y A; y/c^t]}$.

³Every formula of $Q\mathbf{K}_t$ can be presented in the form $B(Q_1/\square_1 A_1, \dots, Q_n/\square_n A_n)$ where $\square_i \in \{G, H\}$ and $B(Q_1, \dots, Q_n)$ is a modal free classical formula and A_i are general $Q\mathbf{K}_t$ formulae. P/A means the substitution of A for P . A set of formulae of the form $B_i(Q_j^i/\square_j A_j^i)$ proves using classical rules only a formula $B(Q_j/\square_j A_j)$ iff $\{B_i(Q_j^i)\}$ proves classically $B(Q_j)$.

7. Visa rules

- (a) For $t, s \in D_1, t < s < t' \in D_2$ and $c \in U_t$ and $c \in U_{t'}$, Δ' is like Δ except that $U'_s = U_s \cup \{c\}$.
- (b) $U'_t = U_t \cup \{c^t\}$. In other words any c^t can be put in the domain of world t .

Symbolically we write $\Delta' = \Delta_{[t:c, t':c \text{ to } s:c]}$ and $\Delta' = \Delta_{[t:c^t]}$ respectively.

8. Inconsistency rules

- (a) If $t, s \in D_1$ and $\perp \in \mathbf{f}(t)$ then let Δ' be like Δ except that $\mathbf{f}'(s) = \mathbf{f}(s) \cup \{\perp\}$ and $\mathbf{f}'(x) = \mathbf{f}(x)$, for $x \neq s$.
Symbolically we write $\Delta' = \Delta_{[t:\perp \text{ to } s:\perp]}$.
- (b) If $(D, <, d)$ is classically inconsistent and $s \in D_1$, we let Δ' be as in (a) above.
Symbolically we write $\Delta' = \Delta_{[\perp \text{ to } s:\perp]}$.

9. \square introduction rule

We say Δ' is obtained from Δ by a single-level $n+1$ introduction rule if the following holds. For some $t \in D_1$ we have $\mathbf{f}'(t) = \mathbf{f}(t) \cup \{\square A\}$, $\square \in \{G, H\}$ and Δ_2 follows from Δ_1 using a sequence of applications of single, forward rules or of single-level $m \leq n$ introduction rules, and Δ_1 is like Δ except that

$$D_1^1 = D_1 \cup \{t_1\}, D_2^1 = D_2 \cup \{t < t_1\} \text{ for } \square = G$$

$$\text{(and respectively } D_2^1 = D_2 \cup \{t_1 < t\} \text{ for } \square = H)$$

where t_1 is a completely new constant label and $\mathbf{f}^1(t_1) = \{\top\}$.

Δ_2 is like Δ_1 except that $\mathbf{f}^2(t_1) = \mathbf{f}^1(t_1) \cup \{A\}$.

Symbolically we write $\Delta' = \Delta_{[t:\square A]}$.

10. Diagram rule

Δ' is an extension of Δ as a diagram, i.e. $D \subseteq D', \mathbf{f}'(t) = \mathbf{f}(t), t \in D_1$ and $\mathbf{f}'(t) = \{\top\}$, for $t \in D'_1 - D_1$, and we have $(D, <, d) \vdash_{\mathcal{A}} (D', <, d)$.

Symbolically we write $\Delta' = \Delta_{[D \vdash D']}$.

Note that for our logic, $Q\mathbf{K}_t$, this rule just closes $<$ under transitivity.

11. We write $\Delta \vdash \Delta'$ iff there exists a sequence of steps of any level leading from Δ to Δ' . We write $\vdash \Delta'$ if $\Delta_0 \vdash \Delta'$, for Δ_0 the theory with $\{d\}$ only with $\mathbf{f}(d) = \{\top\}$.

Let t be a label of Δ . We write $\Delta \vdash t : A$ iff for any Δ' such that $\Delta \vdash \Delta'$ there exists a Δ'' such that $\Delta' \vdash \Delta''$ and $A \in \mathbf{f}''(t)$. In other

words, Δ can be proof-theoretically manipulated until A is proved at node t .

12. Notice that if $\Delta \vdash \Delta'$ then the language \mathbf{L}' of Δ' is slightly richer in labels and Skolem functions than the language \mathbf{L} .

Note also that if $\Delta \vdash \Delta'$ then there is a sequence of symbols π_1, \dots, π_n such that $\Delta' = \Delta_{\pi_1, \dots, \pi_n}$.

In fact Δ' is uniquely determined up to symbolic isomorphism by the sequence π_1, \dots, π_n .

13. **Local cut rule**

\vdash of item 11 above is without the following *local cut rule*. Let $\Delta_{t:B}$ denote the database obtained from Δ by adding B at label t . Then $\Delta_{t:B} \vdash \Delta'$ and $\Delta_{t:\sim B} \vdash \Delta'$ imply $\Delta \vdash \Delta'$.

14. The consequence $\Delta \vdash \Delta'$ can be implicitly formulated in a ‘sequent’-like form as follows:

- $\Delta \vdash \Delta_\pi$ (axiom)
for π as in any of items 1–10 above.
- $$\frac{\Delta \vdash \Delta'; \Delta' \vdash \Delta''}{\Delta \vdash \Delta''}$$
.
- Local cut rule.

DEFINITION 60 (Inconsistency).

1. A theory $\Delta = (D, <, \mathbf{f}, d, U)$ is immediately inconsistent iff either $(D, <, d)$ is inconsistent as a classical diagram or for some $t \in D_1$, $\perp \in \mathbf{f}(t)$.
2. Δ is inconsistent iff $\Delta \vdash \Delta'$ and Δ' is immediately inconsistent.
3. Note that if we do not provide the following inconsistency rules, namely

$$\frac{t : \perp}{s : \perp}$$

and

$$\frac{(D, <, d) \text{ is inconsistent}}{s : \perp},$$

then two inconsistent modal configurations cannot necessarily prove each other.

THEOREM 61 (Soundness). *Let Δ be in \mathbf{L} and Δ' in \mathbf{L}' . Then $\Delta \vdash \Delta'$ implies $\Delta \vDash \Delta'$. In words, if \mathbf{n} is a model in \mathbf{L} such that $\mathbf{n} \vDash \Delta$, then \mathbf{n} can be extended to $\mathbf{n}' \vDash \Delta'$, where \mathbf{n}' is like \mathbf{n} except that the assignments are extended to \mathbf{L}' . In particular $\vdash \Delta'$ implies $\vDash \Delta'$.*

Proof. By induction on the number of single steps proving Δ' from Δ . We can assume Δ is consistent. It is easy enough to show that if Δ' is obtained from Δ by a single step then there is an $\mathbf{n}' \vDash \Delta'$.

Let $\mathbf{n} = (S, R, a, V, h, g)$ be a model of $\Delta = (D, <, \mathbf{f}, d, U)$. Let Δ' be obtained from Δ by a single proof step and assume $\mathbf{n} \vDash \Delta$. We show how to modify \mathbf{n} to an \mathbf{n}' such that $\mathbf{n}' \vDash \Delta'$.

We follow the proof steps case by case:

1. \diamond **introduction case**

Here take $\mathbf{n}' = \mathbf{n}$.

2. \diamond **elimination case**

Here Δ' contains a completely new constant $s \in D'_1$. We can assume g is not defined for this constant. Since $\mathbf{n} \vDash \Delta$, we have $g(t) \vDash \diamond A$ and so for some $b \in S, g(t)Rb$ and $b \vDash A$. Let g' be like g except $g'(s) = b$. Then $\mathbf{n}' \vDash \Delta'$.

3. \square **elimination case**

Here let $\mathbf{n}' = \mathbf{n}$.

4. **Local classical case**

Let $\mathbf{n}' = \mathbf{n}$.

5. **Local \forall elimination**

Let $\mathbf{n}' = \mathbf{n}$.

6. **Local \exists elimination**

We can assume the new function $c^t(x_1, \dots, x_n)$ is new to the language of Δ and that h is not defined for c^t . Since in \mathbf{n} , $t \vDash \forall x_1, \dots, x_n \exists y A(x_1, \dots, x_n, y)$, for every $(x_1, \dots, x_n) \in V_t^n$ a $y \in V_t$ exists such that $t \vDash A(x_i, y)$. Thus an assignment $h'(c^t)$ can be given to c^t by defining it to be this y for $(x_1, \dots, x_n) \in V_t^n$ and to be a fixed element of V_t for tuples (x_1, \dots, x_n) not in V_t^n . Let \mathbf{n}' be like \mathbf{n} except we take h' instead of h .

7. **Visa rules**

(a) Take $\mathbf{n}' = \mathbf{n}$.

(b) Take $\mathbf{n}' = \mathbf{n}$.

(c) Take $\mathbf{n}' = \mathbf{n}$.

8. Inconsistency rules are not applicable as we assume Δ is consistent.

9. Let \mathbf{n}_1 be a model for the language of Δ_1 and assume $\mathbf{n}_1 \models \Delta_1$. Then by the induction hypothesis there exists $\mathbf{n}_2 \models \Delta_2$, where \mathbf{n}_2 extends \mathbf{n}_1 . Assume now that $\mathbf{n} \not\models \Delta'$. Then $t \not\models \Box A$, and hence for some b such that $tRb, b \not\models A$.

Let \mathbf{n}_1 be defined by extending g to $g_1(t_1) = b$. Clearly $\mathbf{n}_1 \models \Delta_1$. Since $\Delta_1 \vdash \Delta_2$, g_1 can be extended to g_2 so that $\mathbf{n}_2 \models \Delta_2$, i.e. $b \models A$, but this contradicts our previous assumption. Hence $\mathbf{n} \models \Delta'$.

10. Let $\mathbf{n}' = \mathbf{n}$.

The above completes the proof of soundness. \blacksquare

THEOREM 62 (Completeness theorem for LDS proof rules). *Let Δ be a consistent configuration in \mathbf{L} ; then Δ has a model $\mathbf{n} \models \Delta$.*

Proof. We can assume that there are an infinite number of constants, labels and variables in \mathbf{L} which are not mentioned in Δ . We can further assume that there are an infinite number of Skolem functions $c_{n,i}^t(x_1, \dots, x_n)$ in \mathbf{L} , which are not in Δ , for each t and n .

Let $\delta(n)$ be a function such that

$$\delta(n) = (t_n, B_n, t'_n, \alpha_n, k_n),$$

where t_n, t'_n are labels or variables, α_n a term of \mathbf{L} and B_n a formula of \mathbf{L} , and k_n a number between 0 and 7.

Assume that for each pair of labels t, t' of \mathbf{L} and each term α and each formula B of \mathbf{L} and each $0 \leq k \leq 7$ there exist an infinite number of numerals m such that $\delta(m) = (t, B, t', \alpha, k)$.

Let $\Delta_0 = \Delta$. Assume we have defined $\Delta_n = (D^n, <, \mathbf{f}^n, d, U^n)$ and it is consistent.

We now define Δ_{n+1} . Our assumption implies that $(D^n, <, d)$ is classically consistent as well as each $\mathbf{f}^n(t)$. Consider $(t_n, B_n, t'_n, \alpha_n, k_n)$. It is possible that the formulae and labels of $\delta(n)$ are not even in the language of Δ_n , but if they are we can carry out a construction by case analysis.

Case $k_n = 0$

This case deals with the attempt to add either the formula B_n or its negation $\sim B_n$ to the label t_n in D^n . We need to do that in order to build eventually a Henkin model. We first try to add B_n and see if the resulting database $(\Delta_n)_{t_n \cdot B_n}$ is LDS-consistent. If not then we try to add $\sim B_n$. If both are LDS-inconsistent then Δ_n itself is LDS-inconsistent, by the local cut rule (see item 13 of Definition 59).

The above is perfectly acceptable if we are prepared to adopt the local cut rule. However, if we want a system without cut then we must try to add B_n or $\sim B_n$ using possibly other considerations, maybe a different notion of local consistency, which may be heavily dependent on our particular logic.

The kind of notion we use will most likely be correlated to the kind of traditional cut elimination available to us in that logic.

Let us motivate the particular notion we use for our logic, while at the same time paying attention to the principles involved and what possible variations are needed for slightly different logics.

Let us consider an LDS-consistent theory $\Delta = (D, <, \mathbf{f}, d, U)$ and an arbitrary B . We want a process which will allow us to add either B or $\sim B$ at node t (i.e. form $\Delta_{t:B}$ or $\Delta_{t:\sim B}$) and make sure that the resulting theory is LDS-consistent. We do not have the cut rule and so we must use a notion of local consistency particularly devised for our particular logic.

Let us try the simplest notion, that of classical logic consistency. We check whether $\mathbf{f}(t) \cup \{B\}$ is classically consistent. If yes, take $\Delta_{t:B}$, otherwise take $\Delta_{t:\sim B}$. However, the fact that we have classical consistency at t does not necessarily imply that the database is LDS-consistent. Consider $\{t : FA \rightarrow \sim B, s : A; t < s\}$. Here $\mathbf{f}(t) = FA \rightarrow \sim B$. $\mathbf{f}(s) = A$. If we add B to t then we still have local consistency but as soon as we apply the F introduction rule at t we get inconsistency.

Suppose we try to be more sophisticated. Suppose we let $\mathbf{f}_*(t) = \mathbf{f}(t) \cup \{F^k X \mid X \in \mathbf{f}(s), \text{ for some } k, t <^k s\} \cup \{Y \mid G^k Y \in \mathbf{f}(s), \text{ for some } k, s <^k t\}$ and try to add either B or $\sim B$ to $\mathbf{f}_*(t)$ and check for classical consistency. If neither is consistent then for some X_i, Y_k, X'_i, Y'_j we have

$$\begin{aligned} \mathbf{f}(t), X_i, Y_j &\vdash \sim B \\ \mathbf{f}(t), X'_i, Y'_j &\vdash B. \end{aligned}$$

Hence $\mathbf{f}_*(t)$ is inconsistent. However, we do have LDS rules that can bring the X and Y into $\mathbf{f}(t)$ which will make Δ LDS-inconsistent.

So at least one of B and $\sim B$ can be added. Suppose $\Delta_{t:B}$ is locally consistent. Does that make it LDS-consistent?

Well, not necessarily. Consider

$$\{t < s; t : F^k A \rightarrow \sim B; s : A\}$$

and assume we have a condition ∂_1 on the diagrams

$$\partial_1 = \forall xy(x < y \rightarrow \exists z(x < z < y)).$$

We would have to apply the diagram rule k times at the appropriate labels to get inconsistency.

It is obvious from the above discussion that to add B or $\sim B$ at node t we have to make it consistent with all possible wffs that can be proved using LDS rules to have label t (i.e. to be at t).

Let us define then, for t in Δ ,

$$\Delta_{(t)} = \{A \mid \Delta \vdash t : A\}.$$

We say B is locally consistent with Δ at t , or that $\mathbf{f}(t) \cup \{B\}$ is locally consistent iff it is classically consistent with $\Delta_{(t)}$. Note that if $\Delta_{(t)} \vdash A$ classically then $\Delta \vdash t : A$.

We can now proceed with the construction:

1. if $t_n \notin D_1^n$ then $\Delta_{n+1} = \Delta_n$;
2. if $t_n \in D_1^n$ and $\mathbf{f}^n(t_n) \cup \{B_n\}$ is locally consistent, then let $\mathbf{f}^{n+1}(t_n) = \mathbf{f}^n(t_n) \cup \{B_n\}$.
Otherwise $\mathbf{f}^n(t_n)$ is locally consistent with $\sim B_n$ and we let $\mathbf{f}^{n+1}(t_n) = \mathbf{f}^n(t_n) \cup \{\sim B_n\}$. For other $x \in D_1^n$, let $\mathbf{f}^{n+1}(x) = \mathbf{f}^n(x)$. Let $\Delta_{n+1} = (D^n, <, d, \mathbf{f}^{n+1}, U^n)$.

We must show the following:

- if Δ is LDS-consistent and $\Delta_{t_i:B_i}$ is obtained from Δ by simultaneously adding the wffs B_i to $\mathbf{f}(t_i)$ of Δ and if for all i $\mathbf{f}(t_i) \cup \{B_i\}$ is *locally*-consistent, then $\Delta_{t_i:B_i}$ is LDS-consistent.

To show this, assume that $\Delta_{t_i:B_i}$ is LDS-inconsistent. We show by induction on the complexity of the inconsistency proof that Δ is also inconsistent.

Case one step

In this case $\Delta_{t_i:B_i}$ is immediately inconsistent. It is clear that Δ is also inconsistent, because the immediate inconsistency cannot be at any label t_i , and the diagram is consistent.

Case $(l + 1)$ steps

Consider the proof of inconsistency of $\Delta_{t_i:B_i}$. Let π be the first proof step leading to this inconsistency. Let $\Delta' = (\Delta_{t_i:B_i})_\pi$. π can be one of several cases as listed in Definition 59. If π does not touch the labels t_i , then it can commute with the insertion of B_i , i.e. $\Delta' = (\Delta_\pi)_{t_i:B_i}$ and by the induction hypothesis Δ_π is LDS-inconsistent and hence so is Δ .

If π does affect some label t_i , we have to make a case analysis:

- $\pi = [t_i < s; s : A]$, i.e. $\diamond A$ is put in t . In this case consider $(\Delta_\pi)_{t_i:B_i}$. If adding B_i is still locally consistent then by the induction hypothesis $(\Delta_\pi)_{t_i:B_i}$ is consistent. But this is Δ' and so Δ' is consistent. If adding B_i is locally inconsistent, this means that $\Delta_{(t_i)} \cup \{B_i\}$ classically proves \perp , contrary to assumption.
- $\pi = [s < t_i; s : GA]$ (resp. $\pi = [t_i < s; s : HA]$) i.e. A is put in t_i . The reasoning is similar to the previous case.
- $\pi = [t_i : \square A]$, $\square \in \{G, H\}$, the reasoning is similar to previous cases.
- $\pi = [t_i \vdash A]$, similar to the previous ones.
- $\pi =$ classical quantifier rules. This case is also similar to previous ones;

- $\pi = \text{visa rule}$. This means some new constants are involved in the new inconsistency from $\Delta_{(t_i)} \cup \{B_i\}$. These will turn into universal quantifiers and contradict the assumptions.
- The inconsistency rules are not a problem.
- The diagram rule does not affect t_i .
- π applies to B_i itself. Assume that $B_i = \Box C_i$ where \Box is G (resp. H) and that C_i is put in some $s, t_i < s$ (resp. $s < t_i$).

Let us first check whether C_i is locally consistent at s . This will not be the case if $\Delta_{(s)} \vdash \sim C_i$. This would imply $\Delta_{(t)} \vdash \Diamond \sim C_i$ contradicting the fact that B_i is consistent with $\Delta_{(t)}$. Thus consider $\Delta_{t_i; B_i; s; C_i}$. This is the same as Δ' . It is *LDS*-inconsistent, by a shorter proof; hence by the induction hypothesis Δ is *LDS*-consistent;

- B_i is $\Diamond C_i$ and π eliminates \Diamond , i.e. a new point s is introduced with $t_i < s$ for $\Diamond = F$ (resp. $s < t_i$ for $\Diamond = P$) and $s : C_i$ is added to the database.

We claim that C_i is locally consistent in s , in Δ^+ , where Δ^+ is the result of adding s to Δ but not adding $s : C_i$. Otherwise $\Delta_{(s)}^+ \vdash \sim C_i$, and since s is a completely new constant and $\Delta^+ \vdash s : \sim C_i$ this means that $\Delta \vdash t_i : \Box \sim C_i$, a contradiction. Hence C_i is locally consistent in $\Delta_{(s)}^+$. Hence by the induction hypothesis if $\Delta_{s; C_i; t_i; B_i}^+$ is *LDS*-inconsistent so is Δ^+ . If Δ^+ is *LDS*-inconsistent then $\Delta^+ \vdash s : \sim C_i$ and hence $\Delta \vdash t : \Box \sim C_i$ contradicting the local consistency of B_i at t .

- π applies to B_i and π adds $\Diamond B_i$ to $s < t_i$ for $\Diamond = F$ (resp. $t_i < s$ for $\Diamond = P$).

Again we claim $\Diamond B_i$ is locally consistent at s . Otherwise $\Delta_{(s)} \vdash \Box \sim B_i$ and so B_i would not be locally consistent at t_i . We now consider $\Delta_{t_i; B_i; s; \Diamond B_i}$ and get a contradiction as before.

- π is a use of a local classical rule, i.e. $\mathbf{f}(t) \cup \{B_i\} \vdash C_i$, and π adds C_i at t_i .

We claim we can add $B_i \wedge C_i$ at t , because it is locally consistent. Otherwise $\Delta_{(t)} \vdash B_i \rightarrow \sim C_i$ contradicting consistency of $\Delta_{(t)} \cup \{B_i\}$ since $\mathbf{f}(t) \vdash B_i \rightarrow C_i$.

- π is a Skolemization on B_i or an instantiation from B_i . All these classical operations are treated as in the previous case.

Case $k_n = 1$

1. If $t_n, t'_n \in D_1^n$ and $t_n < t'_n \in D_2^n$ and $B_n \in \mathbf{f}^n(t'_n)$ then let $\mathbf{f}^{n+1}(t_n) = \mathbf{f}^n(t_n) \cup \{\diamond B_n\}$ and $\mathbf{f}^{n+1}(x) = \mathbf{f}^n(x)$, for $x \neq t_n$. Let $\Delta_{n+1} = (D^n, <, \mathbf{f}^{n+1}, d, U^n)$.
2. Otherwise let $\Delta_{n+1} = \Delta_n$.

Case $k_n = 2$

1. If $t_n \in D_1^n$ and $B_n = \diamond C \in \mathbf{f}^n(t_n)$, then let s be a completely new constant and let $D_1^{n+1} = D_1^n \cup \{s\}$, $D_2^{n+1} = D_2^n \cup \{t_n < s\}$ for $\diamond = F$ (resp. $s < t_n$ for $\diamond = P$). Let \mathbf{f}^{n+1} be like \mathbf{f}^n or D_1 and let $\mathbf{f}^{n+1}(s) = \{C\}$. Let $\Delta_{n+1} = (D^{n+1}, <, \mathbf{f}^{n+1}, d, U^n)$ and let the new domain at s, U_s^{n+1} , contain all free variables of C .
2. Otherwise let $\Delta_{n+1} = \Delta_n$.

Case $k_n = 3$

1. If $t_n, t'_n \in D_1^n$ and $t_n < t'_n \in D_2^n$ and $B_n = \square C$ and $\square = G$ (resp. $t'_n < t_n$ and $\square = H$) and $B_n \in \mathbf{f}^n(t_n)$ and all free variables of C are in the domain $U_{t'_n}^n$ then let $\mathbf{f}^{n+1} = \mathbf{f}^n(x)$, for $x \neq t'_n$ and $\mathbf{f}^{n+1}(t'_n) = \mathbf{f}^n(x) \cup \{C\}$.
Let $\Delta_{n+1} = (D^n, <, \mathbf{f}^{n+1}, d, U^n)$.
2. Otherwise let $\Delta_{n+1} = \Delta_n$.

Case $k_n = 4$

1. We have $t_n \in D_1^n$ and $\mathbf{f}^n(t_n) \vdash B_n$ classically. Let $\mathbf{f}^{n+1}(x) = \mathbf{f}^n(x)$ for $x \neq t_n$ and let $\mathbf{f}^{n+1}(t_n) = \mathbf{f}^n(t_n) \cup \{B_n\}$.
Let $\Delta_{n+1} = (D^n, <, \mathbf{f}^{n+1}, d, U^n)$.
2. Otherwise let $\Delta_{n+1} = \Delta_n$.

Case $k_n = 5$

1. $t_n \in D_1^n$ and $B_n = \forall x C(x) \in \mathbf{f}^n(t_n)$ and $\alpha_n \in U^n$. Then let $\mathbf{f}^{n+1}(t_n) = \mathbf{f}^n(t_n) \cup \{C(\alpha_n)\}$ and $\mathbf{f}^{n+1}(x) = \mathbf{f}^n(x)$ for $x \neq t_n$ and $\Delta_{n+1} = (D^n, <, \mathbf{f}^{n+1}, d, U^n)$.
2. Otherwise let $\Delta_{n+1} = \Delta_n$.

Case $k_n = 6$

1. $t_n \in D_1^n$ and $B_n \in \mathbf{f}^n(t_n)$ and $B_n = \exists u C(u, y_1, \dots, y_k)$.

Let $c^{t_n}(y_1, \dots, y_k)$ be a completely new Skolem function of this arity not appearing in Δ_n and let

$$\mathbf{f}^{n+1}(t_n) = \mathbf{f}^n(t_n) \cup \{C(c^{t_n}(y_1, \dots, y_k), y_1, \dots, y_k)\}.$$

This is consistent by classical logic. Let $U_{t_n}^{n+1} = U_{t_n}^n \cup \{c^{t_n}(y_1, \dots, y_k)\}$.

Let U^{n+1} and \mathbf{f}^{n+1} be the same as U^n and \mathbf{f}^n respectively, for $x \neq t_n$. Take $\Delta_{n+1} = (D^n, <, \mathbf{f}^{n+1}, d, U^{n+1})$.

2. Otherwise let $\Delta_{n+1} = \Delta_n$.

Case $k_n = 7$

1. If $t_n, t'_n < s_n \in D_1^n$ and $t_n < t'_n < s_n \in D_2^n$ and $\alpha_n \in U_{t_n}^n \cap U_{s_n}^n$ then let $U_{t_n}^{n+1} = U_{t_n}^n \cup \{\alpha_n\}$ and $U_x^{n+1} = U_x^n$ for $x \neq t'_n$. Let $\Delta_{n+1} = (D^n, <, \mathbf{f}^n, d, U^{n+1})$.

2. Otherwise let $\Delta_{n+1} = \Delta_n$.

Let Δ_∞ be defined by $D_i^\infty = \bigcup_n D_i^n$, $\mathbf{f}^\infty = \bigcup_n \mathbf{f}^n$, $U^\infty = \bigcup_n U^n$.

Δ_∞ is our Henkin model. Let $\mathbf{n} = (S, R, a, V, h, g)$, where

$$S = D_1^\infty$$

$$R = \{(x, y) \mid x < y \in D_2^\infty\}$$

$$a = d$$

$$V_t = U_t$$

$$V = U^\infty$$

$$g = \text{identity};$$

then $h(t, P) = \{(x_1, \dots, x_n) \mid P(x_1, \dots, x_n) \in \mathbf{f}^\infty(t)\}$ for $t \in S$ and P n -place atomic predicate, and $x_1, \dots, x_n \in V_t$. ■

LEMMA 63.

1. \mathbf{n} is an acceptable structure of the semantics.
2. For any t and B , $t \vDash B$ iff $B \in \mathbf{f}^\infty(t)$.

Proof.

1. We need to show that R is irreflexive and transitive. This follows from the construction and the diagram rule.

2. We prove this by induction. Assume $\diamond A \in \mathbf{f}^\infty(t)$. Then for some n we have $t \in D_1^n$ and $\diamond A \in \mathbf{f}^n(t)$. Thus at some $n' \geq n$ we put $s \in D_1^{n'}, t < s \in D_2^{n'}$ for $\diamond = F$ (resp. $s < t$ for $\diamond = P$) and $A \in \mathbf{f}^{n'}(s)$.

Assume $\diamond A \notin \mathbf{f}^\infty(t)$. At some n , $B_n = \diamond A$ and had $\mathbf{f}^n(t) \cup \{\diamond A\}$ been consistent, B_n would have been put in \mathbf{f}^{n+1} .

Hence $\Box \sim A \in \mathbf{f}^{n+1}$.

Assume $t < s$ (resp. $s < t$), $s \in D_1^\infty$. Hence for some $n'' \geq n'$ we have $\delta(n'') = (t, \Box \sim A, s, -, 3)$. At this stage $\sim A$ would be in $\mathbf{f}^{n''+1}(s)$. Thus for all $s \in S$ such that tRs (resp. sRt) we have $s \vDash \sim A$.

The classical cases follow the usual Henkin proof.

This completes the proof of the lemma and the proof of Theorem 62. ■

5.4 Label-dependent connectives

We saw earlier that *since* and *until* cannot be defined from $\{G, H, F, P\}$ but if we allow names for worlds we can write

$$\sim q \wedge Gq \wedge Hq \rightarrow [U(A, B) \leftrightarrow F(A \wedge H(P \sim q \rightarrow B))].$$

We can introduce the label-dependent connectives $G^x A, H^x A$ meaning

$$t \vDash G^x A \text{ iff for all } y(t < y < x \rightarrow y \vDash A);$$

$$t \vDash H^x A \text{ iff for all } y(x < y < t \rightarrow y \vDash A).$$

We can then define

$$t : U(A, B) \text{ as } t : F(A \wedge H^t B).$$

Let $F^x A$ be $\sim G^x \sim A$ and $P^x A$ be $\sim H^x \sim A$. Then

$$t \vDash F^x A \text{ iff for some } y, t < y < x \text{ and } y \vDash A \text{ hold.}$$

$$t \vDash P^x A \text{ iff for some } y, x < y < t \text{ and } y \vDash A \text{ hold.}$$

Consider $t \vDash G^x \perp$ and $t \vDash F^x \top$. The first holds iff $\sim \exists y(t < y < x)$ which holds if either $\sim(t < x)$ or x is an immediate successor of t . The second holds if $\exists y(t < y < x)$.

Label-dependent connectives are very intuitive semantically since they just restrict the temporal range of the connectives. There are many applications where such connectives are used. In the context of LDS such connectives are also syntactically natural and offer no additional complexity costs.

We have the option of defining two logical systems. One is an ordinary predicate temporal logic (which is not an LDS) where the connectives G, H are labelled. We call it LQK_t (next definition). This is the logic analogous

to $Q\mathbf{K}_t$. The other system is an LDS formulation of $LQ\mathbf{K}_t$. This system will have (if we insist on being pedantic) two lots of labels: labels of the LDS and labels for the connectives. Thus we can write $t : F^x A$, where t is an LDS label from the labelling algebra \mathcal{A} and x is a label from L ; when we give semantics, both t and x will get assigned possible worlds. So to simplify the LDS version we can assume $L = \mathcal{A}$.

DEFINITION 64 (The logic $LQ\mathbf{K}_t$).

1. Let L be a set of labels, and for each $x \in L$, let G^x and H^x be temporal connectives. The language of $LQ\mathbf{K}_t$ has the classical connectives, the traditional connectives G, H and the labelled connectives G^x, H^x , for each $x \in L$.
2. An $LQ\mathbf{K}_t$ model has the form (S, R, a, V, h, g) , where (S, R, A, V, h) is a $Q\mathbf{K}_t$ model (see Definition 55) and $g : L \mapsto S$, assigning a world to each label. Satisfaction for G^x (resp. H^x) is defined by

$$(3x) \quad t \vDash_{h,g} G^x(a_1, \dots, a_n) \text{ iff for all } s \text{ such that } tRs \wedge sRg(x) \text{ such that } a_1, \dots, a_n \in B_s, \text{ we have } s \vDash_{h,g} A.$$

The mirror image condition is required for H^x .

DEFINITION 65 (LDS version of $LQ\mathbf{K}_t$). Our definition is in parallel to Definitions 56–58. We have the added feature that the language \mathbf{L} of the LDS allows for the additional connectives F^t, P^t, G^t, H^t , where t is from the labelling algebra. For this reason we must modify the LDS notion of an $LQ\mathbf{K}_t$ theory and require that all the labels appearing in the connectives of the formulae of the theory are also members of D_1 , the diagram of labels of the theory.

DEFINITION 66 (LDS proof rules for $LQ\mathbf{K}_t$). We modify Definition 59 as follows:

1. F^x introduction case
For some $t, s \in D_1, t < s < x \in D_2$ and $A \in \mathbf{f}(s)$, Δ' is the same as Δ except that $\mathbf{f}'(t) = \mathbf{f}(t) \cup \{F^x A\}$.

Symbolically we write

$$\Delta' = \Delta_{[t < s < x; s : A]}^x.$$

2. F^x elimination case
For some $t \in D_1$ and some $A, F^x A \in \mathbf{f}(t)$, and for some new atomic

$s \in U$ that does not appear in Δ , we have that Δ' is the same as Δ except that

$$\begin{aligned} D'_1 &= \Delta_1 \cup \{s\}. \\ D'_2 &= D_2 \cup \{t < s < x\}. \\ \mathbf{f}'(s) &= \{A\}. \end{aligned}$$

Note that it may be that $\Delta_2 \cup \{t < s < x\}$ is inconsistent in which case Δ is inconsistent.

3. G^x elimination case

For some $t \in D_1$ such that $t < s < x \in D_2$ we have $G^x A \in \mathbf{f}(t)$ and Δ' is like Δ except that $\mathbf{f}'(s) = \mathbf{f}(s) \cup \{A\}$.

The P^x, H^x rules are the mirror images of all the above and all the other rules remain the same.

4. G^x, H^x introduction case

This case is the same as in Definition 59 except that in the text we replace

$$D_2^1 = D_2 \cup \{t < t_1\}$$

by $D_2^1 = D_2 \cup \{t < t_1 < x\}$ for the case of G^x and the mirror image for the case of H^x .

Similarly we write $\Delta' = \Delta_{[t:\Box^x A]}$.

THEOREM 67 (Soundness and completeness). *The LDS version of $LQ\mathbf{K}_t$ is sound and complete for the proposed semantics.*

Proof. The soundness and completeness are proved along similar lines to the $Q\mathbf{K}_t$ case see Theorems 61 and 62. ■

6 TEMPORAL LOGIC PROGRAMMING

We can distinguish two views of logic, the declarative and the imperative. The declarative view is the traditional one, and it manifests itself both syntactically and semantically. Syntactically a logical system is taken as being characterized by its set of theorems. It is not important how these theorems are generated. Two different algorithmic systems generating the same set of theorems are considered as producing the same logic. Semantically a logic is considered as a set of formulae valid in all models. The model \mathcal{M} is a static

semantic object. We evaluate a formula φ in a model and, if the result of the evaluation is positive (notation $\mathcal{M} \models \varphi$), the formula is valid. Thus the logic obtained is the set of all valid formulae in some class \mathcal{K} of models.

In contrast to the above, the imperative view regards a logic syntactically as a dynamically generated set of theorems. Different generating systems may be considered as different logics. The way the theorems are generated is an integral part of the logic. From the semantic viewpoint, a logical formula is not *evaluated* in a model but performs *actions* on a model to get a *new* model. Formulae are accepted as valid according to what they do to models. For example, we may take φ to be valid in \mathcal{M} if $\varphi(\mathcal{M}) = \mathcal{M}$. (i.e. \mathcal{M} is a fixed point of φ).

Applications of logic in computer science have mainly concentrated on the exploitation of its declarative features. Logic is taken as a language for describing properties of models. The formula φ is evaluated in a model \mathcal{M} . If φ holds in \mathcal{M} (evaluation successful) then \mathcal{M} has property φ . This view of logic is, for example, most suitably and most successfully exploited in the areas of databases and in program specification and verification. One can present the database as a deductive logical theory and query it using logical formulae. The logical evaluation process corresponds to the computational querying process. In program verification, for example, one can describe in logic the properties of the programs to be studied. The description plays the role of a model \mathcal{M} . One can now describe one's specification as a logical formula φ , and the query whether φ holds in \mathcal{M} (denoted $\mathcal{M} \vdash \varphi$) amounts to verifying that the program satisfies the specification. These methodologies rely solely on the declarative nature of logic.

Logic programming as a discipline is also declarative. In fact it advertises itself as such. It is most successful in areas where the declarative component is dominant, e.g. in deductive databases. Its procedural features are not imperative (in our sense) but computational. In the course of evaluating whether $\mathcal{M} \vdash \varphi$, a procedural reading of \mathcal{M} and φ is used. φ does not imperatively act on \mathcal{M} , the declarative logical features are used to guide a procedure—that of taking steps for finding whether φ is true. What does not happen is that \mathcal{M} and φ are read imperatively, resulting in some action. In logic programming such actions (e.g. assert) are obtained by side-effects and special non-logical imperative predicates and are considered undesirable. There is certainly no conceptual framework within logic programming for allowing only those actions which have logical meaning.

Some researchers have come close to touching upon the imperative reading of logic. Belnap and Green [1994] and the later so-called data semantics school regard a formula φ as generating an action on a model \mathcal{M} , and changing it. See [van Benthem, 1996]. In logic programming and deductive databases the handling of integrity constraints borders on the use of logic imperatively. Integrity constraints have to be maintained. Thus one can either reject an update or do some corrections. Maintaining integrity

constraints is a form of executing logic, but it is logically *ad hoc* and has to do with the local problem at hand. Truth maintenance is another form. In fact, under a suitable interpretation, one may view any resolution mechanism as model building which is a form of execution. In temporal logic, model construction can be interpreted as execution. Generating the model, i.e. finding the truth values of the atomic predicates in the various moments of time, can be taken as a sequence of execution.

As the need for the imperative executable features of logic is widespread in computer science, it is not surprising that various researchers have touched upon it in the course of their activity. However, there has been no conceptual methodological recognition of the imperative paradigm in the community, nor has there been a systematic attempt to develop and bring this paradigm forward as a new and powerful logical approach in computing.

The area where the need for the imperative approach is most obvious and pressing is temporal logic. In general terms, a temporal model can be viewed as a progression of ordinary models. The ordinary models are what is true at each moment of time. The imperative view of logic on the other hand also involves step-by-step progression in virtual ‘time’, involving both the syntactic generation of theorems and the semantic actions of a temporal formula on the temporal model. Can the two intuitive progressions, the semantic time and the action (transaction) time, be taken as the same? In the case of temporal logic the answer is ‘yes’. We can act upon the models in the same time order as their chronological time. This means acting on earlier models first. In fact intuitively a future logical statement can be read (as we shall see) both declaratively and imperatively. Declaratively it describes what should be true, and imperatively it describes the actions to be taken to ensure that it becomes true. Since the chronology of the action sequence and the model sequence are the same, we can virtually *create* the future model by our actions. The logic USF, presented in Chapter 10 of [Gabbay *et al.*, 1994], was the first attempt at promoting the imperative view as a methodology, with a proposal for its use as a language for controlling processes.

The purpose of this section is twofold:

1. to present a practical, sensible, logic programming machine for handling time and modality;
2. to present a general framework for extending logic programming to non-classical logics.

Point 1 is the main task of this section. It is done within the framework of 2.

Horn clause logic programming has been generalized in essentially two major ways:

1. using the metalevel features of ordinary Horn clause logic to handle time while keeping the syntactical language essentially the same;
2. enriching the syntax of the language with new symbols and introducing additional computation rules for the new symbols.

The first method is basically a simulation. We use the expressive power of ordinary Horn clause logic to talk about the new features. The *Demo* predicate, the *Hold* predicate and other metapredicates play a significant role.

The second method is more direct. The additional computational rules of the second method can be broadly divided into two:

2.1 Rewrites

2.2 Subcomputations

The rewrites have to do with simplifying the new syntax according to some rules (basically eliminating the new symbols and reducing goals and data to the old Horn clause language) and the subcomputations are the new computations which arise from the reductions.

Given a temporal set of data, this set has the intuitive form:

‘ $A(x)$ is true at time t ’.

This can be represented in essentially two ways (in parallel to the two methods discussed):

1. adding a new argument for time to the predicate A , writing $A^*(t, x)$ and working within an ordinary Horn clause computational environment;
2. leaving time as an external indicator and writing ‘ $t : A(x)$ ’ to represent the above temporal statement.

To compare the two approaches, imagine that we want to say the following:

‘If $A(x)$ is true at t , then it will continue to be true’.

The first approach will write it as

$$\forall s(A^*(t, x) \wedge t < s \rightarrow A^*(s, x)).$$

The second approach has to talk about t . It would use a special temporal connective ‘ G ’ for ‘always in the future’. Thus the data item becomes

$$t : A(x) \rightarrow GA(x).$$

It is equivalent to the following in the first approach:

$$A^*(t, x) \rightarrow \forall s[t < s \rightarrow A^*(s, x)].$$

The statement ‘ GA is true at t ’ is translated as

$$\forall s(t < s \rightarrow A^*(s)).$$

The second part of this section introduces temporal connectives and wants to discover what kind of temporal clauses for the new temporal language arise in ordinary Horn clause logic when we allow time variables in the atoms (e.g. $A^*(t, x)$, $B^*(s, y)$) and allow time relations like $t < s$, $t = s$ for time points. This would give us a clue as to what kind of temporal Horn clauses to allow in the second approach. The computational tractability of the new language is assured, as it arises from Horn clause computation. Skolem functions have to be added to the Horn clause language, to eliminate the F and P connectives which are existential. All we have to do is change the computational rules to rely on the more intuitive syntactical structure of the second approach.

6.1 Temporal Horn clauses

Our problem for this section is to start with Horn clause logic with the ability to talk about time through time coordinates, and see what expressive power in term of connectives (P, F, G, H , etc.) is needed to do the same job. We then extend Prolog with the ability to compute directly with these connectives. The final step is to show that the new computation defined for P, F, G, H is really ordinary Prolog computation modified to avoid Skolemization.

Consider now a Horn clause written in predicate logic. Its general form is of course \bigwedge atoms \rightarrow atom. If our atomic sentences have the form $A(x)$ or $R(x, y)$ or $Q(x, y)$ then these are the atoms one can use in constructing the Horn clause. Let us extend our language to talk about time by following the first approach; that is, we can add time points, and allow special variables t, s to range over a flow of time $(T, <)$ (T can be the set of integers, for example) and write $Q^*(t, x, y)$ instead of $Q(x, y)$, where $Q^*(t, x, y)$ (also written as $Q(t, x, y)$, abusing notation) can be read as

$$\text{‘}Q(x, y) \text{ is true at time } t\text{.’}$$

We allow the use of $t < s$ to mean ‘ t is earlier than s ’. Recall that we do not allow mixed atomic sentences like $x < t$ or $x < y$ or $A(t, s, x)$ because these would read as

‘John loves 1980 at 1979’ or

‘John < 1980’ or

‘John < Mary’.

Assume that we have organized our Horn clauses in such a manner: what kind of time expressive power do we have? Notice that our expressive power is potentially increased. We are committed, when we write a formula of the form $A(t, x)$, to t ranging over time and x over our domain of elements. Thus our model theory for classical logic (or Horn clause logic) does not accept any model for $A(t, x)$, but only models in which $A(t, x)$ is interpreted in this very special way. Meanwhile let us examine the syntactical expressive power we get when we allow for this two-sorted system and see how it compares with ordinary temporal and modal logics, with the connectives P, F, G, H .

When we introduce time variables t, s and the earlier-later relation into the Horn clause language we are allowing ourselves to write more atoms. These can be of the form

$$A(t, x, y)$$

$$t < s$$

(as we mentioned earlier, $A(t, s, y), x < y, t < y, y < t$ are excluded).

When we put these new atomic new sentences into a Horn clause we get the following possible structures for Horn clauses. $A(t, x), B(s, y)$ may also be *truth*.

$$(a0) A(t, x) \wedge B(s, y) \rightarrow R(u, z).$$

Here $<$ is not used.

$$(a1) A(t, x) \wedge B(s, y) \wedge t < s \rightarrow R(u, z).$$

Here $t < s$ is used in the body but the time variable u is not the same as t, s in the body.

$$(a2) A(t, x) \wedge B(s, y) \wedge t < s \rightarrow R(t, z).$$

Same as (a1) except the time variable u appears in the body as $u = t$.

$$(a3) A(t, x) \wedge B(s, y) \wedge t < s \rightarrow R(s, z).$$

Same as (a1) with $u = s$.

$$(a4) A(t, x) \wedge B(s, y) \rightarrow R(t, z).$$

Same as (a0) with $u = t$, i.e. the variable in the head appears in the body.

The other two forms (b) and (c) are obtained when the head is different: (b) for time independence and (c) for a pure $<$ relation.

$$(b) A(t, x) \wedge B(s, y) \rightarrow R1(z)$$

$$(b') A(t, x) \wedge B(s, y) \wedge t < s \rightarrow R1(z).$$

$$(c) A(t, x) \wedge B(s, y) \rightarrow t < s.$$

$$(d) A((1970, x), \text{ where } 1970 \text{ is a } \textit{constant} \text{ date.}$$

Let us see how ordinary temporal logic with additional connectives can express directly, using the temporal connectives, the logical meaning of the above sentences. Note that if time is linear we can assume that one of $t < s$ or $t = s$ or $s < t$ always occur in the body of clauses because for linear time

$$\vdash \forall t \forall s [t < s \vee t = s \vee s < t],$$

and hence $A(t, x) \wedge B(s, y)$ is equivalent to

$$(A(t, x) \wedge B(t, y)) \vee (A(t, x) \wedge B(s, y) \wedge t < s) \vee (A(t, x) \wedge B(s, y) \wedge s < t).$$

Ordinary temporal logic over linear time allows the following connectives:

Fq , read: ‘ q will be true’

Pq , read: ‘ q was true’

$$\diamond q = q \vee Fq \vee Pq$$

$$\square q = \sim \diamond \sim q$$

$\square q$ is read: ‘ q is always true’.

If $[A](t)$ denotes, in symbols, the statement that A is true at time t , then we have

$$[Fq](t) \equiv \exists s > t ([q](s))$$

$$[Pq](t) \equiv \exists s < t ([q](s))$$

$$[\diamond q](t) \equiv \exists s ([q](s))$$

$$[\square q](t) \equiv \forall s ([q](s)).$$

Let us see now how to translate into temporal logic the Horn clause sentences mentioned above.

Case (a0)

Statement (a0) reads

$$\forall t \forall s \forall u [A(t, x) \wedge B(s, y) \rightarrow R(u, z)].$$

If we push the quantifiers inside we get

$$\exists t A(t, x) \wedge \exists s B(s, y) \rightarrow \forall u R(u, z),$$

which can be written in the temporal logic as

$$\diamond A(x) \wedge \diamond B(y) \rightarrow \square R(z).$$

If we do not push the $\forall u$ quantifier inside we get $\square(\diamond A(x) \wedge \diamond B(y) \rightarrow R(z))$.

Case (a1)

The statement (a1) can be similarly seen to read (we do not push $\forall t$ inside)

$$\forall t\{A(t, x) \wedge \exists s[B(s, y) \wedge t < s] \rightarrow \forall uR(u, z)\}$$

which can be translated as: $\Box\{A(x) \wedge FB(y) \rightarrow \Box R(z)\}$. Had we pushed $\forall t$ to the antecedent we would have got

$$\exists t[A(t, x) \wedge \exists s(B(s, y) \wedge t < s)] \rightarrow \forall uR(u, z),$$

which translates into

$$\Diamond[A(x) \wedge FB(y)] \rightarrow \Box R(z).$$

Case (a2)

The statement (a2) can be rewritten as

$$\forall t[A(t, x) \wedge \exists s(B(s, y) \wedge t < s) \rightarrow R(t, z)],$$

and hence it translates to $\Box(A(x) \wedge FB(y) \rightarrow R(z))$.

Case (a3)

Statement (a3) is similar to (a2). In this case we push the external $\forall t$ quantifier in and get

$$\forall s[\exists t[A(t, x) \wedge t < s] \wedge B(s, y) \rightarrow R(s, z)],$$

which translates to

$$\Box[PA(x) \wedge B(y) \rightarrow R(z)].$$

Case (a4)

Statement (a4) is equivalent to

$$\forall t[A(t, x) \wedge \exists sB(s, y) \rightarrow R(t, z)],$$

and it translates to

$$\Box(A(x) \wedge \Diamond B(y) \rightarrow R(z)).$$

Case (b)

The statement (b) is translated as

$$\Diamond(A(x) \wedge \Diamond B(y)) \rightarrow R1(z).$$

Case (b')

The statement (b') translates into

$$\diamond(A(x) \wedge FB(y)) \rightarrow R1(z).$$

Case (c)

Statement (c) is a problem. It reads $\forall t \forall s [A(t, x) \wedge B(s, y) \rightarrow t < s]$; we do not have direct connectives (without negation) to express it. It says for any two moments of time t and s if $A(x)$ is true at t and $B(y)$ true at s then $t < s$. If time is linear then $t < s \vee t = s \vee s < t$ is true and we can write the conjunction

$$\sim \diamond(A(x) \wedge PB(y)) \wedge \diamond(A(x) \wedge B(y)).$$

Without the linearity of time how do we express the fact that t *should be* '<-related to s '?

We certainly have to go beyond the connectives P, F, \diamond, \square that we have allowed here.

Case (d)

$A(1970, x)$ involves a constant, naming the date 1970. The temporal logic will also need a propositional constant 1970 , which is true *exactly* when the time is 1970, i.e.

$$\mathbf{M}t \models 1970 \text{ iff } t = 1970.$$

Thus (d) will be translated as $\square(1970 \rightarrow A(x))$. 1970 can be read as the proposition 'The time now is 1970'.

The above examples show what temporal expressions we can get by using Horn clauses with time variables as an *object* language. We are not discussing here the possibility of 'simulating' temporal logic in Horn clauses by using the Horn clause as a *metalanguage*. Horn clause logic can do that to any logic as can be seen from Hodges [Hodges, 1985].

DEFINITION 68. The language contains \wedge, \rightarrow, F (it will be the case) P (it was the case) and \square (it is always the case).

We define the notions of:

Ordinary clauses;

Always clauses;

Heads;

Bodies;

Goals.

1. A *clause* is either an always clause or an ordinary clause.
2. An *always clause* is $\Box A$ where A is an ordinary clause.
3. An *ordinary clause* is a head or an $A \rightarrow H$ where A is a body and H is a head.
4. A *head* is either an atomic formula or FA or PA , where A is a conjunction of ordinary clauses.
5. A *body* is an atomic formula, a conjunction of bodies, an FA or a PA , where A is a body.
6. A goal is any body.

EXAMPLE 69.

$$a \rightarrow F((b \rightarrow Pq) \wedge F(a \rightarrow Fb))$$

is an acceptable clause.

$$a \rightarrow \Box b$$

is not an acceptable clause.

The reason for not allowing \Box in the head is computational and not conceptual. The difference between a (temporal) logic programming machine and a (temporal) automated theorem prover is *tractability*. Allowing disjunctions in heads or \Box in heads crosses the boundary of tractability. We can give computational rules for richer languages and we will in fact do so in later sections, but we will lose tractability; what we will have then is a theorem prover for full temporal logic.

EXAMPLES 70.

$$P[F(FA(x) \wedge PB(y) \wedge A(y)) \wedge A(y) \wedge B(x)] \rightarrow \\ P[F(A(x) \rightarrow FP(Q(z) \rightarrow A(y)))]$$

is an ordinary clause. So is $a \rightarrow F(b \rightarrow Pq) \wedge F(a \rightarrow Fb)$, but not $A \rightarrow \Box b$.

First let us check the expressive power of this *temporal Prolog*. Consider

$$a \rightarrow F(b \rightarrow Pq).$$

This is an acceptable clause. Its predicate logic reading is

$$\forall t[a(t) \rightarrow \exists s > t[b(s) \rightarrow \exists u < sq(u)]].$$

Clearly it is more directly expressive than the Horn clause *Prolog* with time variables. Ordinary Prolog can rewrite the above as

$$\forall t(a(t) \rightarrow \exists s(t < s \wedge (b(s) \rightarrow \exists u(u < s \wedge q(u))))),$$

which is equivalent to

$$\forall t(\exists s\exists u(a(t) \rightarrow t < s \wedge (b(s) \rightarrow u < s \wedge q(u)))).$$

If we Skolemize with $\mathbf{s}_0(t)$ and $\mathbf{u}_0(t)$ we get the clauses

$$\forall t[(a(t) \rightarrow t < \mathbf{s}_0(t)) \wedge (a(t) \wedge b(\mathbf{s}_0(t)) \rightarrow \mathbf{u}_0(t) < \mathbf{s}_0(t)) \wedge \\ (a(t) \wedge b(\mathbf{s}_0(t)) \rightarrow q(\mathbf{u}_0(t)))].$$

The following are representations of some of the problematic examples mentioned in the previous section.

$$(a1) \quad \Box(A(x) \wedge FB(y) \rightarrow \Box R(z)).$$

This is not an acceptable always clause but it can be equivalently written as

$$\Box(\Diamond(A(x) \wedge FB(y)) \rightarrow R(z)).$$

$$(a2) \quad \Box(A(x) \wedge FB(y) \rightarrow R(z)).$$

$$(b') \quad \Diamond(A(x) \wedge FB(y)) \rightarrow R1(z).$$

(b) can be written as the conjunction below using the equation

$$\begin{aligned} \Diamond q &= Fq \vee Pq \vee q : \\ (A(x) \wedge FB(y) \rightarrow R1(z)) \wedge \\ (F(A(x) \wedge FB(y)) \rightarrow R1(z)). \end{aligned}$$

(a2) Can be similarly written.

(c) can be written as

$$\forall t, s(A(x)(t) \wedge B(y)(s) \rightarrow t < s).$$

This is more difficult to translate. We need negation as failure here and write

$$\begin{aligned} \Box(A(x) \wedge PB(y) \rightarrow \perp) \\ \Box(A(x) \wedge B(y) \rightarrow \perp) \end{aligned}$$

From now on we continue to develop the temporal logic programming machine.

Figure 2. A temporal configuration.

6.2 LDS—Labelled Deductive System

This section will use the labelled deductive methodology of the previous section as a framework for developing the temporal Prolog machine. We begin by asking ourselves what is a temporal database? Intuitively, looking at existing real temporal problems, we can say that we have information about things happening at different times and some connections between them. Figure 2 is such an example.

The diagram shows a finite set of points of time and some labelled formulae which are supposed to hold at the times indicated by the labels. Notice that we have labelled not only assertions but also Horn clauses showing dependences across times. Thus at time t it may be true that B will be true. We represent that as $t : FB$. The language we are using has F and P as connectives. It is possible to have more connectives and still remain within the Horn clause framework. Most useful among them are ' $t : F^s A$ ' and ' $t : P^s A$ ', reading ' $t < s$ and $s : A$ ' and ' $s < t$ and $s : A$ '. In words: ' A will be true at time $s > t$ '.

The temporal configuration comprises two components.

1. A (finite) graph $(\rho, <)$ of time points and the temporal relationships between them.
2. With each point of the graph we associate a (finite) set of clauses and assertions, representing what is true at that point.

In Horn clause computational logic, there is an agreement that if a formula of the form $A(x) \rightarrow B(x)$ appears in the database with x free then it is understood that x is universally quantified. Thus we assume $\forall x(A(x) \rightarrow B(x))$ is in the database. The variable x is then called universal (or type 1). In the case of modal and temporal logics, we need another type of variable, called type 2 or a Skolem variable. To explain the reason, consider the item of data

$$'t : FB(x)'$$

This reads, according to our agreement,

$$'\forall xFB(x) \text{ true at } t.'$$

For example, it might be the sentence: t : 'Everyone will leave'.

The time in the future in which $B(x)$ is true depends on x . In our example, the time of leaving depends on the person x . Thus, for a given unknown (uninstantiated) u , i.e. for a given person u which we are not yet specifying, we know there must be a point t_1 of time (t_1 is dependent on u) with $t_1 : B(u)$. This is the time in which u leaves.

This u is by agreement not a type 1 variable. It is a u to be chosen later. Really u is a Skolem constant and we do not want to and cannot read it as $t_1 : \forall uB(u)$. Thus we need two types of variables. The other alternative is to make the dependency of t_1 on u explicit and to write

$$t_1(x) : B(x)$$

with x a universal type 1 variable, but then the object language variable x appears in the world indices as well. The world indices, i.e. the t , are external to the formal clausal temporal language, and it is simpler not to mix the t and the x . We chose the two types of variable approach. Notice that when we ask for a goal $?G(u)$, u is a variable to be instantiated, i.e. a type 2 variable. So we have these variables anyway, and we prefer to develop a systematic way of dealing with them.

To explain the role of the two types of variables, consider the following classical Horn clause database and query:

$$\begin{aligned} A(x, y) \rightarrow B(x, y) \quad ?B(u, u) \\ A(a, a). \end{aligned}$$

This means 'Find an instantiation u_0 of u such that $\forall x, y[A(x, y) \rightarrow B(x, y)] \wedge A(a, a) \vdash B(u_0, u_0)$ '. There is no reason why we cannot allow for the following

$$\begin{aligned} A(u, y) \rightarrow B(x, u) \quad ?B(u, u) \\ A(a, a). \end{aligned}$$

In this case we want to find a u_0 such that

$$\forall x, y[A(u_0, y) \rightarrow B(x, u_0)] \wedge A(a, a) \vdash B(u_0, u_0)$$

or to show

$$\vdash \exists u\{\forall x, y[A(u, y) \rightarrow B(x, u)] \wedge A(a, a) \rightarrow B(u, u)\}$$

u is called a type 2 (Skolem) variable and x, y are universal type 1 variables. Given a database and a query of the form $\Delta(x, y, u)?Q(u)$, success means $\vdash \exists u[\forall x, y \Delta(x, y, u) \rightarrow Q(u)]$.

The next sequence of definitions will develop the syntax of the temporal Prolog machine. A lot depends on the flow of time. We will give a general definition (Definition 73 below), which includes the following connectives:

□ Always.

F It will be the case.

P It was the case.

G It will always be the case (not including now).

H It has always been the case (up to now and not including now);.

○ Next moment of time (in particular it implies that such a moment of time exists).

● Previous moment of time (in particular it implies that such a moment of time exists).

Later on we will also deal with S (Since) and U (Until).

The flows of time involved are mainly three:

- general partial orders $(T, <)$;
- linear orders;
- the integers or the natural numbers.

The logic and theorem provers involved, even for the same connectives, are different for different partial orders. Thus the reader should be careful to note in which flow of time we are operating. Usually the connectives ○ and ● assume we are working in the flow of time of integers.

Having fixed a flow of time $(T, <)$, the temporal machine will generate finite configurations of points of time according to the information available to it. These are denoted by $(\rho, <)$. We are supposed to have $\rho \subseteq T$ (more precisely, ρ will be homomorphic into T), and the ordering on ρ will be the same as the ordering on T . The situation gets slightly complicated if we have a new point s and we do not know where it is supposed to be in relation to known points. We will need to consider all possibilities. Which possibilities do arise depend on $(T, <)$, the background flow of time we are working with. Again we should watch for variations in the sequel.

DEFINITION 71. Let $(\rho, <)$ be a finite partial order. Let $t \in \rho$ and let s be a new point. Let $\rho' = \rho \cup \{s\}$, and let $<'$ be a partial order on ρ' . Then

$(\rho', <, t)$ is said to be a (one new point) *future* (resp. *past*) *configuration* of $(\rho, <, t)$ iff $t <' s$ (resp. $s <' t$) and $\forall xy \in \rho(x < y \leftrightarrow x <' y)$.

EXAMPLE 72. Consider a general partial flow $(T, <)$ and consider the subflow $(\rho, <)$.

The possible future configurations (relative to $T, <$) of one additional point s are displayed in Fig. 3.

Figure 3.

For a finite $(\rho, <)$ there is a finite number of future and past non-isomorphic configurations. This finite number is exponential in the size of ρ . So in the general case without simplifying assumptions we will have an intractable exponential computation. A configuration gives all possibilities of putting a point in the future or past.

In the case of an ordering in which a next element or a previous element exists (like $t + 1$ and $t - 1$ in the integers) the possibilities for configurations

are different. In this case we must assume that we know the *exact* distance between the elements of $(\rho, <)$.

For example, in the configuration $\{t < x_1, t < x_2\}$ of Fig. 4 we may have the further following information as part of the configuration:

Figure 4.

$$t = \bullet^{18}x_1$$

$$t = \bullet^6x_2$$

so that we have only a finite number of possibilities for putting s in.

Note that although \bullet operates on propositions, it can also be used to operate on points of time, denoting the predecessor function.

DEFINITION 73. Consider a temporal Prolog language with the following connectives and predicates:

1. atomic predicates;
2. function symbols and constants;
3. two types of variables:
 universal variables (type 1) $V = \{x_1, y_1, z_1, x_2, y_2, z_2, \dots\}$
 and Skolem variables (type 2) $U = \{u_1, v_1, u_2, v_2, \dots\}$;
4. the connectives $\wedge, \rightarrow, \vee, F, P, \circ, \bullet, \square$ and \neg .

FA reads: it will be the case that A .

PA reads: it was the case that A .

$\circ A$ reads: A is true tomorrow (if a tomorrow exists; if tomorrow does not exist then it is false).

$\bullet A$ reads: A was true yesterday (if yesterday does not exist then it is false).

\neg : represents negation by failure.

We define now the notions of an *ordinary clause*, an *always clause*, a *body*, a *head* and a *goal*.

1. A *clause* is either an always clause or an ordinary clause.
2. An *always clause* has the form $\Box A$, where A is an ordinary clause.
3. An *ordinary clause* is a head or an $A \rightarrow H$, where A is a body and H is a head.
4. A *head* is an atomic formula or an FA or a PA or an $\bigcirc A$ or an $\bullet A$, where A is a finite conjunction of ordinary clauses.
5. A *body* is an atomic formula or an FA or a PA or an $\bigcirc A$ or an $\bullet A$ or $\neg A$ or a conjunction of bodies where A is a body.
6. A *goal* is a body whose variables are *all* Skolem variables.
7. A disjunction of goals is also a goal.

REMARK 74. Definition 73 included all possible temporal connectives. In practice different systems may contain only some of these connectives. For example, a modal system may contain only \diamond (corresponding to F) and \Box . A future discrete system may contain only \bigcirc and F etc.

Depending on the system and the flow of time, the dependences between the connectives change. For example, we have the equivalence

$$\Box(a \rightarrow \bigcirc b) \text{ and } \Box(\bullet a \rightarrow b)$$

whenever both $\bullet a$ and $\bigcirc b$ are meaningful.

DEFINITION 75. Let $(T, <)$ be a flow of time. Let $(\rho, <)$ be a finite partial order. A *labelled temporal database* is a set of labelled ordinary clauses of the form $(t_i : A_i)$, $t \in \rho$, and always clauses of the form $\Box A_i$, A_i a clause. A labelled goal has the form $t : G$, where G is a goal.

Δ is said to be a labelled temporal database over $(T, <)$ if $(\rho, <)$ is homomorphic into $(T, <)$.

DEFINITION 76. We now define the computation procedure for the temporal Prolog for the language of Definitions 73 and 75. We assume a flow of time $(T, <)$. $\rho \subseteq T$ is the finite set of points of time involved so far in the computation. The exact computation steps depend on the flow of time. It is different for branching, discrete linear, etc. We will give the definition for linear time, though not necessarily discrete. Thus the meaning of $\bigcirc A$ in this logic is that there exists a next moment and A is true at this next moment. Similarly for $\bullet A$. $\bullet A$ reads: there exists a previous moment and A was true at that previous moment.

We define the success predicate $\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0, \Theta)$ where $t \in \rho$, $(\rho, <)$ is a finite partial order and Δ is a set of labelled clauses $(t : A)$, $t \in \rho$.

$\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0, \Theta)$ reads: the labelled goal $t : G$ succeeds from Δ under the substitution Θ to all the type 2 variables of G and Δ in the computation with starting labelled goal $t_0 : G_0$.

When Θ is known, we write $\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0)$ only.

We define the simultaneous success and failure of a set Π of metapredicates of the form $\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0)$ under a substitution Θ to type 2 variables. To explain the intuitive meaning of success or failure, assume first that Θ is a substitution which grounds all the Skolem type 2 variables. In this case (Π, Θ) succeeds if by definition all $\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0, \Theta) \in \Pi$ succeed and (Π, Θ) fails if at least one of $\mathbf{S} \in \Pi$ fails. The success or failure of \mathbf{S} for a Θ as above has to be defined recursively. For a general Θ , (Π, Θ) succeeds, if for some Θ' such that $\Theta\Theta'$ grounds all type 2 variables $(\Pi, \Theta\Theta')$ succeeds. (Π, Θ) fails if for all Θ' such that $\Theta\Theta'$ grounds all type 2 variables we have that $(\Pi, \Theta\Theta')$ fails. We need to give recursive procedures for the computation of the success and failure of (Π, Θ) . In the case of the recursion, a given (Π, Θ) will be changed to a (Π', Θ') by taking $\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0) \in \Pi$ and replacing it by $\mathbf{S}(\rho', <', \Delta', G', t', G_0, t_0)$. We will have several such changes and thus get several Π' by replacing several \mathbf{S} in Π . We write the several possibilities as (Π'_i, Θ'_i) . If we write (Π, Θ) to mean (Π, Θ) succeeds and $\sim(\Pi, \Theta)$ to read (Π, Θ) fails, then our recursive computation rules have the form: (Π, Θ) succeeds (or fails) if some Boolean combination of (Π'_i, Θ'_i) succeeds (or fails). The rules allow us to pick an element in Π , e.g. $\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0)$, and replace it with one or more elements to obtain the different (Π'_i, Θ'_i) , where Θ'_i is obtained from Θ . In case of failure we require that Θ grounds all type 2 variables. We do not define failure for a non-grounding Θ .

To summarize the general structure of the rules is:

(Π, Θ) succeeds (or fails) if some Boolean combination of the successes and failures of some (Π'_i, Θ'_i) holds and (Π, Θ) and (Π'_i, Θ'_i) are related according to one of the following cases:

Case I If $\Pi = \emptyset$ then (Π, Θ) succeeds (i.e. the Boolean combination of (Π_i, Θ_i) is *truth*).

Case II (Π, Θ) fails if for some $\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0)$ in Π we have G is atomic and for all $\Box(A \rightarrow H) \in \Delta$ and for all $(t : A \rightarrow H) \in \Delta, H\Theta$ does *not* unify with $G\Theta$. Further, for all Ω and s such that $t = \Omega s$ and for all $s : A \rightarrow \Omega H$ and all $\Box(A \rightarrow \Omega H)$ we have $H\Theta$ does not unify with $G\Theta$, where Ω is a sequence of \bigcirc and \bullet .

REMARK 77. We must qualify the conditions of the notion of failure. If we have a goal $t : G$, with G atomic, we know for sure that $t : G$ finitely fails under a substitution Θ , if $G\Theta$ cannot unify with any head of a clause. This is what the condition above says. What are the candidates for unification? These are either clauses of the form $t : A \rightarrow H$, with H atomic, or $\Box(A \rightarrow H)$, with H atomic.

Do we have to consider the case where H is not atomic? The answer depends on the flow of time and on the configuration $(\rho, <)$ we are dealing

with. If we have, say, $t : A \rightarrow FG$ then if $A \rightarrow FG$ is true at t , G would be true (if at all) in some s , $t < s$. This s is irrelevant to our query $?t : G$. Even if we have $t' < t$ and $t' : A \rightarrow FG$ and A true at t' , we can still ignore this clause because we are not assured that any s such that $t' < s$ and G true at s would be the desired t (i.e. $t = s$).

The only case we have to worry about is when the flow of time and the configuration are such that we have, for example, $t' : A \rightarrow \bigcirc^5 G$ and $t = \bigcirc^5 t'$.

In this case we must add the following clause to the notion of failure: for every s such that $t = \bigcirc^n s$ and every $s : A \rightarrow \bigcirc^n H$, $G\Theta$ and $H\Theta$ do not unify.

We also have to check what happens in the case of always clauses.

Consider an integer flow of time and the clause $\Box(A \rightarrow \bigcirc^5 \bullet^{27} H)$. This is true at the point $s = \bullet^5 \bigcirc^{27} t$ and hence for failure we need that $G\Theta$ does not unify with $H\Theta$.

The above explains the additional condition on failure.

The following conditions 1–10, 12–13 relate to the success of (Π, Θ) (Π'_i, Θ'_i) succeed. Condition (11) uses the notion of failure to give the success of negation by failure. Conditions 1–10, 12–13 give certain alternatives for success. They give failure if each one of these alternatives ends up in failure.

1. Success rule for atomic query:

$\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0) \in \Pi$ and G is atomic and for some head H , $(t : H) \in \Delta$ and for some substitutions Θ_1 to the universal variables of H and Θ_2 to the existential variables of H and G we have $H\Theta_1\Theta_2 = G\Theta\Theta_2$ and $\Pi' = \Pi - \{\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0)\}$ and $\Theta' = \Theta\Theta_2$.

2. Computation rule for atomic query:

$\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0) \in \Pi$ and G is atomic and for some $(t : A \rightarrow H) \in \Delta$ or for some $\Box(A \rightarrow H) \in \Delta$ and for some Θ_1, Θ_2 , we have $H\Theta_1\Theta_2 = G\Theta\Theta_2$ and $\Pi' = (\Pi - \{\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0)\}) \cup \{\mathbf{S}(\rho, <, \Delta, A\Theta_1, t, G_0, t_0)\}$ and $\Theta' = \Theta\Theta_2$.

The above rules deal with the atomic case. Rules 3, 4 and 4* deal with the case the goal is FG . The meaning of 3, 4 and 4* is the following. We ask FG at t . How can we be sure that FG is true at t ? There are two possibilities, (a) and (b):

- (a) We have $t < s$ and at $s : G$ succeeds. This is rule 3;
- (b) Assume that we have the fact that $A \rightarrow FB$ is true at t . We ask for A and succeed and hence FB is true at t . Thus there should exist a point s' in the future of t where B is true. Where can s' be? We don't know where s' is in the future of t . So we consider all future

configurations for s' . This gives us all future possibilities where s' can be. We assume for each of these possibilities that B is true at s' and check whether either G follows at s' or FG follows at s' . If we find that for all future constellations of where s' can be $G \vee FG$ succeeds in s' from B , then FG holds at t . Here we use the transitivity of $<$. Rule 4a gives the possibilities where s' is an old point s in the future of t ; Rule 4b gives the possibilities where s' is a new point forming a new configuration. Success is needed from *all* possibilities.

3. Immediate rule for F :

$\mathbf{S}(\rho, <, \Delta, FG, t, G_0, t_0) \in \mathbf{\Pi}$ and for some $s \in \rho$ such that $t < s$ we have $\mathbf{\Pi}' = (\mathbf{\Pi} - \{\mathbf{S}(\rho, <, \Delta, FG, t, G_0, t_0)\}) \cup \{\mathbf{S}(\rho, <, \Delta, G, s, G_0, t_0)\}$ and $\Theta' = \Theta$.

4. First configuration rule for F :

$\mathbf{S}(\rho, <, \Delta, FG, t, G_0, t_0) \in \mathbf{\Pi}$ and for some $(t : A \rightarrow F \wedge_j B_j) \in \Delta$ and some Θ_1, Θ_2 we have both (a) and (b) below are true. A may not appear in which case we pretend $A = \text{truth}$.

- (a) For *all* $s \in \rho$ such that $t < s$ we have that
 $\mathbf{\Pi}'_s = (\mathbf{\Pi} - \{\mathbf{S}(\rho, <, \Delta, FG, t, G_0, t_0)\}) \cup \{\mathbf{S}(\rho, <, \Delta, E\Theta_1, t, G_0, t_0)\} \cup \{\mathbf{S}(\rho, <, \Delta \cup \{(s : B_j\Theta_1) \mid j = 1, 2, \dots\}, D, s, G_0, t_0)\}$
 succeeds with $\Theta'_s = \Theta\Theta_2$ and $D = G \vee FG$ and $E = A$.
- (b) For all future configurations of $(\rho, <, t)$ with a new letter s , denoted by the form $(\rho_s, <_s)$, we have that
 $\mathbf{\Pi}'_s = (\mathbf{\Pi} - \{\mathbf{S}(\rho, <, \Delta, FG, t, G_0, t_0)\}) \cup \{\mathbf{S}(\rho, <, \Delta, E\Theta_1, t, G_0, t_0)\} \cup \{\mathbf{S}(\rho_s, <_s, \Delta \cup \{(s : B_j) \mid j = 1, 2, \dots\}, D, s, G_0, t_0)\}$
 succeeds with $\Theta'_s = \Theta\Theta_2$ and $D = G \vee FG$ and $E = A$.

The reader should note that conditions 3, 4a and 4b are needed only when the flow of time has some special properties. To explain by example, assume we have the configuration of Fig. 5 and $\Delta = \{t : A \rightarrow FB, t' : C\}$ as data, and our query is $?t : FG$.

Then according to rules 3, 4 we have to check and succeed in all the following cases:

1. from rule 3 we check $\{t' : C, t : A \rightarrow FB\}?t' : G$;
2. from rule 4a we check $\{t' : C, t : A \rightarrow FB, t' : B\}?t' : G$;
3. from rule 4b we check $\{t' : C, t : A \rightarrow FB, s : B\}?s : G$;

for the three configurations of Fig. 6.

Figure 5.

Figure 6.

If time is linear, configuration 3.3, shown in Fig. 6, does not arise and we are essentially checking 3.1, 3.2 of Fig. 6 and the case 4a corresponding to $t' = s$.

If we do not have any special properties of time, success in case 3.2 is required. Since we must succeed in all cases and 3.2 is the case with *least* assumptions, it is enough to check 3.2 alone.

Thus for the case of no special properties of the flow of time, case 4 can be replaced by case 4 general below:

4 **general** $\mathbf{S}(\rho, <, \Delta, FG, t, G_0, t_0) \in \mathbf{\Pi}$ and for the future configuration $(\rho_1, <_1)$ defined as $\rho_1 = \rho \cup \{s\}$ and $<_1 = < \cup \{t < s\}$, s a new letter, we have that: $\mathbf{\Pi}'s = (\mathbf{\Pi} - \{\mathbf{S}(\rho, <, \Delta, FG, t, G_0, t_0)\}) \cup \{\mathbf{S}(\rho, <, \Delta, E\Theta_1, t, G_0, t_0)\} \cup \{\mathbf{S}(\rho_1, <_1, \Delta \cup \{(s : B_j) \mid j = 1, 2, \dots\}, D, s, G_0, t_0)\}$ succeeds with $\Theta'_s = \Theta\Theta_1$ and $D = G \vee FG$ and $E = A$.

4*. **Second configuration rule for F :**

For some $\mathbf{S}(\rho, <, \Delta, FG, t, G_0, t_0)$ and some $\Box(A \rightarrow F \wedge_j B_j) \in \Delta$ and some $\Theta_1 \Theta_2$ we have both cases 4a and 4b above true with $E = A \vee FA$ and $D = G \vee FG$.

4* **general** Similar to (4 **general**) for the case of general flow.

5. This is the the mirror image of 3 with ' PG ' replacing ' FG ' and ' $s < t$ ' replacing ' $t < s$ '.

6; 6* This is the mirror image of 4 and 4* with ' PG ' replacing ' FG ', ' $s < t$ ' replacing ' $t < s$ ' and 'past configuration' replacing 'future configuration'.

6 **general** This is the image of 4 **general**.

We now give the computation rules 7-10 for \bigcirc and \bullet for orderings in which a next point and/or previous points exist. If $t \in T$ has a next point we denote this point by $s = \bigcirc t$. If it has a previous point we denote it by $s = \bullet t$. For example, if $(T, <)$ is the integers then $\bigcirc t = t + 1$ and $\bullet t = t - 1$. If $(T, <)$ is a tree then $\bullet t$ always exists, except at the root, but $\bigcirc t$ may or may not exist. For the sake of simplicity we must assume that if we have \bigcirc or \bullet in the language then $\bigcirc t$ or $\bullet t$ always exist. Otherwise we can sneak negation in by putting $(t : \bigcirc A) \in \Delta$ when $\bigcirc t$ does not exist!

7. **Immediate rule for \bigcirc :**

$\mathbf{S}(\rho, <, \Delta, \bigcirc G, t, G_0, t_0) \in \mathbf{\Pi}$ and $\bigcirc t$ exists and $\bigcirc t \in \rho$ and $\Theta' = \Theta$ and $\mathbf{\Pi}' = (\mathbf{\Pi} - \{\mathbf{S}(\rho, <, \Delta, \bigcirc G, t, G_0, t_0)\}) \cup \{\mathbf{S}(\rho, <, \Delta, G, \bigcirc t, G_0, t_0)\}$.

8. **Configuration rule for \bigcirc :**

$\mathbf{S}(\rho, <, \Delta, \bigcirc G, t, G_0, t_0) \in \mathbf{\Pi}$ and for some Θ_1, Θ_2 some $(t : A \rightarrow \bigcirc \wedge_j B_j) \in \Delta$ and $\mathbf{\Pi}' = (\mathbf{\Pi} - \{\mathbf{S}(\rho, <, \Delta, \bigcirc G, t, G_0, t_0)\}) \cup \{\mathbf{S}(\rho, <, \Delta, A\Theta_1, t, G_0, t_0)\} \cup \{\mathbf{S}(\rho \cup \{\bigcirc t\}, <', \Delta \cup \{(\bigcirc t : B_j)\}, G, \bigcirc t, G_0, t_0)\}$ succeeds with $\Theta' = \Theta\Theta_2$, and $<'$ is the appropriate ordering closure of $< \cup \{(t, \bigcirc t)\}$.

Notice that case 8 is parallel to case 4. We do not need 8a and 8b because of $\bigcirc t \in \rho$; then what would be case 8b becomes 7.

9. The mirror image of 7 with ' \bullet ' replacing ' \bigcirc '.

10. The mirror image of 8 with ' \bullet ' replacing ' \bigcirc '.

11. **Negation as failure rule:**

$\mathbf{S}(\rho, <, \Delta, \neg G, t, G_0, t_0) \in \mathbf{\Pi}$ and Θ grounds every type 2 variable and the computation for success of $\mathbf{S}(\rho, <, \Delta, G, t, \Theta)$ ends up in failure.

12. **Disjunction rule:**

$\mathbf{S}(\rho, <, \Delta, G_1 \vee G_2, t, G_0, t_0) \in \mathbf{\Pi}$ and $\mathbf{\Pi}' = (\mathbf{\Pi} - \{\mathbf{S}(\rho, <, \Delta, G_1 \vee G_2, t, G_0, t_0)\}) \cup \{\mathbf{S}(\rho, <, \Delta, G_i, t, G_0, t_0) \mid i \in \{1, 2\}\}$ and $\Theta' = \Theta$ and $i \in \{1, 2\}$.

13. **Conjunction rule:**

$\mathbf{S}(\rho, <, \Delta, G_1 \wedge G_2, t, G_0, t_0) \in \mathbf{\Pi}$ and $\mathbf{\Pi}' = (\mathbf{\Pi} - \{\mathbf{S}(\rho, <, \Delta, G_1 \wedge G_2, t, G_0, t_0)\}) \cup \{\mathbf{S}(\rho, <, \Delta, G_i, t, G_0, t_0) \mid i \in \{1, 2\}\}$.

14. **Restart rule:**

$\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0) \in \mathbf{\Pi}$ and $\mathbf{\Pi}' = (\mathbf{\Pi} - \{\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0)\}) \cup \{\mathbf{S}(\rho, <, \Delta, G_1, t_0, G_0, t_0)\}$ where G_1 is obtained from G_0 by substituting completely new type 2 variables u'_i for the type 2 variables u_i of G_0 , and where Θ' extends Θ by giving $\Theta'(u'_i) = u'_i$ for the new variables u'_i .

15. **To start the computation:**

Given Δ and $t_0 : G_0$ and a flow $(T, <)$, we start the computation with $\mathbf{\Pi} = \{\mathbf{S}(\rho, <, \Delta, G_0, t_0, G_0, t_0)\}$, where $(\rho, <)$ is the configuration associated with Δ , over $(T, <)$ (Definition 75).

Let us check some examples.

EXAMPLE 78.

Data:

1. $t : a \rightarrow Fb$
2. $\Box(b \rightarrow Fc)$
3. $t : a$.

Query: $?t : Fc$

Configuration: $\{t\}$

Using rule 4* we create a future s with $t < s$ and ask the two queries (the notation $A?B$ means that we add A to the data 1, 2, 3 and ask $?B$).

4. $?t : C \vee Fb$
and

5. $s : c?s : c \vee Fc$

5 succeeds and 4 splits into two queries by rule 4.

6. $?t : a$
and
7. $s' : b?s' : b$.

EXAMPLE 79.

Data:

1 $t : FA$

2 $t : FB$

Query: $t : F\varphi$ where $\varphi = (A \wedge B) \vee (A \wedge FB) \vee (B \wedge FA)$.

The query will fail in any flow of time in which the future is not linear. The purpose of this example is to examine what happens when time is linear. Using 1 we introduce a point s , with $s : A$, and query from s the following:

$?s : \varphi \vee F\varphi$

If we do not use the restart rule, the query will fail. Now that we are at a point s there is no way to go back to t . We therefore cannot reason that we also have a point $s' : B$ and $t < s$ and $t < s'$ and that because of linearity $s = s'$ or $s < s'$ or $s' < s$. However, if we are allowed to restart, we can continue and ask $t : F\varphi$ and now use the clause $t : FB$ to introduce s' . We now reason using linearity in rule 4 that the configurations are:

$t < s < s'$
or $t < s' < s$
or $t < s = s'$

and φ succeeds at t for each configuration.

The reader should note the reason for the need to use the restart rule. When time is just a partial order, the two assumptions $t : FA$ and $t : FB$ do not interact. Thus when asking $t : FC$, we know that there are two points $s_1 : A$ and $s_2 : B$; see Fig. 7.

C can be true in either one of them. $s_1 : A$ has no influence on $s_2 : B$. When conditions on time (such as linearity) are introduced, s_1 does influence s_2 and hence we must introduce both at the same time. When one does forward deduction one can introduce both s_1 and s_2 going forward. The backward rules do not allow for that. That is why we need the restart rule. When we restart, we keep all that has been done (with, for example, s_1) and have the opportunity to restart with s_2 . The restart rule can be used to solve the linearity problem for classical logic only. Its side-effect is that it turns intuitionistic logic into classical logic; see Gabbay's paper on *N-Prolog* [Gabbay, 1985] and [Gabbay and Olivetti, 2000]. In theorem

Figure 7.

proving based on intuitionistic logic where disjunctions are allowed, forward reasoning cannot be avoided. See the next example.

It is instructive to translate the above into Prolog and see what happens there.

EXAMPLE 80.

1. $t : FA$ translates into $(\exists s_1 > t)A^*(s_1)$.

2. $t : FB$ translates into $(\exists s_2 > t)A^*(s_2)$.

The query translates into the formula $\psi(t)$:

$$\psi = \exists s > t[A^*(s) \wedge B^*(s)] \vee \exists s_1 > t[A^*(s_1) \wedge \exists s_2 > s_1 B^*(s_2)] \vee \exists s_2 > t[B^*(s_2) \wedge \exists s_1 > s_2 A^*(s_2)]$$

which is equivalent to the disjunction of:

(a) $[t < s \wedge A^*(s) \wedge B^*(s)];$

(b) $t < s_1 \wedge s_1 < s_2 \wedge A^*(s_1) \wedge B^*(s_2);$

(c) $t < s_1 \wedge s_2 < s_1 \wedge A^*(s_1) \wedge B^*(s_2).$

All of (a), (b), (c) fail from the data, unless we add to the data the disjunction

$$\forall xy(x < y \vee x = y \vee y < x).$$

Since this is not a Horn clause, we are unable to express it in the database.

The logic programmer might add this as an integrity constraint. This is wrong as well. As an integrity constraint it would require the database to indicate which of the three possibilities it adopts, namely:

- $x < y$ is in the data;
- or $x = y$ is in the data;
- or $y < x$ is in the data.

This is stronger than allowing the disjunction in the data.

The handling of the integrity constraints corresponds to our metahandling of what configurations $(\rho, <)$ are allowed depending on the ordering of time. By labelling data items we are allowing for the metalevel considerations to be done separately on the labels.

This means that we can handle properties of time which are not necessarily expressible by an object language formula of the logic. In some cases (finiteness of time) this is because they are not first order; in other cases (irreflexivity) it is because there is no corresponding formula (axiom) and in still other cases because of syntactical restrictions (linearity).

We can now make clear our classical versus intuitionistic distinction. If the underlying logic is classical then we are checking whether $\Delta \vdash \psi$ in classical logic. If our underlying logic is intuitionistic, then we are checking whether $\Delta \vdash \psi$ in intuitionistic logic where Δ and ψ are defined below.

Δ is the translation of the data together with the axioms for linear ordering, i.e. the conjunction of:

1. $\exists s_1 > tA^*(s_1)$;
2. $\exists s_2 > tB^*(s_2)$;
3. $\forall xy(x < y \vee x = y \vee y < x)$;
4. $\forall x\exists y(x < y)$;
5. $\forall x\exists y(y < x)$;
6. $\forall xyz(x < y \wedge y < z \rightarrow x < z)$;
7. $\forall x\neg(x < x)$.

ψ is the translation of the query as given above.

The computation of Example 79, using restart, answers the question $\Delta \vdash ?\psi$ in classical logic. To answer the question $\Delta \vdash ?\psi$ in intuitionistic logic we cannot use restart, but must use forward rules as well.

EXAMPLE 81. See Example 79 for the case that the underlying logic is intuitionistic. *Data* and *Query* as in Example 79.

Going forward, we get:

- 3 $s : A$ from 1;
- 4 $s' : B$ from 2.

By linearity,

$$t < s < s'$$

or $t < s' < s$

or $t < s = s'$.

ψ will succeed for each case.

Our language does not allow us to ask queries of the form $\Box G(x)$, where x are all universal variables (i.e. $\forall x \Box G(x)$). However, such queries can be computed from a database Δ . The *only* way to get *always* information out of Δ for a general flow of time is via the always clauses in the database. Always clauses are true everywhere, so if we want to know what else is true everywhere, we ask it from the always clauses. Thus to ask

$?\Box G(x)$, x a universal variable

we first Skolemize and then ask

$\{X, \Box X \mid \Box X \in \Delta\} ? G(c)$

where c is a Skolem constant.

We can add a new rule to Definition 76:

16. **Always rule:**

$\mathbf{S}(\rho, <, \Delta, \Box G, t, G_0, t_0) \in \mathbf{\Pi}$ and

$\mathbf{\Pi}' = (\mathbf{\Pi} - \{\mathbf{S}(\rho, <, \Delta, \Box G, t, G_0, t_0)\}) \cup \{\mathbf{S}(\{s\}, \emptyset, \Delta', G', s, g', s)\}$

where s is a completely new point and G' is obtained from G by substituting new Skolem constants for all the universal variables of G and

$$\Delta' = \{B, \Box B \mid \Box B \in \Delta\}.$$

We can use 16 to add another clause to the computation of Definition 76, namely:

17. $\mathbf{S}(\rho, <, \Delta, F(A \wedge B), t, G_0, t_0) \in \mathbf{\Pi}$

and $\mathbf{\Pi}' = (\mathbf{\Pi} - \{\mathbf{S}(\rho, <, \Delta, F(A \wedge B), t, G_0, t_0)\}) \cup \{\mathbf{S}(\rho, <, \Delta, FA, t, G_0, t_0), \mathbf{S}(\rho, <, \Delta, \Box B, t, G_0, t_0)\}$.

EXAMPLE 82.

Data	Query	Configuration
$\Box a$	$t : F(a \wedge b)$	$\{t\}$
$t : Fb$		

First computation

Create $s, t < s$ and get

Data	Query	Configuration
$\Box a$	$s : a \wedge b$	$t < s$
$t : Fb$		
$s : b$		

$s : b$ succeeds from the data. $s : a$ succeeds by rule 2, Definition 76.

Second computation

Use rule 17. Since $?\Box a$ succeeds ask for Fb and proceed as in the first computation.

6.3 Different flows of time

We now check the effect of different flows of time on our logical deduction (computation). We consider a typical example.

EXAMPLE 83.

Data	Query	Configuration
$t : FFA$	$?t : FA$	$\{t\}$

The possible world flow is a general binary relation.

We create by rule 4b of Definition 76 a future configuration $t < s$ and add to the database $s : FA$. We get

Data	Query	Configuration
$t : FFA$	$?t : FA$	$t < s$
$s : FA$		

Again we apply rule 4a of Definition 76 and get the new configuration with $s < s'$ and the new item of data $s' : A$. We get

Data	Query	Configuration
$t : FFA$	$?t : FA$	$t < s$
$s : FA$		$s < s'$
$s' : A$		

Whether or not we can proceed from here depends on the flow of time. If $<$ is transitive, then $t < s'$ holds and we can get $t : FA$ in the data by rule 3.

Actually by rule 4* we could have proceeded along the following sequence of deduction. Rule 4* is especially geared for transitivity.

Data	Query	Configuration
$t : FFA$	$t : FA$	t

Using rule 4* we get

Data	Query	Configuration
$t : FFA$	$s : FA \vee FFA$	$t < s$
$s : FA$		

The first disjunct of the query succeeds.

If $<$ is not transitive, rule 3 does not apply, since $t < s'$ does not hold.

Suppose our query were $?t : FFA$.

If $<$ is reflexive then we can succeed with $?t : FFA$ because $t < t$.

If $<$ is dense (i.e. $\forall xy(x < y \rightarrow \exists z(x < z \wedge z < y))$) we should also succeed because we can create a point z with $t < z < s$.

$z : FFA$ will succeed and hence $t : FFA$ will also succeed.

Here we encounter a new rule (density rule), whereby points can always be ‘landed’ between existing points in a configuration.

We now address the flow of time of the type natural numbers, $\{1, 2, 3, 4, \dots\}$. This has the special property that it is generated by a function symbol \mathbf{s} :

$$\{1, \mathbf{s}(1), \mathbf{ss}(1), \dots\}.$$

EXAMPLE 84.

Data	Query	Configuration
$\Box(q \rightarrow \bigcirc q)$ $1 : \bigcirc q$ $1 : Fp$	$1 : F(p \wedge q)$	$\{1\}$

If time is the natural numbers, the query should succeed from the data. If time is not the natural numbers but, for example, $\{1, 2, 3, \dots, w, w+1, w+2, \dots\}$ then the query should fail.

How do we represent the fact that time is the natural numbers in our computation rule? What is needed is the ability to do some induction. We can use rule 4b and introduce a point t with $1 < t$ into the configuration and even say that $t = n$, for some n . We thus get

Data	Query	Configuration
$\Box(q \rightarrow \bigcirc q)$ $1 : \bigcirc q$ $1 : Fp$ $n : p$	$1 : F(p \wedge q)$	$1 < n$

Somehow we want to derive $n : q$ from the first two assumptions. The key reason for the success of $F(p \wedge q)$ is the success of $\Box q$ from the first two assumptions. We need an induction axiom on the flow of time.

To get a clue as to what to do, let us see what Prolog would do with the translations of the data and goal.

Translated data

$$\begin{aligned} &\forall t[1 \leq t \wedge Q^*(t) \rightarrow Q^*(t+1)] \\ &Q^*(1) \\ &\exists tP^*(t). \end{aligned}$$

Translated query

$$\exists t(P^*(t) \wedge Q^*(t)).$$

After we Skolemize, the database becomes:

1. $1 \leq t \wedge Q^*(t) \rightarrow Q^*(t+1)$
2. $Q^*(1)$
3. $P^*(c)$

and the query is

$$P^*(s) \wedge Q^*(s).$$

We proceed by letting $s = c$. We ask $Q^*(c)$ and have to ask after a slightly generalized form of unification $?1 \leq c \wedge Q^*(c-1)$.

Obviously this will lead nowhere without an induction axiom. The induction axiom should be that for *any* predicate $PRED$

$$PRED(1) \wedge \forall x[1 \leq x \wedge PRED(x) \rightarrow PRED(x+1)] \rightarrow \forall x PRED(x).$$

Written in Horn clause form this becomes

$$\begin{aligned} \exists x \forall y [& PRED(1) \wedge [1 \leq x \wedge PRED(x) \\ & \rightarrow PRED(x+1)] \rightarrow PRED(y)]. \end{aligned}$$

Skolemizing gives us

$$4. PRED(1) \wedge (1 \leq d \wedge PRED(d) \rightarrow PRED(d+1)) \rightarrow PRED(y)$$

where d is a Skolem constant.

Let us now ask the query $P^*(s) \wedge Q^*(s)$ from the database with 1–4. We unify with clause 3 and ask $Q^*(c)$. We unify with clause 4 and ask $Q^*(1)$ which succeeds and ask for the implication

$$?1 \leq d \wedge Q^*(d) \rightarrow Q^*(d+1).$$

This should succeed since it is a special case of clause 1 for $t = d$.

The above shows that we need to add an induction axiom of the form

$$\bigcirc x \wedge \square(x \rightarrow \bigcirc x) \rightarrow \square x.$$

Imagine that we are at time t , and assume $t' < t$. If A is true at t' and $\square(A \rightarrow \bigcirc A)$ is true, then A is true at t .

We thus need the following rule:

18. Induction rule:

$t : F(A \wedge B)$ succeeds from Δ at a certain configuration if the following conditions all hold.

1. $t : FB$ succeed.
2. For some $s < t, s : A$ succeeds.

3. $m : \bigcirc A$ succeeds from the database Δ' , where $\Delta' = \{X, \square X \mid \square X \in \Delta\} \cup \{A\}$ and m is a completely new time point and the new configuration is $\{m\}$.

The above shows how to compute when time is the natural number. This is not the best way of doing it. In fact, the characteristic feature involved here is that the ordering of the flow of time is a Herbrand universe generated by a finite set of function symbols. FA is read as ‘ A is true at a point generated by the function symbols’. This property requires a special study. See Chapter 11 of [Gabbay *et al.*, 1994].

6.4 A theorem prover for modal and temporal logics

This section will briefly indicate how our temporal Horn clause computation can be extended to an automated deduction system for full modal and temporal logic. We present computation rules for propositional temporal logic with $F, P, \bigcirc, \bullet, \wedge \rightarrow$ and \perp . We intend to approach predicate logic in Volume 3 as it is relatively complex. The presentation will be intuitive.

DEFINITION 85. We define the notions of a *full clause*, a *body* and a *head*.

- (a) A *full clause* is an atom q or \perp or $B \rightarrow H$, or H where B is a body and H is a head.
- (b) A *body* is a conjunction of full clauses.
- (c) A *head* is an atom q or \perp or FH or PH or $\bigcirc H$ or $\bullet H$, where H is a body.

Notice that negation by failure is not allowed. We used the connectives $\wedge, \rightarrow, \perp$. The other connectives, \vee and \sim , are definable in the usual way: $\sim A = A \rightarrow \perp$ and $A \vee B = (A \rightarrow \perp) \rightarrow B$. The reader can show that every formula of the language with the connectives $\{\sim, \wedge, \vee, F, G, P, H\}$ is equivalent to a conjunction of full clauses. We use the following equivalences:

$$A \rightarrow (B \wedge C) = (A \rightarrow B) \wedge (A \rightarrow C);$$

$$A \rightarrow (B \rightarrow C) = A \wedge B \rightarrow C;$$

$$GA = F(A \rightarrow \perp) \rightarrow \perp;$$

$$HA = P(A \rightarrow \perp) \rightarrow \perp.$$

DEFINITION 86. A database is a set of labelled full clauses of the form $(\Delta, \rho, <)$, where $\rho = \{t \mid t : A \in \Delta, \text{ for some } A\}$. A query is a labelled full clause.

DEFINITION 87. The following is a definition of the predicate $\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0)$, which reads: the labelled goal $t : G$ succeeds from $(\Delta, \rho, <)$ with parameter (initial goal) $t_0 : G_0$.

- 1(a) $\mathbf{S}(\rho, <, \Delta, q, t, G_0, t_0)$ for q atomic or \perp if for some $t : A \rightarrow q$, $\mathbf{S}(\rho, <, \Delta, A, t, G_0, t_0)$.
- (b) If $t : q \in \Delta$ or $s : \perp \in \Delta$ then $\mathbf{S}(\rho, <, \Delta, q, t, G_0, t_0)$.
- (c) $\mathbf{S}(\rho, <, \Delta, \perp, t, G_0, t_0)$ if $\mathbf{S}(\rho, <, \Delta, \perp, s, G_0, t_0)$.
This rule says that if we can get a contradiction from any label, it is considered a contradiction of the whole system.
2. $\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0)$ if for some $s : A \rightarrow \perp$, $\mathbf{S}(\rho, <, \Delta, A, s, G_0, t_0)$.
3. $\mathbf{S}(\rho, <, \Delta, t, FG, G_0, t_0)$ if for some $s \in \rho, t < s$ and $\mathbf{S}(\rho, <, \Delta, G, s, G_0, t_0)$.
4. $\mathbf{S}(\rho, <, \Delta, FG, t, G_0, t_0)$ if for some $t : A \rightarrow FB \in \Delta$ we have that both (a) and (b) below hold true:
- (a) For all $s \in \rho$ such that $t < s$ we have $\mathbf{S}(\rho, <, \Delta^*, s, D, G_0, t_0)$ and $\mathbf{S}(\rho, <, \Delta, E, t, G_0, t_0)$ hold, where $\Delta^* = \Delta \cup \{s : B\}$ and $D \in \{G, FG\}$ and $E \in \{A, FA\}$.
Note: The choice of D and E is made here for the case of transitive time. In modal logic, where $<$ is not necessarily transitive, we take $D = G, E = A$. Other conditions on $<$ correspond to different choices of D and E .
- (b) For all future configurations of $(\rho, <, t)$ with a new letter s , denoted by $(\rho_s, <_s)$, we have $\mathbf{S}(\rho_s, <_s, \Delta^*, s, D, G_0, t_0)$ and $\mathbf{S}(\rho_s, <_s, \Delta, E, t, G_0, t_0)$ hold, where Δ^*, E, D are as in (a).
5. This is the mirror image of 3.
6. This is the mirror image of 4.
- 7(a) $\mathbf{S}(\rho, <, \Delta, A_1 \wedge A_2, t, G_0, t_0)$ if both $\mathbf{S}(\rho, <, \Delta, A_i, t, G_0, t_0)$ hold for $i = 1, 2$.
- (b) $\mathbf{S}(\rho, <, \Delta, A \rightarrow B, t, G_0, t_0)$ if $\mathbf{S}(\rho, <, \Delta \cup \{t : A\}, B, t, G_0, t_0)$.
8. **Restart rule:**
 $\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0)$ if $\mathbf{S}(\rho, <, \Delta, G_0, t_0, G_0, t_0)$.

If the language contains \bigcirc and \bullet then the following are the relevant rules.

9. $\mathbf{S}(\rho, <, \Delta, \bigcirc G, t, G_0, t_0)$ if $\bigcirc t$ exists and $\bigcirc t \in \rho$ and $\mathbf{S}(\rho, <, \Delta, G, \bigcirc t, G_0, t_0)$.
10. $\mathbf{S}(\rho, <, \Delta, \bigcirc G, t, G_0, t_0)$ if for some $t : A \rightarrow \bigcirc B \in \Delta$ both $\mathbf{S}(\rho, <, \Delta, A, t, G_0, t_0)$ and $\mathbf{S}(\rho \cup \{\bigcirc t\}, <', \Delta \cup \{\bigcirc t : B\}, G, \bigcirc t, G_0, t_0)$ hold where $<'$ is the appropriate ordering closure of $< \cup \{t < \bigcirc t\}$.

11. This is the mirror image of 9 for \bullet .
12. This is the mirror image of 10 for \bullet .

EXAMPLE 88. (Here \square can be either G or H .)

	Data	Query	Configuration
1.	$t : \square a$	$?t : \square b$	$\{t\}$
2.	$t : \square(a \rightarrow b)$		t is a constant

Translation:

	Data	Query	Configuration
1.	$t : F(a \rightarrow \perp) \rightarrow \perp$	$t : F(b \rightarrow \perp) \rightarrow \perp$	$\{t\}$
2.	$t : F((a \rightarrow b) \rightarrow \perp) \rightarrow \perp$		

Computation

The problem becomes

	Additional data	Current query	Configuration
3.	$t : F(b \rightarrow \perp)$	$?t : \perp$	$\{t\}$
from 2		$?t_0 : F((a \rightarrow b) \rightarrow \perp)$	

From 3 using $**$ create a new point s :

	Additional data	Current query	Configuration
4.	$s : b \rightarrow \perp$	$?s : (a \rightarrow b) \rightarrow \perp$	$t < s$
	Add $s : a \rightarrow b$ to the database and ask		
5.	$s : (a \rightarrow b)$	$?s : \perp$	

From 4 and 5 we ask:

$$?s : a.$$

From computation rule 2 and clause 1 of the data we ask

$$?t : F(a \rightarrow \perp).$$

From computation rule 2 we ask

$$?s : a \rightarrow \perp$$

We add $s : a$ to the data and ask

	Additional data	Current query	Configuration
6.	$s : a$	$?s : \perp$	$t < s$

The query succeeds.

6.5 Modal and temporal Herbrand universes

This section deals with the soundness of our computation rules. In conjunction with soundness it is useful to clarify the notion of modal and temporal Herbrand models. For simplicity we deal with temporal logic with P, F only and transitive irreflexive time or with modal logic with one modality \Diamond and a general binary accessibility relation $<$. We get our clues from some examples:

EXAMPLE 89. Consider the database

1. $t : a \rightarrow \Diamond b$
2. $\Box(b \rightarrow c)$
3. $t : a.$

The constellation is $\{t\}$.

If we translate the clauses into predicate logic we get:

1. $a^*(t) \rightarrow \exists s > tb^*(s)$
2. $\forall x[b^*(x) \rightarrow c^*(x)]$
3. $a^*(t).$

Translated into Horn clauses we get after Skolemising:

- 1.1 $a^*(t) \rightarrow b^*(s)$
- 1.2 $a^*(t) \rightarrow t < s$
- 2 $b^*(x) \rightarrow c^*(x)$
- 3 $a^*(t).$

t, s are Skolem constants.

From this program, the queries

$$a^*(t), \neg b^*(t), \neg c^*(t), \neg a(s), b(s), c^*(s)$$

all succeed. \neg is negation by failure.

It is easy to recognize that $\neg a^*(s)$ succeeds because there is no head which unifies with $a^*(s)$. The meaning of the query $\neg a^*(s)$ in terms of modalities is the query $\Diamond \neg a$.

The question is: how do we recognize syntactically what fails in the modal language? The heads of clauses can be whole databases and there is no immediate way of syntactically recognizing which atoms are not heads of clauses.

EXAMPLE 90. We consider a more complex example:

1. $t : a \rightarrow \Diamond b$
2. $\Box(b \rightarrow c)$
3. $t : a$
4. $t : a \rightarrow \Diamond d$.

We have added clause 4 to the database in the previous example. The translation of the first three clauses will proceed as before. We will get

- 1.1 $a^*(t) \rightarrow c^*(s)$
- 1.2 $a^*(t) \rightarrow t < s$
- 2 $b^*(x) \rightarrow c^*(x)$
- 3 $a^*(t)$.

We are now ready to translate clause 4. This should be translated like clause 1 into

- 4.1 $a^*(t) \rightarrow d^*(r)$
- 4.2 $a^*(t) \rightarrow t < r$.

The above translation is correct if the set of possible worlds is just an ordering. Suppose we know further that in our modal logic the set of possible worlds is linearly ordered. Since $t < s \wedge t < r \rightarrow s = r \vee s < r \vee r < s$, this fact must be reflected in the Horn clause database. The only way to do it is to add it as an integrity constraint.

Thus our temporal program translates into a Horn clause program with integrity constraints.

This will be true in the general case. Whether we need integrity constraints or not will depend on the flow of time.

Let us begin by translating from the modal and temporal language into Horn clauses. The labelled wff $t : A$ will be translated into a set of formulae of predicate logic denoted by $Horn(t, A)$. $Horn(t, A)$ is supposed to be logically equivalent to A . The basic translation of a labelled atomic predicate formula $t : A(x_1 \dots x_n)$ is $A^*(t, x_1 \dots x_n)$. A^* is a formula of a two-sorted predicate logic where the first sort ranges over labels and the second sort over domain elements (of the world t).

DEFINITION 91. Consider a temporal predicate language with connectives P and F , and \neg for negation by failure.

Consider the notion of labelled temporal clauses, as defined in Definition 73.

Let $Horn(t, A)$ be a translation function associating with each labelled clause or goal a set of Horn clauses in the two-sorted language described above. The letters t, s which appear in the translation are Skolem constants. They are assumed to be *all different*.

We assume that we are dealing with a general transitive flow of time. This is to simplify the translation. If time has extra conditions, i.e. linearity, additional integrity constraints may need to be added. If time is characterized by non-first-order conditions (e.g. finiteness) then an adequate translation into Horn clause logic may not be possible.

The following are the translation clauses:

1. $Horn(t, A(x_1 \dots x_n)) = A^*(t, x_1 \dots x_n)$, for A atomic;
2. $Horn(t, FA) = \{t < s\} \cup Horn(s, A)$
 $Horn(t, PA) = \{s < t\} \cup Horn(s, A)$;
3. $Horn(t, A \wedge B) = Horn(t, A) \cup Horn(t, B)$;
4. $Horn(t, \neg A) = \neg \bigwedge Horn(t, A)$;
5. $Horn(t, A \rightarrow F \wedge B_j) = \{\bigwedge Horn(t, A) \rightarrow t < s\} \cup \bigcup_{B_j} \{\bigwedge Horn(s, A) \wedge C \rightarrow D \mid (C \rightarrow D) \in Horn(s, B_j)\}$;
6. $Horn(t, A \rightarrow P \wedge B_j) = \{\bigwedge Horn(t, A) \rightarrow s < t\} \cup \bigcup_{B_j} \{\bigwedge Horn(s, A) \wedge C \rightarrow D \mid (C \rightarrow D) \in Horn(s, B_j)\}$;
7. $Horn(t, \Box A) = Horn(x, A)$ where x is a universal variable.

EXAMPLE 92. To explain the translation of $t : A \rightarrow F(B_1 \wedge (B_2 \rightarrow B_3))$, let us write it in predicate logic. $A \rightarrow F(B_1 \wedge (B_2 \rightarrow B_3))$ is true at t if A true at t implies $F(B_1 \wedge (B_2 \rightarrow B_3))$ is true at t . $F(B_1 \wedge (B_2 \rightarrow B_3))$ is true at t if for some s , $t < s$ and $B_1 \wedge (B_2 \rightarrow B_3)$ are true at s .

Thus we have the translation

$$A^*(t) \rightarrow \exists s(t < s \wedge B_1^*(s) \wedge (B_2^*(s) \rightarrow B_3^*(s))).$$

Skolemizing on s and writing it in Horn clauses we get the conjunction

$$\begin{aligned} A^*(t) &\rightarrow t < s \\ A^*(t) &\rightarrow B_1^*(s) \\ A^*(t) \wedge B_2^*(s) &\rightarrow B_3^*(s). \end{aligned}$$

Let us see what the translation $Horn$ does:

$$\begin{aligned} Horn(t, A \rightarrow F(B_1 \wedge (B_2 \rightarrow B_3))) &= \{\bigwedge Horn(t, A) \rightarrow t < s\} \cup \\ &\{\bigwedge Horn(t, A) \rightarrow Horn(s, B_2)\} \cup \{\bigwedge Horn(t, A) \wedge \bigwedge Horn(s, B_2) \rightarrow \\ &\bigwedge Horn(s, B_3)\} = \{A^*(t) \rightarrow t < s, A^*(t) \rightarrow B_2^*(s), A^*(t) \wedge B_2^*(s) \rightarrow B_3^*(s)\}. \end{aligned}$$

We prove soundness of the computation of Definition 76, relative to the Horn clause computation for the Horn database in classical logic. In other words, if the translation $Horn(t, A)$ is accepted as sound, as is intuitively clear, then the computation of $\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0, \Theta)$ can be translated isomorphically into a classical Horn clause computation of the form $Horn(t, \Delta)?Horn(t, G)$, and the soundness of the classical Horn clause computation would imply the soundness of our computation.

This method of translation will also relate our temporal computation to that of an ordinary Horn clause computation.

The basic unit of our temporal computation is $\mathbf{S}(\rho, <, \Delta, G, t, G_0, t_0, \Theta)$. The current labelled goal is $t : G$ and $t_0 : G_0$ is the original goal. The database is $(\rho, <, \Delta)$ and Θ is the current substitution. $t_0 : G_0$ is used in the restart rule. For a temporal flow of time which is ordinary transitive $<$, we do not need the restart rule. Thus we have to translate $(\rho, <, \Delta)$ to classical logic and translates $t : G$ and Θ to classical logic and see what each computation step of \mathbf{S} of the source translates into the classical logic target.

DEFINITION 93. Let $(\rho, <)$ be a constellation and let Δ be a labelled database such that

$$\rho = \{t \mid \text{for some } A, t : A \in \Delta\}.$$

Let $Horn((\rho, <), \Delta) = \{t < s \mid t, s \in \rho \text{ and } t < s\} \cup \bigcup_{t:A \in \Delta} Horn(t, A)$.

THEOREM 94 (Soundness). $\mathbf{S}(\rho, <, \Delta, G, t, \Theta)$ *succeeds in temporal logic if and only if in the sorted classical logic $Horn((\rho, <), \Delta)?Horn(t, G)$ succeeds with Θ .*

Proof. The proof is by induction on the complexity of the computation tree of $\mathbf{S}(\rho, <, \Delta, G, t, \Theta)$.

We follow the inductive steps of Definition 75. The translation of $(\mathbf{\Pi}, \Theta)$ is a conjunction of Horn clause queries, all required to succeed under the same substitution Θ .

Case I The empty goal succeeds in both cases.

Case II $(\mathbf{\Pi}, \Theta)$ fails if for some $\mathbf{S}(\rho, <, \Delta, G, t)$, we have G is atomic and for all $\square(A \rightarrow H) \in \Delta$ and all $t : A \rightarrow H \in \Delta$, $G\Theta$ and $H\Theta$ do not unify. The reason they do not unify is because of what Θ substitutes to the variables u_i .

The corresponding Horn clause predicate programs are

$$\bigwedge Horn(x, A) \rightarrow H^*(x)$$

and

$$\bigwedge Horn(t, A) \rightarrow H^*(t)$$

and the goal is $?G^*(t)$.

Clearly, since x is a general universal variable, the success of the two-sorted unification depends on the other variables and Θ . Thus unification does *not* succeed in the classical predicate case iff it does not succeed in the temporal case.

Rules 1 and 2 deal with the atomic case: the query is $G^*(t)$ and in the database among the data are

$$\bigwedge \text{Horn}(t, A) \rightarrow H^*(t) \text{ and } \bigwedge \text{Horn}(x, A) \rightarrow H^*(x)$$

for the cases of $t : A \rightarrow H$ and $\Box(A \rightarrow H)$ respectively.

For the Horn clause program to succeed $G^*(t)$ must unify with $H^*(t)$. This will hold if and only if the substitution for the domain variables allows unification, which is exactly the condition of Definition 75.

Rules 3, 4(general) and 4*(general) deal with the case of a goal of the form $?t : FG$. The translation of the goal is $t < u \wedge \bigwedge \text{Horn}(u, G)$ where u is an existential variable.

Rule 3 gives success when for some $s, t < s \in \Delta$ and $?s : G$ succeeds. In this case let $u = s$; then $t < u$ succeeds and $\bigwedge \text{Horn}(s, G)$ succeeds by the induction hypothesis.

We now turn to the general rules 4(general) and 4*(general). These rules yield success when for some clause of the form

$$t : A \rightarrow F \wedge B_j$$

or

$$\Box(A \rightarrow F \wedge B_j).$$

$\Delta?t : A$ succeeds and $\Delta \cup \{(s : B_j)\} ?s : G \vee FG$ both succeed. s is a new point.

The translation $\bigwedge \text{Horn}(t, A)$ succeeds by the induction hypothesis.

The translation of

$$t : A \rightarrow F \wedge B_j$$

or

$$\Box(A \rightarrow F \wedge B_j)$$

contains the following database:

1. $\bigwedge \text{Horn}(t, A) \rightarrow t < s$.
2. For every B_j and every $C \rightarrow D$ in $\text{Horn}(s, B_j)$ the clause $\bigwedge \text{Horn}(s, A) \wedge C \rightarrow D$.

Since $\bigwedge \text{Horn}(t, A)$ succeeds we can assume we have in our database:

$$1^* t < s;$$

2* $C \rightarrow D$, for $C \rightarrow D \in \text{Horn}(s, B_j)$ for some j .

These were obtained by substituting *truth* in 1 and 2 for $\bigwedge \text{Horn}(t, A)$.

The goal is to show $t < u \wedge \bigwedge \text{Horn}(u, G)$.

Again for $u = s$, $t < u$ succeeds from (1*) and by the induction hypothesis, since $\Delta \cup \{s : B_j\} ?s : G \vee FG$ is successful, we get

$$\bigcup_j \text{Horn}(s, B_j) ? \bigwedge \text{Horn}(s, G) \vee (s < u' \wedge \bigwedge \text{Horn}(u', G))$$

should succeed, with u' an existential variable.

However, 2* is exactly $\bigcup_j \text{Horn}(s, \bigwedge B_j)$. Therefore we have shown that rules 4(general) and 4*(general) are sound.

Rules 6(general) and 6*(general) are sound because they are the mirror images of 4(general) and 4*(general).

The next relevant rules for our soundness cases are 11–13. These follow immediately since the rules for \wedge, \vee, \neg are the same in both computations.

Rule 14, the restart rule, is definitely sound. If we try to show in general that $\Delta \vdash A$ then since in classical logic $\sim A \rightarrow A$ is the same as A (\sim is classical negation) it is equivalent to show $\Delta, \sim A \vdash A$.

If $\sim A$ is now in the data, we can *at any time* try to show A instead of the current goal G . This will give us A (shown) and $\sim A$ (in Data) which is a contradiction, and this yields *any goal* including the current goal G .

We have thus completed the soundness proof. \blacksquare

6.6 Tractability and persistence

We defined a temporal database Δ essentially as a finite piece of information telling us which temporal formulae are true at what times. In the most general case, for a general flow of time $(T, <)$, all a database can do is to provide a set of the form $\{t_i : A_i\}$, meaning that A_i is true at time t_i and a configuration $(\{t_i\}, <)$, giving the temporal relationships among $\{t_i\}$. A query would be of the form $?t : Q$, where t is one of the t_i . The computation of the query from the data is in the general case exponential, as we found in Section 6.2, from the case analysis of clause 4 of Definition 76 and from Example 72. We must therefore analyse the reasons for the complexity and see whether there are simplifying natural assumptions, which will make the computational problem more tractable.

There are three main components which contribute to complexity:

1. The complexity of the temporal formulae allowed in the data and in the query. We allow $t : A$ into the database, with A having temporal operators. So, for example, $t : FA$ is allowed and also $t : \bigcirc A$. $t : FA$ makes life more difficult because it has a hidden Skolem function in it. It really means $\exists s[t < s \text{ and } (s : A)]$. This gives rise to case

analysis, as we do not know in general where s is. See Example 80 and Examples 89 and 90. In this respect $t : \bigcirc A$ is a relatively simple item. It says $(t+1) : A$. In fact any temporal operator which specifies the time is relatively less complex. In practice, we do need to allow data of the form $t : FA$. Sometimes we know an event will take place in the future but we do not know when. The mere fact that A is going to be true can affect our present actions. A concrete example where such a case may arise is when someone accepts a new appointment beginning next year, but has not yet resigned from their old position. We know they are going to resign but we do not know when;

2. The flow of time itself gives rise to complexity. The flow of time may be non-Horn clause (e.g. linear time which is defined by a disjunctive axiom

$$\forall xy[x < y \vee y < x \vee x = y].$$

This complicates the case analysis of 1 above.

3. Complexity arises from the behaviour. If atomic predicates get truth values at random moments of time, the database can be complex to describe. A very natural simplifying assumption in the case of temporal logic is *persistence*. If atomic statements and their negations remain true for a while then they give rise to less complexity. Such examples are abundant. For example, people usually stay at their residences and jobs for a while. So for example, any payroll or local tax system can benefit from persistence as a simplifying assumption. Thus in databases where there is a great deal of persistence, we can use this fact to simplify our representation and querying. In fact, we shall see that a completely different approach to temporal representation can be adopted when one can make use of persistence.

Another simplifying assumption is *recurrence*. Saturdays, for example, recur every week, so are paydays. This simplifies the representation and querying. Again, a payroll system would benefit from that.

We said at the beginning that a database Δ is a finitely generated piece of temporal information stating what is true and when. If we do not have any simplifying assumptions, we have to represent Δ in the form $\Delta = \{t_i : A_i\}$ and end up needing the computation rules of Section 6.2 to answer queries.

Suppose now that we adopt all three simplifying assumptions for our database. We assume that the A_i are only atoms and their negations, we further assume that each A_i is either persistent or recurrent, and let us assume, to be realistic, that the flow of time is linear. Linearity does not make the computation more complicated in this particular case, because we are not allowing data of the form $t : FA$, and so complicated case analysis

does not arise. In fact, together with persistence and recurrence, linearity becomes an additional simplifying assumption!

Our aim is to check what form our temporal logic programming machine should take in view of our chosen simplifying assumptions.

First note that the most natural units of data are no longer of the form:

$$t : A$$

reading A is true at t , but either of the form

$$[t, s] : A, [t < s]$$

reading A is true in the closed interval $[t, s]$, or the form

$$t||d : A$$

reading A is true at t and recurrently at $t + d, t + 2d, \dots$, that is, every d moments of time.

A is assumed to be a literal (atom or a negation of an atom) and $[t, s]$ is supposed to be a maximal interval where A is true. In $t||d$, d is supposed to be the minimal cycle for A to recur. The reasons for adopting the notation $[t, s] : A$ and $t||d : A$ are not mathematical but simply intuitive and practical. This is the way we think about temporal atomic data when persistence or recurrence is present. In the literature there has been a great debate on whether to evaluate temporal statements at points or intervals. Some researchers were so committed to intervals that they tended, unfortunately, to disregard any system which uses points. Our position here is clear and intuitive. First perform all the computations using intervals. Evaluation at points is possible and trivial. To evaluate $t : A$, i.e. to ask $?t : A$ as a query from a database, compute the (maximal) intervals at which A is true and see whether t is there. To evaluate $[t, s] : A$ do the same, and check whether $[t, s]$ is a subset.

The query language is left in its full generality. i.e. we can ask queries of the form $t : A$ where A is unrestricted (e.g. $A = FB$ etc.). It makes sense also to allow queries of the form $[t, s] : A$, although exactly how we are going to find the answer remains to be seen. The reader should be aware that the data representation language and the query language are no longer the same. This is an important factor. There has been a lot of confusion, especially among the AI community, in connection with these matters. We shall see later that as far as computational tractability is concerned, the restriction to persistent data allows one to strengthen the query language to full predicate quantification over time points.

At this stage we might consider allowing recurrence within an interval, i.e. we allow something like

$$'A \text{ is true every } d \text{ days in the interval } [t, s].'$$

We can denote this by

$$[t||d, s] : A$$

meaning A is true at $t, t + d, t + 2d$, as long as $t + nd \leq s, n = 1, 2, 3, \dots$

We may as well equally have recurrent intervals. An example of that would be taking a two-week holiday every year. This we denote by

$$[t, s]||d : A, \quad t < s, \quad (s - t) < d,$$

reading A is true at the intervals $[t, s], [t + d, s + d], [t + 2d, s + 2d]$, etc.

The reader should note that adopting this notation takes us outside the realm of first-order logic. Consider the integer flow of time. We can easily say that q is true at all even numbers by writing $[0, 0]||1$ as a truth set for q and $[1, 1]||1$ as a truth set for $\sim q$ (i.e. q is true at 0 and recurs every 1 unit and $\sim q$ is true at 1 and recurs every 1 unit).

The exact expressive power of this language is yet to be examined. It is connected with the language USF which we meet later.

The above seem to be the most natural options to consider. We can already see that it no longer makes sense to check how the computation rules of Definition 76 simplify for our case. Our case is so specialized that we may as well devise computation rules especially for it. This should not surprise us. It happens in mathematics all the time. The theory of Abelian groups, for example, is completely different from the theory of semigroups, although Abelian groups are a special case of semigroups. The case of Abelian groups is so special that it does not relate to the general case any more.

Let us go back to the question of how to answer a query from our newly defined simplified databases. We start with an even more simple case, assuming only persistence and assuming that the flow of time is the integers. This simple assumption will allow us to present our point of view of how to evaluate a formula at a point or at an interval. It will also ensure we are still within what is expressible in first-order logic. Compare this with Chapter 13 of [Gabbay *et al.*, 1994].

Assume that the atom q is true at the maximal intervals $[Xx_n, y_n], x_n \leq y_n < x_{n+1}$. Then $\sim q$ is true at the intervals $[y_n + 1, x_{n+1} - 1]$, a sequence of the same form, i.e. $y_n + 1 \leq x_{n+1} - 1$ and $x_{n+1} - 1 < y_{n+1} + 1$.

It is easy to compute the intervals corresponding to the truth values of conjunctions: we take the intersection:

If $I_j = \bigcup_n [x_n^j, y_n^j]$ then $I_1 \cap I_2 = \bigcup_n [x_n, y_n]$ and the points x_n, y_n can be effectively linearly computed. Also, if I_j is the interval set for A_j , the interval set for $U(A_1, A_2)$ can be effectively computed.

In Fig. 8, $U(A_1, A_2)$ is true at $[u_k, y_n - 1], [u_k, y_{n+1} - 1]$ which simplifies to the maximal $[u_k, y_{n+1} - 1]$.

The importance of the above is that we can regard a query formula of the full language with Until and Since as an operator on the model (database)

Figure 8.

to give a new database. If the database Δ gives for each atom or its negation the set of intervals where it is true, then a formula A operates on Δ to give the new set of intervals Δ_A ; thus to answer $\Delta?t : A$ the question we ask is $t \in \Delta_A$. The new notion is that the query operates on the model.

This approach was adopted by I. Torsun and K. Manning when implementing the query language USF. The complexity of computation is polynomial (n^2). Note that although we have restricted the database formulae to atoms, we discovered that for no additional cost we can increase the query language to include the connectives Since and Until. As we have seen in Volume 1, in the case of integers the expressive power of Since and Until is equivalent to quantification over time points.

To give the reader another glimpse of what is to come, note that intuitively we have a couple of options:

1. We can assume persistence of atoms and negation of atoms. In this case we can express temporal models in first-order logic. The query language can be full Since and Until logic. This option does not allow for recurrence. In practical terms this means that we cannot generate or easily control recurrent events. Note that the database does not need to contain Horn clauses as data. Clauses of the form $\Box(\text{present wff}_1 \rightarrow \text{present wff}_2)$ are redundant and can be eliminated (this has to be properly proved!). Clauses of the form $\Box(\text{past wff}_1 \rightarrow \text{present wff}_2)$ are not allowed as they correspond to recurrence;
2. This option wants to have recurrence, and is not interested in first-order expressibility. How do we generate recurrence?

The language USF (which was introduced for completely different reasons) allows one to generate the database using rules of the form $\Box(\text{past formula} \rightarrow \text{present or future formula})$.

The above rules, together with some initial items of data of the form $t : A$, A a literal, can generate persistent and recurrent models.

7 NATURAL NUMBERS TIME LOGICS

Certainly the most studied and widely used temporal logic is one based on a natural numbers model of time. The idea of discrete steps of time heading off into an unbounded future is perfect for many applications in computer science. The natural numbers also form quite a well-known structure and so a wide-range of alternative techniques can be brought to bear. Here we will have a brief look at this temporal logic, PTL, at another, stronger natural numbers time temporal logic *USF* and at the powerful automata technique which can be used to help reason in and about such logics.

7.1 PTL

PTL is a propositional temporal logic with semantics defined on the natural numbers time. It does not have past time temporal connectives because, as we will see, they are not strictly necessary, and, anyway, properties of programs (or systems or machines) are usually described in terms of what happens in the future of the start. So PTL is somewhat, but not exactly, like the propositional logic of the until connective over natural numbers time. By the way, PTL stands for Propositional Temporal Logic because computer scientists are not very interested in any of the other propositional temporal logics which we have met. PTL is also sometimes known as PLTL, for Propositional Linear Temporal Logic, because the only other propositional temporal logic of even vague interest to computer scientists is one based on branching time.

PTL does have a version of the until connective and also a next-time (or tomorrow) connective. The until connective, although commonly written as U , is not the same as the connective U which we have met before. Also, and much less importantly, it is usually written in an infix manner as in pUq . In PTL we write pUq iff either q is true now or q is true at some time in the future and we have p true at all points between now and then, including now but not including then. This is called a non-strict version of U : hence here we will use the notation U^{ns} . From the beginning in [Pnueli, 1977], temporal logic work with computer science applications in mind has used the non-strict version of until. In much of the work on temporal logic with a philosophical or linguistic bent, and in this chapter, $U(q, p)$ means that q is true in the future and p holds at all points strictly in between. This is called the strict version of until.

To be more formal let us here define a structure as a triple $(\mathbb{N}, <, h)$ where $h : L \rightarrow \wp(\mathbb{N})$ is the valuation of the atoms from L . In effect, we have

an ω -long sequence $\sigma = \langle \sigma_0, \sigma_1, \dots \rangle$ of states (i.e. subsets of L) with each $\sigma_i = \{p \in L \mid i \in h(p)\}$. Many presentations of PTL use this sequence of states notation. The truth of a PTL formula A at a point n of a structure \mathcal{T} , written $\mathcal{T}, n \models A$ is defined by induction on the construction of A as usual. The clauses for atoms and Booleans are as usual. Define:

$$\begin{aligned} \mathcal{T}, n \models XA \text{ iff } & \quad \mathcal{T}, n+1 \models A, \text{ and} \\ \mathcal{T}, n \models AU^{ns}B \text{ iff } & \quad \text{there is some } m \geq n \text{ such that } \mathcal{T}, m \models B \text{ and} \\ & \quad \text{for all } j, \text{ if } n \leq j < m \text{ then } \mathcal{T}, j \models A. \end{aligned}$$

Note that in PTL, there are also non-strict versions of all the usual abbreviations. For example $FA = \top U^{ns}A$ holds iff A holds now or at some time in the future, and $GA = \neg F\neg A$ holds iff A holds now and at all time in the future. In many presentations of PTL, the symbols \diamond and \square are used instead of F and G .

In the case of natural numbers time (as in PTL) it is easy to show that the language with strict U is equally expressive as the language with both the next operator X and non-strict U^{ns} . We can define a meaning preserving translation π which preserves atoms and respects Boolean connectives via:

$$\pi U(A, B) = X(\pi(B)U^{ns}\pi(A)).$$

Similarly we can define a meaning preserving translation ρ which preserves atoms and respects Boolean connectives via:

$$\begin{aligned} \rho XA &= U(A, p_0 \wedge \neg p_0), \\ \rho(BU^{ns}A) &= \rho(A) \vee (\rho(B) \wedge U(\rho(A), \rho(B))). \end{aligned}$$

It is easy to show that these are indeed meaning preserving. Notice, though, that is computationally expensive to translate between the non-strict until and strict until (using ρ) as there may be an exponential blow-up in formula length.

In some earlier presentations of PTL, the definitions of the concepts of satisfaction and satisfiability are different from ours. In typical PTL applications, it makes sense to concentrate almost exclusively on the truth of formulas in structures when evaluated at time 0. Thus we might say that structure $(\mathbb{N}, <, h)$ satisfies A iff $(\mathbb{N}, <, h), 0 \models A$. Other presentations define satisfaction by saying $(\mathbb{N}, <, h)$ satisfies A iff for all n , $(\mathbb{N}, <, h), n \models A$. Recall that in this chapter we actually say that $(\mathbb{N}, <, h)$ satisfies A iff there is some n such that $(\mathbb{N}, <, h), n \models A$. In general it is said that a formula A is satisfiable iff there is some structure which satisfies A (whatever notion of satisfaction is used). We will not explore the subtle details of what is sometimes known as the *anchored* versus *floating* version of temporal logics, except to say that no difficult or important issues of expressiveness or axiomatization etc, are raised by these differences. See [Manna and Pnueli, 1988] for more on this.

Given the equivalence of PTL and the temporal logic with U over natural numbers time and our separation result for the $L(U, S)$ logic over the natural numbers, it is easy to see why S (and any other past connective) is not needed. Suppose that we want to check the truth of a formula A in the $L(U, S)$ language at time 0 in a structure $\mathcal{T} = (\mathbb{N}, <, h)$. If we separate A into a Boolean combination of syntactically pure formulas we will see that, for each of the pure past formulas C , either C evaluates at time 0 to true in every structure or C evaluates at time 0 to false in every structure. Thus, we can effectively find some formula B in the language with U such that evaluating A at time 0 is equivalent to evaluating B at time 0. We know that B is equivalent to some formula of PTL which we can also find effectively. Thus adding S adds no expressiveness to PTL (in this specific sense). However, some of the steps in eliminating S may be time-consuming and it may be natural to express some useful properties with S . Thus there are motivations for introducing past-time connectives into PTL. This is the idea seen in [Lichtenstein *et al.*, 1985].

7.2 An axiomatization of PTL

We could axiomatize PTL using either the IRR rule or the techniques of [Reynolds, 1992]. However, the first axiomatization for PTL, given in [Gabbay *et al.*, 1980], uses a different approach with an interesting use of something like the computing concept of fairness. The axioms and proof in [Gabbay *et al.*, 1980] were actually given for a strict version of the logic but, as noted in [Gabbay *et al.*, 1980], it is easy to modify it for the non-strict version, what has now become the official PTL.

The inference rules are modus ponens and generalization,

$$\frac{A, A \rightarrow B}{B} \quad \frac{A}{G^{ns}A} .$$

The axioms are all substitution instances of the following:

- (1) all classical tautologies,
- (2) $G^{ns}(A \rightarrow B) \rightarrow (G^{ns}A \rightarrow G^{ns}B)$
- (3) $X\neg A \rightarrow \neg XA$
- (4) $X(A \rightarrow B) \rightarrow (XA \rightarrow XB)$
- (5) $G^{ns}A \rightarrow A \wedge XG^{ns}A$
- (6) $G^{ns}(A \rightarrow XA) \rightarrow (A \rightarrow G^{ns}A)$
- (7) $(AU^{ns}B) \rightarrow F^{ns}A$
- (8) $(AU^{ns}B) \leftrightarrow (B \vee (A \wedge X(AU^{ns}B)))$

The straightforward induction on the lengths of proof gives us the soundness result. The completeness result which is really a *weak completeness* result — the logic is not compact — follows.

THEOREM 95. *If A is valid in PTL then $\vdash A$ (A is a theorem of the axiom system).*

Proof. We give a sketch. The details are left to the reader: or see [Gabbay *et al.*, 1980] (but note the use of strict versions of connectives in that proof). It is enough to show that if A is consistent then A is satisfiable.

We use the common Henkin technique of forming a model of a consistent formula in a modal logic out of the maximal consistent sets of formulae. These are the infinite sets of formulae which are each maximal in not containing some finite subsets whose conjunction is inconsistent. In our case this model will not have the natural numbers flow of time but will be a more general, not necessarily linear structure with a more general definition of truth for the temporal connectives.

Let \mathcal{C} contain all the maximally consistent sets of formulae. This is a non-linear model of A with truth for the connectives defined via the following (accessibility) relations: for each $\Gamma, \Delta \in \mathcal{C}$, say $\Gamma R_+ \Delta$ iff $\{B \mid XB \in \Gamma\} \subseteq \Delta$ and $\Gamma R_< \Delta$ iff $\{B \mid XG^{ns} B \in \Gamma\} \subseteq \Delta$. For example, if we call this model M then for each $\Gamma \in \mathcal{C}$, we define $M, \Gamma \models p$ iff $p \in \Gamma$ for any atom p and $M, \Gamma \models XB$ iff there is some $\Delta \in \mathcal{C}$, such that $\Gamma R_+ \Delta$ and $M, \Delta \models B$. The truth of formulas of the form $B_1 U^{ns} B_2$ is defined via paths through \mathcal{C} in a straightforward way.

The Lindenbaum technique shows us that there is some $\Gamma_0 \in \mathcal{C}$ with $A \in \Gamma_0$. Using this and the fact that $R_<$ is the transitive closure of R_+ , we can indeed show that $M, \Gamma_0 \models A$.

There is also a common technique for taking this model and factoring out by an equivalence relation to form a finite but also non-linear model. This is the method of *filtration*. See [Gabbay *et al.*, 1994].

To do this in our logic, we first limit ourselves to a finite set of interesting formulae:

$$\text{cl}(A) = \{B, \neg B, XB, X\neg B, F^{ns} B, F^{ns} \neg B \mid B \text{ is a subformula of } A\}.$$

Now we define $C = \{\Gamma \cap \text{cl}(A) \mid \Gamma \in \mathcal{C}\}$ and we impose a relation R_X on C via $a R_X b$ iff there exist $\Gamma, \Delta \in \mathcal{C}$ such that $a = \Gamma \cap \text{cl}(A)$, $b = \Delta \cap \text{cl}(A)$ and $\Gamma R_+ \Delta$.

To build natural numbers flowed model of A we next find an ω -sequence σ of sets from C starting at $\Gamma_0 \cap \text{cl}(A)$ and proceeding via the R_X relation in such a way that if the set Γ appears infinitely often in the sequence then each of its R_X -successors do too. This might be called a *fair* sequence. We can turn σ into a structure $(\mathbb{N}, <, h)$ via $i \in h(p)$ iff $p \in \sigma_i$ (for all atoms p). This is enough to give us a truth lemma by induction on all formulae $B \in \text{cl}(A)$: namely, $B \in \sigma_i$ iff $(\mathbb{N}, <, h), i \models B$. Immediately we have $(\mathbb{N}, <, h), 0 \models A$ as required. ■

7.3 *S1S and Fixed point languages*

PTL is expressively complete in respect of formulas evaluated at time 0. That is, for any first-order monadic formula $\phi(P_1, \dots, P_n, x)$ in the language with $<$ with one free variable, there is a PTL formula A such that for any structure $(\mathbb{N}, <, h)$,

$$(\mathbb{N}, <, h), 0 \models A \text{ iff } (\mathbb{N}, <) \models \phi(h(p_1), \dots, h(p_n), 0).$$

To see this just use the expressive completeness of the $L(U, S)$ logic over natural numbers time, separation, the falsity of since at zero, and the translation to PTL.

However, there are natural properties which can not be expressed. For example, there is no PTL formula which is true exactly at the even numbers (see [Wolper, 1983] for details) and we can not say that property p holds at each even-numbered time point. The reason for this lack of expressivity in an expressively complete language is simply that there are natural properties like evenness which can not be expressed in the first-order monadic theory of the natural numbers.

For these reasons there have been many and varied attempts to increase the expressiveness of temporal languages over the natural numbers. There has also been a need to raise a new standard of expressiveness. Instead of comparing languages to the first-order monadic theory of the natural numbers, languages are compared to another traditional second-order logic, the full second-order logic of one successor function, commonly known as *S1S*.

There are several slightly different ways of defining *S1S*. We can regard it as an ordinary first-order logic interpreted in a structure which actually consists of sets of natural numbers. The signature contains the 2-ary subset relation \subseteq and a 2-ary ordering relation symbol *succ*. Subset is interpreted in the natural way while *succ*(A, B) holds for sets A and B iff $A = \{n\}$ and $B = \{n + 1\}$ for some number n . To deal with a temporal structure using atoms from L we also allow the symbols in L as constant symbols in the language: given an ω -structure σ , the interpretation of the atom p is just the set of times at which p holds.

Consider the example of the formula

$$J(a, b, z)(b \subseteq z) \wedge \forall uv(succ(u, v) \wedge (v \subseteq z) \wedge (u \subseteq a) \rightarrow (u \subseteq z))$$

with constants a, b and z . This will be true of a natural numbers flowed temporal structure with atoms a, b and z iff at every time at which aU^nsb holds, we also have z holding.

In fact, it is straightforward to show that the language of *S1S* is exactly as expressive as the full second-order monadic language of the natural number order. Thus it is more expressive than the first-order monadic language. A well-known and straightforward translation gives an *S1S* version of any

temporal formula. We can translate any temporal formula α using atoms from L into an $S1S$ formula $(*\alpha)(x)$ with a free variable x :

$$\begin{aligned}
*p &= (x = p) \\
(\neg\alpha) &= \neg(\alpha) \\
*(\alpha \wedge \beta) &= *\alpha \wedge *\beta \\
(X\alpha) &= \forall y((\alpha)(y) \rightarrow \forall uv(succ(u, v) \wedge (u \subseteq x) \rightarrow (v \subseteq y))) \\
(\alpha U^{ns} \beta) &= \forall ab((\alpha)(a) \wedge (*\beta)(b)) \rightarrow \\
&\quad (J(a, b, x) \wedge (\forall y(J(a, b, y) \rightarrow (x \subseteq y)))) \\
\text{where } J(a, b, z) &= (b \subseteq z) \\
&\quad \wedge \forall uv(succ(u, v) \wedge (v \subseteq z) \wedge (u \subseteq a) \rightarrow (u \subseteq z))
\end{aligned}$$

An easy induction (on the construction of α) shows that $\sigma \models (*\alpha)(S)$ iff S is the set of times at which α holds.

In order to reach the expressiveness of $S1S$, temporal logics are often given an extra second-order capability involving some kind of quantification over propositions. See, for example, ETL [Wolper, 1983] and the quantified logics in chapter 8 of [Gabbay *et al.*, 1994]. One of the most computationally convenient ways of adding quantification is via the introduction of fixed-point operators into the language. This has been done in [Banniegbal and Barringer, 1986] and in [Gabbay, 1989]. We briefly look at the example of USF from [Gabbay, 1989].

In chapter 8 of [Gabbay *et al.*, 1994] it is established that $S1S$ is exactly as expressive as USF . In order to use the automata-based decision procedures (which we meet in subsection 7.5 below) to give us decision procedures about temporal logics we need only know that the temporal logic of interest is less expressive than USF (or equivalently $S1S$) — as they mostly are. So it is worth here briefly recalling the definition of USF .

In fact we start with the very similar language UYF . We often write \bar{x}, \bar{a}, \dots , for *tuples* — finite sequences of variables, atoms, elements of a structure, etc. If $S \subseteq \mathbb{N}$, we write $S + 1$ (or $1 + S$) for $\{s + 1 \mid s \in S\}$.

We start by developing the syntax and semantics of the fixed point operator. This is not entirely a trivial task. We will fix an infinite set of propositional atoms, with which our formulae will be written; we write p, q, r, s, \dots for atoms.

DEFINITION 96.

1. The set of formulae of UYF is the smallest class closed under the following:
 - (a) Any atom q is a formula of UYF , as is \top .
 - (b) If A is a formula so is $\neg A$.

- (c) If A is a formula so is YA . We read Y as ‘yesterday’.
- (d) If A and B are formulae, so are $A \wedge B$ and $U(A, B)$. ($A \vee B$ and $A \rightarrow B$ are regarded as abbreviations.)
- (e) Suppose that A is a formula such that every occurrence of the atom q in A not within the scope of a φq is within the scope of a Y but not within the scope of a U . Then φqA is a formula. (The conditions ensure that φqA has fixed point semantics.)
2. The *depth of nesting* of φ s in a formula A is defined by induction on its formation: formulae formed by clause (a) have depth 0, clause (e) adds 1 to the depth of nesting, clauses (b) and (c) leave it unchanged, and in clause (d), the depth of nesting of $U(A, B)$ and $A \wedge B$ is the maximum of the depths of nesting of A and B . So, for example, $\neg\varphi r(\neg Yr \wedge \varphi qY(q \rightarrow r))$ has depth of nesting of 2.
3. A UYF-formula is said to be a YF-*formula* if it does not involve U .
4. Let A be a formula and q an atom. A *bound occurrence* of q in A is one in a subformula of A of the form φqB . All other occurrences of q in A are said to be *free*. An occurrence of q in A is said to be *pure past* in A if it is in a subformula of A of the form YB but not in a subformula of the form $U(B, C)$. So φqA is well-formed if and only if all free occurrences of q in A are pure past.

An *assignment* is a map h providing a subset $h(q)$ of \mathbb{N} for each atom q . If h, h' are assignments, and \bar{q} a tuple of atoms, we write $h =_{\bar{q}} h'$ if $h(r) = h'(r)$ for all atoms r not occurring in \bar{q} . If $S \subseteq \mathbb{N}$ and q is an atom, we write $h_{q/S}$ for the unique assignment h' satisfying: $h' =_q h$, $h'(q) = S$.

For each assignment h and formula A of UYF we will define a subset $h(A)$ of \mathbb{N} , the interpretation of A in \mathbb{N} . Intuitively, $h(A) = \{n \in \mathbb{N} \mid A \text{ is true at } n \text{ under } h\} = \{n \in \mathbb{N} \mid (\mathbb{N}, <, h), n \models A\}$. We will ensure that, whenever φqA is well-formed,

$$(*) \quad h(\varphi qA) \text{ is the unique } S \subseteq \mathbb{N} \text{ such that } S = h_{q/S}(A).$$

DEFINITION 97. We define the semantics of UYF by induction. Let h be an assignment. If A is atomic then $h(A)$ is already defined. We set:

- $h(\top) = \mathbb{N}$.
- $h(\neg A) = \mathbb{N} \setminus h(A)$.
- $h(YA) = h(A) + 1$.
- $h(A \wedge B) = h(A) \cap h(B)$.
- $h(U(A, B)) = \{n \in \mathbb{N} \mid \exists m > n(m \in h(A) \wedge \forall m'(n < m' < m \rightarrow m' \in h(B))\}$.

- Finally, if φqA is well-formed we define $h(\varphi qA)$ as follows. First define assignments h_n ($n \in \mathbb{N}$) by induction: $h_0 = h, h_{n+1} = (h_n)_{q/h_n(A)}$. Then $h(\varphi qA) \stackrel{\text{def}}{=} \{n \in \mathbb{N} \mid n \in h_n(A)\} = \{n \in \mathbb{N} \mid n \in h_{n+1}(q)\}$.

To establish (*) we need a theorem.

THEOREM 98 (fixed point theorem).

1. Suppose that A is any UYF-formula and φqA is well formed. Then if h is any assignment, there is a unique subset $S = h(\varphi qA)$ of \mathbb{N} such that $S = h_{q/S}(A)$. Thus, regarding $S \mapsto h_{q/S}(A)$ as a map $\alpha : \wp(\mathbb{N}) \rightarrow \wp(\mathbb{N})$ (depending on h, A), α has a unique fixed point $S \subseteq \mathbb{N}$, and we have $S = h(\varphi qA)$. For any $h, h(A) = h(q) \iff h(\varphi qA) = h(q)$.
2. If q has no free occurrence in a formula A and $g =_q h$, then $g(A) = h(A)$.
3. If φqA is well-formed and r is an atom not occurring in A , then for all assignments $h, h(\varphi qA) = h(\varphi rA(q/r))$, where $A(q/r)$ denotes substitution by r for all free occurrences of q in A .

We define USF using the first-order connectives Until and Since as well as the fixed point operator. The logic UYF is just as expressive as USF: Yq is definable in USF by the formula $S(q, \perp)$, while $S(p, q)$ is definable in UYF by $\varphi rY(p \vee (q \wedge r))$. Using UYF allows easier proofs and stronger results.

As an example, consider the formula

$$A = \varphi q(\neg Yq).$$

It is easy to see that A holds in a structure iff q holds exactly at the even numbered times.

7.4 Decision Procedures

There are many uses for PTL (and extensions such as USF) in describing and verifying systems. Once again, an important task required in many of these applications is determining the validity (or equivalently satisfiability) of formulas. Because it is a widely-used logic and because the natural numbers afford a wide-variety of techniques of analysis, there are several quite different ways of approaching decision procedures here. The main avenues are via finite model properties, tableaux, automata and resolution techniques.

The first proof of the decidability of PTL was based on automata. The pioneer in the development of automata for use with infinite linear structures is Büchi in [1962]. He was interested in proving the decidability of $S1S$ as

a very restricted version of second-order arithmetic. We will look at his proof briefly in subsection 7.5 below. By the time that temporal logic was being introduced to computer scientists in [Pnueli, 1977], it was well known (via [Kamp, 1968b]) that temporal logic formulae can be expressed in the appropriate second-order logic and so via *S1S* we had the first decision procedure for PTL (and *USF*).

Unfortunately, deciding *S1S* is non-elementarily complex (see [Robertson, 1974]) and so this is not an efficient way to decide PTL. Tableaux [Wolper, 1983; Lichtenstein *et al.*, 1985; Emerson, 1990], resolution [Fisher, 1997] and automata approaches (which we meet in subsection 7.5 below) can be much more efficient.

The first PSPACE algorithm for deciding PTL was given in [Sistla and Clarke, 1985]. This result uses a finite model property. We show that if a PTL formula A of length n is satisfiable over the natural numbers then it is also satisfiable in a non-linear model of size bounded by a certain exponential in n . The model has a linear part followed by a loop. It is a straightforward matter to guess the truths of atoms at the states on this structure and then check the truth of the formula. The guessing and checking can be done “on the fly”, i.e. simultaneously as we move along the structure in such a way that we do not need to store the whole structure. So we have an NPSpace algorithm which by the well-known result in [Savitch, 1970] can give us a PSPACE one.

In [Sistla and Clarke, 1985] it was also shown that deciding PTL is PSPACE-hard. This is done by encoding the running of any polynomial space bounded Turing machine into the logic.

For complexities of deciding the logic with strict U and the *USF* version see chapter 15 of [Gabbay *et al.*, 1994]. They are both PSPACE-complete. The same finite model property ideas are used.

7.5 Automata

Automata are finite state machines which are very promising objects to help with deciding the validity of temporal formulae. In some senses they are like formulae: they are finite objects and they distinguish some temporal structures—the ones which they accept—from other temporal structures in much the same way that formulae are true (at some point) in some structures are not in others. In other senses automata are like structures: they contain states and relate each state with some successor states. Being thus mid-way between formulae and structures allows automata to be used to answer questions—such as validity—about the relation between formulae and structures.

An automaton is called *empty* iff it accepts no structures and it turns out to be relatively easy to decide whether a given automaton is empty or not. This is surprising because empty automata can look quite complicated

in much the same way as unsatisfiable formulae can. This fact immediately suggests a possible decision procedure for temporal formulae. Given a formula we might be able to find an automaton which accepts exactly the structures which are models of the formula. If we now test the automaton for emptiness then we are effectively testing the formula for unsatisfiability. Validity of a formula corresponds to emptiness of an automaton equivalent to the negation of the formula.

This is the essence of the incredibly productive automata approach to theorem proving. We only look in detail at the case of PTL on natural numbers time.

The idea of (finite state) automata developed from pioneering attempts by Turing to formalize computation and by Kleene [1956] to model human psychology. The early work (see, for example, [Rabin and Scott, 1959]) was on finite state machines which recognized finite words. Such automata have provided a formal basis for many applications from text processing and biology to the analysis of concurrency. There has also been much mathematical development of the field. See [Perrin, 1990] for a survey.

The pioneer in the development of automata for use with infinite linear structures is Büchi in [1962] in proving the decidability of $S1S$. This gives one albeit inefficient decision procedure for PTL. There are now several useful ways of using the automata stepping stone for deciding the validity of PTL formulae.

The general idea is to translate the temporal formula into an automaton which accepts exactly the models of the formula and then to check for emptiness of the automaton. Variations arise when we consider that there are several different types of automata which we could use and that the translation from the formula can be done in a variety of ways.

Let us look at the automata first. For historical reasons we will switch now to a language Σ of letters rather than keep using a language of propositional atoms. The nodes of trees will be labelled by a single letter from Σ . In order to apply the results in this section we will later have to take the alphabet Σ to be 2^P where P is the set of atomic propositions.

A Σ (linear) Büchi automaton is a 4-tuple $A = (S, T, S_0, F)$ where

- S is a finite non-empty set called the set of *states*,
- $T \subseteq S \times \Sigma \times S$ is the *transition table*,
- $S_0 \subseteq S$ is the *initial state set* and
- $F \subseteq S$ is the *set of accepting states*.

A *run* of A on an ω -structure σ is a sequence of states (s_0, s_1, s_2, \dots) from S such that $s_0 \in S_0$ and for each $i < \omega$, $(s_i, \sigma_i, s_{i+1}) \in T$. We assume that automata never grind to a halt: i.e. we assume that for all $s \in S$, for all $a \in \Sigma$, there is some $s' \in S$ such that $(s, a, s') \in T$.

We say that the automaton accepts σ iff there is a run $\langle s_0, s_1, \dots \rangle$ such that $s_i \in F$ for infinitely many i .

One of the most useful results about Büchi automata, is that we can complement them. That is given a Büchi automata A reading from the language Σ we can always find another Σ Büchi automata \bar{A} which accepts exactly the ω -sequences which A rejects. This was first shown by Büchi in [1962] and was an important step on the way to his proof of the decidability of $S1S$. The automaton \bar{A} produced by Büchi's method is double exponential in the size of A but more recent work in [Sistla *et al.*, 1987] shows that complementation of Büchi automata can always be singly exponential.

As we will see below, it is easy to complement an automaton if we can find a deterministic equivalent. This means an automaton with a unique initial state and a transition table $T \subseteq S \times \Sigma \times S$ which satisfies the property that for all $s \in S$, for all $a \in \Sigma$, there is a unique $s' \in S$ such that $(s, a, s') \in T$. A deterministic automaton will have a unique run on any given structure.

Two automata are equivalent iff they accept exactly the same structures.

The problem with Büchi automata is that it is not always possible to find a deterministic equivalent. A very short argument, see example 4.2 in [Thomas, 1990], shows that the non-deterministic $\{a, b\}$ automaton which recognizes exactly the set

$$L = \{\sigma \mid a \text{ appears only a finite number of times in } \sigma\}$$

can have no deterministic equivalent.

One of our important tasks is to decide whether a given automaton is empty i.e. accepts no ω -structures. For Büchi automata this can be done in linear time [Emerson and Lei, 1985] and co-NLOGSPACE [Vardi and Wolper, 1994].

The lack of a determinization result for Büchi automata led to a search for a class of automata which is as expressive as the class of Büchi automata but which is closed under finding deterministic equivalents. Muller automata were introduced by Muller in [Muller, 1963] and in [Rabin, 1972] variants, now called Rabin automata, were introduced.

The difference is that the accepting condition can require that certain states do not come up infinitely often. There are several equivalent ways of formalizing this. The Rabin method is, for a Σ -automata with state set S , to use a set \mathcal{F} , called the set of *accepting pairs*, of pairs of sets of states from S , i.e. $\mathcal{F} \subseteq \wp(S) \times \wp(S)$.

We say that the Rabin automaton $A = (S, S_0, T, \mathcal{F})$ accepts σ iff there is some run $\langle s_0, s_1, s_2, \dots \rangle$ (as defined for Büchi automata) and some pair $(U, V) \in \mathcal{F}$ such that no state in V is visited infinitely often but there is some state in U visited infinitely often.

In fact, Rabin automata add no expressive power compared to Büchi automata, i.e. for every Rabin automaton there is an equivalent Büchi automaton. The translation [Choueka, 1974] is straightforward and, as it

essentially just involves two copies of the Rabin automata in series with a once-only non-deterministic transition from the first to the second, it can be done in polynomial time. The converse equivalence is obvious.

The most important property of the class of Rabin automata is that it is closed under determinization. In [1966], McNaughton, showed that any Büchi automaton has a deterministic Rabin equivalent. There are useful accounts of McNaughton's theorem in [Thomas, 1990] and [Hodkinson, 200]. McNaughton's construction is doubly exponential. It follows from McNaughton's result that we can find a deterministic equivalent of any Rabin automaton: simply first find a Büchi equivalent and then use the theorem.

The determinization result gives us an easy complementation result for Rabin automata: given a Rabin automata we can without loss of generality assume it is deterministic and complementing a deterministic automaton is just a straightforward negation of the acceptance criteria.

To decide whether Rabin automata are empty can be done with almost the same procedure we used for Büchi case. Alternatively, one can determinize the automaton A , and translate the deterministic equivalent into a deterministic Rabin automaton A' recognizing ω -sequences from the one symbol alphabet $\{a_0\}$ such that A' accepts some sequence iff A does. It is very easy to tell if A' is empty.

Translating formulae into Automata

The first step in using automata to decide a temporal formula is to translate the temporal formula into an equivalent automata: i.e. one that accepts exactly the models of the formula. There are direct ways of making this translation, e.g., in [Sherman *et al.*, 1984] (via a nonelementarily complex procedure). However, it is easier to understand some of the methods which use a stepping stone in the translation: $S1S$.

We have seen that the translation from PTL into $S1S$ is easy. The translation of $S1S$ into an automaton is also easy, given McNaughton's result: it is via a simple induction. Suppose that the $S1S$ sentence uses constants from the finite set P . We proceed by induction on the construction of the sentence. The automaton for $p \subseteq q$ simply keeps checking that $p \rightarrow q$ is true of the current state and falls into a fail state sink if not. The other base cases, of $p = q$ and $succ(p, q)$ are just as easy. Conjunction requires a standard construction of conjoining automata using the product of the state sets. Negation can be done using McNaughton's result to determinize the automaton for the negated subformula. It is easy to find the complement of a deterministic automaton. The case of an existential quantification, e.g., $\exists y \rho(y)$, is done by simply using non-determinism to guess the truth of the quantified variable at each step.

Putting together the results above gives us several alternative approaches to deciding validity of PTL formulae. One route is to translate the formula

into $S1S$, translate the $S1S$ formula into a Büchi automaton as above and then check whether that is empty.

The quickest route is via the alternating automata idea of [Brzozowski and Leiss, 1980] — a clever variation on the automata idea. By translating a formula into one of these automata, and then using a guess and check on the fly procedure, we need only check a polynomial number of states (in the size of ϕ) and then (nondeterministically) move on to another such small group of states. This gives us a PSPACE algorithm. From the results of [Sistla and Clarke, 1985], we know this is best possible as a decision procedure.

Other Uses of Automata

The decision algorithm above using the translation into the language $S1S$ can be readily extended to allow for past operators or fixed point operators or both to appear in the language. This is because formulae using these operators can be expressed in $S1S$.

Automata do not seem well suited to reasoning about dense time or general linear orders. However, the same strategy as we used for PTL also works for the decidability of branching time logics such as CTL*. The only difference is that we must use tree automata. These were invented by Rabin in his powerful results showing the decidability of $S2S$, the second-order logic of two successors. See [Gurevich, 1985] for a nice introduction.

8 EXECUTABLE TEMPORAL LOGIC

Here we describe a useful paradigm in executable logic: that of the *declarative past and imperative future*. A future statement of temporal logic can be understood in two ways: the declarative way, that of describing the future as a temporal extension; and the imperative way, that of making sure that the future will happen the way we want. Since the future has not yet happened, we have a language which can be both declarative and imperative. We regard our theme as a natural meeting between the imperative and declarative paradigms.

More specifically, we describe a temporal logic with Since, Until and fixed point operators. The logic is based on the natural numbers as the flow of time and can be used for the specification and control of process behaviour in time. A specification formula of this logic can be automatically rewritten into an executable form. In an executable form it can be used as a program for controlling process behaviour. The executable form has the structure ‘If A holds in the past then do B ’. This structure shows that declarative and imperative programming can be integrated in a natural way.

Let \mathcal{E} be an environment in which a program \mathcal{P} is operating. The exact nature of the environment or the code and language of the program are not

immediately relevant for our purposes. Suppose we make periodic checks at time $t_0, t_1, t_2, t_3, \dots$ on what is going on in the environment and what the program is doing. These checks could be made after every unit execution of the program or at some key times. The time is not important to our discussion. What is important is that we check at each time the truth values of some propositions describing features of the environment and the program. We shall denote these propositions by $a_1, \dots, a_m, b_1, \dots, b_k$. These propositions, which we regard as units taking truth values \top (true) or \perp (false) at every checkpoint, need not be expressible in the language of the program \mathcal{P} , nor in the language used to describe the environment. The program may, however, in its course of execution, change the truth values of some of the propositions. Other propositions may be controlled only by the environment. Thus we assume that a_1, \dots, a_m are capable of being influenced by the program while b_1, \dots, b_k are influenced by the environment. We also assume that when at checktime t_n we want the program to be executed in such a way as to make the proposition a_i true, then it is possible to do so. We express this command by writing **exec** (a_i). For example, a_1 can be ‘print the screen’ and b_1 can be ‘there is a read request from outside’; a_1 can be controlled by the program while b_1 cannot. **exec** (a_1) will make a_1 true.

To illustrate our idea further, we take one temporal sentence of the form

$$(1) \quad G[\bullet a \Rightarrow Xb].$$

\bullet is the ‘yesterday’ operator, X is the ‘tomorrow’ operator, and G is the ‘always in the future’ operator. One can view (1) as a wff of temporal logic which can be either true or false in a temporal model. One can use a temporal axiom system to check whether it is a temporal theorem etc. In other words, we treat it as a formula of logic.

There is another way of looking at it. Suppose we are at time n . In a real ticking forward temporal system, time $n + 1$ (assume that time is measured in days) has not happened yet. We can find the truth value of $\bullet a$ by checking the past. We do not know yet the value of Xb because tomorrow has not yet come. Checking the truth value of $\bullet a$ is a declarative reading of $\bullet a$. However, we need not read Xb declaratively. We do not need to wait and see what happens to b tomorrow. Since tomorrow has not yet come, we can make b true tomorrow if we want to, and are able to. We are thus reading Xb imperatively: ‘make b true tomorrow’.

If we are committed to maintaining the truth of the specification (1) throughout time, then we can read (1) as: ‘at any time t , if $\bullet a$ holds then execute Xb ’, or schematically, ‘if declarative past then imperative future’. This is no different from the Pascal statement

```
if x<5 then x:=x+1
```

In our case we involve whole formulae of logic.

The above is our basic theme. This section makes it more precise. The rest of this introduction sets the scene for it, and the conclusion will describe existing implementations. Let us now give several examples:

EXAMPLE 99 (Simplified Payroll). Mrs Smith is running a babysitter service. She has a list of reliable teenagers who can take on a babysitting job. A customer interested in a babysitter would call Mrs Smith and give the date on which the babysitter is needed. Mrs Smith calls a teenager employee of hers and arranges for the job. She may need to call several of her teenagers until she finds one who accepts. The customer pays Mrs Smith and Mrs Smith pays the teenager. The rate is £10 per night unless the job requires overtime (after midnight) in which case it jumps to £15.

Mrs Smith uses a program to handle her business. The predicates involved are the following:

$A(x)$	x is asked to babysit
$B(x)$	x does a babysitting job
$M(x)$	x works after midnight
$P(x, y)$	x is paid y pounds .

In this set-up, $B(x)$ and $M(x)$ are controlled mainly by the environment and $A(x)$ and $P(x, y)$ are controlled by the program.

We get a temporal model by recording the history of what happens with the above predicates. Mrs Smith laid out the following (partial) specification:

1. Babysitters are not allowed to take jobs three nights in a row, or two nights in a row if the first night involved overtime.
2. Priority in calling is given to babysitters who were not called before as many times as others.
3. Payment should be made the next day after a job is done.

Figure 9 is an example of a partial model of what has happened to a babysitter called Janet. This model may or may not satisfy the specification.

We would like to be able to write down the specification in an intuitive temporal language (or even English) and have it automatically transformed into an executable program, telling us what to do day by day.

EXAMPLE 100 (J. Darlington, L. While [1987]). Consider a simple program \mathcal{P} , written in a rewrite language, to merge two queues. There are two merge rules:

R1 Merge($a.x, y$) = $a.\text{merge}(x,y)$;

R2 Merge($x,a.y$) = $a.\text{merge}(x,y)$.

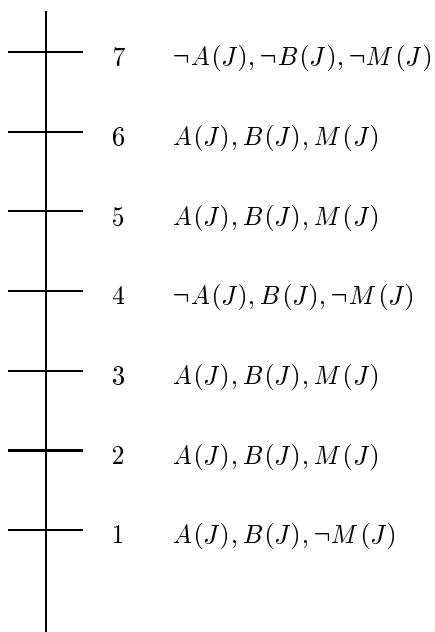

Figure 9. A model for Janet.

That is, we have left or right merges. The environment E with which \mathcal{P} interacts consists of the two queues x and y which get bigger and bigger over time. A real-life example is a policeman merging two queues of traffic. We use t_0, t_1, t_2, \dots as checktimes. The propositions we are interested in are:

- A_1 The program uses the **R1** merge rule (left merge).
- A_2 The program uses the **R2** merge rule (right merge).
- B The left queue is longer than the right queue.

Notice that the proposition B is not under the complete control of the program. The environment supplies the queuing elements, though the merge process does take elements out of the queue. The propositions A_1 and A_2 can be made true by the program, though not in the framework of the rewrite language, since the evaluation is non-deterministic. The program may be modified (or annotated) to a program \mathcal{P}_1 which controls the choice of the merge rules. In the general case, for other possible programs and other possible languages, this may not be natural or even possible to do.

EXAMPLE 101 (Loop checking in Prolog). Imagine a Prolog program \mathcal{P} and imagine predicates A_1, \dots, A_m describing at each step of execution which rule is used and what is the current goal and other relevant data. Let B describe the history of the computation. This can be a list of states defined recursively. The loop checking can be done by ensuring that certain temporal properties hold throughout the computation. We can define in this set-up any loop-checking system we desire and change it during execution.

In the above examples, the propositions A_i, B_j change the truth value at each checktime t_k . We thus obtain a natural temporal model for these propositions (see Fig. 10).

$$\begin{array}{rcl}
 & & \vdots \\
 3 & a_1 = \perp & b_2 = \top \\
 2 & a_1 = \perp & b_2 = \top \\
 1 & a_1 = \top & b_2 = \top \\
 0 & a_1 = \top & b_2 = \perp
 \end{array}$$

Figure 10. An example temporal model.

In the above set-up the programmer is interested in influencing the execution of the program within the non-deterministic options available in the programming language. For example, in the merge case one may want to say that if the left queue is longer than the right queue then use the left merge next. In symbols

$$G[B \Rightarrow XA1].$$

In the Prolog case, we may want to specify what the program should do in case of loops, i.e.

$$G[C \wedge PC \Rightarrow D],$$

where C is a complex proposition describing the state of the environment of interest to us (P is the ‘in the past’ operator). $C \wedge PC$ indicate a loop and D says what is to be done. The controls may be very complex and can be made dependent on the data and to change as we go along.

Of course in many cases our additional controls of the execution of \mathcal{P} may be synthesized and annotated in \mathcal{P} to form a new program \mathcal{P}^* . There are several reasons why the programmer may not want to do that:

1. The programming language may be such that it is impossible or not natural to synthesize the control in the program. We may lose in clarity and structure.

2. Changes in the control structure may be expensive once the program \mathcal{P}^* is defined and compiled.
3. It may be impossible to switch controlling features on and off during execution, i.e. have the control itself respond to the way the execution flows.
4. A properly defined temporal control module may be applicable as a package to many programming languages. It can give both practical and theoretical advantages.

In this section we follow option 4 above and develop an executable temporal logic for interactive systems. The reader will see that we are developing a logic here that on the one hand can be used for specification (of what we want the program to do) and on the other hand can be used for execution. (How to pass from the specification to the executable part requires some mathematical theorems.) Since logically the two formulations are equivalent, we will be able to use logic and proof theory to prove correctness.

This is what we have in mind:

1. We use a temporal language to specify the desirable behaviour of $\{a_i, b_j\}$ over time. Let \mathcal{S} be the specification as expressed in the temporal language (e.g. $G[b_2 \Rightarrow Xa_1]$).
2. We rewrite automatically \mathcal{S} into \mathcal{E} , \mathcal{E} being an executable temporal module. The program \mathcal{P} can communicate with \mathcal{E} at each checktime t_i and get instructions on what to do.

We have to prove that:

- if \mathcal{P} follows the instructions of \mathcal{E} then any execution sequence satisfies \mathcal{S} , i.e. the resulting temporal model for $\{a_i, b_j\}$ satisfies the temporal formula \mathcal{S} ;
- any execution sequence satisfying \mathcal{S} is non-deterministically realizable using \mathcal{P} and \mathcal{E} .

The proofs are tough!

Note that our discussion also applies to the case of shared resources. Given a resource to be shared by several processes, the temporal language can specify how to handle concurrent demands by more than one process. This point of view is dual to the previous one. Thus in the merge example, we can view the merge program as a black box which accepts items from two processes (queues), and the specification organizes how the box (program) is to handle that merge. We shall further observe that since the temporal language can serve as a metalanguage for the program \mathcal{P} (controlling its

execution), \mathcal{P} can be completely subsumed in \mathcal{E} . Thus the temporal language itself can be used as an imperative language (\mathcal{E}) with an equivalent specification element \mathcal{S} . Ordinary Horn logic programming can be obtained as a special case of the above.

We can already see the importance of our logic from the following point of view. There are two competing approaches to programming; the declarative one as symbolized in logic programming and Prolog, and the imperative one as symbolized in many well-known languages. There are advantages to each approach and at first impression there seems to be a genuine conflict between the two. The executable temporal logic described in this section shows that these two approaches can truly complement each other in a natural way.

We start with a declarative specification \mathcal{S} , which is a formula of temporal logic. \mathcal{S} is transformed into an executable form which is a conjunction of expressions of the form

hold C **in the past** \Rightarrow **execute** B **now**.

At any moment of time, the past is given to us as a database; thus **hold**(C) can be evaluated as a goal from this database in a Prolog program. **execute**(B) can be performed imperatively. This creates more data for the database, as the present becomes past. Imperative languages have a little of this feature, e.g. **if** $x < 5$ **let** $x := x + 1$. Here **hold**(C) equates to $x < 5$ and **execute**(B) equates to $x := x + 1$. The $x < 5$ is a very restricted form of a declarative test. On the other hand Prolog itself allows for imperative statements. Prolog clauses can have the form

write(Term) \Rightarrow b

and the goal **write**(Term) is satisfied by printing. In fact, one can accomplish a string of imperative commands just by stringing goals together in a clever way.

We thus see our temporal language as a pointer in the direction of unifying in a logical way the declarative and imperative approaches. The temporal language can be used for planning. If we want to achieve B we try to execute B . The temporal logic will give several ways of satisfying **execute**(B) while **hold**(C) remains true. Any such successful way of executing B is a plan. In logical terms we are looking for a model for our atoms but since we are dealing with a temporal model and the atoms can have an imperative meaning we get a plan. We will try and investigate these points further.

8.1 The logic USF

We describe a temporal system for specification and execution. The logic is USF which we met briefly in section 6 above. It contains the temporal

connectives *since*(S) and *until*(U) together with a fixed point operator φ . The formulae of USF are used for specifying temporal behaviour and these formulae will be syntactically transformed into an executable form. We begin with the definitions of the syntax of USF. There will be four types of well-formed formulae, pure future formulae (talking only about the strict future), pure past formulae (talking only about the strict past), pure present formulae (talking only about the present) and mixed formulae (talking about the entire flow of time).

DEFINITION 102 (Syntax of USF for the propositional case). Let Q be a sufficiently large set of *atoms* (atomic propositions). Let $\wedge, \vee, \neg, \Rightarrow, \top, \perp$ be the usual classical connectives and let U and S be the temporal connectives and φ be the fixed point operator. We define by induction the notions of

- wff (well-formed formula);
- wff^+ (pure future wff);
- wff^- (pure past wff);
- wff^0 (pure present wff).

1. An atomic $q \in Q$ is a pure present wff and a wff. Its atoms are q .
2. Assume A and B are wffs with atoms $\{q_1, \dots, q_n\}$ and $\{r_1, \dots, r_m\}$ respectively. Then $A \wedge B$, $A \vee B$, $A \Rightarrow B$, $U(A, B)$ and $S(A, B)$ are wffs with atoms $\{q_1, \dots, q_n, r_1, \dots, r_m\}$.
 - (a) If both A and B are in $wff^0 \cup wff^+$, then $U(A, B)$ is in wff^+ .
 - (b) If both A and B are in $wff^0 \cup wff^-$, then $S(A, B)$ is in wff^- .
 - (c) If both A and B are in wff^* , then so are $A \wedge B$, $A \vee B$, $A \Rightarrow B$, where wff^* is one of wff^+ , wff^- or wff^0 .
3. $\neg A$ is also a wff and it is of the same type as A with the same atoms as A .
4. \top (truth) and \perp (falsity) are wffs in wff^0 with no atoms.
5. If A is a wff in wff^- (pure past) with atoms $\{q, q_1, \dots, q_n\}$ then $(\varphi q)A$ is a pure past wff (i.e. in wff^-) with the atoms $\{q_1, \dots, q_n\}$.

The intended model for the above propositional temporal language is the set of natural numbers $\mathbb{N} = 0, 1, 2, 3, \dots$ with the ‘smaller than’ relation $<$ and variables $P, Q \subseteq \mathbb{N}$ ranging over subsets. We allow quantification $\forall x \exists y$ over elements of \mathbb{N} . So really we are dealing with the monadic language of the model $(\mathbb{N}, <, =, 0, P_i, Q_j \subseteq \mathbb{N})$. We refer to this model also as the *non-negative integers (flow of) time*. A formula of the monadic language will in general have free set variables, and these correspond to the atoms of temporal formulae. See Volume 1 for more details.

DEFINITION 103 (Syntax of USF for the predicate case). Let $Q^* = \{Q_{n_1}^1, Q_{n_2}^2, \dots\}$ be a set of predicate symbols. $Q_{n_i}^i$ is a symbol for an n_i -place predicate. Let $f^* = \{f_{n_1}^1, f_{n_2}^2, \dots\}$ be a set of function symbols. $f_{n_i}^i$ is a function symbol for an n_i -place function. Let $V^* = \{v_1, v_2, \dots\}$ be a set of variables. Let $\wedge, \vee, \neg, \Rightarrow, \top, \perp, \forall, \exists$ be the usual classical connectives and quantifiers and let U and S be the temporal connectives and φ be the fixed point operator. We define by induction the notions of:

- $wff\{x_1, \dots, x_n\}$ wff with free variables $\{x_1, \dots, x_n\}$;
- $wff^+\{x_1, \dots, x_n\}$ pure future wff with the indicated free variables;
- $wff^-\{x_1, \dots, x_n\}$ pure past wff with the indicated free variables;
- $wff^0\{x_1, \dots, x_n\}$ pure present wff with the indicated free variables;
- $term\{x_1, \dots, x_n\}$ term with the indicated free variables.

1. x is a term in $term\{x\}$, where x is a variable.
2. If f is an n -place function symbol and t_1, \dots, t_n are terms with variables $V_1^*, \dots, V_n^* \subseteq V^*$ respectively, then $f(t_1, \dots, t_n)$ is a term with variables $\bigcup_{i=1}^n V_i^*$.
3. If Q is an n -place atomic predicate symbol and we have t_1, \dots, t_n as terms with variables $V_1^*, \dots, V_n^* \subseteq V^*$ respectively, then $Q(t_1, \dots, t_n)$ is an atomic formula with free variables, $\bigcup_{i=1}^n V_i^*$. This formula is pure present as well as a wff.
4. Assume A, B are formulae with free variables $\{x_1, \dots, x_n\}$ and $\{y_1, \dots, y_m\}$ respectively. Then $A \wedge B, A \vee B, A \Rightarrow B, U(A, B)$ and $S(A, B)$ are wffs with the free variables $\{x_1, \dots, x_n, y_1, \dots, y_m\}$.
 - (a) If both A and B are in $wff^0 \cup wff^+$, then $U(A, B)$ is in wff^+ .
 - (b) If both A and B are in $wff^0 \cup wff^-$, then $S(A, B)$ is in wff^- .
 - (c) If both A and B are in wff^* , then so are $A \wedge B, A \vee B, A \Rightarrow B$, where wff^* is one of wff^+, wff^- or wff^0 .
5. $\neg A$ is also a wff and it is of the same type and has the same free variables as A .
6. \top and \perp are in wff^0 with no free variables.
7. If A is a formula in $wff^*\{x, y_1, \dots, y_m\}$ then $\forall xA$ and $\exists xA$ are wffs in $wff^*\{y_1, \dots, y_m\}$.
8. If $(\varphi q)A(q, q_1, \dots, q_n)$ is a pure past formula of propositional USF as defined in Definition 102, and if $B_i \in wff V_i^*, i = 1, \dots, m$, as defined in the present Definition 103, then $A' = (\varphi q)A(q, B_1, \dots, B_m)$ is a wff in $wff \bigcup_{i=1}^m V_i^*$. If all of the B_i are pure past, then so is A' .

9. A wff A is said to be *essentially propositional* iff there exists a wff $B(q_1, \dots, q_n)$ of propositional USF and wffs B_1, \dots, B_n of classical predicate logic such that $A = B(B_1, \dots, B_n)$.

REMARK 104. Notice that the fixed point operator (φx) is used in propositional USF to define the new connectives, and after it is defined it is exported to the predicate USF. We can define a language HTL which will allow fixed-point operations on predicates as well; we will not discuss this here.

DEFINITION 105. We define the semantic interpretation of propositional USF in the monadic theory of $(\mathbb{N}, <, =, 0)$. An assignment h is a function associating with each atom q_i of USF a subset $h(q_i)$ of \mathbb{N} (sometimes denoted by Q_i). h can be extended to any wff of USF as follows:

$$\begin{aligned} h(A \wedge B) &= h(A) \cap h(B); \\ h(A \vee B) &= h(A) \cup h(B); \\ h(\neg A) &= \mathbb{N} - h(A); \\ h(A \Rightarrow B) &= (\mathbb{N} - h(A)) \cup h(B); \\ h(U(A, B)) &= \{t | \exists s > t (s \in h(A) \text{ and } \forall y (t < y < s \Rightarrow y \in h(B)))\}; \\ h(S(A, B)) &= \{t | \exists s < t (s \in h(A) \text{ and } \forall y (s < y < t \Rightarrow y \in h(B)))\}. \end{aligned}$$

The meaning of U and S just defined is the Until and Since of English, i.e. ‘ B is true until A becomes true’ and ‘ B is true since A was true’, as in Fig. 11 (notice the existential meaning in U and S).

Finally we have the fixed point operator

$$h((\varphi q)A(q, q_i)) = \{n | n \in Q_n\}$$

where the sets $Q_n \subseteq \mathbb{N}$ are defined inductively by

$$\begin{aligned} Q_0 &= h(A) \\ Q_{(n+1)} &= h_n(A(q, q_i)) \end{aligned}$$

where for $n \geq 0$

$$\begin{aligned} h_n(r) &= h(r) \quad \text{for } r \neq q \\ &Q_n \quad \text{for } r = q. \end{aligned}$$

This is an inductive definition. If n is a natural number, we assume inductively that we know the truth values of the formula $(\varphi q)A(q, q_i)$ at each $m < n$; then we obtain its value at n by first changing the assignment so that q has the same values as $(\varphi q)A$ for all $m < n$, and then taking the new value of $A(q, q_i)$ at n . Since A is pure past, the values of q at $m \geq n$ do not matter. Hence the definition is sound. So $(\varphi q)A$ is defined in terms of its own previous values.

Figure 11.

This gives a fixed point semantics to formulae $(\varphi q)A(q, q_i)$, in the following sense. Suppose we have an assignment h . For any subset S of \mathbb{N} , let h_S be the assignment given by $h_S(r) = h(r)$ if $r \neq q$, and S if $r = q$. Then given A as above, we obtain a function $f : \wp\mathbb{N} \Rightarrow \wp\mathbb{N}$, given by $f(S) = h_S(A)$. f depends on h and A .

It is intuitively clear from the above that if $S = h((\varphi q)A)$ then $f(S) = S$, and that S is the unique solution of $f(x) = x$. So $h((\varphi q)A)$ is the unique fixed point of f . This is what we mean when we say that φ has a fixed point semantics. There are some details to be checked, in particular that the value at n of any past formula (even a complicated one involving φ) depends only on the values of its atoms at each $m < n$. For a full proof see [Hodkinson, 1989].

DEFINITION 106 (Semantic definition of predicate USF). Let D be a non-empty set, called the domain, and g be a function assigning the following:

1. for each m -place function symbol f and each $n \in \mathbb{N}$ a function $g(n, f) : D^m \Rightarrow D$;
2. for each variable x and each $n \in \mathbb{N}$, an element $g(n, x) \in D$;
3. for each m -place predicate symbol Q and each $n \in \mathbb{N}$, a function $g(n, Q) : D^m \Rightarrow \{0, 1\}$.

The function g can be extended to a function $g(n, A)$, giving a value in $\{0, 1\}$ for each wff $A(x_1, \dots, x_n)$ of the predicate USF as follows:

1. $g(n, f(t_1, \dots, t_m)) = g(n, f)(g(n, t_1), \dots, g(n, t_m))$;
2. $g(n, Q(t_1, \dots, t_m)) = g(n, Q)(g(n, t_1), \dots, g(n, t_m))$;
3. $g(n, A \wedge B) = 1$ iff $g(n, A) = 1$ and $g(n, B) = 1$;
4. $g(n, A \vee B) = 1$ iff either $g(n, A) = 1$ or $g(n, B) = 1$ or both;
5. $g(n, A \Rightarrow B) = 1$ iff either $g(n, A) = 0$ or $g(n, B) = 1$ or both;
6. $g(n, \neg A) = 1$ iff $g(n, A) = 0$;
7. $g(n, \top) = 1$ and $g(n, \perp) = 0$ for all n ;
8. $g(n, U(A, B)) = 1$ iff for some $m > n$, $g(m, A) = 1$ and for all $n < k < m$, $g(k, B) = 1$;
9. $g(n, S(A, B)) = 1$ iff for some $m < n$, $g(m, A) = 1$ and for all $m < k < n$, $g(k, B) = 1$;
10. $g(n, \forall x A(x)) = 1$ for a variable x iff for all g' such that g' gives the same values as g to all function symbols and all predicate symbols and all variables different from x , we have $g'(n, A(x)) = 1$;
11. $g(n, \exists x A(x)) = 1$ for a variable x iff for some g' such that g' gives the same values as g to all function symbols and all predicate symbols and all variables different from x , we have $g'(n, A(x)) = 1$;
12. let $(\varphi q)A(q, q_1, \dots, q_m)$ be a pure past formula of propositional USF, and let $B_i \in wffV_i^*$ for $i = 1, \dots, m$. We want to define $g(n, A')$, where $A' = (\varphi q)A(q, B_1, \dots, B_m)$. First choose an assignment h such that $h(q_i) = \{n \in \mathbb{N} | g(n, B_i) = 1\}$. Then define $g(n, A') = 1$ iff $n \in h((\varphi q)A(q, q_1, \dots, q_m))$.

REMARK 107. If we let $h_g^*(A)$ be the set $\{n | g(n, A) = 1\}$ we get a function h^* like that of Definition 105.

EXAMPLE 108. Let us evaluate $(\varphi x)A(x)$ for $A(x) = H\neg x$, where $Hx = \neg S(\neg x, \top)$; see Example 109.1. We work out the value of $(\varphi x)A(x)$ at each n , by induction on n . If we know its values for all $m < n$, we assume that the atom x has the same value as $(\varphi x)A(x)$ for $m < n$. We then calculate the value of $A(x)$ at n . So, really, $(\varphi x)A(x)$ is a definition by recursion.

Since $H\neg x$ is a pure past formula, its value at 0 is known and does not depend on x . Thus $A(x)$ is true at 0. Hence $(\varphi x)A(x)$ is true at 0.

Let us compute $A(x)$ at 1. Assume that x is true at 0. Since $A(x)$ is pure past, its value at 1 depends on the value of x at 0, which we know. It

does not depend on the value of x at $n \geq 1$. Thus at 1, $(\varphi x)A(x) = A(x) = H\neg\top = \perp$.

Assume inductively that we know the values of $(\varphi x)A(x)$ at $0, 1, \dots, n$, and suppose that x also has these values at $m \leq n$. We compute $A(x)$ at $n + 1$. This depends only on the values of x at points $m \leq n$, which we know. Hence $A(x)$ at $n + 1$ can be computed; for our example we get \perp . So $(\varphi x)A(x)$ is false at $n + 1$. Thus $(\varphi x)H\neg x$ is (semantically) equivalent to $H\perp$, because $H\perp$ is true at 0 and nowhere else.

Another way to get the answer is to use the fixed point semantics directly. Let $f(S) = h(A)$, where $h(x) = S$, as above. Then by definition of f and g ,

$$\begin{aligned} f(S) &= \{n \in \mathbb{N} \mid \neg \exists m < n (m \in S \wedge \forall k (m < k < n \Rightarrow k \in h(\top)))\} \\ &= \{n \in \mathbb{N} \mid \forall m < n (m \notin S)\}. \end{aligned}$$

So $f(S) = S$ iff $S = \{0\}$. Hence the fixed point is $\{0\}$, as before.

Let us evaluate $(\varphi x)B(x)$ where $B(x) = S(S(x, a), \neg a)$. At time 0 the value of $B(x)$ is \perp . Let x be \perp at 0. At time 1 the value of $B(x)$ is $S(S(\perp, a), \neg a) = S(\perp, \neg a) = \perp$. Let x be \perp at 1 etc. . . . It is easy to see that $(\varphi x)B(x)$ is independent of a and is equal to \perp .

EXAMPLE 109. We give examples of connectives definable in this system.

1. The basic temporal connectives are defined as follows:

Connective	Meaning	Definition
$\bullet q$	q was true 'yesterday'	$S(q, \perp)$
Xq	q will be true 'tomorrow'	$U(q, \perp)$
Gq	q 'will always' be true	$\neg U(\neg q, \top)$
Fq	q 'will sometimes' be true	$U(q, \top)$
Hq	q 'was always' true	$\neg S(\neg q, \top)$
Pq	q 'was sometimes' true	$S(q, \top)$

Note that at 0, both $\bullet q$ and Pq are false.

2. The first time point (i.e. $n = 0$) can be identified as the point at which $H\perp$ is true.
3. The fixed point operator allows us to define non-first-order definable subsets. For example, $e = (\varphi x)(\bullet \bullet x \vee H\perp)$ is a constant true exactly at the even points $\{0, 2, 4, 6, \dots\}$.
4. $S(A, B)$ can be defined from \bullet using the fixed point operator.:

$$S(A, B) = (\varphi x)(\bullet A \vee \bullet (x \wedge B))'$$

5. If we have

$$\text{block}(a, b) \triangleq (\varphi x)S(b \wedge S(a \wedge (x \vee H\perp \vee HH\perp), a), b)$$

then $\text{block}(a, b)$ says that we have the sequence of the form

$$(\text{block of } bs) + (\text{block of } as) + \dots$$

recurring in the pure past, beginning yesterday with b and going into the past. In particular $\text{block}(a, b)$ is false at time 0 and time 1 because the smallest recurring block is (b, a) which requires two points in the past.

DEFINITION 110 (Expressive power of USF). Let $\Psi(t, Q_1, \dots, Q_n)$ be a formula in the monadic language of $(\mathbb{N}, <, =, 0, Q_1, \dots, Q_n \subseteq \mathbb{N})$. Let $Q = \{t \mid \Psi(t, Q_i) \text{ is true}\}$. Then Q is said to be monadic first-order definable from Q_i .

EXAMPLE 111. $\text{even} = \{0, 2, 4, \dots\}$ is not monadic first-order definable from any family of finite or cofinite subsets. It is easy to see that every quantificational wff $\Psi(t, Q_i)$, with Q_i finite or cofinite subsets of \mathbb{N} , defines another finite or co-infinite subset. But even is definable in USF (Example 109.3 above). even is also definable in monadic second-order logic. In fact, given any formula $A(q_1, \dots, q_n)$ of USF, we can construct a formula $A'(x, Y_1, \dots, Y_n)$ of monadic second-order logic in the language with relations \subseteq and $<$, such that for all h ,

$$h(A) = \{m \mid A'(m, h(q_1), \dots, h(q_n)) \text{ holds in } \mathbb{N}\}.$$

(See [Hodkinson, 1989].) Since this monadic logic is decidable, we get the following theorem.

THEOREM 112. *Propositional USF is decidable. In other words, the set of wffs $\{A \mid h(A) = \mathbb{N} \text{ for all } h\}$ is recursive. See for example [Hodkinson, 1989].*

THEOREM 113. *Many nested applications of the fixed point operator are no stronger than a single one. In fact, any pure past wff of USF is semantically equivalent to a positive Boolean combination (i.e. using \wedge, \vee only) of wffs of the form $(\varphi x)A$, where A is built from atoms using only the Boolean connectives and \bullet (as in Example 109.1,4). See [Hodkinson, 1989].*

THEOREM 114 (Full expressiveness of S and U [Kamp, 1968a]). *Let $Q_1, \dots, Q_n \subseteq \mathbb{N}$ be n set variables and let $\Psi(t, Q_1, \dots, Q_n)$ be a first-order monadic formula built up from Q_1, \dots, Q_n using $<, =$ and the quantifiers over elements of \mathbb{N} and Boolean connectives. Then there exists a wff of USF, $A_\Psi(q_1, \dots, q_n)$, built up using S and U only (without the use of the fixed point operator φ) such that for all h and all Q_i the following holds:*

$$\text{If } h(q_i) = Q_i \text{ then } h(A_\Psi) = \{t \mid \Psi(t, Q_i) \text{ holds in } \mathbb{N}\}.$$

Proof. H. Kamp proved this theorem directly by constructing A_Ψ . Another proof was given in [Gabbay *et al.*, 1994]. The significance of this theorem is that S and U alone are exactly as expressive (as a specification language) as first-order quantification \forall, \exists over temporal points. The use of φ takes USF beyond first-order quantification. ■

THEOREM 115 (Well known). *Predicate USF without fixed point applications is not arithmetical ([Kamp, 1968a]).*

8.2 USF as a specification language

The logic USF can be used as a specification language as follows. Let $A(a_1, \dots, a_m, b_1, \dots, b_k)$ be a wff of USF. Let h be an assignment to the atoms $\{a_i, b_j\}$. We say that h satisfies the specification A iff $h(A) = \mathbb{N}$.

In practice, the atoms b_j are controlled by the environment, and the atoms a_i are controlled by the program. Thus the truth values of b_j are determined as *events* and the truth values of a_i are determined by the program *execution*. As time moves forward and the program interacts with the environment, we get a function h , which may or may not satisfy the specification.

Let $\text{event}(q, n)$ mean that the value of q at time n is truth, as determined by the environment and let $\text{exec}(q, n)$ mean that q is executed at time n and therefore the truth value of q at time n is *true*. Thus out of event and exec we can get a full assignment $h = \text{event} + \text{exec}$ by letting:

$$\begin{aligned} h(q) &= \{n \mid \text{event}(q, n) \text{ holds}\} \text{ for } q \text{ controlled by the environment;} \\ h(q) &= \{n \mid \text{exec}(q, n) \text{ holds}\} \text{ for } q \text{ controlled by the program.} \end{aligned}$$

Of course our aim is to execute in such a way that the h obtained satisfies the specification.

We now explain how to execute any wff of our temporal language. Recall that the truth values of the atoms a_i come from the program *via* $\text{exec}(a_i, m)$ and the truth values for the atoms b_j come from the environment via the function $\text{event}(b_j, m)$. We define a predicate $\text{exec}^*(A, m)$ for any wff A , which actually defines the value of A at time m .

For atoms of the form a_i , $\text{exec}^*(a_i, m)$ will be $\text{exec}(a_i, m)$ and for atoms of the form b_j (i.e. controlled by the environment) $\text{exec}^*(b_j, m)$ will be $\text{event}(b_j, m)$. We exec^* an atom controlled by the environment by ‘agreeing’ with the environment. For the case of A a pure past formula, $\text{exec}^*(A, m)$ is determined by past truth values. Thus exec^* for pure past sentences is really a *hold* predicate, giving truth values determined already. For pure future sentences B , $\text{exec}^*(B, m)$ will have an operational meaning. For example, we will have

$$\text{exec}^*(G \text{ print}, m) = \text{exec}^*(\text{print}, m) \wedge \text{exec}^*(G \text{ print}, m + 1).$$

We can assume that the wffs to be executed are pure formulae (pure past, pure present or pure future) such that all negations are pushed next to atoms. This can be done because of the following semantic equivalences.

1. $\neg U(a, b) = G\neg a \vee U(\neg b \wedge \neg a, \neg a)$;
2. $\neg S(a, b) = H\neg a \vee S(\neg b \wedge \neg a, \neg a)$;
3. $\neg Ga = F\neg a$;
4. $\neg Ha = P\neg a$;
5. $\neg Fa = G\neg a$;
6. $\neg Pa = H\neg a$;
7. $\neg[(\varphi x)A(x)] = (\varphi x)\neg A(\neg x)$.

See [Gabbay *et al.*, 1994] for 1 to 6. For 7, let h be an assignment and suppose that $h(\neg[(\varphi x)A(x)]) = S$. Because φ has fixed point semantics, to prove 7 it is enough to show that if h' is the assignment that agrees with h on all atoms except x , and $h'(x) = S$, then $h'(\neg(A\neg x)) = S$. Clearly, $h(\neg[(\varphi x)A(x)]) = \mathbb{N} \setminus S$. We may assume that $h(x) = \mathbb{N} \setminus S$. Then $h(A(x)) = \mathbb{N} \setminus S$. So $h(\neg A(x)) = S$ and $h'(\neg(A\neg x)) = S$ as required; 7 is also easy to see using the recursive approach.

DEFINITION 116. We assume that $\text{exec}^*(A, m)$ is defined for the system for any m and any A which is atomic or the negation of an atom. For atomic b which is controlled by the environment, we assume $\text{event}(b, m)$ is defined and $\text{exec}^*(b, m) = \text{event}(b, m)$. For $\text{exec}^*(a, m)$, for a controlled by the program, execution may be done by another program. It may be a graphical or a mathematical program. It certainly makes a difference what m is relative to now. If we want $\text{exec}^*(a, m)$ for m in the past of now, then a has already been executed (or not) and so $\text{exec}^*(a, m)$ is a hold predicate. It agrees with what has been done. Otherwise (if $m \geq \text{now}$) we do execute*.

1. $\text{exec}^*(\top, m) = \top$.
2. $\text{exec}^*(\perp, m) = \perp$.
3. $\text{exec}^*(A \wedge B, m) = \text{exec}^*(A, m) \wedge \text{exec}^*(B, m)$.
4. $\text{exec}^*(A \vee B, m) = \text{exec}^*(A, m) \vee \text{exec}^*(B, m)$.
5. $\text{exec}^*(S(A, B), 0) = \perp$.
6. $\text{exec}^*(S(A, B), m+1) = \text{exec}^*(A, m) \vee [\text{exec}^*(B, m) \wedge \text{exec}^*(S(A, B), m)]$.

7. $\text{exec}^*(U(A, B), m) = \text{exec}^*(A, m+1) \vee [\text{exec}^*(B, m+1) \wedge \text{exec}^*(U(A, B), m+1)]$.
8. $\text{exec}^*((\varphi x)A(x), 0) = A_0$, where A_0 is obtained from A by substituting \top for any wff of the form HB and \perp for any wff of the form PB or $S(B_1, B_2)$.
9. $\text{exec}^*((\varphi x)A(x), m+1) = \text{exec}^*(A(C), m+1)$, where C is a new atom defined for $n \leq m$ by $\text{exec}^*(C, n) = \text{exec}^*((\varphi x)A(x), n)$. In other words $\text{exec}^*((\varphi x)A(x), m+1) = \text{exec}^*(A((\varphi x)A(x)), m+1)$ and since in the execution of A at time $m+1$ we go down to executing A at time $n \leq m$, we will have to execute $(\varphi x)A(x)$ at $n \leq m$, which we assume by induction that we already know.
10. In the predicate case we can let

$$\begin{aligned} \text{exec}^*(\forall y A(y)) &= \forall y \text{exec}^*(A(y)) \\ \text{exec}^*(\exists y A(y)) &= \exists y \text{exec}^*(A(y)). \end{aligned}$$

We are now in a position to discuss how the execution of a specification is going to be carried out in practice. Start with a specification S . For simplicity we assume that S is written in essentially propositional USF which means that S contains S , U and φ operators applied to pure past formulae, and is built up from atomic units which are wffs of classical logic. If we regard any fixed point wff $(\varphi x)D(x)$ as atomic, we can apply the separation theorem and rewrite S into an executable form \mathcal{E} , which is a conjunction of formulae such that

$$\Omega \equiv \bigwedge_k \left[\bigwedge_i C_{i,k} \Rightarrow \bigvee_j B_{j,k} \right]$$

where $C_{i,k}$ are pure past formulae (containing S only) and $B_{j,k}$ are either atomic or pure future formulae (containing U). However, since we regarded any (φx) formula as an atom, the $B_{j,k}$ can contain $(\varphi x)D(x)$ formulae in them. Thus $B_{j,k}$ can be for example $U(a, (\varphi x)[\bullet \neg x])$. We will assume that any such $(\varphi x)D(x)$ contains only atoms controlled by the environment; this is a restriction on \mathcal{E} . Again, this is because we have no separation theorem as yet for full propositional USF, but only for the fragment US of formulae not involving φ . We conjecture that—possibly in a strengthened version of USF that allows more fixed point formulae—any formula can be separated. This again remains to be done.

However, even without such a result we can still make progress. Although $(\varphi x)[\bullet \neg x]$ is a pure past formula within U , it is still an executable formula that only refers to environment atoms, and so we do not mind having it there. If program atoms were involved, we might have a formula equivalent

to $X \bullet \text{print}$ (say), so that we would have to execute $\bullet \text{print}$ tomorrow. This is not impossible: when tomorrow arrives we check whether we did in fact print yesterday, and return \top or \perp accordingly. But it is not a very intelligent way of executing the specification, since clearly we should have just printed in the first instance. This illustrates why we need to separate \mathcal{S} .

Recall the equation for executing $U(A, B)$:

$$\text{exec}^*(U(A, B)) \equiv X \text{exec}^*(A) \vee (X(\text{exec}^*(B) \wedge \text{exec}^*(U(A, B))).$$

If either A or B is of the form $(\varphi x)D(x)$, we know how to compute $\text{exec}^*((\varphi x) D(x))$ by referring to past values. Thus $(\varphi x)D(x)$ can be regarded as atomic because we know how to execute it, in the same way as we know how to execute `write`.

Imagine now that we are at time n . We want to make sure the specification \mathcal{E} remains true. To keep \mathcal{E} true we must keep true each conjunct of \mathcal{E} . To keep true a conjunct of the form $C \Rightarrow B$ where C is past and B is future, we check whether C is true in the past. if it is true, then we have to make sure that B is true in the future. *Since the future has not happened yet, we can read B imperatively, and try to force the future to be true.* Thus the specification $C \Rightarrow B$ is read by us as

$$\text{hold}(C) \Rightarrow \text{exec}^*(B).$$

Some future formulae cannot be executed immediately. We already saw that to execute $U(A, B)$ now we either execute A tomorrow or execute B tomorrow together with $U(A, B)$. Thus we have to pass a list of formulae to execute from today to tomorrow. Therefore at time $n + 1$, we have a list of formulae to execute which we inherit from time n , in addition to the list of formulae to execute at time $n + 1$. We can thus summarize the situation at time $n + 1$ as follows:

1. Let G_1, \dots, G_m be a list of wffs we have to execute at time $n + 1$. Each G_i is a disjunction of formulae of the form atomic or negation of atomic or FA or GA or $U(A, B)$.
2. In addition to the above, we are required to satisfy the specification \mathcal{E} , namely

$$\bigwedge_k \left[\bigwedge_i C_{i,k} \Rightarrow \bigvee_j B_{j,k} \right]$$

for each k such that $\bigwedge_i C_{i,k}$ holds (in the past). We must execute the future (and present) formula $B_k = \bigvee_j B_{j,k}$ which is again a disjunction of the same form as in 1 above.

We know how to execute a formula; for example,

$$\text{exec}^*(FA) = X\text{exec}^*A \vee X \text{exec}^*(FA).$$

FA means ‘ A will be true’. To execute FA we can either make A true tomorrow or make FA true tomorrow. What we should be careful not to do is not to keep on executing FA day after day because this way A will never become true. Clearly then we should try to execute A tomorrow and if we cannot, only then do we execute FA by doing $X \text{exec}^*(FA)$. We can thus read the disjunction $\text{exec}^*(A \vee B)$ as *first* try to exec^*A and *then only if we fail* exec^*B . This priority (left to right) is not a logical part of ‘ \vee ’ but a procedural addition required for the correctness of the model. We can thus assume that the formulae given to execute at time n are written as disjunctions with the left disjuncts having priority in execution. Atomic sentences or their negations always have priority in execution (though this is not always the best practical policy).

Let $D = \bigvee_j D_j$ be any wff which has to be executed at time $n + 1$, either because it is inherited from time n or because it has to be executed owing to the requirements of the specification at time $n + 1$. To execute D , either we execute an atom and discharge our duty to execute, or we pass possibly several disjunctions to time $n + 2$ to execute then (at $n + 2$), and the passing of the disjunctions will discharge our obligation to execute D at time $n + 1$. Formally we have

$$\text{exec}^*(D) = \bigvee_j \text{exec}^*(D_j).$$

Recall that we try to execute left to right. The atoms and their negations are supposed to be on the left. If we can execute any of them we are finished with D . If an atom is an environment atom, we check whether the environment gives it the right value. If the atom is under the program’s control, we can execute it. However, the negation of the atom may appear in another formula D' to be executed and there may be a clash. See Examples 117 and 118 below. At any rate, should we choose to execute an atom or negation of an atom and succeed in doing so, then we are finished. Otherwise we can execute another disjunct of D of the form $D_j = U(A_j, B_j)$ or of the form GA_j or FA_j . We can pass the commitment to execute to the time $n + 2$. Thus we get

$$\text{exec}^*(D) = \bigvee \text{exec}^*(\text{atoms of } D) \vee \text{exec}^*(\text{future formulae of } D).$$

Thus if we cannot execute the atoms at time $n + 1$, we pass to time $n + 2$ a conjunction of disjunctions to be executed, ensuring that atoms and subformulae should be executed before formulae. We can write the disjunctions to reflect these priorities. Notice further that although, on first impression, the formulae to be executed seem to multiply, they actually do not.

At time $n = 0$ all there is to execute are heads of conditions in the specification. If we cannot execute a formula at time 0 then we pass execution to time 1. This means that at time 1 we inherit the execution of

$A \vee (B \wedge U(A, B))$, where $U(A, B)$ is a disjunct in a head of the specification. This same $U(A, B)$ may be passed on to time 2, or some subformula of A or B may be passed. The number of such subformulae is limited and we will end up with a limited stock of formulae to be passed on. In practice this can be optimized. We have thus explained how to execute whatever is to be executed at time n . When we perform the execution sequence at times $n, n+1, n+2, \dots$, we see that there are now two possibilities:

- We cannot go on because we cannot execute all the demands at the same time. In this case we stop. The specification cannot be satisfied either because it is a contradiction or because of a wrong execution choice (e.g. we should not have printed at time 1, as the specification does not allow anything to be done after printing).
- Another possibility is that we see after a while that the same formulae are passed for execution from time n to time $n+1$ to $n+2$ etc. This is a loop. Since we have given priority in execution to atoms and to the A in $U(A, B)$, such a loop means that it is not possible to make a change in execution, and therefore either the specification cannot be satisfied because of a contradiction or wrong choice of execution, or the execution is already satisfied by this loop.

EXAMPLE 117. All atoms are controlled by the program. Let the specification be

$$Ga \wedge F\neg a.$$

Now the rules to execute the subformulae of this specification are

$$\begin{aligned} \text{exec}^*(Ga) &\equiv \text{exec}^*(a) \wedge \text{exec}^*(Ga) \\ \text{exec}^*(F\neg a) &\equiv \text{exec}^*(\neg a) \vee \text{exec}^*(F\neg a). \end{aligned}$$

To execute Ga we must execute a . Thus we are forced to discharge our execution duty of $F\neg a$ by passing $F\neg a$ to time $n+1$. Thus time $n+1$ will inherit from time n the need to execute $Ga \wedge F\neg a$. This is a loop. The specification is unsatisfiable.

EXAMPLE 118. The specification is

$$b \vee Ga$$

$$Pb \Rightarrow F\neg a \wedge Ga.$$

According to our priorities we execute b first at time 0. Thus we will have to execute $F\neg a \wedge Ga$ at time 1, which is impossible. Here we made the wrong execution choice. If we keep on executing $\neg b \wedge Ga$ we will behave as specified.

In practice, since we may have several choices in execution we may want to simulate the future a little to see if we are making the correct choice.

Having defined exec^* , we need to add the concept of updating. Indeed, the viability of our notion of the declarative past and imperative future depends on adding information to our database. In this section we shall assume that every event that occurs in the environment, and every action exec -ed by our system, are recorded in the database. This is of course unnecessary, and in a future paper we shall present a more realistic method of updating.

8.3 The logic *USF2*

The fixed point operator that we have introduced in propositional USF has to do with the solution of the equation

$$x \leftrightarrow B(x, q_1, \dots, q_m)$$

where B is a pure past formula. Such a solution always exists and is unique. The above equation defines a connective $A(q_1, \dots, q_m)$ such that

$$A(q_1, \dots, q_m) \leftrightarrow B(A(q_1, \dots, q_m), q_1, \dots, q_m).$$

Thus, for example, $S(p, q)$ is the solution of the equation

$$x \leftrightarrow \bullet p \vee \bullet (q \wedge x)$$

as we have $S(p, q) \leftrightarrow \bullet p \vee \bullet (q \wedge S(p, q))$. Notice that the connective to be defined ($x = S(p, q)$) appears as a unit in both sides of the equation.

To prove existence of a solution we proceed by induction. Suppose we know what x is at time $\{0, \dots, n\}$. To find what x is supposed to be at time $n + 1$, we use the equation $x \leftrightarrow B(x, q_i)$. Since B is pure past, to compute B at time $n + 1$ we need to know $\{x, q_i\}$ at times $\leq n$, which we do know. This is the reason why we get a unique solution.

Let us now look at the following equation for a connective $Z(p, q)$. We want Z to satisfy the equation

$$Z(p, q) \leftrightarrow \bullet p \vee \bullet (q \wedge Z(\bullet p, q)).$$

Here we did not take $Z(p, q)$ as a unit in the equation, but substituted a value $\bullet p$ in the right-hand side, namely $Z(\bullet p, q)$. $\bullet p$ is a pure past formula. We can still get a unique solution because $Z(p, q)$ at time $n + 1$ still depends on the values of $Z(p, q)$ at earlier times, and certainly we can compute the values of $Z(\bullet p, q)$ at earlier times.

The general form of the new fixed point equation is as follows:

DEFINITION 119 (Second-order fixed points). Let $Z(q_1, \dots, q_m)$ be a candidate for a new connective to be defined. Let $B(x, q_1, \dots, q_m)$ be a pure

past formula and let $D_i(q_1, \dots, q_m)$ for $i = 1 \dots m$ be arbitrary formulae. Then we can define Z as the solution of the following equation:

$$Z(q_1, \dots, q_m) \leftrightarrow B(Z[D_1(q_1, \dots, q_m), \dots, D_m(q_1, \dots, q_m)], q_1, \dots, q_m).$$

We call this definition of Z *second order*, because we can regard the equation as

$$Z \equiv \text{Application}(Z, D_i, q_j).$$

We define USF2 to be the logic obtained from USF by allowing nested applications of second-order fixed point equations. USF2 is more expressive than USF (Example 120).

Predicate USF2 is defined in a similar way to predicate USF .

EXAMPLE 120. Let us see what we get for the connective $Z_1(p, q)$ defined by the equation

$$Z_1(p, q) \leftrightarrow \bullet p \vee \bullet (q \wedge Z_1(\bullet p, q)).$$

The connective $Z_1(p, q)$ says what is shown in Fig.12:

Figure 12.

$Z_1(p, q)$ is true at n iff for some $m \leq n$, q is true at all points j with $m \leq j < n$, and p is true at the point $m_1 = m - (n - m + 1) = 2m - n - 1$. If we let $k = n - m$, then we are saying that q is true k times into the past and before that p is true at a point which is $k + 1$ times further into the past. This is not expressible with any pure past formula of USF ; see [Hodkinson, 1989].

Let us see whether this connective satisfies the fixed point equation

$$Z_1(p, q) \leftrightarrow \bullet p \vee \bullet (q \wedge Z_1(\bullet p, q)).$$

If $\bullet p$ is true then $k = 0$ and the definition of $Z_1(p, q)$ is correct. If $\bullet (q \wedge Z_1(\bullet p, q))$ is true, then we have for some k the situation in Fig. 13:

Figure 13.

The definition of $Z_1(p, q)$ is satisfied for $k + 1$.

EXAMPLE 121 (Coding of dates). We can encode dates in the logic as follows:

1. The proposition $\neg \bullet \top$ is true exactly at time 0, since it says that there is no yesterday. Thus if we let

$$\begin{aligned} \mathbf{n} &= \perp \text{ if } n \leq 0 \\ 0 &= \neg \bullet \top \\ \mathbf{n} &= \bullet (\mathbf{n} - \mathbf{1}). \end{aligned}$$

then we have that \mathbf{n} is true exactly at time n . This is a way of naming time n . In predicate temporal logic we can use elements to name time. Let $\text{date}(x)$ be a predicate such that the following hold at all times n :

$$\begin{aligned} &\exists x \text{ date}(x) \\ &\forall x (\text{date}(x) \Rightarrow G\neg \text{date}(x) \wedge H\neg \text{date}(x)) \\ &\forall x (\text{date}(x) \vee P \text{date}(x) \vee F \text{date}(x)). \end{aligned}$$

These axioms simply say that each time n is identified by some element x in the domain that uniquely makes $\text{date}(x)$ true, and every domain element corresponds to a time.

2. We can use this device to count in the model. Suppose we want to define a connective that counts how many times A was true in the past. We can represent the number m by the date formula \mathbf{m} , and define $\text{count}(A, \mathbf{m})$ to be true at time n iff the number of times before n in which A was true is exactly \mathbf{m} . Thus in Fig. 14, $\text{count}(A, \bullet \top \wedge \neg \bullet \bullet \top)$ is false at time 3, true at time 2, true at time 1 and false at time 0.

Figure 14.

The connective **count** can be defined by recursion as follows:

$$\begin{aligned} \mathbf{count}(p, \mathbf{n}) \quad \leftrightarrow \quad & \bullet (\neg p \wedge \mathbf{count}(p, \mathbf{n})) \\ & \vee \bullet (p \wedge \mathbf{count}(p, X\mathbf{n})) \\ & \vee (\neg \bullet \top \wedge \mathbf{n}). \end{aligned}$$

Note that $X\mathbf{n}$ is equivalent to $\mathbf{n} - \mathbf{1}$. We have cheated in this example. For the formula $B(x, q_1, q_2)$ in the definition of second-order fixed points is here

$$\bullet (\neg q_1 \wedge x) \vee \bullet (q_1 \wedge x) \vee (\neg \bullet \top \wedge q_2).$$

This is not pure past, as q_2 occurs in the present tense. To deal with this we could define the notion of a formula $B(x, q_1, \dots, q_m)$ being pure past in x . See [Hodkinson, 1989]. We could then amend the definition to allow any B that is pure past in x . This would cover the B here, as all x s in B occur under a \bullet . So the value of the connective at n still depends only on its values at $m \leq n$, which is all we need for there to be a fixed point solution. We do not do this formally here, as we can express **count** in standard USF2; see the next example.

EXAMPLE 122. We can now define the connective **more**(A, B) reading ‘ A was true more times than B ’.

$$\begin{aligned} \mathbf{more}(A, B) \quad \leftrightarrow \quad & \bullet (A \wedge \mathbf{more}(A, B)) \\ & \vee \bullet (\neg A \wedge \neg B \wedge \mathbf{more}(A, B)) \\ & \vee \bullet (\neg A \wedge \mathbf{more}((A \wedge PA), B)). \end{aligned}$$

(If $k > 0$, then at any n , $A \wedge PA$ has been true k times iff A has been true $k + 1$ times.)

Note that for any $k > 0$, the formula $E_k = \neg \bullet^k \top$ is true exactly k times, at $0, 1, \dots, k - 1$. If we define

$$\text{count}^*(p, k) = \text{more}(E_{k+1}, p) \wedge \neg \text{more}(E_k, p),$$

then at any n , p has been true k times iff $\text{count}^*(p, k)$ holds. So we can do the previous example in standard USF2.

THEOREM 123 (For propositional USF2). *Nested applications of the second-order fixed point operator are equivalent to one application. Any wff A of USF2 is equivalent to a wff B of USF2 built up using no nested applications of the second-order fixed point operator.*

8.4 Payroll example in detail

This section will consider in detail the execution procedures for the payroll example in Section 8.

First let us describe, in the temporal logic USF2, the specification required by Mrs Smith. We translate from the English in a natural way. This is important because we want our logical specification to be readable and have the same structure as in English.

Recall that the intended interpretation of the predicates to be used is

$A(x)$	x is asked to babysit
$B(x)$	x does a babysitting job
$M(x)$	x works after midnight
‘ $P(x, y)$	x is paid y pounds.

‘Babysitters are not allowed to take jobs three nights in a row, or two nights in a row if the first night involves overtime’ is translated as

(a) $\forall x \neg [B(x) \wedge \bullet B(x) \wedge \bullet \bullet B(x)]$

(b) $\forall x \neg [B(x) \wedge \bullet (B(x) \wedge M(x))]$

(c) $\forall x [M(x) \Rightarrow B(x)]$.

Note that these wffs are not essentially propositional.

‘Priority in calling is given to those who were not called before as many times as others’ is translated as

(d) $\neg \exists x \exists y [\text{more}(A(x), A(y)) \wedge A(x) \wedge \neg A(y) \wedge \neg \bullet M(y) \wedge \neg \bullet (B(y) \wedge \bullet B(y))]$.

‘Payment should be made the next day after the job was done, with £15 for a job involving overtime, and £10 for a job not involving overtime’ is translated as

- (e) $\forall x[M(x) \Rightarrow XP(x, 15)]$
- (f) $\forall x[B(x) \wedge \neg M(x) \Rightarrow XP(x, 10)]$
- (g) $\forall x[\neg B(x) \Rightarrow X\neg\exists yP(x, y)]$.

Besides the above we also have

- (h) $\forall x[B(x) \Rightarrow A(x)]$.

Babysitters work only when they are called.

We have to rewrite the above into an executable form, namely

Past \Rightarrow Present \vee Future.

We transform the specification to the following:

- (a') $\forall x[\bullet B(x) \wedge \bullet \bullet B(x) \Rightarrow \neg B(x)]$
- (b') $\forall x[\bullet (B(x) \wedge M(x)) \Rightarrow \neg B(x)]$
- (c') $\forall x[\neg M(x) \vee B(x)]$.
- (d') $\forall x\forall y[\text{more}(A(x), A(y)) \wedge \neg \bullet M(y) \wedge \neg \bullet (B(y) \wedge \bullet B(y)) \Rightarrow \neg A(x) \vee \neg A(y)]$
- (e') $\forall x[\neg M(x) \vee XP(x, 15)]$
- (f') $\forall x[\neg B(x) \vee M(x) \vee XP(x, 10)]$
- (g') $\forall x[B(x) \vee X\forall y\neg P(x, y)]$
- (h') $\forall x[\neg B(x) \vee A(x)]$.

Note that (e'), (f') and (h') can be rewritten in the following form using the \bullet operator.

- (e'') $\forall x[\bullet M(x) \Rightarrow P(x, 15)]$
- (f'') $\forall x[\bullet (B(x) \wedge \neg M(x)) \Rightarrow P(x, 10)]$
- (g'') $\forall x[\neg \bullet B(x) \Rightarrow \forall y\neg P(x, y)]$.

Our executable sentences become

- (a*) $\text{hold}(\bullet B(x) \wedge \bullet \bullet B(x)) \Rightarrow \text{exec}(\neg B(x))$
- (b*) $\text{hold}(\bullet (B(x) \wedge M(x))) \Rightarrow \text{exec}(\neg B(x))$
- (c*) $\text{exec}(\neg M(x) \vee B(x))$
- (d*) $\text{hold}(\text{more}(A(x), A(y)) \wedge \neg \bullet M(y) \wedge \neg \bullet (B(y) \wedge \bullet B(y))) \Rightarrow \text{exec}(\neg A(x) \vee \neg A(y))$

(**e***) $\text{exec}(\neg M(x) \vee XP(x, 15))$

(**f***) $\text{exec}(\neg B(x) \vee M(x) \vee XP(x, 10))$

(**g***) $\text{exec}(B(x) \vee X\forall y\neg P(x, y))$

(**h***) $\text{exec}(\neg B(x) \vee A(x))$.

If we use (**e''**), (**f''**), (**g''**) the executable form will be

(**e****) $\text{hold}(\bullet M(x)) \Rightarrow \text{exec}(P(x, 15))$

(**f****) $\text{hold}(\bullet (B(x) \wedge \neg M(x))) \Rightarrow \text{exec}(P(x, 10))$

(**g****) $\text{hold}(\neg \bullet B(x)) \Rightarrow \text{exec}(\forall y\neg P(x, y))$.

In practice there is no difference whether we use (**e****) or (**e***). We execute XP by sending P to tomorrow for execution. If the specification is (**e****), we send nothing to tomorrow but we will find out tomorrow that we have to execute P .

COMBINATIONS OF TENSE AND MODALITY

1 INTERACTIONS WITH TIME

Physics should have helped us to realise that a temporal theory of a phenomenon X is, in general, more than a simple combination of two components: the statics of X and the ordered set of temporal instants. The case in which all functions from times to world-states are allowed is uninteresting; there are too many such functions, and the theory has not begun until we have begun to restrict them. And often the principles that emerge from the interaction of time with the phenomena seem new and surprising. The most dramatic example of this, perhaps, is the interaction of space with time in relativistic space-time.

The general moral, then, is that we shouldn't expect the theory of time + X to be obtained by mechanically combining the theory of time and the theory of X .¹

Probability is a case that is closer to our topic. Much ink has been spilled over the evolution of probabilities: take, for instance, the mathematical theory of Markov processes (Howard [1971a; 1971b] make a good text), or the more philosophical question of rational belief change (see, for example, Chapter 11 of Jeffrey [1990] and Harper [1975].) Again, there is more to these combinations than can be obtained by separate reflection on probability measure and the time axis.

probability shares many features with modalities and, despite the fact that (classical) probabilities are numbers, perhaps in some sense probability *is* a modality. It is certainly the classic case of the use of possible worlds in interpreting a calculus. (Sample points in a state space are merely possible worlds under another name.) But the literature on probability is enormous, and almost none of it is presented from the logician's perspective. So, aside from the references I have given, I will exclude it from this survey. However, it seems that the techniques we will be using can also help to illuminate problems having to do with probability; this is illustrated by papers such as D. Lewis [1981] and Van Fraassen [1971]. For lack of space, these are not discussed in the present essay.

¹For a treatment that follows this procedure, see [Woolhouse, 1973]; [Werner, 1974] may also fit into this category, but I have not been able to obtain a copy of it. The tense logic of Woolhouse's paper is fairly crude: e.g. moments of time appear both in models and in the object language. The paper seems mainly to be of historical interest.

2 INTRODUCTION TO HISTORICAL NECESSITY

Modern modal logic began with necessity (or with things definable with respect to necessity), and the earliest literature, like C. I. Lewis [1918], confuses this with validity. Even in later work that is formally scrupulous about distinguishing these things, it is sometimes difficult to tell what concepts are really metalinguistic. Carnap, for instance [1956, p. 10], begins his account of necessity by directing our attention to *l*-truth; a sentence of a semantical system (or language) is *L*-true when its truth follows from the semantical rules of the language, without auxiliary assumptions. This, of course, is a metalinguistic notion. But later, when he introduces necessity into the object language [Carnap, 1956, p. 174], he stipulates that $\Box\varphi$ is true if and only if φ is *L*-true.

Carnap thinks of the languages with which he is working as fully determinate; in particular, their semantical rules are fixed. This has the consequence that whatever is *L*-true in a language is eternally *L*-true in that language. (See [Schlipp, 1963, p. 921], for one passage in which Carnap is explicit on the point: he says ‘analytic sentences cannot change their truth-value’.) Combining this consequence with Carnap’s explication of necessity, we see that²

$$(1) \quad \Box\varphi \rightarrow HG\Box\varphi$$

will be valid in languages containing both necessity and tense operators: necessary truths will be eternally true. The combination of necessity with tense would then be trivialised.

But there are difficulties with Carnap’s picture of necessity; indeed, it seems to be drastically misconceived.³ For one thing, many things appear to be necessary, even though the sentences that express them can’t be derived from semantical rules. In Kripke [1982], for instance, published 26 years after *Meaning and Necessity*, Saul Kripke argues that it is necessary that Hesperus is Phosphorous, though ‘Hesperus’ and ‘Phosphorous’ are by no means synonymous. Also at work in Kripke’s conception of necessity, and that of many other contemporaries, is the distinction between φ expressing a necessary truth, and φ necessarily expressing a truth. In a well-known defence of the analytic-synthetic distinction, Grice and Strawson [1956] write as follows:

²I use the tense logical notation of the first Chapter in this volume.

³For an early appreciation of the philosophical importance of making necessity time-dependent (the point I myself am leading up to), see [Lehrer and Taylor, 1965]. The puzzles they raise in this paper are genuine and well presented. But the solution they suggest is very implausible, and the considerations that motivate it seem to confuse semantic and pragmatic phenomena. This is a good example of a case in which philosophical reflections could have been aided by an appeal to the technical apparatus of model theory (in this case, to the model theory of tense logic).

Any form of words at one time held to express something true may, no doubt, at another time come to be held to express something false. but it is not only philosophers who would distinguish between the case where this happens as the result of a change of opinion solely as to matters of fact, and the case where this happens at least partly as a result of shift in the sense of the words (p. 157).

This distinction, at least in theory, makes it possible that a sentence φ should necessarily (perhaps, because of semantical rules) express a truth, even though the truth that it expresses is contingent. This idea is developed most clearly in [Kaplan, 1978].

On this view of necessity, it attaches not primarily to sentences, but to propositions. A sentence will express a proposition, which may or may not be necessary. This can be explicated using possible worlds: propositions take on truth values in these worlds, and a proposition is necessary if and only if it is true in all possible worlds.⁴

This conception can be made temporal without trivialising the results. Probably the simplest way of managing this is to begin with nonempty sets T of times and W of worlds;⁵ T is linearly ordered by a relation $<$. I will call this the $T \times W$ approach.

Recall that a tensed formula, say $F\varphi$, is true at $\langle w, t \rangle$, where $w \in W$ and $t \in T$, if and only if φ is true at $\langle w, t' \rangle$, for some t' such that $t < t'$.⁶ We now want to ask under what conditions $\Box\varphi$ is true at $\langle w, t \rangle$. (In putting it this way we are suppressing propositions; this is legitimate, as long as we treat propositional attitudes as unanalysed, and assume that sentences express the same proposition everywhere.)

If we appeal to intuitions about languages like English, it seems that we should treat formulas like $\Box\varphi$ as nontrivially tensed. This is shown most clearly by sentences involving the adjective 'possible', such as 'In 1932 it was possible for Great Britain to avoid war with Germany; but in 1937 it was impossible'. This suggests that when $\Box\varphi$ is evaluated at $\langle w, t \rangle$ we

⁴To simplify matters, I confine the discussion to the absolute necessity of S5. But perhaps I should mention in passing that in explicating the relative breeds of necessity, such as that of S4, it is easy to confuse modal relations with temporal relations, relative necessity with evanescent necessity. And, of course, tense logic was inspired in part by work on relative necessity. But the two notions are separate; an S5 breed of necessity, for instance, can be evanescent. And when tense and modality are combined, it is very important to attend to the distinction.

⁵I dislike this way of arranging things for philosophical reasons. it doesn't strike me as a logical truth that all worlds have the same temporal orderings: some may have an earliest time, for instance, and others not. Also, the notion of different worlds sharing the same time is philosophically problematic; it is hard to reconcile with a plausible theory of time, when the possible worlds differ widely. Finally, I like to think of possible worlds as overlapping, so that at the same moment may have alternative futures. This requires a more complicated representation. However, the $T \times W$ arrangement will do for now.

⁶See the discussion of the interpretation of tense in Chapter 1 of this volume.

are considering what is *then necessary*; what is true in all worlds at that particular time, t .

The rule then is that $\Box\varphi$ is true at $\langle w, t \rangle$ if and only if φ is true at $\langle w', t \rangle$ for all $w' \in W$. If we like, we can make this relational. Let $\{\approx_t: t \in T\}$ be a family of equivalence relations on W , and let $\Box\varphi$ be true at $\langle t, w \rangle$ if and only if φ is true at $\langle t, w' \rangle$ for all $w' \in W$ such that $w \approx_t w'$.

The resulting theory generates some validities arising from the assumption that the worlds share a common temporal ordering. Formulas (2) and (3) are two such validities, corresponding to the principle that one world has a first moment if and only if all worlds do.

$$(2) \quad P[\varphi \vee \neg\varphi] \leftrightarrow \Box P[\varphi \vee \neg\varphi]$$

$$(3) \quad H[\varphi \wedge \neg\varphi] \leftrightarrow \Box H[\varphi \wedge \neg\varphi]$$

In case \approx_t is the universal relation for every t (or the relations \approx_t are simply omitted from the satisfaction conditions) there are other validities, such as (4) and (5).

$$(4) \quad P\Box\varphi \rightarrow \Box P\varphi$$

$$(5) \quad F\Box\varphi \rightarrow \Box F\varphi$$

As far as I know, the general problem of axiomatising these logics has not been solved. But I'm not sure that it is worth doing, except as an exercise. The completeness proofs should not be difficult, using Gabbay's techniques (described in Section 4, below). and these logics do not seem particularly interesting from a philosophical point of view.

But a more interesting case is near to hand. The tendency we have noted to bring Carnap's metalinguistic notion of necessity down to earth has made room for the reintroduction of one of the most important notions of necessity: practical necessity, or historical necessity.⁷ This is the sort of necessity that figures in Aristotle's discussion of the Sea Battle (*De Int.* 18^b25–19^b4), and that arises when free will is debated. It also seems to be an important background notion in practical reasoning. Jonathan Edwards, in his usual lucid way, gives a very clear statement of the matter.

Philosophical necessity is really nothing else than the full and fixed connection between the things signified by the subject and predicate of a proposition, which affirms something to be true [This connection] may be fixed and made certain, because the existence of that thing is already come to pass; and either

⁷I am not sure if there are personal, or relational varieties of inevitability; it seems a bit peculiar to my ear to speak of an accident John caused as inevitable for Mary, but not inevitable for John. If there are such sorts of inevitability I mean to exclude them, and to speak only of impersonal inevitability. Thus 'inevitable' does not belong to the same modal family as 'able', since the latter is personal.

now is, or has been; and so has as it were made sure of existence. And therefore, the proposition which affirms present and past existence of it, may be this means be made certain, and necessarily and unalterably true; the past event has fixed and decided that matter, as to its existence; and has made it impossible but that existence should be truly predicted of it. Thus the existence of whatever is already come to pass, is not become necessity; 'tis become impossible it should be otherwise than true, that such a thing has been. [Edwards, 1957, pp. 152–3]

Historical necessity can be fitted into the $T \times W$ framework; it is merely a matter of adjusting the relations \approx_t so that if $w \approx_t w'$, then w and w' share the same past up to and including t . So for $t' < t$, atomic formulas must be treated the same way in w and w' . Furthermore, we have to stipulate that historical possibilities diminish monotonically with the passage of time: if $t < t'$, then $\{w' : w \approx_{t'} w'\} \subseteq \{w' : w \approx_t w'\}$. This interaction between time and relative necessity creates distinctive validities, such as (6) and (7).

(6) $\varphi \leftrightarrow \Box\varphi$, if φ contains no occurrences of F .

(7) $P\Box\varphi \rightarrow \Box P\varphi$

Formula (8), on the other hand, is clearly invalid.

(8) $\Box Pp \rightarrow P\Box p$

These correspond to rather natural intuitions relating the flow of time to the loss of possibilities.

There is another way of representing historical necessity, which perhaps will seem less straightforward to logicians steeped in possible worlds. Time can be treated as non-linear (branching only towards the future), and worlds represented as branches on the resulting ordered structure. This corresponds very closely to the $T \times W$ account: (6) and (7) remain valid, and (8) invalid. But the validities are not the same. This matter will be taken up below, in Section 4.

So much for necessity; I will deal more briefly with 'ought' and conditionals.

As Aristotle points out, we don't deliberate about just anything; in particular, we deliberate only about what is in our power to determine. [Ne 1112^a 19f.] But the past, and the instantaneous present, are not in our power: deliberation is confined to future alternatives.

This suggests that deontic logic, insofar as it investigates practical oughts, should identify its possibilities with the ones of historical necessity. Unfortunately, this conception played little or no role in the early interpretation of deontic logic; those who developed the deontic applications of possible worlds semantics seemed to think of deontic possibilities ahistorically, as

'perfect worlds' in which all norms are fulfilled.⁸ Historical possibilities, on the other hand, are typically imperfect; life is full of occasions on which we have to make the best of a bad situation. In my opinion, this is one reason why deontic logic has seemed to most philosophers to consist largely of a sterile assortment of paradoxes, and why its influence on moral philosophy has been so fruitless.

Conditionals have been intensively studied by philosophical logicians over the last fifteen years, and this has created an extensive literature. Relatively little of this effort has been devoted to the interaction of conditionals with tense. But there is reason to think that important insights may be lost if conditionals are studied ahistorically. One very common sort of conditional (the philosopher's novel example of a 'subjunctive conditional') is exemplified by (9).

(9) If Oswald hadn't shot Kennedy, then Kennedy would be alive today.

These conditionals seem to be closely related to historical possibilities; they envisage courses of events that diverge at some point in the past from the actual one. And this in turn suggests that there may be close connections between historical necessity and some conditionals.

Examples like the following four provide evidence of a different sort.

(10) He would go if she would go.

(11) He will go if she will go.

(12) he would have gone if she were to have gone.

(13) he went if she went.

Sentences (10) and (11) seem hardly to differ in meaning, if (10) has to do with the future. On the other hand, (12) and (13) are very different. If he didn't go, but would have gone if she had, (12) is true and (13) false.

This suggests that there may be systematic connections between tense, mood and the truth conditions of conditionals. According to one extreme proposal, the difference in 'mood' between (9) and the past-present conditionals form 'If Oswald didn't shoot Kennedy, then Kennedy is alive today' can be accounted for solely in terms of the interaction of tense operators and the conditional.⁹ This has in favour of it the grammatical fact that 'would' is the past tense of 'will'. But the matter is complex, and it is difficult to see how much merit there is in the suggestion.

There have been recent signs of interest in the interaction of tense and conditionals; the most systematic of these is [Thomason and Gupta, 1981]

⁸See [Von Wright, 1968] and Hintikka [1969; 1971].

⁹See [Thomason and Gupta, 1981, pp. 304-305].

If this study is any indication, the topic is surprisingly complicated. But the complications may prove to be of philosophical interest.

The relation between historical necessity and quantum mechanics is a topic that I will not discuss at any great length. The indeterminacy that is associated with microphenomena seems at first glance to invite a treatment using alternative futures; and one of the approaches to the measurement problem in quantum theory, the ‘many-worlds interpretation’, does appear to do just this. (See [DeWitt and Graham, 1973] for more information about the approach.)

But alternative futures don’t provide in themselves an adequate representation of the physical situation, because the quantum mechanical probabilities can’t be treated as distributions over a set of fully determinate worlds.¹⁰ Some further apparatus would have to be introduced to secure the right system of nonboolean probabilities, and as far as I can see, what is required would have to go beyond the resources of possible worlds semantics: there is no escaping an analysis of measurement interactions, or of interactions in general.

Possible world semantics may help to make the ‘many worlds’ approach to quantum indeterminacy seem less frothy; the prose of philosophical modal realists, such as D. Lewis [1970], is much more judicious than that in which the physicists sometimes indulge. (See, for instance, [DeWitt, 1973, p. 161].) So, modal logic may be of some help in sorting out the philosophical issues; but this leaves the fundamental problems untouched. Possible worlds are not in themselves a key to the problem of measurement in quantum mechanics.

The following sections will aim at fleshing out this general introduction with further historical information, more detailed descriptions of the relevant logical theories, and more extensive references to the literature.

3 HISTORICAL NECESSITY

The first sustained discussion of this topic, from the standpoint of modern tense logic is (as far as I know) Chapter 7 of [Prior, 1967] entitled ‘Time and determinism’.¹¹ Prior’s judgement and philosophical depth, as well as his

¹⁰See, for instance [Wigner, 1971] and [Fine, 1982].

¹¹The mention of historical necessity and its combination with deontic operators in the *tour de force* at the end of [Montague, 1968] probably takes precedence if you go by date of composition. But Montague’s discussion is very compressed, and neglects philosophical motivation. And some interesting things are said about indeterminism in Prior’s earlier book [Prior, 1957]. But the connection does not seem to be made there between the philosophical issues and the problem of interpreting future tense in treelike frames. The ingredients of a model theoretic treatment of historical necessity also occurred at an early date to Dana Scott. Like much of his work in modal and tense logic, it remained unpublished, but there is a mimeographed paper [Scott, 1967].

readable style, make this required reading for anyone seriously interested in historical necessity.

Prior's exposition is informal, and sprinkled with historical references to the philosophical debate over determinism. In this debate he unearths a logical determinist argument, that probably goes back to ancient times. According to this argument, if φ is true then, at any previous time, $F\varphi$ must have been true. But choose such a time, and suppose that at this earlier time φ could have failed to come about; then $F\varphi$ could not have been true at this time. It seems to follow that the determinist principle

$$(14) \quad \varphi \rightarrow H\Box F\varphi$$

holds good.

In discussing the argument and some ways of escaping from it, Prior is fairly flexible about this object language; in particular, he allows metric tense operators. Since these complicate matters from a semantic point of view, I will ignore them, and consider languages whose only modal operators are \Box and the nonmetric tenses.

Also (and this is more unfortunate), Prior [1967] speaks loosely in describing models. At the place where his indeterminist models are introduced, for instance, he writes as follows.

... we may define an Ockhamist *model* as a line without beginning or end which may break up into branches as it moves from left to right (i.e. from past to future), though not the other way ...
(p. 126)

From this description it is clear that Prior is representing historical necessity by means of non-linear time, rather than according to the $T \times W$ format described in Section 2, above. But it is a little difficult to tell exactly what mathematical structures have been characterised; probably, Prior had in mind trees whose branches all have the order type of the (negative and non-negative) integers.

To bring this into accord with the usual treatment of linear nonmetric tense logic, we will liberalise Prior's account.

DEFINITION 1. A treelike frame \mathfrak{A} for tense logic is a pair $\langle T, < \rangle$, where T is a non-empty set and $<$ is a transitive ordering on T such that if $t_1 < t$ and $t_2 < t$ then either $t_1 = t_2$ or $t_1 < t_2$ or $t_2 < t_1$.

As in ordinary tense logic, we imagine an assignment of truth values to atomic formulas at each $t \in T$, and truth-functional connectives are treated in the usual way. But things become perplexing when you try to interpret future tense in these structures. Take a very simple branching case, with just three moments, and imagine that p is true at t_0 and t_1 , and false at t_2 .

Is Fp true at t_0 ? It is hard to say.

Moreover, as you reflect on the problem, it becomes clear that Prior's juxtaposition of this technical problem with bits from figures like Diodorus Cronus, Peter de Rivo, and Jonathan Edwards is not merely an antiquarian quirk. There is a genuine connection. These treelike frames represent ways in which things can evolve indeterministically. A definition of satisfaction for a language with tense operators that is suited to such structures would automatically provide a way of making tense compatible with indeterministic cases. And it is just this that the logical argument for determinism claims can't be done. The technical problem can't be solved without getting to the bottom of this argument.

If the argument is correct, any definition of satisfaction for these structures will be incorrect—will generate validities that are at variance with the intended interpretation. Łukasiewicz's [1967] earlier three-valued solution is like this, I believe. Not because it makes some formulas neither true nor false, but because the formulas it endorses as valid are so far off the mark. It is bad enough that $Fp \vee \neg Fp$ is invalid, but also the approach would make $[[\Diamond Fp \wedge \Diamond \neg Fp] \wedge [\Diamond Fq \wedge \Diamond \neg Fq]] \rightarrow [Fp \leftrightarrow Fq]$ valid, if φ is true if and only if φ takes the intermediate truth value.¹²

Nor does the logic that Prior calls 'Peircian' strike me as more satisfactory, from a philosophical standpoint, though it does lead to some interesting technical problems relating to axiomatisability. Here, $F_v arphi$ is treated as true at t in case the moments at which φ is true bar the future paths through t ; i.e., every branch through t contains a moment subsequent to t at which φ is true. On the Peircian approach, $F\varphi \vee \neg F\varphi$ is valid, but $Fp \vee F\neg p$ is not; nor is $p \rightarrow PFP$.¹³ As Prior says, sense can be made of this by reading F as 'will inevitably'. Though this helps us to see what is going on, it is not the intended interpretation.

The most promising of Prior's suggestions for dealing with indeterminist future tense is the one he calls 'Ockhamist'. The theory will be easier to present if we first work out the satisfaction conditions for $\Box\varphi$ in treelike frames. Intuitively, $\Box\varphi$ is true at t if φ is true at t no matter what the

¹²Prior briefly criticises Łukasiewicz's treatment of future tense [Prior, 1967, p. 135]; for a more extended criticism, see [Seeskin, 1971].

¹³Notice that this corresponds to one of the informal principles used in the logical argument for determinism.

future is like. And a way the future can be like will be represented by a fully determinate—i.e. linear—path beyond t . Since the frames are treelike, these correspond to the branches, or maximal chains, through t .

DEFINITION 2. Where $\langle T, < \rangle$ is a treelike model structure and $t \in T$, a branch through t is a maximal linearly ordered subset of T containing t ; B_t .

To make sense of φ being true at t no matter what the future is like, we will have to think of formulas being satisfied not just at moments t , but at pairs $\langle t, b \rangle$, where $b \in B_t$. Prior explains it this way. On the Ockhamist approach formulas like Fp are given ‘*prima facie* assignments’ at t ; such an assignment is made by choosing a particular b in B_t . His idea seems to be that there is something more provisional about the selection of b than about that of t ; but this he does not articulate or defend very fully. In the technical formulation of the theory there is no asymmetry between moments and branches; it is just that two parameters need to be fixed in evaluating formulas.

Once satisfaction is made relative to pairs $\langle t, b \rangle$ for some formulas, it must be relativised in the same way for all formulas; otherwise the recursive definition of satisfaction will become snarled. So, except for future tense, the definition will go like this.

DEFINITION 3. A function h assigning each atomic formula a subset of T is called an (Ockhamist) *assignment*, as in Chapter 1 of this volume.

DEFINITION 4. The h truth value $\|\varphi\|_{\langle t, b \rangle}^h$ of φ at the pair $\langle t, b \rangle$ is defined as follows. We assume here that $\|\varphi\|_{\langle t, b \rangle}^h = 0$ iff $\|\varphi\|_{\langle t, b \rangle}^h \neq 1$.

$$\begin{aligned} \|\varphi\|_{\langle t, b \rangle}^h &= 1 \text{ iff } t \in h(\varphi), \text{ if } \varphi \text{ is atomic,} \\ \|\neg\varphi\|_{\langle t, b \rangle}^h &= 1 \text{ iff } \|\varphi\|_{\langle t, b \rangle}^h = 0, \\ \|\varphi \wedge \psi\|_{\langle t, b \rangle}^h &= 1 \text{ iff } \|\varphi\|_{\langle t, b \rangle}^h = 1 \text{ and } \|\psi\|_{\langle t, b \rangle}^h = 1, \\ \|\varphi \vee \psi\|_{\langle t, b \rangle}^h &= 1 \text{ iff } \|\varphi\|_{\langle t, b \rangle}^h = 1 \text{ or } \|\psi\|_{\langle t, b \rangle}^h = 1, \\ \|\varphi \rightarrow \psi\|_{\langle t, b \rangle}^h &= 1 \text{ iff } \|\varphi\|_{\langle t, b \rangle}^h = 0 \text{ or } \|\psi\|_{\langle t, b \rangle}^h = 1, \\ \|P\varphi\|_{\langle t, b \rangle}^h &= 1 \text{ iff for some } t' < t, \|\varphi\|_{\langle t', b \rangle}^h = 1, \\ \|\Box\varphi\|_{\langle t, b \rangle}^h &= 1 \text{ iff for all } b \in B_t, \|\varphi\|_{\langle t, b \rangle}^h = 1. \end{aligned}$$

This definition renders $p \rightarrow \Box p$ valid, though not every substitution instance of it is valid. This can be easily changed by letting assignments take atomic formulas into subsets of $\{\langle t, b \rangle : t \in T \text{ and } b \in B_t\}$; [Prior, 1967, pp. 123–123] discusses the matter.

At this point, the way to handle $F\varphi$ is forced on us. We use the branch that is provided by the index.

$$\|F\varphi\|_{\langle t, b \rangle}^h = 1 \text{ iff for some } t' \in b \text{ such that } t < t', \|\varphi\|_{\langle t', b \rangle}^h = 1.$$

The Ockhamist logic is conservative; it's easy to show that if φ contains no occurrences of \Box then φ is valid for treelike frames if and only if φ is valid in ordinary tense logic. So indeterminist frames can be accommodated without sacrificing any orthodox validities. This is good for those who (like me) are not determinists, but feel that these validities are intuitively plausible. Finally, the Ockhamist solution thwarts the logical argument for determinism by denying that if φ is true at t (i.e. at $\langle b, t \rangle$, for some selected b in B_t) then $\Box\varphi$ is.

This way out of the argument bears down on its weakest joint; but the argument is so powerful that even this link resists the pressure; it is hard for an indeterminist to deny that $\Box\varphi$ must be true if φ is. To a thoroughgoing indeterminist, the choice of a branch b through t has to be entirely *prima facie*; there is no special branch that deserves to be called the 'actual' future through t .¹⁴ Consider two different branches b_1 and b_2 , through t , with $t < t_1 \in b_1$ and $t < t_2 \in b_2$. From the standpoint of t_1 , b_1 is actual (at least up to t_1). From the standpoint of t_2 , b_2 is actual (at least up to t_2). And neither standpoint is correct in any absolute sense. In exactly the same way, no particular moment of linear time is 'present'.

But then it seems that the Ockhamist theory gives no account of truth relative to a moment t , and it also suggests very strongly that if φ is true at t then $\Box\varphi$ is also true at t . The only way that a thing can be true at a moment is for it to be settled at that moment.

In Thomason [1970], it is suggested that such an absolute notion of truth can be introduced by superimposing Van Fraassen's treatment of truth-value gaps onto Prior's Ockhamist theory.¹⁵ The resulting definition is very simple.

DEFINITION 5.

$$\begin{aligned} \|\varphi\|_t^h = 1 & \text{ iff } \|\varphi\|_{\langle t, b \rangle}^h = 1 \text{ for all } b \in B_t, \\ \|\varphi\|_t^h = 0 & \text{ iff } \|\varphi\|_{\langle t, b \rangle}^h = 0 \text{ for all } b \in B_t. \end{aligned}$$

This logic preserves the validities of linear tense logic; indeed, φ is Ockhamist valid if and only if it is valid here. Also, the rule holds good that if $\|\varphi\|_t^h = 1$ then $\|\Box\varphi\|_t^h = 1$.

Thus, this theory endorses the principle (rejected by the Ockhamist theory) that if a thing is true at t then its truth at t is settled. It may seem at first that it validates all the principles needed for the logical determinist argument, but of course (since the logic allows branching frames) it must sever the argument somewhere. The way in which this is done is subtle. The scheme $\varphi \rightarrow HF\varphi$ is valid, but this does not mean that if φ is true at t then $F\varphi$ is true at any $t' < t$. That is, it is *not* the case that if $\|\varphi\|_t^h = 1$ then

¹⁴See [Lewis, 1970], and substitute 'the actual future' for 'the actual world' in what he says. *That* is the view of the thoroughgoing indeterminist.

¹⁵See, for instance Van Fraassen [1966; 1971].

$\|F\varphi\|_{t'}^h = 1$ for all $t' < t$. The validity of this scheme only means that for all $b \in B_t$, if $\|\varphi\|_{\langle t, b \rangle}^h = 1$ then $\|F\varphi\|_{\langle t', b \rangle}^h = 1$ for all $t' < t$. But there may be $b' \in B_{t'}$ which are not in B_t .

To put it another way, the fact that $F\varphi$ is true at t from the perspective of a later t' does not make $F\varphi$ *absolutely* true at t , and so need not imply that $\Box F\varphi$ is true at t .

This manoeuvre makes use of the availability of truth-value gaps. To make this clearer, take a future-oriented version of the logical determinist argument: $F\varphi \vee F\neg\varphi$ is true at any t ; so $F\varphi$ is true at t or $\neg F\varphi$ is true at t ; so $\Box F\varphi$ is true at t or $\Box\neg F\varphi$ is true at t . The supervaluational theory blocks the second step of this argument: in any such theory, the truth of $\psi \vee \neg\psi$ does not imply that ψ is true or $\neg\psi$ is true.

Thomason suggests that this logic represents the position endorsed by Aristotle in *De Int.* 18^b25 – 19^b4, but his suggestion is made without any analysis of the very controversial text, or discussion of the exegetical literature. For a close examination of the texts, with illuminating philosophical discussion, see [Frede, 1970]; see also [Sorabji, 1980]. for a broadly-based examination of Aristotle's views that nicely illustrates the value of treelike frames as an interpretive device, see [Code, 1976]. The suggestion is also made in [Jeffrey, 1979]. For information about the medieval debate on this topic, see [Normore, 1982].

4 THE TECHNICAL SIDE OF HISTORICAL NECESSITY

The mathematical dimension of the picture painted in the above section is still relatively undeveloped. At present, most of the results known to me deal with axiomatisability in the propositional case.

We have already characterised one important variety of propositional validity: φ is *Ockhamist valid* if it is satisfied at all pairs $\langle t, b \rangle$, relative to all Ockhamist assignments on all treelike frames. (See Definitions 2– 4, above.) The time has come to give an official definition of $T \times W$ validity.

DEFINITION 6. A $T \times W$ frame is a quadruple $\langle W, T, <, \approx \rangle$, where W and T are non-empty sets, $<$ is a transitive relation on T which is also irreflexive and linear (i.e. $t \not< t$ for all $t \in T$, and either $t < t'$ or $t' < t$ or $t = t'$ for all, $t, t' \in T$), and \approx is a 3-place relation on $T \times W \times W$, such that (1) for all t, \approx_t is an equivalence relation (i.e. $w \approx_t w$ for all $t \in T$ and $2 \in W$, etc.), and (2) for all $w_1, w_2 \in W$ and $t, t' \in T$, if $w_1 \approx_t w_2$ and $t' < t$ then $w_1 \approx_{t'} w_2$. The intention is that $w \approx_t w'$ if w and w' are historical alternatives through t , and so differ only in what is future to t .

DEFINITION 7. A function h assigning each atomic formula a subset of $T \times W$ is an *assignment*, provided that if $w \approx_t w'$ and $t_1 \leq t$ then $\langle t_1, w \rangle \in h(\varphi)$ iff $\langle t_1, w' \rangle \in h(\varphi)$.

DEFINITION 8. The h -truth value $\|\varphi\|_{\langle t, w \rangle}^h$ of φ at the pair $\langle t, w \rangle$ is defined by a recursion that treats truth-functional connectives in the usual way. The clauses for tense and necessity run as follows.

$$\begin{aligned} \|P\varphi\|_{\langle t, w \rangle}^h &= 1 \quad \text{iff for some } t' < t, \|\varphi\|_{\langle t', w \rangle}^h = 1, \\ \|F\varphi\|_{\langle t, w \rangle}^h &= 1 \quad \text{iff for some } t' \text{ such that } t < t', \|\varphi\|_{\langle t', w \rangle}^h = 1, \\ \|\Box\varphi\|_{\langle t, w \rangle}^h &= 1 \quad \text{iff for all } w' \text{ such that } w \approx_t w', \|\varphi\|_{\langle t, w' \rangle}^h = 1. \end{aligned}$$

A formula is $T \times W$ valid if it is satisfied at every pair $\langle t, w \rangle$ by every assignment on every $T \times W$ frame.¹⁶

There are some validities that are peculiar to these $T \times W$ frames, and that arise from the fact that only a single temporal ordering is involved in these frames: (15) and (16) are examples,

$$(15) \quad FG[p \wedge \neg p] \rightarrow \Box FG[p \wedge \neg p]$$

$$(16) \quad GF[p \vee \neg p] \rightarrow \Box GF[p \vee \neg p]$$

Example (15) is valid because its antecedent is true at $\langle t, w \rangle$ if and only if there is a t' that is $<$ -maximal with respect to w ; but this holds if and only if there is a t' that is $<$ -maximal absolutely. Example (16) is similar, except that this time what is at stake is the non-existence of a maximal time.

Burgess remarked (in correspondence) that $T \times W$ validity is recursively axiomatisable, since it is essentially first-order. But as far as I know the problem of finding a reasonable axiomatisation for $T \times W$ validity is open. I would expect the techniques discussed below, in connection with Kamp validity, to yield such an axiomatisation.

Although (15) and (16) may be reasonable given certain physical assumptions, they do not seem so plausible from a logical perspective. After all, if $w \approx_t w'$, all that is required is that w and w' should share a certain segment of the past, and this implies that the structure of time should be the same in w and w' on this segment. But it is not so clear that w and w' should participate in the same temporal structure after t . This suggests a more liberal sort of $T \times W$ frame, first characterised by Kamp [1979].¹⁷

¹⁶I will adhere to this terminology here, but I am not confident that it is the best terminology, over the long run. Varieties of $T \times W$ validity tend to proliferate, and this is only one of them, and probably not the most interesting. Perhaps it would be better to speak of (Fixed T) $\times W$ validity— but this is awkward.

¹⁷This paper of Kamp's deserves summary because it became widely known and is historically important, though it was never published. Kamp had evidently been thinking about these matters for several years; the latest draft of the paper that I have seen was finished early in 1979. The paper contains much valuable philosophical discussion of historical necessity, and defines the type of validity that I here call 'Kamp validity'. An axiomatisation is proposed in the paper, which was never published because of difficulties that came to light in the completeness argument that Kamp had sketched for validity in dense Kamp frames. In 1979, Kamp discovered a formula that was Kamp valid but

DEFINITION 9. A Kamp frame is a triple $\langle \mathcal{T}, W, \approx \rangle$ where W is a non-empty set, \mathcal{T} is a function from W to transitive, irreflexive linear orderings (i.e. if $w \in W$ then $\mathcal{T}(w) = \langle T_w, <_w \rangle$, where $<_w$ is an ordering on T_w as in $T \times W$ frames), and \approx is a relation on $\{ \langle t, w, w' \rangle : w, w' \in W \text{ and } t \in \mathcal{T}(w) \cap \mathcal{T}(w') \}$ such that for all t, \approx_t is an equivalence relation, and if $w \approx_t w'$ then $\{ t_1 : t_1 \in T_w \text{ and } t_1 <_w t \} = \{ t_1 : t_1 \in T_{w'} \text{ and } t + 1 <_{w'} t \}$. Also, if $w \approx_t w'$ and $t' <_w t$ then $w \approx_{t'} w'$.

The definitions of an assignment, and of the h -truth value $\|\varphi\|_{\langle t, w \rangle}^h$ of φ at the pair $\langle t, w \rangle$ (where $t \in \mathcal{T}_w$ and h is an assignment) are readily adapted from Definitions 7 and 8.

Besides (AK0) all classical tautologies, Kamp takes as axioms all instances of the following schemes.¹⁸

$$(AK1) \quad H[\varphi \rightarrow \psi] \rightarrow [P\varphi \rightarrow P\psi]$$

$$(AK2) \quad G[\varphi \rightarrow \psi] \rightarrow [F\varphi \rightarrow F\psi]$$

$$(AK3) \quad PP\varphi \rightarrow P\varphi$$

$$(AK4) \quad FF\varphi \rightarrow F\varphi$$

$$(AK5) \quad PG\varphi \rightarrow \varphi$$

$$(AK6) \quad FH\varphi \rightarrow \varphi$$

$$(AK7) \quad PF\varphi \rightarrow [P\varphi \vee \varphi \vee F\varphi]$$

$$(AK8) \quad FP\varphi \rightarrow [P\varphi \vee \varphi \vee F\varphi]$$

$$(AK9) \quad \Box[\varphi \rightarrow \psi] \rightarrow [\Box\varphi \rightarrow \Box\psi]$$

$$(AK10) \quad \Box\varphi \rightarrow \varphi$$

$$(AK11) \quad \Diamond\varphi \rightarrow \Box\Diamond\varphi$$

$$(AK12) \quad \Diamond P\varphi \rightarrow P\Diamond\varphi$$

$$(AK13) \quad \Box\varphi \vee \Box\neg\varphi, \text{ if } \varphi \text{ is atomic.}$$

not provable from the axioms of the paper. Later, Thomason discovered other sorts of counterexamples. As far as I know, the axiomatisation problem for Kamp validity was open until Dov Gabbay encountered the problem at a workshop for [the first edition of] this *Handbook*, in the fall of 1981. Due to the wide circulation of [Kamp, 1979], a number of erroneous references have crept into the literature concerning the existence of an axiomatisation of Kamp validity. Gabbay has not yet published his result [Editors' note: see Section 7.7 of D. M. Gabbay, I. Hodkinson and M. Reynolds. *Temporal Logic*, volume 1, Oxford University Press, 1994.], and any such reference in a work published before [1981, the first edition of] this *Handbook* is likely to be mistaken.

¹⁸I omit the axiom scheme for density, and omit a redundant axiom for \Box . And the system I describe is only one of several discussed by Kamp.

As well as (RK0) *modus ponens*, Kamp posits the rules given by the following three schemes.

$$(RK1) \quad \varphi/H\varphi$$

$$(RK2) \quad \varphi/G\varphi$$

$$(RK3) \quad \varphi/\Box\varphi$$

Readers familiar with axioms for modal and tense logic will see that this list falls into three natural parts. Classical tautologies, *modus ponens*, (RK1), (RK2) and (AK1)–(AK8) are familiar principles of ordinary tense logic without modality. Classical tautologies, *modus ponens*, (RK3), and (AK9)–(AK11) are principles of the modal logic **S5**. Axiom (AK12) is a principle combining tense and modality; this principle was explained informally in Section 2. The validity of (AK13) reflects the treatment of atomic formulas as noncontingent; see the provision in Definition 7. If tense operators were not present, (AK13) would of course trivialise \Box , rendering every formula noncontingent.

To establish the incompleteness of (AK0)–(AK13) + (RK0)–(RK3), consider the formula (17), discovered by Kamp, where $E_1(\varphi)$ is $F\varphi \wedge G[\varphi \vee P\varphi]$.

$$(17) \quad [PE_1(p) \wedge \Diamond PE_1(q)] \rightarrow [P[E_1(p) \wedge P\Diamond E_1(q)] \vee \vee P[\Diamond E_1(q) \wedge \Diamond E_1(p)] \vee P[E_1(p) \wedge \Diamond E_1(q)]]$$

The validity of (17) in Kamp frames follows from the fact that these frames are closed under the sort of diagram completion given in Figure 1. Given $t_1, t_2, t_3, t'_1, t'_3$ and the relations of the diagram, it must be possible to interpolate at t'_2 in w' alternative to t_2 , with $t'_3 < t'_2 < t'_1$.¹⁹ Formula (17) is complicated, but I think I can safely leave the task to checking its Kamp validity to the reader.

One proof that (17) is independent of (AK0)–(AK13) + (RK0)–(RK3) makes use of still another sort of frame, which is closer to a Henkin construction than the $T \times W$ frames. If our task is to build models out of maximal consistent sets of formulas, the ‘times’ of a $T \times W$ frame are rather artificial; they would have to be equivalence sets of maximal consistent sets. In *neutral frames*, the basic elements are moments, or instantaneous slices of evolving worlds, which are organised by intra-world temporal relations, and interworld alternativeness relations. Neutral frames tend to proliferate, because of the many conditions that can be imposed on the relations; hence my use of subscripts in describing them.

DEFINITION 10. A neutral frame₁ is a triple $\langle W, \mathcal{U}, \approx \rangle$, where (1) W is a nonempty set, (2) \mathcal{U} is a function whose arguments are members of w of W

¹⁹In fact, since we are working with Kamp frames, $t'_2 = t_2$. But I put it in this more general way in anticipation of what I will call *neutral frames*, so that Figure 1 will be similar in format to Figure 2.

Figure 1. Interpolation

Figure 2. One-way completion.

and whose values are orderings $\langle U_w, <_w \rangle$ such that $U - w$ is a nonempty set and $<_w$ is a transitive²⁰ ordering on U_w such that for all $a, b \in U_w$ either $a <_w b$ or $b <_w a$ or $a = b$, (3) if $w, w' \in W$ and $w \neq w'$ then U_w and $U_{w'}$ are disjoint, and (4) \approx is an equivalence relation on $\cup\{U_w : w \in W\}$, and (5) if $a \approx a'$ and $b <_w a$ then there is some $b' \in U_{w'}$ (where $a' \in U_{w'}$) such that $b \approx b'$ and $b' <_{w'} a'$.

Here, each U_w corresponds to the set of instantaneous slices of the world w ; \approx is the alternativeness relation between these slices.

The diagram-completion property expressed in (5) looks as shown in this picture. It's important to realise that nothing prevents $a \neq b$ while at the same time $a' = b'$ in Figure 2. Of course, in this case we will also have $a \approx b$, which would be something like history repeating itself, at least in all respects that are settled by the past.

Everything generated by (AK0)–(AK13) + (RK0)–(RK3) is valid in neutral frames₁. (And the fact that the converse holds, so that we have a completeness result; see [Thomason, 1981c].) But it is easy to show that (17) is invalid in neutral frames₁.

²⁰But not necessarily irreflexive!

This process can be continued; for instance, stronger conditions of diagram completion can be imposed on neutral frames, which extend the propositional validities, and completeness conditions obtained for the resulting sorts of frames. Details can be found in [Thomason, 1981c]; but this effort did not produce an axiomatisation of Kamp validity.

Using his method of constructing irreflexive models (see [Gabbay, 1981]), Gabbay has shown that all the Kamp validities will be obtained if (AG1) and (RG1) are added to (AK0)–(AK13) + (RK0)–(RK3). Some terminology is needed to formulate (RG1); we need a way of talking, to put it intuitively, about formulas which record a finite number of steps forwards, backwards and sideways in Kamp frames.

DEFINITION 11. Let $\alpha_i \in \{P, F, \Diamond\}$ for $1 \leq i \leq n, n \geq 0$. Then $f(\varphi) = \varphi$, and

$$f_{\alpha_1, \dots, \alpha_n}(\varphi_0, \dots, \varphi_{n-1}, \varphi_n) = \varphi_0 \wedge \alpha_1[\varphi_1 \wedge \dots \wedge \alpha_{n-1}[\varphi_{n-1} \wedge \alpha_n \varphi_n] \dots].$$

So, for instance, $f_{F, \Diamond, P}(p_0, p_1, p_2, p_3)$ is $p_0 \wedge F[p_1 \wedge \Diamond[p_2 \wedge Pp_3]]$.

The axiom and rule are as follows:

$$(AG1) \quad [\Box \neg \varphi \wedge H\Box \varphi \wedge \Box \psi] \rightarrow G\Box H[[\neg \varphi \wedge H\varphi] \rightarrow \psi]$$

$$(RG2) \quad \frac{f_{\alpha_1, \dots, \alpha_n}(\varphi_0, \dots, \varphi_{n-1}, [\varphi_n \wedge \neg p \wedge Hp]) \rightarrow \psi}{f_{\alpha_1, \dots, \alpha_n}(\varphi_0, \dots, \varphi_{n-1}, \varphi_n) \rightarrow \psi}$$

In RG2, p must be foreign to ψ and $\varphi_0, \dots, \varphi_n$.

I leave it to the reader to verify that the axiom and rules are Kamp valid.

It looks as if the ordering properties of linear frames that can be axiomatised in ordinary tense logic (endlessness towards the past, endlessness towards the future, density, etc.)²¹ can be axiomatised against the background of Kamp frames, using Gabbay's techniques. But even so, there are still many simple questions that need to be settled; to take just two examples, it would be nice to know whether Kamp satisfaction is compact, and whether (RG2) is independent.

The situation with respect to treelike frames (i.e. with respect to Ockhamist validity) was even less well explored until recently. To begin with, a number of people have noticed that, although every propositional formula that is Kamp valid is Ockhamist valid,²² the converse fails. Nishimura [1979b] points this out, giving (18) as a counterexample.²³

$$(18) \quad \frac{GH\Box FP[H\neg p \wedge \neg p \wedge Gp] \rightarrow FP\Diamond FP[\neg p \wedge \Box Gp]}{}$$

²¹See Chapter 1 of this Volume.

²²This follows from the fact that a Kamp model can be made from a treelike model, by making worlds out of its branches.

²³Kamp [1979] ascribes a similar example to Burgess.

Figure 3.

In 1977, Burgess discovered (19), the simplest counterexample known to me.

$$(19) \quad \Box G \Diamond F p \rightarrow \Diamond G F p.$$

And in 1978, Thomason independently constructed the following counterexample.

$$(20) \quad [p \wedge \Box G H [p \rightarrow F p]] \rightarrow G F p$$

Both examples trade on the fact that any linearly-ordered subset of a tree can be extended to a branch (a consequence of the Axiom of Choice). If the antecedent of (20) is true at $\langle t, b \rangle$ in a frame $\langle T, < \rangle$ then there is a linear set X of moments such that p is true at every member of X , and such that there is no upper bound to T to X . This set X can be extended to a branch b^* , and $G F p$ will be true at $\langle t, b^* \rangle$.

But the situation shown in Figure 3 can arise in Kamp models, allowing (19) to be falsified. If we make a Kamp model out of $\{b_i : i \in \omega\}$, omitting b_ω , (19) is false at $\langle t_0, b_0 \rangle$.

Nishimura [1979a; 1979b] seems to feel that these examples show treelike frames to be inadequate. But the technical results only establish a difference between the treelike and the $T \times W$ approaches. Adequacy has to do with intuitions about what should be valid. Intuitions may differ, but to me the natural notion is that of a possible future—not that of a possible course of events. Thus, (20) strikes me as clearly valid. The metric examples discussed in Nishimura [1979a] affect me similarly. The person who holds both (21) and (22) seems to me to have contradicted himself.

- (21) Inevitably, life on earth will come to an end at some date in the future.
- (22) For every date in the future, it is not inevitable that life on earth will have come to an end by that date.

For this reason, it seems to me that the $T \times W$ frames do not have the philosophical interest of the treelike ones, though they are certainly interesting for technical reasons. This makes Ockhamist validity appear worth investigating; until recently, however, very little was known about it.²⁴ In [Burgess, 1979], it is claimed that Ockhamist validity is recursively axiomatisable, and a proof is sketched. Later (in conversation), Kripke challenged the proof and Burgess has been unable to substantiate all the details. Very recently, Gurevich and Shelah have proved a result implying that Ockhamist validity is decidable. (See [Gurevich and Shelah, 1985].) At present (October 1982) their paper is not yet written, and I have not had an opportunity to see their proof. The main result is that the theory of trees with second-order quantification over maximal chains is decidable.

Of course a proof of decidability would allow axioms to be recovered for Ockhamist validity; but this would be done in Craigian fashion. And unfortunately, Gabbay's completeness techniques do not seem (at first glance, anyway) to extend to the treelike case. Burgess' example [1979, p. 577], of an Ockhamist invalid formula valid in countable treelike frames, helps to bring home the complexity of the case.²⁵

There are some interesting technical results regarding logics other than the treelike and $T \times W$ ones that I have stressed here; the most important of these is Burgess' [1980] proof that the Peircian validities are decidable. Burgess has pointed out to me that the method of Section 5 of Burgess [1980] can be used to prove Kamp validity decidable, as well as $T \times W$ validity with dense time. He also remarks that the most interesting technical questions about the case in which atomic formulas are treated like complex ones (so that $p \rightarrow \Box p$ is not valid, and substitution is an admissible rule) are unresolved, and may prove more difficult.

5 DEONTIC LOGIC COMBINED WITH HISTORICAL NECESSITY

For a general discussion of deontic logic, with historical background, see Føllesdal and Hilpinen [1971] and Aqvist's chapter on Deontic Logic in Volume 8 of this *Handbook*. This presentation will concentrate on combinations

²⁴In note 15 of [Thomason, 1970], Thomason says that he 'means to present an axiomatisation' of Ockhamist validity in a forthcoming paper. Since the paper has never appeared, this intention was evidently premature.

²⁵I owe much of the information in this paragraph to Burgess and Gurevich.

of deontic modalities with temporal ones, and, in particular, with historical necessity.

Deontic logic seems to have suffered from a lack of communication. Even now, papers are written in which the relevant literature is not mentioned and the authors appear to be reinventing the wheel. In the hope that a survey of the literature will help to correct this situation, I have tried to make the bibliographical coverage of the present discussion thorough.

One facet of this lack of communication can be seen at work in the late 1960s. On the one hand, quite sophisticated model theoretic studies were developed during this time, treating deontic possibilities historically, as future alternatives. Montague [1968, pp. 116–117] and Scott [1967] represent the earliest such studies. (Unfortunately, Montague's presentation is tucked away in a rather forbidding technical paper that discusses many other topics, and the publication of the paper was delayed. And Scott's paper was never published.) But in 1969 Chellas [1969] appeared, giving an extended and very readable presentation of the California Theory.²⁶ (Montague's, Scott's and Chellas' theories are quite similar variations of the $T \times W$ approach; the treatment of historical necessity is similar, and indeed identical in all important respects to Kamp's.)

But although Chellas' monograph contains an extensive and valuable bibliography of deontic logic, including many references to the literature in moral philosophy and practical reasoning, and though Chellas is evidently familiar with this literature, there is no attempt in the work to relate the theory to the more general philosophical issues, or even to discuss its application to the 'paradoxes' of deontic logic, which by then were well known. Chellas concentrates on the mathematical portion of the task. Thus although the presentation is less compressed than Montague's it remains relatively impenetrable to most moral philosophers, and there is no advertisement of the genuine help that the theory can give in dealing with these puzzles.

On the other hand, in the philosophical literature, it is easy to find studies that would have benefited from vigorous contact with logical theories such as Chellas'. To consider an example almost at random, take [Chisholm, 1974]. This paper has the word 'logic' in its title and deals with a topic that is thoroughly entangled with Chellas' investigation, but Chisholm's paper has no references to such logical work and seems entirely ignorant of it. Moreover, the paper is written in an axiomatic style that makes no use of semantical techniques that had been current in the logical literature for many years. And Chisholm commits errors that could have been avoided by awareness of these things. ([Chisholm, 1974, D9 on p. 13] is an example;

²⁶Chellas' study is concerned with imperatives; but he starts with the assumption that these express obligations, so that the work belongs to deontic logic. Chellas [1969] is difficult to obtain; the theory is also presented in [Chellas, 1971], which is more accessible. McKinney [1975], a dissertation written under Chellas, is a later work belonging to this genre.

compare this with [Thomason, 1981a, pp. 183–184].)

To take another example, Wiggins [1973] provides an informal discussion, within the context of the determinist-libertarian debate in moral philosophy, of issues very similar to those treated by Chellas [1971] (and, so far as historical necessity goes in [Prior, 1967, Chapter 7]). Again, the paper contains no references to the logical literature. Though Wiggins' firm intuitive grasp of the issues prevents his argument from being affected,²⁷ it would have been nice to see him connect his account to the very relevant modal theoretic work.

There are a number of general discussions of the 'paradoxes' of deontic logic: see, for example, Åqvist [1967, pp. 364–373], Føllesdal and Hilpinen [1971, pp. 21–26], Hansson [1971, pp. 130–133], Al-Hibri [1978, pp. 22–29] and Van Eck [1981, pp. 28–35]. It should be apparent from the shudder quotes that I prefer not to dignify these puzzles with the same term that is applied to profoundly deep (perhaps unanswerable) questions like the Liar Paradox. The puzzles are a disparate assortment, and require a spectrum of solutions, some of which have little to do with tense. The Good Samaritan problem, for instance (the problem of reparational obligations), seems from one point of view to simply be a rediscovery of the frailties of the material conditional as a formalisation of natural language conditionals.

But part of the solution²⁸ of this problem seems to lie in the development of an *ought kinematics*,²⁹ in analogy to the probability kinematics that is the topic of [Jeffrey, 1990, Chapter 11]. As we would expect from probability, where there are interactions (surprisingly complex ones) between the rules of probability kinematics and locutions that combine conditionality and probability, we should expect there to be close relationships between ought kinematics and the semantics of conditional oughts. Nevertheless, we can formulate the kinematics of ought without having to work with conditional oughts in the object language.

²⁷The one exception is Wiggins' definition of 'deterministic theory' and his assumption that macroscopic physical theories are deterministic. Here his argument could have been genuinely improved by familiarity with Montague [1962]. I haven't discussed this much-neglected paper here, because it belongs more to philosophy of science than to modal logic.

²⁸Another part consists in developing an account of conditional oughts. Since this is a combination of the modalities rather than of tense and modality, I do not discuss it here. See De Cew [1981] for a recent survey of the topic.

²⁹I have coined this term, since there seems to be a terminological niche for it. The sources are Jeffrey's 'probability kinematics' (I believe the term is his) and Greenspan's use of 'ought' as a substantive. I think there are good reasons for the terminology she recommends in [Greenspan, 1975] where she speaks of 'having an ought'. A theory like Chellas' cannot, of course, be deployed without containing an ought kinematics; but, as I said, the California writers did not advertise the theory as a solution of some of the deontic puzzles. Powers [1967] juxtaposes the two, though his pay-off machines present the model theory informally. Thomason [1981b] states the modal theory in terms of treelike frames, and discusses it in relation to some of the deontic puzzles.

The technical resolution of this problem is very simple, and this is precisely what the California theory that I referred to above provides: e.g. the theory of Chellas [1969]. for the sake of variety, I will formulate it with respect to treelike frames; this is something that, to my knowledge, was first done in Thomason [1981b].³⁰

DEFINITION 12. A treelike frame \mathfrak{A} for deliberative deontic tense logic is a pair $\langle T, <, O \rangle$, where $\langle T, < \rangle$ is a treelike frame for tense logic and O is a function on T such that for all $t \in T$, (1) O_t is nonempty, (2) $O_t \subseteq B_t$, and (3) if $t < t'$ and $t' \in b$ for some $b \in O_t$, then $O_{t'} = O_t \cap B_{t'}$.

The satisfaction clause for oughts is as follows.

$$\|O_\varphi\|_{\langle t, b \rangle}^h = 1 \text{ iff for all } b' \in O_t, \quad \|\varphi\|_{\langle t, b' \rangle}^h = 1.$$

We are dealing with the result of extending a propositional language of the sort we discussed in previous sections (truth- functional connectives, past and future tense, and historical \square) by adding a one-place connective O for ought.³¹

Something needs to be said about Condition (3) on frames, which is not to be found in Thomason [1981b], and, as far as I know, has also been overlooked by other authors who (like Chellas) formulate the model theory of ought kinematics. This condition yields validities such as the following two.

$$(23) \quad OG[F\varphi \rightarrow \neg OG\neg\varphi]$$

$$(24) \quad OG\varphi \rightarrow OGO\varphi$$

These do strike me as valid in this context, and at any rate are interesting tense-deontic principles having to do with the coherence of plans. Principle (23), for instance, disallows an alternative future in O_t along which some outcome will happen, but is forbidden from ever happening. Such an alternative can't correspond to a coherent plan.

This set-up can readily deal with reparational obligations. Suppose that, because of a promise to my aunt, at 4:00 I ought to catch an airplane at 5:00, but that at 5:00 I have broken my promise because of the attractions of the airport bar. Then at 5:00 I should call my aunt to tell her I won't be on the plane. Though this is the sort of situation that is sometimes represented as paradoxical in the literature, it is easily modelled in ought kinematics, with no apparent conceptual strain. At one time we have $O\neg Fp$ true, where p stands for 'I tell my aunt I won't be on the plane'. At a later time (one that involves the occurrence of something that shouldn't have happened) OFp is true.

³⁰The theory of Thomason [1981b] is more general, but yields an account of deliberative ought as a special case.

³¹Since 'P' is already used for past tense, I will not use any special symbol for the dual of O .

If we press the account a bit harder, we can change the example; it also is true at 5:00 that I ought to inform my aunt I won't be on the plane, and this can be taken to entail that I ought not to be on the plane, since I can only inform someone of what is true, and because $\Box[\varphi \rightarrow \psi] \rightarrow [O\varphi \rightarrow O\psi]$ is a validity of our logic.

The response to this pressure is, of course, a Gricean manoeuvre;³² it is true at 5:00 (on the understanding of 'ought' in question) that I ought not to be on the plane. But it is not worth saying at 5:00, and if I were to say it then, I would be taken to have said something else, something false. And all of this can be made plausible in terms of general principles of reasonable conversation. I will not give the details here, since they can easily be reconstructed from [Lewis, 1979b].³³ On balance, the approach seems to be well braced against pressure from this direction. It is hard to imagine a reasonable theory of truth conditions that will not have to deploy Gricean tactics at some point. And this can be made to look like a very reasonable place to deploy them.

These linguistic reflections are nicely supported by quite independent philosophical considerations. Greenspan [1975] is a sustained study of ought kinematics from a philosophical standpoint, in which it is argued that a time-bound treatment of oughts is essential to an understanding of their logic, and that the proper view of deontic detachment is that a conditional ought licenses a 'consequent ought' when the antecedent is unalterably true. The paper contains many useful references to the philosophical literature, and provides a good example of the results that can be obtained by combining this philosophical material with the logical apparatus.

The fact that 'I ought to be on the plane' would ordinarily be taken to be false at 5:00 in the example we discussed above shows that 'ought' has employments that are not practical or deliberative: ones that perhaps have to do with wishful thinking. Also, there is its common use to express a kind of necessity: 'The butter is warm enough now; it ought to melt'.

Philosophers are inclined to speak of ambiguity in cases like this, but this is either a failure to appreciate the facts or an abuse of the word 'ambiguity'. The word 'ought' is indexical or context-sensitive, not ambiguous. The matter is argued, and some of its consequences are explored, in Kratzer [1977]; see [Lewis, 1979b] for a study of the consequences in a more general setting.

In Thomason [1981b] this is taken into account by a more general interpretation of O , according to which the relevant alternatives at t need not be possible futures for t . Probably the most general account would make the interpretation of O in a context relative to a set of alternatives which are regarded as possible in some sense relative to that context.

³²With an added wrinkle, due to the contextual adjustability of oughts.

³³See especially [Lewis, 1979b, pp. 354–355].

This is of course related to the philosophical debate over whether ‘ought’ implies ‘can’.³⁴ The most sophisticated linguistic account makes the issue appear rather boring: if we attend to a reasonable distinction between ambiguity and context-sensitivity, ‘ought’ doesn’t imply ‘can’, since there are contexts that provide counterexamples. But in practical contexts, when the one is true the other will be, even if for technical reasons we can’t relate this to an implication among linguistic forms.³⁵ This result is rather disappointing. But maybe there are ways of extracting interesting consequences for moral philosophy from a pragmatic account of oughts and other practical phenomena. An idea that I find intriguing is that manipulation of the context is the typical—perhaps the only—mechanism of moral weakness. The idea is suggested in [Thomason, 1981a], but is not much developed.

There seems to be no point in discussing the technical side of temporal deontic logic here. Not much work has been done in the area,³⁶ and the best strategy seems to be to let the matter wait until more is known about the interpretation of historical necessity.

Strictly speaking, conditional oughts are more closely related to the combination of conditionals with oughts than that of tense with modalities. Because the topic is complex and a thorough discussion of it would take up much space I have decided to neglect it in this article, even though (as Greenspan [1975] makes clear) tense enters into the matter. For an illuminating discussion of some of the problems, see DeCew [1981].³⁷

6 CONDITIONAL LOGIC COMBINED WITH HISTORICAL NECESSITY

In the present essay, ‘modality’ has been confined to what can be interpreted using possible worlds semantics. So here, ‘conditional logic’ has to do with the modern theories that were introduced by Stalnaker and then by D. Lewis; see [Lewis, 1973].³⁸ For surveys of this work, see the chapter on

³⁴See, for instance [Hare, 1963, Chapter 4].

³⁵The fate of the validity of ‘I exist’ seems to be much the same. Maybe linguistics is a graveyard for some philosophical slogans.

³⁶Some results are presented in [Åqvist and Hoepelman, 1981].

³⁷I have not discussed Castañeda’s work here, though it may offer an alternative to the kinematic approach to some of the deontic puzzles; see for instance [Castañeda, 1981]. For one thing, the work falls outside the topic of this article; for another, Castañeda’s writings on deontic logic strike me as too confused and poorly presented to repay close study.

³⁸Thus, for instance, I will not discuss [Slote, 1978], for although it deals with conditionals and the time it seeks to replace the possible worlds semantics with an analysis in the philosophical tradition. Another recent paper, [Kvart, 1980] uses techniques that are more model theoretic; but philosophical preconceptions have crept into the semantic theory at every point and uglified it. The usefulness of logical techniques in philosophy is largely dependent on the independence of the intuitions that guide the two disciplines; this enables them to reinforce one another in certain instances.

Conditional Logic by Nute and Cross in Volume 4 of this *Handbook*, and [Harper, 1981] and the volume in which it appears: Harper *et al.* [1981].

The interaction of conditionals and historical necessity is a topic that is only beginning to receive attention.³⁹ As in the case of deontic logic there is a fairly venerable philosophical tradition, involving issues that are still debated in the philosophical literature, and a certain amount of technical model theoretic work that may be relevant to these issues. But this time, the philosophical topic is causality.⁴⁰

A conditional like D. Lewis', which does not satisfy the principle of conditional excluded middle, $[\varphi > \psi] \vee [\varphi > \neg\psi]$, is much more easy to relate to causal notions than Stalnaker's, since it is possible to say (with only a little hedging) that such a conditional is true in case there is a connection of determination of some sort between the antecedent and the consequent. But it has seemed less easy to reconcile the theory of such a conditional with simple tensed examples, like the case of Jim and Jack, invented much earlier by Downing [1959].

Jim and Jack quarrelled yesterday; Jack is unforgiving, and Jim is proud. The example is this.

- (25) If Jim were to ask Jack for help today,
 Jack would help him.

Most authors feel that (25) could be taken in two ways. It could be taken to be false, because they quarrelled and Jack is so unforgiving. It could be taken to be true, because Jim is so proud that if he were to ask for help they would not have quarrelled yesterday. But the preferred understanding of (25) seems to be the first of these; and this is only one way in which a systematic preference for alternatives that involve only small changes in the past⁴¹ seems to affect our habits of evaluating such conditionals. An examination of such preferences and their influence on the sort of similarity that is involved in interpreting conditions can be found in [Lewis, 1979a]. Further information can be found in [Bennett, 1982; Thomason, 1982].

This, of course, relates conditionals to time in a philosophical way. But Lewis' informal way of attacking the problem assumes that the logic has

³⁹Judging from some unpublished manuscripts that I have recently received, it is likely to receive more before long. But these are working drafts, which I should not discuss here.

⁴⁰See [Sosa, 1975] for a collection juxtaposing some recent papers on causality with ones on conditionals. (Many of the papers seek to establish links between the two.) Also see [Downing, 1959; Jackson, 1977].

⁴¹Though I put it this way D. Lewis (who assumes determinism for the sake of argument in [Lewis, 1979a], so that changes in the future must be accompanied by changes in the past) has to resort to a hierarchy of maxims to achieve a like effect. (In particular, Maxim 1, [Lewis, 1979a, p. 472], enjoins us to avoid wholesale violations of law, and Maxim 2 tells us to seek widespread perfect match of particular fact; together, these have much the same effect as the principle I stated in the text.)

to come to an end, and in particular that there are no new validities to be discovered by placing conditionals in a temporal setting.⁴² In view of the lessons we have learned about the combination of tense with other modalities, this may be a methodological oversight; it runs the risk of not getting the most out of the possible worlds semantics that is to be put to philosophical use.⁴³

Thomason and Gupta [1981] and Van Fraassen [1981] are two recent studies that pursue this model theoretic route: the former uses treelike frames and the latter a version of the $T \times W$ approach. The two treatments are very similar in essentials, though a decision about how to secure the validity of (27) leads to much technical complexity in [Thomason and Gupta, 1981]. Since Van Fraassen's exposition is so clear, and I fear I would be repeating myself if I attempted a detailed account of [Van Fraassen, 1981], I will be very brief.

Both papers endorse certain validities involving a mixture of tense, historical necessity, and the conditional. The following examples are representative.

$$(26) \quad [\Diamond\varphi \wedge [\varphi > \psi]] \rightarrow \Diamond\psi$$

$$(27) \quad [\Box\neg\varphi \wedge \Box[\varphi > \psi]] \rightarrow [\varphi \rightarrow \Box[\varphi \rightarrow \psi]]$$

The first of these represents one way in which selection principles for $>$ can be formulated in terms of alternative histories; the validity of (26) corresponds to a preference at $\langle t, w \rangle$ for alternatives that are possible futures for $\langle t, w \rangle$.

Example (27) called the Edelberg inference after Walter Edelberg, who first noticed it, represents a principle of 'conditional transmission of settledness' that can be made quite plausible; see the discussion in Thomason and Gupta [1981, pp. 306–307]. Formally, its validity depends on there being no 'unattached' counterfactual futures—ones that are not picked out as counterfactual alternatives on condition φ with respect to actual futures. At least, this is the way that Van Fraassen secures the validity of (28); Thomason and Gupta do it in a circuitous way, at the cost of making their theory much more difficult to explain.

If there advantages to offset this cost, they have to do with causality. The key notion introduced in [Thomason and Gupta, 1981], which is not

⁴²I mean that in [Lewis, 1979a], Lewis phrases the discussion in terms of 'similarity'. This is the intuitive notion used to explicate the technical gadgets (assignments of sets of possible worlds to each world) that yield Lewis' theory in [Lewis, 1973] of the satisfaction conditions for the conditional. In [Lewis, 1979a], he leaves things at this informal level, and doesn't try to build temporal conditional frames which can be used to define satisfaction for an extended language.

⁴³If Lewis' adoption of a determinist position in [Lewis, 1979a] is not for the sake of argument, there may be a philosophical issue at work here. A philosophical determinist would be much more likely to follow an approach like Lewis' than to base conditional logic on the logic of historical necessity.

needed by Van Fraassen,⁴⁴ is that of a *future choice function*: a function \mathcal{F} that for each moment t in a treelike frame chooses a branch in B_t . future choice functions must choose coherently, so that if $t' \in \mathcal{F}_t$ then $\mathcal{F}_t = \mathcal{F}_{t'}$. By considering restricted sets of choice functions, Thomason and Gupta are able to introduce a modal notion that, they claim, may help to explicate causal independence. If this claim could be made good it would be worth the added complexity, since so far the techniques of possible worlds semantics have not been of much direct help in clarifying the philosophical debate about causality. But in [Thomason and Gupta, 1981], the idea is not developed enough to see very clearly what the prospects of success are.

University of Michigan, USA.

EDITORIAL NOTE

The present chapter is reproduced from the first edition of the Handbook. A continuation chapter will appear in a later volume of the present, second edition. The logic of historical necessity is technically a special combination of modality and temporal operators. Combinations with temporal logic, (or *temporalising*) are discussed in chapter 2 of this volume. Branching temporal logics with modalities in the spirit of the logics of this chapter have been very successfully introduced in theoretical computer science. These are the CTL (computation tree logic) family of logics. For a survey, see the chapter by Colin Stirling in Volume 2 of the *Handbook of Logic in Computer Science*, S. Abramsky, D. Gabbay and T. Maibaum, editors, pp. 478–551. Oxford University Press, 1992.

PHILOSOPHICAL PERSPECTIVES ON QUANTIFICATION IN TENSE AND MODAL LOGIC

INTRODUCTION

The trouble with modal logic, according to its critics, is quantification into modal contexts—i.e. *de re* modality. For on the basis of such quantification, it is claimed, essentialism ensues, and perhaps a bloated universe of *possibilia* as well. The essentialism is avoidable, these critics will agree, but only by turning to a Platonic realm of individual concepts whose existence is no less dubious or problematic than mere *possibilia*. Moreover, basing one's semantics on individual concepts, it is claimed, would in effect render all identity statements containing only proper names either necessarily true or necessarily false—i.e. there would then be no contingent identity statements containing only proper names.

None of these claims is true quite as it stands, however; and in what follows we shall attempt to separate the chaff from the grain by examining the semantics of (first-order) quantified modal logic in the context of different philosophical theories. Beginning with the primary semantics of logical necessity and the philosophical context of logical atomism, for example, we will see that essentialism not only does not ensue but is actually rejected in that context by the validation of the modal thesis of anti-essentialism, and that in consequence all *de re* modalities are reducible to *de dicto* modalities.

Opposed to logical atomism, but on a par with it in its referential interpretation of quantifiers and proper names, is Kripke's semantics for what he properly calls metaphysical necessity. Unlike the primary semantics of logical necessity, in other words, Kripke's semantics for metaphysical necessity is in direct conflict with some of the basic assumptions of logical atomism; and in the form which that conflict takes, which we shall refer to here as the form of a *secondary* semantics for necessity, Kripke's semantics amounts to the initial step toward a proper formulation of Aristotelian essentialism. (A secondary semantics for necessity stands to the primary semantics in essentially the same way that non-standard models for second-order logic stand to standard models.) The problem with this initial step toward Aristotelian essentialism, however, is the problem of all secondary semantics; viz. that of its objective, as opposed to its merely formal, significance—a problem which applies all the more so to Kripke's deepening of his formal semantics by the introduction of an accessibility relation between possible worlds. This, in fact, is the real problem of essentialism.

There are no individual concepts, it will be noted in what follows, in either logical atomism or Kripke's implicit philosophical semantics, and yet in both contexts proper names are rigid designators; that is, in both there can be no contingent identity statements containing only proper names. One need not, accordingly, turn to a Platonic realm of individual concepts in order to achieve this result. Indeed, quite the opposite is the case. That is, it has in fact been for the defence of contingent identity, and not its rejection, that philosophical logicians have turned to a Platonic realm of individual concepts, since, on this view, it is only through the mere coincidence of the denotations of the individual concepts expressed by proper names that an identity statement containing those names can be contingent. Moreover, unless such a Platonic realm is taken as the intensional counterpart of logical atomism (a marriage of dubious coherence), it will not validate the modal thesis of anti-essentialism. That is, one can in fact base a Platonic or logical essentialism—which is not the same thing at all as Aristotelian essentialism—upon such a realm. However, under suitable assumptions, essentialism can also be avoided in such a realm; or rather it can in the weaker sense in which, given these assumptions, all *de re* modalities are reducible to *de dicto* modalities.

Besides the Platonic view of intensionality, on the other hand, there is also a socio-biologically based conceptualist view according to which concepts are not independently existing Platonic forms but cognitive capacities or related structures of the human mind whose realisation in thought is what informs a mental act with a predicable or referential nature. This view, it will be seen, provides an account in which there can be contingent identity statements, but not such as to depend on the coincidence of individual concepts in the platonic sense. Such a conceptualist view will also provide a philosophical foundation for quantified tense logic and paradigmatic analyses thereby of metaphysical modalities in terms of time and causation. The problem of the objective significance of the secondary semantics for the analysed modalities, in other words, is completely resolved on the basis of the nature of time, local or cosmic. The related problem of a possible ontological commitment to *possibilia*, moreover, is in that case only the problem of how conceptualism can account for direct references to past or future objects.

1 THE PRIMARY SEMANTICS OF LOGICAL NECESSITY

We begin by describing what we take to be the primary semantics of logical necessity. Our terminology will proceed as a natural extension of the syntax and semantics of standard first-order logic with identity. Initially, we shall assume that the only singular terms are individual variables. As primitive *logical constants* we take $\rightarrow, \neg, \forall, =$, and \square for the material conditional sign, the negation sign, the universal quantifier, the identity sign and the

necessity sign, respectively. (The conjunction, disjunction, biconditional, existential quantifier and possibility signs— $\wedge, \vee, \leftrightarrow, \exists$ and \diamond , respectively—are understood to be defined in the usual way as metalinguistic abbreviatory devices.) The only non-logical or *descriptive constants* at this point are predicates of arbitrary (finite) degree. We call a set of such predicates a *language* and understand the well-formed formulas (*wffs*) of a language to be defined in the usual way.

A *model* \mathfrak{A} indexed by a language L , or for brevity, an *L-model*, is a structure of the form $\langle D, R \rangle$, where D , the *universe* of the model, is a non-empty set and R is a function with L as domain and such that for each positive integer n and each n -place predicate F^n in L , $R(F^n) \subseteq D^n$, i.e. $R(F^n)$ is a set of n -tuples of members of D . An *assignment in D* is a function A with the set of individual variables as domain and such that $A(x) \in D$, for each variable x . Where $d \in D$, we understand $A(d/x)$ to be that assignment in D which is exactly like A except for its assigning d to x . The *satisfaction* of a wff φ of L in \mathfrak{A} by an assignment A in D , in symbols $\mathfrak{A}, A \vDash \varphi$, is recursively defined as follows:

1. $\mathfrak{A}, A \vDash (x = y)$ iff $A(x) = A(y)$;
2. $\mathfrak{A}, A \vDash P^n(x_1, \dots, x_n)$ iff $\langle A(x_1), \dots, A(x_n) \rangle \in R(P^n)$;
3. $\mathfrak{A}, A \vDash \neg\varphi$ iff $\mathfrak{A}, A \not\vDash \varphi$;
4. $\mathfrak{A}, A \vDash (\varphi \rightarrow \psi)$ iff either $\mathfrak{A}, A \not\vDash \varphi$ or $\mathfrak{A}, A \vDash \psi$;
5. $\mathfrak{A}, A \vDash \forall x\varphi$ iff for all $d \in D$, $\mathfrak{A}, A(d/x) \vDash \varphi$; and
6. $\mathfrak{A}, A \vDash \Box\varphi$ iff for all R' , if $\langle D, R' \rangle$ is an L -model, then $\langle D, R' \rangle, A \vDash \varphi$.

The *truth* of a wff in a model (indexed by a language suitable to that wff) is as usual the satisfaction of the wff by every assignment in the universe of the model. *Logical truth* is then truth in every model (indexed by any appropriate language). One or another version of this primary semantics for logical necessity, it should be noted, occurs in [Carnap, 1946]; [Kanger, 1957]; [Beth, 1960] and [Montague, 1960].

2 LOGICAL ATOMISM AND QUANTIFIED MODAL LOGIC

These definitions, as already indicated, are extensions of essentially the same semantical concepts as defined for the modal free wffs of standard first-order predicate logic with identity. The clause for the necessity operator has a particularly natural motivation within the framework of logical atomism. In such a framework, a model $\langle D, R \rangle$ for a language L represents a *possible world* of a *logical space* based upon (1) D as the universe of objects of that space and (2) L as the predicates characterising the *atomic states of affairs*

of that space. So based, in other words, a logical space consists of the totality of atomic states of affairs all the constituents of which are in D and the characterising predicates of which are in L . A possible world of such a logical space then amounts in effect to a partitioning of the atomic states of affairs of that space into two cells: those that obtain in the world in question and those that do not.

Every model, it is clear, determines both a unique logical space (since it specifies both a domain and a language) and a possible world of that space. In this regard, the clause for the necessity operator in the above definition of satisfaction is the natural extension of the standard definition and interprets that operator as ranging over *all* the possible worlds (models) of the logical space to which the given one belongs.

Now it may be objected that logical atomism is an inappropriate framework upon which to base a system of quantified modal logic; for if any framework is a paradigm of anti-essentialism, it is logical atomism. The objection is void, however, since in fact the above semantics provides the clearest validation of the modal thesis of anti-essentialism. Quantified modal logic, in other words, does not in itself commit one to any non-trivial form of essentialism (cf. [Parsons, 1969]).

The general idea of the modal thesis of anti-essentialism is that if a predicate expression or open wff φ *can be true of* some individuals in a given universe (satisfying a given identity-difference condition with respect to the variables free in φ), then φ *can be true of* any individuals in that universe (satisfying the same identity-difference conditions). In other words, no conditions are essential to some individuals that are not essential to all, which is as it should be if necessity means logical necessity.

The restriction to identity-difference conditions mentioned (parenthetically) above can be dropped, it should be noted, if nested quantifiers are interpreted exclusively and not (as we have done) inclusively where, e.g. it is allowed that the value of y in $\forall x\exists y\varphi(x, y)$ can be the same as the value of x . (Cf. [Hintikka, 1956] for a development of the exclusive interpretation.) Indeed, as Hintikka has shown, when nested quantifiers are interpreted exclusively, identity and difference wffs are superfluous—which is especially apropos of logical atomism where an identity wff does not represent an atomic state of affairs. (Cf. Wittgenstein's *Tractatus Logico-Philosophicus* 5.532–5.53 and [Cocchiarella, 1975a, Section V].)

Retaining the inclusive interpretation and identity as primitive, however, an *identity-difference condition* for distinct individual variables x_1, \dots, x_n is a conjunction of one each but not both of the wffs $(x_i = x_j)$ or $(x_i \neq x_j)$, for all i, j such that $1 \leq i < j \leq n$. It is clear of course that such a conjunction specifies a complete identity-difference condition for the variables x_1, \dots, x_n . Since there are only a finite number of non-equivalent such conditions for x_1, \dots, x_n , moreover, we understand $ID_j(x_1, \dots, x_n)$, relative to an assumed ordering of such non-equivalent conjunctions, to be the j th

conjunction in the ordering. *The modal thesis of anti-essentialism* may now be stated as the thesis that every wff of the form

$$\begin{aligned} & \exists x_1 \dots \exists x_n (\text{ID}_j(x_1, \dots, x_n) \wedge \diamond\varphi) \\ & \rightarrow \forall x_1 \dots \forall x_n (\text{ID}_j(x_1, \dots, x_n) \rightarrow \diamond\varphi) \end{aligned}$$

is to be logically true, where x_1, \dots, x_n are all the distinct individual variables occurring free in φ . (Where $n = 0$, the above wff is understood to be just $(\diamond\varphi \rightarrow \diamond\varphi)$; and where $n = 1$, it is understood to be just $\exists x \diamond\varphi \rightarrow \forall x \diamond\varphi$.) The validation of the thesis in our present semantics is easily seen to be a consequence of the following lemma (whose proof is by a simple induction on the wffs of L).

LEMMA If L is a language, $\mathfrak{A}, \mathfrak{B}$ are L-models, and h is an isomorphism of \mathfrak{A} with \mathfrak{B} , then for all wffs φ of L and all assignments A in the universe of \mathfrak{A} , $\mathfrak{A}, A \models \varphi$ iff $\mathfrak{B}, A/h \models \varphi$.

One of the nice consequences of the modal thesis of anti-essentialism in the present semantics, it should be noted, is the reduction of all *de re* wffs to *de dicto* wffs. (A *de re* wff is one in which some individual variable has a free occurrence in a subwff of the form $\Box\psi$. A *de dicto* wff is a wff that is not *de re*.) Naturally, such a consequence is a further sign that all is well with our association of the present semantics with logical atomism.

THEOREM (De Re Elimination Theorem) For each *de re* wff φ , there is a *de dicto* wff ψ such that $(\varphi \leftrightarrow \psi)$ is logically true.¹

These niceties aside, however, another result of the present semantics is its essential incompleteness with respect to any language containing at least one relational predicate. (It is not only complete but even decidable when restricted to monadic wffs—of which more anon.) The incompleteness is easily seen to follow from the following lemma and the well-known fact that the modal free non-logical truths of a language containing at least one relational predicate is not recursively enumerable (cf. [Cocchiarella, 1975b]). (It is also for the statement of the infinity condition of this lemma that a relational predicate is needed.)

LEMMA If ψ is a sentence which is satisfiable, but only in an infinite model, and φ is a modal and identity-free sentence, then $(\psi \rightarrow \neg\Box\varphi)$ is logically true iff φ is not logically true.

¹A proof of this theorem can be found in [McKay, 1975]. Briefly, where x_1, \dots, x_n are all the distinct individual variables occurring free in φ and $ID_1(x_1, \dots, x_n), \dots, ID_k(x_1, \dots, x_n)$ are all the non-equivalent identity-difference conditions for x_1, \dots, x_n , then the equivalence in question can be shown if ψ is obtained from φ by replacing each subwff $\Box\chi$ of φ by:

$$\begin{aligned} & [ID_1(x_1, \dots, x_n) \wedge \Box\forall x_1 \dots \forall x_n (ID_1(x_1, \dots, x_n) \rightarrow \chi)] \vee \dots \\ & \vee [ID_k(x_1, \dots, x_n) \wedge \Box\forall x_1 \dots \forall x_n (ID_k(x_1, \dots, x_n) \rightarrow \chi)]. \end{aligned}$$

THEOREM If L is a language containing at least one relational predicate, then the set of wffs of L that are logically true is not recursively enumerable.

This last result does not affect the association we have made of the primary semantics with logical atomism. Indeed, given the Löwenheim–Skolem theorem, what this lemma shows is that there is a complete concurrence between logical necessity as an internal condition of modal free propositions (or of their corresponding states of affairs) and logical truth as a semantical condition of the modal free sentences expressing those propositions (or representing their corresponding states of affairs). And that of course is as it should be if the operator for logical necessity is to have only formal and no material content.

Finally, it should be noted that the above incompleteness theorem explains why Carnap was not able to prove the completeness of the system of quantified modal logic formulated in [Carnap, 1946]. For on the assumption that the number of objects in the universe is denumerably infinite, Carnap's state description semantics is essentially that of the primary semantics restricted to denumerably infinite models; and, of course, precisely because the models are denumerably infinite, the above incompleteness theorem applies to Carnap's formulation as well. Thus, the reason why Carnap was unable to carry through his proof of completeness is finally answered.

3 THE SECONDARY SEMANTICS OF METAPHYSICAL NECESSITY

Like the situation in standard second-order logic, the incompleteness of the primary semantics can be avoided by allowing the quantificational interpretation of necessity in the metalanguage to refer not to *all* the possible worlds (models) of a given logical space but only to those in a given non-empty set of such worlds. Of course, since a model may belong to many such sets, the relativisation to the one in question must be included as part of the definition of satisfaction.

Accordingly, where L is a language and D is a non-empty set, we understand a *model structure* based on D and L to be a pair $\langle \mathfrak{A}, K \rangle$, where K is a set of L -models all having D as their universe and $\mathfrak{A} \in K$. The *satisfaction* of a wff φ of L in such a model structure by an assignment A in D , in symbols $\langle \mathfrak{A}, K \rangle, A \models \varphi$, is recursively defined exactly as in Section 1, except for clause (6) which is defined as follows:

6. $\langle \mathfrak{A}, K \rangle, A \models \Box\varphi$ iff for all $\mathfrak{B} \in K$, $\langle \mathfrak{B}, K \rangle, A \models \varphi$.

Instead of logical truth, a wff is understood to be *universally valid* if it is satisfied by every assignment in every model structure based on a language to which the wff belongs. Where **QS5** is standard first-order logic with

identity supplemented with the axioms of **S5** propositional modal logic, a completeness theorem for the secondary semantics of logical necessity was proved by Kripke in [1959].

THEOREM (Completeness Theorem). A set Γ of wffs is consistent in **QS5** iff all the members of Γ are simultaneously satisfiable in a model structure; and (therefore) a wff φ is a theorem of **QS5** iff φ is universally valid.

The secondary semantics, despite the above completeness theorem, has too high a price to pay as far as logical atomism is concerned. In particular, unlike the situation in the primary semantics, the secondary semantics does not validate the modal thesis of anti-essentialism—i.e. it is false that every instance of the thesis is universally valid. This is so of course because necessity no longer represents an invariance through all the possible worlds of a given logical space but only through those in arbitrary non-empty sets of such worlds; that is, necessity is now allowed to represent an internal condition of propositions (or of their corresponding states of affairs) which has material and not merely formal content—for what is invariant through all the members of such a non-empty set need not be invariant through all the possible worlds (models) of the logical space to which those in the set belong.

One example of how such material content affects the implicit metaphysical background can be found in monadic modal predicate logic. It is well-known, for example, that modal free monadic predicate logic is decidable and that no modal free monadic wff can be true in an infinite model unless it is true in a finite model as well. Consequently, any substitution instance of a modal free monadic wff for a relational predicate in an infinity axiom is not only false but logically false. It follows, accordingly, that there can be no modal free analysis or reduction otherwise of all relational predicates or open wffs in terms only of monadic predicates, i.e. in terms only of modal free monadic wffs.

Now it turns out that the same result also holds in the primary semantics for quantified modal logic. That is, in the primary semantics, modal monadic predicate logic is also decidable and no monadic wff, modal free or otherwise, can be true in an infinite model unless it is also true in a finite model (cf. [Cocchiarella, 1975b]). Consequently, there can also be no modal analysis or reduction otherwise of all relational predicates or open wffs in terms only of monadic wffs, modal free or otherwise.

With respect to the secondary semantics, however, the situation is quite different. In particular, as Kripke has shown in [1962], modal monadic predicate logic, as interpreted in the secondary semantics, is not decidable. Moreover, on the basis of that semantics a modal analysis of relational predicates in terms of monadic predicates can in general be given. E.g.,

substituting $\diamond(Fx \wedge Gy)$ for the binary predicate R in the infinity axiom

$$\begin{aligned} &\forall x \neg R(x, x) \wedge \forall x \exists y R(x, y) \wedge \forall x \forall y \forall z [R(x, y) \\ &\quad \wedge R(y, z) \rightarrow R(x, z)] \end{aligned}$$

results in a modal monadic sentence which is true in some model structure based on an infinite universe and false in all model structures based on a finite domain. Somehow, in other words, relational content has been incorporated in the semantics for necessity, and thereby of possibility as well. In this respect, the secondary semantics is not the semantics of a merely formal or logical necessity but of a necessity having additional content as well.

Kripke himself, it should be noted, speaks of the necessity of his semantics not as a formal or logical necessity but as a metaphysical necessity (cf. [Kripke, 1971, p. 150]). Indeed, it is precisely because he is concerned with a metaphysical or material necessity and not a logical necessity that not every necessary proposition needs to be *a priori*, nor every *a posteriori* proposition contingent (*ibid.*). Needless to say, however, but that the latter result should obtain does not of itself amount to a refutation, as it is often taken, of the claim of logical atomism that every logically necessary proposition is *a priori* and that every *a posteriori* proposition is logically contingent. We are simply in two different metaphysical frameworks, each with its own notion of necessity and thereby of contingency as well.

4 PROPER NAMES AS RIGID DESIGNATORS

Ordinary proper names in the framework of logical atomism are not what Bertrand Russell called ‘logically proper names’, because the things they name, if they name anything at all, are not the simple objects that are the constituents of atomic states of affairs. However, whereas the names of ordinary language have a sense (*Sinn*) insofar as they are introduced into discourse with identity criteria (usually provided by a sortal common noun with which they are associated—cf. [Geach, 1962, p. 43 f]), the logically proper names of logical atomism have no sense other than what they designate. In other words, in logical atomism, ‘a name means (*bedeutet*) an object. The object is its meaning (*Bedeutung*)’ (*Tractatus* 3.203). Different identity criteria have no bearing on the simple objects of logical atomism, and (pseudo) identity propositions, strictly speaking, have no sense (*Sinn*)—i.e. they do not represent an atomic state of affairs.

Semantically, what this comes to is that logically proper names, or *individual constants*, are rigid designators; that is, their introduction into formal languages requires that the wff

$$\exists x \Box(a = x)$$

be logically true in the primary semantics for each individual constant a . Carnap, in his formulation of the primary semantics, also required that $(a \neq b)$ be logically true for distinct individual constants; but that was because his semantics was given in terms of state descriptions where redundant proper names have a complicating effect. Carnap's additional assumption that there is an individual constant for every object in the universe is, of course, also an assumption demanded by his use of state descriptions and is not required by our present model-theoretic approach. (It is noteworthy, however, that the assumption amounted in effect to perhaps the first substitution interpretation of quantifiers, and that in fact it was Carnap who first observed that a strong completeness theorem even for modal free wffs could not be established for an infinite domain on the basis of such an interpretation. Cf. [Carnap, 1938, p. 165].)

Kripke also claims that proper names are rigid designators, but his proper names are those of ordinary language and, as already noted, his necessity is a metaphysical and not a logical necessity. Nevertheless, in agreement with logical atomism the function of a proper name, according to Kripke, is simply to refer, and not to describe the object named [Kripke, 1971, p. 140]; and this applies even when we fix the reference of a proper name by means of a definite description—for the relation between a proper name and a description used to fix the reference of the name is not that of synonymy [Kripke, 1971, p. 156f]. To the objection that we need a criterion of identity across possible worlds before we can determine whether a name is rigid or not, Kripke notes that we should distinguish *how we would speak* in a counterfactual situation from *how we do speak* of a counterfactual situation [Kripke, 1971, p. 159]. That is, the problem of cross-world identity, according to Kripke, arises only through confusing the one way of speaking with the other and that it is otherwise only a pseudo-problem.

5 NON-CONTINGENT IDENTITY AND THE CARNAP–BARCAN FORMULA

As rigid designators, proper names cannot be the only singular terms occurring in contingent identity statements. That is, a contingent identity statement must contain at least one definite description whose descriptive content is what accounts for the possibility of different designata and thereby of the contingency of the statement in question. However, in general, as noted by [Smullyan, 1948], there is no problem about contingent identity in quantified modal logic if one of the singular terms involved is a definite description; or rather there is no problem so long as one is careful to observe the proper scope distinctions. On the other hand, where scope distinctions are not assumed to have a bearing on the occurrence of a proper name, the problem of contingent identity statements involving only proper names is trivially resolved by their construal as rigid designators. That is, where a

and b are proper names or individual constants, the sentences

$$(a = b) \rightarrow \Box(a = b), \quad (a \neq b) \rightarrow \Box(a \neq b)$$

are to be logically true in the primary semantics and universally valid in the secondary. In other words, whether in the context of logical atomism or Kripke's metaphysical necessity, there are only non-contingent identity statements involving only proper names.

Now it is noteworthy that the incorporation of identity-difference conditions in the modal thesis of anti-essentialism disassociates these conditions from the question of essentialism. This is certainly as it should be in logical atomism, since in that framework, as F. P. Ramsey was the first to note, 'numerical identity and differences are necessary relations' [Ramsey, 1960, p. 155]. In other words, even aside from the use of logically proper names, the fact that there can be no contingent identities or non-identities in logical atomism is reflected in the logical truth of both of the wffs

$$\forall x \forall y (x = y \rightarrow \Box x = y), \quad \forall x \forall y (x \neq y \rightarrow \Box x \neq y)$$

in the primary semantics. But then even in the framework of Kripke's metaphysical necessity (where quantifiers also refer *directly* to objects), an object cannot but be the object that it is, nor can one object be identical with another—a metaphysical fact which is reflected in the above wffs being universally valid as well.

Another observation made by Ramsey in his adoption of the framework of logical atomism was that the number of objects in the world is part of its logical scaffolding [Ramsey, 1960]. That is, for each positive integer n , it is either necessary or impossible that there are exactly n individuals in the world; and if the number of objects is infinite, then, for each positive integer n , it is necessary that there are at least n objects in the world (cf. [Cocchiarella, 1975a, Section 5]. This is so in logical atomism because every possible world consists of the same totality of objects that are the constituents of the atomic states of affairs constituting the actual world. In logical atomism, in other words, an object's existence is not itself an atomic state of affairs but consists in that object's being a constituent of atomic states of affairs.

One important consequence of the fact that every possible world (of a given logical space) consists of the same totality of objects is the logical truth in the primary semantics of the well-known Barcan formula (and its converse):

$$\forall x \Box \varphi \leftrightarrow \Box \forall x \varphi.$$

Carnap, it should be noted, was the first to argue for the logical truth of this principle (in [Carnap, 1946, Section 10] and [1947, Section 40]) which he validated in terms of the substitution interpretation of quantifiers in

his state description semantics. The validation does not depend, of course, on the number of objects being denumerably infinite, though, as already noted, Carnap did impose that condition on his state descriptions. But then—even though Carnap himself did not give this argument— given the non-contingency of identity, the logical truth of the Carnap–Barcan formula, and the assumption for each positive integer n that it is not necessary that there are just n objects in the world, it follows that the number of objects in the world must be infinite. (For if everything is one of a finite number n of objects, then, by the non-contingency of identity, everything is necessarily one of n objects, and therefore by the Carnap–Barcan formula, necessarily everything is one of n objects; i.e. contrary to the assumption, it is necessary after all that there are just n objects in the world.)

As the above remarks indicate, the validation of the Carnap–Barcan formula in the framework of logical atomism is unproblematic; and therefore its logical truth in the primary semantics is as it should be. However, besides being logically true in the primary semantics the principle is also universally valid in the secondary semantics; and it is not clear that this is as it should be for Kripke’s metaphysical necessity. Indeed, Kripke’s later modified semantics for quantified modal logic in [Kripke, 1963] suggests he thinks otherwise, since there the Carnap–Barcan formula is no longer validated. Nevertheless, as indicated above, even with the rejection of the Carnap–Barcan formula, it is clear that Kripke intends his metaphysical context to be such as to support the validation of the non-contingency of identity.

6 EXISTENCE IN THE PRIMARY AND SECONDARY SEMANTICS

In rejecting the Carnap–Barcan formula, one need not completely reject the assumption upon which it is based, *viz.* that every possible world (of a given logical space) consists of the same totality of objects. All one need do is take this totality not as the set of objects existing in each world but as the sum of objects that exist in some world or other (of the same logical space), i.e. as the totality of possible objects (of that logical space). Quantification with respect to a world, however, is always to be restricted to the objects existing in that world—though free variables may, as it were, range over the possible objects, thereby allowing a single interpretation of both *de re* and *de dicto* wffs. The resulting quantificational logic is of course free of the presupposition that singular terms (individual variables and constants) always designate an existing object and is for this reason called *free logic* (cf. [Hintikka, 1969]).

Thus, where L is a language and D is a non-empty set, then $\langle\langle\mathfrak{A}, X\rangle, K\rangle$ is a *free model structure* based on D and L iff (1) $\langle\mathfrak{A}, X\rangle \in K$, (2) K is a set every member of which is a pair $\langle\mathfrak{B}, Y\rangle$ where \mathfrak{B} is an L -model having

D as its universe and $Y \subseteq D$ and (3) $D = \cup\{Y : \text{for some L-model } \mathfrak{B}, \langle \mathfrak{B}, Y \rangle \in K\}$. Possible worlds are now represented by the pairs $\langle \mathfrak{B}, Y \rangle$, where the (possibly empty) set Y consists of just the objects existing in the world in question; and of course the pair $\langle \mathfrak{A}, X \rangle$ is understood to represent the actual world. Where A is an assignment in D , the *satisfaction by* A of a wff φ of L in $\langle \langle \mathfrak{A}, X \rangle, K \rangle$ is defined as in the secondary semantics, except for clause (5) which is now as follows:

5. $\langle \langle \mathfrak{A}, X \rangle, K \rangle, A \models \forall x\varphi$ iff for all $d \in X$, $\langle \langle \mathfrak{A}, X \rangle, K \rangle, A(d/x) \models \varphi$.

Now if K is the set of *all* pairs $\langle \mathfrak{B}, Y \rangle$, where \mathfrak{B} is an L-model having D as its universe and $Y \subseteq D$, then $\langle \langle \mathfrak{A}, X \rangle, K \rangle$ is a *full* free model structure. Of course, whereas validity with respect to all free model structures (based on an appropriate language) is the free logic counterpart of the secondary semantics, validity with respect to all full free model structures is the free logic version of the primary semantics. Moreover, because of the restricted interpretation quantifiers are now given, neither the Carnap–Barcan formula nor its converse is valid in either sense, i.e. neither is valid in either the primary or secondary semantics based on free logic.

If a formal language L contains proper names or individual constants, then their construal as rigid designators requires that a free model structure $\langle \langle \mathfrak{A}, X \rangle, K \rangle$ based on L be such that for all $\langle \mathfrak{B}, Y \rangle \in K$ and all individual constants a in L , the designation of a in \mathfrak{B} is the same as the designation of a in \mathfrak{A} , i.e. in the actual world. Note that while it is assumed that every individual constant designates a possible object, i.e. possibly designates an existing object, it need not be assumed that it designates an existing object, i.e. an object existing in the actual world. In that case, the rigidity of such a designator is not given by the validity of $\exists x\Box(a = x)$ but by the validity of $\Diamond\exists x\Box(a = x)$ instead. Existence of course is analysable as follows:

$$E!(a) = df \exists x(a = x).$$

Note that since possible worlds are now differentiated from one another by the objects existing in them, the concept of existence, despite its analysis in logical terms, must be construed here as having material and not merely formal content. In logical atomism, however, that would mean that the existence or non-existence of an object is itself an atomic state of affairs after all, since now even merely possible objects are constituents of atomic states of affairs. To exclude the later situation, i.e. to restrict the constituents of atomic states of affairs to those that exist in the world in question, would mean that merely possible worlds are not after all merely alternative combinations of the same atomic states of affairs that constitute the actual world; that is, it would involve rejecting one of the basic features of logical atomism, and indeed one upon which the coherence of the framework depends. In this regard, it should be noted, while it is one thing to reject logical

atomism (as probably most of us do) as other than a paradigm of logical analysis, it is quite another to accept some of its basic features (such as the interpretation of necessity as referring to *all* the possible worlds of a given logical space) while rejecting others (such as the constitutive nature of a possible world); for in that case, even if it is set-theoretically consistent, it is no longer clear that one is dealing with a philosophically coherent framework.

That existence should have material content in the secondary semantics, on the other hand is no doubt as it should be, since as already noted, necessity is itself supposed to have such content in that semantics. The difficulty here, however, is that necessity can have such content in the secondary semantics only in a free model structure that is *not* full; for with respect to the full free model structure, the modal thesis of anti-essentialism (with quantifiers now interpreted as respecting existing objects only) can again be validated, just as it was in the original primary semantics. (A full free model structure, incidentally, is essentially what Parsons in [1969] calls a maximal model structure.) The key lemma that led to its validation before continues to hold, in other words, only now for free model structures $\langle\langle\mathfrak{A}, X\rangle, K\rangle$ and $\langle\langle\mathfrak{B}, Y\rangle, K\rangle$ instead of the models \mathfrak{A} and \mathfrak{B} , and for an isomorphism h between \mathfrak{A} and \mathfrak{B} such that $Y = h^{\ast}(X)$. Needless to say, moreover, but the incompleteness theorem of the primary semantics for logical truth also carries over to universal validity with respect to all full free model structures.

No doubt one can attempt to avoid this difficulty by simply excluding full free model structures; but that in itself would hardly constitute a satisfactory account of the metaphysical content of necessity (and now of existence as well). For there remains the problem of explaining how arbitrary non-empty subsets of the set of possible worlds in a free model structure can themselves be the referential basis for necessity in other free model structures. Indeed, in general, the problem with the secondary semantics is that it provides no explanation of why *arbitrary* non-empty sets of possible worlds can be the referential basis of necessity. In this regard, the secondary semantics of necessity is quite unlike the secondary semantics of second-order logic where, e.g. general models are subject to the constraints of the compositional laws of a comprehension principle.

7 METAPHYSICAL NECESSITY AND RELATIONAL MODEL STRUCTURES

It is noteworthy that in his later rejection of the Carnap–Barcan formula, Kripke also introduced a further restriction into the quantificational semantics of necessity, viz. that it was to refer not to all the possible worlds in a given model structure but only to those that are possible alternatives to

the world in question. In other words, not only need not all the worlds in a given logical space be in the model structure (the first restriction), but now even the worlds in the model structure need not all be possible alternatives to one another (the second restriction). Clearly, such a restriction within the first restriction only deepens the sense in which the necessity in question is no longer a logical but a material or metaphysical modality.

The virtue of a relational interpretation, as is now well-known, is that it allows for a general semantical approach to a whole variety of modal logics by simply imposing in each case certain structural conditions on the relation of accessibility (or alternative possibility) between possible worlds. Of course, in each such case, the question remains as to the real nature and content of the structural conditions imposed, especially if our concern is with giving necessity a metaphysical or material interpretation as opposed to a merely formal or set-theoretical one. How this content is explained and filled in, needless to say, will no doubt affect how we are to understand modality *de re* and the question of essentialism.

Retaining the semantical approach of the previous section where the restrictions on possible worlds (models with a restricted existence set) are rendered explicit, we shall understand a *relational model structure* based on a universe D and a language L to be a triple $\langle\langle\mathfrak{A}, X\rangle, K, R\rangle$ where (1) $\langle\langle\mathfrak{A}, X\rangle, K\rangle$ is a free model structure and (2) $R \subseteq K \times K$. If A is an assignment in D , then *satisfaction* by A is defined as in Section 6, except for clause (6) which now is as follows:

6. $\langle\langle\mathfrak{A}, X\rangle, K, R\rangle, A \models \Box\varphi$ iff for all $\langle\mathfrak{B}, Y\rangle \in K$, if $\langle\mathfrak{A}, X\rangle R \langle\mathfrak{B}, Y\rangle$, then $\langle\langle\mathfrak{B}, Y\rangle, K, R\rangle, A \models \varphi$.

Needless to say, but if $R = K \times K$ and K is full, then once again we are back to the free logic version of the primary semantics; and, as before, even excluding relational model structures that are full in this extended sense still leaves us with the problem of explaining how otherwise arbitrary non-empty sets of possible worlds of a given logical space, together now with a relation of accessibility between such worlds, can be the basis of a metaphysical modality.

No doubt it can be assumed regarding the implicit metaphysical framework of such a modality that in addition to the objects that exist in a given world there are properties and relations which these objects either do or do not have and which account for the truths that obtain in that world. They do so, of course, by being what predicate expressions stand for as opposed to the objects that are the designata of singular terms. (Nominalism, it might be noted, will not result in a coherent theory of predication in a framework which contains a metaphysical modality—a point nominalists themselves insist on.)

On the other hand, being only what predicates stand for, properties and relations do not themselves exist in a world the way objects do. That

is, unlike the objects that exist in a world and which might not exist in another possible world, the properties and relations that are predicable of objects in one possible world are the same properties and relations that are predicable of objects in any other possible world. In this regard, what is semantically peculiar to a world about a property or relation is not the property or relation itself but only its extension, i.e. the objects that are in fact conditioned by that property or relation in the world in question. Understood in this way, a property or relation may be said to have in itself only a transworld or non-substantial mode of being.

Following Carnap [1955], who was the first to make this sort of proposal, we can represent a property or relation in the sense indicated by a function from possible worlds to extensions of the relevant sort. With respect to the present semantics, however, it should be noted that the extension which a predicate expression has in a given world need not be drawn exclusively from the objects that exist in that world. That is, the properties and relations that are part of the implicit metaphysical framework of the present semantics may apply not only to existing objects but to possible objects as well—even though quantification is only with respect to existing objects. Syntactically, this is reflected in the fact that the rule of substitution:

$$\text{if } \models \varphi, \text{ then } \models \check{S}_{\psi}^{F(x_1, \dots, x_n)} \varphi \mid$$

is validated in the present semantics; and this in turn indicates that any open wff ψ , whether *de re* or *de dicto*, may serve as the definiens of a possible definition for a predicate. That is, it can be shown by means of this rule that such a definiens will satisfy both the criterion of eliminability and the criterion of non-creativity for explicit definitions of a new predicate constant. (Beth's Definability Theorem fails for the logic of this semantics, however, and therefore so does Craig's Interpolation Lemma which implies the Definability Theorem, cf. [Fine, 1979].)

We can, of course, modify the present semantics so that the extension of a predicate is always drawn exclusively from existing objects. That perhaps would make the metaphysics implicit in the semantics more palatable—especially if metaphysical necessity in the end amounts to a physical or natural necessity and the properties and relations implicit in the framework are physical or natural properties and relations rather than properties and relations in the logical or intensional sense. However, in that case we must then also give up the above rule of substitution and restrict the conditions on what constitutes a possible explicit definition of a predicate; e.g. not only would modal wffs in general be excluded as possible definiens but so would the negation of any modal free wff which itself was acceptable. In consequence, not only would many of the predicates of natural language not be representable by predicates of a formal modal language—their associated 'properties' being dispositional or modal—but even their possible analyses in terms of predicates that are acceptable would also be excluded.

8 QUANTIFICATION WITH RESPECT TO INDIVIDUAL CONCEPTS

One way out of the apparent impasse of the preceding semantics is the turn to intensionality, i.e. the turn to an independently existing Platonic realm of intensional existence (and inexistence) and away from the metaphysics of either essentialism (natural kinds, physical properties, etc.) or anti-essentialism (logical atomism). In particular, it is claimed, problems about states of affairs, possible objects and properties and relations (in the material sense) between such objects are all avoidable if we would only turn instead to propositions, individual concepts and properties and relations in the logical sense, i.e. as the intensions of predicate expressions and open wffs in general. Thus, unlike the problem of whether there can be a state of affairs having merely possible objects among its constituents, there is nothing problematic, it is claimed, about the intensional existence of a proposition having among its components intensionally inexistent individual concepts, i.e. individual concepts that fail to denote (*bedeuten*) an existing object.

Intensional entities (*Sinne*), on this approach, do not exist in space and time and are not among the individuals that differentiate one possible world from another. They are rather non-substantial transworld entities which, like properties and relations, may have different extensions (*Bedeutungen*) in different possible worlds. For example, the extension of a proposition in a given world is its truth-value, i.e. truth or falsity (both of which we shall represent here by 1 and 0, respectively), and the extension of an individual concept in that world is the object which it denotes or determines. We may, accordingly, follow Carnap once again and represent different types of intensions in general as functions from possible worlds to extensions of the relevant type. In doing so, however, we shall no longer identify possible worlds with the extensional models of the preceding semantics; that is, except for the objects that exist in a given world, the nature and content of that world will otherwise be left unspecified. Indeed, because intensionality is assumed to be conceptually prior to the functions on possible worlds in terms of which it will herein be represented, the question of whether a merely possible world, or of whether a merely possible object existing in such a world, has an ontological status independent of the realm of intensional existence (or inexistence) is to be left open on this approach (if not closed in favour of an analysis or reduction of such worlds and objects in terms of propositions and the intensional inexistence of individual concepts).

Accordingly, a triple $\langle W, R, E \rangle$ will be said to be a *relational world system* if W is a non-empty set of possible worlds, R is an accessibility relation between the worlds in W , i.e. $R \subseteq W \times W$, and E is a function on W into (possibly empty) sets, though for some $w \in W$ (representing the actual world), $E(w)$ is non-empty. (The sets $E(w)$, for $w \in W$, consist of the objects existing in each of the worlds in W .) Where $D = \cup_{w \in W} E(w)$, an

individual concept in $\langle W, R, E \rangle$, is a function in D^W ; and for each natural number n , P is an n -place *predicate intension* in $\langle W, R, E \rangle$ iff $P \in \{X : X \subseteq D^n\}^W$. (Note: for $n = 0$, we take an n -place predicate intension in $\langle W, R, E \rangle$ to be a *proposition* in $\langle W, R, E \rangle$, and therefore since $D^0 = \{0\}$ and $2 = \{0, 1\}$, P is a proposition in $\langle W, R, E \rangle$ iff $P \in 2^W$. For $n \geq 2$, an n -place predicate intension is also called an n -ary *relation-in-intension*, and for $n = 1$, it is taken as a property in the logical sense.)

Where L is a language, I is said to be an *interpretation* for L based on a relational world system $\langle W, R, E \rangle$ if I is a function on L such that (1) for each individual constant $a \in L$, $I(a)$ is an individual concept in $\langle W, R, E \rangle$; and (2) if F^n is an n -place predicate in L , then $I(F^n)$ is an n -place predicate intension in $\langle W, R, E \rangle$. An *assignment* A in $\langle W, R, E \rangle$ is now a function on the individual variables such that $A(x)$ is an individual concept in $\langle W, R, E \rangle$, for each such variable. The *intension* with respect to I and A of an individual variable or constant b in L , in symbols $\text{Int}(b, I, A)$ is defined to be $(I \cup A)(b)$.

Finally, the *intension with respect to I and A of an arbitrary wff φ of L* is defined recursively as follows:

1. where a, b are individual variables or constants in L , $\text{Int}(a = b, I, A) =$ the $p \in 2^W$ such that for $w \in W$, $P(w) = 1$ iff $\text{Int}(a, I, A)(w) = \text{Int}(b, I, A)(w)$;
2. where a_1, \dots, a_n are individual variables or constants in L and $F^n \in L$, $\text{Int}(F(a_1, \dots, a_n), I, A) =$ the $P \in 2^W$ such that for $w \in W$, $P(w) = 1$ iff $\langle \text{Int}(a_1, I, A)(w), \dots, \text{Int}(a_n, I, A)(w) \rangle \in I(F^n)(w)$;
3. $\text{Int}(\neg\varphi, I, A) =$ the $P \in 2^W$ such that for $w \in W$, $P(w) = 1$ iff $\text{Int}(\varphi, I, A)(w) = 0$;
4. $\text{Int}((\varphi \rightarrow \psi), I, A) =$ the $P \in 2^W$ such that for $w \in W$, $P(w) = 1$ iff either $\text{Int}(\varphi, I, A)(w) = 0$ or $\text{Int}(\psi, I, A)(w) = 1$;
5. $\text{Int}(\forall x\varphi, I, A) =$ the $P \in 2^W$ such that for $w \in W$, $P(w) = 1$ iff for *all* individual concepts f in $\langle W, R, E \rangle$, $\text{Int}(\varphi, I, A(f/x))(w) = 1$; and
6. $\text{Int}(\Box\varphi, I, A) =$ the $P \in 2^W$ such that for $w \in W$, $P(w) = 1$ iff for all $v \in W$, if wRv , then $\text{Int}(\varphi, I, A)(v) = 1$.

Different notions of *intensional validity*, needless to say, can now be defined as in the earlier semantics depending on the different structural properties that the relation of accessibility might be assumed to have. It can be shown, however, from results announced by Kripke in [1976] that if the relation is only assumed to be reflexive, or reflexive and symmetric but not also transitive, or reflexive and transitive but not also symmetric, then the wffs that are intensionally valid with respect to the relational structures in

question are not recursively enumerable; that is, the resulting semantics is then essentially incomplete. Whether the semantics is also incomplete for intensional validity with respect to the class of relational world systems in which the relation of accessibility is an equivalence relation, or, equivalently, in which it is universal between all the worlds in the system, has apparently not yet been determined (or at any rate not yet announced or published in the literature). However, because of its close similarity to Thomason's system **Q2** in [Thomason, 1969], the **S5** version of which Kripke in [1976] has claimed to be complete, we conjecture that it too is complete, i.e. that the set of wffs (of a given language) that are intensionally valid with respect to all relational world systems in which the relation of accessibility is universal is recursively enumerable. For convenience, we shall speak of the members of this set hereafter as being *intensionally valid simpliciter*; that is, we shall take the members of this set as being intensionally valid in the primary sense (while those that are valid otherwise are understood to be so in a secondary sense).

It is possible of course to give a secondary semantics in the sense in which quantification need not be with respect to *all* of the individual concepts in a given relational world system but only with respect to some non-empty set of such. (Cf. [Parks, 1976] where this gambit is employed—but in a semantics in which predicates have their extensions drawn in a given world from the restricted set of individual concepts and not from the possible objects.) As might be expected, completeness theorems are then forthcoming in the usual way even for classes of relational world systems in which the relation of accessibility is other than universal. Of course the question then arises as to the rationale for allowing *arbitrary* non-empty sets of individual concepts to be the basis for quantifying over such in any given relational world system. This question, moreover, is not really on a par with that regarding allowing arbitrary non-empty subsets of the set of possible worlds to be the referential basis of necessity (even where the relation of accessibility is universal); for in a framework in which the realm of intensionality is conceptually prior to its representation in terms of functions on possible worlds, the variability of the sets of possible world may in the end be analogous to the similar variability of the universes of discourses in standard (modal free) first-order logic. Such variability within the intensional realm itself, on the other hand, would seem to call for a different kind of explanation.

Thomason's semantical system **Q2** in [Thomason, 1969], it should be noted, differs from the above semantics for intensional validity *simpliciter* in requiring first that the set of existing objects of each possible world be non-empty, and, secondly, that although free individual variables range over the entire set of individual concepts, quantification in a given world is to be restricted to those individual concepts which denote objects that exist in that world. (Thomason also gives an 'outer domain' interpretation for improper definite descriptions which we can ignore here since definite de-

scriptions are not singular terms of the formal languages being considered.) Thus, clause (5) for assigning an intension to a quantified wff is replaced in **Q2** by:

(5') $\text{Int}(\forall x\varphi, I, A) = \text{the } P \in 2^W \text{ such that for } w \in W, P(w) = 1 \text{ if for all individual concepts } f \text{ in } \langle W, R, E \rangle, \text{ if } f(w) \in E(w), \text{ then } \text{Int}(\varphi, I, A(f/x))(w) = 1.$

Intensional **Q2**-validity can now be defined as intensional validity with respect to all relational world systems in which (1) the set of objects existing in each world is non-empty, (2) the relation of accessibility is universal, and (3) quantification is interpreted as in clause(5'). According to Kripke [1976], the set of wffs (of a given language) that are intensionally **Q2**-valid is recursively enumerable. (Cf. [Bacon, 1980] for some of the history of these results and of an earlier erroneous claim by David Kaplan.) The completeness proof given in [Kamp, 1977], it should be noted, is not for **Q2**-validity (as might be thought from Kamp's remark that he is reconstructing Kripke's proof), but for a semantics in which individual concepts always denote only existing objects and in which the extension of a predicate's intension in a given world is drawn exclusively from the objects that exist in that world. Both conditions are too severe, however—at least from the point of view of the realm of intensional existence (an inexistence). In particular, whereas the rule of substitution:

$$\text{if } \models \varphi, \text{ then } \models \tilde{S}_\psi^{F(x_1, \dots, x_n)} \varphi \mid$$

is validated in both the semantics of intensional validity *simpliciter* and in the **Q2**-semantics, it is not validated in Kamp's more restricted semantics. Not all open wffs, in other words, represent predicate intensions, i.e. properties or relations in the logical sense, in Kamp's semantics—a result contrary to one of the basic motivations for the turn to intensionality.

9 INDIVIDUAL CONCEPTS AND THE ELIMINATION OF *DE RE* MODALITIES

One of the nice things about Thomason's **Q2**-semantics is that existence remains essentially a quantifier concept; that is, the definition of $E!$ given earlier remains in effect in the **Q2** semantics. This is not so of course in the semantics for intensional validity *simpliciter* where $E!$ would have to be introduced as a new intensional primitive (cf. [Bacon, 1980]). There would seem to be nothing really objectionable about doing so, however; or at least not from the point of view of the realm of intensional existence (and inexistence). Quantifying over all individual concepts, whether existent or in-existent—i.e. whether they denote objects that exist in the world in

question or not—can hardly be compared from this point of view with the different situation of quantifying over all possible objects in the semantics of a metaphysical necessity (as opposed to quantifying only over the objects that exist in the world in question in that metaphysical context).

One of the undesirable features of the **Q2**-semantics, however, is its validation of the wff

$$\exists x \Box E!(x)$$

which follows from the **Q2**-validity of

$$\Box \exists x \varphi \rightarrow \exists x \Box \varphi \quad \text{and} \quad \Box \exists x E!(x).$$

This situation can be easily rectified, of course, by simply rejecting the semantics of the latter wff, i.e. by not requiring the set of objects existing in each world of the **Q2**-semantics to be non-empty. The converse of the above conditional is not intensionally **Q2**-valid, incidentally, though both are intensionally valid in the primary sense; that is

$$(\Box \exists / \exists \Box) \exists x \Box \varphi \leftrightarrow \Box \exists x \varphi$$

is intensionally valid *simpliciter*. So of course is the Carnap–Barcan formula (and its converse), which also fails (in both directions) in the **Q2**-semantics; for this formula and its converse, it is well-known, is a consequence of the **S5** modal principles together with those of standard first-order predicate logic without identity (LPC). Of course, whereas every wff which is an instance of a theorem of LPC is intensionally valid in the primary sense, it is only their modal free-logic counterparts that are valid in the **Q2**-semantics. For example, whereas

$$\forall x \varphi \rightarrow \varphi(a/x)$$

is intensionally valid *simpliciter*, only its modal free-logic counterpart

$$\exists x \Box (a = x) \rightarrow [\forall x \varphi \rightarrow \varphi(a/x)]$$

is intensionally **Q2**-valid.

One rather important consequence of these results of the semantics for intensional validity in the primary sense, it should be noted, is the validation in this sense, of Von Wright's principle of predication (cf. [von Wright, 1951]) i.e. the principle (as restated here in terms of individual concepts) that if a property or relation in the logical sense is contingently predicable of the denotata of some individual concepts, then it is contingently predicable of the denotata of all individual concepts:

$$(Pr) \quad \exists x_1 \dots \exists x_n (\Diamond \varphi \wedge \Diamond \neg \varphi) \rightarrow \forall x_1 \dots \forall x_n (\Diamond \varphi \wedge \Diamond \neg \varphi).$$

The fact that (Pr) is intensionally valid *simpliciter* can be seen from the syntactic proof in [Broido, 1976] that

$$\text{LPC} + \mathbf{S5} + (\Box\exists/\exists\Box) \vdash (\text{Pr}).$$

That is, since every wff which is an axiom of $\text{LPC} + \mathbf{S5} + (\Box\exists/\exists\Box)$ is intensionally valid *simpliciter*, and *modus ponens* and universal modal generalisation preserve validity in this sense, then (Pr) is also intensionally valid *simpliciter*.

Now although not every wff which is an axiom of $\text{LPC} + (\Box\exists/\exists\Box)$ is valid in the **Q2**- semantics, nevertheless, it follows from the intensional validity of (Pr) in the primary sense that (Pr) is intensionally **Q2**-valid as well. To see this, assume that $E!$ is added as a new intensional primitive with the following clause added to the semantics of the preceding section:

$$\begin{aligned} \text{Int}(E!(a), I, A) &= \text{the } P \in 2^W \text{ such that for } w \in W, P(w) = 1 \\ &\text{iff } \text{Int}(a, I, A)(w) \in E(w). \end{aligned}$$

Then, where t translates each wff into its $E!$ restricted counterpart, i.e. where $t(\varphi) = \varphi$, for atomic wffs, $t(\neg\varphi) = \neg t(\varphi)$, $t(\varphi \rightarrow \psi) = (t(\varphi) \rightarrow t(\psi))$, $t(\Box\varphi) = \Box t(\varphi)$ and $t(\forall x\varphi) = \forall x(E!(x) \rightarrow t(\varphi))$, it can be readily seen that a wff φ is intensionally **Q2**-valid iff $[\exists x\Box E!(x) \rightarrow t(\varphi)]$ is intensionally valid *simpliciter*; and therefore if $t(\varphi)$ is intensionally valid *simpliciter*, then φ is intensionally **Q2**-valid. Now since

$$\exists x_1 \dots \exists x_n [\diamond t(\varphi) \wedge \diamond \neg t(\varphi)] \rightarrow \forall x_1 \dots \forall x_n [\diamond t(\varphi) \wedge \diamond \neg t(\varphi)]$$

is an instance of (Pr), it is intensionally valid *simpliciter*, and therefore so is

$$\begin{aligned} \exists x_1 \dots \exists x_n [E!(x_1) \wedge \dots \wedge E!(x_n) \wedge \diamond t(\varphi) \wedge \diamond \neg t(\varphi)] \rightarrow \\ \rightarrow \forall x_1 \dots \forall x_n [E!(x_1) \wedge \dots \wedge E!(x_n) \rightarrow \diamond t(\varphi) \wedge \diamond \neg t(\varphi)]. \end{aligned}$$

This last wff, however, is trivially equivalent to $t(\text{Pr})$. That is, $t(\text{Pr})$ is intensionally valid *simpliciter*, and therefore (Pr) is intensionally **Q2**-valid.

It is noteworthy, finally, that on the basis of $\text{LPC} + \mathbf{S5} + (\text{Pr}) + (\Box\exists/\exists\Box)$, [Broido, 1976] has shown that every *de re* wff is provably equivalent to a *de dicto* wff. Accordingly, since all of the assumptions or wffs essential to Broido's proof are intensionally valid *simpliciter*, it follows that every *de re* wff is eliminable in favour of only *de dicto* wffs (of modal degree ≤ 1) in the semantics of intensional validity in the primary sense.

THEOREM (De Re Elimination Theorem) For each *de re* wff φ , there is a *de dicto* wff ψ such that $(\varphi \leftrightarrow \psi)$ is intensionally valid *simpliciter*.

Kamp [1977] has shown, incidentally, that a *de re* elimination theorem also holds for the more restricted semantics in which individual concepts always denote existing objects and the extensions of predicate intensions

are always drawn exclusively from the objects existing in the world in question. (This theorem is in fact the basis of Kamp's completeness theorem for his semantics—and therefore perhaps also the basis for a similar proof of completeness for the semantics of intensional validity *simpliciter*.) Accordingly, since the logic of the **Q2**-semantics is intermediate between Kamp's semantics and the semantics of intensional validity in the primary sense, it is natural to conjecture that a similar *de re* elimination theorem also holds for intensional **Q2**-validity—though of course not one which depends on the consequences of $\text{LPC} + (\Box\exists/\exists\Box)$.

10 CONTINGENT IDENTITY

Identity in logical atomism, as we have already noted, does not stand for an atomic state of affairs; that is, despite its being represented by an atomic wff, an object's self-identity is part of the logical scaffolding of the world (which the world shares with every other possible world) and not part of the world itself. This is why identity is a non-contingent relation in logical atomism.

Identity in the realm of intensionality, on the other hand, is really not an identity of individual concepts but a world-bound relation of coincidence between these concepts. That is, as a relation in which individual concepts need not themselves be the same but only have the same denotation in a given world, 'identity' need not hold between the same individual concepts from world to world. This is why 'identity' can be a contingent relation from the intensional point of view.

In other words, whereas

$$\exists x\exists y(x = y \wedge \Diamond x \neq y), \quad \exists x\exists y(x \neq y \wedge \Diamond x = y)$$

are logically false from the point of view of the primary semantics for logical atomism, both can be true (and in fact must be true if there are at least two objects in the world) from the point of view of the realm of intensionality.

One argument in favour of contingent identity as a relation of coincidence between individual concepts is given in [Gibbard, 1975]. In Gibbard's example a clay statue named Goliath (hereafter represented by a) is said to be contingently identical with the piece of clay of which it is made and which is named Lump1 (hereafter represented by b). For convenience, we may suppose that a and b begin to exist at the same time; e.g. the statue is made first in two separate pieces which are then struck together 'thereby bringing into existence simultaneously a new piece of clay and a new statue' [Gibbard, 1975, p. 191]. Now although Goliath is Lump1—i.e. ($a = b$) is true in the world in question—it is nevertheless possible that the clay is squeezed into a ball before it dries; and if that is done, then 'at that point . . . the statue Goliath would have ceased to exist, but the piece of clay Lump1 would still

exist in a new shape. Hence Lumpl would not be Goliath, even though both existed' [Gibbard, 1975]. That is, according to Gibbard, the wff

$$a = b \wedge \diamond[a \neq b \wedge E!(a) \wedge E!(b)]$$

would be true in the world in question.

Contrary to Gibbard's claim, however, the above wff is not really a correct representation of the situation he describes. In particular, it is not true that Goliath exists in the world in which Lumpl has been squeezed into a ball. The correct description, in other words, is given by

$$a = b \wedge \diamond[\neg E!(a) \wedge E!(b)],$$

which, since

$$a = b \rightarrow [E!(a) \leftrightarrow E!(b)]$$

is both intensionally valid *simpliciter* and intensionally **Q2**-valid, implies:

$$a = b \wedge \diamond[a \neq b \wedge \neg E!(a) \wedge E!(b)]$$

and this wff in turn implies

$$\neg[a = b \rightarrow \Box a = b],$$

which is the conclusion Gibbard was seeking in any case. That is, the identity of Goliath with Lumpl, though true, is only contingently true.

Now it should be noted in this context that the thesis that proper names are rigid designators can be represented neither by

$$\exists x \Box(a = x) \quad \text{nor} \quad \diamond \exists x \Box(a = x)$$

in the present semantics. For both wffs are in fact intensionally valid *simpliciter*, and the latter would be **Q2**-valid if we assumed that any individual concept expressed by a proper name always denotes an object which exists in at least one possible world—and yet, it is not required in either of these semantics that the individual concept expressed by a proper name is to denote the same object in every possible world. The question arises, accordingly, whether and in what sense Gibbard's example shows that the names 'Goliath' and 'Lumpl' are not rigid designators. For surely there is nothing in the way each name is introduced into discourse to indicate that its designation can change even when the object originally designated has continued to exist; and yet if it is granted that 'Goliath' and 'Lumpl' are rigid designators in the sense of designating the same object in every world in which it exists, then how is it that 'Goliath' can designate Lumpl in the one world where Goliath and Lumpl exist but not in the other where Lumpl but not Goliath exists? Doesn't the same object which 'Goliath' designates in the one world exist in the other? An answer to this problem is forthcoming, as we shall see, but from an entirely different perspective of the realm of intensionality; and indeed one in which identity is not a contingent relation either between objects or individual concepts.

11 QUANTIFIERS AS REFERENTIAL CONCEPTS

Besides the Platonic view of intensionality there is also the conceptualist view according to which concepts are not independently existing Platonic forms but cognitive capacities or related structures whose realisation in thought is what informs our mental acts with a predicable or referential nature. However, as cognitive capacities which may or may not be exercised on a given occasion, concepts, though they are not Platonic forms, are also neither mental images nor ideas in the sense of particular mental occurrences. That is, concepts are not objects or individuals but are rather unsaturated cognitive structures or dispositional abilities whose realisation in thought is what accounts for the referential and predicable aspects of particular mental acts.

Now the conceptual structures that account for the referential aspect of a mental act on this view are not the same as those that inform such acts with a predicable nature. A categorical judgement, for example, is a mental act which consists in the joint application of both types of concepts; that is, it is a mental event which is the result of the combination and mutual saturation of a referential concept with a predicable concept. Referential concepts, in other words, have a type of structure which is complementary to that of predicable concepts in that each can combine with the other in a kind of mental chemistry which results in a mental act having both a referential aspect and a predicable nature.

Referential concepts, it should be noted, are not developed initially as a form of reference to individuals *simpliciter* but are rather first developed as a form of reference to individuals of a given sort of kind. By a *sort* (or *sortal concept*) we mean in this context a type of common noun concept whose use in thought and communication is associated with certain identity criteria, i.e. criteria by which we are able to distinguish and count individuals of the kind in question. Typically, perceptual criteria such as those for shape, size and texture (hard, soft, liquid, etc.) are commonly involved in the application of such a concept; but then so are functional criteria (especially edibility) as well as criteria for the identification of natural kinds of things (animals, birds, fish, trees, plants, etc.) (cf. [Lyons, 1977, Vol. 2, Section 11.4]).

Though sortal concepts are expressed by common (count) nouns, not every common (count) noun, on the other hand, stands for a sort or kind in the sense intended here. Thus, e.g., whereas 'thing' and 'individual' are common (count) nouns, the concept of a thing or individual *simpliciter* is not associated in its use with any particular identity criteria, and therefore it is not a sortal concept in the sense intended here. Indeed, according to conceptualism, the concept of a thing or individual *simpliciter* has come to be constructed on the basis of the concept of a thing or individual of a certain sort (cf. [Sellars, 1963]). (It might be noted in this context, inci-

dentally, that while there are no explicit grammatical constructions which distinguish sortal common nouns from non-sortal common (count) nouns in the Indo-European language family, nevertheless there are ‘classifier-languages’—e.g. Tzeltal, a Mayan language spoken in Mexico, Mandarin Chinese, Vietnamese, etc.—which do contain explicit and obligatory constructions involving sortal classifiers (cf. [Lyons, 1977]).

Reference to individuals of a given sort, accordingly, is not a form of restricted reference to individuals *simpliciter*; that is, referential concepts regarding these individuals are not initially developed as derived concepts based on a quantificational reference to individuals in general, but are themselves basic or underived sortal quantifier concepts. Thus, where S and T stand for sortal concepts, $(\forall xS)$, $(\forall yT)$, $(\exists zS)$, $(\exists xT)$, etc. can be taken on the view in question as basic forms of referential concepts whose application in thought enable us to refer to all S , all T , some S , some T , etc. respectively. For example, where S stands for the sort *man* and F stands for the predicable concept of *being mortal*, a categorical judgement that every man is mortal, or that some man is not mortal, can be represented by $(\forall xS)F(x)$ and $(\exists xS)\neg F(x)$, respectively. These formulas, it will be noted, are especially perspicuous in the way they represent the judgements in question as being the result of a combination and mutual saturation of a referential and predicable concept.

Though they are themselves basic or underived forms of referential concepts, sortal quantifiers are nevertheless a special type of common (count) noun quantifier—including, of course, the ultimate common (count) noun quantifiers $\forall x$ and $\exists x$ (as applied with respect to a given individual variable x). Indeed, the latter, in regard to the referential concepts they represent, would be more perspicuous if written out more fully as $(\forall x \textit{Individual})$ and $(\exists x \textit{Individual})$, respectively. The symbols \forall and \exists , in other words, do not stand in conceptualism for separate cognitive elements but are rather ‘incomplete symbols’ occurring as parts of common (count) noun quantifiers. For convenience, however, we shall continue to use the standard notation $\forall x$ and $\exists x$ as abbreviations of these ultimate common (count) noun quantifiers.

12 SINGULAR REFERENCE

As represented by common (count) noun quantifiers, referential concepts are indeed complementary to predicable concepts in exactly the way described by conceptualism; that is, they are complementary in the sense that when both are applied together it is their combination and mutual saturation in a kind of mental chemistry which accounts for the referential and predicable aspects of a mental act. It is natural, accordingly, that a parallel interpretation should be given for the referential concepts underlying the use of singular terms.

Such an interpretation, it will be observed, is certainly a natural comitant of Russell's theory of definite descriptions—or rather of Russell's theory somewhat modified. Where S , for example, is a common (count) noun, including the ultimate common (count) noun 'individual', the truth-conditions for a judgement of the form

1. the S wh. is F is G

will be semantically equivalent in conceptualism to those for the wff

2. $(\exists xS)[(\forall yS)(F(y) \leftrightarrow y = x) \wedge G(x)]$

if, in fact, the definite description is being used in that judgement with an existential presupposition. If it is not being so used, however, then the truth-conditions for the judgement are semantically equivalent to

3. $(\forall xS)[(\forall yS)[F(y) \leftrightarrow y = x] \rightarrow G(x)]$

instead. Note however that despite the semantical equivalence of one of these wffs with the judgement in question, neither of them can be taken as a direct representation of the cognitive structure of that judgement. Rather, where ' S wh F '; abbreviates ' S wh. is F ', a more perspicuous representation of the judgement can be given either by

4. $(\exists_1 xS \text{ wh } F)G(x)$

or

5. $(\forall_1 xS \text{ wh } F)G(x)$

respectively, depending on whether the description is being used with or without an existential presupposition. (The 'incomplete' quantifier symbols \exists_1 and \forall_1 are, of course, understood here in such a way as to render (4) and (5) semantically equivalent to (2) and (3), respectively.) The referential concept which underlies using the definite description with an existential presupposition, in other words, is the concept represented by $(\exists_1 xS \text{ wh } F)$; and of course the referential concept which underlies using the description without an existential presupposition is similarly represented by $(\forall_1 xS \text{ wh } F)$.

Now while definite descriptions are naturally assimilated to quantifiers, proper names are in turn naturally assimilated to sortal common nouns. For just as the use of a sortal is associated in thought with certain identity criteria, so too is the introduction and use of a proper name (whose identity criteria are provided in part by the most specific sortal associated with the introduction of that name and to which the name is thereafter subordinate). In this regard, the referential concept underlying the use of a proper name is determined by the identity criteria associated with that name's introduction into discourse.

On this interpretation, accordingly, the referential concept underlying the use of a proper name corresponds to the referential concept underlying the use of a sortal common noun; that is, both are to be represented by sortal quantifiers (where ‘sortal’ is now taken to encompass proper names as well). The only difference between the two is that when such a quantifier contains a proper name, it is always taken to refer to at most a single individual. Thus, if in someone’s statement that Socrates is wise, ‘Socrates’ is being used with an existential presupposition, then the statement can be represented by

$$(\exists x \text{ Socrates})(x \text{ is wise}).$$

If ‘Socrates’ is being used without an existential presupposition, on the other hand, then the statement can be represented by

$$(\forall x \text{ Socrates})(x \text{ is wise})$$

instead. That is, the referential concepts underlying using ‘Socrates’ with and without an existential presupposition can be represented by $(\exists x \text{ Socrates})$ and $(\forall x \text{ Socrates})$, respectively. (Such a quantifier interpretation of the use of proper names will also explain, incidentally, why the issue of scope is relevant to the use of a proper name in contexts involving the expression of a propositional attitude.)

Now without committing ourselves at this point as to the sense in which conceptualism can allow for the development of alethic modal concepts, i.e. modal concepts other than those based upon a propositional attitude, it seems clear that the identity criteria associated with the use of a proper name do not change when that name is used in such a modal context. That is, the demand that we need a criterion of identity across the possible worlds associated with such a modality in order to determine whether a proper name is a rigid designator or not is without force in conceptualism since, in fact, such a criterion is already implicit in the use of a proper name. In other words, where S is a proper name, we can take it as a conceptual truth that the identity criteria associated with the use of S (1) always picks out at most one object and (2) that it is the same object which is so picked out whenever it exists:

$$(PN) \quad (\forall xS)[\Box(\forall yS)(y = x) \wedge \Box(E!(x) \rightarrow (\exists yS)(x = y))].$$

Nothing in this account of proper names conflicts, it should be noted, with Gibbard’s example of the statue Goliath which is identical with Lump1, the piece of clay of which it consists, during the time of its existence, but which ceases to be identical with Lump1 because it ceases to exist when Lump1 is squeezed into a ball. Both names, in other words, can be taken as rigid designators in the above sense without resulting in a contradiction in the situation described by Gibbard. Where S and T , for example, are proper

name sortals for ‘Goliath’ and ‘Lumpl’, respectively, the situation described by Gibbard is consistently represented by the following wff:

$$(\exists xS)(\exists yT)(x = y) \wedge \diamond(\exists yT)(\forall xS)(x \neq y).$$

That is, whereas the identity criteria associated with ‘Goliath’ and ‘Lumpl’ enable us to pick out the same object in the original world or time in question, it is possible that the criteria associated with ‘Lumpl’ enable us to pick out an object identifiable as Lumpl in a world or time in which there is no object identifiable as Goliath. In this sense, conceptualism is compatible with the claim that there can be contingent identities containing only proper names—even though proper names are rigid designators in the sense of satisfying (PN).

It does not follow, of course, that identity is a contingent relation in conceptualism; and, indeed, quite the opposite is the case. That is, since *reference in conceptualism is directly to objects*, albeit mediated by referential concepts, it is a conceptual truth to say that an object cannot but be the object that it is or that one object cannot be identical with another. In other words, the following wffs:

$$\forall x\forall y(x = y \rightarrow \Box x = y), \quad \forall x\forall y(x \neq y \rightarrow \Box x \neq y)$$

are to be taken as valid theses of conceptualism. This result is the complete opposite, needless to say, from that obtained *on the Platonic view* where *reference is directly to individual concepts* (as independently existing platonic forms) and only indirectly to the objects denoted by these concepts in a given possible world.

13 CONCEPTUALISM AND TENSE LOGIC

As forms of conceptual activity, thought and communication are inextricably temporal phenomena, and to ignore this fact in the semantics of a formal representation of such activity is to court possible confusion of the Platonic with the conceptual view of intensionality. Propositions, for example, on the conceptual view, are not abstract entities existing in a platonic realm independently of all conceptual activity. Rather, according to conceptualism, they are really conceptual constructs corresponding to the truth-conditions of our temporally located assertions; and on the present level of analysis where propositional attitudes are not being considered, their status as constructs can be left completely in the metalanguage.

What is also a construction, but which should not be left to the metalanguage, are certain cognitive schemata characterising our conceptual orientation in time and implicit in the form and content of our assertions as mental acts. These schemata, whether explicitly recognised as such or not, are usually represented or modelled in terms of a tenseless idiom (such as

our set-theoretic metalanguage) in which reference can be made to moments or intervals of time (as individuals of a special type); and for most purposes such a representation is quite in order. But to represent them only in this way in a context where our concern is with a perspicuous representation of the form of our assertions as mental acts might well mislead us into thinking that the schemata in question are not essential in conceptualism to the form and content of an assertion after all—the way they are not essential to the form and content of a proposition on the Platonic view. Indeed, even though the cognitive schemata in question can be modelled in terms of a tenseless idiom of moments or intervals of time (as in fact they will be in our set-theoretic metalanguage), they are themselves the conceptually prior conditions that lead to the construction of our referential concepts for moments or intervals of time, and therefore of the very tenseless idiom in which they are subsequently modelled. In this regard, no assumption need be made in conceptualism about the ultimate nature of moments or intervals of time, i.e. whether such entities are really independently existing individuals or only constructions out of the different events that actually occur.

Now since what the temporal schemata implicit in our assertions fundamentally do is enable us to orientate ourselves in time in terms of the distinction between the past, the present, and the future, a more appropriate or perspicuous representation of these schemata is one based upon a system of quantified tense logic containing at least the operators \mathcal{P} , \mathcal{N} , \mathcal{F} for ‘it was the case that’, ‘it is now the case that’, and ‘it will be the case that’, respectively. As applied in thought and communication, what these operators correspond to is our ability to refer to what was the case, what is now the case, and what will be the case—and to do so, moreover, without having first to construct referential concepts for moments or intervals of time.

Keeping our analysis as simple as possible, accordingly, let us now understand a language to consist of symbols for common (count) nouns, including always one for ‘individual’, as well as proper names and predicates. Where L is such a language, the atomic wffs of L are expressions of the form $(x = y)$ and $F(x_1, \dots, x_n)$, where x, y, x_1, \dots, x_n are variables and F is an n -place predicate in L . The wffs of L are then the expressions in every set K containing the atomic wffs of L and such that $\neg\varphi, \mathcal{P}\varphi, \mathcal{N}\varphi, \mathcal{F}\varphi, (\varphi \rightarrow \psi), (\forall xS)\varphi$ are all in K whenever $\varphi, \psi \in K, x$ is an individual variable and S is either a proper name or a common (count) noun symbol in L . As already noted, where S is the symbol for ‘individual’, we take $\forall x\varphi$ to abbreviate $(\forall xS)\varphi$, and similarly $\exists x\varphi$ abbreviates $\neg(\forall xS)\neg\varphi$.

In regard to a set-theoretic semantics for these wffs, let us retain the notion of a relational world system $\langle W, R, E \rangle$ already defined, but with the understanding that the members of W are now to be the moments of a *local time* (*Eigenzeit*) rather than complete possible worlds, and that the

relation R of accessibility is the earlier-than relation between the moments of that local time. The only constraint imposed by conceptualism on the structure of R is that it be a linear ordering of W , i.e. that R be asymmetric, transitive and connected in W . This constraint is based upon the implicit assumption that a local time is always the local time of a continuant.

There is nothing in set theory itself, it should be noted, which directly corresponds to the unsaturated nature of concepts as cognitive capacities; and for this reason we shall once again follow the Carnapian approach and represent concepts as functions from the moments of a local time to the classes of objects falling under the concepts at those times. Naturally, on this approach one and the same type of function will be used to represent the concepts underlying the use of common (count) nouns, proper names, and one-place predicates—despite the conceptual distinctions between them and in the way they account for different aspects of a mental act.

Accordingly, where L is a language and $\langle W, R, E \rangle$ is a relational world system, we shall now understand an *interpretation* for L based upon $\langle W, R, E \rangle$ to be a function I on L such that (1) for each n -place predicate F^n in L , $I(F^n)$ is an n -place predicate intension in $\langle W, R, E \rangle$; (2) for each common (count) noun symbol S in L , $I(S)$ is a one-place predicate intension in $\langle W, R, E \rangle$; and for the symbol S for 'individual' in particular, $I(S)(w) = E(w)$, for all $w \in W$; and (3) for each proper name S in L , $I(S)$ is a one-place predicate intension in $\langle W, R, E \rangle$ such that for some $d \in \cup_{w \in W} E(w)$, $I(S)(w) \subseteq \{d\}$, for all $w \in W$. (Note that at any given time $w \in W$, nothing need, in fact, be identifiable by means of the identity criteria associated with the use of a proper name—though if anything is so identifiable, then it is always the same individual. In this way we trivially validate the thesis (PN) of the preceding section that proper names are rigid designators with respect to the modalities analysable in terms of time.)

By a *referential assignment* in a relational world system $\langle W, R, E \rangle$, we now understand a function A which assigns to each variable x a member of $\cup_{w \in W} E(w)$, hereafter called the *realia* of $\langle W, R, E \rangle$. *Realia*, of course, are the objects that exist at some time or other of the local time in question. Referential concepts, at least in the semantics formulated below, do not refer directly to *realia*, but only indirectly (of which more anon); and in this regard *realia* are in tense logic what *possibilia* are in modal logic.

Finally, where t is construed as *the present moment* of a local time $\langle W, R, E \rangle$, i.e. $t \in W$, A is a referential assignment in $\langle W, R, E \rangle$ and I is an interpretation for a language L based on $\langle W, R, E \rangle$, we recursively define with respect to I and A *the proposition* (or intension in the sense of the truth-conditions) *expressed by a wff φ of L when part of an assertion made at t* as follows:

1. $\text{Int}_t(x = y, I, A) =$ the $P \in 2^W$ such that for $w \in W, P(w) = 1$ iff $A(x) = A(y)$;
2. $\text{Int}_t(F^n(x_1, \dots, x_n), I, A) =$ the $P \in 2^W$ such that for $w \in W, P(w) = 1$ iff $\langle A(x_1), \dots, A(x_n) \rangle \in I(F^n)(w)$;
3. $\text{Int}_t(\neg\varphi, I, A) =$ the $P \in 2^W$ such that for $w \in W, P(w) = 1$ iff $\text{Int}_t(\varphi, I, A)(w) = 0$;
4. $\text{Int}_t(\varphi \rightarrow \psi, I, A) =$ the $P \in 2^W$ such that for $w \in W, P(w) = 1$ iff $\text{Int}_t(\varphi, I, A)(w) = 0$ or $\text{Int}_t(\psi, I, A)(w) = 1$;
5. $\text{Int}_t((\forall xS)\varphi, I, A) =$ the $P \in 2^W$ such that for $w \in W, P(w) = 1$ iff for all $d \in E(w)$, if $d \in I(S)(w)$, then $\text{Int}_t(\varphi, I, A(d/x))(w) = 1$;
6. $\text{Int}_t(\mathcal{P}\varphi, I, A) =$ the $P \in 2^W$ such that for all $w \in W, P(w) = 1$ iff $\text{Int}_t(\varphi, I, A)(u) = 1$, for some u such that uRw ;
7. $\text{Int}_t(\mathcal{N}\varphi, I, A) =$ the $P \in 2^W$ such that for all $w \in W, P(w) = 1$ iff $\text{Int}_t(\varphi, I, A)(t) = 1$; and
8. $\text{Int}_t(\mathcal{F}\varphi, I, A) =$ the $P \in 2^W$ such that for all $w \in W, P(w) = 1$ iff $\text{Int}_t(\varphi, I, A)(u) = 1$, for some u such that wRu .

The double-indexing involved in this semantics and critically used in clause (7) is to account for the role of the now-operator. It was first given in [Kamp, 1971] and, of course, is particularly appropriate for conceptualism's concern with the semantics of assertions as particular mental acts. That is, as constructed in terms of the truth-conditions for assertions, propositions on the conceptualist's view of intensionality differ from those of the Platonist in being bound to the time at which the assertion in question occurs. For the Platonist, propositions exist independently of time, and therefore of the truth-conditions for assertions as well.

In regard to truth and validity, we shall say, relative to an interpretation I and referential assignment A in a local time $\langle W, R, E \rangle$, that a wff φ of the language in question is *true* if $\text{Int}_t(\varphi, I, A)(t) = 1$, where t is the present moment of the local time $\langle W, R, E \rangle$. The wff φ is said to be *valid* or *tense-logically true*, on the other hand, if for all local time systems $\langle W, R, E \rangle$, all $t \in W$, all referential assignments A in $\langle W, R, E \rangle$, and all interpretations I for a language of which φ is a wff, $\text{Int}_t(\varphi, I, A)(t) = 1$.

A completeness theorem is forthcoming for this semantics, but we shall not concern ourselves with establishing one in the present essay—especially since the overall logic is rather weak or minimal in the way it accounts for our conceptual orientation in time. Instead, let us briefly examine the problem of referring to *realia* in general, and in particular to past or future objects—i.e. the problem of how the conceptual structure of such a minimal system can either account for such reference or lead to a conceptual development where such an account can be given.

14 THE PROBLEM OF REFERENCE TO PAST AND FUTURE OBJECTS

Our comparison of the status of *realia* in tense logic with *possibilia* in modal logic is especially appropriate, it might be noted, insofar as quantificational reference to either is said to be feasible only *indirectly*—i.e. through the occurrence of a quantifier within the scope of a modal or tense operator (cf. [Prior, 1967, Chapter 8]). The reference to a past individual in ‘Someone did exist who was a King of France’, for example, can be accounted for by the semantics of $\mathcal{P}(\exists xS)(\exists yT)(x = y)$, where S and T are sortal common noun symbols for ‘person’ and ‘King of France’, respectively. What is apparently not feasible about a *direct* quantificational reference to such objects, on this account, is our present inability to actually confront and apply the relevant identity criteria to objects which do not now exist.

A present ability to identify past or future objects of a given sort, however, is not the same as the ability to actually confront and identify those objects in the present; that is, our existential inability to do the latter is not the same as, and should not be confused with, what is only presumed to be our inability to directly refer to past or future objects. Indeed, the fact is that we can and do make *direct reference* to *realia*, and to past and future objects in particular, and that we do so not only in ordinary discourse but also, and especially, in most if not all of our scientific theories. The real problem is not that we cannot directly refer to past and future objects, but rather how it is that conceptually we come to do so.

One explanation of how this comes to be can be seen in the analysis of the following English sentences:

1. There did exist someone who is an ancestor of everyone now existing.
2. There will exist someone who will have everyone now existing as an ancestor.

Where S is a sortal common noun symbol for ‘person’ and $R(x, y)$ is read as ‘ x is an ancestor of y ’, it is clear that (1) and (2) cannot be represented by:

3. $\mathcal{P}(\exists xS)(\forall yS)R(x, y)$
4. $\mathcal{F}(\exists xS)(\forall yS)R(y, x)$.

For what (3) and (4) represent are the different sentences:

5. There did exist someone who was an ancestor of everyone then existing.
6. There will exist someone who will have everyone then existing as an ancestor.

Of course, if referential concepts that enabled us to refer directly to past and future objects were already available, then the obvious representation of (1) and (2) would be:

$$7. (\exists x \text{ Past-}S)(\forall yS)R(x, y)$$

$$8. (\exists x \text{ Future-}S)(\forall yS)\mathcal{F}R(y, x)$$

where ‘Past-’ and ‘Future-’ are construed as common noun modifiers. (We assume here that the relational ancestor concept is such that x is an ancestor of y only at those times when either y exists and x did exist, though x need not still exist at the time in question, or when x has continued to exist even though y has ceased to exist. When y no longer exists as well as x , we say that x *was* an ancestor of y ; and where y has yet to exist, we say that x *will be* an ancestor of y .)

Now although these last analyses are not available in the system of tense logic formulated in the preceding section, nevertheless semantical equivalences for them are. In this regard, note that although the indirect references to past and future objects in (3) and (4) fail to provide adequate representations of (1) and (2), the same indirect references followed by the now-operator succeed in capturing the direct references given in (7) and (8):

$$9. \mathcal{P}(\exists xS)\mathcal{N}(\forall yS)R(x, y)$$

$$10. \mathcal{F}(\exists xS)\mathcal{N}(\forall yS)\mathcal{F}R(y, x).$$

In other words, at least relative to any present tense context, we can in general account for direct reference to past and future objects as follows:

$$(\forall x \text{ Past-}S)\varphi \leftrightarrow \neg\mathcal{P}\neg(\forall xS)\mathcal{N}\varphi$$

$$(\forall x \text{ Future-}S)\varphi \leftrightarrow \neg\mathcal{F}\neg(\forall xS)\mathcal{N}\varphi.$$

These equivalences, it should be noted, cannot be used other than in a present tense context; that is, the above use of the now-operator would be inappropriate when the equivalences are stated within the scope of a past- or future-tense operator, since in that case the direct reference to past or future objects would be from a point of time other than the present. Formally, what is needed in such a case is the introduction of so-called ‘backwards-looking’ operators, such as ‘then’, which can be correlated with occurrences of past or future tense operators within whose scope they lie and which semantically evaluate the wffs to which they are themselves applied in terms of the past or future times already referred to by the tense operators with which they are correlated (cf. [Vlach, 1973] and [Saarinen, 1976]). Backwards-looking operators, in other words, enable us to conceptually return to a past or future time already referred to in a given context in the same way that the now-operator enables us to return to the present. In that regard, their role in the cognitive schemata characterising our conceptual orientation in time

and implicit in each of our assertions is essentially a projection of the role of the now-operator.

We shall not formulate the semantics of these backwards-looking operators here, however; but we note that with their formulation equivalences of the above sort can be established for all contexts of tense logic, past and future as well as present. In any case, it is clear that the fact that conceptualism can account for the development of referential concepts that enable us to refer directly to past or future objects is already implicit in the fact that such references can be made with respect to the present alone. For this already shows that whereas the reference is direct at least in effect, nevertheless the application of any identity criteria associated with such reference will itself be indirect, and in particular, not such as to require a present confrontation, even if only in principle, with a past or future object.

15 TIME AND MODALITY

One important feature of the cognitive schemata characterising our conceptual orientation in time and represented in part by quantified tense logic, according to conceptualism, is the capacity they engender in us to form modal concepts having material content. Indeed, some of the first such modal concepts every to be formulated in the history of thought are based precisely upon the very distinction between the past, the present, and the future which is contained in these schemata. For example, the Megaric logician Diodorus is reported as having argued that the possible is that which either is or will be the case, and that therefore the necessary is that which is and always will be the case (cf. [Prior, 1967, Chapter 2]):

$$\Diamond^f \varphi = df \varphi \vee \mathcal{F}\varphi, \quad \Box^f \varphi = df \varphi \wedge \neg \mathcal{F}\neg\varphi.$$

Aristotle, on the other hand, included the past as part of what is possible; that is, for Aristotle the possible is that which either was, is, or will be the case (in what he assumed to be the infinity of time), and therefore the necessary is what is always the case (cf. [Hintikka, 1973]):

$$\Diamond^t \varphi = df \mathcal{P}\varphi \vee \varphi \vee \mathcal{F}\varphi, \quad \Box^t \varphi = df \neg \mathcal{P}\neg\varphi \wedge \varphi \wedge \neg \mathcal{F}\neg\varphi.$$

Both Aristotle and Diodorus, it should be noted, assumed that time is real and not ideal—as also does the socio-biologically based conceptualism being considered here. The temporal modalities indicated above, accordingly, are in this regard intended to be taken as material or metaphysical modalities (of a conceptual realism); and, indeed, they serve this purpose rather well, since in fact they provide a paradigm by which we might better understand what is meant by a material or metaphysical modality. In particular, not only do these modalities contain an explanatory, concrete

interpretation of the accessibility relation between possible worlds (now reconstrued as momentary states of the universe), but they also provide a rationale for the secondary semantics of a metaphysical necessity—since clearly not every possible world (of a given logical space) need ever actually be realised in time (as a momentary state of the universe). Moreover, the fact that the semantics (as considered here) is concerned with concepts and not with independently real material properties and relations (which may or may not correspond to some of these concepts but which can in any case also be considered in a supplementary semantics of conceptual realism) also explains why predicates can be true of objects at a time when those objects do not exist. For concepts, such as that of being an ancestor of everyone now existing, are constructions of the mind and can in that regard be applied to past or future objects no less so than to presently existing objects. In addition, because the intellect is subject to the closure conditions of the laws of compositionality for systematic concept-formation, there is no problem in conceptualism regarding the fact that a concept can be constructed corresponding to every open wff—thereby validating the rule of substitution of wffs for predicate letters.

As a paradigm of a metaphysical modality, on the other hand, one of the defects of Aristotle's notion of necessity is its exclusion of certain situations that are possible in special relativity. For example, relative to the present of a given local time, a state of affairs can come to have been the case, according to special relativity, without its ever actually being the case (cf. [Putnam, 1967]). That is, where $\mathcal{FP}\varphi$ represents φ 's coming (future) to have been (past) the case, and $\neg\Diamond^t\varphi$ represents φ 's never actually being the case, the situation envisaged in special relativity might be thought to be represented by:

$$\mathcal{FP}\varphi \wedge \neg\Diamond^t\varphi.$$

This conjunction, however, is incompatible with the linearity assumption of the local time in question; for on the basis of that assumption

$$\mathcal{FP}\varphi \rightarrow \mathcal{P}\varphi \vee \varphi \vee \mathcal{F}\varphi$$

is tense-logically true, and therefore $\mathcal{FP}\varphi$, the first conjunct, implies $\Diamond^t\varphi$, which contradicts the second conjunct, $\neg\Diamond^t\varphi$. The linearity assumption, moreover, cannot be given up without violating the notion of a local time or that of a continuant upon which it is based; and the notion of a continuant, as already indicated, is a fundamental construct of conceptualism. In particular, the notion of a continuant is more fundamental even than that of an event, which (at least initially) in conceptualism is always an occurrence in which one or more continuants are involved. Indeed, the notion of a continuant is even more fundamental in a socio-biologically based conceptualism than the notion of the self as a centre of conceptual activity, and it

is in fact one of the bases upon which the tense-logical cognitive schemata characterising our conceptual orientation in time are constructed.

This is not to say, on the other hand, that in the development of the concept of a self as a centre of conceptual activity we do not ever come to conceive of the ordering of events from perspectives other than our own. Indeed, by a process which Jean Piaget calls decentering, children at the stage of concrete operational thought (7–11 years) develop the ability to conceive of projections from their own positions to that of others in their environment; and subsequently, by means of this ability, they are able to form operational concepts of space and time whose systematic co-ordination results essentially in the structure of projective geometry. Spatial considerations aside, however, and with respect to time alone, the cognitive schemata implicit in the ability to conceive of such projections can be represented in part by means of tense operators corresponding to those already representing the past and the future as viewed from one's own local time. That is, since the projections in question are to be based on actual causal connections between continuants, we can represent the cognitive schemata implicit in such projections by what we shall here call *causal tense operators*, viz. \mathcal{P}_c for 'it causally was the case that' and \mathcal{F}_c for 'it casually will be the case that'. Of course, the possibility in special relativity of a state of affairs coming to have been the case without its ever actually being the case is a possibility that should be represented in terms of these operators and not in terms of those characterising the ordering of events within a single local time.

Semantically, in other words, the causal tense operators go beyond the standard tenses by requiring us to consider not just a single local time but a causally connected system of such local times. In this regard, the causal connections between the different continuants upon which such local times are based can simply be represented by a signal relation between the momentary states of those continuants—or rather, and more simply yet, by a signal relation between the moments of the local times themselves, so long as we assume that the sets of moments of different local times are disjoint. (This assumption is harmless if we think of a moment of a local time as an ordered pair one constituent of which is the continuant upon which that local time is based.) The only constraint that should be imposed on such a signal relation is that it be a strict partial ordering, i.e. transitive and asymmetric. Of course, since we assume that there is a causal connection from the earlier to the later momentary states of the same continuant, we shall also assume that the signal relation contains the linear temporal ordering of the moments of each local time in such a causally connected system. (Cf. [Carnap, 1958, Sections 49–50], for one approach to the notion of a causally connected system of local times.) Needless to say, but such a signal relation provides yet another concrete interpretation of the accessibility relation between possible worlds (reconstructed as momentary

states of the universe); and it will be in terms of this relation that the semantics of the causal tense operators will be given.

Accordingly, by a *system of local times* we shall understand a pair $\langle K, S \rangle$ such that (1) K is a non-empty set of relational world systems $\langle W, R, E \rangle$ for which (a) R is a linear ordering of W and (b) for all $\langle W', R', E' \rangle \in K$, if $\langle W, R, E \rangle \neq \langle W', R', E' \rangle$, then W and W' are disjoint; and (2) S is a strict partial ordering of $\{w : \text{for some } \langle W, R, E \rangle \in K, w \in W\}$ and such that for all $\langle W, R, E \rangle \in K, R \subseteq S$. Furthermore, if $\langle W, R, E \rangle, \langle W', R', E' \rangle \in K, t \in W$, and $t' \in W'$, then t is said to be *simultaneous* with t' in $\langle K, S \rangle$ iff neither tSt' nor $t'St$; and t is said to *coincide with* t' iff for all $\langle W'', R'', E'' \rangle \in K$ and all $w \in W''$, (1) w is simultaneous with t in $\langle K, S \rangle$ iff w is simultaneous with t' in $\langle K, S \rangle$, and (2) tSw if $t'Sw$.

Now a system $\langle K, S \rangle$ of local times is said to be *causally connected* iff for all $\langle W, R, E \rangle, \langle W', R', E' \rangle \in K$, (1) for all $t \in W, t' \in W'$, if t coincides with t' in $\langle K, S \rangle$, then $E(t) = E'(t')$, i.e. the same objects exist at coinciding moments of different local times; and (2) for all $t, w \in W$, all $t', w' \in W'$, if t is simultaneous with t' in $\langle K, S \rangle$, w is simultaneous with w' in $\langle K, S \rangle$, tRw and $t'R'w'$, then $\{(t, u) : tRu \wedge uRw\} \cong \{(t', u) : t'R'u \wedge uR'w'\}$; i.e. the structure of time is the same in any two local intervals whose end-points are simultaneous in $\langle K, S \rangle$.

Note that although the relation of coincidence in a causally connected system is clearly an equivalence relation, the relation of simultaneity, at least in special relativity, need not even be transitive. This will, in fact, be a consequence of the principal assumption of special relativity, viz. that the signal relation S of a causally connected system $\langle K, S \rangle$ has a *finite limiting velocity*; i.e. for all $\langle W, R, E \rangle, \langle W', R', E' \rangle \in K$ and all $w \in W$, if w does not coincide in $\langle K, S \rangle$ with any moment of W' , then there are moments u, v of W' such that $uR'v$ and yet w is simultaneous with both u and v in $\langle K, S \rangle$ (cf. [Carnap, 1958]). It is, of course, because of this assumption that a state of affairs can come (causal future) to have been (causal past) the case without its ever actually being the case (in the local time in question).

Finally, where

$$[t]_{\langle K, S \rangle} = \{t' : t' \text{ coincides with } t \text{ in } \langle K, S \rangle\},$$

$$W_{\langle K, S \rangle} = \{[t]_{\langle K, S \rangle} : \text{for some } \langle W, R, E \rangle \in K, t \in W\},$$

$$R_{\langle K, S \rangle} = \{([t]_{\langle K, S \rangle}, [w]_{\langle K, S \rangle}) : tSw\},$$

$$E_{\langle K, S \rangle} = \{([t]_{\langle K, S \rangle}, E(t)) : \text{for some } W, R, \langle W, R, E \rangle \in K \text{ and } t \in W\},$$

then $\langle W_{\langle K, S \rangle}, R_{\langle K, S \rangle}, E_{\langle K, S \rangle} \rangle$ is a relational world system (in which every theorem of **S4** is validated). Accordingly, if I is an interpretation for a language L based on $\langle W_{\langle K, S \rangle}, R_{\langle K, S \rangle}, E_{\langle K, S \rangle} \rangle$, A is a referential assignment in $\langle W_{\langle K, S \rangle}, R_{\langle K, S \rangle}, E_{\langle K, S \rangle} \rangle$, $\langle W, R, E \rangle \in K$, and $t \in W$, then we recursively define with respect to I and A the *proposition expressed by a wff* φ of L *when part of an assertion made at* t (as the present of the local time

$\langle W, R, E \rangle$ which is causally connected in the system $\langle K, S \rangle$, in symbols $\text{Int}_t(\varphi, I, A)$, exactly as before (in Section 13), except for the addition of the following two clauses:

9. $\text{Int}_t(\mathcal{P}_c\varphi, I, A) =$ the $P \in 2^W$ such that for $w \in W, P(w) = 1$ iff there are a local time $\langle W', R', E' \rangle \in K$ and moments $t', u \in W'$ such that t is simultaneous with t' in $\langle K, S \rangle, uSw$, and $\text{Int}_{t'}(\varphi, I, A)(u) = 1$; and
10. $\text{Int}_t(\mathcal{F}_c\varphi, I, A) =$ the $P \in 2^W$ such that for $w \in W, P(w) = 1$ iff there are a local time $\langle W', R', E' \rangle \in K$ and moments $t', u \in W'$ such that t is simultaneous with t' in $\langle K, S \rangle, wSu$ and $\text{Int}_{t'}(\varphi, I, A)(u) = 1$.

Except for an invariance with respect to the added parameter $\langle K, S \rangle$, validity or tense-logical truth is understood to be defined exactly as before. It is clear of course that although

$$\mathcal{P}\varphi \rightarrow \mathcal{P}_c\varphi, \quad \mathcal{F}\varphi \rightarrow \mathcal{F}_c\varphi$$

are valid, their converses can be invalidated in a causally connected system which has the finite limiting velocity. On the other hand, were we to exclude such systems (as was done in classical physics) and validate the converse of the above wffs as well (as perhaps is still implicit in our common sense framework), then, of course, the causal tense operators would be completely redundant (which perhaps explains why they have no counterparts in natural language). It should perhaps be noted here that unlike the cognitive schemata of the standard tense operators whose semantics is based on a single local time, those represented by the causal tense operators are not such as must be present in one form or another in every act of thought. That is, they are derived schemata, constructed on the basis of those de-centering abilities whereby we are able to conceive of the ordering of events from a perspective other than our own. Needless to say, but the importance and real significance of these derived schemata was unappreciated until the advent of special relativity.

One important consequence of the divergence of the causal from the standard tense operators is the invalidity of

$$\mathcal{F}_c\mathcal{P}_c\varphi \rightarrow \mathcal{P}_c\varphi \vee \varphi \vee \mathcal{F}_c\varphi$$

and therefore the consistency of

$$\mathcal{F}_c\mathcal{P}_c\varphi \wedge \neg\Diamond^t\varphi.$$

Unlike its earlier counterpart in terms of the standard tenses, this last wff of course is the appropriate representation of the possibility in special relativity of a state of affairs coming (in the causal future) to have been the case (in the causal past) without its ever actually being the case (in a given local

time). Indeed, not only can this wff be true at some moment of a local time of a causally connected system, but so can the following wff:

$$[\mathcal{P}_c \diamond^t \varphi \vee \mathcal{F}_c \diamond^t \varphi] \wedge \neg \diamond^t \varphi.$$

Quantification over *realia*, incidentally, finds further justification in special relativity. For just as some states of affairs can come to have been the case (in the causal past of the causal future) without their actually ever being the case, so too there can be things that exist only in the past or future of our own local time, but which nevertheless might exist in a causally connected local time at a moment which is simultaneous with our present. In this regard, reference to such objects as real even if not presently existing would seem hardly controversial—or at least not at that stage of conceptual development where our decentering abilities enable us to construct referential concepts that respect other points of view causally connected with our own.

Finally, it should be noted that whereas the original Diodorean notion of possibility results in the modal logic **S4.3**, i.e. the system **S4** plus the additional thesis

$$\diamond^f \varphi \wedge \diamond^f \psi \rightarrow \diamond^f (\varphi \wedge \psi) \vee \diamond^f (\varphi \wedge \diamond^f \psi) \vee \diamond^f (\psi \wedge \diamond^f \varphi),$$

the same Diodorean notion of possibility, but redefined in terms of \mathcal{F}_c instead, results in the modal logic **S4**. If we also assume, as is usual in special relativity, that the causal futures of any two moments t, t' of two local times of a causally connected system $\langle K, S \rangle$ *eventually* intersect, i.e. that there is a local time $\langle W, R, E \rangle \in K$ and a moment $w \in W$ such that tSw and $t'Sw$, then the thesis

$$\mathcal{F}_c \neg \mathcal{F}_c \neg \varphi \rightarrow \neg \mathcal{F}_c \neg \mathcal{F}_c \varphi$$

will be validated, and the Diodorean modality defined in terms of \mathcal{F}_c will result in the modal system **S4.2** (cf. [Prior, 1967, p. 203]), i.e. the system **S4** plus the thesis

$$\diamond^{fc} \square^{fc} \varphi \rightarrow \square^{fc} \diamond^{fc} \varphi.$$

Many other modal concepts, it is clear, can also be characterised in terms of the semantics of a causally connected system of local times, including, e.g. the notion of something being necessary because of the way the past has been. What is distinctive about them all, moreover, is the unproblematic sense in which they can be taken as material or metaphysical modalities. This may indeed not be all there is to such a modality, but taking account of more will confront us once again with the problem of providing a philosophically coherent interpretation of the secondary semantics for such.

TENSE AND TIME

1 INTRODUCTION

The semantics of tense has received a great deal of attention in the contemporary linguistics, philosophy, and logic literatures. This is probably due partly to a renewed appreciation for the fact that issues involving tense touch on certain issues of philosophical importance (viz., determinism, causality, and the nature of events, of time and of change). It may also be due partly to neglect. Tense was noticeably omitted from the theories of meaning advanced in previous generations. In the writings of both Russell and Frege there is the suggestion that tense would be absent altogether from an ideal or scientifically adequate language. Finally, in recent years there has been a greater recognition of the important role that all of the so-called indexical expressions must play in an explanation of mental states and human behavior. Tense is no exception. Knowing that one's friend *died* is cause for mourning, knowing that he *dies* is just another confirmation of a familiar syllogism.

This article will survey some attempts to make explicit the truth conditions of English tenses, with occasional discussion of other languages. We begin in Section 2 by discussing the most influential early scholarship on the semantics of tense, that of Jespersen, Reichenbach, and Montague. In Section 3 we outline the issues that have been central to the more linguistically-oriented work since Montague's time. Finally, in Section 4 we discuss recent developments in the area of tense logic, attempting to clarify their significance for the study of the truth-conditional semantics of tense in natural language.

2 EARLY WORK

2.1 *Jespersen*

The earliest comprehensive treatment of tense and aspect with direct influence on contemporary writings is that of Otto Jespersen. Jespersen's *A Modern English Grammar on Historical Principles* was published in seven volumes from 1909 to 1949. Jespersen's grammar includes much of what we would call semantics and (since he seems to accept some kind of identification between meaning and use) a good deal of pragmatics as well. The

aims and methods of Jespersen's semantic investigations, however, are not quite the same as ours.¹

First, Jespersen is more interested than we are in cataloging and systematizing the various uses of particular English constructions and less interested in trying to characterize their meanings in a precise way. This leads him to discuss seriously uses we would consider too obscure or idiomatic to bother with. For example, Jespersen notes in the *Grammar* that the expressions of the form *I have got A* and *I had got A* are different than other present perfect and past perfect sentences. *I have got a body*, for example, is true even though there was no past time at which an already existent me received a body. Jespersen suggests *I have in my possession* and *I had in my possession* as readings for *I have got* and *I had got*. And this discussion is considered important enough to be included in his *Essentials of English Grammar*, a one volume summary of the *Grammar*.

Jespersen however does *not* see his task as being merely to collect and classify rare flora. He criticizes Henry Sweet, for example, for a survey of English verb forms that includes such paradigms as *I have been being seen* and *I shall be being seen* on the grounds that they are so extremely rare that it is better to leave them out of account altogether. Nevertheless there is an *emphasis* on cataloging, and this emphasis is probably what leads Jespersen to adhere to a methodological principle that we would ignore; viz., that example sentences should be drawn from published literature wherever possible rather than manufactured by the grammarian. Contemporary linguists and philosophers of language see themselves as investigating fundamental intuitions shared by all members of a linguistic community. For this reason it is quite legitimate for them to produce a sentence and assert without evidence that it is well-formed or ill-formed, ambiguous or univocal, meaningful or unmeaningful. This practice has obvious dangers. Jespersen's methodological scruples, however, provide no real safety. On the one hand, if one limits one's examples to a small group of masters of the language one will leave out a great deal of commonly accepted usage. On the other hand, one can't accept *anything* as a legitimate part of the language just because it has appeared in print. Jespersen himself criticizes a contemporary by saying of his examples that 'these three passages are the only ones adduced from the entire English literature during nearly one thousand years'.

A final respect in which Jespersen differs from the other authors discussed here is his concern with the recent history of the language. Although the *Grammar* aims to be a compendium of contemporary idiom, the history of a construction is recited whenever Jespersen feels that such a discussion might be illuminating about present usage. A good proportion of the discussion of the progressive form, for example, is devoted to Jespersen's

¹By 'ours' we mean those of the authors discussed in the remainder of the article. Some recent work, like that of F. Palmer and R. Huddleston, is more in the tradition of Jespersen than this.

thesis that *I am reading* is a relatively recent corruption of *I am a-reading* or *I am on reading*, a construction that survives today in expressions like *I am asleep* and *I am ashore*. This observation, Jespersen feels, has enabled him to understand the meaning of the progressive better than his contemporaries.² In discussing Jespersen's treatment of tense and aspect, no attempt will be made to separate what is original with Jespersen from what is borrowed from other authors. Jespersen's grammar obviously extends a long tradition. See Binnick for a recent survey.³ Furthermore there is a long list of grammarians contemporaneous with Jespersen who independently produced analyses of tenses. See, for example, Curme, Kruisinga and Poutsma. Jespersen, however, is particularly thorough and insightful and, unlike his predecessors and contemporaries, he continues to be widely read (or at least cited) by linguists and philosophers. Jespersen's treatment of tense and aspect in English can be summarized as follows:

2.1.1 Time

It is important to distinguish *time* from *tense*. Tense is the linguistic device which is used (among other things) for expressing time relations. For example, *I start tomorrow* is a present tense statement about a future time. To avoid time-tense confusion it is better to reserve the term *past* for time and to use *preterit* and *pluperfect* for the linguistic forms that are more commonly called past tense and past perfect. Time must be thought of as something that can be represented by a straight line, divided by the present moment into two parts: the past and the future. Within each of the two divisions we may refer to some point as lying either before or after the main point of which we are speaking. For each of the seven resulting divisions of time there are *retrospective* and *prospective* versions. These two notions are not really a part of time itself, but have rather to do with the perspective from which an event on the time line is viewed. The prospective present time, for example, is a variety of present that looks forward into the future. In summary, time can be pictured as in Figure 2.1.1. The three divisions marked with *A*'s are past; those marked with *C*'s are future. The short pointed lines at each division indicate retrospective and prospective times.

2.1.2 Tense morphology

The English verb has only two tenses proper, the present tense and the preterit. There are also two tense phrases, the perfect (e.g., *I have written*) and the pluperfect or anteperfect (e.g., *I had written*). (Modal verbs,

²A similar claim is made in Vlach [1981]. For the most part, however, the history of English is ignored in contemporary semantics.

³Many of the older grammars have been reprinted in the series *English Linguistics: 1500-1800 (A Collection of Facsimile Reprints)* edited by R.C. Alston and published by Scholar Press Limited, Menston, England in 1967.

Figure 1.

including *can*, *may*, *must*, *ought*, *shall*, and *will*, cannot form perfects and pluperfects.) Corresponding to each of the four tenses and tense phrases there is an *expanded* (what is more commonly called today the *progressive*) form. For example, *had been writing* is the expanded pluperfect of *write*. It is customary to admit also future and future perfect tenses, as in *I will write* and *I shall have written*. But these constructions lack the fixity of the others. On the one hand, they are often used to express nontemporal ideas (e.g., volition, obstinacy) and on the other hand future time can be indicated in many other ways.

The present tense is primarily used about the present time, by which we mean an interval containing the present moment whose length varies according to circumstances. Thus the time we are talking about in *He is hungry* is shorter than in *None but the brave deserve the fair*. Tense tells us nothing about the duration of that time. The same use of present is found in expressions of intermittent occurrences (*I get up every morning at seven* and *Whenever he calls, he sits close to the fire*). Different uses of the present occur in statements of what might be found at all times by all readers (*Milton defends the liberty of the press in his Areopagitica*) and in expressions of feeling about what is just happening or has just happened (*That's capital!*). The present can also be used to refer to past times. For example, the *dramatic* or *historical* present can alternate with the preterit: *He perceived the surprise, and immediately pulls a bottle out of his pocket, and gave me a dram of cordial*. And the present can play the same role as the perfect in subordinate clauses beginning with *after*: *What happens to the sheep after they take its kidney out?* Present tense can be used to refer to future time when the action described is considered part of a plan already fixed: *I start for Italy on Monday*. The present tense can also refer to future events when it follows *I hope*, *as soon as*, *before*, or *until*.

The perfect is actually a kind of present tense that seems to connect the present time with the past. It is both a retrospective present, which looks upon the present as a result of what happened in the past and an inclusive present, which speaks of a state that is continued from the past into the present time (or at least one that has results or consequences bearing on the present time).

The preterit differs from the perfect in that it refers to some time in the past without telling anything about its connection with the present moment. Thus *Did you finish?* refers to a past time while *Have you finished?* is a question about present status. It follows that the preterit is appropriate with words like *yesterday* and *last year* while the perfect is better with *today*, *until now* and *already*. *This morning* requires a perfect tense when uttered in the morning and a preterit in the afternoon. Often the correct form is determined by context. For example, in discussing a schoolmate's Milton course, *Did you read Samson Agonistes?* is appropriate,

whereas in a more general discussion *Have you read Samson Agonistes?* would be better. In comparing past conditions with present the preterit may be used (*English is not what it was*), but otherwise vague times are not expressed with the preterit but rather by means of the phrase *used to* (*I used to live at Chelsea*). The perfect often seems to imply repetition where the preterit would not. (Compare *When I have been in London*, with *When I was in London*).

The pluperfect serves primarily to denote before-past time or retrospective past, two things which cannot easily be kept apart. (An example of the latter use is *He had read the whole book before noon*.) After *after*, *when*, or *as soon as*, the pluperfect is interchangeable with the preterit.

The expanded tenses indicate that the action or state denoted provides a temporal frame encompassing something else described in the sentence or understood from context. For example, if we say *He was writing when I entered*, we mean that his writing (which may or may not be completed now) had begun, but was not completed, at the moment I entered. In the expanded present the shorter time framed by the expanded time is generally considered to be *very recently*. The expanded tenses also serve some other purposes. In narration simple tenses serve to carry a story forward while expanded tenses have a retarding effect. In other cases expanded tense forms may be used in place of the corresponding simple forms to indicate that a fact is already known rather than new, that an action is incomplete rather than complete or that an act is habitual rather than momentary. Finally, the expanded form is used in two clauses of a sentence to mark the simultaneity of the actions described. (In that case neither really frames the other.)

In addition to the uses already discussed, all the tenses can have somewhat different functions in passive sentences and in indirect speech. They also have uses apparently unrelated to temporal reference. For example, forms which are primarily used to indicate past time are often used to denote unreality, impossibility, improbability or non-fulfillment, as in *If John had arrived on time, he would have won the prize*.⁴

⁴From the contemporary perspective we would probably prefer to say here that *had*

2.1.3 Tense syntax

In the preceding discussion we started with the English tense forms and inquired about their meanings. Alternatively we can start with various temporal notions and ask how they can be expressed in English. If we do so, several additional facts emerge:

1. The future time can be denoted by present tense (*He leaves on Monday*), expanded present tense (*I am dining with him on Monday*), *is sure to*, *will*, *shall*, *come to* or *get to*.
2. The after-past can be expressed by *would*, *should*, *was to*, *was destined to*, expanded preterit (*They were going out that evening* and *When he came back from the club she was dressing*) or *came to* (*In a few years he came to control all the activity of the great firm*).
3. The before-future can be expressed by *shall have*, *will have* or present (*I shall let you know as soon as I hear from them* or **Wait until the rain stops**).
4. The after-future is expressed by the same means as the future (*If you come at seven, dinner will soon be ready*).
5. Retrospective pasts and futures are not distinguished in English from before-pasts and before-futures. (But retrospective presents, as we have seen, are distinct from pasts. The former are expressed by the perfect, the latter by the preterit.)
6. Prospectives of the various times can be indicated by inserting expressions like *on the point of*, *about to* or *going to*. For example, *She is about to cry* is a prospective present.

2.2 Reichenbach

In his general outlook Reichenbach makes a sharp and deliberate break with the tradition of grammarians like Jespersen. Jespersen saw himself as studying the English language by any means that might prove useful (including historical and comparative investigations). Reichenbach saw himself as applying the methods of contemporary logic in a new arena. Thus, while Jespersen's writings about English comprise a half dozen scholarly treatises, Reichenbach's are contained in a chapter of an introductory logic text. (His treatment of tense occupies twelve pages.) Where Jespersen catalogs dozens of uses for an English construction, Reichenbach is content to try to characterize carefully a single use and then to point out that this paradigm does not cover all the cases. While Jespersen uses, and occasionally praises, the *arrived* is a subjunctive preterit which happens to have the same form as a pluperfect.

efforts of antecedent and contemporary grammarians, Reichenbach declares that the state of traditional grammar is hopelessly muddled by its two-millennial ties to a logic that cannot account even for the simplest linguistic forms.

Despite this difference in general outlook, however, the treatment of tenses in Reichenbach is quite similar to that in Jespersen. Reichenbach's chief contribution was probably to recognize the importance of the distinction between what he calls the *point of the event* and the *point of reference* (and the relative unimportance and obscurity of Jespersen's notions of prospective and retrospective time.) In the sentence *Peter had gone*, according to Reichenbach, the point of the event is the time when Peter went. The point of reference is a time between this point and the point of speech, whose exact location must be determined by context. Thus Reichenbach's account of the past perfect is very similar to Jespersen's explanation that the past perfect indicates a 'before past' time. Reichenbach goes beyond Jespersen, however, in two ways.

First, Reichenbach is a little more explicit about his notion of reference times than is Jespersen about the time of which we are speaking. He identifies the reference time in a series of examples and mentions several rules that might be useful in determining the reference time in other examples. Temporally specific adverbials like *yesterday*, *now* or *November 7, 1944*, for example, are said to refer to the reference point. Similarly, words like *when*, *after*, and *before* relate the reference time of an adjunct clause to that of the main clause. And if a sentence does not say anything about the relations among the reference times of its clauses, then every clause has the same point of reference.

Second, Reichenbach argues that the notion of reference time plays an important role in *all* the tenses. The present perfect, for example, is distinguished by the fact that the event point is before the point of reference and the point of reference coincides with the point of speech. (So *I have seen Sharon* has the same meaning as *Now I have seen Sharon*.) In general, each tense is determined by the relative order of the point of event (*E*), the point of speech (*S*), and the point of reference (*R*). If *R* precedes *S* we have a kind of past tense, if *S* precedes *R* we have a kind of future tense and if *R* coincides with *S* we have a kind of present. This explains Jespersen's feeling that the simple perfect is a variety of the present. Similarly the labels 'anterior', 'posterior' and 'simple' indicate that *E* precedes, succeeds or coincides with *R*. The account is summarized in the following table.

Each of the tenses on this table also has an expanded form which indicates, according to Reichenbach, that the event covers a certain stretch of time.

Notice that the list of possible tenses is beginning to resemble more closely the list of tenses realized in English. According to Jespersen there are seven divisions of time, each with simple, retrospective and prospective versions. This makes twenty-one possible tenses. According to Reichenbach's scheme

Structure	New Name	Traditional Name
E_R_S	Anterior past	Past perfect
E, R_S	Simple past	Simple past
R_E_S		
R_S, E	Posterior past	_____
R_S_E		
E_S, R	Anterior present	Present perfect
S, R, E	Simple present	Present
S, R_E	Posterior present	Simple future
S_E_R		
S, E_R	Anterior future	Future perfect
E_S_R		
S_R, E	Simple future	Simple future
S_R_E	Posterior future	_____

there should be thirteen possible tenses, corresponding to the thirteen orderings of E , S , and R . Looking more closely at Reichenbach, however, we see that the *tense* of a sentence is determined only by the relative order of S and R , and the *aspect* by the relative order of R and E . Since there are three possible orderings of S and R , and independently three possible orderings of R and E , there are really only nine possible complex tenses (seven of which are actually realized in English).⁵

Finally, Reichenbach acknowledges that actual language does not always keep to the scheme set forth. The expanded forms, for example, sometimes indicate repetition rather than duration: *Women are wearing larger hats this year*. And the present perfect is used to indicate that the event has a certain duration which reaches up to the point of speech: *I have lived here for ten years*.

2.3 Montague

Despite Reichenbach's rhetoric, it is probably Montague, rather than Reichenbach, who should be credited with showing that modern logic can be fruitfully applied to the study of natural language. Montague actually had very little to say about tense, but his writings on language have been very influential among those who do have something to say. Two general principles underlie Montague's approach.

⁵There are actually only six English tense constructions on Reichenbach's count, because two tenses are realized by one construction. The simple future is ambiguous between S, R_E , as in *Now I shall go* or S_R, E , as in *I shall go tomorrow*. Reichenbach suggests that, in French the two tenses may be expressed by different constructions: *je vais voir* and *je verrai*.

- (1a) Compositionality. The meaning of an expression is determined by the meaning of its parts.
- (1b) Truth conditions. The meaning of a declarative sentence is something that determines the conditions under which that sentence is true.

Neither of these principles, of course, is original with Montague, but it is Montague who shows how these principles can be used to motivate an explicit account of the semantics of particular English expressions.

Initially, logic served only as a kind of paradigm for how this can be done. One starts with precisely delineated sets of *basic expressions* of various categories. *Syntactic rules* show how complex expressions can be generated from the basic ones. A class of permissible *models* is specified, each of which assigns interpretations to the basic expressions. *Rules of interpretation* show how the interpretation of complex expressions can be calculated from the interpretations of the expressions from which they are built.

The language of classical predicate logic, for example, contains predicates, individual variables, quantifiers, sentential connectives, and perhaps function symbols. Generalizations of this logic are obtained by adding additional expressions of these categories (as is done in modal and tense logic) or by adding additional categories (as is done in higher order logics). It was Montague's contention that if one generalized enough, one could eventually get English itself. Moreover, clues to the *direction* this generalization should take are provided by modal and tense logic. Here sentences are interpreted by functions from possible worlds (or times or *indices* representing aspects of context) to truth values. English, for Montague, is merely an exceedingly baroque intensional logic. To make this hypothesis plausible, Montague constructed, in [1970; 1970a] and [1973], three 'fragments' of English of increasing complexity. In his final fragment, commonly referred to as PTQ, Montague finds it convenient to show how the expressions can be translated into an already-interpreted intensional logic rather than to specify an interpretation directly. The goal is now to find a translation procedure by which every expression of English can be translated into a (comparatively simple) intensional logic.

We will not attempt here to present a general summary of PTQ. (Readable introductions to Montague's ideas can be found in Montague [1974] and Dowty [1981].) We will, however, try to describe its treatment of tense. To do so requires a little notation. Montague's intensional logic contains tense operators **W** and **H** meaning roughly *it will be the case that* and *it was the case that*. It also contains an operator \wedge that makes it possible to refer to the intension of an expression. For example, if *a* is an expression referring to the object **a**, then $\wedge a$ denotes the function that assigns **a** to every pair of a possible world *w* and a time *t*.

Among the expressions of English are *terms* and *intransitive verb phrases*. An intransitive verb phrase B is translated by an expression \mathbf{B}' which denotes a function from entities to truth values. (That is, \mathbf{B}' is of type $\langle e, t \rangle$.) A term A is translated by an expression \mathbf{A}' which denotes a function whose domain is intensions of functions from entities to truth values and whose range is truth values. (That is, \mathbf{A}' is of type $\langle \langle s, \langle e, t \rangle, t \rangle \rangle$.) Tense and negation in PTQ are treated together. There are six ways in which a term may be combined with an intransitive verb phrase to form a sentence. These generate sentences in the present, future, present perfect, negated present, negated future and negated present perfect forms. The rules of translation corresponding to these six constructions are quite simple. If B is an intransitive verb phrase with translation \mathbf{B}' and A is a term with translation \mathbf{A}' then the translations of the six kinds of sentences that can be formed by combining A and B are just $\mathbf{A}'(\wedge \mathbf{B}')$, $\mathbf{WA}'(\wedge \mathbf{B}')$, $\mathbf{HA}'(\wedge \mathbf{B}')$, $\neg \mathbf{A}'(\wedge \mathbf{B}')$, $\neg \mathbf{WA}'(\wedge \mathbf{B}')$ and $\neg \mathbf{HA}'(\wedge \mathbf{B}')$.

A simple example will illustrate. Suppose that A is *Mary* and that B is *sleeps*. The future tense sentence *Mary will sleep* is assigned translation $\mathbf{WMary}(\wedge \mathbf{sleeps})$. \mathbf{Mary} denotes that function which assigns 'true' to a property P in world w at time t if and only if Mary has P in w at t . The expression $\wedge \mathbf{sleeps}$ denotes the property of sleeping, i.e. the function f from indices to functions from individuals to truth values such that $f(\langle w, t \rangle)(a) = \text{'true'}$ if and only if a is an individual who is asleep in world w at time t (for any world w , time t , and individual a). Thus $\mathbf{Mary}(\wedge \mathbf{sleeps})$ will be true at $\langle w, t \rangle$ if and only if Mary is asleep in w at t . Finally, the sentence $\mathbf{WMary}(\wedge \mathbf{sleeps})$ is true in a world w at a time t if and only if $\mathbf{Mary}(\wedge \mathbf{sleeps})$ is true at some $\langle w, t' \rangle$, where t' is a later time than t .

This treatment is obviously crude and incomplete. It was probably intended merely as an illustration of how tense *might* be handled within Montague's framework. Nevertheless, it contains the interesting observation that the past tense operator found in the usual tense logics corresponds more closely to the present perfect tense than it does to the past. In saying *John has kissed Mary* we seem to be saying that there was *some* time in the past when *John kisses Mary* was true. In saying *John kissed Mary*, we seem to be saying that *John kisses Mary* was true at *the* time we happen to be talking about. This distinction between *definite* and *indefinite* past times was pointed out by Jespersen, but Jespersen does not seem to have thought it relevant to the distinction between present perfect and past.

Reichenbach's use of both event time and reference time, leading to a three-dimensional logic, may suggest that it will not be easy to add the past tenses to a PTQ-like framework. However, one of the differences between Reichenbach's reference time and event time seems to be that the former is often fixed by an adverbial clause or by contextual information whereas the latter is less often so fixed. So it is approximately correct to say that the reference time is determinate whereas the event time is indetermi-

nate. This may help explain the frequent remarks that only two times are needed to specify the truth conditions of all the tenses. In one sense these remarks are wrong. S , R and E all play essential roles in Reichenbach's explanation of the tenses. But only S and R ever need to be extracted from the context. All that we need to know about E is its position relative to R and this information is contained in the sentence itself. Thus a tense logic following Reichenbach's analysis could be two-dimensional, rather than three-dimensional. If s and r are the points of speech and reference, for example, we would have $(s, r) \models \text{PASTPERFECT}(A)$ if and only if $r < s$ and, for some $t < r$, $t \models A$. (See Section 4 below.)

Still, it seems clear that the past tenses cannot be added to PTQ without adding something like Reichenbach's point of reference to the models. Moreover, adherence the idea that there should be a separate way of combining tenses and intransitive verb phrases for every negated and unnegated tense would be cumbersome and would miss important generalizations. Montague's most important legacies to the study of tense were probably his identification of meaning with truth conditions, and his high standards of rigor and precision. It is striking that Jespersen, Reichenbach and Montague say successively less about tense with correspondingly greater precision. A great deal of the contemporary work on the subject can be seen as an attempt to recapture the insights of Jespersen without sacrificing Montague's precision.

3 CONTEMPORARY VIEWS

In Sections 3.1 and 3.2 below we outline what seem to us to be two key issues underlying contemporary research into the semantics of tense. The first has to do with whether tense should be analyzed as an operator or as something that refers to particular time or times; this is essentially a type-theoretic issue. The second pertains to a pair of truth-conditional questions which apparently are often confused with the type-theoretic ones: (i) *does the semantics of tense involve quantification over times, and if so how does this quantification arise?*, and (ii) *to what extent is the set of times relevant to a particular tensed sentence restricted or made determinate by linguistic or contextual factors?* Section 3.3 then outlines how contemporary analytical frameworks have answered these questions. Finally, Section 3.4 examines in more detail some of the proposals which have been made within these frameworks about the interpretation of particular tenses and aspects.

3.1 *Types for Tense*

The analyses of Reichenbach and Montague have served as inspiration for two groups of theorists. Montague's approach is the one more familiar

from traditional tense logics developed by Prior and others. The simplest non-syncategorematic treatment of tense which could be seen as essentially that of Montague would make tenses propositional operators, expressions of type $\langle\langle s, t \rangle, t\rangle$ or $\langle\langle s, t \rangle, \langle s, t \rangle\rangle$, that is, either as functions from propositions to truth values or as functions from propositions to propositions (where propositions are taken to be sets of world-time pairs). For example, the present perfect might have the following interpretation:

- (2) **PrP** denotes that function f from propositions to propositions such that, for any proposition p , $f(p)$ = the proposition q , where for any world w and time t , $q(\langle w, t \rangle)$ = ‘true’ iff for some time t' preceding t , $p(\langle w, t' \rangle)$ = ‘true’.

Two alternative, but closely related, views would take tense to have the type of a verb phrase modifier $\langle\langle s, \langle e, t \rangle \rangle, \langle e, t \rangle\rangle$ ([Bäuerle, 1979; Kuhn, 1983]) or as a ‘mode of combination’ in $\langle\text{type}(\text{TERM}), \langle\langle s, \langle e, t \rangle \rangle, t \rangle\rangle$ or $\langle\langle s, \langle e, t \rangle \rangle, \langle\text{type}(\text{TERM}), t \rangle\rangle$. We will refer to these approaches as representative of the *operator* view of tense.

The alternative approach is more directly inspired by Reichenbach’s views. It takes the semantics of tense to involve reference to particular times. This approach is most thoroughly worked out within the framework of Discourse Representation Theory (DRT; [Kamp, 1983; Kamp and Rohrer, 1983; Hinrichs, 1986; Partee, 1984]), but for clarity we will consider the type-theoretic commitments of the neo-Reichenbachian point of view through the use of a Predicate Calculus-like notation. We may take a tense morpheme to introduce a free variable to which a time can be assigned. Depending on which tense morpheme is involved, the permissible values of the variable should be constrained to fall within an appropriate interval. For example, the sentence *Mary slept* might have a logical form as in (3).

- (3) **PAST**(t) & **AT**(t , **sleeps**(**Mary**)).

With respect to an assignment g of values to variables, (3) should be true if and only if $g(t)$ is a time that precedes the utterance time and one at which Mary sleeps. On this approach the semantics of tense is analogous to that of pronouns, a contention defended most persuasively by Partee.

A more obviously Reichenbachian version of this kind of analysis would introduce more free variables than simply t in (3). For example, the pluperfect *Mary had slept* might be rendered as in (4):

- (4) **PAST**(r) & $t < r$ & **AT**(t , **sleeps**(**Mary**)).

This general point of view could be spelled out in a wide variety of ways. For example, times might be taken as arguments of predicates, or events and states might replace times. We refer to this family of views as *referential*.

3.2 Quantification and determinacy

3.2.1 Quantification

In general, the operator theory has taken tense to involve quantification over times. Quantification is not an inherent part of the approach, however; one might propose a semantics for the past tense of the following sort:

- (5) $(r, u) \models \mathbf{PAST}(S)$ iff $r < u$ and $(r, r) \models S$.

Such an analysis of a non-quantificational past tense might be seen as especially attractive if there are other tense forms that are essentially quantificational. An operator-based semantics would be a natural way to introduce this quantification, and in the interest of consistency one might then prefer to treat all tenses as operators—just as PTQ argues that all NP's are quantifiers because some are inherently quantificational. On the other hand, if no tenses are actually quantificational it might be preferable to utilize a less powerful overall framework.

The issue of quantification for the referential theory of tense is not entirely clear either. If there are sentences whose truth conditions must be described in terms of quantification over times, the referential theory cannot attribute such quantification to the tense morpheme. But this does not mean that such facts are necessarily incompatible with the referential view. Quantification over times may arise through a variety of other, more general, means. Within DRT and related frameworks, several possibilities have been discussed. The first is that some other element in the sentence may bind the temporal variable introduced by tense. An adverb of quantification like *always*, *usually*, or *never* would be the classical candidate for this role.

- (6) When it rained, it always poured.

- (7) $\forall t[(\mathbf{PAST}(t) \ \& \ \mathbf{AT}(t, \mathbf{it-rains})) \rightarrow (\mathbf{PAST}(t) \ \& \ \mathbf{AT}(t, \mathbf{it-pours}))]$.

DRT follows Lewis [1975] in proposing that *always* is an unselective universal quantifier which may bind any variables present in the sentence. Hinrichs and Partee point out that in some cases it may turn out that a variable introduced by tense is thus bound; their proposals amount to assigning (6) a semantic analysis along the lines of (7).

The other way in which quantification over times may arise in referential analyses of tense is through some form of default process. The most straightforward view along these lines proposes that, in the absence of explicit quantificational adverbs, the free variable present in a translation like (3), repeated here, is subject to a special rule that turns it into a quantified formula like (8):

(3) **PAST**(t) & **AT**(t , **sleeps**(**Mary**)).

(8) $\exists t$ [**PAST**(t) & **AT**(t , **sleeps**(**Mary**))].

This operation is referred to as *existential closure* by Heim; something similar is proposed by Parsons [1995]. It is also possible to get the effect of existential quantification over times through the way in which the truth of a formula is defined. This approach is taken by DRT as well as Heim [1982, Ch. III]. For example, a formula like (3) would be true with respect to a model M if and only if there is *some* function g from free variables in (3) to appropriate referents in M such that $g(t)$ precedes the utterance time in M and $g(t)$ is a time at which Mary is asleep in M .

To summarize, we may say that one motivation for the operator theory of tense comes from the view that some tense morphemes are inherently quantificational. The referential analysis, in contrast, argues that all examples of temporal quantification are to be attributed not to tense but to independently needed processes.

3.2.2 *Determinacy*

An issue which is often not clearly distinguished from questions of the type and quantificational status of tense is that of the determinacy or definiteness of tense. Classical operator-based tense logics treat tense as all but completely indeterminate: a past tense sentence is true if and only if the untensed version is true at *any* past time. On the other hand, Reichenbach's referential theory seemingly considers tense to be completely determinate: a sentence is true or false with respect to the *particular* utterance time, reference time, and event time appropriate for it. However, we have already seen that a referential theory might allow that a time variable can be bound by some quantificational element, thus rendering the temporal reference less determinate. Likewise, we have seen that an operator-based theory may be compatible with completely determinate temporal reference, as in (5). In this section, we would like to point out how varying degrees of determinacy can be captured within the two systems.

If temporal reference is fully indeterminate, it is natural to adopt an operator view: **PAST**(B) is true at t if and only if B is true at some $t' < t$. A referential theory must propose that in every case the time variable introduced by tense is bound by some quantificational operator (or effectively quantified over by default, perhaps merely through the effects of the truth definition). In such cases it seems inappropriate to view the temporal parameters as 'referring' to times.

If temporal reference is fully determinate, the referential theory need make no appeal to any ancillary quantification devices. The operator theory may use a semantics along the lines of (3). Alternatively, tense might be seen as an ordinary quantificational operator whose domain of quantification has

been severely restricted. We might implement this idea as follows: Suppose that each tense morpheme bears an index, as *Mary PAST₃sleeps*. Sentences are interpreted with respect to a function R from indices to intervals. (The precedence order is extended from instants to intervals and instants in the appropriate way, with $<$ indicating ‘completely precedes’.) The formula in (9a) would then have the truth conditions of (9b).

(9a) **PAST₃ (sleeps(Mary))**.

(9b) $(R, u) \models \mathbf{PAST}_3(\mathbf{sleeps}(\mathbf{Mary}))$ iff for some time $t \in R(3)$, $t < u$ and $(R, t) \models \mathbf{sleeps}(\mathbf{Mary})$.

Plainly, R in (9b) is providing something very similar to that of the reference time in Reichenbach’s system. This can be seen by the fact that the identity of $R(3)$ should be fixed by temporal adverbs like *yesterday*, as in *Yesterday, Mary slept*.

Finally, we should examine what could be said about instances of tense which are partially determinate. The immediately preceding discussion makes it clear what the status of such examples would be within an operator account; they would simply exemplify restricted quantification ([Bennett and Partee, 1972; Kuhn, 1979]). Instead of the analysis in (9), we would propose that R is a function from indices to sets of intervals, and give the truth conditions as in (10).

(10) $(R, u) \models \mathbf{PAST}_3(\mathbf{sleeps}(\mathbf{Mary}))$ iff for some time $t \in R(3)$, $t < u$ and $(R, t) \models \mathbf{sleeps}(\mathbf{Mary})$.

According to (10), (9a) is true if and only if Mary was asleep at some past time which is within the set of contextually relevant past times. Temporal quantification would thus be seen as no different from ordinary nominal quantification, as when *Everyone came to the party* is taken to assert that everyone *relevant* came to the party.

Referential analyses of tense would have to propose that partial determinacy arises when temporal variables are bound by restricted quantifiers. Let us consider a Reichenbach-style account of *Mary slept* along the lines of (11).

(11) $\exists t [\mathbf{PAST}(r) \ \& \ t \in r \ \& \ \mathbf{AT}(t, \mathbf{sleeps}(\mathbf{Mary}))]$.

The remaining free variable in (11), namely r , will have to get its value (the reference *set*) from the assignment function g . The formula in (11) has $t \in r$ where Reichenbach would have $t = r$; the latter would result in completely determinate semantics for tense, while (11) results in restricted quantification. The sentence is true if and only if Mary slept during some past interval contained in $g(r)$.

The only difference between (10) and (11) is whether the quantificational restriction is represented in the translation language as a variable, the r in (11), or as a special index on the operator, the subscripted β in (10). In each case, one parameter of interpretation must be some function which identifies the set of relevant times for the quantification. In (11), it is the assignment function, g , while in (10) it is R . Clearly at this point the differences between the two theories are minor. To summarize, we need to distinguish three closely related ways in which theories of tense may differ: (i) They may take tense to be an operator or to introduce elements which refer to times; (ii) they may involve quantification over times through a considerable variety of means—the inherent semantics of tense itself, the presence of some other quantificational element within the sentence, or a default rule; and (iii) they may postulate that the temporal reference of sentences is fully determinate, fully indeterminate, or only partially determinate.

3.3 *Major contemporary frameworks*

Most contemporary formal work on the semantics of tense takes place within two frameworks: Interval Semantics and Discourse Representation Theory. In this section we describe the basic commitments of each of these, noting in particular how they settle the issues discussed in 3.1 and 3.2 above. We will then consider in a similar vein a couple of other influential viewpoints, those of Situation Semantics [Cooper, 1986] and the work of Enç [1986; 1987].

By *Interval Semantics* we refer to the framework which has developed out of the Intensional Logic of Montague's PTQ. There are a number of implementations of a central set of ideas; for the most part these differ in fairly minor ways, such as whether quantification over times is to be accomplished via operators or explicit quantifiers. The key aspects of Interval Semantics are: (i) the temporal part of the model consists of set I of *intervals*, the set of open and closed intervals of the reals, with precedence and temporal overlap relations defined straightforwardly; (ii) the interpretation of sentences depends on an *evaluation interval* or *event time*, an *utterance time*, and perhaps a *reference interval* or set of reference intervals; (iii) interpretation proceeds by translating natural language sentences into some appropriate higher-order logic, typically an intensional λ -calculus; and (iv) tenses are translated by quantificational operators or formulas involving first-order quantification to the same effect. The motivation for (i) comes initially from the semantics for the progressive, a point which we will see in Section 3.4 below. We have already examined the motivation for (ii), though in what follows we will see more clearly what issues arise in trying to understand the relationship between the reference interval and the evaluation interval. Points (iii) and (iv) are implementation details with which we will not much concern ourselves.

From the preceding, it can be seen what claims Interval Semantics makes

concerning the issues in 3.1 and 3.2. Tense has the type of an operator. It is uniformly quantificational, but shows variable determinacy, depending on the nature of the reference interval or intervals.

Discourse Representation Theory is one of a number of theories of *dynamic interpretation* to be put forth since the early 1980's; others include File Change Semantics [Heim, 1982] and Dynamic Montague Grammar [Groenendijk and Stokhof, 1990]. What the dynamic theories share is a concern with the interpretation of multi-sentence texts, concentrating on establishing means by which information can be passed from one sentence to another. The original problems for which these theories were designed had to do with nominal anaphora, in particular the relationships between antecedents and pronouns in independent sentences like (12) and donkey sentences like (13).

(12) A man walked in. He sat down.

(13) When a man walks in, he always sits down.

Of the dynamic theories, by far the most work on tense has taken place within DRT. It will be important over time to determine whether the strengths and weaknesses of DRT analyses of tense carry over to the other dynamic approaches.

As noted above, work on tense within DRT has attempted to analogize the treatment of tense to that of nominal anaphora. This has resulted in an analytical framework with the following general features: (i) the temporal part of the model consists of a set of *eventualities* (events, processes, states, etc.), and possibly of a set of intervals as well; (ii) the semantic representation of a discourse (or sub-part thereof) contains explicit variables ranging over to reference times, events, and the utterance time; (iii) interpretation proceeds by building up a *Discourse Representation Structure* (DRS), a partial model consisting of a set of objects (*discourse markers*) and a set of conditions specifying properties of and relations among them; the discourse is true with respect to a model M if and only if the partial model (DRS) can be embedded in the full model M ; (iv) tenses are translated as conditions on discourse markers representing events and/or times. For example, consider the discourse in (14).

(14) Pedro entered the kitchen. He took off his coat.

We might end up with discourse markers representing Pedro (x), the kitchen (y), the coat (z), the event of entering the kitchen (e_1), the event of taking off the coat (e_2), the utterance time (u), the reference time for the first sentence (r_1) and the reference time for the second sentence (r_2). The DRS would contain at least the following conditions: **Pedro= x , kitchen(y), coat(z), entering(e_1, x, y), taking-off(e_2, x, z), $r_1 < u$, $r_2 < u$, $r_1 < r_2$, $e_1 \circ$**

r_1 , and $e_2 \circ r_2$ (where \circ represents temporal overlap). The algorithms for introducing conditions may be rather complex, and typically are sensitive to the aspectual class of the eventualities represented (that is, whether they are events, processes, states, etc.).

DRT holds a referential theory of tense, treating it via discourse markers plus appropriate conditions. It therefore maintains that tense is not inherently quantificational, and that any quantificational force which is observed must come from either an independent operator, as with (6), or default rule. Given the definition of truth mentioned above, tense will be given a default existential quantificational force—the DRS for (14) will be true if there is *some* mapping from discourse markers to entities in the model satisfying the conditions. The DRT analysis of tense also implies that temporal reference is highly determinate, since the events described by a discourse typically must overlap temporally with a contextually determined reference time.

Closely related to the DRT view of tense are a pair of *indexical* theories of tense. The first is developed by Cooper within the framework of *Situation Semantics* (Barwise and Perry [1983]). Situation Semantics constructs objects known as *situations* or *states of affairs* set-theoretically out of properties, relations, and individuals (including space-time locations). Let us say that the situation of John loving Mary is represented as $\langle l, \langle \langle \mathbf{love}, \mathbf{John}, \mathbf{Mary} \rangle, 1 \rangle \rangle$, l being a spatiotemporal location and 1 representing ‘truth’. A set of states of affairs is referred to as a *history*, and it is the function of a sentence to describe a history. A simple example is given in (15).

- (15) *John loved Mary* describes a history h with respect to a spatiotemporal location l iff $\langle l, \langle \langle \mathbf{love}, \mathbf{John}, \mathbf{Mary} \rangle, 1 \rangle \rangle \in h$.

Unless some theory is given to explain how the location l is arrived at, a semantics like (15) will of course not enlighten us much as to the nature of tense. Cooper proposes that the location is provided by a *connections function*; for our purposes a connections function can be identified with a function from words to individuals. When the word is a verb, a connections function c will assign it a spatiotemporal location. Thus,

- (16) *John loved Mary* describes a history h with respect to a connections function c iff $\langle c(\mathit{loved}), \langle \langle \mathbf{love}, \mathbf{John}, \mathbf{Mary} \rangle, 1 \rangle \rangle \in h$.

Cooper’s theory is properly described as an ‘indexical’ approach to tense, since a tensed verb directly picks out the location which the sentence is taken to describe.⁶

⁶Unlike ordinary indexicals, verbs do not refer to the locations which they pick out. The verb *loved* still denotes the relation **love**.

Enç's analysis of tense is somewhat similar to Cooper's. She proposes that tense morphemes refer to intervals. For example, the past tense morpheme *-ed* might refer, at an utterance time u , to the set of moments preceding u . For Enç, a verb is a semi-indexical expression, denoting a contextually relevant subrelation of the relation which it is normally taken to express—e.g., any occurrence of *kiss* will denote a subset of $\{\langle x, y \rangle: x \text{ kisses } y \text{ (at some time)}\}$. Tense serves as one way of determining which subrelation is denoted. The referent of a verb's tense morpheme serves to constrain the denotation of the verb, so that, for instance, the verb *kissed* must denote a set of pairs of individuals where the first kissed the second during the past, i.e. during the interval denoted by the tense.

- (17) *kissed* denotes a (contextually relevant) subset of $\{\langle x, y \rangle: \text{for some } t \in \text{-ed}, x \text{ kissed } y \text{ at } t\}$.

In (17), *-ed* is the set of times denoted by *-ed*, i.e. that set of times preceding the utterance time.

Both Enç's theory and the Situation Semantics approach outlined above seem to make the same commitments on the issues raised in Sections 3.1 and 3.2 as DRT. Both consider tense to be non-quantificational and highly determinate. They are clearly referential theories of tense, taking its function to be to pick out a particular time with respect to which the eventualities described by the sentence are temporally located.

3.4 *The compositional semantics of individual tenses and aspects*

Now that we have gone through a general outline of several frameworks which have been used to semantically analyze tense in natural language, we turn to seeing what specific claims have been made about the major tenses (present, past, and future) and aspects (progressive and perfect) in English.

3.4.1 *Tense*

Present Tense. In many contemporary accounts the semantic analysis of the present underlies that of all the other tenses.⁷ But despite this allegedly fundamental role, the only use of the present that seems to have been treated formally is the 'reportive' use, in which the sentence describes an event that is occurring or a state that obtains at the moment of utterance.⁸ The preoccupation with reportive sentences is unfortunate for two reasons. First, the reportive uses are often the less natural ones—consider the sentence

⁷This is true, for example, of Bennett and Partee. But there is no consensus here. Kuhn [1983], for example, argues that past, present, and future should be taken as (equally fundamental) modes of combination of noun phrases and verb phrases.

⁸Many authors restrict the use of the term 'reportive' to event sentences.

Jill walks to work (though many languages do not share this feature with English). Second, if the present tense is taken as fundamental, the omission of a reading in the present tense can be transferred to the other tenses. (*John walked to work* can mean that John habitually walked to work.) The neglect is understandable, however, in view of the variety of uses the present can have and the difficulty of analyzing them. One encounters immediately, for example, the issue discussed below.

Statives and non-statives. There is discussion in the philosophical literature beginning with Aristotle about the kinds of verb phrases there are and the kinds of things verb phrases can describe. Details of the classification and terminology vary widely. One reads about events, processes, accomplishments, achievements, states, activities and performances. The labels are sometimes applied to verb phrases, sometimes to sentences and sometimes to eventualities. There seems to be general agreement, however, that some kind of classification of this kind will be needed in a full account of the semantics of tense. In connection with the present tense there is a distinction between verb phrases for which the reportive sense is easy (e.g., *John knows Mary*, *The cat is on the mat*, *Sally is writing a book*) and those for which the reportive sense is difficult (e.g., *John swims in the channel*, *Mary writes a book*). This division almost coincides with a division between verb phrases that have a progressive form and those that do not. (Exceptions—noted by Bennett and Partee—include *John lives in Rome* and *John resides in Rome*, both of which have easy reportive uses but common progressive forms.) It also corresponds closely to a division of sentences according to the kind of *when* clauses they form. The sentence *John went to bed when the cat came in* indicates that John went to bed after the cat came in, while *John went to bed when the cat was on the mat* suggests that the cat remained on the mat for some time after John went to bed. In general, if the result of prefixing a sentence by *when* can be paraphrased using *just after* it will have difficult reportive uses and common progressive forms. If it can be paraphrased using *still at the time* it will have easy reportive uses and no common progressive forms. (Possible exceptions are ‘inceptive readings’ like *She smiled when she knew the answer*; see the discussion in Section 3.4.4 below.)

The correspondence among these three tests suggests that they reflect some fundamental ways in which language users divide the world. The usual suggestion is that sentences in the second class (easy reportive readings, no progressives and *when = still at the time*) describe *states*. States are distinguished by the fact that they seem to have no temporal parts. The way Emmon Bach puts it is that it is possible to imagine various states obtaining even in a world with only one time, whereas it is impossible to imagine events or processes in such a world. (Other properties that have been regarded as

characteristic of states are described in Section 4.2 below.) Sentences that describe states are *statives*; those that do not are *non-statives*.

There is some disagreement about whether sentences in the progressive are statives. The fact that Harry is building a house, for example, can go on at discontinuous intervals and the fact that Mary is swimming in the Channel is composed of a sequence of motions, none of which is itself swimming, lead Gabbay and Moravcsik to the conclusion that present progressives do not denote states. But according to the linguistic tests discussed above progressives clearly do belong with the state sentences. For this reason, Vlach, Bach, and Bennett all take the other side. The exact importance of this question depends on what status one assigns to the property of being a stative sentence. If it means that the sentence implies that a certain kind of eventuality known as a state obtains, then it seems that language users assume or pretend that there is some state that obtains steadily while Mary makes the swimming motions and another while Harry is involved in those house-building activities. On the other hand, if ‘stative’ is merely a label for a sentence with certain temporal properties, for example passing the tests mentioned above, then the challenge is just to assign a semantics to the progressive which gives progressive sentences the same properties as primitive statives; this alternative does not commit us to the actual existence of states (cf. Dowty’s work). Thus, the implications of deciding whether to treat progressives as statives depends on one’s overall analytical framework, in particular on the basic eventuality/time ontology one assumes.

A recent analysis of the present tense which relates to these issues has been put forth by Cooper. As mentioned above, Cooper works within the Situation Semantics framework, and is thereby committed to an analysis of tense as an element which describes a spatiotemporal region. A region of this kind is somewhat more like an eventuality, e.g. a state, than a mere interval of time; however, his analysis does not entail a full-blown eventuality theory in that it doesn’t (necessarily) propose primitive classes of states, events, processes, etc. Indeed, Cooper proposes to define states, activities, and accomplishments in terms very similar to those usual in interval semantics. For instance, stative and process sentences share the property of describing some temporally included sublocation of any spatiotemporal location which they describe (*temporal ill-foundedness*); this is a feature similar to the *subinterval property*, which arises in purely temporal analyses of the progressive (see 3.4.2 below).

Cooper argues that this kind of framework allows an explanation for the differing effects of using the simple present with stative, activity, and accomplishment sentences. The basic proposal about the present tense is that it describes a present spatiotemporal location—i.e. the location of discourse. Stative sentences have both temporal ill-foundedness and the property of *independence of space*, which states that, if they describe a location l , they also describe the location $l+$ which is l expanded to include

all of space. This means that if, for example, John loves Mary anywhere for a length of time including the utterance time, *John loves Mary* will describe all of space for the utterance time. This, according to Cooper, allows the easy use of the present tense here. It seems, though, that to get the result we need at least one more premise: either a stative must describe any spatial sublocation of any location it describes (so that it will precisely describe the utterance location) or we must count the location of utterance for a stative to include all of space.

Activity sentences do not have independence of space. This means that, if they are to be true in the present tense, the utterance location will have to correspond spatially to the event's location. This accounts for the immediacy of sentences like *Mary walks away*. On the other hand, they do have temporal ill-foundedness, which means that the sentence can be said even while the event is still going on. Finally, accomplishment sentence lack the two above properties but have *temporal well-foundedness*, a property requiring them not to describe of any temporal subpart of any location they describe. This means that the discourse location of a present tense accomplishment sentence will have to correspond exactly to the location of the event being described. Hence such sentences have the sense of narrating something in the vicinity just as it happens (*He shoots the ball!*)

Cooper goes on to discuss how locations other than the one where a sentence is actually uttered may become honorary utterance locations. This happens, for example, in the historical present or when someone narrates events they see on TV (following Ejerhed). Cooper seems correct in his claim that the variety of ways in which this occurs should not be a topic for formal semantic analysis; rather it seems to be understandable only in pragmatic or more general discourse analytic terms.

Past Tense. Every account of the past tense except those of Dowty and Parsons accommodates in some way the notion that past tense sentences are more definite than the usual tense logic operators. Even Dowty and Parsons, while claiming to treat the more fundamental use of the past tense, acknowledge the strength of the arguments that the past can refer to a definite time. Both cite Partee's example:

When uttered, for instance, half way down the turnpike such a sentence [as *I didn't turn off the stove*] clearly does not mean that there exists some time in the past at which I did not turn off the stove or that there exists no time in the past at which I turned off the stove.

There are, however, some sentences in which the past does seem completely indefinite. We can say, for example, *Columbus discovered America* or *Oswald killed Kennedy* without implying or presupposing anything about the date those events occurred beyond the fact that it was in the past. It

would be desirable to have an account of the past that could accommodate both the definite and indefinite examples. One solution, as discussed in Section 3.2, is that we interpret the past as a quantifier over a set of possible reference times.⁹ *I left the oven on* is true now only if the oven was left on at one of the past times I might be referring to. The context serves to limit the set of possible reference times. In the absence of contextual clues to the contrary the set comprises *all* the past times and the past is completely indefinite. In any case, the suggestion that the context determines a set of possible reference times seems more realistic than the suggestion that it determines a unique such time.

There is still something a little suspicious, however, about the notion that context determines a reference interval or a range of reference times for past tense sentences to refer to. One would normally take the ‘context of utterance’ to include information like the time and place the utterance is produced, the identity of the speaker and the audience, and perhaps certain other facts that the speaker and the audience have become aware of before the time of the utterance. But in this case it is clear that *Baltimore won the Pennant* and *Columbus discovered America* uttered in *identical* contexts would have *different* reference times.

A way out of the dilemma might be to allow the sentence itself to help identify the relevant components of a rich utterance context. Klein [1994] emphasizes the connection between the topic or background part of a sentence and its reference time (for him *topic time*). A full explanation of the mechanism will require taking into account the presupposition-focus structure of a sentence—that is, what new information is being communicated by the sentence. For example, when a teacher tells her class *Columbus discovered America*, the sentence would most naturally be pronounced with focal intonation on *Columbus*:

(18) COLUMBUS discovered America.

(19) ??Columbus discovered AMERICA.

??Columbus DISCOVERED America.

⁹The proposal is made in these terms in Kuhn [1979]. In Bennett–Partee the idea is rather that the reference time is an interval over whose subintervals the past tense quantifies. Thus the main difference between these accounts has to do with whether the reference time (or range of reference times) can be discontinuous. One argument for allowing it to be is the apparent reference to such times in sentences like *John came on a Saturday*. Another such argument might be based on the contention of Kuhn [1979] that the possible reference times are merely the times that happen to be maximally *salient* for speaker and audience. Vlach [1980] goes Partee–Bennett one further by allowing the past to indicate what obtains *in*, *at*, or *for* the reference interval.

The teacher is presupposing that someone discovered America, and communicating the fact that the discovery was made by Columbus. Similarly, when the teacher says *Bobby discovered the solution to problem number seven*, teacher and students probably know that Bobby was trying to solve problem number seven. The new information is that he succeeded. In those cases it is plausible to suppose that possible reference times would be the times at which the sentence's presupposition is true—the time of America's discovery and the times after which Bobby was believed to have started working on the problem. (As support for the latter claim consider the following scenario: Teacher assigns the problems at the beginning of class period. At the end she announces *Bobby discovered the solution to problem seven*. Susy objects *No he didn't. He had already done it at home.*)

A variety of theories have been proposed in recent years to explain how the intonational and structural properties of a sentence serve to help identify the presuppositions and 'new information' in a sentence.¹⁰ We will not go into the details of these here, but in general we can view a declarative sentence as having two functions. First, it identifies the relevant part of our mutual knowledge. Second, it supplies a new piece of information to be added to that part. It is the first function that helps delimit possible reference times. Previous discourse and non-linguistic information, of course, also play a role. When I say *Baltimore won the Pennant* it matters whether we have just been talking about the highlights of 1963 or silently watching this week's Monday Night Baseball.

Frequency. Bäuerle and von Stechow point out that interpreting the past tense as a quantifier ranging over possible reference times (or over parts of the reference time) makes it difficult to explain the semantics of frequency adverbs. Consider, for example, the sentence *Angelika sneezed exactly three times*, uttered with reference to the interval from two o'clock to three o'clock yesterday morning. We might take the sentence to mean that there are exactly three intervals between two and three with reference to which *Angelika sneezed* is true. But if *Angelika sneezed* means that she sneezed at least once within the time interval referred to, then whenever there is one such interval there will be an infinite number of them. So *Angelika sneezed exactly three times* could never be true. Alternatively we might take the sentence to mean that there was at least one time interval within which Angelika sneezed-three-times. But the intervals when Angelika sneezed three times will contain subintervals in which she sneezed twice. So in this case *Angelika sneezed exactly three times* would imply *Angelika sneezed exactly twice*.

This problem leads Bäuerle and von Stechow to insist that the past tense itself indicates simply that the eventuality described occupies that part of

¹⁰On the theory of focus, see for example Jackendoff, Rooth [1985; 1992], and Cresswell and von Stechow. On the nature of presupposition and factivity more generally, Levinson provides a good overview.

the reference time that lies in the past. On this interpretation, it does make sense to say that *Angelika sneezed three times* means that there were three times with reference to which *Angelika sneezed* is true. Tichý, using a different framework, arrives at a similar analysis. Unfortunately, this position also has the consequence that the simple sentence *Angelika sneezed*, taken literally, would mean that Angelika's sneeze lasted for the full hour between two and three. Bäuerle–von Stechow and Tichý both suggest that past tense sentences without explicit frequency operators often contain an *implicit* 'at least once' adverb. In a full treatment the conditions under which the past gets the added implicit adverb would have to be spelled out, so it is not clear how much we gain by this move. The alternative would seem to be to insist that the 'at least once' qualification is a normal part of the meaning of the tense which is dropped in the presence of frequency adverbs. This seems little better.

Vlach handles the frequency problem by allowing sentences to be true either 'in' or 'at' a time interval. *Angelika sneezed exactly three times* is true *at* the reference interval if it contains exactly three subintervals *at* which Angelika sneezes. On the other hand *Angelika sneezed* would normally be taken to assert that Angelika sneezed *in* the reference interval, i.e., that there is at least one time in the interval at which she sneezed. Again, a complete treatment would seem to require a way of deciding, for a given context and a given sentence, whether the sentence should be evaluated in or at the reference time.

We might argue that *all* the readings allowed by Vlach (or Bäuerle–von Stechow) are always present, but that language users tend to ignore the implausible ones—like those that talk about sneezes lasting two hours. But the idea that ordinary past tense sentences are riddled with ambiguities is not appealing.

The DRT analysis, on which frequency adverbs are examples of adverbs of quantification, can provide a somewhat more attractive version of the Bäuerle–von Stechow analysis. According to this view, *three times* binds the free time (or eventuality) variable present in the translation, as *always* did in (6)–(7) above. The situation is more straightforward when an additional temporal expression is present:

(20) On Tuesday, the bell rang three times.

(21) **three-times**_{*t*}(**past**(*t*) & **Tuesday**(*t*))(**rang**(**the-bell**,*t*)).

Here *Tuesday* helps to identify the set of times *three-times* quantifies over. **Tuesday**(*t*) indicates that *t* is a subinterval of Tuesday. A representation of this kind would indicate that there were three assignments of times during Tuesday to *t* at which the bell rang, where we say that the bell rang at *t* iff *t* is precisely the full interval of bell-ringing. The issue is more difficult when there is no restrictive argument for the adverb, as with *Angelika sneezed*

three times. One possibility is that it ranges over all past times. More likely, context would again provide a set of reference times to quantify over. In still other cases, as argued by Klein [1994], it ranges over times which are identified by the ‘background’ or presuppositions of the sentence. Thus, *Columbus sailed to AMERICA four times* means that, of the times when Columbus sailed somewhere, four were ones at which he sailed to America.

In terms of a DRT analysis, when there is no adverbial, as with *Angelika sneezed*, the temporal variable would be bound by whatever default process normally takes care of free variables (‘existential closure’ or another, as discussed above). This parallels the suggestion in terms of Bäuerle–von Stechow’s analysis, that ‘at least once’ is a component of meaning which is ‘dropped’ in the presence of an overt adverbial. Thus, in the DRT account there wouldn’t need to be a special stipulation for this.

There is still a problem with adverbials of duration, such as in *On Tuesday, the bell rang for five minutes*. This should be true, according to the above, if for some subinterval t of Tuesday, t is precisely the full time of the bell’s ringing and t lasts five minutes. Whether the sentence would be true if the bell in fact rang for ten minutes depends on whether *for five minutes* means ‘for at least five’ or ‘for exactly five’. If the former, the sentence would be true but inappropriate (in most circumstances), since it would generate an implicature that the bell didn’t ring for more than five minutes. If the latter, it would be false. It seems better to treat the example via implicature, since it is not as bad as *The bell rang for exactly five minutes* in the same situation, and the implication seems defeasible (*The bell rang for five minutes, if not more.*)

Future Tense. The architects of fragments of English with tense seem to have comparatively little to say about the future. Vlach omits it from his very comprehensive fragment, suggesting he may share Jespersen’s view that the future is not a genuine tense. Otherwise the consensus seems to be that the future is a kind of mirror image of the past with the exception, noted by Bennett and Partee, that the times to which the future can refer include the present. (Compare *He will now begin to eat* with *He now began to eat.*)

There appears to be some disagreement over whether the future is definite or indefinite. Tichý adopts the position that it is ambiguous between the two readings. This claim is difficult to evaluate. The sentence *Baltimore will win* can indicate either that Baltimore will win next week or that Baltimore will win eventually. But this difference can be attributed to a difference in the set of possible reference times as easily as to an ambiguity in the word *will*. It is of course preferable on methodological grounds to adopt a uniform treatment if possible.

3.4.2 Aspect

The Progressive. Those who wrote about the truth conditions of English tenses in the 1960's assumed that sentences were to be evaluated at instants of time. Dana Scott suggested (and Mongague [1970] seconds) a treatment of the present progressive according to which *Mary is swimming in the Channel* is true at an instant t if *Mary swims in the Channel* is true at every instant in an open interval that includes t . This account has the unfortunate consequence of making the present progressive form of a sentence imply its (indefinite) past. For a large class of sentences this consequence is desirable. If John is swimming in the Channel he did, at some very recent time, swim in the Channel. On the other hand there are many sentences for which this property does not hold. *John is drawing a circle* does not imply that John drew a circle. *Mary is climbing the Zugspitze* does not imply that Mary climbed the Zugspitze.

In Bennett–Partee, Vlach [1980] and Kuhn [1979] this difficulty avoided by allowing some present tense sentences to be evaluated at extended intervals of time as well as instants. *John is drawing a circle* means that the present instant is in the interior of an interval at which *John draws a circle* is true. The present instant can clearly be in such an interval even though *John drew a circle* is false at that instant. Sentences like *John swims in the Channel*, on the other hand, are said to have what Bennett and Partee label the *subinterval* property: their truth at an interval entails their truth at all subintervals of that interval. This stipulation guarantees that *Mary is swimming in the Channel* does imply *Mary swam in the Channel*.

Instantaneous events and gappy processes. Objections have been made to the Bennett–Partee analysis having to do with its application to two special classes of sentences. The first class comprises sentences that cannot plausibly be said to be true at extended intervals, but that do have progressive forms. Vlach, following Gilbert Ryle, calls these achievement sentences. We will follow Gabbay–Moravcsik and Bach in calling them instantaneous event sentences. They include *Baltimore wins*, *Columbus reaches North America*, *Columbus leaves Portugal* and *Mary starts to sweat*. It seems clear that instantaneous event sentences fail all the tests for statives. But if they are really true only instantaneously then the interval analysis would predict that they would never form true progressives.

The second class contains just the sentences whose present progressive implies their indefinite past. These are the *process* sentences. The Bennett–Partee analysis (and its modalized variation discussed below) have the consequence that process sentences can't have 'gappy' progressives. If *I sat in the front row of the Jupiter theater* was true at the interval from two o'clock to four o'clock last Saturday afternoon, then *I was sitting in the front row of the Jupiter theater* was true at all instants between those times including, perhaps, some instants at which I was really buying popcorn. This accord-

ing to Vlach, Bennett, and Gabbay–Moravcsik, is a conclusion that must be avoided.¹¹

Vlach's solution to the problems of instantaneous events and gappy processes is to give up the idea that a uniform treatment of the progressive is possible. For every non-stative sentence A , according to Vlach, we understand a notion Vlach calls the *process of A* or, simply $\text{proc}(A)$. The present progressive form of A simply says that our world is now in the state of $\text{proc}(A)$'s going on.

The nature of $\text{proc}(A)$, however, depends on the kind of sentence A is. If A is a process sentence then $\text{proc}(A)$ is 'the process that goes on when A is true.' For the other non-stative sentences, $\text{proc}(A)$ is a process that 'leads to' the truth of A , i.e., a process whose 'continuation... would eventually cause A to become true.' In fact, Vlach argues, to really make this idea precise we must divide the non-process, non-stative sentences into at least four subclasses.

The first subclass contains what we might (following Bach) call extended event sentences. Paradigm examples are *John builds a house* and *Mary swims across the Channel*. If an extended event sequence is true at an interval I then $\text{proc}(A)$ starts at the beginning of I and ends at the end of I . For the second subclass (*John realizes his mistake*, *Mary hits on an idea*) proc is not defined at all. For the third class (*Mary finishes building the house*, *Columbus reaches North America*) the progressive indicates that the corresponding process is in its final stages. For the fourth class (*Max dies*, *The plane takes off*) proc must give a process that culminates in a certain state.

Vlach's account is intended only as a rough sketch. As Vlach himself acknowledges, there remain questions of clarification concerning the boundaries of the classes of sentences and the formulation of the truth conditions. Furthermore, Vlach's account introduces a new theoretical term. If the account is to be really enlightening we would like to be sure that we have an understanding of proc that is independent of, but consistent with, the truth conditions of the progressive. Even if all the questions of clarification were resolved, Vlach's theory might not be regarded as particularly attractive because it abandons the idea of a uniform account of the progressive. Not even the sources of irregularity are regular. The peculiarity of the truth conditions for the progressive form of a sentence A are explained sometimes by the peculiarity of A 's truth conditions, sometimes by the way proc operates on A and sometimes by what the progressive says about $\text{proc}(A)$. In

¹¹This argument is not completely decisive. It would seem quite natural to tell a friend one meets at the popcorn counter *I am sitting in the front row*. On the other hand, if one is prepared to accept *I am not sitting in the front row* at popcorn buying time, then perhaps one should be prepared to accept *I sat in the front row before I bought the popcorn and again after*. This would suggest the process went on *twice* during the long interval rather than at one time with a gap.

this sense, Vlach's account is *pessimistic*. Other attempts have been made to give a more uniform account of the progressive. These *optimistic* theories may be divided into two groups depending on whether they propose that the progressive has a modal semantics.

Non-Modal Accounts. The analysis of Bennett-Partee discussed above was the first optimistic account presented developed in the formal semantic tradition. Since that time, two other influential non-modal proposals have been put forth. One is by Michael Bennett [1981] and one by Terence Parsons [1985; 1990]. The accounts of Vlach, Bennett and Parsons (and presumably anyone else) must distinguish between statives and non-statives because of the differences in their ability to form progressives. Non-statives must be further divided between processes and events if the inference from present progressive to past is to be selectively blocked. But in the treatments of Bennett and Parsons, as opposed to that of Vlach, all the differences among these three kinds of sentences are reflected in the untensed sentences themselves. Tenses and aspects apply uniformly.

Bennett's proposal is extremely simple.¹² The truth conditions for the present perfect form of *A* (and presumably all the other forms not involving progressives) require that *A* be true at a *closed* interval with the appropriate location. The truth conditions for the progressive of *A* require that *A* be true in an open interval with the appropriate location. Untensed process sentences have two special properties. First, if a process sentence is true at an interval, it is true at all closed subintervals of that interval. Second, if a process sentence is true at every instant in an interval (open or closed) then it is true at that interval. Neither of these conditions need hold for event sentences. Thus, if *John is building a house* is true, there must be an open interval at which *John builds a house* is true. But if there is no *closed* interval of that kind, then *John has built a house* will be false. On the other hand, *Susan is swimming* does imply *Susan has (at some time) swum* because the existence of an open interval at which *Susan swims* is true guarantees the existence of the appropriate closed intervals.

If this proposal has the merit of simplicity, it has the drawback of seeming very *ad hoc*—'a logician's trick' as Bennett puts it. Bennett's explanatory remarks are helpful. Events have a beginning and an end. They therefore occupy closed intervals. Processes, on the other hand, need not. But a process is composed, at least in part, of a sequence of parts. If Willy walks then there are many subintervals such that the eventualities described by *Willy walks* are also going on at these intervals. Events, however, need not be decomposable in this way.

The account offered by Parsons turns out to be similar to Bennett's. Parson's exposition seems more natural, however, because the metaphysical underpinnings discussed above are exposed. Parsons starts with the

¹²Bennett attributes the idea behind his proposal to Glen Helman.

assumption that there are three kinds of eventualities: *states*, *processes*, and *events*. Eventualities usually have *agents* and sometimes *objects*. An agent may or may not be *in* a state at a time. Processes may or may not be *going on* at a time. Events may or may not be *in development* at a time. In general, if e is an eventuality, we say that e *holds* at time t if the agent of e is in e at t or e is in development or going on at t . In addition, events can have the property of *culminating* at a time. The set of times at which an event holds is assumed to be an open interval and the time, if any, at which it culminates is assumed to be the least upper bound of the times at which it holds.

The structure of language mirrors this metaphysical picture. There are three kinds of untensed sentences: stative, process sentences and event sentences. Tensed sentences describe properties of eventualities. Stative and process sentences say that an eventuality *holds* at a time. Event sentences say that an eventuality *culminates* at a time. So, for example, *John sleeps* can be represented as (22) and *Jill bought a cat* as (23):

$$(22) \quad \exists e \exists t [\text{pres}(t) \wedge \text{sleeping}(e) \wedge \text{holds}(e, t) \wedge \text{agent}(e, \text{john})]$$

$$(23) \quad \exists e \exists t \exists x [\text{past}(t) \wedge \text{buying}(e) \wedge \text{culm}(e, t) \wedge \text{agent}(e, \text{jill}) \wedge \text{cat}(x) \wedge \text{obj}(e, x)].$$

The treatment of progressives is remarkably simple. Putting a sentence into the progressive has no effect whatsoever, other than changing the sentence from a non-stative into a stative. This means that, for process sentences, the present and progressive are equivalent. *John swims* is true if and only if *John is swimming* is true. Similarly, *John swam* is true if and only if *John was swimming* is true. For event sentences, the change in classification does affect truth conditions. *John swam across the Channel* is true if the event described *culminated* at some past time. *John was swimming across the Channel*, on the other hand, is true if the state of John's swimming across the Channel *held* at a past time. But this happens if and only if the event described by *John swims across Channel* was *in development* at that time. So it can happen that *John was swimming across the Channel* is true even though John never got to the other side.

Landman [1992] points out a significant problem for Parsons' theory. Because it is a purely extensional approach, it predicts that *John was building a house* is true if and only if there is a house x and a past event e such that e is an event of John building x and e holds. This seems acceptable. But Landman brings up examples like *God was creating a unicorn (when he changed his mind)*. This should be true iff there is a unicorn x and a past event e such that e is an event of God creating x and e holds. But it may be that the process of creating a unicorn involves some mental planning or magic words but doesn't cause anything to appear until the last moment,

when all of a sudden there is a fully formed unicorn. Thus no unicorn need ever exist for the sentence to be true. Landman's problem arises because of Parsons' assumption that eventualities are described primarily by the verb alone, as a swimming, drawing, etc., and by thematic relations connecting them to individuals, as **agent**(*e*, **jill**) or **obj**(*e*, *x*). There is no provision for more complex descriptions denoting a property like 'house-building'. The question is how intrinsic this feature is to Parsons' analysis of tense and aspect. One could adjust his semantics of verbs to make them multi-place intensional relations, so that *John builds a house* could be analyzed as:

$$(24) \quad \exists e \exists t [\text{pres}(t) \wedge \text{building}(e, \text{john}, \text{a house}) \wedge \text{culm}(e, t)].$$

But then we must worry about how the truth conditions of **building**(*e*, **john**, **a house**) are determined on a compositional basis and how one knows what it is for an eventuality of this type to hold or culminate. However, while the challenge is real, it is not completely clear that it is impossible to avoid Landman's conclusion that the progressive cannot be treated in extensional terms.

It seems likely that, with the proper understanding of theoretical terms, Parsons, Vlach, and Bennett could be seen as saying very similar things about the progressive. Parsons' exposition seems simpler than Vlach's, however, and more natural than Bennett's. These advantages may have been won partly by reversing the usual order of analysis from ordinary to progressive forms. Vlach's account proceeds from *A* to *proc*(*A*) to the state of *proc*(*A*)'s holding. In Bennett's, the truth conditions for the progressive of *A* are explained in terms of those for *A*. If one compares the corresponding progressive and non-progressive forms on Parson's account, however, one sees that in the progressive of an event sentence, something is *subtracted* from the corresponding non-progressive form. The relations between the progressive and non-progressive forms seem better accommodated by viewing events as processes plus culminations rather than by viewing processes as eventualities 'leading to' events.

On the other hand the economy of Parsons' account is achieved partly by ignoring some of the problems that exercise Vlach. The complexity of Vlach's theory increases considerably in the face of examples like *Max is dying*. To accommodate this kind of case Parsons has two options. He can say that they are ordinary event sentences that are in development for a time and then culminate, or he can say that they belong to a new category—achievement—of sentences that culminate but never hold. The first alternative doesn't take account of the fact that such eventualities can occur at an instant (compare *Max was dying and then died at 5:01* with *Jane was swimming across the Channel and then swam across the Channel at 5:01*). The second requires us to say that the progressive of these sentences, if it can be formed at all, involves a 'change in meaning' (cf. Parsons [1990,

p. 24, 36]). But the progressive *can* be formed and spelling out the details of the meaning changes involved will certainly spoil some of Parsons' elegance.

Unfinished progressives and Modal Accounts. According to the Bennett–Partee account of progressives, *John was building a house* does not imply that John built a house. It does, however, imply that John will eventually have built a house. Yet it seems perfectly reasonable to say:

(25) John was building a house when he died.

One attempt to modify the account to handle this difficulty is given by Dowty [1979]. Dowty's proposal is that we make the progressive a *modal* notion.¹³ The progressive form of a sentence *A* is true at a time *t* in world *w* just in case *A* is true at an interval containing *t* in all worlds *w'* such that *w'* and *w* are exactly alike up to *t* and the course of events after *t* develops in the way most compatible with past events. The *w'*-worlds mentioned are referred to as 'inertia worlds'. (25) means that *John builds a house* is eventually true in all the worlds that are inertia worlds relative to ours at the interval just before John's death.

If an account like this is to be useful, of course, we must have some understanding of the notion of inertia world independent of its role in making progressive sentences true. The idea of a development maximally compatible with past events may not be adequate here. John's death and consequent inability to finish his house may have been natural, even inevitable, at the time he was building it. In Kuhn [1979] the suggestion is that it is the expectations of the language users that are at issue. But this seems equally suspect. It is quite possible that because of a bad calculation, we all mistakenly expect a falling meteor to reach earth. We would not want to say in this case that the meteor *is* falling to earth.

Landman attempts to identify in more precise terms the alternate possible worlds which must be considered in a modal semantics of the progressive. We may label his the *counterfactual analysis*, since it attempts to formalize the following intuition: Suppose we are in a situation in which John fell off the roof and died, and so didn't complete the house, though he would have finished it if he hadn't died. Then (25) is true *because* he would have finished if he hadn't died. Working this idea out requires a bit more complexity, however. Suppose not only that John fell off the roof and died, but also that if he hadn't fallen, he would have gotten ill and not finished the house anyway. The sentence is still true, however, and this is because he would have finished the house if he hadn't fallen and died and hadn't gotten ill. We can imagine still more convoluted scenarios, where other dangers lurk for John. In the end, Landman proposes that (25) is true iff *John builds a*

¹³Dowty attributes this idea to David Lewis.

house would be true if nothing were to interrupt some activity that John was engaged in.

Landman formalizes his theory in terms of the notion of the *continuation branch* of an event e in a world w . He assumes an ontology wherein events have *stages* (cf. Carlson [1977]); the notion of ‘stage of an eventuality’ is not defined in a completely clear way. Within a single world, all of the temporally limited subeventualities of e are stages of e . An eventuality e' may also be a stage of an eventuality e in another world. It seems that this can occur when e' is duplicated in the world of e by an eventuality which is a stage of e . The continuation branch of e in w , $C(e, w)$, is a set of event-world pairs; $C(e, w)$ contains all of the pairs $\langle a, w \rangle$ where a is a stage of e in w . If e is a stage of a larger event in some other possible world, we say that it *stops* in w (otherwise it simply ends in w). If e stops in w at time t , the continuation branch moves to the world w_1 most similar to w in which e does not stop at t . Suppose that e_1 is the event in w_1 of which e is a stage; then all pairs $\langle a, w_1 \rangle$, where a is a stage of e_1 in w_1 , are also in $C(e, w)$. If e_1 stops in w_1 , the continuation branch moves to the world most similar to w_1 in which e_1 does not stop, etc. Eventually, the continuation branch may contain a pair $\langle e_n, w_n \rangle$ where a house gets built in e_n . Then the continuation branch ends. We may consider the continuation branch to be the maximal extension of e . *John was building a house* is true in w iff there is some event in w whose continuation branch contains an event of John building a house.

Landman brings up one significant problem for his theory. Suppose Mary picks up her sword and begins to attack the whole Roman army. She kills a few soldiers and then is cut down. Consider (26):

(26) Mary was wiping out the Roman army.

According to the semantics described above, (26) ought to be true. Whichever soldier actually killed Mary might not have, and so the continuation branch should move to a world in which he didn't. There some soldier kills Mary but might not have, so . . . Through a series of counterfactual shifts, the continuation branch of Mary's attack will eventually reach a world in which she wipes out the whole army. Landman assumes that (26) ought not be true in the situation envisioned. The problem, he suggests, is that the worlds in which Mary kills a large proportion of the Roman army, while possible, are outlandishly unreasonable. He therefore declares that only ‘reasonable worlds’ may enter the continuation branch.

Landman's analysis of the progressive is the most empirically successful optimistic theory. Its major weaknesses are its reliance on two undefined terms: *stage* and *reasonable*. The former takes part in the definition of when an event stops, and so moves the continuation branch to another world. How do we know with (as) the event John was engaged in didn't end when he

died? Lots of eventualities did end there; we wouldn't want to have *John was living to be 65* to be true simply because he would probably have lived that long if it weren't for the accident. We know that the construction event didn't end because we know it was supposed to be a house-building. Thus, Landman's theory requires a primitive understanding of when an event is complete, ending in a given world, and when it is not complete and so may continue on in another world. In this way, it seems to recast in an intensional theory Parsons' distinction between holding and culminating. The need for a primitive concept of reasonableness of worlds is perhaps less troubling, since it could perhaps be assimilated to possible worlds analyses of epistemic modality; still, it must count as a theoretical liability.

Finally, we note that Landman's theory gives the progressive a kind of interpretation quite different from any other modal or temporal operator. In particular, since it is nothing like the semantics of the perfect, the other aspect we will consider, one wonders why the two should be considered members of a common category. (The same might be said for Dowty's theory, though his at least resembles the semantics for modalities.)

The Perfect. Nearly every contemporary writer has abandoned Montague's position that the present perfect is a completely indefinite past. The current view (e.g. [McCoard, 1978; Richards, 1982; Mittwoch, 1988]) seems to be that the time to which it refers (or the range of times to which it might refer) must be an *Extended Now*, an interval of time that begins in the past and includes the moment of utterance. The event described must fall somewhere within this interval. This is plausible. When we say *Pete has bought a pair of shoes* we normally do not mean just that a purchase was made at some time in the past. Rather we understand that the purchase was made recently. The view also is strongly supported by the observation that the present perfect can always take temporal modifiers that pick out intervals overlapping the present and never take those that pick out intervals entirely preceding the present: *Mary has bought a dress since Saturday*, but not **Mary has bought a dress last week*. These facts can be explained if the adverbials are constrained to have scope over the perfect, so that they would have to describe an extended now.

There is debate, however, about whether the extended now theory should incorporate two or even three readings for the perfect. The uncontroversial analysis, that suggested above, locates an event somewhere within the extended now. This has been called the *existential use*. Others have argued that there is a separate *universal* or *continuative use*. Consider the following, based on some examples of Mittwoch:

- (27) Sam has lived in Boston since 1980.

This sentence is compatible with Sam's still living in Boston, or with his having come, stayed for a while, and then left. Both situations are com-

patible with the following analysis: the extended now begins in 1980, and somewhere within this interval Sam lives in Boston. However, supporters of the universal use (e.g. [McCawley, 1971; Mittwoch, 1988; Michaelis, 1994]) argue that there is a separate reading which requires that Sam's residence in Boston continue at the speech time: (27) is true iff Sam lives in Boston throughout the whole extended now which begins in 1980.

Michaelis argues that the perfect has a third reading, the *resultative use*. A resultative present perfect implies that there is a currently existing result state of the event alluded to in the sentence. For example, *John has eaten poison* could be used to explain the fact that John is sick. Others (McCawley [1971], Klein [1994]) argue that such cases should be considered examples of the existential use, with the feeling that the result is especially important being a pragmatic effect. At the least one may doubt analyses in terms of result state on the grounds that precisely which result is to be focused on is never adequately defined. Any event will bring about some new state, if only the state of the event having occurred, and most will bring about many. So it is not clear how this use would differ in its truth conditions from the existential one.

Stump argues against the Extended Now theory on the basis of the occurrence of perfects in nonfinite contexts like the following (his Chapter IV, (11); cf. McCoard, Klein, Richards who note similar data):

- (28) Having been on the train yesterday, John knows exactly why it derailed.

Stump provides an analysis of the perfect which simply requires that no part of the event described be located after the evaluation time. In a present perfect sentence, this means that the event can be past or present, but not future. Stump then explains the ungrammaticality of **Mary has bought a dress last week* in pragmatic terms. This sentence, according to Stump, is truth conditionally equivalent to *Mary bought a dress last week*. Since the latter is simpler and less marked in linguistic terms, the use of the perfect should implicate that the simple past is inappropriate. But since the two are synonymous, it cannot be inappropriate. Therefore, the present perfect with a definite past adverbial has an implicature which can never be true. This is why it cannot be used (cf. Klein [1992] for a similar explanation).

Klein [1992; 1994] develops a somewhat different analysis of perfect aspect from those based on interval semantics. He concentrates on the relevance of the aspectual classification of sentences for understanding different 'uses' of the perfect. He distinguishes *0-state*, *1-state*, and *2-state* clauses: A 0-state clause describes an unchanging state of affairs (*The Nile is in Africa*); a 1-state sentence describes a state which obtains at some interval while not obtaining at adjoining intervals (*Peter was asleep*); and a 2-state clause denotes a change from one lexically determined state to another (*John opened*

the window). Here, the first state (the window's being closed) is called the *source state*, and the second (the window's being open) the *target state*. He calls the maximal intervals which precede and follow the interval at which a state holds its *pretime* and *posttime* respectively.

Given this framework, Klein claims that all uses of the perfect can be analyzed as the reference time falling into the posttime of the most salient situation described by the clause. Since the states described by 0-state sentences have no posttime, the perfect is impossible (**The Nile has been in Africa*). With 1-state sentences, the reference time will simply follow the state in question, so that *Peter has been asleep* will simply indicate that Peter has at some point slept ('experiential perfect'). With 2-state sentences, Klein stipulates that the salient state is the source state, so that *John has opened the window* literally only indicates that the reference time (which in this case corresponds to the utterance time) follows a state of the window being closed which itself precedes a state of the window being open. It may happen that the reference time falls into the target state, in which case the window must still be open ('perfect of result'); alternatively, the reference time may follow the target state as well—i.e. it may be a time after which the window has closed again—giving rise to another kind of experiential perfect.

One type of case which is difficult for Klein is what he describes as the 'perfect of persistent situation', as in *We've lived here for ten years*. This is the type of sentence which motivated the universal/continuative semantics within the Extended Now theory. In Klein's terms, here it seems that the reference time, the present, falls into the state described by a 1-state sentence, and not its posttime. Klein's solution is to suggest that the sentence describes a state which is a substate of the whole living-here state, one which comprises just the first ten years of our residency, a 'living-here-for-ten-years' state. The example indicates that we are in the posttime of this state, a fact which does not rule out that we're now into our eleventh year of living here. On the other hand, such an explanation does not seem applicable to other examples, such as *We've lived here since 1966*.

Existence presuppositions. Jespersen's observation that the present perfect seems to presuppose the present existence of the subject in cases where the past tense does not has been repeated and 'explained' many times. We are now faced with the embarrassment of a puzzle with too many solutions. The contemporary discussion begins with Chomsky, who argues that *Princeton has been visited by Einstein* is all right, but *Einstein has visited Princeton* is odd. James McCawley points out that the alleged oddity of the latter sentence actually depends on context and intonation. Where the existence presupposition does occur, McCawley attributes it to the fact that the present perfect is generally used when the present moment is included in an interval during which events of the kind being described *can* be true.

Thus, *Have you seen the Monet exhibition?* is inappropriate if the addressee is known to be unable to see it. (*Did you* is appropriate in this case.) *Frege has contributed a lot to my thinking* is appropriate to use even though Frege is dead because Frege *can* now contribute to my thinking. *My mother has changed my diapers many times* is appropriate for a talking two year old, but not for a normal thirty year old. *Einstein has visited Princeton* is odd because Einsteinian visits are no longer possible. *Princeton has been visited by Einstein* is acceptable because Princeton's being visited *is* still possible.

In Kuhn [1983] it is suggested that the explanation may be partly syntactic. Existence presuppositions can be canceled when a term occurs in the scope of certain operators. Thus *Santa is fat* presupposes that Santa exists, but *According to Virginia, Santa is fat* does not. There are good reasons to believe that past and future apply to sentences, whereas perfect applies only to intransitive verb phrases. But in that case it is natural that presuppositions concerning the subject that do hold in present perfect sentences fail in past and future sentences.

Guenther requires that at least one of the objects referred to in a present perfect sentence (viz., the topic of the sentence) must exist at utterance time. Often, of course, the subject will be the topic.

The explanation given by Tichý is that, in the absence of an explicit indication of reference time, a present perfect generally refers to the lifetime of its subject. If this does not include the present, then the perfect is inappropriate.

Overall, the question of whether these explanations are compatible, and whether they are equally explanatory, remains open.

3.4.3 Tense in Subordinate Clauses

The focus in all of the preceding discussion has been on occurrences of tense in simple sentences. A variety of complexities arise when one tries to accommodate tense in subordinate clauses. Of particular concern is the phenomenon known as *Sequence of Tense*. Consider the following:

(29) John believed that Mary left.

(30) John believed that Mary was pregnant.

Example (29) says that at some past time t John had a belief that at some time $t' < t$, Mary left. This reading is easily accounted for by a classic Priorean analysis: the time of evaluation is shifted into the past by the first tense operator, and then shifted further back by the second. (30), which differs from (29) in having a stative subordinate clause, has a similar reading, but has another as well, the so-called 'simultaneous reading', on which the time of Mary's alleged pregnancy overlaps with the time of John's belief. It would seem that the tense on *was* is not semantically active. A

traditional way of looking at things is to think of the tense form of *was* as triggered by the past tense of *believed* by a morphosyntactic sequence of tense (SOT) rule. Following Oghihara [1989; 1995], we could formalize this idea by saying that a past tense in a subordinate clause governed by another past tense verb is deleted prior to the sentence's being interpreted. For semantic purposes, (30) would then be *John believed that Mary be (tenseless) pregnant*. Not every language has the SOT rule. In Japanese, for example, the simultaneous reading of (30) would be expressed with present tense in the subordinate clause.

The SOT theory does not explain why simultaneous readings are possible with some clauses and not with others. The key distinction seems to be between states and non-states. One would hope to be able to relate the existence of simultaneous readings to the other characteristic properties of statives discussed in Section 3.4.1 above.

Sentences like (31) pose special problems. One might expect for it to be equivalent to either (30), on the simultaneous reading, or (32).

(31) John believed that Mary is pregnant.

(32) John believed that Mary would now be pregnant.

A simultaneous interpretation would be predicted by a Priorian account, while synonymy with (32) would be expected by a theory which said that present tense means 'at the speech time'. However, as pointed out by Enç [1987], (31) has a different, problematical interpretation; it seemingly requires that the time of Mary's alleged pregnancy extend from the belief time up until the speech time. She labels this the *Double Access Reading* (DAR). Recent theories of SOT, in particular those of Oghihara [1989; 1995] and Abusch [1991; 1995], have been especially concerned with getting a correct account of such 'present under past' sentences.

Enç's analysis of tense in intensional contexts begins with the proposal that tense is a referential expression. She suggests that the simultaneous interpretation of (30) should be obtained through a 'binding' relationship between the two tenses, indicated by coindexing as in (33). The connection is similar to that holding with nominal anaphora, as in (34).

(33) John PAST₁ believed that Mary PAST₁ was pregnant.

(34) John₁ thinks that he₁ is smart.

This point of view lets Enç say that both tense morphemes have a usual interpretation. Her mechanisms entail that all members of a sequence of coindexed tense morphemes denote the same time, and that each establishes the same temporal relationship as the highest ('first') occurrence. Oghihara elucidates the intended interpretation of structures like (33) by translating them into Intensional Logic.

$$(35) \quad t_1 < s^* \& \text{believe}'(t_1, j, ^\wedge [t_1 < s^* \wedge \text{be-pregnant}(t_1, m)]).$$

Here s^* denotes the speech time. If the two tenses were not coindexed, as in (36), the second would introduce $t_2 < t_1$ to the translation:

$$(36) \quad \text{John PAST}_1 \text{ believed that Mary PAST}_2 \text{ was pregnant.}$$

$$(37) \quad t_1 < s^* \& \text{believe}'(t_1, j, ^\wedge [t_2 < t_1 \wedge \text{be-pregnant}(t_2, m)]).$$

This represents the non-simultaneous ('shifted') reading.

Accounting for the DAR is more complex. Enç proposes that there need to be two ways that temporal expressions may be linked. Expressions receive pairs of indices, so that with a configuration $A\langle i, j \rangle \dots B\langle k, l \rangle$, if $i = k$, then A and B refer to the same time, while if $j = l$, then the time if B is included in that of A . The complement clause *that Mary is pregnant* is then interpreted outside the scope of the past tense. The present tense is linked to the speech time. As usual, however, the two tenses may be coindexed, but only via their second indices. This gives us something like (38).

$$(38) \quad \exists x(x = [\text{Mary PRES}_{\langle 0,1 \rangle} \text{ be pregnant}] \text{ John PAST}_{\langle 2,1 \rangle} \text{ believes } x).$$

This representation says that Mary is pregnant at the speech time and that the time of John's belief is a subinterval of Mary's pregnancy. Thus it encodes the DAR.

The mechanisms involved in deriving and interpreting (38) are quite complicated. In addition, examples discussed by Abusch [1988], Baker [1989] and Ogihara [1995] pose a serious difficulty for Enç's view.

$$(39) \quad \text{John decided a week ago that in ten days at breakfast he would say to his mother that they were having their last meal together.}$$

Here, on the natural interpretation of the sentence, the past tense of *were* does not denote a time which is past with respect to either the speech time or any other time mentioned in the sentence. Thus it seems that the tense component of this expression cannot be semantically active.

As mentioned above, Ogihara proposes that a past tense in the right relation with another past tense may be deleted from a sentence prior to semantic interpretation. (Abusch has a more complex view involving feature passing, but it gets similar effects.) This would transform (39) into (40).

$$(40) \quad \text{John PAST decided a week ago that in ten days at breakfast he } \emptyset \text{ woll say to his mother that they } \emptyset \text{ be having their last meal together.}$$

Notice that we have two deleted tenses (marked ‘ \emptyset ’) here. *Would* has become tenseless *woll*, a future operator evaluated with respect to the time of the deciding. Then breakfast time ten days after the decision serves as the time of evaluation for *he say to his mother that they be having their last meal together*. Since there are no temporal operators in this constituent, the time of the saying and that of the last meal are simultaneous.

The double access sentence (31) is more difficult story. Both Ogihara and Abusch propose that the DAR is actually a case of *de re* interpretation, similar to the famous Orcutt examples of Quine [1956]. Consider example (31), repeated here:

(31) John believed that Mary is pregnant.

Suppose John has glimpsed Mary two months ago, noticing that she is quite large. At that time he thought ‘Mary is pregnant’. Now you and I are considering why Mary is so large, and I report John’s opinion to you with (31). The sentence could be paraphrased by *John believed of the state of Mary’s being large that it is a state of her being pregnant*. (Abusch would frame this analysis in terms of a *de re* belief about an interval, rather than a state, but the difference between these two formulations appears slight.) Both Ogihara and Abusch give their account in terms of the analysis of *de re* belief put forward by Lewis [1979] and extended by Cresswell and von Stechow [1982]. These amount to saying that (31) is true iff the following conditions are met: (i) John stands in a suitable *acquaintance relation* *R* to a state of Mary’s (such as her being large), in this case the relation of having glimpsed it on a certain occasion, and (ii) in all of John’s belief-worlds, the state to which he stands in relation *R* is a state of Mary being pregnant.

A *de re* analysis of present under past sentences may hope to give an account of the DAR. Suppose we have an analysis of tense whereby the present tense in (31) entails that the state in question holds at the speech time. Add to this the fact that the acquaintance relation, that John had glimpsed this state at the time he formed his belief, entails that the state existed already at that time. Together these two points require that the state stretch from the time of John’s belief up until the speech time. This is the DAR.

The preceding account relies on the acquaintance relation to entail that the state have existed already at the past time. The idea that it would do so is natural in light of Lewis’ suggestion that the relation must be a causal one: in this case that John’s belief has been caused, directly or indirectly, by the state. However, as Abusch [1995] points out, there is a problem with this assumption: it sometimes seems possible to have a future-oriented acquaintance relation. Consider Abusch’s example (41) (originally due to Andrea Bonomi).

- (41) Leo will go to Rome on the day of Lea's dissertation. Lia believes that she will go to Rome with him then.

Here, according to Abusch, we seem to have a *de re* attitude by Lia towards the future day of Lea's dissertation. Since the acquaintance relation cannot be counted on to require in (31) that the time of Mary's being large overlaps the time when John formed his belief, both Abusch and Ogihara have had to introduce extra stipulations to serve this end. But at this point the explanatory force of appealing to a *de re* attitude is less clear.

There are further reasons to doubt the *de re* account, at least in the form presented. Suppose that we're wondering whether the explanation for Mary's appearance is that she's pregnant. John has not seen Mary at all, but some months ago her mother told John that she is, he believed her, and he reported on this belief to me. It seems that I could say (31) as evidence that Mary is indeed pregnant. In such a case it seems that the sentence is about the state *we're* concerned with, not one which provided John's evidence.

3.4.4 *Tense and discourse*

One of the major contributions of DRT to the study of tense is its focus on 'discourse' as the unit of analysis rather than the sentence. Sentential analyses treat reference times as either completely indeterminate or given by context. In fact the 'context' that determines the time a sentence refers to may just be the sentences that were uttered previously. Theorists working within DRT have sought to provide a detailed understanding of how the reference time of a sentence may depend on the tenses of the sentence and its predecessors.

As mentioned above, DRS's will include events, states, and times as objects in the universe of discourse and will specify relations of precedence and overlap among them. Precisely which relations hold depends on the nature of the eventualities being described. The key distinction here is between 'atelic' eventualities (which include both states and processes) and 'telic' ones. Various similar algorithms for constructing DRS's are given by Kamp, Kamp and Rohrer, Hinrichs, and Partee, among others. Let us consider the following pair of examples:

- (42) Mary was eating a sandwich. Pedro entered the kitchen.

- (43) Pedro went into the hall. He took off his coat.

In (42), the first sentence describes an atelic eventuality, a process, whereas the second describes a telic event. The process is naturally taken to temporally contain the event. In contrast, in (43) both sentences describe telic events, and the resulting discourse indicates that the two happened in sequence.

A DRS construction procedure for these two could work as follows: With both the context provides an initial past reference time r_0 . Whenever a past tense sentence is uttered, it is taken to temporally coincide with the past reference time. A telic sentence introduces a new reference time that follows the one used by the sentence, while an atelic one leaves the reference time unchanged. So, in (42), the same reference time is used for both sentences, implying temporal overlap, while in (43) each sentence has its own reference time, with that for the second sentence following that for the first.

Dowty [1986a] presents a serious critique of the DRT analysis of these phenomena. He points out that whether a sentence describes a telic or atelic eventuality is determined by compositional semantics, and cannot be read off of the surface form in any direct way. He illustrates with the pair (44)–(45).

(44) John walked. (activity)

(45) John walked to the station. (accomplishment)

Other pairs are even more syntactically similar (*John baked a cake* vs. *John baked cakes*.) This consideration is problematical for DRT because that theory takes the unit of interpretation to be the entire DRS. A complete DRS cannot be constructed until individual sentences are interpreted, since it must be determined whether sentences describe telic or atelic eventualities before relations of precedence and overlap are specified. But the sentences cannot be interpreted until the DRS is complete.

Dowty proposes that the temporal sequencing facts studied by DRT can be accommodated more adequately within interval semantics augmented by healthy amounts of Gricean implicature and common-sense reasoning. First of all, individual sentences are compositionally interpreted within a Montague Grammar-type framework. Dowty [1979] has shown how differences among states, processes, and telic events can be defined in terms of their temporal properties within interval semantics. (For example, as mentioned above, A is a stative sentence iff, if A is true at interval I , then A is true at all moments within I .) The temporal relations among sentence are specified by a single, homogeneous principle, the *Temporal Discourse Interpretation Principle* (TDIP), which states:

- (46) **TDIP** Given a sequence of sentences S_1, S_2, \dots, S_n to be interpreted as a narrative discourse, the reference time of each sentence S_i (for i such that $1 < i \leq n$) is interpreted to be:
- (a) a time consistent with the definite time adverbials in S_i , if there are any;
 - (b) otherwise, a time which immediately follows the reference time of the previous sentence S_{i-1} .

Part (b) is the novel part of this proposal. It gives the same results as DRT in all-telic discourses like (43), but seems to run into trouble with atelic sentences like the one in (42). Dowty proposes that (42) really does describe a sequence of a process or state of Mary eating a sandwich followed by an event of Pedro entering the kitchen; this is the literal contribution of the example (Nerbonne [1986] makes a similar proposal.) However, common sense reasoning allows one to realize that a process of eating a sandwich generally takes some time, and so the time at which Mary was actually eating a sandwich might have started some time before the reference time and might continue for some time afterwards. Thus (42) is perfectly consistent with Mary continuing to eat the sandwich while Pedro entered the kitchen. In fact, Dowty would suggest, in normal situations this is just what someone hearing (42) would be likely to conclude.

Dowty's analysis has an advantage in being able to explain examples of inceptive readings of atelic sentences like *John went over the day's perplexing events once more in his mind. Suddenly, he was fast asleep. Suddenly* tells us that the state of being asleep is new. World knowledge tells us that he could not have gone over the days events in his mind if he were asleep. Thus the state must begin after the event of going over the perplexing events in his mind. DRT would have a more difficult time with this example; it would have to propose that *be asleep* is ambiguous between an atelic (state) reading and a telic (achievement) reading, or that the word *suddenly* cancels the usual rule for atelics.

As Dowty then goes on to discuss, there are a great many examples of discourses in which the temporal relations among sentences do not follow the neat pattern described by the DRT algorithms and the TDIP. Consider:

- (47) Mary did the dishes carefully. She filled the sink with hot water. She added a half cup of soap. Then she gently dipped each glass into the sudsy liquid.

Here all of the sentences after the first one describe events which comprise the dish-washing. To explain such examples, an adherent of DRT must propose additional DRS construction procedures. Furthermore, there exists the problem of knowing which procedures to apply; one would need rules to determine which construction procedures apply before the sentences within the discourse are interpreted, and it is not clear whether such rules can be formulated in a way that doesn't require prior interpretation of the sentences involved. Dowty's interval semantics framework, on the other hand, would say that the relations among the sentences here are determined pragmatically, overriding the TDIP. The weakness of this approach is its reliance on an undeveloped pragmatic theory.

4 TENSE LOGICS FOR NATURAL LANGUAGE

4.1 *Motivations*

General surveys of tense logic are contained elsewhere in this Handbook (Burgess, Finger, Gabbay and Reynolds, and Thomason, all in this Volume). In this section we consider relations between tense logic and tense and aspect in natural language. Work on tense logic, even among authors concerned with linguistic matters, has been motivated by a variety of considerations that have not always been clearly delineated. Initially, tense logic seems to have been conceived as a generalization of classical logic that could better represent logical forms of arguments and sentences in which tense plays an important semantic role. To treat such items within classical logic requires extensive ‘paraphrase’. Consider the following example from Quine [1982]:

- (48) George *V* married Queen Mary, Queen Mary is a widow, therefore George *V* married a widow.

An attempt to represent this directly in classical predicate logic might yield

$$(48a) \quad Mgm, Wm \vDash \exists x(Mgx \wedge Wx),$$

which fallaciously represents it as valid. When appropriately paraphrased, however, the argument becomes something like:

- (49) Some time before the present is a time when George *V* married Queen Mary, Queen Mary is a widow at the present time, therefore some time before the present is a time at which George *V* married a widow,

which, in classical logic, is represented by the nonvalid:

$$(49a) \quad \exists t(Tt \wedge Btn \wedge Mgmt), Wmn \vDash \exists t(Tt \wedge Btn \wedge \exists x(Wxn \wedge Mgmt)).$$

If we want a logic that can easily be *applied* to ordinary discourse, however, such extensive and unsystematized paraphrase may be unsatisfying. Arthur Prior formulated several logical systems in which arguments like (48) could be represented more directly and, in a series of papers and books in the fifties and sixties, championed, chronicled and contributed to their development. (See especially [Prior, 1957; Prior, 1967] and [Prior, 1968].) A sentence like *Queen Mary is a widow* is not to be represented by a formula that explicitly displays the name of a particular time and that is interpreted simply as *true* or *false*. Instead it is represented as *Wm*, just as in (48), where such formulas are now understood to be true or false only relative to a time. Past

and future sentences are represented with the help of *tense logical operators* like those mentioned in previous sections. In particular, most of Prior's systems contained the past and future operators with truth conditions:

$$(50) \quad t \models \mathcal{P}A \text{ if and only if } \exists s(s < t \ \& \ s \models A)$$

$$t \models \mathcal{F}A \text{ if and only if } \exists s(t < s \ \& \ s \models A)$$

(where $t \models A$ means A is true at time t and $s < t$ means time s is before time t). This allows (48) to be represented:

$$(48b) \quad \mathcal{P}Mgm, Wm \models \mathcal{P}\exists x(Mgx \wedge Wx).$$

Quine himself thought that a logic to help prevent us misrepresenting (48) as (48a) would be 'needlessly elaborate'. 'We do better,' he says, 'to make do with a simpler logical machine, and then, when we want to apply it, to paraphrase our sentences to fit it.' In this instance, Quine's attitude seems too rigid. The advantages of the simpler machine must be balanced against a more complicated paraphrase and representation. While (49a) may represent the form of (49), it does not seem to represent the form of (48) as well as (48b) does. But if our motivation for constructing new tense logics is to still better represent the logical forms of arguments and sentences of natural language, we should be mindful of Quine's worries about their being needlessly elaborate. We would not expect a logical representation to capture all the nuances of a particular tense construction in a particular language. We would expect a certain economy in logical vocabulary and rules of inference.

Motivations for many new systems of tense logic may be seen as more semantical than logical. A semantics should determine, for any declarative sentence S , context C , and possible world w , whether the thought expressed when S is uttered in C is true of w . As noted in previous sections, the truth conditions associated with Prior's \mathcal{P} and \mathcal{F} do not correspond very closely to those of English tenses. New systems of tense logic attempt to forge a closer correspondence. This might be done with the view that the tense logic would become a convenient *intermediary* between sentences of natural language and their truth conditions. That role was played by tensed intensional logic in Montague's semantics. An algorithm translates English sentences into formulas of that system and an inductive definition specifies truth conditions for the formulas. As noted above, Montague's appropriation of the Priorean connectives into his intensional logic make for a crude treatment of tense, but refined systems might serve better. Specifications of truth conditions for the tensed intensional logic (and, more blatantly for the refined tense logics), often seem to use a first order theory of temporal precedence (or containment, overlap, etc.) as yet another intermediary. (Consider clauses (50) above, for example.) One may wonder, then, whether it wouldn't be

better to skip the first intermediary and translate English sentences directly into such a first order theory. Certainly the most perspicuous way to give the meaning of a particular English sentence is often to ‘translate’ it by a formula in the language of the first order theory of temporal precedence, and this consideration may play a role in some of the complaints against tense logics found, for example, in [van Benthem, 1977] and [Massey, 1969]. Presumably, however, a *general* translation procedure could be simplified by taking an appropriate tense logic as the target language.

There is also another way to understand the attempt to forge a closer correspondence between tense logical connectives and the tense constructions of natural language. We may view tense logics as ‘toy’ languages, which, by isolating and idealizing certain features of natural language, help us to understand them. On this view, the tense logician builds models or simulations of features of language, rather than parts of linguistic theories. This view is plausible for, say Kamp’s logic for ‘now’ and Galton’s logic of aspect (see below), but it is difficult to maintain for more elaborate tense logics containing many operators to which no natural language expressions correspond.

Systems of tense logic are sometimes defended against classical first order alternatives on the grounds that they don’t commit language users to an ontology of temporal moments, since they don’t explicitly quantify over times. This defense seems misguided on several counts. First, English speakers do seem to believe in such an ontology of moments, as can be seen from their use of locutions like ‘at three o’clock sharp’. Second, it’s not clear what kind of ‘commitment’ is entailed by the observation that the language one uses quantifies over objects of a certain kind. Quine’s famous dictum, ‘to be is to be the value of a bound variable,’ was not intended to express the view that we are committed to what we quantify over in ordinary language, but rather that we are committed to what our best scientific theories quantify over, when these are cast in first order logic. There may be some weaker sense in which, by speaking English, we may be committing ourselves to the existence of entities like chances, sakes, average men and arbitrary numbers, even though we may not believe in these objects in any ultimate metaphysical sense. Perhaps we should say that *the language* is committed to such objects. (See Bach [1981].) But surely the proper test for this notion is simply whether the best interpretation of our language requires these objects: ‘to be is to be an element of a model.’ And, whether we employ tense logics or first order theories, our best models do contain (point-like and/or extended) times. Finally, even if one were sympathetic to the idea that the weaker notion of commitment was revealed by the range of first order quantifiers, there is reason to be suspicious of claims that a logic that properly models any substantial set of the temporal features of English would have fewer ontological commitments than a first order theory of temporal precedence. For, as Cresswell has argued in detail [1990; 1996],

the languages of such logics turn out to be equivalent in expressive power to the language of the first order theories. One might reasonably suppose in this case that the ontological commitments of the modal language should be determined by the range of the quantifiers of its first order equivalent. As discussed in Section 3.1, then, the proper defense of tense logic's replacement of quantifiers by operators is linguistic rather than metaphysical.

4.2 Interval based logics

One of the most salient differences between the traditional tense logical systems and natural language is that all the formulas of the former are evaluated at instants of time, whereas at least some of the sentences of the latter seem to describe what happens at extended temporal periods. We are accustomed to thinking of such periods as comprising continuous stretches of instants, but it has been suggested, at least since Russell, that extended periods are the real objects of experience, and instants are abstractions from them. Various recipes for constructing instants from periods are contained in Russell [1914], van Benthem [1991], Thomason [1984; 1989] and Burgess [1984]. Temporal relations among intervals are more diverse than those among instants, and it is not clear which of these relations should be taken as primitive for an interval based tense logic. Figure 4.2 shows 13 possible relations that an interval A can bear to the fixed interval B .

We can think of $<$ and $>$ as precedence and succession, \ll and \gg as immediate precedence and succession and \subset , \supset , and \circ as inclusion, containment and overlap. The subscripts l and r are for 'left' and 'right'. Under reasonable understandings of these notions and reasonable assumptions about the structure of time, these can all be defined in elementary logic from precedence and inclusion. For example, $A \ll B$ can be defined by $A < B \wedge \neg \exists x(A < x \wedge x < B)$, and $A \circ_l B$ by $\exists x(x \subset A \wedge x < B) \wedge (\exists x)(x \subset A \wedge x \subset B) \wedge \exists x(x \subset A \wedge x > B)$. It does not follow, however, that a tense operator based on any of these relations can be defined from operators based on $<$ and \subset . Just as instant based tense logics include both \mathcal{P} and \mathcal{F} despite the fact that $>$ is elementarily definable from $<$, we may wish to include operators based on a variety of the relations above in an interval based tense logic. For each of the relations R listed in the above chart, let $[R]$ and $\langle R \rangle$ be the box and diamond operators defined with R as the accessibility relation. (We are presupposing some acquaintance with the Kripke semantics for modal logics here. See Bull and Segerberg in this *Handbook* for background.) Then $\langle < \rangle$ and $\langle > \rangle$ are interval analogs of Prior's \mathcal{P} and \mathcal{F} , and $\langle \subset \rangle$ is a connective that Dana Scott suggested as a rough analog of the progressive. Halpern and Shoham [1986] (and Shoham [1988]) point out that if we take the three converse pairs $[\ll]$ and $[\gg]$, $[\subset_l]$ and $[\supset_l]$ and $[\subset_r]$ and $[\supset_r]$ as primitive we can give simple definitions of the connectives associated with the remaining relations:

Figure 2.

$$[<] = [\ll] [\ll] \quad [>] = [\gg] [\gg]$$

$$[\supset] = [\supset_l] [\supset_r] \quad [\subset] = [\subset_l] [\subset_r]$$

$$[\circ_l] = [\supset_l] [\subset_r] \quad [\circ_r] = [\supset_r] [\subset_l]$$

If it is assumed that intervals always contain durationless atoms, i.e., subintervals s such that $\neg \exists t(t \subset s)$, then Venema shows that we can do better. For then $[\supset_l] \perp$ and $[\supset_r] \perp$ will be true only at atoms, and there are formulas $[l]A = (A \wedge [\supset_l] \perp) \vee \langle \supset_l \rangle (A \wedge [\supset_l] \perp)$ and $[r]A = (A \wedge [\supset_l] \perp) \vee \langle \supset_r \rangle (A \wedge [\supset_l] \perp)$ saying that A is true at the left and right ‘endpoints’ of an interval. $[\ll]$ and $[\gg]$ can now be defined by $[r][\subset_l]$ and $[l][\subset_r]$. (The assumption that there are durationless ‘intervals’ undercuts the idea that instants are mere abstractions, but it seems appropriate for linguistic applications of tense logic, since language users do, at some level, presume the existence of both intervals and instants.)

Call the tense-logical language with operators $[\subset_l]$, $[\supset_l]$, $[\subset_r]$ and $[\supset_r]$, HSV in honor of its inventors. Since HSV can so easily express all the relations on the table above, one might expect it to be sufficient to express any temporal relations that common constructions in natural language do. As Venema shows, however, there are limitations to its expressive power. Consider the binary connective \wedge^* such that $(s, t) \models (A \wedge^* B)$ iff, for some $r, s < r < t$, $(s, r) \models A$ and $(r, t) \models B$. Lloyd Humberstone argues that \wedge^* is the tense logical connective that properly expresses temporal conjunction, i.e., *and* in the sense of *and next*. But no formula in HSV can express \wedge^* . Further, as Venema shows, there is a sense in which this expressive poverty is unavoidable in interval logics. Call a model $M = (I, \subset_l, \subset_r, \supset_l, \supset_r, V)$ for HSV ‘instant generated’ if there is some nonempty set T ordered by $<$ such that I is the set of all $(x, y) \in (T \times T)$ for which $x \leq y$, and $\subset_l, \subset_r, \supset_l$ and \supset_r are the appropriate relations on I . (For example $(r, s) \supset_l (u, v)$ iff $u = r$ and $s > v$.) Instant generated HSV-models, then, are models in which formulas are evaluated at pairs of indices, i.e., they are two-dimensional models. The truth conditions for the connectives determine a translation that maps formulas of HSV to ‘equivalent’ formulas in predicate logic with free variables r and s . Similar translations could be obtained for any language in which the truth conditions of the connectives can be expressed in elementary logic. Venema shows, however, that for no finite set of connectives will this translation include in its range every formula with variable r and s . This result holds even when the equivalent formulas are required to agree only on models for which the instants form a dense linear order. This contrasts with a fundamental result in instant-based tense logics, that for dense linear orders, the two connectives ‘since’ and ‘until’ are sufficient to express everything that can be said in elementary logic with one free variable. (See Burgess [2001]).

Several authors have suggested that in tense logics appropriate for natural language there should be constraints on the set of intervals at which a formula can be true. The set $\|A\|_M$ of indices at which formula A is true in model M is often called the truth set of A . Humberstone requires that valuations be restricted so that truth sets of sentence letters be closed under containment. That ‘downward closure’ property seems natural for stative sentences (see Section 3.4.2). The truth of *The cat is on the mat* at the interval from two to two to two thirty apparently entails its truth at the interval from two ten to two twenty. But downward closure is not preserved under ordinary logical negation. If *The cat is on the mat* is true at (2:00,2:30) and all its subintervals, but not at (1:30, 3:00) then $\neg(\textit{the cat is on the mat})$ is true at (1:30,3:00) but not all of its subintervals. Humberstone suggests a stronger form of negation, which we might call $[\neg]$. $[\neg]A$ is true at interval i if A is false at all subintervals of i . Such a negation may occur in one reading of *The cat isn't on the mat*. It can also be used to express a more purely tense logical connective: $[\supset]$ can be defined as $[\neg][\neg]$. We obtain a reasonable tense logic by adding the standard past and future connectives $\langle \rangle$ and $\langle \rangle$.

Statives also seem to obey an upward closure constraint. If A is true in each of some sequence of adjoining or overlapping intervals, it is also true in the ‘sum’ of those intervals. Peter Röper observes that, in the presence of downward closure, upwards closure is equivalent to the condition that A is true in i if it is true ‘almost everywhere’ in i , i.e., if every subinterval of i contains a subinterval at which A is true. (See Burgess [1982a] for an interesting list of other equivalents of this and related notions.) Following Röper, we may call a truth set homogeneous if it satisfies both upwards and downwards closure. Humberstone’s strong negation preserves homogeneity, but the tense connectives $\langle \rangle$ and $\langle \rangle$ do not. For suppose the temporal intervals are the open intervals of some densely ordered set of instants, and A is true only at (s, t) and its subintervals. Then the truth set of A is homogeneous. But every proper subinterval of (s, t) verifies $\langle \rangle A$, and so every subinterval of (s, t) contains a subinterval that verifies the formula, whereas (s, t) itself does not verify the formula, and so the truth set of $\langle \rangle A$ is not homogeneous. To ensure that homogeneity is preserved, Röper replaces the standard truth conditions for the future operator by a condition stating that $\langle \rangle A$ is true at i if every subinterval of i contains a subinterval i' such that A is true at some $w > i'$. The past operator is similarly altered. This ensures that all formulas have homogeneous truth sets and the resulting system admits a simple axiomatization. One may wonder whether the future and past tenses of statives really are themselves statives in natural language, and thus whether homogeneity really ought to be preserved. But if one is thoroughgoing (as Humberstone and Röper seem to be, but Venema does not), about the attitude that (extended) intervals are the genuine temporal objects, then it does seem reasonable to suppose that for stative A , $A \rightarrow$

$\langle \rangle A$ and $A \rightarrow \langle \rangle A$ are logical truths. If the cat is on the mat, then, if one looks sufficiently close to the present, it will be on the mat, and if one looks sufficiently close in the other direction, it was on the mat. For otherwise we would have to believe that the present was the instant at which it came or left. Indeed, the ‘present implies past’ property was cited by Aristotle (in *Metaphysics IX*) as a distinguishing feature of ‘energaie,’ a category that surely includes the statives. The formulas $A \rightarrow \langle \rangle A$ and $A \rightarrow \langle \rangle A$ are not theorems of HSV or standard tense logics unless \langle is reflexive, but they are theorems of Röper’s homogeneous interval tense logic.

4.3 ‘Now’, ‘then’, and keeping track of times

Another way in which natural language differs from Priorean tense logics is its facility in conveying that the eventualities described in various scattered clauses of a sentence obtain simultaneously. Consider first an example in which exterior and interior clauses describe what obtains at the moment of utterance.

(51) This is 1996 and one day everyone now alive will be dead.

If we represent this as $P \wedge \forall x(Lx \rightarrow \mathcal{F}Dx)$, we fail to imply that those alive today will all be dead at a common future moment. If we pull the future operator outside the quantifier, we get $P \wedge \mathcal{F}\forall x(Lx \rightarrow Dx)$, which wrongly implies that there will be a time when live people are (simultaneously) dead. A solution (following Kamp [1971] and Prior [1968]) is to evaluate formulas at pairs of times, the first of which ‘keeps track’ of the moment of utterance and the second of which is used to evaluate expressions inside tense operators. $(s, t) \vDash A$ can be understood as asserting that A is true at t when part of an expression uttered at s . The truth conditions for the Priorean operators use the second coordinate: $(s, t) \vDash \mathcal{P}A$ iff $\exists t' < t(s, t') \vDash A$ and $(s, t) \vDash \mathcal{F}A$ iff $\exists t' > t(s, t') \vDash A$. A new connective \mathcal{N} corresponding to the adverb *now* is added satisfying $(s, t) \vDash \mathcal{N}A$ iff $(s, s) \vDash A$. Validity in a model is to be understood as truth whenever uttered, i.e., $M \vDash A$ iff for every time t in M , $(t, t) \vDash A$. On this understanding $A \leftrightarrow \mathcal{N}A$ is valid, so it may appear that \mathcal{N} is vacuous. Its effect becomes apparent when it appears within the scope of the other tense operators. $\mathcal{P}(A \leftrightarrow \mathcal{N}A)$, for example, is false when A assumes a truth value at utterance time that differs from the value it had until then. This condition can still be expressed without the new connective by $(A \wedge \neg \mathcal{P}A) \vee (\neg A \wedge \neg \mathcal{P}\neg A)$, and in general, as Kamp shows, \mathcal{N} is eliminable in propositional Priorean tense logics. If the underlying language has quantifiers, however, \mathcal{N} does increase its expressive power. For example, the troublesome example above can be represented as

(51a) $P \wedge \mathcal{F}\forall x(\mathcal{N}Lx \rightarrow Dx)$.

The new connective can be used to ensure that embedded clauses get evaluated after the utterance moment as well as simultaneously with it. Consider Kamp's

(52) A child was born who will be king.

To represent this as $\mathcal{P}(A \wedge \mathcal{F}B)$ would imply only that the child is king after its birth. To capture the sense of the English *will*, that the child is king after the utterance moment, we need $\mathcal{P}(A \wedge \mathcal{N}\mathcal{F}B)$.

Vlach [1973] shows that in a somewhat more general setting \mathcal{N} can be used to cause evaluation of embedded clauses at still other times. Take the sentence *It is three o'clock and soon Jones will cite all those who are now speeding*, which has a structure like (51), and put it into the past:

(53) It was three o'clock and Jones would soon cite those who were then speeding.

We cannot represent this by simply applying a past operator to (51a) because the resulting formula would imply that Jones was going to ticket those who were speeding at the time of utterance. Vlach suggests we add an 'index' operator to the language with truth conditions very similar to \mathcal{N} 's

$$(s, t) \models \mathcal{I}A \text{ iff } (t, t) \models A.$$

If an \mathcal{N} occurs within the scope of an \mathcal{I} it can be read as *then*. This allows, for example, the sentence (44) to be represented as

$$\mathcal{P}\mathcal{I}(P \wedge \forall x(\mathcal{N}Sx \rightarrow Cx)).$$

In general, if A contains no occurrence of \mathcal{I} , the utterance time is 'fixed' in the sense that the truth value of A at $\langle u, t \rangle$ depends on the truth values of its subformulas at pairs $\langle u, t' \rangle$. The occurrence of an \mathcal{I} 'shifts' the utterance time so that evaluating A at $\langle u, t \rangle$ may require evaluating the subformulas that are within the scope of the \mathcal{I} at pairs $\langle u', t' \rangle$ for u' different than u .

With Kamp's *now*, we can keep track of the utterance time and one other time. With Vlach's *then*, we still track two times, although neither need coincide with utterance. Several authors have suggested that a tense-logical system adequate to represent natural language must allow us to keep track of more than two times. The evidence is not entirely convincing, but it has motivated some interesting revisions in the Priorean framework. Gabbay [1974; 1976] points to examples like the following:

(54) John said he would come.

(55) Ann will go to a school her mother attended and it will become better than Harvard,

which, he maintains, have interpretations suggested by the formulas

(54a) $\exists t_1 < t_0$ (John says at t_1 that $\exists t_2(t_1 < t_2 < t_0 \wedge$ John comes at t_2))

(55a) $\exists t_1 > t_0 \exists s$ (s is a school Ann goes to s at $t_1 \wedge \exists t_2 < t_0$ (Ann's mother goes to s at $t_2 \wedge \exists t_3 > t_1$ (s is better than Harvard at t_3))).

Saarinen's exhibits include

(56) Every man who ever supported the Vietnam War believes now that one day he will have to admit that he was an idiot then,

interpreted as

(56a) $\forall x(x$ is a man $\rightarrow \forall t_1 < t_0(x$ supports the Vietnam War at $t_1)(x$ believes at t_0 that $\exists t_2 > t_0(x$ has to admit at t_2 that x is an idiot at $t_1))$,

and (57) Joe said that a child had been born who would become ruler of the world,

which, Saarinen argues, has at least the two readings

(57a) $\exists t < t_0$ (Joe says at t that $\exists s < t \exists x$ (Child $x \wedge$ Born $xs \wedge \exists u > s$ Ruler xu))

(57b) $\exists t < t_0$ (Joe says at t that $\exists s < t \exists x$ (Child $x \wedge$ Born $xs \wedge \exists u > t$ Ruler xu))

according to whether the sentence reported is *A child was born who would become ruler*, or *A child was born who will become ruler*. (Note that the sequence of tense theories discussed in Section 3.4.3 above conflict with the readings proposed here for (54) and (57).)¹⁴

Cresswell [1990] points to examples of a more explicitly quantificational form:

¹⁴They hold that requirement in (54a) that t_2 precede t_0 is not part of the truth conditions for (54) (though it may be implicated). Similarly, they hold that (57a) is the sole reading of (57).

(58) There will be times such that all persons now alive will be A_1 at the first or A_2 at the second or... A_n at the n th.

(58a) $\exists t_1 \dots \exists t_n (t_0 < t_1 \wedge \dots \wedge t_0 < t_n \wedge \forall x (x \text{ is alive at } t_0 \rightarrow (x \text{ is } A_1 \text{ at } t_1 \vee \dots \vee x \text{ is } A_n \text{ at } t_n)))$.

Some of the troublesome examples could be expressed in a Priorean language. For example, for (55) we might propose:

(55b) $\exists s (\text{SCHOOL}(s) \wedge \mathcal{P} \text{ATTEND}(\text{ann's mother}, s) \wedge \mathcal{F}(\text{ATTEND}(\text{ann}, s) \wedge \mathcal{F} \text{BETTER}(s, \text{harvard})))$

But as a toy version of (55) or the result of applying a uniform English-to-tense-logic translation procedure, this may seem implausible. It requires a reordering of the clauses in (55), which removes *that her mother attended* from inside the scope of the main tense operator. Other troublesome examples can be represented with the help of novel two-dimensional operators. For example, Gabbay suggests that the appropriate reading of (54) might be represented $\mathcal{P} \text{Johnsaythat} \mathcal{F}_2 A$, where $\langle u, t \rangle \models \mathcal{F}_2 A$ iff either $t < u$ and $\exists s (t < s < u \wedge \langle u, s \rangle \models A)$ or $u < t$ and $\exists s (u < s < t \wedge \langle u, s \rangle \models A)$. (A variety of other two dimensional tense operators are investigated in Åqvist and Guenther ([1977; 1978]). This approach, however, seems somewhat *ad hoc*. In the general case, Gabbay argues, “we must keep record of the entire sequence of points that figure in the evaluation of a formula] and not only that, but also keep track of the kind of operators used.”

We sketch below five more general solutions to the problem of tracking times. Each of these introduces an interesting formal system in which the times that appear at one stage in the evaluation of a formula can be remembered at later stages, but none of these seems to provide a fully accurate model of the time-tracking mechanisms of natural language.

4.3.1 Backwards-looking operators (Saarinen)

Add to the language of tense logic a special ‘operator functor’ \mathbf{D} . For any operator \square , $\mathbf{D}(\square)$ is a connective that ‘looks back’ to the time at which the preceding \square was evaluated. For example, (47) can be represented

(56b) $\forall x (x \text{ is a man} \rightarrow \neg \mathcal{P} \neg (x \text{ supported the Vietnam war} \rightarrow \mathbf{D}(\mathcal{P})(x \text{ believesthat } \mathcal{F}(x \text{ hastoadmitthat } \mathbf{D}(\mathbf{D}(\mathcal{P}))(x \text{ is an idiot}))))))$

if we have the appropriate **believesthat** and **hastoadmitthat** operators. Within a more standard language,

(59) $A \wedge \mathcal{F}(B \wedge \mathcal{P}(C \wedge \mathcal{F}(\mathbf{D} \wedge \mathbf{D}(\mathcal{P})E) \wedge \mathbf{D}(\mathcal{F})F)$

is true at w iff $\exists x\exists y\exists z(w < x, y < x, y < z, w \vDash A, x \vDash B, y \vDash C, z \vDash D, x \vDash E$ and $y \vDash F)$. In this example $\mathbf{D}(\mathcal{P})$ and $\mathbf{D}(\mathcal{F})$ ‘look back’ to the times at which the preceding \mathcal{P} and \mathcal{F} were evaluated, namely, x and y . This condition can be expressed without the backwards operators by

$$(59a) \quad A \wedge \mathcal{F}(B \wedge E \wedge \mathcal{P}(C \wedge F \wedge \mathcal{F}D)),$$

but (as with (55b)) this requires a reordering of the clauses, and (as with (56b)) the reordering may be impossible in a richer formal language. It is a little hard to see how the semantics for \mathbf{D} might be made precise in Tarski-style truth definition. Saarinen suggests a game-theoretic interpretation, in which each move is made with full knowledge of previous moves. Iterated $\mathbf{D}(\Box)$ ’s look back to more distant \Box ’s so that, for example,

$$A \wedge \mathcal{P}(B \wedge \mathcal{F}(C \wedge \mathcal{F}(D \wedge \mathbf{D}(\mathcal{F})\mathbf{D}(\mathcal{F})E) \wedge \mathbf{D}(\mathcal{P})F))$$

is true at w iff $\exists x\exists y\exists z(x < w, x < y < z, w \vDash A, x \vDash B, y \vDash C, z \vDash D, x \vDash E$ and $w \vDash A)$. Logics based on this language would differ markedly from traditional ones. For example, if time is dense $\mathcal{F}A \rightarrow \mathcal{F}\mathcal{F}A$ is valid when A does not contain \mathbf{D} ’s, but not when A is of the form $\mathbf{D}(\mathcal{F})B$.

4.3.2 Dating sentences (Blackburn [1992; 1994])

Add a special sort of sentence letters, each of which is true at exactly one moment of time. Blackburn thinks of these as naming instants and calls his systems ‘nominal tense logics,’ but they are more accurately viewed as ‘dating sentences’, asserting, for example *It is now three pm on July 1, 1995*. Tense logical systems in this language can be characterized by adding to the usual tense logical axioms the schema

$$n \wedge \mathcal{E}(n \wedge A) \rightarrow A$$

where n is a dating sentence and \mathcal{E} is any string of \mathcal{P} ’s and \mathcal{F} ’s. In place of (59), we can now write:

$$(59b) \quad A \wedge \mathcal{F}(B \wedge i \mathcal{P}(C \wedge j \wedge \mathcal{F}D)) \wedge \mathcal{P}\mathcal{F}(i \wedge E) \wedge \mathcal{P}\mathcal{F}(j \wedge F).$$

Here i and j ‘date’ the relevant times at which B and C are true, so that the truth of $i \wedge E$ and $j \wedge F$ requires the truth of E and F at those same times.

4.3.3 Generalization of $\mathcal{N}\text{-}\mathcal{I}$ (Vlach [1973, appendix])

To the language of Priorean tense logic, add connectives \mathcal{N}_i and \mathcal{I}_i for all non-negative integers i . Let formulas be evaluated at pairs (s, i) where $s = (s_0, s_1, \dots)$ is an infinite sequence of times and i is a non-negative integer, specifying the coordinate of s relevant to the evaluation. $\mathcal{N}_i A$ indicates that

A is to be evaluated at the time referred to when \mathcal{I}_i was encountered. More precisely,

$$(\mathbf{s}, i) \vDash \mathcal{P}A \text{ iff } \exists t < s_i((s_0, \dots, s_{i-1}, t, s_{i+1}, \dots), i) \vDash A$$

$$(\mathbf{s}, i) \vDash \mathcal{F}A \text{ iff } \exists t < s_i((s_0, \dots, s_{i-1}, t, s_{i+1}, \dots), i) \vDash A$$

$$(\mathbf{s}, i) \vDash \mathcal{I}_j A \text{ iff } ((s_0, \dots, s_{j-1}, s_i, s_{j+1}, \dots), i) \vDash A$$

$$(\mathbf{s}, i) \vDash \mathcal{N}_j A \text{ iff } (\mathbf{s}, j) \vDash A$$

The truth of sentence letters at (\mathbf{s}, i) depend only on s_i and formulas are to be considered valid in a model if they are true at all pairs $((t, t, \dots), 0)$. In this language (59) can be expressed

$$(59c) \quad A \wedge \mathcal{F}\mathcal{I}_1(B \wedge \mathcal{P}\mathcal{I}_2(C \wedge \mathcal{F}(D \wedge \mathcal{N}_2 E \wedge \mathcal{N}_1 F))).$$

Here \mathcal{I}_1 and \mathcal{I}_2 ‘store’ in s_1 and s_2 the times at which B and C are evaluated and \mathcal{N}_2 and \mathcal{N}_1 shift the evaluation to s_2 and s_1 , causing F and E to be evaluated at times there stored.

4.3.4 The backspace operator (Vlach [1973, appendix])

Add to the language of Priorean tense logic a single unary connective \mathbf{B} . Let formulas be evaluated at finite (nonempty) sequences of times according to the conditions:

$$(t_1, \dots, t_n) \vDash \mathcal{P}A \text{ iff } \exists t_{n+1} < t_n((t_1, \dots, t_{n+1}) \vDash A)$$

$$(t_1, \dots, t_n) \vDash \mathcal{F}A \text{ iff } \exists t_{n+1} > t_n((t_1, \dots, t_{n+1}) \vDash A)$$

$$(t_1, \dots, t_{n+1}) \vDash \mathbf{B}A \text{ iff } (t_1 \dots, t_n) \vDash A$$

$$(\text{and, if } n = 0, (t_1) \vDash \mathbf{B}A \text{ iff } (t_1) \vDash A)$$

The truth value of sentence letters depends only on the last time in the sequence, and formulas are considered valid in a model when they are true at all length-one sequences. (59) is now represented

$$(59d) \quad A \wedge \mathcal{F}(B \wedge \mathcal{P}(C \wedge \mathcal{F}(D \wedge \mathbf{B} E \wedge \mathbf{B} B F))).$$

The indices of evaluation here form a stack. In the course of evaluating a formula a new time is pushed onto the stack whenever a Priorean tense connective is encountered and it is popped off whenever a \mathbf{B} is encountered. Thus, \mathbf{B} is a ‘backspace’ operator, which causes its argument to be evaluated at the time that had been considered in the immediately preceding stage of evaluation. In terms of this metaphor, Kamp’s original ‘now’ connective

was, in contrast, a ‘return’ operator, causing its argument to be evaluated at the time that was given at the initial moment of evaluation.

4.3.5 Generalization of $\mathcal{N}\text{-}\mathcal{I}$ (Cresswell [1990])

Generalize the language of Vlach’s $\mathcal{N}\text{-}\mathcal{I}$ system just as in solution 3. Let formulas be evaluated at infinite sequences of times and let the truth definition contain the following clauses:

$$(s_0, s_1, s_2, \dots) \vDash \mathcal{P}A \text{ iff } \exists s < s_0 ((s, s_1, s_2, \dots) \vDash A)$$

$$(s_0, s_1, s_2, \dots) \vDash \mathcal{F}A \text{ iff } \exists s > s_0 ((s, s_1, s_2, \dots) \vDash A)$$

$$(s_0, s_1, \dots, s_i, \dots) \vDash \mathcal{I}_i A \text{ iff } (s_0, s_1, \dots, s_{i-1}, s_0, s_{i+1}, \dots) \vDash A$$

$$(s_0, s_1, \dots, s_i, \dots) \vDash \mathcal{N}_i A \text{ iff } (s_i, s_1, s_2, \dots) \vDash A$$

A formula is considered valid if it is true at all constant sequences (s, s, \dots) . Then we can express (59) above as:

$$(59e) \quad A \wedge \mathcal{F}\mathcal{I}_1(B \wedge \mathcal{P}\mathcal{I}_2(C \wedge \mathcal{F}(D \wedge \mathcal{N}_2 E \wedge \mathcal{N}_1 F))).$$

As in solution 3, \mathcal{I}_1 and \mathcal{I}_2 store in s_1 and s_2 the times at which B and C are evaluated. Subsequent occurrences of \mathcal{N}_2 and \mathcal{N}_1 restore those times to s_0 so that E and F can be evaluated—with respect to them.

Each of the systems described in 4.3.1–4.3.5 has a certain appeal, and we believe that none of them has been investigated as thoroughly as it deserves. We confine ourselves here to a few remarks about their expressive powers and their suitability to represent tense constructions of natural language. Of the five systems, only Cresswell’s $\mathcal{N}\text{-}\mathcal{I}$ generalization permits atomic formulas to depend on more than one time. This makes it possible, for example, to represent *Johnson ran faster than Lewis*, meaning that Johnson ran faster in the 1996 Olympics than Lewis did in the 1992 Olympics, by Rmn. We understand R to be a predicate (*runs faster than*) which, at every pair of times, is true or false of pairs of individuals. Since the issues involved in these representations are somewhat removed from the ones discussed here, and since the other systems could be generalized in this way if desired, this difference is not significant. If we stipulate that the truth value of a sentence letter at s in Cresswell’s system depends only on s_0 then, for each of the systems, there is a translation of formulas into the classical first order language with identity and a countable collection of temporally monadic predicates and a single temporally dyadic predicate $<$ (and, in the case of nominal tense logic, a countable collection of temporal constants). We say ‘temporally’ monadic and dyadic because, if the base language of these systems is the language of predicate logic, it will already

contain polyadic predicates that apply to tuples of *individuals*. The translation maps these to predicates with an additional temporal argument, and it maps tense formulas with free individual variables into classical formulas with those same free variables and additional free temporal variables. The sentential version of Cresswell's \mathcal{N} - \mathcal{I} provides an example. Associate with each sentence letter p a unary predicate letter p^τ and fix two (disjoint) sequences of variables x_0, x_1, \dots and y_0, y_1, \dots . A translation τ from Cresswell-formulas into classical formulas is defined by the following clauses (where A^x/y is the result of replacing all free occurrences of y in A by x):

$$\text{i) } \tau p = p^\tau x_0$$

$$\text{ii) } \tau \mathcal{P}A = \exists y < x_0 (\tau A)^y /_{x_0}, \text{ where } y \text{ is the first } y_i \text{ that does not occur in } \tau A$$

$$\text{iii) } \tau \mathcal{F}A = \exists y > x_0 (\tau A)^y /_{x_0}, \text{ where } y \text{ is as above}$$

$$\text{iv) } \tau \mathcal{I}_j A = (\tau A)^{x^0} /_{x_j}$$

$$\text{v) } \tau \mathcal{N}_j A = (\tau A)^{x^j} /_{x_0}$$

To every model M for Cresswell's language there corresponds a classical model M' with the same domain which assigns to each predicate letter p^τ the set of times at which p is true in M . τA expresses A in the sense that $(s_0, s_1, \dots) \models_M A$ iff τA is true in M' under the assignment that assigns s_i to x_i for $i = 0, 1, \dots$. Viewing M and M' as the same model, we can say that a tense-logical formula expresses a classical one when the two formulas are true in the same models. (Of course in defining a tense-logical system, we may restrict the class of appropriate models. By 'true in the same models' we mean true in the same models appropriate for the tense logic.) A formula with one free variable in the first order language with unary predicates and $<$ might be called a 'classical tense'. From the translation above we may observe that every Cresswell formula in which each occurrence of a connective \mathcal{N}_j lies within the scope of an occurrence of \mathcal{I}_j expresses a classical tense. If every classical tense is expressible in tense-logical system, the system is said to be temporally complete.

An argument in Chapter IV of Cresswell establishes that, as long as $<$ is assumed to be connected (so that quantification over times can be expressed in the tense language), every classical tense without $<$ can be expressed in his generalization of the \mathcal{N} - \mathcal{I} language. It is not difficult to see that this holds as well for Vlach's generalization. For consider the following translation τ mapping Cresswell's system into Vlach's:

$\tau A = \mathcal{N}_0 A$ if A is a sentence letter,

$\tau \mathcal{P} A = \mathcal{P} \tau A$,

$\tau \mathcal{F} A = \mathcal{F} \tau A$,

$\tau \mathcal{I}_i A = \mathcal{I}_i \tau A$,

$\tau \mathcal{N}_i A = \mathcal{I}_x \mathcal{I}_{x+1} \dots \mathcal{I}_{2x} \mathcal{N}_i \mathcal{I}_{x-i} \mathcal{N}_{x-i} \tau A$ where x is the successor of the least integer greater than every subscript that occurs in $\mathcal{N}_i A$.

Then, using the subscripts C and V for Vlach's system and Cresswell's, $\mathfrak{s} \models_C A$ iff $(\mathfrak{s}, 0) \models_V \tau A$. So, if A is a classical tense without $<$, there is a formula A_C that expresses A in Cresswell's system, and τA_C will express A in Vlach's system.

The question of whether every classical tense is expressible is more difficult. As we saw with Kamp's \mathcal{N} , questions about expressive power are sensitive to the underlying language. \mathcal{N} adds nothing to the expressive power of sentential tense logic, but it does add to the expressive power of predicate tense logic. The examples suggest that the same is true of the backwards-looking and backspace operators. A well known result of Kamp (see Burgess [2001]) states that, if time is like the reals, every tense can be expressed with the connectives U (*until*) and S (*since*) with truth conditions $U(A, B)$ iff $\exists t > t_0 (t \models A \wedge \forall s (t_0 < s < t \rightarrow s \models B))$ and $S(A, B)$ iff $\exists t < t_0 (t \models A \wedge \forall s (t < s < t_0 \rightarrow s \models B))$. By constructing a pair of models that can be discriminated by formulas with U and S but not by any Priorean formulas, one can show that Priorean tense logic is not temporally complete. A reduction of the sentential backwards-looking and backspace systems to the ordinary ones, therefore, would imply their temporal incompleteness. From the pairs of ordinary models that are indistinguishable by Priorean formulas, we can easily construct pairs that are indistinguishable in the language of Blackburn's dating sentences. (Pick corresponding times t and t' in the two models and require that every dating sentence be true exactly at t in the first model and exactly at t' in the second.) So that system also fails to be temporally complete.¹⁵

For a number of reasons, the suitability of a system of tense logic for natural language should not be identified with its expressive power, and the observation that the formulas in the five systems described here are all expressible as classical tenses does not imply that the language of classical tenses is itself a suitable tense logical system. Although we can express all

¹⁵There is a weaker sense in which U and S can be expressed with dating sentences. Let $U(i, A, B)$ be $i \wedge \mathcal{F}(A \wedge \neg \mathcal{P} \neg (\mathcal{F}_i \vee i \vee B))$ and $S(i, A, B)$ be $i \wedge \mathcal{P}(A \wedge \neg \mathcal{F}(\mathcal{P}_i \vee i \vee B))$. Then $U(i, A, B)$ is satisfiable in Blackburn's system iff $U(A, B)$ is satisfiable in the since-until system and $S(i, A, B)$ is satisfiable iff $S(A, B)$ is.

the classical tenses in English, it is not the tense mechanism that allows us to do so. English sentences like *For every instant t , if t succeeds t_0 there is an instant t' , such that t' succeeds t and t succeeds t_0 and John is asleep at t'* , however useful in explaining the meaning of first order formulas, are not the sort of sentences for which one would expect to find a phrase-by-phrase representatives in an idealized language isolating the tense-and-aspect features of English. One can object to Saarinen's **D**, Blackburn's dating sentences, Vlach's **B**, and Vlach and Cresswell's \mathcal{L}_j 's and \mathcal{N}_j 's on similar grounds. It is possible, of course, that some of these systems make particularly good intermediaries between tense constructions of natural language and truth conditions, or that there is some other sense in which they are especially suitable as tense logics for natural language, but such claims need arguments beyond demonstrations of expressive capacity. Indeed the fact that we can express very simply in these languages ideas that in English require complex constructions (perhaps involving quantifier phrases variable expressions) suggests that they are unsuitable on some conceptions of tense logic. On the other hand, if there are ideas we can express simply and uniformly in English, the mere observation that a tense-logical system has sufficient expressive power to somehow express them, may not be evidence in favor of the system. For example, the fact that prefixing a sufficiently long string of backspace operators to an embedded formula causes it to be evaluated at the moment of utterance does not mean that the backspace system is a good model of the English *now*.

Part of the difficulty in judging the adequacy of tense logical systems for natural language is discerning the linguistic data itself. It is not clear, for example, whether *John said he would come* does have the reading indicated in (54a) implying that he said he would come *by now*, or whether that inference, when legitimate, is based on (extralinguistic) contextual cues. Similarly, the observation that *Joe said that a child had been born who would become ruler of the world* is consistent with two possible utterances by Joe does not establish that (57) is ambiguous between (57a) and (57b). Saarinen maintains that a sentence of the form *A reported that B believed that C said John would go* has at least four readings, according to whether John's alleged departure occurs in the future of C's saying, B's believing, A's reporting, or the utterance time. Since the first of these readings is true if any of the others is, one can't expect to find a case which *requires* readings other than the first. The plausibility of there being such readings is undermined by observation that a similar ambiguity does not occur when the *would* is in the scope of future operators. *A will report (next week) that B said (the previous day) that C would go* is not made true by A's reporting next week that B said 'C went yesterday,' as it would if 'C would go' could refer to a time future to the utterance moment. While an adequate logic for the tenses of natural language may require greater 'time-tracking' capabilities than Priorean tense logic, there is not strong evidence for the

thesis that it be able to ‘remember’ at each stage in the evaluation times at which previous clauses were evaluated.

4.4 Galton’s logic of aspects and events

English discourse presumes a universe of events and states with internal structure as well as temporal location. The language of Priorean tense logic is built solely from formulas, boolean connectives, and operators of temporal location. It is reasonable to try to enrich the language so that more of the internal structure of events can be described. In recent years there has been a proliferation of work in this area motivated by concerns in deontic logic and action theory. (See, for example, Jones and Sergot [1996] and the references therein.) For the most part, however, that work has not focussed on temporal or natural language considerations. There is a large and growing semantics literature on events and aspect, but much of it is too detailed to be considered part of a ‘logic’ of tense. In this section we sketch some ideas in the spirit of Galton [1984; 1987a], which seem to strike a good balance between simplicity and fidelity to ‘surface’ phenomena of English.

The idea that sentences in the future and present perfect can be represented by attaching \mathcal{F} and \mathcal{P} to some more basic sentence is plausible for sentences describing states but not those describing events. *The cat has been on the mat* is true now if *the cat is on the mat* was true before, but to say that *John has built a house* is true now if *John builds a house* was true before is confusing, since we don’t normally use the present tense to indicate that an event is true at the present time. (Indeed, since events like house building occur over extended intervals, it is not clear what the ‘present’ time would be in this case.) Let us instead add a class of *event letters* E_1, E_2, \dots to the language along with two event-to-formula *e-f aspect operators* $\mathcal{P}erf$ and $\mathcal{P}ros$, which attach to event letters to produce formulas.¹⁶ (The tense operators \mathcal{P} and \mathcal{F} and the boolean operators, as usual, apply to formulas to form formulas.) Let us provisionally say that an interpretation assigns to each event letter a set $I(E)$ of *occurrence intervals*. $\mathcal{P}rosE$ is true at t if t precedes (all of) some interval in $I(E)$; $\mathcal{P}erfE$, if t succeeds (all of) some interval in $I(E)$. One may wonder what hinges on the distinction between an event’s occurring at a time and a formula’s being true at a time. Granting that we don’t normally say that *John builds a house* is true, say, in the spring of 1995, we might find it convenient to stipulate that it be true then if one of John’s house buildings occurs at that time. One advantage of not doing so is that the event/formula distinction

¹⁶Galton uses the label ‘imperfective’ in place of ‘e-f’, and the label ‘perfective’ in place of our *f-e*.

provides a sorting that blocks inappropriate iterations of aspect operators. Another is that the distinction makes it possible to retain the Priorean notion that all formulas are to be evaluated at instants even when the events they describe occupy extended intervals. The tense logical systems that result from this language so interpreted will contain the usual tense logical principles, like $\mathcal{F}A \rightarrow \mathcal{F}\mathcal{P}A$ as well as event analogs of some of these, like $\mathcal{P}rosE \rightarrow \mathcal{F}\mathcal{P}erfE$. Some tense theorems lack event analogs. For example, $\mathcal{F}\mathcal{P}A \rightarrow (\mathcal{F}A \vee \mathcal{P}A \vee A)$ is valid when time does not branch towards the past, but $\mathcal{F}\mathcal{P}erfE \rightarrow \mathcal{P}erfE \vee \mathcal{P}rosE$ is not (because E may occur only at intervals containing the present moment).

We may add to this logic another *e-f* operator $\mathcal{P}rog$ such that $\mathcal{P}rogE$ is true at t iff t belongs to an interval at which E occurs. Thus $\mathcal{P}rogE$ asserts that event E is in progress. In view of the discussion in Section 3.4 above, it should be obvious that $\mathcal{P}rog$ is a poor representation of the English progressive. It can perhaps be viewed as an idealization of that construction which comes as close to its meaning as is possible with a purely temporal truth condition. (Analogous justifications are sometimes given for claims that the material conditional represents the English ‘if...then’ construction.) The new connective allows us to express the principle that eluded us above: $\mathcal{F}\mathcal{P}erfE \rightarrow \mathcal{P}erfE \vee \mathcal{P}rosE \vee \mathcal{P}rogE$.

Since Zeno of Elea posed his famous paradoxes in the fifth century *BC*, accounts of events and time have been tested by a number of puzzles. One Zeno-like puzzle, discussed in Hamblin [1971; 1971a], Humberstone, and Galton [Humberstone, 1979; Galton, 1984; Galton, 1987a], is expressed by the following question. ‘At the instant a car starts to move, is it moving or at rest?’ To choose one alternative would seem to distort the meaning of *starting to move*, to choose both or neither would seem to violate the laws of non-contradiction or excluded middle. Such considerations lead Galton to a slightly more complicated interpretation for event logic. Events are not assigned sets of occurrence intervals, but rather sets of interval pairs (B, A) , where B and A represent the times before the event and the times after the event (so that, if time is linear, B and A are disjoint initial and final segments of the set of times.) The clauses in the truth definition are modified appropriately. For example, $\mathcal{P}rogE$ is true at t if, for some $(B, A) \in I(E)$, $t \in -B \cap -A$, where $-A$ and $-B$ are those times of the model that do not belong to A and B . $\mathcal{P}erfE$ is true at t if, for some $(B, A) \in I(E)$, $t \in B$. For an event like the car’s starting to move, any (B, A) in the occurrence set will be exhaustive, i.e., $B \cup A$ will contain all times. Such events are said to be *punctual* (although we must distinguish these from events that occupy a ‘point’ in the sense that $B \cup A$ always omits a single time). A punctual event does not really occur ‘at’ a time, nor is it ever in the process of occurring. Instead, it marks a boundary between two states, like the states of rest and motion. When E is punctual, $\mathcal{P}rogE$ is always false, and so the principle $\mathcal{F}\mathcal{P}erfE \rightarrow \mathcal{P}erfE \vee \mathcal{P}rosE \vee \mathcal{P}rogE$

reduces to $\mathcal{F}\mathcal{P}erfE \rightarrow \mathcal{P}erfE \vee \mathcal{P}rosE$, which we have observed not to be valid without the stipulation that E is punctual.

We may also wish to add f - e aspect operators that apply to formulas to form event-expressions. Galton suggests the ‘ingressive’ operator $\mathcal{I}ngr$ and the ‘pofective’ operator $\mathcal{P}o$, where, for any formula A , $\mathcal{I}ngrA$ is the event of A ’s *beginning* to be true, and $\mathcal{P}oA$ is the event (or state) of A ’s being *true for a time*. In the ‘before-after’ semantics, these operators can be interpreted by the clauses below:

$$I(\mathcal{I}ngrA) = \{(B, -B) : A \text{ is true throughout a non-empty initial segment of } -B, \text{ and false throughout a nonempty final segment of } B\}$$

$$I(\mathcal{P}oA) = \{(B, C) : -B \cap -C \text{ is not empty, } A \text{ is true throughout } -B \cap -C \text{ and } A \text{ is false at some point in every interval that properly contains } -B \cap -C\}$$

Thus, $\mathcal{I}ngrA$ is always punctual, and $\mathcal{P}oA$ is never punctual. Notice that $-B \cap -C$ can be a singleton, so that being true for ‘a time,’ on this interpretation, includes being true for an instant. We get principles like $\mathcal{P}ros \mathcal{I}ngrA \rightarrow (\neg A \wedge \mathcal{F}A) \wedge \mathcal{F}(\neg A \wedge \mathcal{F}A)$, $\mathcal{P}erf \mathcal{I}ngr \mathcal{P}erfE \rightarrow \mathcal{P}erfE$, and $\mathcal{P}rog \mathcal{P}oA \rightarrow \mathcal{P}\neg A \wedge A \wedge \mathcal{F}\neg A$. It is instructive to consider the converses of these principles. If A is true and false at everywhere dense subsets of the times (for example if time is the reals and A is false at all rationals and true at all irrationals), then at the times A is false $\neg A \wedge \mathcal{F}A$ is true, but $\mathcal{I}ngrA$ has no occurrence pairs, and so $\mathcal{P}ros \mathcal{I}ngrA$ is false. Thus the converse of the first principle fails. Likewise, if E occurs repeatedly throughout the past (for example, if time is the reals and $I(E) = \{(-\infty, n][n + 1, \infty)\}$) then $\mathcal{P}erfE$ is true at all times, which implies that $\mathcal{I}ngr \mathcal{P}erfE$ has an empty occurrence set, $\mathcal{P}erf \mathcal{I}ngr \mathcal{P}erfE$ is everywhere false, and the converse to the second principle fails. The converse to the third principle is valid, for if $\mathcal{P}\neg A \wedge A \wedge \mathcal{F}\neg A$ is true at t , then, letting $\cap S$ be the intersection of all intervals S such that $t \in S$ and A is true throughout S , the occurrence set of $\mathcal{P}oA$ includes the pair $(\{x : \forall y \in \cap S, x < y\}, \{x : \forall y \in \cap S, x > y\})$ and $\mathcal{P}rog \mathcal{P}oA$ is true at t . (The principle would fail, however, if we took $\mathcal{P}oA$ to require that A be true throughout an *extended* period.) As a final exercise in Galtonian event logic, we observe that it provides a relatively straightforward expression of Dedekind continuity (see Burgess [2001]). The formula $\mathcal{P}erf \mathcal{I}ngr \mathcal{P}erfE \rightarrow \mathcal{P}(\mathcal{P}erfE \wedge \neg \mathcal{P} \mathcal{P}erfE) \vee \mathcal{P}(\neg \mathcal{P}erfE \wedge \neg \mathcal{F} \neg \mathcal{P}erfE)$ states that, if there was a cut between times at which $\mathcal{P}erfE$ was false and times at which it was true, then either there was a first time when it was true or a last time when it was false. It corresponds to Dedekind continuity in the sense that a dense frame verifies the formula if and only if the frame is Dedekind continuous.

The view represented by the ‘before-after’ semantics suggests that events of the form *IngrA* and other punctual events are never in the process of occurring, but somehow occur ‘between’ times. However plausible as a metaphysical theory, this idea seems not to be reflected in ordinary language. We sometimes accept as true sentences like *the car is starting to move*, which would seem to be of the form *ProgIngrA*. To accommodate these ordinary-language intuitions, we might wish to revert to the simpler occurrence-set semantics. *IngrA* can be assigned short intervals, each consisting of an initial segment during which *A* is false and a final segment at which *A* is true. On this view, *IngrA* exhibits *vagueness*. In a particular context, the length of the interval (or a range of permissible lengths) is understood. When the driver engages the gear as the car starts to move he invokes one standard, when the engineer starts the timer as the car starts to move she invokes a stricter one. As in Galton’s account, the Zeno-like puzzle is dissolved by denying that there is an instant at which the car starts to move. The modified account concedes, however, that there are instants at which the car is starting to move while moving and other instants at which it is starting to move while not moving.

Leaving aside particular issues like the semantics of punctual events and the distinction between event-letters and sentence-letters, Galton’s framework suggests general tense-logical questions. The *f–e* aspect operators, like *Ingr* and *Po* can be viewed as operations transforming instant-evaluated expressions into interval-evaluated (or interval-occupying?) expressions, and the *e–f* aspect operators, like *Perf* and *Prog*, as operations of the opposite kind. We might say that traditional tense logic has investigated general questions about instant/instant operations and that interval tense logic has investigated general questions about operations taking intervals (or pairs of intervals) to intervals. A general logic of aspect would investigate questions about operations between instants and intervals. Which such operations can be defined with particular metalinguistic resources? Is there anything logically special about those (or the set of all those) that approximate aspects of natural language? The logic of events and aspect would seem to be a fertile ground for further investigation.

PREFACE TO THE SECOND EDITION

It is with great pleasure that we are presenting to the community the second edition of this extraordinary handbook. It has been over 15 years since the publication of the first edition and there have been great changes in the landscape of philosophical logic since then.

The first edition has proved invaluable to generations of students and researchers in formal philosophy and language, as well as to consumers of logic in many applied areas. The main logic article in the *Encyclopaedia Britannica* 1999 has described the first edition as ‘the best starting point for exploring any of the topics in logic’. We are confident that the second edition will prove to be just as good!

The first edition was the second handbook published for the logic community. It followed the North Holland one volume *Handbook of Mathematical Logic*, published in 1977, edited by the late Jon Barwise. The four volume *Handbook of Philosophical Logic*, published 1983–1989 came at a fortunate temporal junction at the evolution of logic. This was the time when logic was gaining ground in computer science and artificial intelligence circles.

These areas were under increasing commercial pressure to provide devices which help and/or replace the human in his daily activity. This pressure required the use of logic in the modelling of human activity and organisation on the one hand and to provide the theoretical basis for the computer program constructs on the other. The result was that the *Handbook of Philosophical Logic*, which covered most of the areas needed from logic for these active communities, became their bible.

The increased demand for philosophical logic from computer science and artificial intelligence and computational linguistics accelerated the development of the subject directly and indirectly. It directly pushed research forward, stimulated by the needs of applications. New logic areas became established and old areas were enriched and expanded. At the same time, it socially provided employment for generations of logicians residing in computer science, linguistics and electrical engineering departments which of course helped keep the logic community thriving. In addition to that, it so happens (perhaps not by accident) that many of the Handbook contributors became active in these application areas and took their place as time passed on, among the most famous leading figures of applied philosophical logic of our times. Today we have a handbook with a most extraordinary collection of famous people as authors!

The table below will give our readers an idea of the landscape of logic and its relation to computer science and formal language and artificial intelligence. It shows that the first edition is very close to the mark of what was needed. Two topics were not included in the first edition, even though

they were extensively discussed by all authors in a 3-day Handbook meeting. These are:

- a chapter on non-monotonic logic
- a chapter on combinatory logic and λ -calculus

We felt at the time (1979) that non-monotonic logic was not ready for a chapter yet and that combinatory logic and λ -calculus was too far removed.¹ Non-monotonic logic is now a very major area of philosophical logic, alongside default logics, labelled deductive systems, fibring logics, multi-dimensional, multimodal and substructural logics. Intensive re-examinations of fragments of classical logic have produced fresh insights, including at time decision procedures and equivalence with non-classical systems.

Perhaps the most impressive achievement of philosophical logic as arising in the past decade has been the effective negotiation of research partnerships with fallacy theory, informal logic and argumentation theory, attested to by the Amsterdam Conference in Logic and Argumentation in 1995, and the two Bonn Conferences in Practical Reasoning in 1996 and 1997.

These subjects are becoming more and more useful in agent theory and intelligent and reactive databases.

Finally, fifteen years after the start of the Handbook project, I would like to take this opportunity to put forward my current views about logic in computer science, computational linguistics and artificial intelligence. In the early 1980s the perception of the role of logic in computer science was that of a specification and reasoning tool and that of a basis for possibly neat computer languages. The computer scientist was manipulating data structures and the use of logic was one of his options.

My own view at the time was that there was an opportunity for logic to play a key role in computer science and to exchange benefits with this rich and important application area and thus enhance its own evolution. The relationship between logic and computer science was perceived as very much like the relationship of applied mathematics to physics and engineering. Applied mathematics evolves through its use as an essential tool, and so we hoped for logic. Today my view has changed. As computer science and artificial intelligence deal more and more with distributed and interactive systems, processes, concurrency, agents, causes, transitions, communication and control (to name a few), the researcher in this area is having more and more in common with the traditional philosopher who has been analysing

¹I am really sorry, in hindsight, about the omission of the non-monotonic logic chapter. I wonder how the subject would have developed, if the AI research community had had a theoretical model, in the form of a chapter, to look at. Perhaps the area would have developed in a more streamlined way!

such questions for centuries (unrestricted by the capabilities of any hardware).

The principles governing the interaction of several processes, for example, are abstract and similar to principles governing the cooperation of two large organisations. A detailed rule based effective but rigid bureaucracy is very much similar to a complex computer program handling and manipulating data. My guess is that the principles underlying one are very much the same as those underlying the other.

I believe the day is not far away in the future when the computer scientist will wake up one morning with the realisation that he is actually a kind of formal philosopher!

The projected number of volumes for this Handbook is about 18. The subject has evolved and its areas have become interrelated to such an extent that it no longer makes sense to dedicate volumes to topics. However, the volumes do follow some natural groupings of chapters.

I would like to thank our authors and readers for their contributions and their commitment in making this Handbook a success. Thanks also to our publication administrator Mrs J. Spurr for her usual dedication and excellence and to Kluwer Academic Publishers for their continuing support for the Handbook.

King's College London

Logic	IT			
	Natural language processing	Program control specification, verification, concurrency	Artificial intelligence	Logic programming
Temporal logic	Expressive power of tense operators. Temporal indices. Separation of past from future	Expressive power for recurrent events. Specification of temporal control. Decision problems. Model checking.	Planning. Time dependent data. Event calculus. Persistence through time—the Frame Problem. Temporal query language. temporal transactions.	Extension of Horn clause with time capability. Event calculus. Temporal logic programming.
Modal logic. Multi-modal logics	generalised quantifiers	Action logic	Belief revision. Inferential databases	Negation by failure and modality
Algorithmic proof	Discourse representation. Direct computation on linguistic input	New logics. Generic theorem provers	General theory of reasoning. Non-monotonic systems	Procedural approach to logic
Non-monotonic reasoning	Resolving ambiguities. Machine translation. Document classification. Relevance theory	Loop checking. Non-monotonic decisions about loops. Faults in systems.	Intrinsic logical discipline for AI. Evolving and communicating databases	Negation by failure. Deductive databases
Probabilistic and fuzzy logic	logical analysis of language	Real time systems	Expert systems. Machine learning	Semantics for logic programs
Intuitionistic logic	Quantifiers in logic	Constructive reasoning and proof theory about specification design	Intuitionistic logic is a better logical basis than classical logic	Horn clause logic is really intuitionistic. Extension of logic programming languages
Set theory, higher-order logic, λ-calculus, types	Montague semantics. Situation semantics	Non-well-founded sets	Hereditary finite predicates	λ -calculus extension to logic programs

Imperative vs. declarative languages	Database theory	Complexity theory	Agent theory	Special comments: A look to the future
Temporal logic as a declarative programming language. The changing past in databases. The imperative future	Temporal databases and temporal transactions	Complexity questions of decision procedures of the logics involved	An essential component	Temporal systems are becoming more and more sophisticated and extensively applied
Dynamic logic	Database updates and action logic	Ditto	Possible actions	Multimodal logics are on the rise. Quantification and context becoming very active
Types. Term rewrite systems. Abstract interpretation	Abduction, relevance	Ditto	Agent's implementation rely on proof theory.	
	Inferential databases. Non-monotonic coding of databases	Ditto	Agent's reasoning is non-monotonic	A major area now. Important for formalising practical reasoning
	Fuzzy and probabilistic data	Ditto	Connection with decision theory	Major area now
Semantics for programming languages. Martin-Löf theories	Database transactions. Inductive learning	Ditto	Agents constructive reasoning	Still a major central alternative to classical logic
Semantics for programming languages. Abstract interpretation. Domain recursion theory.		Ditto		More central than ever!

Classical logic. Classical fragments	Basic back-ground language	Program synthesis	A basic tool	
Labelled deductive systems	Extremely useful in modelling		A unifying framework. Context theory.	Annotated logic programs
Resource and substructural logics	Lambek calculus		Truth maintenance systems	
Fibering and combining logics	Dynamic syntax	Modules. Combining languages	Logics of space and time	Combining features
Fallacy theory				
Logical Dynamics	Widely applied here			
Argumentation theory games		Game semantics gaining ground		
Object level/metalevel			Extensively used in AI	
Mechanisms: Abduction, default relevance			ditto	
Connection with neural nets				
Time-action-revision models			ditto	

	Relational databases	Logical complexity classes	The workhorse of logic	The study of fragments is very active and promising.
	Labelling allows for context and control.		Essential tool.	The new unifying framework for logics
Linear logic			Agents have limited resources	
	Linked databases. Reactive databases		Agents are built up of various fibred mechanisms	The notion of self-fibring allows for self-reference
				Fallacies are really valid modes of reasoning in the right context.
			Potentially applicable	A dynamic view of logic
				On the rise in all areas of applied logic. Promises a great future
			Important feature of agents	Always central in all areas
			Very important for agents	Becoming part of the notion of a logic
				Of great importance to the future. Just starting
			A new theory of logical agent	A new kind of model

DAVID HARRAH

THE LOGIC OF QUESTIONS

1 INTRODUCTION

1.1 *Basic Notions*

Most theorists use ‘interrogative’ to refer to a type of sentence. Some theorists posit questions as distinct entities that may be *asked*, or *put*, or *expressed* by interrogatives, just as propositions may be expressed by declaratives and commands may be expressed by imperatives. Intuitively it seems that some questions may be expressed by sentences other than interrogatives, and some interrogatives can be used to do other things besides ask questions. Thus it is reasonable to say that there are two overlapping subject matters: the logic of interrogatives, and the logic of questions.

Most theorists use ‘reply’ to refer to any verbal response that can be given to a question, and use ‘answer’ to refer to a distinguished kind of reply. Many kinds of reply may be appropriate from the respondent’s point of view, but the replies that are appropriate from the questioner’s point of view, the replies that the question calls for, are the answers.

Most theorists define various types of answer. The most important distinction is between direct answers, each of which gives exactly what the question calls for, and partial answers, each of which may give some (but perhaps not all) of what the question calls for. The label ‘direct’ was introduced in Harrah [1961] because it connotes both logical sufficiency and immediacy, as in the request:

‘Please give me a direct answer?’

Just as statements and commands can be ‘good’ or ‘bad’ in various ways (valid or not, true or not, possible or not, and the like), so too with questions. The details, however, vary from theory to theory.

Most theorists agree on labels for question-types approximately as follows:

Label	Example
<i>whether</i>	‘Is two even or odd?’
<i>yes-no</i>	‘Is two a prime number?’
<i>which</i>	‘Which even numbers are prime?’
<i>what</i>	‘What is Church’s Thesis?’
<i>who</i>	‘Who is Bourbaki?’
<i>why</i>	‘Why does two divide zero?’
<i>deliberative</i>	‘What shall I do now?’

<i>disjunctive</i>	‘How long is your new proof, or do you have a shorter one?’
<i>hypothetical</i>	‘If you had a proof, how long would it be?’
<i>conditional</i>	‘If you now have a proof, how long is it?’
<i>given-that</i>	‘Given that Turing’s Conjecture is provable, is Church’s Thesis provable?’

No theorist holds that this is a complete list of question-types, and most would divide each of the types listed here into several sub-types. For discussions, see Hamblin [1967], Prior and Prior [1955], Belnap and Steel [1976], and Wiśniewski [1995].

To see how problematic these basic notions can be, and how theorists’ intuitions may differ, consider the English sentence:

‘Where is Jane or Ann?’

Harrah [1975] formalizes this as a disjunction of two interrogatives (one about Jane, one about Ann); each of these interrogatives expresses one question that has its own set of answers. Belnap and Steel [1976] formalizes this as one interrogative that expresses one disjunctive question whose answers are the answers about Jane plus the answers about Ann. Groenendijk and Stokhof [1984] construes it as one interrogative that expresses two questions; the semantics of the interrogative yields one set of answers that contains the Jane answers and the Ann answers.

There is another subject matter that is a generalization on the first two: erotetic logic. In the narrow sense, ‘erotetic’ can be paraphrased as ‘pertaining to questioning’. In this sense erotetic logic is the theory of questions, interrogatives, and the use of interrogatives. Generalizing on this notion, we may use ‘erotetic’ with the sense of ‘pertaining to calling-for-reply’. Under such an interpretation, erotetic logic is the theory of all the sentences (interrogative, imperative, declarative, or whatever) that call for reply, or that are vulnerable to replies of certain sorts, and the theory of all the entities that can thus be called for. Erotetic logic in this general sense has not yet been developed to any significant depth, and we discuss it only briefly in Sections 7.7 – 7.8. For this reason, and because most of the theories discussed in this chapter are logics of questions, this chapter is most appropriately titled ‘The Logic of Questions’.

(Helpful comments and advice concerning this chapter were supplied by Andrzej Wiśniewski.)

1.2 Motivations

The theories that have been developed up to now differ not only in superstructure and points of detail but also in foundation and basic conception. Many of these differences are due to differences in motivation. For this

reason we take note of motivation in our survey below. The following descriptive labels are used in our exposition:

Empirical. This is the motivation of linguists and psychologists, for example, who wish to describe the sentences of a natural language and describe how those sentences are understood and used by the speakers of the language.

Platonic. This is the motivation of some philosophers and logicians who wish to describe linguistic or semantic entities considered as mathematical objects, objects that exist in their own right, so to speak.

Normative. This is the motivation of some philosophers and logicians who wish to describe how one ought to ask and answer question, or how a rational person asks and answers.

Engineering. This is the motivation of those whose purpose is simply to construct a system that will be usable for certain practical purposes (e.g. computer-assisted information-retrieval) and satisfy certain criteria (e.g. efficiency, effectiveness).

Metalogical. This is the motivation of one who wishes to study how far, within a given logical system, a system of question-and-answer can be developed, or, more generally, to study what sorts of question-and answer system can be developed within a given logical system, where the given system might or might not have been intended by its creators to provide a question-and-answer system.

Technical and *aesthetic.* These are additional motivations felt by the theorist in the course of constructing the theory. The most important of course are the desire to facilitate construction of theory and the desire to achieve simplicity or elegance of other kinds.

Two cautions: First, the foregoing characterizations are rough and usually require some qualification when applied to particular cases. Second, in any particular case there may be more than one motivation present; we note some examples below.

1.3 *History and Bibliography*

Discussion of questions is at least as old as Aristotle; Kubiński [1980], pp. 118 – 119, says that Cohen [1929] “is the earliest known to me in which the logic of questions is treated by means of formal logic”. Cohen suggested identifying questions with sentential functions having free variables. Closely related ideas were considered by Carnap and Reichenbach. Gornstein [1967], p. v – 1, says that Carnap seems to be the first author who wrote a question in a formalized manner.

Current activity in the field began in the 1950s, stimulated to a large extent by Prior and Prior [1955], Stahl [1956], Hamblin [1958], and Kubiński [1960]. Since then many approaches have been suggested, and several have been developed in detail.

For a general discussion of the history of the field to about 1965, see Hamblin [1967]. Gornstein [1967] presents a detailed summary and discussion of many theories and logics from Aristotle to the 1960s. Kubiński [1980] offers many historical remarks and useful bibliography.

Probably the most comprehensive and complete bibliography published to 1976 is the one by Egli and Schleichert that is included in Belnap and Steel [1976]. It contains sections on Logic and Philosophy of Language; Linguistics; Automatic Question-Answering; and Psychology and Pedagogy. Abstracts are included for many of the items listed. Ficht [1978] presents an updated version of this bibliography with an additional section on dialogue. Other bibliographies, more limited in scope but quite useful, are found in Hiz (ed.) [1978], Lehnert [1978], Belnap [1981] and [1983], and Higginbotham [1993]. The bibliography presented in Wiśniewski [1995] is valuable in many ways and has good coverage of the important work done up to 1994. Note: The list of References given at the end of this chapter is very selective. In general it concentrates on logic and ignores psychology, pedagogy, and heuristics. In particular it concentrates on the topics and authors discussed in this chapter.

1.4 *Scope of this Chapter*

The main aims of this chapter are to indicate the variety of motivations, basic conceptions, and approaches to theorizing that are now evident in the field, and to outline some topics and aspects that invite further study. This chapter does not aim at a complete historical account, or a complete catalogue of possible theories. We concentrate on some work, by a few logicians, that is especially significant and fruitful for further developments in various directions.

1.5 *Abbreviations and Notation*

In most cases, when summarizing the work of another author, we use that author's terminology and notation. In a few cases we depart for the sake of clarity or simplicity. Occasionally, where there is no danger of ambiguity, we use symbols as names of themselves. Except where noted otherwise, we use

wff	for	well-formed formula
iff		if and only if
$d(I)$		direct answer to I (or, in Sections 7.3 – 7.4, the set of these answers)
$D(I)$		the set of direct answers to I
$\neg X$		the negation of X
Λ		the empty set

2 SET-OF-ANSWERS METHODOLOGY

2.1 Hamblin's Postulates

In an informal paper Hamblin [1958] proposed three postulates:

1. An answer to a question is a statement.
2. Knowing what counts as an answer is equivalent to knowing the question.
3. The possible answers to a question are an exhaustive set of mutually exclusive possibilities.

Hamblin also suggested a calculus of questions to formalize such ideas as containment and equivalence. For example, one question *contains* another when from every answer to the first we can deduce an answer to the second; and the two questions are *equivalent* if they contain each other. This paper stimulated much formal work by others (see, e.g. Belnap and Steel [1976], p. 35).

Some linguists and logicians have argued against adopting Postulate (1) (Hintikka [1976], Tichý [1978]). For those who adopt it, however, it effects an important simplification. Replies that are not statements (e.g. noun phrases, nods, grunts) can be treated as *coded answers* that are abbreviations of statements. Thus the logic of answers is concerned only with statements.

Some logicians have argued against adopting Postulate (2) (Åqvist [1965], Hintikka [1976]). For those who adopt it, however, it represents another giant step toward formalization. The techniques inspired by it are perhaps best thought of under the label 'set-of-answers methodology' (or 'SA methodology' for short). Hamblin's own technique for defining containment and equivalence is one example; others appear below.

Postulate (2), and SA methodology in general, are compatible with several different theories about the logical nature of questions, and about the connection between a question and its answers. In fact, most of the approaches to theorizing surveyed in this chapter exemplify SA methodology at various points.

(Note: Postulate (3) is controversial and there is much unfinished business connected with it, but we do not discuss it in this chapter beyond the brief mentions in 6.6 and 7.2.)

2.2 The SA Reduction of Questions

One idea, not required by SA methodology but obviously compatible with it, is to identify a question with its set of answers. Let us call this the *SA reduction of questions*. In radical versions of SA reduction one allows

arbitrary sets of sentences to count as questions, regardless of whether these sets have defining characteristics that can be expressed in a given language. In conservative versions one considers only certain kinds of sets — e.g. sets that are definable in terms of the syntactical form of the sentences that are their members.

In several papers in the 1960s Stahl developed an SA reduction. The following is a summary of Stahl [1962].

We assume a higher-order function calculus, and then distinguish three types of questions: (1) *individual* questions (e.g. $[Hx?]$, read ‘Which things satisfy $H?$ ’), (2) *function* questions (e.g. $[F?a]$, read ‘Which functions are satisfied by $a?$ ’), and (3) *truth* questions (e.g. $[Af?B]$, read ‘Which truth-functions hold between A and $B?$ ’). To (1), *simple* answers are Ha , Hb , etc.; *direct* answers are simple answers that are not negations of theorems. We can form finite conjunctions $[Ha \wedge Hb \wedge Hd]$, $(\neg Ha \wedge \neg Hc)$, etc., and also infinite conjunctions $(x)\neg Hx$, $(x)(H'x \rightarrow Hx)$, etc. A *perfect* answer is such a conjunction which is not the negation of a theorem. A *sufficient* answer is a wff F such that F is not the negation of a theorem, and either F implies a perfect answer which is not a theorem or else F is a theorem and some perfect answer is a theorem. We now define the question $[Hx?]$ as the class of its sufficient answers.

To (2) the simple answers are Ha , $H'a$, $H''a$, etc.; as before we then form direct, perfect, and sufficient answers, and the question is defined as the class of its sufficient answers. For (3) we proceed likewise, except that there are no infinite conjunctions; e.g. $((A \vee B) \wedge (A \rightarrow B))$ is in $[Af?B]$.

The initial definitions can be generalized and made relative to a system X and a set of premises S ; we write $[P]_X S$ to mean that P is a question in X relative to S . Here the sufficient answers are required to be consistent with consequences of S . For discussion and criticism of Stahl [1962], see Harrah [1963b]. See also Section 7.5 below.

2.3 Motivation

There are several motivations for adopting an SA reduction. Besides the metalogical one (to see what can be done within set theory) there are technical and aesthetic motivations. All the operations on sets and relations between sets are directly available as operations on questions and relations between questions, and theorems about sets become theorems about questions.

For some researchers there are also Platonic, normative, and engineering motivations. It has been argued that for a rational decision-maker in a choice situation the only essential thing about a question is its set of answers (e.g. Szaniawski [1973] and Dacey [1981]).

Another motivation (a technical one?) appears in connection with Fregean principles of language construction. If every declarative sentence is to be

assigned a sense and a denotation, uniformity would suggest a similar treatment for interrogatives. The natural technique is to let each interrogative denote the set of its direct answers. Some logicians and linguists have adopted this technique, though others have argued that an interrogative denotes just the set of its true direct answers. For an entry into the literature of this topic, see Karttunen [1978], Belnap [1981], Kiefer [1983], Groenendijk and Stokhof [1984], and Higginbotham [1993].

2.4 *Some Problems*

Some logicians have argued that the SA reduction is not intuitively or empirically plausible (e.g. Tichý [1978], pp. 279 – 280). Even for those who favor it, however, it presents the problem of deciding what kind of answers are to be in the sets under consideration. It might seem that all the direct answers must be included; but, as noted above, some theorists in the tradition of Montague Grammar have equated questions with the sets of just their true direct answers.

Regardless of whether a question includes all of its direct answers, should it be allowed to include partial answers? and replies like ‘I don’t know’? Some linguists have argued for a view that in effect obliterates the distinction between direct and partial, and that would (on the SA reduction) treat a question as the set of its direct and partial answers together (e.g. Bolinger [1978], p. 104). For logicians who wish to preserve a sharp distinction between the direct and partial the simplest course (with the SA reduction) is to identify a question with the direct (or, true direct) answers, and then to define the partial answers separately. As noted above, this is the technique used in Stahl [1962].

On some motivations one who adopts SA reduction cares about questions but not about interrogatives, and specifically does not care whether there are enough interrogatives to express all questions. On other motivations one is not so indifferent, and decisions about what sets are to count as questions depend on what sentences are available as interrogatives for expressing questions.

Among many possible policies of question-definition the following are the natural ones:

1. Choose any arbitrary collection C of sets S of sentences.
2. Choose any C such that every S in C is describable in the assumed metalanguage.
3. Choose any C such that there is a set S' of sentences of L (the ‘interrogatives’) with this property: There is a many-one mapping from S' onto C (so that every question S in C is expressible by at least one interrogative in S').

4. As in (3), with the additional requirement that there is an effective procedure for recognizing interrogatives, and an effective procedure whereby, given an interrogative, we can recognize the question that it expresses.
5. Choose a C only if it, in effect, represents the set of questions belonging to some given natural language.

In fact, most logicians in the field thus far have followed (5) or (4). An empirical motivation of course leads to (5). A Platonic motivation might lead to any of (1)–(5), and would lead also to metatheoretic questions about completeness. The topics of effectiveness and completeness are of such importance that we discuss them in a separate section below.

3 EFFECTIVENESS AND COMPLETENESS

3.1 Introduction

It is usually of interest to investigate whether certain aspects of a question-and-answer system are effective, and whether the system is complete in certain respects. On some motivations it is required that certain kinds of completeness and effectiveness do indeed obtain. Probably the first theorist to note the importance of these properties and to study them in a systematic way was Belnap [1963]; we outline his ideas and results in Section 4. In this section we give a more general discussion, because the topic is important for many theories of questions.

3.2 The Problem of Effectiveness

Should the notion of *interrogative*, or *question-expresser*, be effective? Suppose it is not. Then, when questioner Q utters X , respondent R might have to ask ‘Are you asking a question?’ and then Q might have to ask ‘Is the latter a question?’ and so on back and forth indefinitely. This argument does not prove that all interrogatives must be recognizable as such, but it does suggest that some must be. Either all must be, or else there must be in the language some interrogatives with the force of ‘Does the expression X express a question?’, where these are recognizable as such.

A similar argument applies to answers. Suppose that Q utters X , and R recognizes that X expresses a question, but that *answer-to- X* is not effective. Then, when R gives a reply, Q must ask ‘Was that an answer?’ As before, this argument does not prove that every question must have an effective set of answers, but it does suggest that some must. Either all must, or there must be some question with the force of ‘Is W an answer to X ?’ and with an effective set of answers.

On the other hand one might want to allow noneffectiveness for certain types of question and answer. There seems to be no effective method for determining whether English sentences of the form ‘I wonder whether . . .’ express questions as distinct from statements. Also it seems that many who-, what-, and why- questions do not have effective answer sets.

3.3 *Concepts of Expressive Completeness*

A question system might be expressively complete (or fail to be complete) in any of several senses. First, it might be empirically complete, in that it provides for all the questions that natural languages do. Second, it might be complete in a Platonic sense, in that it provides for all the questions that ‘really exist’.

The Platonic conception may be made precise via model theory without reference to a particular language. One theory for which this would be possible is that of Tichý [1978]; see below in Section 6.6. Alternatively, we may speak of ‘all the questions that really exist, relative to a given language’. This is Belnap’s conception; see Section 4. With this conception the problem of completeness is to determine whether everything that counts as a real question is expressible by an interrogative in the given language.

Further senses of completeness are generated by semantic and pragmatic considerations. For example, a system that fails to provide for all the real questions may nevertheless provide for all the questions that have a true direct answer, or all that are truly answerable by a human being.

With respect to answers, a system may be complete if, for each of its questions, all the ‘real answers’ (again, see Belnap) are expressible. A more reasonable alternative is to require merely that, for each question that has true real answers, at least one true real answer is expressible. For further discussion of concepts of completeness, see Belnap and Steel [1976] and Harrah [1969].

3.4 *Diagonalization and Expressive Incompleteness*

In the logic of questions generally, and in SA methodology especially, we deal with sets of linguistic expressions, or sets of sets of them. Sometimes there is enough structure in the situation to permit Cantorian diagonalization. We give one example here, from Harrah [1969].

We assume that we have a language L with denumerably many expressions, and that an effective alphabetical ordering of them has been established. We assume that there is a set S of questions, and that S is recursively enumerable. Suppose that each question has denumerably many direct answers, or can be assigned denumerably many in a harmless way (e.g. by adding instances of $(P \wedge \neg P)$). Suppose next that, given a question q , the

set of direct answers to q is recursively enumerable. Finally suppose that direct answers are sentences, and that *sentence* is effective.

Now we can diagonalize to construct new sets of sentences each of which is not the set of direct answers to any question in the assumed enumeration of questions. Viz: Choose any positive integer j . Then for the alphabetically first member of the new set D we choose the alphabetically j th sentence after the first direct answer of the first question, and for the alphabetically $(i + 1)$ th member of D we choose the alphabetically j th sentence after the first direct answer d of the $(i + 1)$ th question such that d is alphabetically later than the i th member of D . To make D more interesting we can specify in advance some recursive property P and stipulate that the construction is to move at least j sentences and keep going until it finds a sentence with the property P .

One consequence that is relevant to many theories but to the SA reduction in particular is this: If *question* and *direct answer* are effective (or merely enumerable, as assumed above), then the system is incomplete in the sense that not every set of sentences can be the set of direct answers to a question. For further discussion, see Harrah [1969].

3.5 *Deductive Completeness*

There is another family of completeness concepts that has been suggested by work of Kubiński and Wiśniewski (see 8.5 in Wiśniewski [1995]). The basic idea is that relations like implication can hold between (1) wffs and questions and (2) questions, and the particular relationships that do hold can be described or expressed via statements of a certain form F in a metalanguage ML of the given language L . Then, in analogy with the development of systems of logic for declarative sentences, we may choose some set S of statements of ML and ask whether S is a complete axiom set for all of the true statements of the form F .

This area invites and awaits exploration.

4 BELNAP'S ANALYSIS

In this section we summarize a part of Belnap and Steel [1976]. That book presents (1) a formal system for question-and-answer, (2) a rich metatheory for the system, (3) discussion of application to English, (4) discussion of application to data processing and information retrieval, and (5) an extensive bibliography by U. Egli and H. Schleichert. Here we summarize just (1) and (2). Because they were the work of Belnap (completed in 1968), we shall call them Belnap's system and Belnap's theory. We present Belnap's theory in detail because many of his concepts apply to systems other than his own, and many of his concepts deserve to become standard.

4.1 Motivation

The main motivation is a normative one: to construct a rational system applicable in situations of a certain kind — namely, where questioner Q and respondent R are motivated to help each other, and R has access to a well structured information source. In particular R may be a machine, and the information source may be a data bank.

For Belnap, a system is adequate for these situations only if it meets certain conditions of effectiveness. First, the interrogatives must be effectively recognizable as such. Second, given any question, its direct answers must be effectively recognizable as such. The latter is the fundamental criterion, emphasized in both Belnap [1963] and Belnap and Steel [1976].

4.2 The Assertoric Basis

The language L is an applied first-order functional calculus with identity. There are denumerably many individual variables w, x, y, z, \dots , and countably many individual constants, n -ary function constants f, g, \dots , and n -ary predicate constants F, G, \dots . There are signs $=$ for identity, \wedge for conjunction, \vee for disjunction, \rightarrow for the material conditional, \leftrightarrow for the material biconditional, \exists and \forall for the existential and universal quantifiers. *Term* and *wff* are defined as usual, except that n -ary conjunctions $(A_1 \wedge \dots \wedge A_n)$ and disjunctions $(A_1 \vee \dots \vee A_n)$ are permitted for each n . We use a, b, c, \dots for terms and A, B, \dots for wffs. An *n -place condition* is a wff with exactly n free variables. A *statement* is a wff with no free variables. A *name* is a term with no free variables. Given $Ax_1 \dots x_n$, we understand that $Ab_1 \dots b_n$ comes from $Ax_1 \dots x_n$ by proper substitution of b_i for x_i .

Some one-place conditions are designated as *elementary category conditions* (including $(x = a)$ for each name a). The set of *category conditions* is defined recursively by:

1. Every elementary category condition is a category condition.
2. If Ax and Bx are category conditions with x as the only free variable, then $(Ax \wedge Bx)$ and $(Ax \vee Bx)$ are category conditions, and so too is any result of changing variables (free or bound) in Ax .

With each elementary category condition Ax there is associated a decidable set of names, called the *nominal category determined by Ax* . If Ax is $(x = a)$, the nominal category must be $\{a\}$. If Ax and Bx differ only in their variables (free or bound), they determine the same nominal category. If Ax is $(Bx \wedge Cx)$ or $(Bx \vee Cx)$, then its nominal category is the intersection or union of the nominal categories determined by Bx and Cx .

For the semantics of L , a *candidate interpretation* consists of a nonempty domain of individuals D and an interpretation function of the usual extensional kind. *Denotation* and *truth* are defined as usual. The *range* of a

one-place condition Ax in a candidate interpretation M is the set of individuals i in the domain of M such that Ax is true in M' , where M' is like M except in assigning i to the free variable x in Ax . The range in M of a category condition is also called the *real range*, or the *real category determined by* that condition in M . Category conditions differing only in their free or bound variables are *equivalent*; we write $\mathbf{C}x$ for the set of conditions that are equivalent to Cx .

An *interpretation* is a candidate interpretation M in which, for every category condition Ax , every name in the nominal category determined by Ax denotes in M some individual in the real category determined by Ax in M . *Consistency*, *validity*, *logical implication* and *logical equivalence* are defined as usual. Where there is no explicit reference to an interpretation, it is understood that there is implicit reference to some *principal interpretation*.

4.3 Elementary Questions

The elementary questions are whether-questions and which-questions. An elementary question is expressed by an *elementary interrogative*. These have the form $?\rho\sigma$, where ρ denotes a request, σ denotes a subject and $?$ denotes the function which takes a request and a subject as arguments and produces a question as value.

An *abstract whether-subject* is a finite set of wffs. The *range determined by* this subject is the set itself; likewise, the set of *alternatives presented by* this subject is the set itself. A *lexical whether-subject* is a finite list of wffs enclosed in parentheses, as: (A_1, \dots, A_n) . To simplify matters it is required of both abstract whether-subjects $\{A_1, \dots, A_n\}$ and lexical whether-subjects (A_1, \dots, A_n) that there be no repetitions among A_1, \dots, A_n , and that no A_i be a conjunction of other statements in the list A_1, \dots, A_n . The lexical whether-subject (A_1, \dots, A_n) *signifies* the abstract whether-subject $\{A_1, \dots, A_n\}$.

An *abstract which-subject* is a triple $\langle X, g, A \rangle$ such that X is a nonempty set of variables (the *queriables*), g is a *category mapping* in X (i.e. a mapping from a subset of X into the set of equivalence classes of category conditions), and A is a matrix (a wff whose free variables include the queriables).

Let $\langle X, g, Ax_1 \dots x_n \rangle$ be an abstract which-subject, where $X = \{x_1, \dots, x_n\}$, and g is a category mapping in X . Then the *nominal alternatives* making up the *nominal range determined by* this subject and *presented by* any question with this subject are the results $Aa_1 \dots a_n$ of substituting a name a_i for a queriable x_i (for each i) in the matrix $Ax_1 \dots x_n$, under the restriction that, if $g(x_i)$ is defined and is $\mathbf{C}x$, then a_i must be in the nominal category determined by Cx .

For any interpretation M , the *real M -alternatives*, or *alternatives in M* , which make up the *real M -range* or *range in M* , *determined by* $\langle X, g, Ax_1 \dots x_n \rangle$, and *presented by* any question with this subject are all the

pairs $\langle f, Ax_1 \dots x_n \rangle$, where f is a function from X into the domain in M , under the restriction that, if $g(x_i)$ is defined and is $\mathbf{C}\mathbf{x}$, then $f(x_i)$ is in the real range in M of Cx . A real M -alternative $\langle f, Ax_1 \dots x_n \rangle$ is *true in M* just in case $Ax_1 \dots x_n$ is true in that M' which is like M except in assigning $f(x_i)$ to x_i for each i . Roughly, a nominal alternative $Aa_1 \dots a_n$ *signifies in M* the real alternative $\langle f, Ax_1 \dots x_n \rangle$, provided that a_i denotes in M the individual $f(x_i)$.

A *lexical which-subject* is an expression of the form

$$(C_1x_1, \dots, C_r x_r, x_{r+1}, \dots, x_n \| Ax_1 \dots x_n),$$

where x_1, \dots, x_n is a nonempty nonrepeating sequence of variables, and $C_1x_1, \dots, C_r x_r$ is a possibly empty sequence of category conditions, each $C_i x_i$ being a category condition with x_i as its one free variable. Here each x_i is *governed by* the category condition $C_i x_i$, while x_{r+1}, \dots, x_n are *category-free*.

Given such a lexical which-subject, we can recover the abstract which-subject that it *signifies*, in the obvious way. The queriables are all of x_1, \dots, x_n , but g is defined only for x_1, \dots, x_r .

In a footnote added late (p. 26), Belnap and Steel say that it was a mistake to define an abstract which-subject as the triple $\langle X, g, A \rangle$, because then $(x \| Fx)$ and $(y \| Fy)$ signify distinct abstract which-subjects. They suggest defining an abstract which-subject not as $\langle X, g, A \rangle$ but rather as “something amounting to the equivalence-class generated from this by means of uniform substitution for queriables”. To avoid complicating our exposition here we shall not make this change but will continue as in Belnap’s original development.

A *which-interrogative* has the form

$$?\rho(C_1x_1, \dots, C_r x_r, x_{r+1}, \dots, x_n \| Ax_1 \dots x_n).$$

The variables x_1, \dots, x_n occur free in $Ax_1 \dots x_n$, and are said to be free in the list $C_1x_1, \dots, C_r x_r, x_{r+1}, \dots, x_n$, but are considered to be *bound* in the interrogative as a whole.

Roughly: Every direct answer to an elementary question is a conjunction $(S \wedge C \wedge D)$, where S is a selection drawn from among the presented alternatives, C is a completeness-claim, and D is a distinctness-claim. The selection S is itself a conjunction $(S_1 \wedge \dots \wedge S_p)$ without repetitions. $(S_1 \wedge \dots \wedge S_p)$ is a *lexical selection*, and the corresponding set $\{S_1, \dots, S_p\}$ is an *abstract selection*. In the case of which-questions, the *nominal selection signified by* $(S_1 \wedge \dots \wedge S_p)$ is $\{S_1, \dots, S_p\}$; if each of the S_i is in the range of a which-subject σ , then the *real selection signified by* $(S_1 \wedge \dots \wedge S_p)$ *in M relative to σ* is the set of real alternatives signified by the S_i in M relative to σ .

Because direct answers have $(S \wedge C \wedge D)$ structure, the request ρ in $?\rho\sigma$ has a structure of the form $(\mathbf{s} \mathbf{c} \mathbf{d})$. Here \mathbf{s} is a selection-size specification,

which is a pair of numerals $\overset{\mu}{\nu}$, where ν is a positive numeral representing a lower bound on the selection size, and μ is either a positive numeral ($\geq \nu$) representing an upper bound, or a dash signifying the absence of an upper bound. The $\overset{\mu}{\nu}$ notation is a *lexical selection-size specification*, and it *signifies* the corresponding *abstract selection-size specification*, which is the corresponding ordered pair of cardinals (or the dash).

A subject σ *sanctions* a selection $(S_1 \wedge \dots \wedge S_p)$ if each S_i is in the range determined by σ . A request ρ *sanctions* a selection if the length of the selection falls within the limits specified by the selection-size specification of ρ . An interrogative $?\rho\sigma$ *sanctions* a selection if both ρ and σ do.

Roughly: The completeness-claim made by a direct answer is a claim as to how complete the selection is when measured against the totality of true alternatives presented by the question. Completeness-claims may be analyzed in terms of quantifiers, where a *quantifier* Q is defined as a binary relation between classes T and S (here T would be the set of true alternatives, and S would be the selection) such that whether or not $Q(T, S)$ holds depends on the cardinalities of $T \cap S$ and $T - S$ (e.g. the universal quantifier is the quantifier in which $T - S = 0$). Belnap mentions various examples of quantifiers that might be used, and the possibility of letting the specification indicate a range of completeness-claims. To develop these possibilities would require an enrichment of the assertoric basis, so Belnap confines attention to just the universal quantifier and the claim it represents, the maximal completeness-claim. Notation: $\text{Max}(\sigma, S)$.

For whether-questions: Given a lexical whether-subject and a selection $S(S_1 \wedge \dots \wedge S_p)$ sanctioned by that subject, we define $\text{Max}(\sigma, S)$, the *maximum completeness-claim in σ and S* , as $(\neg B_1 \wedge \dots \wedge \neg B_r)$, where B_1, \dots, B_r are (in order) all the members of the subject that are not in the selection S .

For which-questions: Assume as given a lexical which-subject

$$\sigma = (C_1 x_1, \dots, C_r x_r, x_{r+1}, \dots, x_n \parallel A x_1 \dots x_n)$$

and a selection

$$S = (A a_{1_1} \dots a_{1_n} \wedge \dots \wedge A a_{p_1} \dots a_{p_n})$$

sanctioned by σ . Then we define $\text{Max}(\sigma, S)$ as

$$\forall x_1 \dots \forall x_n [C_1 x_1 \wedge \dots \wedge C_r x_r \rightarrow [A x_1 \dots x_n \rightarrow [(x_{1,n} = a_{1_1,n}) \vee \dots \vee (x_{1,n} = a_{p_1,n})]]],$$

where $(x_{1,n} = a_{k_1,n}) = [(x_1 = a_{k_1}) \wedge \dots \wedge (x_n = a_{k_n})]$.

A dash is used for the *lexical empty completeness-claim* specification. Then $?(s - \mathbf{d})\sigma$ *specifies no completeness-claim*, and $?(s \forall \mathbf{d})\sigma$ *specifies the maximum completeness-claim*. Given an interrogative I and a selection S

sanctioned by I , the *completeness-claim sanctioned by I relative to S* , or $Comp(I, S)$, is not defined if I specifies no completeness-claim, and is defined as $Max(\sigma, S)$ if I specifies the maximum completeness-claim.

Single-example questions have the form $?(1 - \mathbf{d})\sigma$.

Some-examples questions have the form $?(1 - \mathbf{d})\sigma$.

Unique-alternative questions have the form $?(1 \forall \mathbf{d})\sigma$.

Complete-list questions have the form $?(1 \forall \mathbf{d})\sigma$.

For the following theorem we say that I_1 is *erotetically equivalent to I_2* iff, for every $d(I_1)$ there is an equivalent $d(I_2)$, and for every $d(I_2)$ there is an equivalent $d(I_1)$.

THEOREM 1. *The completeness-claim specification is dispensable in some cases but not in all. Viz: (A) For each whether-question interrogative, there is an erotetically equivalent single-example whether-interrogative. (B) Unique-alternative which-interrogatives are erotetically equivalent to certain single-example which-interrogatives. (C) There are certain complete-list which-interrogatives that are not erotetically equivalent to any some-examples which-interrogative.*

Result (B) can be generalized from exactly-one to exactly- n . The trick is to add to the subject the appropriate completeness-clause $\forall y(Ay \rightarrow (y = x_1 \vee \dots \vee y = x_n))$. Compare Åqvist [1965], pp. 123ff. Further results on equivalence of this sort are noted in Åqvist [1965] and Kubiński [1980], pp. 61–68.

Concerning distinctness-claims, Belnap says that only two kinds have a systematic use in question logic: the empty and the nonempty. Let σ and S be as in the definition of Max . Then $Dist(\sigma, S)$ is defined as a conjunction of disjunctions of the form $((a_{i_1} \neq a_{j_1}) \vee \dots \vee (a_{i_n} \neq a_{j_n}))$ which says that the conjuncts of S signify, relative to σ , distinct real alternatives.

Notation. $-$ for the lexical empty distinctness-claim specification, and \neq for the lexical nonempty distinctness-claim specification. Given an interrogative I and a selection sanctioned by I , the *distinctness-claim sanctioned by I relative to S* , or $Dist(I, S)$, is not defined if I specifies no distinctness-claim, and is defined as $Dist(\sigma, S)$ if I does specify a distinctness-claim.

4.4 Answers

Let I be an elementary interrogative and S be a selection sanctioned by I . Then A is a *direct answer to I* iff I and A have the corresponding forms indicated:

I	A
$?(s - -)\sigma$	S
$?(s\forall -)\sigma$	$S \wedge \text{Comp}(I, S)$
$?(s - \neq)\sigma$	$S \wedge \text{Dist}(I, S)$
$?(s\forall \neq)\sigma$	$S \wedge \text{Comp}(I, S) \wedge \text{Dist}(I, S)$

4.5 Effectivity, Univocity, Completeness

Belnap says that his elementary interrogatives and their answers as defined above satisfy criteria of *effectivity* and *univocity*. One can effectively tell whether an expression is an elementary interrogative (effectivity) and, given that it is, what question it puts (univocity). Given a wff A and interrogative I , one can effectively tell whether A is a $d(I)$ (effectivity) and, if it is, how it answers I (univocity). It is for the sake of effectivity that we require the nominal ranges of category conditions to be effective, allow n -ary conjunction, and bar conjunctions of alternatives from counting as alternatives.

Roughly, a *real answer* to a which-question is a sequence of real alternatives presented by that question, and the system is *complete* only if every real answer is expressible by some nominal answer. Completeness can fail if some entities do not have names, or do not have names in the proper nominal categories, and also if some true real answers are infinite. Also, as Belnap points out, no category system can be complete; for there are only denumerably many one-place wffs available to serve as category conditions, while there are nondenumerably many sets of names that might be wanted as categories. Roughly speaking, the positive result is that, for any given category system, Belnap's answer system is complete up to these limitations: the real answers must be finite, the entities involved must have names, and the names must be in the right nominal categories. (For the precise account, see Belnap and Steel [1976], Section 1.34.)

4.6 Useful Abbreviations

Belnap suggests the following rules for abbreviating requests: (1) Drop parentheses around the request. (2) Omit dashes. (3) Omit '1' as a lower limit. Then, where σ is a subject, these rules allow

$?^1\sigma$	for	single-example questions,
$?\sigma$		some-examples questions,
$?\neq\sigma$		some-distinct-examples questions,
$?^1\forall\sigma$		unique alternative questions,
$?\forall\sigma$		complete-list questions,
$?\forall\neq\sigma$		complete-and-distinct-list questions.

For abbreviating subjects, where A has no free variables, A abbreviates $(A, \neg A)$; and, where A contains exactly x_1, \dots, x_n free (given in order), then A abbreviates $(x_1, \dots, x_n \parallel A)$. Then ‘Is it the case that A ?’ can be expressed by either $?^1 A$ or $?A$.

4.7 Elementary-like Questions

In first-order functional calculi there are six parts of speech: open and closed wffs, open and closed terms, connectives, and quantifiers. These generate 36 types of *elementary-like* questions, each type *positing* an entity of some part of speech and having as *desiderata* entities of some parts of speech; e.g. a whether-question can be analyzed as positing a sequence of statements and asking for a truth-functional connection between them. Belnap credits this idea to Stahl [1962].

As noted above, Stahl assumed a higher-order function calculus and analyzed just individual-questions, function-questions, and truth-questions. Kubiński has considered enriched languages in which one can ask these and related questions (Kubiński [1980], Section I.12). It does not appear that anyone has yet made a full study of all 36 of the possibilities noted above, or of the analogous set for higher-order languages. The possibilities that Belnap discusses are six:

1. *Whether-questions.* Each of these posits a sequence (conjunction?) of statements and has truth-functional connectives as desiderata. The presented alternatives are formed by constructing truth-functional compounds of the posited wffs.
2. *Which-questions.* Each of these posits an open wff and has closed terms as desiderata. The presented alternatives are formed by substituting one of the closed terms for one of the free variables in the posited wff.
3. *Description-questions.* Each of these posits a closed term and has *descriptors* (i.e. open wffs) as desiderata. One way to formalize is this: Let L have a list of *determinables*, which are open wffs, and with each determinable let there be associated a list of *descriptors*. (E.g. with ‘ x is a color’ we associate ‘ x is red’, ‘ x is green’, etc.) For semantic coherence each candidate interpretation must be such that an individual satisfies a determinable only if also satisfying some descriptor associated with it. Where Hx is a determinable with H_1x, \dots, H_ix, \dots with it, to posit a term b and call for H_1x, \dots, H_ix, \dots as desiderata we would use a new sort of subject $\text{Des}(Hx \parallel b)$ whose range is the set of presented alternatives H_1b, \dots, H_ib, \dots . For this sort of question distinctness-claims can be expressed via wffs of the form

$\neg\forall x(H_i x \leftrightarrow H_j x)$. Completeness-claims can be expressed in a first-order way only in special cases, however — e.g. in the case where the set of the associated descriptors is finite.

4. *Identity-questions*. Each of these posits a closed term and has closed terms as desiderata. We define the subject as $\text{Ident}(Cx||b)$, where b is the posit and Cx is a category condition with associated names a_1, \dots, a_i, \dots . The presented alternatives are $(b = a_1)$, $(b = a_2), \dots$
5. *What-questions*. Belnap distinguishes four sub-types: *equivalence questions*, with subject $\text{Equiv}(Hx||Ax)$ and alternatives $\forall x(Ax \leftrightarrow H_i x)$; *necessity-questions*, with subject $\text{Nec}(Hx||Ax)$ and alternatives $\forall x(Ax \rightarrow H_i x)$; *sufficiency-questions*, with subject $\text{Suf}(Hx||Ax)$ and alternatives $\forall x(H_i x \rightarrow Ax)$; and *intersection-questions*, with subject $\text{Inter}(Hx||Ax)$ and alternatives $\exists x(H_i x \wedge Ax)$. In all cases here the H_i are descriptors associated with Hx . As with description-questions, completeness-claims can be expressed in a first-order language only in the finite case.
6. *How-many Questions*. Each of these posits an open wff and has quantifiers as desiderata. The alternatives are formed by prefixing the quantifier to the wff. Full study of this awaits further work on the logic of quantifiers.

4.8 Compounding

Given interrogatives I_1, \dots, I_n , we write $(I_1 \cup \dots \cup I_n)$ for the *unionized interrogative* of I_1, \dots, I_n . For this interrogative the concepts of subject and request are not defined. We say that A is a direct answer to it iff A is a direct answer to at least one of the I_i . In a similar way we can form intersection, complement, and set-difference questions. Belnap says that intersections and complements of questions do not appear to be useful, but set-difference might be (cf. ‘Tell me about ..., without telling me about —’).

The above-mentioned operations are boolean. In contrast there are other operations best thought of as logical or syntactical. Viz:

We define $(I_1 \wedge \dots \wedge I_n)$ as the *conjunction* of I_1, \dots, I_n . Its direct answers are conjunctions $(A_1 \wedge \dots \wedge A_n)$, where each A_i is a direct answer to I_i . Belnap says that negation, disjunction, implication, and equivalence, conceived as logical operations on questions, do not seem to be of much interest.

Incidentally, the connective ‘or’ in English interrogatives is ambiguous.

Compare:

‘Who or what killed the dog?’ [exclusive *or*]

‘Have you been to Sweden, or have you been to Germany?’
[inclusive *or*]

‘What day have you chosen, or what week?’ [nonsymmetric *or*]

‘Is it a bird or is it a plane?’ [simple whether-question]

For discussion see Stahl [1962], and Belnap and Steel [1976], p. 91.

Given a list of whether- and which-subjects $\sigma_1, \dots, \sigma_n$, we can form the *unionized subject* $(\sigma_1 \cup \dots \cup \sigma_n)$. The set of *presented alternatives* is the union of the sets presented by $\sigma_1, \dots, \sigma_n$, but the selections sanctioned by the unionized subject are conjunctions of alternatives presented by it. Expression of the appropriate completeness- and distinctness-claims is tedious.

Given elementary requests ρ_1, \dots, ρ_n , we let $(\rho_1 \cup \dots \cup \rho_n)$ be a *unionized request*. The interrogative $?(\rho_1 \cup \dots \cup \rho_n) \sigma$ is to be treated like the union of the interrogatives $?\rho_1 \sigma, \dots, ?\rho_n \sigma$.

To formalize hypothetical questions, Belnap introduces *hypothetical interrogatives* $(P \mid \rightarrow \mid I)$, where P is a wff and I is an interrogative. The direct answers are wffs $(P \rightarrow A)$, where A is a $d(I)$.

To formalize *given-that questions*, Belnap introduces interrogatives $(P \mid \wedge \mid I)$, with direct answers $(P \wedge A)$, where A is a $d(I)$.

Belnap says that $(P \mid \rightarrow \mid I)$ could be called an *added-condition* question, and $(P \mid \wedge \mid I)$ an *added-conjunct* question. “We leave it to the reader to determine whether there is any point in introducing ‘added disjunction’ or ‘added equivalence’ questions” (pp. 98 – 99).

Let I be an interrogative with x free (hence, not a querable). Then we can allow $\forall x I x$ to be an interrogative, and define the direct answers as conjunctions

$$(A_1 a_1 \wedge \dots \wedge A_n a_n \wedge \forall x (x \neq a_1 \wedge \dots \wedge x \neq a_n \rightarrow Bx)),$$

where $A_1 x, \dots, A_n x, Bx$ are all direct answers to I .

To allow for qualification in terms of a category condition Cx , we use $\forall_{[Cx]} I$ and define its direct answers as conjunctions

$$(A_1 a_1 \wedge \dots \wedge A_n a_n \wedge \forall x (Cx \rightarrow (x \neq a_1 \wedge \dots \wedge x \neq a_n \rightarrow Bx)))$$

as above, but requiring also that each a_i is in the nominal category determined by Cx .

To formalize ‘Answer I for some x in the domain’ (where x is not free in I), Belnap uses not $\exists x I$ but $\cup x I$, whose direct answers are the wffs Aa such that Ax is a direct answer to Ix . Thus $\cup x ?^1(Px)$ has the same answers as $?^1(x \parallel Px)$. Belnap says that $\exists x I$ might have a use if the operation of disjunction on questions can be shown to have a use.

As emphasized by many writers, conditional questions call for an answer only if a given condition obtains. A general theory may use these basic notions: I calls for an answer in an interpretation M , and A is a *direct answer to I in M* . The latter is undefined unless I is *operative* (i.e. calls for an answer) in M . *Absolute* interrogatives are those for which direct answer is defined without relativization to M . *Relativized* interrogatives are those for which direct answerhood is relativized to interpretations. *Categorical* interrogatives call for an answer in every M and have the same direct answers in every M .

Belnap writes (P/I) for a *conditional interrogative* with *condition P* and *conditioned interrogative I* . Then (P/I) calls for an answer in an interpretation M iff P is true in M and I calls for an answer in M . If (P/I) calls for an answer in M , then A is a *direct answer to (P/I)* iff A is a direct answer to I in M .

Belnap also discusses conjunction and union of relativized interrogatives, and points out the natural generalization via universal quantification.

4.9 *Presupposition and Truth*

Belnap's intention is, roughly, that every question presupposes precisely that at least one of its direct answers is true. (For relativized questions we should prefix 'if the question is operative, then ...'.) Presuppositions can be attached to interrogatives in a way that parallels their attachment to questions. For simplicity we formulate the discussion here in terms of interrogatives. We assume throughout that A is any wff, and M is any interpretation. As before, $d(I)$ abbreviates 'direct answer to I ', and $D(I)$ denotes the set of direct answers to I .

Let I be a whether-interrogative. Then: I is *true in M* iff some $d(I)$ is true in M , and I is *false in M* otherwise. I *presupposes A* if A is true in every M in which I is true. A *expresses-the-presupposition-of I* if A is true in exactly those M in which I is true.

Let I be a which-interrogative. Then: I is *really true* [*really false*] in M iff some real answer to I is true in M [every real answer to I is false in M]. I is *nominally true* [*nominally false*] in M iff some (nominal) $d(I)$ is true in M [every $d(I)$ is false in M]. I *really* [*nominally*] *presupposes A* iff A is true in every M in which I is really [nominally] true. A *expresses-the-real-* [*nominal-*] *presupposition of I* iff A is true in exactly those M in which I is really [nominally] true. For uniformity we use unqualified ' I is true in M ', ' I presupposes A ', and ' A expresses-the-presupposition-of I ' for both which- and whether-interrogatives, meaning for which-interrogatives the 'real' variety.

If there is an A that expresses-the-presupposition-of I , then there are indefinitely many such A , so it is convenient to pick one such and call it *the* presupposition of I ; notation: $\text{Pres}(I)$. For whether-interrogatives we

choose some disjunction of the direct answers. For which-interrogatives the construction is straightforward but tedious. Belnap's example: Let I be $? \rho(Cx \parallel Fx)$. Then $\text{Pres}(I)$ will be a conjunction $(P_1 \wedge P_2 \wedge P_3)$ of at most three conjuncts. P_1 is always present, and says that at least one C is an F . P_2 is present just in case ρ is $(\overset{\nu}{\mu} \forall \mathbf{d})$, where ν is an integer; P_2 says that at most ν C 's are F 's. P_3 is present just in case ρ has the form $(\overset{\nu}{\mu} \mathbf{c} \neq)$; P_3 says that at least μC 's are F 's.

It is possible to define $\text{Pres}(I)$ in such a way that, for each elementary interrogative I , $\text{Pres}(I)$ is an effectively specified wff that expresses-the-presupposition-of I . In the case of nominal presuppositions it is not in general possible to find for each which-interrogative I a wff that expresses-the-presupposition-of I . See Belnap [1963], Section 7.5.

Let us say that X is a *quasi-wff* iff X is a wff or an interrogative. Then, using X for quasi-wffs and H for sets of quasi-wffs, we define: M is an *H-interpretation* iff every member of H is true in M . X is *logically H-true*, *H-consistent*, or *H-inconsistent* according as X is true in all, some, or no H -interpretations. H' *propositionally H-implies* X iff X is true in every H -interpretation in which every member of H' is true. Similarly with other semantic concepts. For brevity the 'propositionally' may be omitted before 'H-implies' and 'H-equivalent'.

4.10 Types of Answer

Let us say that a wff, considered as a reply to I , is *H-uninformative* if it is H -implied by I , and otherwise *H-informative*. Such a wff is *H-foolish* if it is H -inconsistent, and otherwise *H-possible*. It is *relatively H-foolish* if it is H -inconsistent with I , and otherwise *relatively H-possible*.

Such a wff is an *H-complete answer to I* iff it H -implies some $d(I)$, and an *H-just-complete answer* if it is H -equivalent to some $d(I)$. It is an *H-partial answer* iff it is H -implied by some $d(I)$. It is an *H-eliminative answer* iff it H -implies the negation of some $d(I)$, and *H-quasi-eliminative answer* iff it is H -implied by the negation of some $d(I)$.

Belnap says that A is a *Harrah-H-complete answer to I* iff A is a $(H \cup \{I\})$ -complete answer to I . The essential idea, which was suggested by Harrah [1961], is that in normal cases the questioner believes that I is true and thus includes $\text{Pres}(I)$ in his background knowledge. Example: Let I be $?^1((A \vee B), (C \wedge D))$. Then $\neg C$ is not a complete answer, but it is a Harrah-complete answer. The same idea can be used to generate 'Harrah' variants on many other concepts, some of which are noted below. Suggestion: Find a substitute for the label 'Harrah', preferably a short word meaning 'presupposition-aided'.

A *proper H-partial answer* is a partial answer that is implied by some H -consistent $d(I)$. A is a *highly proper H-partial answer* iff A is both H -

informative and a proper H -partial answer. (In contrast, the *safe* answers are the uninformative partial answers.)

A is a *nominal H -corrective answer to I* iff A implies the negation of every $d(I)$. A is an *H -corrective answer to I* iff I is (really) false in every M in which A is true. For a standard corrective answer we may choose $\neg\text{Pres}(I)$ and abbreviate it (following Åqvist [1965]) by $\text{Corr}(I)$.

Any wff that counts as an answer to I relative to H , in any of the senses of answer defined above, may be said to be *erotetically H -relevant to I* .

4.11 Properties of Interrogatives

An interrogative I is *H -safe* iff I is logically H -true (i.e., H implies I); otherwise I is *H -risky*. I is *H -foolish* iff I is H -inconsistent; otherwise I is *H -possible*. (Thus I is H -safe if H implies $\text{Pres}(I)$, and H -foolish if H implies $\text{Corr}(I)$.) Parallel to these (real) concepts for interrogatives there are nominal variants, and there are concepts for questions.

THEOREM 2. [*Belnap's Hauptsatz, or, the Theorem of the Fifth Gymnosophist (see Plutarch's Alexander)*] *Ask a foolish question and you get a foolish answer.*

Belnap gives a proof of the corresponding result for interrogatives. The proof is straightforward. (See Belnap and Steel [1976], pp. 131 – 133.)

Continuing in terms of interrogatives: I is *dumb* iff I has no direct answers. I is *H -exclusive* if in each H -interpretation there is at most one true real answer (for which-interrogatives) or abstract answer (for whether-interrogatives). (Thus $?^1\forall(\dots)$ and $?^1\forall(A_1, \dots, A_n)$ turn out to be exclusive.) I is a *Hobson's Choice* if I has exactly one direct answer (e.g. $?^1(A)$).

I is *answerable by H* iff H implies some $d(I)$; otherwise I is *H -unanswerable*. I is *Harrah-answerable by H* if $(H \cup \{I\})$ implies some $d(I)$. Here, if H is the questioner's beliefs, we can say that I is *H -rhetorical*. Similarly, I may be *Harrah-unanswerable by H* , and, if H is the questioner's beliefs, we say that I is *moot*, or *open*. I is *hyper- H -moot*, or *H -wide-open*, if H provides neither a Harrah-complete answer nor an eliminative answer.

Following the suggestion of Åqvist (who used the label 'normal'), I is *H -independent* if no $d(I)$ H -implies any other $d(I)$. I is *H -minimal* if, for every A in $D(I)$, there is an H -interpretation M in which A is the one and only true $d(I)$. Minimality implies independence, but not conversely.

I_1 *H -contains I_2* just in case every H -consistent $d(I_1)$ is an H -complete answer to I_2 . I_1 *Harrah- H -contains I_2* iff every $d(I_1)$ is a Harrah- H -complete answer to I_2 .

Example: $?^1(A, B)$ Harrah-contains $?^1\forall(A, B)$.

I_1 is *erotetically H -equivalent* to I_2 iff for every $d(I_1)$ there is an H -equivalent $d(I_2)$, and, for every $d(I_2)$ there is an H -equivalent $d(I_1)$. I_1 is

Harrah-erotetically H-equivalent to I_2 iff I_1 is erotetically $(\{I_1, I_2\} \cup H)$ -equivalent to I_2 . Example: $?^1(A, B)$ and $?^1\forall(A, B)$.

I_1 is *erotetically H-relevant* to I_2 iff some $d(I_1)$ is erotetically H -relevant to I_2 .

Example: $?^1(A, \neg A)$ is (propositionally) equivalent to $?^1(B, \neg B)$ but is not erotetically relevant to it.

I_1 *H-obviates* I_2 iff every $d(I_1)$ is either an H -corrective answer or an H -complete answer to I_2 .

4.12 Extending Belnap's Analysis

There are many possibilities for further development of Belnap's system. Some of these are suggested in an obvious way by the system itself.

First: Belnap formalizes six types of elementary-like question (4.7 above), but, as Belnap and Steel point out, thirty types remain. How should they be formalized? Do they have a natural semantics? Do they have any interesting use? (For a relevant discussion, see Hiž [1962].)

Second: Belnap formalizes the maximum completeness-claim. As he points out, indefinitely many other types of completeness-claim remain to be studied.

Third: Belnap and Steel say that only one type of distinctness-claim seems to have a systematic use in question logic. This may be doubted, however, because of examples like the police chief who says

‘Give me a (nominal) list of at least ten suspects, of whom at least seven are (really) distinct.’

Surely the matter warrants further study.

Fourth: Several possibilities are suggested by ideas of Kubiński. (For a summary in English, see Kubiński [1980].) Kubiński assumes an indefinitely large stock of interrogative operators. Simple interrogatives are formed by prefixing an interrogative operator to a sentential function that contains free variables (which are then bound by the queriables in the operator). One interesting difference from Belnap concerns answer-size specifications. Belnap's interrogatives contain a selection-size specification, but each of Kubiński's interrogative operators is in effect a string of numerical quantifiers, with each quantifier binding its corresponding queriable, so the quantity specifications are attached to the queriables individually. This makes possible a straightforward formalization of interrogatives like:

‘Which two ministers voted against which three projects on which five committees?’

‘Which at most three kings have ruled which at least two countries?’

(Possible objection: English does not provide interrogatives like these. Reply: Polish shows that it ought to.) For more on interrogatives like these, and efficient ways of formalizing them, see Wiśniewski [1995], §2.2.6.2. In connection with Belnap’s system, what remains to be studied are (1) which of these are warranted in the system, and (2) how they can be accommodated in a smooth way.

Fifth: As noted by many authors, the more one enriches the underlying assertoric logic, the more questions one can construct. Some possible enrichments mentioned by Belnap and Steel are: adding variables of higher type, adding modal operators, and allowing infinite conjunctions.

Sixth: Although Belnap has argued for the importance of effectiveness at certain points in a logic of questions, and indeed one might take this as essential to his approach, we might study how the system could be extended if various of the effectivity requirements were relaxed. One example: If we drop the requirement that nominal categories be decidable, we can allow questions like

‘Which theorems of set theory should a number-theorist know?’

5 EPISTEMIC ANALYSIS OF QUESTIONS

5.1 *Motivation*

In this section we outline what is called the *imperative-epistemic* approach to questions. The object of study is said to be the ‘standard’ situation, in which (1) the questioner does not know any direct answer, and (2) the interrogative is taken to be synonymous with an imperative of the form

‘Let it be the case that I know . . .’ or

‘Make it the case that I know . . .’.

In our discussion below we may refer to this as the MMK (or ‘Make Me Know’) approach.

Kubiński mentions Bolzano and Loeser as precursors of this approach (Kubiński [1980], p. 131), but the first to give a substantial formal analysis was Åqvist. Accordingly we begin here by summarizing, in 5.2 – 5.6, the work presented in Åqvist [1965].

In the next sections (5.7 – 6.3) we outline some refinements and further developments, and some other theories that analyze questions in terms of imperatives of various kinds. Many of these theories have an empirical (perhaps phenomenological) motivation, with an implied claim that most actual question situations are “standard” (see, e.g., Wachowicz [1978], p. 157). Complications may arise if one formalizes via a logical framework (e.g., epistemic logic) that has a normative motivation.

On all variants of this general approach one may use SA methodology, but it is not necessary. It is possible to develop a substantial part of the logic of questions within the logic of imperatives, without considering answers at all. To show this in detail is a contribution of Åqvist.

5.2 Foundations

Åqvist assumes an applied first-order predicate calculus with the quantifiers (Ux) and (Ex) and identity, supplemented with the operators

$!$	(‘Let it turn out to be the case that’)
i	(‘It is permissible that’)
K	(‘I know that’)
P	(‘It is compatible with everything that I know that’)

To refer to free individual symbols (individual constants and free variables) Åqvist uses: a, b, c . To refer to bound individual variables: x, y, z . For one-place predicate constants: J_i . For n -place predicate constants: F_i^n . For the result of putting x for all free occurrences of the variable a in p we write: $p(x/a)$.

For QIE (quantified imperative-epistemic) logic:

1. Every propositional constant, predication (predicate followed by its arguments), and identity ($a = b$) is a QIE-wff.
2. If p and q are QIE-wffs, then so are $\neg p$, $(p \wedge q)$, $(p \vee q)$.
3. If p is a QIE-wff containing free occurrences of a , but not containing $!$ or i , then $(Ux)p(x/a)$ and $(Ex)p(x/a)$ are QIE-wffs.
4. If p is a QIE-wff not containing $!$ or i , then Kp and Pp are QIE-wffs.
5. If p is a QIE-wff not containing $!$ or i or any free variables, then $!p$ and ip are QIE-wffs.

A *sentence* is a QIE-wff with no free variables. A *statement* is a sentence that does not contain $!$ or i . An *ordinary statement* is a sentence that does not contain $!$, i , K , or P .

For the semantics Åqvist adopts (with some refinements) Hintikka’s notions of *model set* and *model system* for the logic of K and P , and (following Kanger) adds a relation of imperative alternativeness and imposes appropriate conditions, e.g. if μ is a model set in a model system Ω and μ^+ is an imperative alternative to μ in Ω , then, if $!p$ is in μ then p is in μ^+ . On the other hand, $!$ and i are to act as genuine imperative operators only when their arguments are epistemic statements; if p is an ordinary statement in μ and μ^+ is an imperative alternative to μ , then p is in μ^+ . To have

a complete logic of imperatives one would have to add further imperative operators (with distinct properties) that apply to ordinary statements.

If one wants to satisfy both normative and empirical motivations, one must impose a relatively complex set of conditions on model systems. We omit details. The culminating idea is the usual one: A set of sentences is *consistent* if it can be embedded in a model set that is a member of a model system. A sentence p is *valid* if $\{\neg p\}$ is not consistent, and p *entails* q if $\{q\}$ is embeddable wherever $\{p\}$ is.

5.3 Definition of Questions

Åqvist defines interrogatives by introducing various interrogative operators in abbreviations of sentences of the form $!p$. The following are examples.

Whether-questions.

$$(1) \quad ?_n(p_1, \dots, p_n) =_{df}!(Kp_1 \vee \dots \vee Kp_n),$$

where $n \geq 2$ and each p_i is an ordinary statement.

$$(2) \quad ?_{n/m}(p_1, \dots, p_n \mid r_1, \dots, r_m) =_{df}!(r_1 \wedge \dots \wedge r_m \rightarrow (Kp_1 \vee \dots \vee Kp_n))$$

where $n \geq 2$, $m \geq 1$, and each p_i and r_i is an ordinary statement.

Monadic *complete-list* which-questions. Let p be a QIE-wff not containing $!$, i , K , or P and containing just one free variable a ; let x , y , z be the alphabetically earliest variables not bound in p . Then we define:

$$(3) \quad (?_Aa)p =_{df}!(Ux)(p(x/a) \rightarrow (Ey)(y = x \wedge (Ez)K(z = y)))$$

$$(4) \quad (?_Ba)p =_{df}!(Ux)(p(x/a) \rightarrow (Ey)(y = x \wedge Kp(y/a)))$$

$$(5) \quad (?_KBa)p =_{df}!K(Ux)(p(x/a) \rightarrow (Ey)(y = x \wedge Kp(y/a)))$$

$$(6) \quad (?_EBa)p =_{df}!((Ex)Kp(x/a) \wedge (Ux)(p(x/a) \rightarrow (Ey)(y = x \wedge Kp(y/a))))$$

$$(7) \quad (?_EKBa)p =_{df}!((Ex)Kp(x/a) \wedge K(Ux)(p(x/a) \rightarrow (Ey)(y = x \wedge Kp(y/a))))$$

The latter two are equivalent to

$$(8) \quad (Ex)p(x/a) \wedge (?_Ba)p$$

$$(9) \quad (Ex)p(x/a) \wedge (?_KBa)p$$

Thus $(?_EKBa)$ and $(?_EBa)$ carry a nonemptiness claim; $(?_EKBa)$ and $(?_KBa)$ carry a completeness request. Åqvist says that $(?_Aa)$ is too weak to be of interest, and that $(?_EKBa)$ best reflects ordinary use.

Monadic *at-least-which* and *exactly-which*.

$$(10) \quad (?_{C_n} a)p =_{df}!(Ex_1) \dots (Ex_n)K(p(x_1/a) \wedge \dots \wedge p(x_n/a) \wedge x_i \neq x_j)$$

$$(11) \quad (?_{D_n} a)p =_{df}!(Ex_1) \dots (Ex_n)K(p(x_1/a) \wedge \dots \wedge p(x_n/a) \wedge x_i \neq x_j \wedge \\ \wedge (Uy)(p(y/a) \rightarrow y = x_1 \vee \dots \vee y = x_n))$$

where x_1, \dots, x_n, y are the earliest distinct variables not bound in p , and where ' $x_i \neq x_j$ ' abbreviates the obvious distinctness-clause.

The interrogative $(?_{D_n} a)p$ is equivalent to $(?_{C_n} a)p'$, where p' is

$$(p \wedge (Uy)(p(y/a) \rightarrow y = x_1 \vee \dots \vee y = x_n)).$$

Cf. the comments on the Theorem in Section 4.3 above.

Pure polyadic *relational* which-questions. The generalization to the case where monadic p is replaced by polyadic p is straightforward. Here, the defined operators have the form $(?_{*}^m a_1, \dots, a_m)$, where $*$ is B, KB, EB, EKB, C_n , or D_n .

Mixed polyadic which-questions. Let R be a binary relation. Åqvist shows how to define operators for: 'Which [At least which n] [Exactly which n] objects bear R to which (or, at least which k , or, exactly which k) objects?' e.g., the interrogative $(?_{D_n-B}^2 a, b)$ is introduced to abbreviate

$$\begin{aligned} &!(Ex)(Ey)K((Ez)Rzx \wedge (Ez)Ryz \wedge x \neq y \wedge \\ &\wedge (Ut)((Ez)Rtz \rightarrow t = x \vee t = y) \wedge (Uu)(Rxu \rightarrow \\ &\quad \rightarrow (Ew)(w = u \wedge KRxw) \wedge \\ &\quad \wedge (Uu)(Ryu \rightarrow (Ew)(w = u \wedge KRyw))), \end{aligned}$$

which expresses

'Exactly which two objects bear R to which things?'

Generalization from binary R to n -ary R is straightforward but tedious.

Categorically qualified which-questions. One way to provide for categorial qualification is to use many sorts of variables x^α and then define interrogatives of the form

$$(?_{*}^m x_1^{\alpha_1} \dots x_m^{\alpha_m})p.$$

Åqvist prefers to retain one-sorted theory and define interrogatives of the form

$$(?_{*a_1, \dots, a_m}^{J_1, \dots, J_m})p.$$

Roughly, the latter are defined by inserting $[J_i x_i \rightarrow]$ or $[J_i x_i \wedge]$ in the appropriate places.

Mixed whether-which and *conditional-which* questions. Åqvist defines *CoreQ* as the epistemic statement that is the scope of the ! operator in *Q*. Now let r_1, \dots, r_k be ordinary QIE-statements. Then:

$$(12) \quad \begin{aligned} & (?_{EKB}^m a_1, \dots, a_m; + k)(p; r_1, \dots, r_k) \\ & =_{df}!(\text{Core}(?_{EKB}^m a_1, \dots, a_m)p \vee Kr_1 \vee \dots \vee Kr_k) \end{aligned}$$

$$(13) \quad \begin{aligned} & (?_{EKB}^m a_1, \dots, a_m | k)(p | r_1, \dots, r_k) \\ & =_{df}!(r_1 \wedge \dots \wedge r_k \rightarrow \text{Core}(?_{EKB}^m a_1, \dots, a_m)p). \end{aligned}$$

Similar operators can be defined for *EB*, C_n , D_n . Also, categorial qualification can be added in the obvious way.

5.4 Presupposition, Riskiness, and Guarding

Let us use *Q* as a variable over questions. Then: *Q presupposes p* iff *p* is an ordinary statement, and *CoreQ* entails *p*. [For *Core*, see above.] A statement *p* is a *correction* to *Q* iff *p* is the negation of some presupposition of *Q*. A *safe* question is one whose presuppositions are valid. A *risky* question is one that is not safe.

PresQ is the result of dropping all occurrences of imperative and epistemic operators from *Q*. Claim: If *Q* entails an ordinary statement *p*, then *PresQ* entails *p* (Åqvist [1965], p. 133). We interpret *PresQ* as being *the* presupposition of *Q*.

The *correction of Q* = *CorrecQ* = \neg *PresQ*.

Roughly, guarding a risky question consists of transforming it into a safe one. Three methods for guarding a risky whether-question of the form $?_n(p_1, \dots, p_n)$ are:

I. [Whether-Whether Method] Use

$$?_{n+1}(\text{Correc}(?_n(p_1, \dots, p_n)), p_1, \dots, p_n)$$

II. [Whately-Prior Method] Use

$$(?_1 \text{Pres}(?_n(p_1, \dots, p_n)) \wedge ?_{n/1}(p_1, \dots, p_n / \text{Pres}(?_n(p_1, \dots, p_n))))$$

III. [Whether-If Method] Use

$$?_{n/1}(p_1, \dots, p_n / \text{Pres}(?_n(p_1, \dots, p_n)))$$

Here methods I and II are equivalent.

Four methods for guarding a risky which-question of the form $(?_{EKB}^m a_1, \dots, a_m)p$ are:

IV. [Mixed Whether-Which Method] Use

$$({}^m_{EKB}a_1, \dots, a_m; +1)(p; \text{Correc}({}^m_{EKB}a_1, \dots, a_m)p))$$

V. [Whately-Prior Method] Use

$$({}_1\text{Pres}({}^m_{EKB}a_1, \dots, a_m)p) \wedge \\ ({}^m_{EKB}a_1, \dots, a_m/1)(p/\text{Pres}({}^m_{EKB}a_1, \dots, a_m)p))$$

VI. [Which-If Method] Use

$$({}^m_{EKB}a_1, \dots, a_m/1)(p/\text{Pres}({}^m_{EKB}a_1, \dots, a_m)p))$$

VII. [Weak Mixed Whether-Which Method] Use

$$({}^m_{KB}a_1, \dots, a_m)p.$$

Here methods IV and V are equivalent. Similar techniques can be used for the cases of EB , C_n , and D_n .

5.5 Direct Answers

Roughly, a direct answer d to Q should be such that, if the questioner comes to know that d is true, then the epistemic request expressed by Q is satisfied. Specific criteria that a theory should meet include the following. (These criteria will become clear in terms of the examples below.) First, if p is either a direct answer to Q [relative to r] or a direct pseudo-answer to Q , then $p[p \wedge r]$ should entail $\text{Pres}Q$. Second, Q_1 is to entail Q_2 iff every direct proper answer to Q_1 , as well as every direct pseudo-answer (if any) to Q_1 , entails some direct proper answer or direct pseudo-answer to Q_2 . Åqvist does not yet have a complete theory of direct answers, but makes at least the following specific proposals. The numbers refer to the questions defined above in section 5.3.

To (1) the direct answers are p_1, \dots, p_n .

To (2) the direct answers are p_1, \dots, p_n ; and $\neg(r_1 \wedge \dots \wedge r_m)$ is a direct pseudo-answer.

To (7) the direct answers are

$$(p(c_1/a) \wedge \dots \wedge p(c_k/a) \wedge (Ux)(p(x/a) \rightarrow \\ \rightarrow (x = c_1 \vee \dots \vee x = c_k)) \wedge [\dots (Ey)(y = c_k)]).$$

Here, and below, x and y are to be the earliest variables not bound in p , and $[\dots (Ey)(y = c_k)]$ abbreviates

$$((Ey)(y = c_1) \wedge \dots \wedge (Ey)(y = c_k)).$$

To (6) the statements

$$(p(c_1/a) \wedge \dots \wedge p(c_k/a) \wedge [\dots (Ey)(y = c_k)])$$

are direct answers *relative to* the ordinary statement

$$(Ux)(p(x/a) \rightarrow (x = c_1 \vee \dots \vee x = c_k)).$$

To (10) the direct answers are

$$(p(c_1/a) \wedge \dots \wedge p(c_n/a) \wedge [(c_i \neq c_j)] \wedge [\dots (Ey)(y = c_n)]),$$

where there are no repetitions among the c 's and $[(c_i \neq c_j)]$ is the obvious conjunction of nonidentities.

To (11) the direct answers are

$$\begin{aligned} &(p(c_1/a) \wedge \dots \wedge p(c_n/a) \wedge [(c_i \neq c_j)] \wedge (Ux)(p(x/a) \rightarrow \\ &\rightarrow (x = c_1 \vee \dots \vee x = c_n)) \wedge [\dots (Ey)(y = c_n)]). \end{aligned}$$

To (12) the direct answers are the direct answers to (7), plus r_1, \dots, r_k .

To $(?_{EBa; +k})(p; r_1, \dots, r_k)$ the direct answers are the relativized direct answers to (6), plus r_1, \dots, r_k .

Each direct answer to $(?_{C_n a} p)$ [i.e. (10)] is a direct answer to $(?_{C_n}^J p)$ relative to the statement $(Jc_1 \wedge \dots \wedge Jc_n)$.

Each direct answer to $(?_{D_n a} p)$ [i.e. (11)] is a direct answer to $(?_{D_n}^J p)$ relative to $(Jc_1 \wedge \dots \wedge Jc_n)$, except that in the direct answer we insert $[Jx \rightarrow]$ after (Ux) .

$(?_{EKB a}^J)$ is handled in the same way $(?_{D_n}^J)$ is. For $(?_{EB a}^J)$ we relativize to a complete-list statement.

For all the cases given above the generalization from monadic p to polyadic p is straightforward. For details see Åqvist [1965], pp. 156 – 158.

Åqvist indicates, but does not prove, that the foregoing proposals satisfy the criteria mentioned at the beginning of Section 5.5 (Åqvist [1965], p. 156). On the other hand, he says that the theory is not yet complete. There is, e.g., an open problem concerning how to define direct answer for $(?_{KB})$ questions (*Ibid.*, p. 158).

Åqvist cites the following as an incoherence. Let Q be $(?_{EKB}^1 x)Nx$, expressing ‘Which things are the natural numbers?’. Then $\text{Pres}Q$ is true, but no $d(Q)$ is true. He conjectures that this is the only type of question that falsifies the *Coherence Principle*: For every Q and M , $\text{Pres}Q$ is true in M iff some $d(Q)$ is true in M . (*Ibid.*, p. 160) (Cf. Section 4.9 above.)

5.6 Extending the System

Åqvist conjectures: We can accommodate all of Belnap’s questions if we add set theory to QIE, construe questions as presenting sets of alternatives, construe Belnap’s request-indicators as quantifiers over these sets, and interpret these quantifiers in terms of imperative, epistemic, and ordinary quantifiers (*Ibid.*, p. 82). This program remains to be carried out.

5.7 Revising the Foundations

Several motivations led to a revised proposal in Åqvist [1971]. Roughly: The 1965 analysis assumed a single context of use, a single knower, a nonindexical K , and monadic imperative operators $!$ and i . The revision assumes a set of possible contexts (each context being a tuple $C = \langle s, r, t, \dots \rangle$, where s is a sender, r a receiver, t a time, \dots). It also assumes a set of possible knowers, an indexical K , and imperative operators $!$ and i that are dyadic (to express conditional obligation and permission) and may be indexical as well.

The new K carries a subscript for the knower and may carry other subscripts for other parameters such as time. Thereby we have not only standard questions ('Make me know') but also test questions ('Make me know that you know').

Because $!$ is conditional, the basic form of interrogative is now the conditional. However, unconditional forms can be defined straightforwardly, e.g.

$$?_n(p_1, \dots, p_n) =_{df} (Kp_1 \vee \dots \vee Kp_n / p_1 \vee \dots \vee p_n) \wedge \wedge (p_1 \vee \dots \vee p_n).$$

To make the epistemic logic work more smoothly, Åqvist introduces several new kinds of existential quantifier. These might generate new types of interrogative, but this matter has not been studied in detail.

5.8 Hintikka's Development

In general, on the MMK approach the point of a question is to express an epistemic request, and the point of an answer is to satisfy this request. Loosely speaking, in the 1960s Åqvist developed a theory of epistemic requests, and, since the mid 1970s, Hintikka has been articulating a theory of epistemic request-satisfaction.

Consider

'Bring it about that I know that A or I know that B .'

In Hintikka's exposition this has a presupposition — namely,

' A or B '

and a *desideratum* — namely,

'I know that A or I know that B .'

A reply that satisfies the epistemic request of the questioner completely is a *conclusive* or *full* answer. A reply that is not conclusive but does contribute some information toward satisfying the request is a *partial* answer. One of Hintikka's aims is to develop the logic of conclusiveness.

The conditions for conclusiveness may differ from one type of question to another. For example, the question

‘Who killed Julius Caesar?’

has

‘I know who killed Julius Caesar.’

as desideratum, and the reply

‘Cassius killed Julius Caesar.’

is a conclusive answer only if the questioner knows who Cassius is. Hintikka says that, for all simple questions (without intensional operators), if the desideratum has the form

$$(\exists x)KS(x),$$

then b is a conclusive answer to the question if and only if

$$(\exists x)K(b = x)$$

is established. Loosely speaking, conclusiveness requires that bound variables range over the questioner’s domain of acquaintance, and singular terms denote things in that domain. One consequence is that *conclusive answer* is not effectively recognizable from the syntactical form of the question.

For an introduction to Hintikka’s theory, see Hintikka [1976], [1983], and [1992], and Hintikka (ed.) [1988]. For further discussion and criticism of Hintikka, see Harrah [1979] and [1987]. For further studies of the epistemics and pragmatics of questions, see Kiefer (ed.) [1983] and Groenendijk and Stokhof [1984].

Hintikka and others have developed what has come to be called an *interrogative model of inquiry* that is intended to correspond to rational inquiry in science and other fields. In general, using the basic concepts of a given theory of questions one can formulate rules for rational question-and-answer procedures, including question-and-answer dialogues. In the case of Hintikka’s approach the idea is to choose rules whose rationale derives from his epistemic logic and game theoretic semantics.

One promising way of developing the semantics for this approach uses the concept of interrogative tableau. Such tableaux are formed from Beth-style deductive tableaux by adding interrogative rules — namely, rules that concern the formula that is being queried and the responses that might be given. Different sets of rules are possible, and correspondingly different systems of tableaux may be developed. For an introduction to this approach and the techniques involved, see Hintikka (ed.) [1988], Hintikka [1992], and Harris [1994].

6 OTHER APPROACHES

6.1 *MMB* ('*Make Me Believe*')

The MMK analysis of questions, and especially Hintikka's development of it, is really a family of different analyses. Family members share the reference to knowledge; family members may differ in their conception of knowledge. Consider the following (where B means 'I believe that'):

1. $KP \rightarrow P$
2. $KP \rightarrow KKP$
3. $KP \rightarrow BP$
4. $(KP \wedge [P \text{ implies } P']) \rightarrow KP'$

This set of assertions articulates a conception of knowledge that is appropriate for some normative models of knowledge and belief.

One might for various reasons hold that such a conception is too strong. One might decide to drop (4) and perhaps also (2). One might decide to drop knowledge altogether. Instead of using epistemic imperatives, one would use doxastic imperatives like

'Bring it about that I believe that A or I believe that B .'

Conclusive answers would bring sufficient evidence to produce stable firm belief. Obviously there is a spectrum of possible systems, corresponding to possible conceptions of belief and evidence. This spectrum awaits detailed study.

6.2 *TMT* ('*Tell Me Truly*')

D. and S. Lewis criticize Åqvist's MMK approach and argue that a more adequate theory results if one takes interrogatives to be synonymous with imperatives of the form 'Tell me truly ...' (Lewis [1975]). Adopting some of the Lewises' ideas, Åqvist [1983] outlines a way of developing this approach.

Åqvist assumes a three-place relation of *presentation* (sender X presents sentence S to receiver Y). The language includes an 'empty' sentence representing silence, so that each X always presents some S to each Y . Then the question 'Is it the case that P ?' is to be analyzed as

Let it be the case in the immediate future that *either* there is a sentence S such that (i) you present S to me, (ii) S is true iff P , and (iii) S is true, *or* there is a sentence S such that (i) you present S to me, (ii) S is true iff not- P , and (iii) S is true.

The question ‘For which time x is it the case that Fx ?’ is to be analyzed as:

Let it be the case in the immediate future that, for some time x , there is a sentence S such that (i) you present S to me, (ii) S is true iff Fx , and (iii) S is true.

The locution ‘ S is true’ is to be analyzed as suggested in Kripke [1975]. A detailed working out of this approach remains to be undertaken.

6.3 *GMA (‘Give Me an Answer’)*

In some situations the questioner doesn’t need MMK or TMT. What will suffice is simply ‘Give me an answer.’ For arguments and examples, see Harrah [1987].

One way to develop this approach is to assume set theory and a predicate like Åqvist’s presentation predicate. Suppose that b is a term denoting a set D of sentences. Then, to ask the question whose direct answers are the members of D , we use ‘Let it be the case that, for some x in b , you present me with x ’.

Suppose we want GMACT (Give me an answer and claim that it is true’). One method is to add syntax (including the theory of the concatenation operator $\hat{\ }^{\wedge}$) and a sentential operator \vdash , so that we have “... you present me with $\vdash x$.”

The GMA and GMACT approaches, like TMT, await detailed study. The general problem is to determine which systems model the GMA or GMACT idea at some level of abstraction (see Belnap [1969], p. 122, concerning his own system). The specific problem is to develop systems in which the GMA or GMACT idea is directly expressed by interrogative-imperatives.

6.4 *Questions as Context Descriptions*

Hamblin discusses analyses like that of Jeffreys, in which an interrogative is taken to be synonymous with

‘I do not know ...; I want to know ...; and I think you know ...’

He says that even if such analyses can be made precise in a noncircular way (avoiding the phrase ‘know whether’), they nevertheless confuse two things that should always be kept distinct: (1) the description of the situation, and (2) the content of the question (Hamblin [1958]).

6.5 Questions as their Presuppositions

Another kind of analysis takes an interrogative to be synonymous with the declarative sentence that is (roughly) the presupposition in the sense of Belnap or Åqvist (see Section 4.9 and 5.4 above). In Harrah [1961, 1963a] a whether-question is an exclusive disjunction; its direct answers are the disjuncts. A which-question is an existential generalization (the existentially quantified variables being the queriables); the direct answers are substitution-instances of the quantified matrix. In Harrah [1961] a question is required to be true. In Harrah [1963a] a question may be true or false; if false, it is said to commit the fallacy of many questions.

The motivation for this sort of analysis is metalogical (to see what can be done within first-order languages) and technical, rather than empirical. The analysis becomes plausible for application if the question-and-answer situation is interpreted as an information-matching game. The questioner begins by making an assertion (e.g. $(A_1 \vee A_2)$), and the respondent then replies by making another assertion (e.g. A_1) that gives more information about the given subject matter.

There is of course no provision for ‘tagging’ sentences to indicate when they are being used to ask questions and when they are being used simply to make assertions. Thus the analysis is plausible where the communication situation can be interpreted as a question-and-answer situation and hence as an information-matching game, but is less plausible in wider contexts where this interpretation is not possible.

6.6 Questions as Intensional Entities

According to Tichý [1978], an interrogative expresses a question, and a question is an *office* — i.e. a function defined on possible worlds. The commonest types of question are propositions, individual concepts, and properties. These are functions whose values for a given world are a truth value, an individual, and a set of individuals, respectively.

To answer a question is to cite an entity of the right type (depending on the type of question); the answer is *right* if the entity is a value of the function at the actual world. A *complete* answer cites a single entity of the right type. An *incomplete* answer cites a class of entities of the right type. An incomplete answer is *correct* if the right complete answer is one of its members.

The motivation here is partly empirical (to account for intuitions about the informativeness of answers to questions), partly metalogical (to see what can be done within the logic of propositional entities), and partly philosophical. It is based on the assumption that logic is the study of logical objects or topics, rather than speakers’ concerns and attitudes. It assumes that the declarative-interrogative distinction is not one of logic, and that the logi-

cian does not have to provide distinct syntactic forms corresponding to the various distinct speech acts such as asserting, asking, and the like.

Higginbotham [1993] presents an intensional analysis that is motivated in large part by empirical-linguistic considerations. The aim is to discover the semantics of English interrogatives. The strategy is to develop a theory of questions as intensional entities, and then show how questions may be expressed by interrogatives.

For Higginbotham, an *elementary abstract question* is a nonempty partition Π of the possible states of nature into cells P such that no more than one cell corresponds to the true state of nature. A partition is *proper* if at least one cell must correspond to the true state of nature. (The elements of a cell may be thought of as statements; the cell corresponds to the true state of nature if all the statements in the cell are true.) An *answer* to a question Π is a set S of sentences that is inconsistent with one or more cells in Π . An answer is *proper* if it is consistent with at least one cell. A *partial answer* is one that is inconsistent with some (but not with all but one) of the cells. X is a *presupposition* of Π if every cell in Π implies X .

Complex abstract questions are constructed from elementary ones by quantification, conjunction, or disjunction; these form a hierarchy of orders, with abstract questions of order n being sets of abstract questions of order $n - 1$. Elementary abstract questions may be expressed by simple interrogatives and referred to by indirect-question phrases. Complex abstract questions may be expressed by various syntactical means. Most abstract questions are not expressed by any interrogative (there are too many of them).

Each interrogative may indicate partition of a limited universe, or partition of a limited part of a given universe.

‘Who did John see?’

has the form

$[WH\alpha : \text{person}(\alpha)]? \text{ John saw } \alpha$

where the quantification is restricted to persons. This interrogative expresses a partition whose cells describe the possibilities of John’s seeing (or not seeing) persons.

To account for multiple questions (see below), Higginbotham generalizes as follows. Where Q is a restricted quantifier, φ is the restriction on Q , and Θ is another interrogative, an interrogative of the form

$[Qv : \varphi]\Theta$

expresses a question that is composed of sets of questions, one set for each way in which the quantifier, construed as a function from pairs of extensions to truth values, gives the value *true*. Consider

‘Where can I find two screwdrivers?’

This has the form

[Two x : screwdriver(x)] [What α : place(α)] x at α

and the question it expresses is the class of all classes of partitions each of which, for at least two screwdrivers a and b as values of x (and for no objects other than screwdrivers as values of x), contains the partition for the interrogatives

[What α : place(α)] a at α

[What α : place(α)] b at α

Classes of partitions are *blocs*, and classes of them are *questions of order 1*. To *answer* a question of order 1 is to answer every question in one of its blocs.

On this approach the interrogative-question-answer relationship is not effective; one reason is that some English interrogatives are ambiguous. For example, where an interrogative seems to involve quantifiers, the semantics might not involve quantifiers and sets of questions but might instead involve a functional interpretation. E.g., to

‘Which of his poems does every poet like least?’

the answers that are wanted are not lists of poet-poem pairs but are replies like

‘His earliest poems.’

Concerning the various motivations for, and the rich potential of, the intensional approach, see Tichý [1978], Materna [1981], Belnap [1981], Higginbotham [1993], and Groenendijk and Stokhof [1984]. The latter work is rich in discussion and examples, and it argues that many theories can be articulated to provide a semantic equivalent of some Hintikka-type pragmatic dimensions.

(Incidental note: On many approaches, Hamblin’s Postulate (3) [recall 2.1 above] is false. On the intensional approach it might be true; see 7.2 below.)

6.7 *Questions as Incomplete Entities*

Several linguists have proposed theories in which the semantically meaningful unit (or at least the unit of truth) is not the question but the question-answer pair. One example is Keenan and Hull [1973]. Here the motivation is to account for our intuitions about the presuppositions of questions in

natural language — in particular, the intuitions that (1) questions have no truth value, but (2) questions have presuppositions, and (3) presuppositions are to be analyzed in terms of truth-value.

Keenan and Hull in effect identify questions with interrogatives. They define the class of *L-sentences* so that every declarative is an L-sentence, and, if Q is a question and A is a definite noun phrase, then $\langle Q, A \rangle$ is an L-sentence.

For the case of wh-L-questions Q , which have the form (which, NP , S), we say: Q is *valid* in a state of affairs iff NP specifies a nonempty set (the *domain* of the question) and S , which is an L-sentence expressing the question property, is true of some members of the domain. The *answer set* determined by $\langle Q, A \rangle$ is the set of objects denoted by A that are also in the domain. The L-sentence $\langle Q, A \rangle$ is *true* in i iff (1) Q is valid in i , (2) the answer set determined by $\langle Q, A \rangle$ is nonempty in i , and (3) S is true in i of every member of the answer set. Similarly, $\langle Q, A \rangle$ is *false* in i iff (1) and (2) hold but S is false of some member of the answer set. In addition, $\langle Q, A \rangle$ is *zero* in i iff it is neither true nor false in i .

On the basis of these definitions we can in an obvious way define consequence and presupposition. This definitional chain rests on (begins with) the definition of *valid*, and the concept of validity adopted here is similar to Belnap's concept of real truth. Thus it remains to be seen whether there is any formal advantage in using this framework rather than Belnap's or Åqvist's.

Hiz [1978] presents a development of the question-answer pair approach that is like Keenan and Hull's in some of its basic conceptions but differs considerably in details of superstructure. It remains to be seen whether there are any advantages from a formal point of view.

6.8 Questions as Hyper-complete Entities

According to an approach suggested by Finn [1974] (generalizing on Harrah [1963a]), a question may be treated as an ordered pair $\langle A, B \rangle$ such that (roughly) B is an interrogative (or 'inquiry') term, and A is a statement that expresses the presuppositions of the question. In general this approach is motivated by technical and engineering considerations; and, if the context of application is narrowly conceived, then A and B can be narrowly conceived. This idea leads, however, to the following generalization. If the context of application is a relatively general type of problem-solving or inquiry situation, then A and B can be conceived in a relatively general way. Among the interrogative terms B there may be noun phrases like 'an x such that ...'; this phrase indicates what sort of entity is to be found. Among the presupposition statements A there may be any statements giving background information or imposing constraints on the search.

6.9 IQW (*‘It Is the Question Whether’*)

Hoepelman [1983] proposes to read the propositional operator ? as

‘It is the question whether’

Cf. the German

‘Es ist die Frage ob’

and in English

‘[For me] there is the question whether’

‘[For me] it is an open question whether’

The basic assumption is that

‘Is it the case that p ?’

is a question for me not when p has a truth value for me but when its truth value is still undetermined for me. Hoepelman develops a truth value analysis of interrogatives to serve an empirical motivation — in general, to account for interrogatives in natural language, and in particular to account for distinctions that reflect differences in the questioner’s certainty, as in the following pairs:

‘Is John ill?’

‘Isn’t John ill?’

Inter alia, Hoepelman adopts the following truth tables:

	$\neg p$	$(p \rightarrow q)$	$(p \leftrightarrow q)$	$?p$
q	...	11 10 01 00	11 10 01 00	...
p				
11	00	11 10 01 00	11 10 01 00	00
10	01	11 11 01 01	10 11 00 01	00
01	10	11 10 11 10	01 00 11 10	10
00	11	11 11 11 11	00 01 10 11	00

The idea here is to articulate the questioner’s certainty in terms of a comparison of two worlds — the world known by the questioner and the world known by the authority to whom the question is to be put. In the truth tables each pair of numbers represents a comparison; think of the first number as the questioner’s certainty about the given statement, and the second number as what the questioner believes is the authority’s certainty. According to these truth tables, the following are valid:

- $\neg?(p \rightarrow p)$
- $? \neg p \rightarrow \neg?p$
- $?p \rightarrow ? \neg?p$
- $?(p \rightarrow q) \rightarrow (?p \rightarrow?q)$
- $?p \rightarrow (p \rightarrow q)$

The following are not valid:

$$\begin{aligned} ?p &\rightarrow ?\neg p \\ (p \leftrightarrow q) &\rightarrow (?p \leftrightarrow ?q) \end{aligned}$$

To accommodate predicate logic and wh-questions Hoepelman extends the propositional apparatus by assuming a pair of models (each with its domain of individuals and assignment of denotations), incorporating the propositional truth value conditions, and then adding truth value conditions for the two quantifiers and wffs with free variables. Loosely speaking:

1. $? \varphi x = 10$ if $\varphi x = 01$, and $? \varphi x = 00$ otherwise.
2. The value of $\forall x \varphi x$ is the minimum of the values for φx .
3. The value of $\exists x \varphi x$ is the maximum of the values for φx .

If the two domains of individuals are identical, then the following are valid:

$$\begin{aligned} \forall x ? \varphi &\rightarrow ? \forall x \varphi \\ ? \exists x \varphi &\rightarrow \exists x ? \varphi \end{aligned}$$

If we add $=$ as a predicate, then

$$\forall x \forall y \forall z (x = y \wedge ?(y = z) \rightarrow ?(x = z))$$

is valid, but

$$\forall x \forall y (? (x = y) \wedge P x \rightarrow ? P y)$$

is not.

For some readers it is an open question whether all of the validity results noted above accord well enough with intuition; but the assertion that this sort of approach is interesting and worth exploring further is not in question.

7 OTHER TOPICS AND FURTHER WORK

7.1 Other Types of Question

Some logicians have been concerned to theorize in a global way about questions in general, setting aside or de-emphasizing the problem of distinguishing and analyzing particular types of question (e.g. Tichý [1978], and radical SA reduction). Most logicians, however, have concentrated on distinguishing and analyzing question types, one at a time; and most have concentrated on whether- and which-questions.

Little progress was made on who, what, and why questions until the 1970s. See Belnap and Steel [1976], pp. 78 – 87. Hintikka, beginning with Hintikka [1976], has made an aggressive attack on who questions. See also,

e.g., Grewendorf [1983]. Since the 1970s many logicians and linguists have studied the various types of wh-question found in natural languages, but everyone would agree that much more work needs to be done. In particular, why questions pose a special challenge.

Bromberger [1992] contains illuminating and suggestive discussion of why questions, and proposals concerning one important type. This type is exemplified by:

‘Why is it the case that X has property Y (instead of property Z)?’

Bromberger’s conception is that normally, for such questions, the questioner has had in mind a general rule R that represents some expectation E about X but the questioner fails to observe E and hence asks the question. The respondent answers the question by citing (1) an abnormic law L that specifies exceptions to the rule R , and (2) one or more exceptions that are specified by L . E.g., expecting the milk to taste good, the child asks

‘Why does this milk taste sour?’

and is told

‘All milk tastes good unless it is spoiled or adulterated, and this milk is spoiled.’

To formulate this proposal in a way that is general, precise, and not subject to counterexamples is a task that is not yet complete; see Bromberger [1992], pp. 88 – 97. On the difficulties of accommodating a Bromberger-style analysis within an extensional framework see Belnap and Steel [1976], pp. 84 – 87.

Koura [1988] outlines a Hintikka-style analysis of one family of why questions. In these the explanandum is the occurrence of event e , and the question in effect is

‘Which event caused the event e ?’

Different subtypes correspond to different types of causation. For example, let

$$E(x) =_{df} \exists y(y = x)$$

and let N be a primitive signifying nomical necessity. Then

$$N[E(x) \rightarrow E(y)]$$

expresses that x is a possible (sufficient) cause of y , and to say that x causes y we use

$$E(x) \wedge N[E(x) \rightarrow E(y)].$$

Following Hintikka’s approach the desideratum of

‘What caused e ?’

is

$$\exists xK[E(x) \wedge N[E(x) \rightarrow E(e)]].$$

Koura shows that a reply f is an adequate answer — i.e., brings about the desideratum — if and only if the conclusiveness conditions

$$\begin{aligned} &KN[E(f) \rightarrow E(e)] \text{ (relevance)} \\ &\exists xKN(x = f) \text{ (uniqueness)} \end{aligned}$$

both hold. Koura discusses other concepts of cause and suggests that some types of why question might involve pragmatic parameters.

Hintikka and Halonen [1995] (hereafter ‘H&H’) rejects this approach and says in particular that no modal element is needed for why questions per se. The gist of the H&H proposal is as follows. Consider

‘Why does b have property P ?’

Suppose we have a sentence T (e.g., a general theory) and a sentence A (e.g., some additional ad hoc information supplied by an oracle) such that

1. $(T \wedge A) \vdash P(b)$
2. $\text{not } T \vdash P(b)$
3. $\text{not } A \vdash P(b)$
4. b does not occur in T
5. P does not occur in A

where ‘ \vdash ’ indicates derivability in a Hintikka-style interrogation game based on first-order logic. Then by Craig’s Interpolation Theorem it follows that there is a formula $H[b]$ such that

1. $T \vdash (\forall x)(H[x] \rightarrow P(x))$
2. All the constants in H , except for b , occur in both T and A .
3. $A \vdash H[b]$

Call $H[b]$ the *initial condition* and $(\forall x)(H[x] \rightarrow P(x))$ the *covering law*. The proposal is that we answer the given why question by citing the initial condition or the covering law or both. The claim is that these answers are conclusive for anyone who believes that $(T \wedge A)$ is true and sees that $P(b)$ is derivable from $(T \wedge A)$.

(Comment: Those who are not committed to Hintikka-style interrogation games or criteria of conclusiveness may wish to say simply that to ‘Why

$P(b)$?' the direct answers are all sentences of the form $(H[b] \wedge (\forall x)(H[x] \rightarrow P(x)))$, where $H[x]$ is restricted in certain ways to exclude cases that are trivial or unacceptable for other reasons. The restrictions imposed by H&H are probably minimal; in practice, users of why interrogatives usually want to put further restrictions on the size or content of $H[x]$. This matter of restrictions on T , A , and H deserves much more study.)

Concerning how questions: H&H suggests briefly that, if b is allowed to occur in T , then no covering law is obtainable in general and deriving $P(b)$ from $(T \wedge A)$ seems more like answering a how question than answering a why question. This suggestion deserves to be clarified and studied in detail.

Another type of question awaiting further study is the deliberative question, exemplified by,

'What shall I do?'

These seem to call for a decision or resolution (Wheatley [1955]). They might be analyzed as genuine questions, but of a type peculiar to one-person decision-making situations. Alternatively they might be analyzed as having properties appropriate to the usual two-person question-and-answer situation, plus further pragmatic properties as well (so that they call for both an answer and a resolution). Alternatively, as suggested by Mayo [1956], they might be interpreted as calling for an imperative ('Do X !').

7.2 Other Types of Reply

As noted in Section 2.1, Hamblin's Postulate (1) has not been universally accepted. In the first place, as already noted, some logicians and many linguists have argued for allowing noun phrases to count as direct answers. There is much unfinished business here, e.g. no one has yet provided a comprehensive formal system for connecting noun phrases with the system of completeness-claims and distinctness-claims. Natural language seems to have at least a rudimentary system; e.g. to questions like

'Who were all the students who passed?'

we give answers like

'Only two: Shane and Mark.'

The problems for research are: What exactly is the system in natural language? and How can we formalize analogs for artificial languages?

In the second place, we might accept Hamblin's assumption that every direct answer is a sentence, but question whether it must be a statement. The suggestion of Mayo (see Section 7.1) that imperatives like 'Do X !' should count as direct answers presumably applies to deliberative questions and their close relatives. In the case of most other kinds of question, however, it often seems appropriate to reply with certain kinds of imperative, as in

‘Ask someone who knows the Lexitron!’

or interrogative, as in

‘How detailed an answer do you want?’

Also, of course, there are nonanswer declaratives like

‘I don’t know’ and

‘That’s a long story’

It might be argued that some of these nonanswer sentences are evasions (or possibly corrections) of the given question, but some should count as *illuminations* or at least *helps*. In any case the field awaits formalization. For a beginning, on ‘I don’t know’ replies at least, see Todt and Schmidt-Radefeldt [1979], p. 15.

There is much work to be done on the general topic of appropriate response, and in particular on the topic of finding or constructing an appropriate response. See, e.g., Lehnert [1978].

The notions of incomplete answer and partial answer invite further study. In the usual conception a partial answer is one that is implied by a direct answer. Belnap and Steel [1976] emphasize that this conception is relative to the type of implication assumed, and that we may refine the type of partial answerhood by refining the type of implication. For other problems and other perspectives on partial answerhood, see Cresswell [1965], Kubiński [1967], Groenendijk and Stokhof [1984], pp. 233 – 236, Higginbotham [1993], and Wiśniewski [1995], pp. 114 – 115, 179 – 180.

Finally, there is the challenge of Hamblin’s Postulate (3). If it is interpreted as saying that, for every question, exactly one answer is true, then it seems obviously false. Is there some other plausible interpretation under which it is true? Consider Higginbotham’s concept of proper partition (noted in 6.6 above), in which exactly one cell corresponds to the true state of nature. This might provide an intensional-analytic rationale for Postulate (3). On this and related matters, see Groenendijk and Stokhof [1984].

7.3 *Implying, Raising, and Suppressing*

Hamblin’s *containment* (recall 2.1 above) may be thought of as a kind of implication between questions. When that relation holds, each answer to the first question implies an answer to the second, so the first covers the second, so, if you ask the first, you need not ask the second. Belnap’s *propositional implication* (recall 4.9) is a simple generalization from implication between statements to, loosely speaking, implication between statements and questions. When that relation holds, truth of the implying statements and questions guarantees truth of the implied statements and questions; so,

if you know that the first question is good, you know that the second is good.

Wiśniewski [1994a and 1995] defines a cluster of concepts that are less like the Hamblin and Belnap concepts and more like the informal notion of *raising*, as in

‘Your statement raises some hard questions.’

‘Your question raises a more basic question.’

Loosely speaking, Wiśniewski’s concept of implication expresses the idea that, if you need to ask the first question, then you would be well advised to ask the second also. The remainder of this section, except for the final three paragraphs, summarizes part of Wiśniewski’s analysis.

Wiśniewski defines his concepts for a very wide class of languages. This class includes more than the usual first-order languages, but it will be helpful here for the reader to think of a first-order language with the usual extensional semantics. Wiśniewski uses ‘d-wff’ for ‘declarative well-formed formula’, Q for questions, and dQ for the set of direct answers to Q . Some interpretations are distinguished as *normal*. A set X *entails* a d-wff A iff A is true in every normal interpretation in which all the d-wffs in X are true. X *logically entails* A iff A is true in every interpretation in which all the d-wffs in X are true. X *multiple-conclusion entails* Y (or, X *mc-entails* Y) iff, for each normal interpretation I where all the d-wffs in X are true, at least one d-wff in Y is true in I .

Assumptions about questions:

1. Each question has at least two direct answers.
2. Direct answers are sentences (*d-wffs* without free variables). (Hence each dQ is at most denumerable.)
3. Each set of sentences that is finite and has at least two members is the dQ for some Q .

Q is *sound in* an interpretation I iff some A in dQ is true in I . Q is *safe* iff Q is sound in every normal I . Q is *sound relative to* X iff X mc-entails dQ . Q is *risky* iff Q is not safe.

X *evokes* Q iff (i) X mc-entails dQ , (ii) for each A in dQ , X does not entail A .

X *generates* Q iff X evokes Q and Q is risky.

Q *implies* Q' *on the basis of* a set X of d-wffs [or $\text{Im}(Q, X, Q')$] iff (i) for each A in dQ : $X + A$ mc-entails dQ' , and (ii) for each B in dQ' : there is a nonempty proper subset Y of dQ such that $X + B$ mc-entails Y . (Roughly, the implying question Q raises the implied Q' because Q' helps to answer Q ; Q' helps because each B in dQ' directs attention to a proper subset of dQ .) Q *implies* Q' [or $\text{Im}(Q, Q')$] iff $\text{Im}(Q, \Lambda, Q')$.

It is not the case that every safe question is implied by every Q on the basis of every X ; safety guarantees that clause (i) holds but does not guarantee that clause (ii) holds. On the other hand, if $\text{Im}(Q, Q')$, then Q' is safe iff Q is safe.

THEOREM 3. *If Q is sound relative to X , then there exists a sequence Z of simple yes-no questions (i.e., questions of the form $\{A, \neg A\}$) such that:*

1. *each question in Z is implied by Q on the basis of X ,*
2. *each set consisting of direct answers to the questions in Z that contains exactly one direct answer to each question in Z entails along with X some A in dQ , and*
3. *each nonlogical constant that occurs in some direct answer to a question in Z occurs in some A in dQ .*

(Note: If dQ is finite, then Z can be finite.)

Let X be a finite nonempty set of d-wffs. Then the pair $\langle X, Q \rangle$ is an e_1 -argument, and is *valid* iff X evokes Q . The triple $\langle Q, X, Q' \rangle$ is an e_2 -argument, and is *valid* iff Q implies Q' on the basis of X . For any given language L having d-wffs and questions, we can construct a metalanguage ML that has statements asserting that evocation and implication hold between particular X 's and Q 's. Then, for the given L , the set of all of these ML statements that are true can be regarded as the logic of questions of L . (The basic idea for this conception was suggested by Kubiński.)

In addition to establishing his general framework as outlined above, Wiśniewski studies several particular languages of the usual kinds (propositional, first-order, etc.) and gives many results and examples for these. Many of these results and examples are for the case where everything has a name — i.e., where every entity in the universe of the assumed interpretation I is denoted by some closed term in the language (under I). A problem for future research is to explore in detail the cases in which this is not so — i.e., where there are ‘real answers’ (in Belnap’s sense) that are not expressed by nominal answers.

Another area that awaits development is the case of questions in logic and mathematics, questions whose direct answers are logical or normal truths. Wiśniewski’s definition of evocation is tailored to fit the case of factual questions, where no direct answer is normally or logically true. The challenge is to extend the analysis to capture the concept of evocation for the wider class of questions.

Questions can be raised. Can questions be suppressed? Is suppression a dual of evocation? Is it sufficient to say simply that X *suppresses* Q iff X entails $\neg A$ for all A in dQ , and that Q' *suppresses* Q iff every B in dQ' suppresses Q ? Or are there other conditions that are sufficient for suppression? Why don’t we know more about suppression? Don’t ask.

7.4 *Reduction of Questions*

As noted in earlier sections, some theorists hold that questions are reducible to entities of other kinds. E.g., some hold that each interrogative is semantically or pragmatically equivalent to an imperative sentence. We might say that this sort of reduction is *inter-categorial*. In contrast, as common speech has long recognized, there is what we might call *intra-categorial* reduction, where one interrogative is construed as equivalent to some other interrogative, as indicated by locutions like

‘Let me rephrase my question; what I am really asking is . . .’

There are several problems of interest to logicians. One is to develop precise concepts for the general notions of equivalence and reduction, another is to find techniques for demonstrating reducibility, and another is to establish particular results.

Wiśniewski [1994b and 1995] has suggested some general concepts and established some results. The basic definition is this: [Concerning notation, see 7.3 above.] A question Q is *reducible to* a nonempty set S of questions iff:

1. for each A in dQ , for each question Q' in S , A mc-entails dQ' ,
2. each set consisting of direct answers to questions in S that contains exactly one direct answer to each question in S entails some A in dQ , and
3. no question in S has more direct answers than Q .

Some of Wiśniewski’s theorems are these: [Concerning terminology see 7.3.]

1. A question Q is safe iff Q is reducible to some set of simple yes-no questions that are implied by Q .
2. If dQ is finite, then Q is safe iff Q is reducible to some finite set of simple yes-no questions that are implied by Q .
3. If Q is risky but dQ is finite, then Q is reducible to a finite set of conditional yes-no questions [i.e., questions of the form $\{A \wedge B, A \wedge \neg B\}$] that are implied by Q .
4. If Q is risky but there is a d-wff B such that (i) B is entailed by every A in dQ and (ii) B mc-entails dQ , then Q is reducible to some set of conditional yes-no questions that are implied by Q .

Wiśniewski proves these and other theorems using straightforward model-theoretic arguments, and it might seem that such arguments are the only

means available for establishing reducibility results. Without making any claims, we conjecture that there might also be exotic methods available, perhaps different methods for different types of question. We mention two examples:

The first is the set of techniques suggested in the paper of Todt and Schmidt-Radefeldt [1979]. Among the primitive signs of the language adopted are \top (for the true) and \perp (for the false). This allows interrogatives of the form

$$?v^b(v^b \leftrightarrow A)$$

which literally say

‘Which Boolean truth-value is equivalent to the statement A ?’

or colloquially

‘Is it the case that A ?’.

It remains to be seen how much can be done with this sort of apparatus, and in general what its advantages are.

The second is the methodology suggested by Leszko [1980]. According to that work certain types of question can be represented via graphs. (Leszko concentrates on the Kubiński questions noted in Section 4.12 above, questions like ‘For which n x ’s and m y ’s is it the case that ...?’.) Once a question type has been represented via graphs, we can study the questions by studying the matrices associated with the graphs. See also Leszko [forthcoming].

7.5 *Sequencing and Programming*

The general problems here are to evaluate sequences of questions with respect to their answer-yield, their safety, or other properties, and to compare sequences with respect to various concepts of containment, implication, and equivalence. One special class of problems concerns question trees, including the case of trees in which the nodes represent questions and the branches represent answers. Such a question tree can be used to represent a strategy or plan for asking questions one at a time, where at any time the choice of question depends on what previous questions have been asked and what answers have been given. Some problems for study are:

Under what conditions does a question tree represent a safe plan?

Under what conditions are two trees equivalent?

Under what conditions is a tree equivalent to a single question?

Not much has been done on these matters in general, but a few useful concepts have been developed. In Belnap and Steel [1976], p. 138, a sequence of interrogatives (I_1, \dots, I_n) is said to be a *direct partition* of an interrogative I if the conjunctive interrogative $(I_1 \wedge \dots \wedge I_n)$ is erotetically equivalent to I , and a *subdirect partition* if $(I_1 \wedge \dots \wedge I_n)$ is erotetically equivalent to $(I \wedge \dots \wedge I)$, i.e. I conjoined n times.

One special kind of sequence that has received some attention is the ‘corrections-accumulating’ sequence. The basic idea was presented in Stahl [1962]. Consider the three questions:

1. Which are the two primes between 13 and 17?
2. Which are at least two primes between 13 and 17?
3. Is there any prime between 13 and 17, or not?

Stahl pointed out that in natural language we occasionally put the sequence 1-2-3 by saying ‘1, or 2, or 3,’ where the *or* is understood to be noncommutative.

Stahl generalized and formalized as follows [recall Section 2.2 above]: An *inferential question series* is a series in which the first question is relative to some S and the $n + 1$ st question is relative to $S \cup \{A_n\}$, where A_n is a sufficient answer to the n th question, A_n is not a consequence of S , and all the sufficient answers to the n th question which neither imply A_n nor are consequences of S are not compatible with A_n . A *sufficient answer of the n th degree* is a wff which either is a consequence of S or implies a conjunction $(A_1 \wedge A_2 \wedge \dots \wedge A_{n-1} \wedge B)$ which is consistent with S , where B is a sufficient answer to the n th question which does not imply A_n . The intention is to yield the theorem: A sufficient answer of n th degree is incompatible with sufficient answers of lower degree, unless these are consequences of S .

Åqvist develops this idea within his framework as follows. Let Q be a QIE-question, and let $\{p_1, \dots, p_n\}$ be a finite set of ordinary statements. Define $Q[p_1, \dots, p_n]$ as $(p_1 \wedge \dots \wedge p_n \wedge Q)$, define its Core as $(p_1 \wedge \dots \wedge p_n \wedge \text{Core}Q)$, and define its Pres as $(p_1 \wedge \dots \wedge p_n \wedge \text{Pres}Q)$. Recall that $\text{Correc}X = \neg \text{Pres}X$.

Now let $S = \{Q_1, \dots, Q_n\}$ be any finite set of QIE-questions. Form out of S the $n!$ distinct n -termed sequences such that each member of S occurs exactly once in the sequence. Next, name these sequences and arrange them in some fixed order:

$$S_1 = \langle Q_{1_1}, \dots, Q_{n_1} \rangle, S_2 = \langle Q_{1_2}, \dots, Q_{n_2} \rangle, \dots, \\ S_{n!} = \langle Q_{1_{n!}}, \dots, Q_{n_{n!}} \rangle.$$

Then, for each S_j , define the *simplest corrections-accumulating sequence associated with S_j* (or $\text{sca}(S_j)$ for short) as

$$\langle Q_{1_j}, Q_{2_j}[\text{Correc}Q_{1_j}], \dots, \dots \rangle$$

$$Q_{n_j}[\text{Correc}Q_{1_j}, \text{Correc}Q_{2_j}, \dots, \text{Correc}Q_{(n-1)_j}].$$

Finally, for each S_j , let its QIE-translation = the QIE-translation of $\text{sca}(S_j) =$

$$\begin{aligned} &!(\text{Core}Q_{1_j} \vee \text{Core}(Q_{2_j}[\text{Correc}Q_{1_j}]) \vee \dots \vee \\ &\text{Core}(Q_{n_j}[\text{Correc}Q_{1_j}, \dots, \text{Correc}Q_{(n-1)_j}])). \end{aligned}$$

Let $S = \langle Q_1, \dots, Q_n \rangle$ be a question sequence. We say that S is *corrections-accumulable* iff, for all $1 \leq i < j \leq n$, $\text{Pres}Q_j$ does not entail $\text{Pres}Q_i$. It is *successively presupposition-containing* iff, for all $1 \leq i < j \leq n$, $\text{Pres}Q_i$ entails $\text{Pres}Q_j$. It is *quite reasonable* iff all the disjuncts inside the ! in the QIE-translation of $\text{sca}(S)$ are consistent.

It turns out that, for each finite question-set $S = \{Q_1, \dots, Q_n\}$, there is at most one sequence S_j ($1 \leq j \leq n!$) formable out of S that is both corrections-accumulable and successively presupposition-containing. In the example above, the sequence would be $\langle 1, 2, 3 \rangle$. Also, for a sequence to be quite reasonable it is necessary that it be corrections-accumulable.

One other fact: A corrections-accumulable sequence can have a safe question Q (i.e. with valid $\text{Pres}Q$) only in its final position. (For all of the above, see Åqvist [1969].)

Similar concepts and constructions can be developed in Belnap's framework by using his conditional and given-that questions. We form the appropriate sequence of interrogatives and then construct their union. See Belnap [1969].

Picard [1980] studies question sequences in the light of practical considerations like probability, cost, and utility. The general problem is how to replace a single complex and costly question Q by a questionnaire Q' (which is a sequence of simple which and whether questions), such that Q' will yield the true answer to Q but asking Q' will be more efficient and economical than asking Q . Questionnaires are represented as weighted finite circuitless graphs meeting certain conditions. (Think of a questionnaire as a bush — starting from one node — whose non-terminal nodes are questions and whose branches are the direct answers.) Each answer is assigned a probability. Answers and questions can be assigned utilities and costs. For more in this area see, e.g., Kampé de Fériet and Picard (eds.) [1974].

7.6 Comparison of Approaches

Is there a correct approach to the theory and logic of questions? It is not yet clear that we have a correct approach to clarifying and answering that question; especially, it is not yet clear that we have a correct criterion for recognizing a correct answer.

What is clear is that much more work remains to be done in comparing different approaches and evaluating their respective advantages. A little

work of this sort has been done, but most of it has been done on small aspects and points of detail. What we offer below are some rough surmises. We don't claim that these are accurate or correct; we do hope that they are clear enough to stimulate further study.

1. The systems that can provide the most questions are those that assume questions as metaphysical or intensional entities — as in the theories of Tichý [1978] or Higginbotham [1993].
2. Is one approach better than others at providing interrogatives? There is some appeal in the idea noted in 6.8 above, that we can adopt a very rich language and thus have interrogatives that specify a detailed description of what is wanted and how to search for it. On the other hand, interrogatives are instruments for communication, and our choice of interrogative system is influenced by the purposes at hand. Thus it is meaningful or useful to compare interrogative systems relative to specific motivations (e.g. the motivation to model the question-and-answer system of the Danish people, or the motivation to construct an information-retrieval system for the Yale Medical School Library), but not useful to make comparisons otherwise.
3. The systems that would be most useful in machine-assisted interactions, and especially in formal systems of information retrieval, will have the effectiveness properties emphasized in Belnap and Steel [1976].
4. For empirical models of the question-and-answer process in natural language several different kinds of system will be needed, including not only those of the MMK approach (designed to fit the 'standard' situation, as noted in 5.1 above) but also others (designed to fit other types of situation).
5. Theorizing about questions requires theorizing about interrogatives. We can be confident that an intensional theory of questions is complete and correct only if we are confident that we have a complete and correct theory of human concepts and intentions, and we can be confident of the latter only if we are confident that we have a complete and correct theory of human language, including a complete and correct theory of interrogatives.

7.7 General Erotetic Logic: Motivations

There are several motivations for generalizing from erotetic logic in the narrow sense, concerned with question and answer, to erotetic logic in a broader sense, concerned with all the kinds of expression that call for reply.

First consider mixed sentences — e.g.:

1. ‘The old machine is broken, or does it need fuel?’
2. ‘The new one is missing, but do we need it?’
3. ‘What is wrong with the old one? or find the new one.’

To provide for such sentences we want a logic that will specify for declaratives, imperatives, interrogatives, . . . (?) what compounds are permissible, what expressions call for replies, and what replies are called for.

Second, consider vectored sentences such as

‘As Provost, I ask you, Dean Smith, will the plan be approved?’

This may be construed as a sentence that, at some level of analysis, consists of two parts:

1. the *body* (‘Will the plan be approved?’), and
2. the *vector* (indicating that the message comes from ‘I’ *qua* Provost and is for Smith *qua* Dean).

For discussions of vectored sentences see Harrah [1994]. To provide for such sentences we want a logic that will specify what expressions count as vectored sentences, and what expressions (vectored or unvectored) count as replies.

Third, consider vectored messages such as the formal memos used in large organizations and the formal letters used in commercial and legal correspondence. These have a vector that specifies a *to*, a *from*, a *when*, and possibly other parameters, and a body that may contain any number of sentences of various kinds. For such messages we want a logic that specifies what expressions count as messages and, for each message, what counts as a sufficient reply.

In 7.8 below we outline a way of developing a logic that provides for mixed sentences, vectored sentences, and vectored messages. This logic may be viewed as a system of general erotetic logic, and our sketch of it should serve to indicate what a general erotetic logic is. From another perspective it may be viewed as a logic of message and reply, or a *communicational logic*. Perhaps the concepts of general erotetic logic and communicational logic coincide, for in both cases the essential concern is with (a) a set of expressions and (b) for each expression, its set of sufficient replies.

7.8 *General Erotetic Logic: Systems*

In this section we outline a way of developing a particular system of general erotetic logic. It will be clear that we are in effect describing a class of systems, and indeed a fairly wide approach. We don’t claim that this is the only correct or fruitful approach. The motivation for this approach is

both empirical and engineering; the aim is to construct systems that will be useful in connection with human communication. (For more on motivation, empirical grounding, and details of development, see Harrah [1985, 1987, 1994].) In the paragraphs below we first describe the part of the system that handles unvectored sentences, and then the part for vectored sentences and vectored messages.

We begin with a standard first-order system having identity, descriptions, and some nonlogical axioms for set theory and syntax. We write U and E for its quantifiers and F, G, H, \dots for its wffs, which we call d -wffs. We add an infinite stock of *speech act operators* O, O', O'', \dots . A *basic speech act wff* (or *bsa-wff*) is an expression OVY such that O is a speech act operator, V is a (possibly empty) string of distinct variables, and Y is a list (Y_1, \dots, Y_n) in which each Y_i is a term or d -wff.

The *basic wffs* (or *b-wffs*) are the d -wffs and *bsa*-wffs. To every b -wff F we assign a d -wff CA , a d -wff CP , a set IR , and a set WR , such that:

1. IR consists of d -wffs (the *indicated replies* to F).
2. CA (the *core assertion* in F) is implied by every d -wff in IR .
3. WR (the *wanted replies* to F) is a subset of IR .
4. CP (the *core projection* in F) is implied by every d -wff in WR .
5. CA is implied by CP .

Given a *bsa*-wff F , with its CA and CP , we say that:

The *negative reply* to F is $\neg CP$.

The *corrective reply* to F is $\neg CA$.

The *direct replies* to F are:

1. the wanted replies, and $\neg CP$, if WR is nonempty;
2. the indicated replies, and $\neg CA$, if WR is empty but IR is not;
3. CP , $(CA \wedge \neg CP)$, and $\neg CA$, if IR is empty.

The *full replies* to F are the d -wffs that imply direct replies.

The *partial replies* to F are the d -wffs that are implied by direct replies.

The *relevant replies* to F are the full replies plus the partial replies.

To give examples, we use the signs

$!w, !c, !d, .d, .as, .an, ?w, ?!$

to refer to distinct speech act operators (expressing respectively ultimatum, command, directive, declaration, assertion, announcement, whether-question, one-example question). To the eight kinds of *bsa*-wffs at the left below, content may be assigned as follows:

	<i>CA</i>	<i>CP</i>	<i>IR</i>	<i>WR</i>
$!^u(G)$	$(G \vee G')$	G	$\{G\}$	$\{G\}$
$!^c(G)$	$(G \vee G')$	G	$\{G\}$	Λ
$!^d(G)$	$(G \vee G')$	G	Λ	Λ
$:^d(G)$	G	G	$\{G\}$	$\{G\}$
$:^{as}(G)$	G	G	$\{G\}$	Λ
$:^{an}(G)$	G	G	Λ	Λ
$?^w(G, G')$	$(G \vee G')$	$(G \vee G')$	$\{G, G'\}$	$\{G, G'\}$
$?^1x(Gx)$	$ExGx$	$ExGx$	$\{Ga, \dots\}$	$\{Ga, \dots\}$

For smoothness, in the case of each *d*-wff F , we say that $CP(F) = CA(F) = F$, and the $WR(F) = IR(F) = \Lambda$. (Note: occasionally, as here, we use ‘*CA*’, . . . , ‘*WR*’ as functors.)

An *erotetic wff* (or *e*-wff) is a *bsa*-wff F such that $WR(F) \neq \Lambda$. The *speech act wffs* (or *sa*-wffs) are defined recursively:

1. Every *b*-wff is an *sa*-wff.
2. If F and G are *sa*-wffs and x is a variable, then $(F \wedge G)$, $(F \vee G)$, $Ux F$, $Ex F$ are *sa*-wffs, and $(F \rightarrow G)$ is an *sa*-wff if F is a *d*-wff.

A *proper sa*-wff is an *sa*-wff that is not a *d*-wff, and a *non-basic sa*-wff is an *sa*-wff that is not a *b*-wff.

If F is an *sa*-wff, then G is the *core assertion in F* (or $CA(F)$ for short) iff G is like F except that, wherever F contains a *bsa*-wff H , G contains $CA(H)$. Similarly for $CP(F)$.

To any non-basic *sa*-wff F :

1. The *negative* reply is $\neg CP(F)$.
2. The *corrective* reply is $\neg CA(F)$.
3. The *direct* replies are $CP(F)$, $(CA(F) \wedge \neg CP(F))$, and $\neg CA(F)$.
4. The *full* replies are the *d*-wffs that imply direct replies.
5. The *partial* replies are the *d*-wffs implied by direct replies.
6. The *relevant* replies are the full replies plus the partial replies.

(Note that the non-basic *sa*-wffs do not have indicated or wanted replies.)

We assume that for the *d*-wffs we have a first-order predicate logic of the usual kind, and that in addition there might be axioms for set theory, syntax, or the like. To provide for analysis of *sa*-wffs we add the following *rules of ca-derivation*:

- (1) $(F \wedge G) \vdash F$
- (2) $(F \wedge G) \vdash (G \wedge F)$
- (3) $((F \wedge G) \wedge H) \vdash (F \wedge (G \wedge H))$
- (4) $F, G \vdash (F \wedge G)$
- (5) $(F \vee F) \vdash F$
- (6) $(F \vee G) \vdash (G \vee F)$
- (7) $((F \vee G) \vee H) \vdash (F \vee (G \vee H))$
- (8) $(F \vee G) \vdash (CA(F) \rightarrow F)$
- (9) $\neg G, (G \vee F) \vdash F$
- (10) $G, (G \rightarrow F) \vdash F$
- (11) $Ux Fx \vdash Ft$
- (12) $Ex Fx \vdash (CA(Ft) \rightarrow Ft)$
- (13) $F \vdash G$, where G is any one-step alphabetic variant of F
- (14) $F \vdash CA(F)$

Z is a *ca-derivation from S* iff Z is a finite nonempty sequence of *sa-wffs* such that, for every member F of Z , either F is an axiom, F is a member of S , or F comes from preceding members of Z by a rule of *ca-derivation*. If F is the last member of Z , we say that Z is a *ca-derivation of F from S* and that F is *ca-derivable from S* , and we write $S \vdash_{ca} F$.

The following theorem shows that *ca-derivation* is conservative with respect to the derivation of *d-wffs*. Let F be any *d-wff*, let S be any set of *sa-wffs*, and let $CA(S)$ be the set of *d-wffs* that are the core assertions in the members of S . Let us say that F is *standardly derivable from a set S'* just in case there is a finite nonempty sequence Z of *d-wffs* G (including F) such that every G either is in S' or is an axiom or comes from preceding members of Z by some rule of first-order predicate logic. Then:

THEOREM 4. *F is ca-derivable from S iff F is standardly derivable from $CA(S)$.*

Various types of content are now definable. E.g. the *assertive commitment* of S is the set of all *d-sentences* F such that $S \vdash_{ca} F$; the *projective commitment* of S is the set of all *d-sentences* F such that $S' \vdash_{ca} F$ (where S' is the union of S and the set of core projections in members of S); and the *erotetic commitment* of S is the set of all *e-sentences* F such that $S \vdash_{ca} F$.

Let Z be a *ca-derivation from S* , and let S' be a finite set of closed terms. Then Z is *ca-complete for S relative to S'* iff all the members of S have been put into Z and all the rules that can be applied have been applied. More precisely:

1. For any proper *sa-wff* $(F \wedge G)$, if it is in Z , so is F . [and analogously for *ca-rules* 2, 3, 5, 6, 7, 9, 10, and 14]
2. For any proper *sa-wff* $(F \vee G)$, if it is in Z , and some X is such that X is a proper *sa-wff*, X is either F or G , and $S \vdash_{ca} CA(X)$, then, for at least one such X , $(CA(X) \rightarrow X)$ is in Z .

3. For any proper *sa*-wff $(G \vee F)$, if it is in Z , and $S \vdash_{ca} \neg G$, then $\neg G$ is in Z .
4. For any proper *sa*-wff $(G \rightarrow F)$, if it is in Z , and $S \vdash_{ca} G$, then G is in Z .
5. For any proper *sa*-wff $Ux Fx$, if it is in Z , and t is a closed term in S' , then Ft is in Z .
6. For any proper *sa*-wff $Ex Fx$, if it is in Z , and some closed term t in S' is such that $S \vdash_{ca} CA(Ft)$, then, for at least one such term t , $(CA(Ft) \rightarrow Ft)$ is in Z .

Where S is a finite set of *sa*-wffs, a *sufficient reply to S* is constructed in the following way: First find a *ca*-derivation Z from S that is *ca*-complete for S relative to the set of closed terms that occur in members of S . Choose *b*-sentences F_1, \dots, F_n that occur in Z , provided that all the *e*-sentences in Z are included among F_1, \dots, F_n . Then choose G_1, \dots, G_n such that each G_i is a direct reply to F_i . Then $(G_1 \wedge \dots \wedge G_n)$ is a sufficient reply to S .

Unfortunately *ca*-complete derivations are not effectively recognizable as such, so sufficient replies are not effectively recognizable as such. On the other hand, by making certain additions and changing some details, we can make the reply process more effective in certain respects. The key is to extend the language by adding a stock of reply indicators r_i and *r*-wffs of the form

$$(r_{j_1} F_1 : G_1) \wedge \dots \wedge (r_{j_n} F_n : G_n)$$

Roughly, each $(r_i F : G)$ says that G is a reply to F of the kind i . In particular, a sufficient reply to S would have the form displayed above, where each r_i would be an indicator for direct reply. For details, see Harrah [1985].

Concerning vectored sentences and vectored messages: Each such expression X consists of a body B and a vector V ; the content of X is a function of the content of B and the content of V . To simplify here we assume that the body of a vectored message is a finite nonempty string of *sa*-sentences; thus each vectored sentence counts as a vectored message, but a vectored sentence cannot occur inside a vectored message.

Vectors are expressions of various kinds, and each kind of vector brings certain *presumptions*. Example:

‘To: Jane Smith, Dean of the College’

brings the presumption

‘Jane Smith is Dean of the College’

(For discussion of vectors and presumptions, see Harrah [1994].) The content of the vector is determined by these presumptions. We assume that each vectored X has finitely many presumptions, that the presumptions are d -sentences, and that each presumption of X is effectively recognizable from ‘ X ’.

For message analysis: Let M be a vectored message, and let $S(M)$ be the set consisting of (1) the sa -sentences in the body of M and (2) the presumptions of M . Then Z is an *ma-derivation from M* iff Z is a *ca-derivation from $S(M)$* , and Z is *ma-complete for M* iff Z is *ca-complete for $S(M)$* relative to the set of terms that occur in M .

We construct a *sufficient reply to M* in either of three ways:

Option I: First find an *ma-derivation Z from M* that is *ma-complete for M* . Choose b -sentences F_1, \dots, F_n that occur in Z and include all the e -sentences in Z . Then choose direct replies G_i to these F_i and form $(G_1 \wedge \dots \wedge G_n)$ as a sufficient reply to M .

Option II: Find a d -sentence F that is *ca-derivable* from the set of presumptions of M (an F that you believe is false). Then the negation $\neg F$ is a *vector-challenge to M* and may be given as a sufficient reply to M .

Option III: Find a d -sentence F such that (1) F is *ma-derivable from M* , and (2) every *ma-derivation of F from M* contains at least one presumption of M . Then the negation $\neg F$ is a *vector-challenge* and is a sufficient reply to M .

SEQUENT SYSTEMS FOR MODAL LOGICS

INTRODUCTION

[T]he framework of ordinary sequents is not capable of handling all interesting logics. There are logics with nice, simple semantics and obvious interest for which no decent, cut-free formulation seems to exist Larger, but still satisfactory frameworks should, therefore, be sought. A. Avron [1996, p. 3]

This chapter surveys the application of various kinds of sequent systems to modal and temporal logic, also called tense logic. The starting point are ordinary Gentzen sequents and their limitations both technically and philosophically. The rest of the chapter is devoted to generalizations of the ordinary notion of sequent. These considerations are restricted to formalisms that do not make explicit use of semantic parameters like possible worlds or truth values, thereby excluding, for instance, Gabbay's labelled deductive systems, indexed tableau calculi, and Kanger-style proof systems from being dealt with. Readers interested in these types of proof systems are referred to [Gabbay, 1996], [Goré, 1999] and [Pliuškeviene, 1998]. Also Orłowska's [1988; 1996] Rasiowa-Sikorski-style relational proof systems for normal modal logics will not be considered in the present chapter. In relational proof systems the logical object language is associated with a language of relational terms. These terms may contain subterms representing the accessibility relation in possible-worlds models, so that semantic information is available at the same level as syntactic information. The derivation rules in relational proof systems manipulate finite sequences of relational formulas constructed from relational terms and relational operations. An overview of *ordinary* sequent systems for non-classical logics is given in [Ono, 1998], and for a general background on proof theory the reader may consult [Troelstra and Schwichtenberg, 2000]. In this chapter we shall pay special attention to *display logic*, a general proof-theoretic approach developed by Belnap [1982]. Two applications of the modal display calculus are included as case studies: the formulas-as-types notion of construction for temporal logic and a display calculus for propositional bi-intuitionistic logic (also called Heyting-Brouwer logic). This logic comprises both constructive implication and coimplication (see, for example, [Goré, 2000], [Rauszer, 1980], [Wolter, 1998]), and its sequent-calculus presentation to be given is based on a modal translation into the temporal propositional logic **S4t**.¹

¹The chapter consists of revised and expanded material from [Wansing, 1998] and includes the contents of the unpublished report [Wansing, 2000] on formulas-as-types for temporal logics. Moreover, the sequent calculus for bi-intuitionistic logic and subsystems of bi-intuitionistic logics in Section 3.8 and the translation of multiple-sequent systems into higher-arity sequent systems in Section 4.1 are new.

A note on notation. In the present chapter, both classical and constructive logics will be considered. Therefore it makes sense to reflect this distinction in the notation for the logical operations. In particular, the following symbols will be used: \triangleright (constructive, intuitionistic implication), \blacktriangleleft (coimplication), \supset (Boolean implication), \frown (intuitionistic negation), \smile (conegation), \neg (Boolean negation).

1 ORDINARY SEQUENT SYSTEMS

The presentation of normal modal logics as ordinary (standard) sequent systems has turned out to be problematic for both technical and philosophical reasons. The technical problems chiefly result from a lack of flexibility of the ordinary notion of sequent for dealing with the multitude of interesting and important modal logics in a uniform and perspicuous way. In this section a number of standard Gentzen systems for normal modal propositional logics is reviewed in order to give an impression of what has been and what can be done to present normal modal logics as ordinary Gentzen calculi. An ordinary Gentzen system is a collection of rule schemata for manipulating *Gentzen sequents*; these are derivability statements of the form $\Delta \rightarrow \Gamma$, where Δ and Γ are finite, possibly empty sets of formulas. The set terms ‘ Δ ’ and ‘ Γ ’ are called the antecedent and the succedent of $\Delta \rightarrow \Gamma$, respectively. Often, a sequent

$$\{A_1, \dots, A_m\} \rightarrow \{B_1, \dots, B_n\}$$

is written as $A_1, \dots, A_m \rightarrow B_1, \dots, B_n$. This notation supports viewing the ‘,’ (the comma) as a *structure connective* in the language of sequents. Indeed, the sequent arrow in Gentzen’s [1934] denotes a derivability relation between finite *sequences* of formulas separated by the comma. Gentzen, however, postulated structural rules that justify thinking of antecedents and succedents as denoting sets:

$$\text{(permutation)} \quad \frac{\Delta, A, B, \Gamma \rightarrow \Sigma}{\Delta, B, A, \Gamma \rightarrow \Sigma} \quad \frac{\Delta \rightarrow \Sigma, A, B, \Gamma}{\Delta \rightarrow \Sigma, B, A, \Gamma}$$

$$\text{(contraction)} \quad \frac{\Delta, A, A, \Gamma \rightarrow \Sigma}{\Delta, A, \Gamma \rightarrow \Sigma} \quad \frac{\Delta \rightarrow \Sigma, A, A, \Gamma}{\Delta \rightarrow \Sigma, A, \Gamma}$$

Gentzen also postulated

$$\text{(monotonicity)} \quad \frac{\Delta, \Gamma \rightarrow \Sigma}{\Delta, A, \Gamma \rightarrow \Sigma} \quad \frac{\Delta \rightarrow \Gamma, \Sigma}{\Delta \rightarrow \Gamma, A, \Sigma}$$

These three rules are structural in the sense of exhibiting no operation from an underlying logical object language. If the polymorphic comma is interpreted as a binary structure connective that may or may not be associative, the antecedent and the succedent of a sequent are *Gentzen terms*,

and in generalized sequent calculi, the sequents display Gentzen terms or other, much more complex data structures. We shall use ‘ \vdash ’ to denote the derivability relation in a given axiomatic system or a consequence relation between finite sets of sequents and single sequents satisfying identity, cut, and monotonicity. In other words, if Δ and Γ are finite sets of sequents and s, s' are sequents, then we assume that $\{s\} \vdash s$,

$$\frac{\Delta \vdash s}{\Delta \cup \{s'\} \vdash s} \quad \text{and} \quad \frac{\Delta \vdash s \quad \Gamma \cup \{s\} \vdash s'}{\Delta \cup \Gamma \vdash s'}.$$

1.1 Ordinary Gentzen systems for normal modal logics

The syntax of modal propositional logic (in Backus-Naur form, see for example [Goldblatt, 1992, p. 3]) is given by:

$$A ::= p \mid \mathbf{t} \mid \mathbf{f} \mid \neg A \mid A \wedge B \mid A \vee B \mid A \supset B \mid A \equiv B \mid \diamond A \mid \Box A.$$

The smallest normal modal propositional logic **K** admits a simple presentation as an ordinary Gentzen system (see, for instance, [Leivant, 1981], [Mints, 1990], [Sambin and Valentini, 1982]). In the language with \Box (“necessarily”) as the only primitive modal operator and $\diamond A$ (“possibly A ”) being defined as $\neg\Box\neg A$, one may just add the rule

$$(\rightarrow \Box)_1 \quad \Delta \rightarrow A \vdash \Box \Delta \rightarrow \Box A$$

to the standard sequent system **LCPL** for classical propositional logic **CPL**, where $\Box \Delta = \{\Box A \mid A \in \Delta\}$. A sequent calculus **LK4** for **K4** can be obtained by supplementing **LCPL** with the rule

$$(\rightarrow \Box)_2 \quad \Delta, \Box \Delta \rightarrow A \vdash \Box \Delta \rightarrow \Box A$$

(see [Sambin and Valentini, 1982]). In [Goble, 1974] it is shown that the pair of modal sequent rules $(\rightarrow \Box)_1$ and

$$(\Box \rightarrow)_1 \quad \Delta, A \rightarrow \emptyset \vdash \Box \Delta, \Box A \rightarrow \emptyset$$

yields a sequent system for **KD** (where ‘ \emptyset ’ denotes the empty set) and that a sequent calculus for **KD4** is obtained, if $(\rightarrow \Box)_1$ is replaced by the rule

$$(\rightarrow \Box)_3 \quad \Delta' \rightarrow A \vdash \Box \Delta \rightarrow \Box A,$$

where Δ' results from Δ by prefixing zero or more formulas in Δ by \Box . Shvarts [1989] gives a sequent calculus formulation of **KD45** by adjoining to **LCPL** the following rule for \Box :

$$[\Box] \quad \Box \Delta_1, \Delta_2 \rightarrow \Box \Gamma_1, \Gamma_2 \vdash \Box \Delta_1, \Box \Delta_2 \rightarrow \Box \Gamma_1, \Box \Gamma_2,$$

where Γ_2 contains at most one formula. If in addition Γ_1 and Γ_2 are required to be non-empty, this results in a sequent system for **K45**.

Among the most important modal logics are the almost ubiquitous systems **S4** and **S5**. Standard sequent systems for the axiomatic calculi **S4** (= **KT4**) and **S5** (= **KT5** = **KT4B**) were studied by Ohnishi and Matsumoto [1957]. They considered the following schematic sequent rules for \Box and \Diamond :

$$\begin{aligned} (\rightarrow \Box)_0 & \quad \Box\Delta \rightarrow \Box\Gamma, A \vdash \Box\Delta \rightarrow \Box\Gamma, \Box A; \\ (\Box \rightarrow)_0 & \quad \Delta, A \rightarrow \Gamma \vdash \Delta, \Box A \rightarrow \Gamma; \\ (\rightarrow \Diamond)_0 & \quad \Delta \rightarrow \Gamma, A \vdash \Delta \rightarrow \Gamma, \Diamond A; \\ (\Diamond \rightarrow)_0 & \quad \Diamond\Gamma, A \rightarrow \Diamond\Delta \vdash \Diamond\Gamma, \Diamond A \rightarrow \Diamond\Delta; \end{aligned}$$

where $\Diamond\Delta = \{\Diamond A \mid A \in \Delta\}$. If either the rules $(\rightarrow \Box)_0$ and $(\Box \rightarrow)_0$ or the rules $(\rightarrow \Diamond)_0$ and $(\Diamond \rightarrow)_0$ are adjoined to **LCPL**, then the result is a sequent calculus **LS5*** for **S5**. If Γ is empty in $(\rightarrow \Box)_0$ or $(\Diamond \rightarrow)_0$, this yields a sequent calculus **LS4** for **S4**. Several other modal logics can be obtained by imposing suitable constraints on the structures exhibited in $(\rightarrow \Box)_0$ and $(\Diamond \rightarrow)_0$, respectively. Ohnishi and Matsumoto show that if $(\rightarrow \Box)_0$ and $(\Diamond \rightarrow)_0$ are replaced by $(\rightarrow \Box)_1$ and

$$(\Diamond \rightarrow)_1 \quad A \rightarrow \Gamma \vdash \Diamond A \rightarrow \Diamond\Gamma,$$

one obtains a Gentzen-system **LKT** for **KT** (= **T**). Kripke [1963] noted that the equivalences between $\Box A$ and $\neg\Diamond\neg A$ and between $\Diamond A$ and $\neg\Box\neg A$ cannot be proved by means of Ohnishi's and Matsumoto's rules. In the case of **S4**, Kripke suggested remedying this by using sequent rules which exhibit both \Box and \Diamond , namely in addition to $(\Box \rightarrow)_0$ and $(\rightarrow \Diamond)_0$ the rules

$$\begin{aligned} (\rightarrow \Box)' & \quad \Box\Gamma \rightarrow A, \Diamond\Delta \vdash \Box\Gamma \rightarrow \Box A, \Diamond\Delta \\ \text{and } (\Diamond \rightarrow)' & \quad A, \Box\Gamma \rightarrow \Diamond\Delta \vdash \Diamond A, \Box\Gamma \rightarrow \Diamond\Delta. \end{aligned}$$

Such rules fail to give a separate account of the inferential behaviour of \Box and \Diamond , since only the combined use of these operations is specified. Another problem with Ohnishi's and Matsumoto's sequent rules for **S5** is that the cut-rule

$$\Delta \rightarrow \Sigma, A; \quad \Gamma, A \rightarrow \Theta \vdash \Gamma, \Delta \rightarrow \Sigma, \Theta$$

cannot be eliminated: the system without cut allows proving less formulas than the full system containing cut. Ohnishi and Matsumoto [1959] give the following counter-example to cut-elimination:

$$\frac{\frac{\frac{\Box p \rightarrow \Box p}{\emptyset \rightarrow \neg\Box p, \Box p}}{\emptyset \rightarrow \Box\neg\Box p, \Box p} \quad \frac{p \rightarrow p}{\Box p \rightarrow p}}{\emptyset \rightarrow \Box\neg\Box p, p}$$

A solution to the problem of defining a cut-free ordinary Gentzen system for **S5** has been given in [Bräuner, 2000].² The logic **S5** can be faithfully

²Another, perhaps less convincing solution has been presented by Ohnishi [1982]. Define the degree $\text{deg}(A)$ of a modal formula in the language with \Box primitive as follows:

embedded into monadic predicate logic, the first-order logic of unary predicates, under a translation \mathfrak{t} employing a single individual variable x , see for instance [Mints, 1992]. The translation \mathfrak{t} assigns to every propositional variable p an atomic formula $P(x)$, and for compound formulas it is defined as follows:

$$\begin{aligned} \mathfrak{t}(t) &= t, \\ \mathfrak{t}(\neg A) &= \neg \mathfrak{t}(A), \\ \mathfrak{t}(A \sharp B) &= \mathfrak{t}(A) \sharp \mathfrak{t}(B), \text{ for } \sharp \in \{\supset, \wedge, \vee\}, \\ \mathfrak{t}(\Box A) &= \forall x \mathfrak{t}(A), \\ \mathfrak{t}(\Diamond A) &= \exists x \mathfrak{t}(A). \end{aligned}$$

THEOREM 1. *A modal formula A is provable in **S5** if and only if $\mathfrak{t}(A)$ is provable in monadic predicate logic.*

The familiar cut-free sequent calculus for monadic predicate logic can serve as a starting point for defining a cut-free ordinary sequent system for **S5** with side-conditions on the introduction rules for \Box on the right and \Diamond on the left of the sequent arrow. The side conditions are simple, though their precise formulation requires some terminology that will be useful also in other contexts. An inference *inf* is a pair (Δ, s) , where Δ is a set of sequents (the premises of *inf*) and s is a single sequent (the conclusion of *inf*). A rule of inference R is a set of inferences. If $\text{inf} \in R$, then *inf* is said to be an instantiation of R . The rule R is an axiomatic rule, if $\Delta = \emptyset$ for every $(\Delta, s) \in R$. We assume that inference rules are stated by using variables for structures (in the present case finite sets of formulas) and formulas. Every structure occurrence in an inference *inf* (a sequent s) is called a constituent of *inf* (s). The *parameters* of $\text{inf} \in R$ are those constituents which occur as substructures of structures assigned to structure variables in the statement of R . Constituents of *inf* are defined as *congruent* in *inf* if and only if (iff) they are occupying similar positions in occurrences of structures assigned to the same structure variable, in the present case iff they belong to a set assigned to the same set variable.

DEFINITION 2. Two formula occurrences are immediately connected in a proof Π iff Π contains an inference *inf* such that one of the following

1. $\text{deg}(p) = 0$, for every propositional variable p ;
2. $\text{deg}(\neg A) = \text{deg}(A)$;
3. $\text{deg}(A \wedge B) = \max(\text{deg}(A), \text{deg}(B))$;
4. $\text{deg}(\Box A) = \text{deg}(A) + 1$.

Ohnishi adds to $(\Box \rightarrow)_0$ and $(\rightarrow \Box)_0$ two further rules that deviate considerably from familiar introduction schemata:

$$\Gamma, A^*, \Delta \rightarrow \Sigma \vdash \Gamma, A, \Delta \rightarrow \Sigma \quad \text{and} \quad \Gamma \rightarrow \Delta, A^*, \Sigma \vdash \Gamma \rightarrow \Delta, A, \Sigma,$$

where the formula A^* is defined in such a way that (i) A and A^* are equivalent in **S5** and (ii) $\text{deg}(A^*) \leq 1$.

conditions holds:

1. both occurrences are non-parametric, one in the conclusion and the other in a premise of *inf*;
2. *inf* belongs to an axiomatic sequent rule and both occurrences are non-parametric in *inf*;
3. *inf* \in cut and both occurrences are non-parametric in *inf*;
4. the occurrences are parametric and congruent in *inf*.

A list of formula occurrences A_1, \dots, A_n in a proof Π is called a connection between A_1 and A_n in Π iff for every $i \in \{1, \dots, n-1\}$, the occurrences A_i and A_{i+1} are immediately connected in Π . A formula is said to be modally closed if every propositional variable in the formula occurs in the scope of an occurrence \diamond or \square .

DEFINITION 3. Two formula occurrences in a proof Π are said to be dependent on each other in Π iff there exists a connection between these occurrences that does not contain any modally closed formula.

The sequent system **LS5** extends **LCPL** by $(\square \rightarrow)_0$, $(\rightarrow \diamond)_0$ and the rules:

$$\begin{array}{l} (\rightarrow \square)'' \quad \Gamma \rightarrow \Delta, A \vdash \Gamma \rightarrow \Delta, \square A \\ \text{and } (\diamond \rightarrow)'' \quad \Gamma, A \rightarrow \Delta \vdash \Gamma, \diamond A \rightarrow \Delta, \end{array}$$

where applications of $(\rightarrow \square)''$ and $(\diamond \rightarrow)''$ in a proof Π must be such that in Π none of the formula occurrences in Γ and Δ depends on the displayed occurrence of A . A cut-free proof of the notorious sequent $\emptyset \rightarrow \square \neg \square p, p$ is then easily available (as it is also in Ohnishi's [1982] calculus):

$$\frac{\frac{\frac{p \rightarrow p}{\square p \rightarrow p}}{\emptyset \rightarrow \neg \square p, p}}{\emptyset \rightarrow \square \neg \square p, p}$$

THEOREM 4. ([Braüner, 2000]) *A sequent $\Delta \rightarrow \Gamma$ is provable in **LS5** iff $\bigwedge \Delta \supset \bigvee \Gamma$ is provable in **S5**.*

Avron [1984] (see also [Shimura, 1991]) presents a sequent calculus **LS4Grz** for **S4Grz** (= **KGrz**). He replaces the rule $(\rightarrow \square)_0$ in Ohnishi and Matsumoto's sequent calculus for **S4** by the rule

$$(\rightarrow \square)_4 \quad \square(A \supset \square A), \square \Delta \rightarrow A \vdash \square \Delta \rightarrow \square A$$

exhibiting both \square and \supset . In [Takano, 1992], Takano defines sequent calculi **LKB**, **LKTB**, **LKDB**, and **LK4B** for **KB**, **KTB** (= **B**), **KDB**, and **K4B**.

The systems **LKB** and **LK4B** are obtained from **LCPL** by including the rules

$$\begin{aligned} (\rightarrow \Box)_B \quad & \Gamma \rightarrow \Box\Theta, A \vdash \Box\Gamma \rightarrow \Theta, \Box A \\ \text{and } (\rightarrow \Box)_{ABE} \quad & \Gamma, \Box\Gamma \rightarrow \Box\Theta, \Box\Delta, A \vdash \Box\Gamma \rightarrow \Box\Theta, \Delta, \Box A \end{aligned}$$

respectively. **LKTB** and **LKDB** result from **LKB** by adjoining $(\Box \rightarrow)_0$ and

$$(\Box \rightarrow)_D \quad \Gamma \rightarrow \Box\Delta \vdash \Box\Gamma \rightarrow \Delta$$

respectively. Standard sequent systems for several other modal logics can be found in [Goré, 1992] and [Zeman, 1973]. The sequent calculus for **S4.3** ($= \mathbf{S4} + \Box(\Box A \supset B) \vee \Box(\Box B \supset A)$) in [Zeman, 1973] results from **LS4** by the addition of the *axiomatic sequent*

$$\Box(A \vee \Box B), \Box(\Box A \vee B) \rightarrow \Box A, \Box B.$$

Shimura [1991] obtains a cut-free sequent system **LS4.3** by adding to **LCPL** the rules $(\Box \rightarrow)_0$ and

$$(\rightarrow \Box)_5 \quad \Box\Gamma \rightarrow (\Box\Delta) \setminus \{\Box A_1\} \dots \Box\Gamma \rightarrow (\Box\Delta) \setminus \{\Box A_n\} \vdash \Box\Gamma \rightarrow \Box\Delta,$$

where $\Delta = \{A_1, \dots, A_n\}$ and \setminus is set-theoretic difference.

1.2 Ordinary Gentzen systems for normal temporal logics

The syntax of temporal propositional logic is given by:

$$\begin{aligned} A ::= & p \mid \mathbf{t} \mid \mathbf{f} \mid \neg A \mid A \wedge B \mid A \vee B \mid A \supset B \mid A \equiv \\ & B \mid \langle P \rangle A \mid [P]A \mid \langle F \rangle A \mid [F]A. \end{aligned}$$

Also a number of normal temporal propositional logics have been presented as ordinary sequent calculi. Nishimura [1980], for example, defines sequent systems **LKt** and **LK4t** for the minimal normal temporal logic **Kt** and the tense-logical counterpart **K4t** of **K4**. The sequent calculus **LKt** comprises the following introduction rules for forward-looking necessity $[F]$ (“always in the future”) and backward-looking necessity $[P]$ (“always in the past”):³

$$\begin{aligned} (\rightarrow [F]) \quad & \Gamma \rightarrow A, [P]\Delta \vdash [F]\Gamma \rightarrow [F]A, \Delta; \\ (\rightarrow [P]) \quad & \Gamma \rightarrow A, [F]\Delta \vdash [P]\Gamma \rightarrow [P]A, \Delta, \end{aligned}$$

where $[F]\Delta = \{[F]A \mid A \in \Delta\}$ and $[P]\Delta = \{[P]A \mid A \in \Delta\}$. In **K4t**, these rules are replaced by the following pair of rules:

$$\begin{aligned} (\rightarrow [F])_4 \quad & [F]\Gamma, \Gamma \rightarrow A, [P]\Delta, [P]\Sigma \vdash [F]\Gamma \rightarrow [F]A, \Delta, [P]\Sigma; \\ (\rightarrow [P])_4 \quad & [P]\Gamma, \Gamma \rightarrow A, [F]\Delta, [F]\Sigma \vdash [P]\Gamma \rightarrow [P]A, \Delta, [F]\Sigma. \end{aligned}$$

³Nishimura allows infinite sets in antecedent and succedent position. It is proved, however, that if a sequent $\Gamma \rightarrow \Delta$ is provable, then there are finite sets $\Gamma' \subseteq \Gamma$ and $\Delta' \subseteq \Delta$ such that the sequent $\Gamma' \rightarrow \Delta'$ is provable.

In both systems, $\langle P \rangle$ (“sometimes in the past”) and $\langle F \rangle$ (“sometimes in the future”) are treated not as primitive but as defined by $\langle P \rangle A := \neg[P]\neg A$ and $\langle F \rangle A := \neg[F]\neg A$. Note also that this approach gives completely parallel rules for $[F]$ and $[P]$ and that these rules do not exploit the interrelation between the backward and the forward-looking modalities, that shows up, for instance, in the provability of $A \supset [F]\langle P \rangle A$ and $A \supset [P]\langle F \rangle A$.

In summary, it may be said that many normal modal and temporal logics are presentable as ordinary Gentzen calculi, and that in some cases suitable constraints on the structures exhibited in the statement of the sequent rules for the modal operators allow for a number of variations. However, no uniform way of presenting only the most important normal modal and temporal propositional logics as ordinary Gentzen calculi is known. Further, the standard approach fails to be *modular*: in general it is not the case that a single axiom schema is captured by a single sequent rule (or a finite set of such rules). In the following section a more philosophical critique of ordinary Gentzen systems is advanced.

1.3 Introduction schemata and the meaning of the logical operations

The philosophical (and methodological) problems with applying the notion of a Gentzen sequent to modal logics have to do with the idea of *defining* the logical operations by means of introduction schemata (together with structural assumptions about derivability formulated in terms of structural rules). This ‘anti-realistic’ conception of the meaning of the logical operations is often traced back to a certain passage on natural deduction from Gentzen’s *Investigations into Logical Deduction* [Gentzen, 1934, p. 80]:

[I]ntroductions represent, as it were, the ‘definitions’ of the symbols concerned, and the eliminations are no more, in the final analysis, than the consequences of these definitions.

To qualify as a definition of a logical operation, an introduction schema must satisfy certain adequacy criteria. Such conditions are discussed, for instance, by Hacking [1994]. Following Hacking, if introduction rules are to be regarded as defining logical operations, these rules must be such that the structural rules monotonicity (also called weakening, thinning, or dilution), reflexivity, and cut can be eliminated. Hacking claims that

[i]t is not provability of cut-elimination that excludes modal logic, but dilution-elimination . . . The serious modal logics such as **T**, **S4** and **S5** have cut-free sequent-calculus formalizations, but the rules place restrictions on side formulas. Gentzen’s rules for sentential connections are all ‘local’ in that they concern

only the components from which the principal formula is built up, and place no restrictions on the side formulas. Gentzen's own first-order rules, though not strictly local, are equivalent to local ones. That is why dilution-elimination goes through for first-order logic but not for modal logics ([Hacking, 1994, p. 24]).

By dilution-elimination Hacking means that the monotonicity rules

$$\Delta \rightarrow \Gamma \vdash \Delta, A \rightarrow \Gamma, \quad \Delta \rightarrow \Gamma \vdash \Delta \rightarrow \Gamma, A$$

may be replaced by atomic thinning rules

$$\Delta \rightarrow \Gamma \vdash \Delta, p \rightarrow \Gamma, \quad \Delta \rightarrow \Gamma \vdash \Delta \rightarrow \Gamma, p.$$

without changing the set of provable sequents. Similarly, reflexivity-elimination amounts to replaceability of $\vdash A \rightarrow A$ by $\vdash p \rightarrow p$. The term ‘‘cut-elimination’’ is reserved for something stronger than replaceability of cut by the atomic cut-rule

$$\Delta \rightarrow \Sigma, p; \quad \Gamma, p \rightarrow \Theta \vdash \Gamma, \Delta \rightarrow \Sigma, \Theta.$$

A cut-elimination proof shows the admissibility of cut: the rule has no effect on the set of provable sequents.

The introduction rules for \Box in **LS4** prevent dilution-elimination. Obviously, the sequent $\Box B, \Box A \rightarrow \Box A$, for example, cannot be proved using only these rules and atomic thinning. A problem with the requirement of dilution-elimination is the weak status monotonicity has acquired as a defining characteristic of logical deduction. In view of the substantial work on relevance logic, many other substructural logics, and a plethora of non-monotonic reasoning formalisms extending a monotonic base system, monotonicity of inference is not generally viewed as a touchstone of logicity anymore. Moreover, also reflexivity and cut have been questioned. Unrestricted transitivity of deduction as expressed by the cut-rule does not hold, for instance, in Tennant's intuitionistic relevant logic [1994], and both reflexivity and cut fail to be validated by Update-to-Test semantic consequence as defined in Dynamic Logic, see [van Benthem, 1996]. Reflexivity-elimination and cut-elimination are, however, important. According to Belnap [1982, p. 383], the provability of $A \rightarrow A$ constitutes

half of what is required to show that the ‘‘meaning’’ of formulas . . . is not context-sensitive, but that instead formulas ‘‘mean the same’’ in both antecedent and consequent position. (The [Cut] Elimination Theorem . . . is the other half of what is required for this purpose).

A similar remark can be found in [Girard, 1989, p. 31]. Cut-elimination is indispensable, because it amounts to the familiar non-creativity requirement

for definitions (see, for instance, [Hacking, 1994], [von Kutschera, 1968]). If one adds introduction rules for a (finitary) operation f to a sequent calculus, this addition ought to be conservative, so that in the extended formalism, every proof of an f -free formula A is convertible into a proof of A without any application of an introduction rule for f .

There are other reasons why the eliminability of cut is a desirable property. Usually, cut-elimination implies the subformula property: every cut-free proof of a sequent s contains only subformulas of formulas in s . In sequent calculi for decidable logics, the subformula property can often be used to give a syntactic proof of decidability. According to Sambin and Valentini [1982, p. 316], it

is usually not difficult to choose suitable [sequent] rules for each modal logic if one is content with completeness of rules. The real problem however is to find a set of rules also satisfying the subformula-property.

The sequent calculi for **S5** in [Mints, 1970], [Sato, 1977], and [Sato, 1980], although admitting cut-elimination, do not have the subformula property. In a sequent calculus with an enriched structural language, the subformula property need not be accompanied by a *substructure property*. In such systems the subformula property for the logical vocabulary need neither imply nor be of direct use for syntactic decidability proofs. Avron [1996, p. 2] requires of a decent sequent calculus simplicity of the structures employed and a ‘real’ subformula property. But even without the substructure property, the subformula property may be useful, for instance in proving conservative extension results, see also Section 3.8.

It is well-known that cut-elimination itself does not guarantee efficient proof search (see [D’Agostino and Mondadori, 1994], [Boolos, 1984]), so that it may be attractive to work with an analytic, subformula property preserving cut-rule, if possible. An application of cut

$$\Delta \rightarrow \Sigma, A \quad \Gamma, A \rightarrow \Theta \vdash \Gamma, \Delta \rightarrow \Sigma, \Theta$$

is *analytic* (see [Smullyan, 1968]), if the cut-formula A is a subformula of some formula in the conclusion sequent $\Gamma, \Delta \rightarrow \Sigma, \Theta$. Let $\text{Sub}(\Delta)$ denote the set of all subformulas of formulas in Δ . Applications of the sequent rules

$$\begin{aligned} (\rightarrow \Box)_B & \quad \Gamma \rightarrow \Box\Theta, A \vdash \Box\Gamma \rightarrow \Theta, \Box A \\ (\rightarrow \Box)_{ABE} & \quad \Gamma, \Box\Gamma \rightarrow \Box\Theta, \Box\Delta, A \vdash \Box\Gamma \rightarrow \Box\Theta, \Delta, \Box A \\ \text{and } (\Box \rightarrow)_D & \quad \Gamma \rightarrow \Box\Delta \vdash \Box\Gamma \rightarrow \Delta \end{aligned}$$

may be said to be analytic if $\Box\Theta \subseteq \text{Sub}(\Gamma \cup \{A\})$, $\Box\Delta \subseteq \text{Sub}(\Box\Gamma \cup \Box\Theta \cup \{A\})$, and $\Box A \subseteq \text{Sub}(\Gamma)$, respectively. Takano [1992] shows that the cut-rule in

LS5*, **LKB**, **LKTB**, **LKDB**, **LK4B**, **LKt** and **LK4t** can be replaced by the analytic cut-rule: every proof in these sequent calculi can be transformed into a proof of the same sequent such that every application of cut (and, moreover, every application of the rules $(\rightarrow \Box)_B$, $(\rightarrow \Box)_{4BE}$, and $(\rightarrow \Box)_D$) in this proof is analytic.

Although admissibility of analytic cut is a welcome property, in general, unrestricted cut-elimination is to be preferred over elimination of analytic cut. Admissibility of cut has great conceptual significance. The cut-rule justifies certain substitutions of data; in particular it justifies the use of previously proved formulas. Moreover, if the cut-rule is assumed, the non-creativity requirement for definitions implies that cut must be eliminable.

There are other nice properties of introduction schemata as definitions in addition to enabling cut-elimination and reflexivity-elimination. The assignment of meaning to the logical operations should, for instance, be non-holistic, and hence sequent rules like the above $(\rightarrow \Box)'$ and $(\diamond \rightarrow)'$ are unsuitable. If (the statement of) an introduction rule for a logical operation f exhibits no connective other than f , the rule is called *separated*, see [Zucker and Tragesser, 1978]. An even stronger condition is *segregation*, requiring that the antecedent (succedent) of the conclusion sequent in a left (right) introduction rule must not exhibit any structure operation. Segregation has been suggested (although not under this name) by Belnap [1996] who explains that

[t]he nub is this. If a rule for \supset only shows how $A \supset B$ behaves *in context*, then that rule is not *merely* explaining the meaning of \supset . It is also and inextricably explaining the meaning of the context. Suppose we give sufficient conditions for

$$A \supset B, \Delta \rightarrow \Gamma$$

in part by the rule

$$\frac{\Delta \rightarrow A \quad B \rightarrow \Gamma}{A \supset B, \Delta \rightarrow \Gamma}$$

Then we are not explaining $A \supset B$ alone. We are simultaneously involving the comma not just in our explicans (that would surely be all right), but in our explicandum. We are explaining two things at once. There is no way around this. You do not have to take it as a defect, but it is a fact. ... If you are a 'holist', probably you will not care; but then there is not much about which holists much care. [Belnap, 1996, p. 81 f.] (notation adjusted)

Moreover, the rules for f may be required to be *weakly symmetrical* in the sense that every rule should either belong to a set of rules $(f \rightarrow)$ which introduce f on the left side of \rightarrow in the conclusion sequent or to a set of rules $(\rightarrow f)$ which introduce f on the right side of \rightarrow in the conclusion sequent. The introduction rules for f are called *symmetrical*, if they are weakly symmetrical and both $(\rightarrow f)$ and $(f \rightarrow)$ are non-empty. The sequent rules for f are called *weakly explicit*, if the rules $(\rightarrow f)$ and $(f \rightarrow)$ exhibit f in their conclusion sequents only, and they are called *explicit*, if in addition to being weakly explicit, the rules in $(\rightarrow f)$ and $(f \rightarrow)$ exhibit only one occurrence of f on the right, respectively the left side of \rightarrow . Separation, symmetry, and explicitness of the rules imply that in a sequent calculus for a given logic Λ , every connective that is explicitly definable in Λ also has separate, symmetrical, and explicit introduction rules. These rules can be found by decomposition of the defined connective, if it is assumed that the deductive role of $f(A_1, \dots, A_n)$ only depends on the deductive relationships between A_1, \dots, A_n . It is therefore desirable to have introduction rules for \Box , \Diamond , $\langle P \rangle$, $[P]$, $\langle F \rangle$ and $[F]$ as primitive operations, so that the familiar mutual definitions are derivable.

A further desirable property, reminiscent of implicit definability in predicate logic, is the unique characterization of f by its introduction rules. Suppose that Λ is a logical system with a syntactic presentation S in which f occurs. Let S^* be the result of rewriting f everywhere in S as f^* , and let $\Lambda\Lambda^*$ be the system presented by the union SS^* of S and S^* in the combined language with both f and f^* . Let A_f denote a formula (in this language) that contains a certain occurrence of f , and let A_{f^*} denote the result of replacing this occurrence of f in A by f^* . The connectives f and f^* are said to be *uniquely characterized* in $\Lambda\Lambda^*$ iff for every formula A_f in the language of $\Lambda\Lambda^*$, A_f is provable in SS^* iff A_{f^*} is provable in SS^* . Došen [1985] has proved that unique characterization is a non-trivial property and that the connectives in his higher-level systems $S4p/D$ and $S5p/D$ for **S4** and **S5**, respectively, are uniquely characterized.

As we have seen, the standard sequent-style proof-theory for normal modal and temporal logic fails to be modular. The idea that modularity can be achieved by systematically varying structural features of the derivability relation while keeping the introduction rules for the logical operations untouched can be traced back to Gentzen [1934] and has been referred to as Došen's Principle in [Wansing, 1994]. In [Došen, 1988, p. 352], Došen suggests that "the rules for the logical operations are never changed: all changes are made in the structural rules." This methodology is adopted, for example in Došen's [1985] higher-level sequent systems for **S4** and **S5**, Blamey and Humberstone's [1991] higher-arity sequent calculi for certain extensions of **K**, Nishimura's [1980] higher-arity sequent systems for **Kt** and **K4t**, and the presentation of normal modal and temporal logics as cut-free display sequent calculi.

Another methodological aspect is generality. Is there a type of sequent system that allows not only a uniform treatment of the most important modal and temporal logics but also a treatment of substructural logics, other non-classical logics and systems combining operations from different families of logics and that, moreover, is rich enough to suggest important, hitherto unexplored logics? The framework of display logic to be presented in the next section has been devised explicitly as an instrument for combining logics (see [Belnap, 1982]), and has been suggested, for example, as a tool for defining subsystems of classical predicate logic (see [Wansing, 1999]). In addition to generality, a ‘real’ subformula property, and Došen’s principle, Avron [1996] requires of a good sequent calculus framework also *semantics independence*. The framework should not be so closely tied to a particular semantics that one can more or less read off the semantic structures in question. Moreover, the proof systems instantiating the framework should lead to a better understanding of the respective logics and the differences between them.

Note that each of the ordinary sequent systems presented in the present section fails to satisfy some of the more philosophical requirements mentioned. The same holds true for the ordinary sequent systems for various non-normal, classical modal logics investigated in [Lavendhomme and Lucas, 2000]. There are thus not only technical but also methodological and philosophical reasons for investigating generalizations of the notion of a Gentzen sequent.

2 GENERALIZED SEQUENT SYSTEMS

In this section the application of a number of generalizations of the ordinary notion of sequent to normal modal propositional and temporal logics is surveyed.

2.1 Higher-level sequent systems

Došen [1985] has developed certain non-standard sequent systems for **S4** and **S5**. In these Gentzen-style systems one is dealing with sequents of arbitrary finite level. Sequents of level 1 are like ordinary sequents, whereas sequents of level $n + 1$ ($0 < n < \omega$) have finite sets of sequents of level n on both sides of the sequent arrow. The main sequent arrow in a sequent of level n carries the superscript n , and \emptyset is regarded as a set of any finite level. The rules for logical operations are presented as *double-line* rules. A double-line rule

$$\frac{s_1, \dots, s_n}{s_0}$$

involving sequents s_0, \dots, s_n , denotes the rules

$$\frac{s_1, \dots, s_n}{s_0}, \frac{s_0}{s_1}, \dots, \frac{s_0}{s_n}.$$

Došen gives the following double-line sequent rules for \Box and \Diamond :

$$\frac{\frac{X + \{\emptyset \rightarrow^1 \{A\}\} \rightarrow^2 X_2 + \{X_3 \rightarrow^1 X_4\}}{X_1 \rightarrow^2 X_2 + \{X_3 + \{\Box A\} \rightarrow^1 X_4\}}}{X_1 + \{\{A\} \rightarrow^1 \emptyset\} \rightarrow^2 X_2 + \{X_3 \rightarrow^1 X_4\}} \rightarrow^2 X_1 \rightarrow^2 X_2 + \{X_3 \rightarrow^1 X_4 + \{\Diamond A\}\},$$

where $+$ refers to the union of disjoint sets. If these rules are added to Došen's higher-level sequent calculus Cp/D for **CPL**, this results in the sequent system $\text{S5p}/D$ for **S5**. The sequent calculus $\text{S4p}/D$ for **S4** is then obtained by imposing a structural restriction on the monotonicity rule of level 2:

$$X \rightarrow^2 Y \vdash X \cup Z_1 \rightarrow^2 Y \cup Z_2.$$

The restriction is this: if $Y = \emptyset$, then Z_2 must be a singleton or empty; if $Y \neq \emptyset$, then Z_2 must be empty. If the same restriction is applied to monotonicity of level 1 in Cp/D , then this gives a higher-level sequent system for intuitionistic propositional logic **IPL**.

Note that \Diamond and \Box are interdefinable in $\text{S4p}/D$ and $\text{S5p}/D$. The double-line rules for \Box and \Diamond , however, do not satisfy weak symmetry and weak explicitness, but the upward directions of these rules can be replaced by:

$$\emptyset \rightarrow^1 \{A\} \vdash \emptyset \rightarrow^1 \{\Box A\} \quad \text{and} \quad \{A\} \rightarrow^1 \emptyset \vdash \{\Diamond A\} \rightarrow^1 \emptyset.$$

Whereas cut can be eliminated at levels 1 and 2, cut of all levels fails to be eliminable [Došen, 1985, Lemma 1]. Moreover, in Došen's higher-level framework it is not clear how restrictions similar to the one used to obtain $\text{S4p}/D$ from $\text{S5p}/D$ would allow to capture further axiomatic systems of normal modal propositional logic.

2.2 Higher-dimensional sequent systems

A 'higher-dimensional' proof theory for modal logics has been developed by Masini [1992; 1996]. This approach is based on the notion of a *2-sequent*. In order to define this notion, various preparatory definitions are useful. Any finite sequence of modal formulas is called a 1-sequence. The empty 1-sequence is denoted by ϵ . A 2-sequence is an infinite 'vertical' succession of 1 sequences, $\Gamma = \{\alpha_i\}_{0 < i < \omega}$ such that $\exists j \geq 1, \forall k \geq j : \alpha_k = \epsilon$. For each i , α_i is said to be at level i . The depth of Γ ($\text{hp}\Gamma$) is defined as $\min\{i \mid i \geq 0, \forall k > i : \alpha_k = \epsilon\}$. A *2-sequent* is an expression $\Gamma \rightarrow \Delta$, where Γ and Δ

are 2-sequents. The depth of $\Gamma \rightarrow \Delta$ ($\natural(\Gamma \rightarrow \Delta)$) is defined as $\max(\natural\Gamma, \natural\Delta)$. If $\Gamma \rightarrow \Delta$ is a 2-sequent and A an occurrence of a modal formula in $\Gamma \rightarrow \Delta$, then A is said to be maximal in $\Gamma \rightarrow \Delta$, if A is at level k in Γ or in Δ and $k = \natural(\Gamma \rightarrow \Delta)$. A is the maximum in $\Gamma \rightarrow \Delta$, if A is the unique maximal formula in $\Gamma \rightarrow \Delta$. The sequent rules for \Box are based on the idea of “internalizing the level structure of 2-sequents” [Masini, 1992, p. 231]:

$$\begin{array}{c}
 \Gamma \\
 \alpha \\
 \beta, A \quad \rightarrow \Delta \\
 \Gamma' \\
 \hline
 \Gamma \\
 \alpha, \Box A \quad \rightarrow \Delta \\
 \beta \\
 \Gamma'
 \end{array}
 \quad
 (\Box \rightarrow)
 \quad
 \begin{array}{c}
 \Delta \\
 \Gamma \rightarrow \mu \\
 A \\
 \hline
 \Gamma \rightarrow \Delta \\
 \mu, \Box A
 \end{array}
 \quad
 (\rightarrow \Box)$$

$$\begin{array}{c}
 \Gamma \\
 \alpha \quad \rightarrow \Delta \\
 A \\
 \hline
 \Gamma \\
 \alpha, \Diamond A \quad \rightarrow \Delta
 \end{array}
 \quad
 (\Diamond \rightarrow)
 \quad
 \begin{array}{c}
 \Delta \\
 \Gamma \rightarrow \mu \\
 \pi, A \\
 \Delta' \\
 \hline
 \Gamma \rightarrow \Delta \\
 \mu, \Diamond A \\
 \pi \\
 \Delta'
 \end{array}
 \quad
 (\rightarrow \Diamond)$$

where α , β , π , and μ denote arbitrary 1-sequents, and A must be the maximum of the premise 2-sequent in $(\rightarrow \Box)$ and $(\Diamond \rightarrow)$. According to Masini, these introduction rules give rise to a “general basic proof theory of modalities” [Masini, 1992, p. 232]. If added to a 2-sequent calculus for **CPL**, the above rules result, however, in a sequent calculus for **KD** instead of the basic system **K**. This sequent system for **KD** admits cut-elimination, \Box and \Diamond are interdefinable, and the introduction rules are separate, symmetrical, and explicit, but no indication is given of how to present axiomatic extensions of **KD** as higher-dimensional sequent systems. Moreover, it is not clear how Masini’s framework may be modified in order to obtain a 2-sequent calculus for **K**.

2.3 Higher-arity sequent systems

In search of generalizations of the standard Gentzen-style sequent format, it is a natural move to consider consequence relations with an arity greater than 2. It seems that the first higher-arity sequent calculus was formulated by Schröter [1955], see also [Gottwald, 1989]. This formalism is a natural generalization of Gentzen’s sequent calculus for **CPL** to truth-functional

n -valued logic. The intended truth-functional reading of a Gentzen sequent $s = \Delta \rightarrow \Gamma$ is given by a translation σ of s into a formula:

$$\sigma(\Delta \rightarrow \Gamma) = \bigwedge \Delta \supset \bigvee \Gamma,$$

The sequent s thus is true under a given interpretation if either some formula in Δ is false, or some formula in Γ is true, and the two places of the sequent arrow correspond to the two truth-values of classical logic. In general, in n -valued logic (with $2 \leq n$) one obtains n -place sequents $s = \Delta_1; \Delta_2; \dots; \Delta_n$, with the understanding that s is true under an interpretation if for every $i \leq n$, some formula in Δ_i has truth-value i ; for a comprehensive treatment of sequent calculi for truth-functional many-valued logics see [Zach, 1993]. We shall here briefly review some relevant parts of the work of Blamey and Humberstone [1991], who investigate an application of three-place and, ultimately, four-place sequent arrows to normal modal logic. This approach is congenial to display logic with respect to a realization of the Došen-Principle insofar as Blamey and Humberstone emphasize that distinctions between various well-known normal modal logics can “be reflected at the purely structural level, if an appropriate notion of *sequent*” is adopted [Blamey and Humberstone, 1991, p. 763]. Let Γ, Δ, Θ , and Σ range over finite sets of formulas in the modal propositional language with \Box as primitive. The four-place sequent

$$\Gamma \rightarrow_{\Sigma}^{\Theta} \Delta$$

has the following heuristic reading:

$$(\bigwedge \Gamma \wedge \bigwedge \Box \Sigma) \supset (\bigvee \Delta \vee \bigvee \Box \Theta).$$

This kind of sequent had independently been used by Sato [1977], where a cut-free sequent calculus for **S5** is presented containing a left introduction rule for \Box that fails to be weakly explicit. Blamey’s and Humberstone’s introduction rules for \Box are:

$$(\Box \downarrow)_0 \quad \vdash \emptyset \rightarrow_A^{\emptyset} \Box A \quad (\Box \uparrow)_0 \quad \vdash \Box A \rightarrow_{\emptyset}^A \emptyset.$$

In order to obtain a sequent calculus for **K** the following structural rules are assumed:

$$\begin{aligned} (R) \quad & \vdash A \rightarrow_{\emptyset}^{\emptyset} A & (\text{vertical } R) \quad & \vdash \emptyset \rightarrow_A^A \emptyset \\ (M) \quad & \Gamma \rightarrow_{\Sigma}^{\Theta} \Delta \vdash \Gamma, \Gamma' \rightarrow_{\Sigma, \Sigma'}^{\Theta, \Theta'} \Delta, \Delta' \\ (\text{undercut}) \quad & \Sigma \rightarrow_{\emptyset}^{\emptyset} A \quad \Gamma \rightarrow_{\Sigma', A}^{\Theta} \Delta \vdash \Gamma \rightarrow_{\Sigma, \Sigma'}^{\Theta} \Delta \\ (T) \quad & \Gamma, A \rightarrow_{\Sigma}^{\Theta} \Delta \quad \Gamma \rightarrow_{\Sigma}^{\Theta} A, \Delta \vdash \Gamma \rightarrow_{\Sigma}^{\Theta} \Delta \\ (\text{vertical } T) \quad & \Gamma \rightarrow_{\Sigma, A}^{\Theta} \Delta \quad \Gamma \rightarrow_{\Sigma}^{\Theta, A} \Delta \vdash \Gamma \rightarrow_{\Sigma}^{\Theta} \Delta. \end{aligned}$$

Against the background of these rules, the introduction rules $(\Box \downarrow)_0$ and $(\Box \uparrow)_0$ are interplaceable with the following rules, respectively:

$$\begin{aligned} (\Box \downarrow) \quad & \Gamma, \Box A \rightarrow_{\Sigma}^{\Theta} \Delta \vdash \Gamma \rightarrow_{\Sigma, A}^{\Theta} \Delta \\ (\Box \uparrow) \quad & \Gamma \rightarrow_{\Sigma, A}^{\Theta} \Delta \vdash \Gamma, \Box A \rightarrow_{\Sigma}^{\Theta} \Delta. \end{aligned}$$

The introduction rules for the Boolean operations are adaptations of the familiar rules to the higher-arity case. Here is a simple example of a derivation in this formalism (using some obvious notational simplifications):

$$\frac{\frac{\frac{A \wedge B \rightarrow A}{A \wedge B \rightarrow A, B} \quad \frac{\Box A, \Box B \rightarrow \Box A \wedge \Box B}{\Box A \rightarrow_B \Box A \wedge \Box B} (\Box \downarrow)}{\emptyset \rightarrow_{A, B} \Box A \wedge \Box B} (\text{undercut}) \text{ twice}}{\frac{\emptyset \rightarrow_{A \wedge B} \Box A \wedge \Box B}{\Box(A \wedge B) \rightarrow \Box A \wedge \Box B} (\Box \uparrow)}$$

The axiom schemata D , T , $\not\downarrow$, and B are captured by purely structural rules not exhibiting any logical operations:

$$\begin{aligned} D \quad & \Sigma \rightarrow_{\emptyset}^{\emptyset} \emptyset \vdash \emptyset \rightarrow_{\Sigma}^{\emptyset} \emptyset \\ T \quad & \vdash \emptyset \rightarrow_A^{\emptyset} A \\ \not\downarrow \quad & \Sigma \rightarrow_{\Sigma}^{\Theta} A \quad \Gamma \rightarrow_{\Sigma', A}^{\Theta} \Delta \vdash \Gamma \rightarrow_{\Sigma, \Sigma'}^{\Theta} \Delta \\ B \quad & \Sigma \rightarrow_{\emptyset}^{\Delta} A \quad \Gamma \rightarrow_{\Sigma, A}^{\Theta} \Delta \vdash \Gamma \rightarrow_{\Sigma}^{\Theta} \Delta. \end{aligned}$$

Since Blamey and Humberstone are primarily interested in semantical aspects of their sequent systems, they do not consider cut-elimination. Although their calculi satisfy Došen's Principle, it remains unclear whether their approach is fully modular for the most important systems of normal modal propositional logic. They do not present a structural equivalent of the 5-axiom schema, but rather treat **S5** as **KTB4**.

In [Nishimura, 1980], Nishimura uses six-place sequents

$$\Theta_1; \Gamma; \Theta_2 \rightarrow \Sigma_1; \Delta; \Sigma_2.$$

These higher-arity sequents can intuitively be read as follows:

$$(\bigwedge [P]\Theta_1 \wedge \bigwedge \Gamma \wedge \bigwedge [F]\Theta_2) \supset (\bigvee [P]\Sigma_1 \vee \bigvee \Delta \vee \bigvee [F]\Sigma_2).$$

Nishimura defines introduction rules for the tense logical operations $[F]$ and $[P]$, which are explicit in the sense of Section 1.3:

$$\begin{aligned} (\rightarrow [F])' \quad & \frac{\Theta_1; \Gamma; \Theta_2 \rightarrow \Sigma_1; \Delta; A; \Sigma_2}{\Theta_1; \Gamma; \Theta_2 \rightarrow \Sigma_1; \Delta; [F]A; \Sigma_2} \\ ([F] \rightarrow)' \quad & \frac{\Theta_1; \Gamma; A; \Theta_2 \rightarrow \Sigma_1; \Delta; \Sigma_2}{\Theta_1; \Gamma; [F]A; \Theta_2 \rightarrow \Sigma_1; \Delta; \Sigma_2} \\ (\rightarrow [P])' \quad & \frac{\Theta_1; \Gamma; \Theta_2 \rightarrow \Sigma_1; A; \Delta; \Sigma_2}{\Theta_1; \Gamma; \Theta_2 \rightarrow \Sigma_1; [P]A; \Delta; \Sigma_2} \\ ([P] \rightarrow)' \quad & \frac{\Theta_1, A; \Gamma; \Theta_2 \rightarrow \Sigma_1; \Delta; \Sigma_2}{\Theta_1; [P]A, \Gamma; \Theta_2 \rightarrow \Sigma_1; \Delta; \Sigma_2} \end{aligned}$$

In accordance with the Došen Principle, these rules are held constant in sequent systems for **Kt** and **K4t**. The difference between these logics is accounted for by different structural rules, namely

$$\begin{array}{c} \text{(r-trans)} \quad \frac{\emptyset; \Gamma; \emptyset \rightarrow \Delta; A; \emptyset}{\emptyset; \emptyset; \Gamma \rightarrow \emptyset; \Delta; A} \quad \text{(l-trans)} \quad \frac{\emptyset; \Gamma; \emptyset \rightarrow \emptyset; A; \Delta}{\Gamma; \emptyset; \emptyset \rightarrow A; \Delta; \emptyset} \end{array}$$

in the case of **Kt** and

$$\begin{array}{c} \text{(r-trans)}_4 \quad \frac{\emptyset; \Gamma; \Gamma \rightarrow \Delta, \Sigma; A; \emptyset}{\emptyset; \emptyset; \Gamma \rightarrow \Sigma; \Delta; A} \quad \text{(l-trans)}_4 \quad \frac{\Gamma; \Gamma; \emptyset \rightarrow \emptyset; A; \Delta, \Sigma}{\Gamma; \emptyset; \emptyset \rightarrow A; \Delta; \Sigma} \end{array}$$

in the case of **K4t**. Nishimura observes that although in the introduction rules for $\langle F \rangle$ and $\langle P \rangle$ subformulas are preserved from premise sequent to conclusion sequent, cut-elimination fails to hold in the six-place sequent systems for **Kt** and **K4t**. There is, for instance, no cut-free proof of $; p; \rightarrow ; [F] \neg [P] \neg p$.⁴

2.4 Multiple-sequent systems

Indrzejczak, in [1997; 1998], suggested non-standard sequent systems for certain extensions of the minimal regular modal logic **C** using three sequent arrows \rightarrow , $\Box \rightarrow$, and $\Diamond \rightarrow$. These sequent arrows denote binary relations between finite sets of S -formulas, where the set of S -formulas is defined as the union of the set of modal formulas and $\{-A \mid A \text{ is a modal formula}\}$. As before, we shall use A, B, C, \dots to denote modal formulas. The symbol ‘ \neg ’ is a unary structure connective that may not be nested, and the sequent arrows $\Box \rightarrow$ and $\Diamond \rightarrow$ are auxiliary in the sense that they fail to represent consequence relations, because (in general) neither $\vdash A \Box \rightarrow A$ nor $\vdash A \Diamond \rightarrow A$. The logics presented by such multiple-sequent systems are given by the set of provable sequents $\Delta \rightarrow \Gamma$. The intended meaning of a sequent is captured by a translation σ from sequents into ordinary sequents using a translation δ from S -formulas to modal formulas. For every modal formula A , $\delta(\neg A) := \neg A$ and $\delta(A) := A$. The translation σ is defined as follows:

$$\begin{aligned} \sigma(\Gamma \rightarrow \Delta) &= \bigwedge \delta(\Gamma) \rightarrow \bigvee \delta(\Delta) \\ \sigma(\Gamma \Box \rightarrow \Delta) &= \bigwedge \delta(\Gamma) \rightarrow \Box \bigvee \delta(\Delta) \\ \sigma(\Gamma \Diamond \rightarrow \Delta) &= \Diamond \bigwedge \delta(\Gamma) \rightarrow \bigvee \delta(\Delta) \end{aligned}$$

Here $\delta(\Gamma) := \{A \mid A \in \Gamma\} \cup \{\neg A \mid \neg A \in \Gamma\}$. For every modal formula A , A^* is defined as $\neg A$ and $\neg A^*$ as A . If Δ is a set of S -formulas, $\Delta^* :=$

⁴Note that Nishimura allows infinite sets in antecedent and succedent position. It is, however, shown that if a sequent $\Theta_1; \Gamma; \Theta_2 \rightarrow \Sigma_1; \Delta; \Sigma_2$ is provable, then there are finite sets $\Theta'_i \subseteq \Theta_i$, $\Sigma'_i \subseteq \Sigma_i$, ($i = 1, 2$), $\Gamma' \subseteq \Gamma$, and $\Delta' \subseteq \Delta$ such that the sequent $\Theta'_1; \Gamma'; \Theta'_2 \rightarrow \Sigma'_1; \Delta'; \Sigma'_2$ is provable.

$\{A \mid \neg A \in \Delta\} \cup \{\neg A \mid A \in \Delta\}$. Let (\rightarrow) be any of $\rightarrow, \Box\rightarrow, \Diamond\rightarrow$. The following reflexivity and monotonicity rules are assumed:

$$\vdash A \rightarrow A; \quad \Delta (\rightarrow) \Gamma \vdash \Delta (\rightarrow) \Gamma, A; \quad \Delta (\rightarrow) \Gamma \vdash \Delta, A (\rightarrow) \Gamma.$$

Next, there are further structural rules called shifting rules:

$$\begin{array}{ll} [\rightarrow^*] & A, \Delta \rightarrow \Gamma \vdash \Delta \rightarrow \Gamma, A^* \quad [* \rightarrow] \quad \Delta \rightarrow \Gamma, A \vdash \Delta, A^* \rightarrow \Gamma \\ [\text{TR}] & \Delta \Box\rightarrow \Gamma \vdash \Gamma^* \Diamond\rightarrow \Delta^* \quad \Delta \Diamond\rightarrow \Gamma \vdash \Gamma^* \Box\rightarrow \Delta^* \end{array}$$

The introduction rules for \wedge, \vee, \supset and \neg are formulated for arbitrary sequent arrows. Whereas the rules for \wedge and \vee are versions of the familiar introduction rules, the rules for \neg and \supset can be formulated such that they make use of the structure connective \neg :

$$\begin{array}{l} \Delta, \neg A (\rightarrow) \Gamma \vdash \Delta, \neg A (\rightarrow) \Gamma \\ \Delta (\rightarrow) \Gamma, \neg A \vdash \Delta (\rightarrow) \Gamma, \neg A \\ \Delta, \neg A (\rightarrow) \Gamma \quad \Sigma, B (\rightarrow) \Theta \vdash \Delta, \Sigma, A \supset B (\rightarrow) \Gamma, \Theta \\ \Delta (\rightarrow) \Gamma, \neg A, B \vdash \Delta (\rightarrow) \Gamma, A \supset B \end{array}$$

The introduction rules for the modal operators are not formulated for arbitrary sequent arrows:

$$\begin{array}{ll} [\Box\Box\rightarrow] & A \rightarrow \Delta \vdash \Box A \Box\rightarrow \Delta \quad [\rightarrow \Box] \quad \Delta \Box\rightarrow A \vdash \Delta \rightarrow \Box A \\ [\Diamond\Diamond\rightarrow] & A \Diamond\rightarrow \Delta \vdash \Diamond A \rightarrow \Delta \quad [\Diamond\rightarrow \Diamond] \quad \Delta \rightarrow A \vdash \Delta \Diamond\rightarrow \Diamond A \\ [\Diamond\rightarrow \Diamond] & \neg A, \Delta \Diamond\rightarrow \Gamma \vdash \Delta \Diamond\rightarrow \Gamma, \Diamond A \quad [\Box\Box\rightarrow] \quad \Delta \Box\rightarrow \Gamma, \neg A \vdash \Delta \Box A \Box\rightarrow \Gamma \end{array}$$

The above collection of sequent rules forms a multiple-sequent calculus **MC** for the system **C**. An axiomatization of **C** can be obtained by replacing the necessitation rule in the familiar axiomatization of **K** by the weaker rule

$$(\text{RR}) \quad \text{if } (A \wedge B) \supset C \text{ is provable, then so is } (\Box A \wedge \Box B) \supset \Box C,$$

see [Chellas, 1980]. The necessitation rule and the modal axiom schemata $D, T,$ and 4 can be captured in a modular fashion by pairs of sequent rules:

$$\begin{array}{ll} [\text{nec}] & \Delta \rightarrow \emptyset \vdash \Delta \Diamond\rightarrow \emptyset \quad \emptyset \rightarrow \Delta \vdash \emptyset \Box\rightarrow \Delta \\ [D] & \Delta \Box\rightarrow \emptyset \vdash \Delta \rightarrow \emptyset \quad \emptyset \Diamond\rightarrow \Delta \vdash \emptyset \rightarrow \Delta \\ [T] & \Delta \Box\rightarrow \Gamma \vdash \Delta \rightarrow \Gamma \quad \Delta \Diamond\rightarrow \Gamma \vdash \Delta \rightarrow \Gamma \\ [4] & \Delta \rightarrow \Sigma \vdash \Delta \Box\rightarrow \Sigma \quad \Theta \rightarrow \Gamma \vdash \Theta \Diamond\rightarrow \Gamma, \end{array}$$

where in rule $[4]$, every S -formula in Δ has the shape $\Box A$ or $\neg \Diamond A$ and every S -formula in Γ has the shape $\Diamond A$ or $\neg \Box A$. All sequent systems obtained in this way satisfy a generalized subformula property: for every modal formula A , it holds that if A or $\neg A$ is used in a proof of $\Delta \rightarrow \Gamma$, then A is a subformula of $\Delta \cup \Gamma$ (where the notion of a subformula of an S -formula is defined in the obvious way). Indrzejczak does not investigate the admissibility of

cut for \rightarrow or the admissibility of cut for $\Box\rightarrow$ and $\Diamond\rightarrow$ in extensions of **CT** (where $\vdash A\Box\rightarrow A$ and $\vdash A\Diamond\rightarrow A$). Note that the introduction rules for the modal operators fail to be symmetrical, since there are no introduction rules for \Box on the left and \Diamond on the right of \rightarrow . Moreover, the side conditions on [4] are such that the status of this rule as a purely structural rule is doubtful. The multiple-sequent systems for extensions of **KB** make use of denumerably many sequent arrows \xrightarrow{n} ($n \geq 0$), where logics are defined by the provable sequents $\Delta \xrightarrow{0} \Gamma$. The introduction rules

$$\begin{array}{ll} A \xrightarrow{n} \Delta \vdash \Box A \xrightarrow{n+1} \Delta & \Delta \xrightarrow{n+1} A \vdash \Delta \xrightarrow{n} \Box A \\ A \xrightarrow{n+1} \Delta \vdash \Diamond A \xrightarrow{n} \Delta & \Delta \xrightarrow{n} A \vdash \Delta \xrightarrow{n+1} \Diamond A \end{array}$$

fail to introduce \Box on the left and \Diamond on the right of $\xrightarrow{0}$, so that also these rules are not symmetrical.

In Section 4.1, we shall point to a simple relation between Indrzejczak's multiple-sequent systems and higher-arity sequent systems for modal logics.

2.5 Hypersequents

Hypersequents were introduced into the literature by Pottinger [1983], and have later systematically been studied by Avron [1991; 1991a; 1996]. A *hypersequent* is a sequence

$$\Gamma_1 \rightarrow \Delta_1 \mid \Gamma_2 \rightarrow \Delta_2 \mid \dots \mid \Gamma_n \rightarrow \Delta_n$$

of ordinary sequents (or, more generally, sequents in which Δ_i and Γ_i are sequences of formula occurrences) as their *components*. The symbol ' \mid ' in the statement of a hypersequent enriches the language of sequents and is intuitively to be read as disjunction. This expressive enhancement “makes it possible to introduce *new* types of structural rules, and . . . to allow greater versatility in developing interesting logical systems” [Avron, 1996, p. 6]. In particular, a distinction may be drawn between internal and external versions of structural rules. The internal rules deal with formulas within a certain component, whereas the external rules deal with components within a hypersequent. Let G, H, H_1, H_2 etc. be schematic letters for possibly empty hypersequents. External monotonicity, for instance, can be contrasted with internal monotonicity:

$$H_1 \mid H_2 \vdash H_1 \mid G \mid H_2 \quad \text{vs.} \quad H_1 \mid \Gamma \rightarrow \Delta \mid H_2 \vdash H_1 \mid A, \Gamma \rightarrow \Delta \mid H_2.$$

Cut only has an internal version:

$$\frac{G_1 \mid \Gamma_1 \rightarrow \Delta_1, A \mid H_1 \quad G_2 \mid A, \Gamma_2 \rightarrow \Delta_2 \mid H_2}{G_1 \mid G_2 \mid \Gamma_1, \Gamma_2 \rightarrow \Delta_1, \Delta_2 \mid H_1 \mid H_2}$$

The use of hypersequents allows a cut-free presentation **GS5** of **S5** satisfying the subformula property. The system **GS5** consists of hypersequential

versions of the rules of **LS4**, in particular, external and internal versions of contraction and monotonicity, the above cut-rule, and a structural rule of a new kind, namely the *modalized splitting rule*:

$$(MS) \quad G \mid \Box\Gamma_1, \Gamma_2 \rightarrow \Box\Delta_1, \Delta_2 \mid H \vdash G \mid \Box\Gamma_1 \rightarrow \Box\Delta_1 \mid \Gamma_2 \rightarrow \Delta_2 \mid H.$$

In the next section we shall define display sequents, and in Section 4.2 we shall define a translation of hypersequents into display sequents.

3 DISPLAY LOGIC

We shall develop display logic only to the extent needed to cover a variety of normal modal and temporal logics based on classical or intuitionistic logic. A more comprehensive presentation of display logic and its application to modal and non-classical logics can be found in [Belnap, 1982], [Belnap, 1990], [Belnap, 1996], [Goré, 1998], [Kracht, 1996], [Restall, 1998], [Wansing, 1998]. Note that except for the substructure property, all requirements examined in the previous sections are satisfied by the display sequent systems to be presented.

3.1 Introduction rules through residuation

Whereas the ordinary sequent systems for temporal logics presented in Section 1.2 fail to exploit the interaction between the backward and the forward looking modalities, the modal display calculus is based on observing that the operators $\langle P \rangle$ and $[F]$ form a residuated pair. The following definition is taken from Dunn [1990, p. 32]:

DEFINITION 5. Consider two partially ordered sets $\mathcal{A} = (\mathbf{A}, \leq)$ and $\mathcal{B} = (\mathbf{B}, \leq')$ with functions $f: \mathbf{A} \rightarrow \mathbf{B}$ and $g: \mathbf{B} \rightarrow \mathbf{A}$. The pair (f, g) is called

$$\begin{aligned} & \text{residuated} && \text{iff} && (fa \leq' b \text{ iff } a \leq gb); \\ & \text{a Galois connection} && \text{iff} && (b \leq' fa \text{ iff } a \leq gb); \\ & \text{a dual Galois connection} && \text{iff} && (fa \leq' b \text{ iff } gb \leq a); \\ & \text{a dual residuated pair} && \text{iff} && (b \leq' fa \text{ iff } gb \leq a). \end{aligned}$$

Obviously, $(\langle P \rangle, [F])$ forms a residuated pair with respect to the provability relation in normal extensions of **Kt**, and $(\neg\langle F \rangle, \neg\langle P \rangle)$ is a Galois connection.⁵ These ideas of residuation and Galois connection can be generalized. In [Dunn, 1990], [Dunn, 1993], Dunn has defined an abstract law of

⁵The fact that $\langle P \rangle$ and $[F]$ form a residuated pair is also used in Kashima's [1994] sequent calculi for various normal temporal logics. The approach of Kashima is similar to the modal display calculus and the modal signs approach developed by Cerrato [1993; 1996] insofar as the structural language of sequents is extended by unary structure operations. Whereas nesting of these operations is not allowed in Cerrato's sequent systems for normal modal propositional logics, Kashima allows iteration. Kashima inductively defines a notion of sequent as follows:

residuation for n -place connectives f and g . The formulation of this principle refers to *traces* of operations and assumes the presence (or definability) of a truth constant t and a falsity constant f . We shall use $A \dashv\vdash B$ to express that A and B are interderivable in a given axiom system.

DEFINITION 6. An n -place connective f ($n \geq 0$) has a trace $(\rho_1, \dots, \rho_n) \mapsto +$ (in symbols $T(f) = (\rho_1, \dots, \rho_n) \mapsto +$) iff

- $f(A_1, \dots, t, \dots, A_n) \dashv\vdash t$, if $\rho_i = +$ (the indicated t is in position i);
- $f(A_1, \dots, f, \dots, A_n) \dashv\vdash t$, if $\rho_i = -$ (the indicated f is in position i);
- if $A \vdash B$ and $\rho_i = +$, then $f(A_1, \dots, A, \dots, A_n) \vdash f(A_1, \dots, B, \dots, A_n)$;
- if $A \vdash B$ and $\rho_i = -$, then $f(A_1, \dots, B, \dots, A_n) \vdash f(A_1, \dots, A, \dots, A_n)$.

The operation f has a trace $(\rho_1, \dots, \rho_n) \mapsto -$ ($T(f) = (\rho_1, \dots, \rho_n) \mapsto -$) iff

- $f(A_1, \dots, f, \dots, A_n) \dashv\vdash f$, if $\rho_i = +$ (the indicated f is in position i);
- $f(A_1, \dots, t, \dots, A_n) \dashv\vdash f$, if $\rho_i = -$ (the indicated t is in position i);
- if $A \vdash B$ and $\rho_i = +$, then $f(A_1, \dots, B, \dots, A_n) \vdash f(A_1, \dots, A, \dots, A_n)$;
- if $A \vdash B$ and $\rho_i = -$, then $f(A_1, \dots, A, \dots, A_n) \vdash f(A_1, \dots, B, \dots, A_n)$.

In \mathbf{Kt} , \neg has traces $- \mapsto +$ and $+ \mapsto -$, whereas $[F]$ has trace $+ \mapsto +$ and $\langle P \rangle$ has trace $- \mapsto -$.

DEFINITION 7. Two n -place operations f and g are *contrapositives in place j* iff $T(f) = (\rho_1, \dots, \rho_j, \dots, \rho_n) \mapsto \rho$ implies $T(g) = (\rho_1, \dots, -\rho, \dots, \rho_n) \mapsto -\rho_j$, where $-+ = -$ and $-- = +$.

DEFINITION 8. Let

$$\underline{S(f, A_1, \dots, A_n, B)} \text{ iff } \begin{cases} B \vdash f(A_1, \dots, A_n) & \text{if } T(f) = (\dots) \mapsto + \\ f(A_1, \dots, A_n) \vdash B & \text{if } T(f) = (\dots) \mapsto - \end{cases}$$

1. every temporal formula is a sequent;
2. if Γ is a sequent, then so is $^P\{\Gamma\}$ and $^F\{\Gamma\}$;
3. if $n \geq 0$ and every Γ_i ($1 \leq i \leq n$) is a sequent, then so is $\Gamma_1, \dots, \Gamma_n$.

The intuitive meaning of a sequent is given by the following inductively defined translation $(\cdot)^*$ from sequents into formulas:

1. $(\Gamma)^* = A$, if Γ is the formula A ;
2. $(^P\{\Gamma\})^* = [P]^P(\Gamma)^*$; $(^F\{\Gamma\})^* = [F]^F(\Gamma)^*$;
3. if $n > 0$, then $(\Gamma_1, \dots, \Gamma_n)^* = \bigvee\{(\Gamma_1)^*, \dots, (\Gamma_n)^*\}$;
4. $(\cdot)^* = (p \wedge \neg p)$, for some atom p .

Residuation then shows up in Kashima's "turn rules":

$$\Gamma, ^F\{\Delta\} \vdash ^P\Gamma, \Delta; \quad \Gamma, ^P\{\Delta\} \vdash ^F\Gamma, \Delta.$$

Most of Kashima's sequent rules used to capture various structural properties of accessibility either fail to be explicit or separated in the sense of Section 1.3. Cut-elimination for these systems is shown semantically, i.e., in a non-constructive way.

A pair of n -place connectives f and g satisfies the abstract law of residuation just in case for some j ($1 \leq j \leq n$), f and g are contrapositives in place j , and

$$S(f, A_1, \dots, A_j, \dots, A_n, B) \text{ iff } S(g, A_1, \dots, B, \dots, A_n, A_j).$$

OBSERVATION 9. The abstract law of residuation holds for the pairs (\mathbf{t}, \mathbf{f}) , (\neg, \neg) , $(\langle P \rangle, [F])$, (\wedge, \triangleright) , $(\blacktriangleleft, \vee)$, $(\wedge, \neg \dots \vee \dots)$, and $(\dots \wedge \neg \dots, \vee)$, where \triangleright is intuitionistic implication and \blacktriangleleft is coimplication.

Coimplication \blacktriangleleft is characterized by

$$A \vdash B \vee C, \Delta \text{ iff } A \blacktriangleleft B \vdash C, \Delta.$$

In classical logic, the residual of disjunction is definable, since

$$A \vdash B \vee C, \Delta \text{ iff } A \wedge \neg B \vdash C, \Delta \text{ iff } \neg(A \supset B) \vdash C,$$

but in bi-intuitionistic logic it is not, see Section 3.8. For each of the pairs (\mathbf{t}, \mathbf{f}) , (\neg, \neg) , $(\langle P \rangle, [F])$, (\wedge, \triangleright) , $(\blacktriangleleft, \vee)$, the structural language of display sequents contains one structure connective. Since in classical logic \wedge and \vee are interdefinable using \neg , the pairs $(\wedge, \neg \dots \vee \dots)$ and $(\dots \wedge \neg \dots, \vee)$ require only a single structure connective in addition to the unary structure operation associated with (\neg, \neg) . We shall use X, Y, Z (possibly with subscripts) as variables for structures. A display sequent is an expression $X \rightarrow Y$; X is called the antecedent and Y is called the succedent of $X \rightarrow Y$. The structures are defined by:

$$X ::= A \mid \mathbf{I} \mid *X \mid \bullet X \mid X \circ Y \mid X \times Y \mid X \bowtie Y.$$

The association of structure connectives with pairs of operations satisfying the abstract law of residuation is accomplished by the following translations τ_1 of antecedents and τ_2 of succedents into formulas:

$$\begin{array}{ll} \tau_1(A) = A & \tau_2(A) = A \\ \tau_1(\mathbf{I}) = \mathbf{t} & \tau_2(\mathbf{I}) = \mathbf{f} \\ \tau_1(*X) = \neg\tau_2(X) & \tau_2(*X) = \neg\tau_1(X) \\ \tau_1(\bullet X) = \langle P \rangle\tau_1(X) & \tau_2(\bullet X) = [F]\tau_2(X) \\ \tau_1(X \times Y) = \tau_1(X) \wedge \tau_1(Y) & \tau_2(X \times Y) = \tau_2(X) \triangleright \tau_2(Y) \\ \tau_1(X \bowtie Y) = \tau_1(X) \blacktriangleleft \tau_1(Y) & \tau_2(X \bowtie Y) = \tau_2(X) \vee \tau_2(Y) \\ \tau_1(X \circ Y) = \tau_1(X) \wedge \tau_1(Y) & \tau_2(X \circ Y) = \tau_2(X) \vee \tau_2(Y) \end{array}$$

Under these translations, the following basic structural rules are valid ((1)–(4) in normal temporal logic; (5) and (6) in bi-intuitionistic logic) if \rightarrow is

understood as provability:

Basic structural rules

- (1) $X \circ Y \rightarrow Z \dashv\vdash X \rightarrow Z \circ *Y \dashv\vdash Y \rightarrow *X \circ Z$
- (2) $X \rightarrow Y \circ Z \dashv\vdash X \circ *Z \rightarrow Y \dashv\vdash *Y \circ X \rightarrow Z$
- (3) $X \rightarrow Y \dashv\vdash *Y \rightarrow *X \dashv\vdash X \rightarrow **Y$
- (4) $X \rightarrow \bullet Y \dashv\vdash \bullet X \rightarrow Y$
- (5) $X \rtimes Y \rightarrow Z \dashv\vdash Y \rightarrow X \rtimes Z \dashv\vdash X \rightarrow Y \rtimes Z$
- (6) $X \rightarrow Y \rtimes Z \dashv\vdash X \rtimes Y \rightarrow Z \dashv\vdash X \rtimes Z \rightarrow Y,$

where $X_1 \rightarrow Y_1 \dashv\vdash X_2 \rightarrow Y_2$ abbreviates $X_1 \rightarrow Y_1 \vdash X_2 \rightarrow Y_2$ and $X_2 \rightarrow Y_2 \vdash X_1 \rightarrow Y_1$. If two sequents are interderivable by means of (1)–(6), then these sequents are said to be *structurally* or *display equivalent*. The following pairs of sequents, for example, are display equivalent on the strength of (1)–(3):

$$\begin{array}{llll} X \circ Y \rightarrow Z & *Z \rightarrow *Y \circ *X; & X \rightarrow Y \circ Z & *Z \circ *Y \rightarrow *X; \\ X \rightarrow Y & *Y \rightarrow X; & X \rightarrow *Y & Y \rightarrow *X; \\ X \rightarrow Y & **X \rightarrow Y. & & \end{array}$$

The name ‘display logic’ derives from the fact that any substructure of a given display sequent s may be *displayed* as the entire antecedent or succedent of a structurally equivalent sequent s' . In order to state this fact precisely, we define the notion of a polarity vector and antecedent and succedent part of a sequent (cf. [Goré, 1998]).

DEFINITION 10. To each n -place structure connective c we assign two *polarity vectors* $ap(c, \pm_1, \dots, \pm_n)$ and $sp(c, \pm_1, \dots, \pm_n)$, where $\pm_i \in \{+, -\}$ and $1 \leq i \leq n$:

$$\begin{array}{llllll} ap(*, -) & ap(\bullet, +) & ap(\circ, +, +) & ap(\rtimes, +, +) & ap(\rtimes, +, -) \\ sp(*, -) & sp(\bullet, +) & sp(\circ, +, +) & sp(\rtimes, -, +) & sp(\rtimes, +, +) \end{array}$$

We write $ap(c, j, \pm)$ and $sp(c, j, \pm)$ to express that c has antecedent, respectively succedent polarity \pm at place j .

DEFINITION 11. Let $s = X \rightarrow Y$. The exhibited occurrence of X is an antecedent part of s , and the exhibited occurrence of Y is a succedent part of s . If $c(X_1, \dots, X_n)$ is an antecedent [succedent] part of s , then the substructure occurrence X_j ($1 \leq j \leq n$) is

1. an antecedent [succedent] part of s if $ap(c, j, +)$ [$sp(c, j, +)$];
2. a succedent [antecedent] part of s if $ap(c, j, -)$ [$sp(c, j, -)$].

THEOREM 12. (Display Theorem, Belnap) *For each display sequent s and each antecedent [succedent] part X of s there exists a display sequent s' structurally equivalent to s such that X is the entire antecedent [succedent] of s' .*

Proof. The theorem was first proved in [Belnap, 1982]; we shall follow the proof in [Restall, 1998]. A *context* results from a structure by replacing one occurrence of a substructure by the ‘Void’ (in symbols ‘ $-$ ’). If f is a context and X is a structure, then $f(X)$ is the result of substituting X for the Void in f . A context f is called *antecedent positive (negative)* if the indicated X is an antecedent part (a succedent part) of $f(X) \rightarrow Y$; f is said to be *succedent positive (negative)* if the indicated X is a succedent part (an antecedent part) of $Y \rightarrow f(X)$. A contextual sequent has the shape $f \rightarrow Z$ or $Z \rightarrow f$, and a pair of contextual sequents is said to be structurally equivalent if the sequents are interderivable by means of rules (1)–(6). The Display Theorem then follows from the following lemma.

LEMMA 13. (i) *Suppose f is a context in antecedent position. If f is antecedent positive, then $f(X) \rightarrow Y$ is structurally equivalent to $X \rightarrow f^a(Y)$, where f^a is a context obtained by unraveling the Void in f . If f is antecedent negative, then $f(X) \rightarrow Y$ is structurally equivalent to $f^a(Y) \rightarrow X$.* (ii) *Suppose f is a context in succedent position. If f is succedent positive, then $Y \rightarrow f(X)$ is structurally equivalent to $f^c(Y) \rightarrow X$, where f^c is a context obtained by unraveling the Void in f . If f is succedent negative, then $Y \rightarrow f(X)$ is structurally equivalent to $X \rightarrow f^c(Y)$.*

The proof is by induction on the complexity of contexts.

Case 1: $f = -$. Then f is antecedent and succedent positive, and $f^a(Y) = f^c(Y) = Y$.

Case 2: $f = \bullet g$. Then $f(X) \rightarrow Y$ is structurally equivalent to $g(X) \rightarrow \bullet Y$, and $Y \rightarrow f(X)$ is equivalent to $\bullet Y \rightarrow g(X)$. By the induction hypothesis, these sequents are equivalent to $X \rightarrow f^a(\bullet Y)$, $f^a(\bullet Y) \rightarrow X$, $f^c(\bullet Y) \rightarrow X$, or $X \rightarrow f^c(\bullet Y)$. Hence $f^a = g^a(\bullet -)$ and $f^c = g^c(\bullet -)$.

Case 3: $f = *g$. Then $f(X) \rightarrow Y$ is equivalent to $*Y \rightarrow g(X)$. Depending on whether g is succedent positive or negative, $f(X) \rightarrow Y$ is structurally equivalent to $g^c(*Y) \rightarrow X$ or to $X \rightarrow g^c(*Y)$. Therefore, by the induction hypothesis, $f^a = g^c(*-)$. Similarly, $f^c = g^a(*-)$.

Case 4: $f = Z \circ g$. Then $f(X) \rightarrow Y$ is equivalent to $g(X) \rightarrow *Z \circ Y$. By the induction hypothesis, this sequent is equivalent to $X \rightarrow g^a(*Z \circ Y)$ or $g^a(*Z \circ Y) \rightarrow X$, and hence $f^a = g^a(*Z \circ -)$. Similarly, $f^c = g^a(- \circ *Z)$.

Case 5: $f = g \circ Z$. Similar to Case 4.

Case 6: $f = g \times Z$. Then $Y \rightarrow f(X)$ is equivalent to $g(X) \rightarrow Y \times Z$, and by the induction hypothesis, the latter is equivalent to $X \rightarrow g^a(Y \times Z)$ or to $g^a(Y \times Z) \rightarrow X$. Thus $f^c = g^a(- \times Z)$. Similarly, $f^a = g^c(Z \times -)$.

Case 7: $f = Z \times g$. Analogous to the previous case.

Cases 8 and 9: $f = g \times Z$ and $f = Z \times g$. Analogous to Cases 6 and 7. ■

If (for suitable notions of structural equivalence, antecedent part, and succedent part) a sequent calculus satisfies the Display Theorem, it is said to enjoy the *display property*. Note that the set of rules (1)–(6) is not the only

<i>truth and falsity rules</i>

Table 2. Additional structural rules.

possible choice of display rules warranting the display property, see [Belnap, 1996] and [Goré, 1998].⁶ The display property allows an “‘essentials-only’ proof of cut elimination relying on easily established and maximally general properties of structural and connective rules” [Belnap, 1996, p. 80]. Further, the display property enables a statement of the introduction rules that satisfies the segregation requirement. Belnap emphasizes that the display property may be used to keep certain proof-theoretic components as separate as possible. In a sequent calculus enjoying the display property, the behaviour of the structural elements can be described by the structural rules, and the right (left) introductions rules for an n -place logical operation f can be formulated with $f(A_1, \dots, A_n)$ standing alone as the entire succedent (antecedent) of the conclusion sequent. Since $f(A_1, \dots, A_n)$ plays no inferential roles beyond being derived and allowing to derive, these left and right rules provide a complete explanation of the inferential meaning of f . The constant \mathbf{I} induces introduction rules for t and f . The operations $*$ and \circ give rise to introduction rules for the Boolean connectives. The structure operation \bullet permits formulating introduction rules for the modal-

⁶Goré [Goré, 1998] introduces binary structure connectives $<$ and $>$ to be interpreted as directional versions of implication in succedent position and coimplication in antecedent position. The display property is guaranteed by the following structural rules (notation adjusted):

$$\begin{aligned}
 X \rightarrow Z < Y \dashv\vdash X \circ Y \rightarrow Z \dashv\vdash Y \rightarrow X > Z \\
 Z < Y \rightarrow X \dashv\vdash Z \rightarrow X \circ Y \dashv\vdash X > Z \rightarrow Y.
 \end{aligned}$$

ities, whereas \times and \ltimes give rise to introduction schemata for conjunction, disjunction, implication, and coimplication in bi-intuitionistic logic. These introduction rules are assembled in Table 1. The further structural rules in Table 2 contain many redundancies when they are assumed as a set. Such a rich inventory of structural inference rules is, however, an advantage in a treatment of substructural subsystems of normal modal and temporal logics, see [Goré, 1998]. In addition to a set of structural rules and a set of introduction rules, every display sequent system contains two *logical* rules exhibiting neither structural nor logical operations, namely reflexivity for atoms (alias identity) and cut:

$$(id) \quad \vdash p \rightarrow p \quad \text{and} \quad (cut) \quad X \rightarrow A \quad A \rightarrow Y \vdash X \rightarrow Y.$$

The identity rule (id) can be generalized to arbitrary formulas from temporal or bi-intuitionistic logic.

OBSERVATION 14. For every formula A , $\vdash A \rightarrow A$.

Proof. The proof is by induction on the complexity of A . For example,

$$\frac{A \rightarrow A}{[P]A \rightarrow * \bullet * A} \quad \frac{A \rightarrow A}{\bullet A \rightarrow \langle P \rangle A} \quad \frac{A \rightarrow A \quad B \rightarrow B}{A \times B \rightarrow A \blacktriangleleft B}$$

$$\frac{[P]A \rightarrow * \bullet * A}{[P]A \rightarrow [P]A} \quad \frac{A \rightarrow \bullet \langle P \rangle A}{\langle P \rangle A \rightarrow \langle P \rangle A} \quad \frac{A \times B \rightarrow A \blacktriangleleft B}{A \blacktriangleleft B \rightarrow A \blacktriangleleft B}.$$

■

DEFINITION 15. The display sequent system **DCPL** is given by (id), (cut), the Boolean rules, and the structural rules exhibiting **I**, *****, and **o**. The system **DKt** consists of **DCPL** plus the tense logical rules and the structural rules exhibiting **•**. The system **DK** results from **DKt** by removing the introduction rules for $[P]$ and $\langle P \rangle$.

A sequent rule is invertible if every premise sequent can be derived from the conclusion sequent.

OBSERVATION 16. The following holds in every purely structural extension of **DKt** and **DK**. (i) The logical operations are uniquely characterized. (ii) The introduction rules for \neg , \wedge , and \vee , the left introduction rules for t , $\langle P \rangle$, and $\langle F \rangle$, and the right introduction rules for f , \supset , \equiv , $[P]$, and $[F]$ are invertible. (iii) The modalities $[F]$ and $\langle F \rangle$ ($[P]$ and $\langle P \rangle$) are interdefinable using \neg .

Note that there exist various duality and symmetry transformations on proofs in display logic, see [Goré, 1998], [Kracht, 1996].

3.2 Completeness

We shall first consider weak completeness of **DKt** and **DK**, that is, the coincidence of **Kt** (**K**) and **DKt** (**DK**) with respect to provable formulas. We shall then strengthen this result and in Section 3.4 turn to axiomatic extensions of **K** and **Kt**.

THEOREM 17. (i) If $\vdash A$ in **Kt**, then $\vdash \mathbf{I} \rightarrow A$ in **DKt**. (ii) If $\vdash X \rightarrow Y$ in **DKt**, then $\tau_1(X) \vdash \tau_2(Y)$ in **Kt**.

Proof. (i) We may take any axiomatization of **Kt** and show that the axiom schemata are provable in **DKt**, and the proof rules preserve provability in **DKt**. The following is a cut-free proof of the K axiom schema for $[F]$; the proof for $[P]$ is analogous:

$$\begin{array}{c}
 \frac{A \rightarrow A}{[F]A \rightarrow \bullet A} \\
 \frac{[F]A \rightarrow \bullet A}{[F](A \supset B) \circ [F]A \rightarrow \bullet A} \\
 \frac{\bullet([F](A \supset B) \circ [F]A) \rightarrow A \quad B \rightarrow B}{A \supset B \rightarrow * \bullet ([F](A \supset B) \circ [F]A) \circ B} \\
 \frac{A \supset B \rightarrow * \bullet ([F](A \supset B) \circ [F]A) \circ B}{[F](A \supset B) \rightarrow \bullet (* \bullet ([F](A \supset B) \circ [F]A) \circ B)} \\
 \frac{[F](A \supset B) \rightarrow \bullet (* \bullet ([F](A \supset B) \circ [F]A) \circ B)}{[F](A \supset B) \circ [F]A \rightarrow \bullet (* \bullet ([F](A \supset B) \circ [F]A) \circ B)} \\
 \frac{\bullet([F](A \supset B) \circ [F]A) \rightarrow * \bullet ([F](A \supset B) \circ [F]A) \circ B}{\bullet([F](A \supset B) \circ [F]A) \circ \bullet([F](A \supset B) \circ [F]A) \rightarrow B} \\
 \frac{\bullet([F](A \supset B) \circ [F]A) \rightarrow B}{[F](A \supset B) \circ [F]A \rightarrow [F]B} \\
 \frac{[F](A \supset B) \circ [F]A \rightarrow [F]B}{[F](A \supset B) \rightarrow [F]A \supset [F]B} \\
 \frac{[F](A \supset B) \rightarrow [F]A \supset [F]B}{\mathbf{I} \circ [F](A \supset B) \rightarrow [F]A \supset [F]B} \\
 \frac{\mathbf{I} \circ [F](A \supset B) \rightarrow [F]A \supset [F]B}{\mathbf{I} \rightarrow [F](A \supset B) \supset [F]A \supset [F]B}
 \end{array}$$

Necessitation for $[F]$ and $[P]$ is taken care of by the (MN) rules. It remains to derive the tense logical interaction schemata $A \supset [F]\langle P \rangle A$ and $A \supset [P]\langle F \rangle A$:

$$\begin{array}{c}
 \frac{A \rightarrow A}{\bullet A \rightarrow \langle P \rangle A} \\
 \frac{\bullet A \rightarrow \langle P \rangle A}{A \rightarrow [F]\langle P \rangle A} \\
 \frac{A \rightarrow A}{* \bullet * A \rightarrow \langle F \rangle A} \\
 \frac{* \bullet * A \rightarrow \langle F \rangle A}{* \langle F \rangle A \rightarrow \bullet * A} \\
 \frac{* \langle F \rangle A \rightarrow \bullet * A}{A \rightarrow * \bullet * \langle F \rangle A} \\
 \frac{A \rightarrow * \bullet * \langle F \rangle A}{A \rightarrow [P]\langle F \rangle A}
 \end{array}$$

(ii) By induction on the complexity of proofs in **DKt**. ■

COROLLARY 18. (i) In **Kt**, $\vdash A$ iff $\vdash \mathbf{I} \rightarrow A$ in **DKt**. (ii) In **K**, $\vdash A$ iff $\vdash \mathbf{I} \rightarrow A$ in **DK**.

Proof. (i) By the previous theorem. (ii) This follows from the fact that every frame complete normal propositional tense logic is a conservative extension of its modal fragment. ■

LEMMA 19. *In every extension of \mathbf{DKt} by structural inference rules, it holds that $\vdash X \rightarrow \tau_1(X)$ and $\vdash \tau_2(X) \rightarrow X$.*

Proof. By induction on the complexity of X . ■

This lemma allows one to prove strong completeness.

THEOREM 20. *In \mathbf{DKt} , $\vdash X \rightarrow Y$ iff $\tau_1(X) \vdash \tau_2(Y)$ in \mathbf{Kt} .*

Proof. (\Rightarrow): This is Theorem 17, (ii). (\Leftarrow): Suppose that in \mathbf{Kt} , $\tau_1(X) \vdash \tau_2(Y)$. Hence $\vdash_{\mathbf{Kt}} \tau_1(X) \supset \tau_2(Y)$. By Corollary 18, $\vdash_{\mathbf{DKt}} \mathbf{I} \rightarrow \tau_1(X) \supset \tau_2(Y)$ and thus $\vdash_{\mathbf{DKt}} \tau_1(X) \rightarrow \tau_2(Y)$. Since by Lemma 19, $\vdash X \rightarrow \tau_1(X)$ and $\vdash \tau_2(Y) \rightarrow Y$ in \mathbf{DKt} , an application of cut gives $\vdash X \rightarrow Y$. ■

COROLLARY 21. *\mathbf{DK} is strongly sound and complete with respect to \mathbf{K} .*

3.3 Strong cut-elimination

A remarkable quality of display logic is that a strong cut-elimination theorem holds for every properly displayable and every displayable logic. Proper displayability and displayability are easily checkable properties. A *proper display calculus* is a calculus of sequents whose rules of inference satisfy the following eight conditions (recall the terminology from Section 1.1):

- C1 *Preservation of formulas.* Each formula which is a constituent of some premise of *inf* is a subformula of some formula in the conclusion of *inf*.
- C2 *Shape-alikeness of parameters.* Congruent parameters are occurrences of the same structure.
- C3 *Non-proliferation of parameters.* Each parameter of *inf* is congruent to at most one constituent in the conclusion of *inf*.
- C4 *Position-alikeness of parameters.* Congruent parameters are either all antecedent or all succedent parts of their respective sequents.
- C5 *Display of principal constituents.* A principal formula of *inf* is either the entire antecedent or the entire succedent of the conclusion of *inf*.
- C6 *Closure under substitution for consequent parts.* Each rule is closed under simultaneous substitution of arbitrary structures for congruent formulas which are consequent parts.

C7 *Closure under substitution for antecedent parts.* Each rule is closed under simultaneous substitution of arbitrary structures for congruent formulas which are antecedent parts.

C8 *Eliminability of matching principal formulas.* If there are inferences inf_1 and inf_2 with respective conclusions (1) $X \rightarrow A$ and (2) $A \rightarrow Y$ with A principal in both inferences, and if cut is applied to obtain (3) $X \rightarrow Y$, then either (3) is identical to one of (1) or (2), or there is a proof of (3) from the premises of inf_1 and inf_2 in which every cut-formula of any application of cut is a proper subformula of A .

Obviously, every display calculus satisfying C1 enjoys the subformula property, that is, every cut-free proof of any sequent s contains no formulas which are not subformulas of constituents of s . If a logical system can be presented as a proper display calculus, it is said to be *properly displayable*. Belnap [1982] showed that in every properly displayable logic, a proof of a sequent s can be converted into a proof of s not containing any application of cut

$$\frac{(1) X \rightarrow A \quad (2) A \rightarrow Y}{(3) X \rightarrow Y}.$$

The proof of strong cut-elimination reveals that every sufficiently long sequence of steps in a certain process of cut-elimination terminates with a cut-free proof. The elimination process consists of various kinds of actions, *principal moves*, *parametric moves*, and a combination of parametric and principal moves. If the cut-formula A is principal in the final inference in the proofs of both (1) and (2), a principal move is performed. Otherwise, if there is no previous application of cut, a parametric move or a combination of parametric and principal moves is executed. According to this distinction we define primitive reductions of proofs Π ending in an application of cut. Recently, Jeremy Dawson and Rajeev Goré discovered a gap in the proof of strong normalization presented in [Wansing, 1998]. To avoid the problem, the primitive reduction steps have to be redefined. Let Π_i be the proof of (i) we are dealing with, ($i = 1, 2$).

Principal moves. By C8, there are two subcases:

Case 1. (3) is the same as (i): $\frac{\Pi_1 \quad \Pi_2}{(3)} \rightsquigarrow \Pi_i$

Case 2. There is a proof Π of (3) from the premises s_1, \dots, s_n of (1) and s'_1, \dots, s'_m of (2) in which every cut-formula of any application of cut is a proper subformula of A :

$$\frac{\frac{\Pi^1 \quad \Pi^2}{s_1, \dots, s_n \quad s'_1, \dots, s'_m} \quad (1) \quad (2)}{(3)} \rightsquigarrow \frac{\Pi^1 \quad \Pi^2}{\Pi} (3)$$

Parametric moves. The parametric moves modify proofs on a larger scale than the principal moves. The parametric moves show that applications of structural rules need never immediately precede applications of cut. Suppose that A is parametric in the inference ending in (1). The case for (2) is completely symmetrical. In order to define the parametric moves, we inductively define a set Q of occurrences of A , called the set of ‘parametric ancestors’ of A (in Π_1), cf. [Belnap, 1982, p. 394]. We start with putting the displayed occurrence of A in (1) into Q . Then, by working up Π_1 , we add for every inference *inf* in Π_1 each constituent of a premise of *inf* which is congruent (with respect to *inf*) to a constituent of the conclusion of *inf* already in Q . What we obtain is a finite tree of parametric ancestors of A rooted in the displayed occurrence of A in (1). This tree and the tree of parametric ancestors of the displayed occurrence of A in (2) either contain an application of cut or not. If so, we do *not* perform a reduction, but instead consider one of these applications of cut above (1) or (2) for reduction. If not, that is, if there is no application of cut in the trees of parametric ancestors, then for each path of parametric ancestors of A in Π_1 , we distinguish two subcases. Let A_u be the uppermost element of the path and let *inf* be the inference ending in the sequent s which contains A_u .

Case 1. A_u is not parametric in *inf*. By C4 and C5, it is the entire consequent of s . We cut with Π_2 and replace every parametric ancestor of A below A_u in the path by Y .

Case 2. A_u is parametric in *inf*. Then, with respect to *inf*, A_u is congruent only to itself, and we just replace every parametric ancestor of A below A_u in the path by Y . Moreover, we delete Π_2 , which is now superfluous.

Call the result of simultaneously carrying out these operations for every path of parametric ancestors of A in Π_1 and removing the initial occurrence of (3) (since now (2) = (3)) Π^l . If the tree of parametric ancestors of the displayed occurrence of A in (1) contains at most one element A_u that is not parametric in *inf*, Π reduces to Π^l : $\Pi \rightsquigarrow \Pi^l$. Typically we have the situation of Figure 1.

By C3 and the bottom-up definition of Q , for every inference *inf* in Π_1 , Q must contain the whole congruence class of *inf*, if Q is inhabited at all. By C4, Q only consists of consequent parts. Hence, by C2 and C6, the result of such a reduction is in fact a proof of (3), since on the path from (1) to $Z \rightarrow A$ we have the same sequence of inference rules being applied as on the path from (3) to $Z \rightarrow Y$. If the cut-formula A is parametric in the inference ending in (2), we rely on C7 instead of C6 and obtain a proof Π^r .

If the tree of parametric ancestors of the displayed occurrence of A in (1) contains more than one element A_u that is not parametric in *inf*, parametric and principal moves have to be combined. If A is non-parametric in the final inference of Π_2 , we apply to Π^l a principal move on every cut with Π_2 . Call

Figure 1.

the resulting proof Π^{l*} : $\Pi \rightsquigarrow \Pi^{l*}$. If A is parametric in the final inference of Π_2 , consider Π^{lr} . We apply to Π^{lr} a principal move on every cut with any subproof of Π_2 ending in a sequent containing a parametric ancestor A_u . Call the resulting proof Π^{lr*} : $\Pi \rightsquigarrow \Pi^{lr*}$. Thus, if the tree of parametric ancestors of the displayed occurrence of A in (1) contains more than one element A_u that is not parametric in *inf*, the primitive reduction of Π gives a proof that is calculated via some intermediate steps. Moreover, instead of a cut with cut-formula A , we obtain several cuts with subformulas of A as the cut-formula. Here is a worked out example:

$$\Pi = \frac{\frac{\frac{\frac{\frac{\Pi^1}{*(A \circ B) \circ X \rightarrow (A \circ B)}}{*(A \circ B) \circ X \rightarrow (A \vee B)}}{*(A \vee B) \circ X \rightarrow (A \circ B)}}{*(A \vee B) \circ X \rightarrow (A \vee B)}}{X \rightarrow (A \vee B) \circ (A \vee B)} \quad \frac{\frac{\Pi^{2_1}}{A \rightarrow Y} \quad \frac{\Pi^{2_2}}{B \rightarrow Z}}{(A \vee B) \rightarrow (Y \circ Z)}}{(A \vee B) \rightarrow (Y \circ Z) \circ W}}{X \rightarrow (Y \circ Z) \circ W}$$

$$\Pi^l = \frac{\frac{\frac{\frac{\frac{\Pi^1}{*(A \circ B) \circ X \rightarrow (A \circ B)}}{*(A \circ B) \circ X \rightarrow (A \vee B)}}{*(A \circ B) \circ X \rightarrow (Y \circ Z) \circ W}}{*((Y \circ Z) \circ W) \circ X \rightarrow (A \circ B)}}{*((Y \circ Z) \circ W) \circ X \rightarrow (A \vee B)} \quad \frac{\Pi_2}{*((Y \circ Z) \circ W) \circ X \rightarrow (Y \circ Z) \circ W}}{X \rightarrow ((Y \circ Z) \circ W) \circ ((Y \circ Z) \circ W)}}{X \rightarrow ((Y \circ Z) \circ W)}$$

$$\begin{array}{c}
\begin{array}{c}
\Pi^1 \\
\frac{*(A \circ B) \circ X \rightarrow (A \circ B)}{*(A \circ B) \circ X \rightarrow (A \vee B)} \quad \frac{\Pi^{2_1} \quad \Pi^{2_2}}{A \rightarrow Y \quad B \rightarrow Z} \\
\frac{*(A \circ B) \circ X \rightarrow (Y \circ Z)}{*(A \circ B) \circ X \rightarrow (Y \circ Z) \circ W} \\
\frac{*(A \circ B) \circ X \rightarrow (Y \circ Z) \circ W}{*(Y \circ Z) \circ W \circ X \rightarrow (A \circ B)} \quad \frac{\Pi^{2_1} \quad \Pi^{2_2}}{A \rightarrow Y \quad B \rightarrow Z} \\
\frac{*(Y \circ Z) \circ W \circ X \rightarrow (A \vee B)}{*(Y \circ Z) \circ W \circ X \rightarrow (Y \circ Z)} \quad \frac{A \rightarrow Y \quad B \rightarrow Z}{(A \vee B) \rightarrow (Y \circ Z)} \\
\frac{*(Y \circ Z) \circ W \circ X \rightarrow (Y \circ Z)}{*((Y \circ Z) \circ W) \circ X \rightarrow (Y \circ Z) \circ W} \\
\frac{*((Y \circ Z) \circ W) \circ X \rightarrow (Y \circ Z) \circ W}{X \rightarrow ((Y \circ Z) \circ W) \circ ((Y \circ Z) \circ W)} \\
\frac{X \rightarrow ((Y \circ Z) \circ W) \circ ((Y \circ Z) \circ W)}{X \rightarrow ((Y \circ Z) \circ W)}
\end{array} \\
\Pi^{lr} =
\end{array}$$

$$\begin{array}{c}
\begin{array}{c}
\Pi^1 \\
\frac{*(A \circ B) \circ X \rightarrow (A \circ B)}{(* (A \circ B) \circ X) \circ *B \rightarrow A} \quad \frac{\Pi^{2_1}}{A \rightarrow Y} \\
\frac{(* (A \circ B) \circ X) \circ *B \rightarrow Y}{*Y \circ (* (A \circ B) \circ X) \rightarrow B} \quad \frac{\Pi^{2_2}}{B \rightarrow Z} \\
\frac{*Y \circ (* (A \circ B) \circ X) \rightarrow Z}{*(A \circ B) \circ X \rightarrow (Y \circ Z)} \\
\frac{*(A \circ B) \circ X \rightarrow (Y \circ Z)}{*(A \circ B) \circ X \rightarrow (Y \circ Z) \circ W} \\
\frac{*(A \circ B) \circ X \rightarrow (Y \circ Z) \circ W}{*((Y \circ Z) \circ W) \circ X \rightarrow A \circ B} \quad \frac{\Pi^{2_1}}{A \rightarrow Y} \\
\frac{*((Y \circ Z) \circ W) \circ X \circ *B \rightarrow A}{(* ((Y \circ Z) \circ W) \circ X) \circ *B \rightarrow Y} \quad \frac{\Pi^{2_2}}{B \rightarrow Z} \\
\frac{*Y \circ (* ((Y \circ Z) \circ W) \circ X) \rightarrow B}{*Y \circ (* ((Y \circ Z) \circ W) \circ X) \rightarrow Z} \\
\frac{*Y \circ (* ((Y \circ Z) \circ W) \circ X) \rightarrow Z}{*((Y \circ Z) \circ W) \circ X \rightarrow (Y \circ Z)} \\
\frac{*((Y \circ Z) \circ W) \circ X \rightarrow (Y \circ Z)}{*((Y \circ Z) \circ W) \circ X \rightarrow ((Y \circ Z) \circ W)} \\
\frac{*((Y \circ Z) \circ W) \circ X \rightarrow ((Y \circ Z) \circ W)}{X \rightarrow ((Y \circ Z) \circ W) \circ ((Y \circ Z) \circ W)} \\
\frac{X \rightarrow ((Y \circ Z) \circ W) \circ ((Y \circ Z) \circ W)}{X \rightarrow ((Y \circ Z) \circ W)}
\end{array} \\
\Pi \rightsquigarrow \Pi^{lr*} =
\end{array}$$

THEOREM 23. *Every proper display calculus enjoys strong cut-elimination.*

Proof. See Appendix A. ■

COROLLARY 24. *Cut is an admissible rule of every proper display calculus.*

Theorem 23 can straightforwardly be applied to **DK** and **DKt**. It can easily be checked that in these systems conditions C1 – C7 are satisfied.

Verification of C8 is also a simple exercise. We have for instance:

$$\begin{array}{c}
 \frac{\bullet X \rightarrow A \quad A \rightarrow Y}{X \rightarrow [F]A \quad [F]A \rightarrow \bullet Y} \\
 \hline
 X \rightarrow \bullet Y
 \end{array}
 \quad \rightsquigarrow \quad
 \frac{\bullet X \rightarrow A \quad A \rightarrow Y}{\bullet X \rightarrow Y} \\
 \hline
 X \rightarrow \bullet Y$$

$$\frac{\frac{X \rightarrow A \quad \bullet \bullet * A \rightarrow Y}{* \bullet * X \rightarrow \langle A \rangle \quad \langle A \rangle \rightarrow Y}}{* \bullet * X \rightarrow Y}
 \quad \rightsquigarrow \quad
 \frac{X \rightarrow A \quad \frac{\frac{\frac{\frac{* \bullet * A \rightarrow Y}{* Y \rightarrow \bullet * A}}{\bullet * Y \rightarrow * A}}{A \rightarrow * \bullet * Y}}{X \rightarrow * \bullet * Y}}{\bullet * Y \rightarrow * X}}{* Y \rightarrow \bullet * X}}{* \bullet * X \rightarrow Y}$$

THEOREM 25. *Strong cut-elimination holds for DK and DKt .*

COROLLARY 26. *DKt is a conservative extension of DK .*

We shall now briefly consider generalizations of Theorem 23. By conditions C6 and C7, the inference rules of a proper display calculus are closed under simultaneous substitution of arbitrary structures for congruent formulas. The proof of strong normalization can be generalized to logics which for formulas of a certain shape satisfy closure under substitution either only for congruent formulas (of this shape) which are consequent parts or only for congruent formulas (of this shape) which are antecedent parts. In order to extend the proof of strong cut-elimination to such systems, C6 and C7 have to be replaced by the more general condition of *regularity*, see [Belnap, 1990]. A formula A is defined as *cons-regular* if the following holds: (i) if A occurs as a consequent parameter of an inference *inf* in a certain rule R , then R contains also the inference resulting by replacing every member of the congruence class of A in *inf* with an arbitrary structure X , and (ii) if A occurs as an antecedent parameter of an inference *inf* in a certain rule R , then R contains also the inference resulting by replacing every member of the congruence class of A in *inf* with any structure X such that $X \rightarrow A$ is the conclusion of an inference in which A is *not* parametric. The notion of *ant-regularity* is defined in exactly the dual way. The new condition on rules then is

C6/C7 Regularity. Every formula is regular.

A display calculus *simpliciter* is a calculus of sequents satisfying C1 - C5, C6/7, and C8. If a logic can be presented as a display calculus, then it is said to be displayable. Obviously, every properly displayable logic is displayable. Also the parametric moves must be redefined. Suppose in what follows that the cut-formula A is parametric in both the final inference of Π_1 and the final inference of Π_2 . Moreover, suppose that the trees of parametric ancestors

of A in Π_1 and in Π_2 do not contain any application of cut. If A_u is the tip of a path of parametric ancestors of A in Π_i , let inf be the inference ending in the sequent which contains A_u . Let us call A_u significant, if it is not parametric in inf . Then, in a *proper* display calculus we may choose whether we cut every significant tip A_u in the tree of parametric ancestors of A in Π_1 with Π_2 or whether we cut every significant tip A_u in the tree of parametric ancestors of A in Π_2 with Π_1 to obtain Π' or Π'' . Both operations form an essential part in the definition of certain primitive reductions. In a display calculus simpliciter this indeterministic choice has to be abandoned. If the cut-formula is cons-regular, we cut with Π_2 , and if the cut-formula is ant-regular, we cut with Π_1 . This further restriction on parametric moves does not affect the proof of strong cut-elimination.

THEOREM 27. *Every displayable logic enjoys strong cut-elimination.*

A further strengthening of the strong cut-elimination theorem has recently been proved in [Demri and Goré, 1999], where it is shown that condition C8 may be relaxed. A proof Π ending in a principal application of cut may also be replaced by a proof Π' of the same sequent if the degree of any application of cut in Π' is the same as the degree of the cut-formula in Π , and in Π' , every inference except possibly one falls under a structural rule with a single premise. Moreover, in [Demri and Goré, 1999] a display sequent calculus for the minimal nominal tense logic is defined, and it is shown that every extension of this calculus by structural rules satisfying conditions C1 – C7 enjoys strong cut-elimination.

3.4 Kracht's algorithm

The class of all properly displayable normal propositional tense logics has been characterized by Kracht [1996]. The idea is to obtain a canonical way of capturing axiomatic extensions of \mathbf{Kt} by purely structural inference rules over \mathbf{DKt} .

DEFINITION 28. Let $\mathbf{Kt} + \alpha$ be an extension of \mathbf{Kt} by a tense logical axiom schema α , and let $\mathbf{DKt} + \alpha'$ be an extension of \mathbf{DKt} by a set α' of purely structural inference rules. $\mathbf{Kt} + \alpha$ is said to be *properly displayed* by $\mathbf{DKt} + \alpha'$ if (i) $\mathbf{DKt} + \alpha'$ is a proper display calculus and (ii) every derived rule of $\mathbf{Kt} + \alpha$ is the τ -translation of a sequent rule derivable in $\mathbf{DKt} + \alpha'$.

Now, every axiom schema is equivalent to a schema of the form $A \supset B$, where A and B are implication-free. The schema $A \supset B$ has the same deductive strength as the rule

$$B \rightarrow X \vdash A \rightarrow X.$$

Moreover, if A and B are only built up from propositional variables, t , \wedge ,

\vee , $\langle F \rangle$, and $\langle P \rangle$, then by classical logic and distribution of $\langle F \rangle$ and $\langle P \rangle$ over disjunction, we have

$$A \equiv \bigvee_{i \leq m} C_i \quad \text{and} \quad B \equiv \bigvee_{j \leq n} D_j,$$

where every C_i and D_j is only built up from t , \wedge , $\langle F \rangle$, and $\langle P \rangle$. Therefore $A \supset B$ may as well be replaced by the rule schemata

$$\frac{D_1 \rightarrow Y \quad \dots \quad D_n \rightarrow Y}{C_i \rightarrow Y}$$

These rule schemata can now be translated into purely structural display sequent rules, using the following translation η from formulas of the fragment under consideration into structures:

$$\begin{aligned} \eta(p) &= p & \eta(t) &= \mathbf{I} \\ \eta(\langle F \rangle A) &= * \bullet * \eta(A) & \eta(\langle P \rangle A) &= \bullet \eta(A) \\ \eta(A \wedge B) &= \eta(A) \wedge \eta(B) \end{aligned}$$

The resulting structural rules

$$\frac{\eta(D_1) \rightarrow Y \quad \dots \quad \eta(D_n) \rightarrow Y}{\eta(C_i) \rightarrow Y}$$

may still violate condition C3. In order to avoid this obstruction of proper display, it must be required that in the inducing schema $A \supset B$, the schematic formula A contains each formula variable *only once*. A tense logical formula schema is then said to be *primitive* if it has the form $A \supset B$, A contains each formula variable only once, and A , B are built up from t , \wedge , \vee , $\langle F \rangle$, and $\langle P \rangle$.

LEMMA 29. *Every extension of \mathbf{Kt} by primitive axiom schemata can be properly displayed.*

Next, if $\mathbf{DKt} + \alpha'$ properly displays $\mathbf{Kt} + \alpha$, by condition (ii) of Definition 28, the structural rules in α' may all have the form

$$\frac{X_1 \rightarrow Y \quad \dots \quad X_n \rightarrow Y}{Z \rightarrow Y}$$

This rule has the same deductive strength as the axiom schema

$$\tau_1(Z) \supset \bigvee_i \tau_1(X_i),$$

which is a primitive formula schema.

THEOREM 30. (Kraicht) *An axiomatic extension of \mathbf{Kt} can be properly displayed in precisely the case that it is axiomatizable by a set of primitive axiom schemata.*

The question whether an axiomatically presented normal temporal logic Λ is properly displayable thus reduces to the question whether Λ can be axiomatized by primitive axioms over \mathbf{Kt} . The implicit use of tense logic in the structural language of sequents may help to find simple structural sequent rules expressing less simple modal axiom schemata. The following example is taken from [Kracht, 1996]. The .3 axiom schema $\Box(\Box A \supset \Box B) \vee \Box(\Box B \supset \Box A)$ has the primitive modal equivalent

$$(\Diamond A \wedge \Diamond B) \supset ((\Diamond(A \wedge \Diamond B) \vee \Diamond(B \wedge \Diamond A)) \vee \Diamond(A \wedge B)),$$

which in tense logic is equivalent to the simpler primitive schema

$$\langle P \rangle \langle F \rangle A \supset ((\langle F \rangle A \vee A) \vee \langle P \rangle A).$$

Application of Kracht's algorithm results in the following structural rule:

$$X \rightarrow Y \quad \bullet X \rightarrow Y \quad * \bullet * X \rightarrow Y \vdash \bullet * \bullet * X \rightarrow Y.$$

Kracht also proves a semantic characterization of the properly displayable tense logics. Let \mathcal{F} be a class of Kripke frames $\langle W, \mathcal{R}, \mathcal{R}^{-1} \rangle$ for temporal logics, where \mathcal{R}^{-1} is the inverse of \mathcal{R} (i.e., $\mathcal{R} = \{(x, y) \mid (y, x) \in \mathcal{R}\}$). A first-order sentence (open formula) over two binary relation symbols R and R^{-1} is said to be *primitive* if it has the form $(\forall)(\exists)A$, where every quantifier is restricted with respect to R or R^{-1} , and A is built up from \wedge , \vee , and atomic formulas $x = y$, xRy , $xR^{-1}y$, where at least one of x, y is not in the scope of an existential quantifier.

THEOREM 31. (Kracht) *A class \mathcal{F} of Kripke frames for temporal logics is describable by a set of primitive first-order sentences iff the tense logic of \mathcal{F} can be properly displayed.*

The characteristic axiom schemata of quite a few fundamental systems of modal and tense logic are equivalent to primitive schemata, and therefore these systems can be presented as proper display calculi, cf. Table 3.⁷ A set of structural sequent rules α' is said to *correspond* to a property of an accessibility relation \mathcal{R} (with a modal or tense logical axiom schema α) iff under the τ -translation the rules in α' are admissible just in the event that

⁷Goré recently observed that Theorem 20 in [Kracht, 1996] is incorrect. This theorem states that an axiomatic extension of \mathbf{K} can be properly displayed iff it is axiomatizable by a set of primitive *modal* axiom schemata. There are, however, first-order frame properties that correspond to a primitive tense logical schema but fail to correspond to a primitive *modal* axiom schema. An example of such a frame property is weak directedness:

$$\forall s \forall t \forall u (sRt \wedge sRu \supset \exists v (tRv \wedge uRv)).$$

Weak directedness corresponds to the .2 schema $\Diamond \Box A \supset \Box \Diamond A$ (alias $\langle F \rangle [F] A \supset [F] \langle F \rangle A$). Although .2 has no primitive modal equivalent, it has a primitive tense logical equivalent, namely $\langle P \rangle \langle F \rangle A \supset \langle F \rangle \langle P \rangle A$. The latter schema induces a structural rule that may be added to display calculi for (extensions of) \mathbf{K} . Therefore, $\mathbf{K.2}$ is properly displayable, although .2 is not primitive.

\mathcal{R} enjoys the property (the rules in α' have the same deductive strength as α). Every axiom schema α in Table 3 corresponds to a purely structural sequent rule α' which can directly be determined from α , see Table 4.

Table 3. Axioms and primitive axioms.

Let $\Gamma(\Theta)$ be the set of all (all purely modal) axiom schemata from Table 3, $\bar{\Gamma} \subseteq \Gamma$, $\bar{\Theta} \subseteq \Theta$, $\Gamma' = \{\alpha' \mid \alpha \in \bar{\Gamma}\}$, and $\Theta' = \{\alpha' \mid \alpha \in \bar{\Theta}\}$.

THEOREM 32. *In $\mathbf{DKt}\cup\Gamma'$, $\vdash X \rightarrow Y$ iff $\vdash \tau_1(X) \supset \tau_2(Y)$ in $\mathbf{Kt}\cup\Gamma$. In $\mathbf{DK}\cup\Theta'$, $\vdash X \rightarrow Y$ iff $\vdash \tau_1(X) \supset \tau_2(Y)$ in $\mathbf{K}\cup\Theta$.*

Proof. This follows from axiomatizability by primitive schemata. \blacksquare

THEOREM 33. *Strong cut-elimination holds for $\mathbf{DKt}\cup\Gamma'$ and $\mathbf{DK}\cup\Theta'$.*

Proof. The rules in Γ' and Θ' satisfy conditions C2 – C7. \blacksquare

COROLLARY 34. *$\mathbf{DKt}\cup\Gamma'$ is a conservative extension of $\mathbf{DK}\cup\Gamma'$.*

Kracht's algorithm can be dualized. Every schema $A \supset B$ is interreplaceable with the rule

$$X \rightarrow A \vdash X \rightarrow B.$$

D'	$* \bullet * \mathbf{I} \rightarrow Y \vdash \mathbf{I} \rightarrow Y$
T'	$* \bullet * X \rightarrow Y \vdash X \rightarrow Y$
A'	$* \bullet * X \rightarrow Y \vdash * \bullet \bullet * X \rightarrow Y$
$\bar{5}'$	$* \bullet * X \rightarrow Y \vdash \bullet * \bullet * X \rightarrow Y$
B'	$* \bullet * (X \circ * \bullet * Y) \rightarrow Z \vdash Y \circ * \bullet * X \rightarrow Z$
$AltI'$	$* \bullet * (X \circ Y) \rightarrow Z \vdash * \bullet * X \circ * \bullet * Y \rightarrow Z$
$T^{c'}$	$X \rightarrow Y \vdash * \bullet * X \rightarrow Y$
$4^{c'}$	$* \bullet \bullet * X \rightarrow Y \vdash * \bullet * X \rightarrow Y$
$.2'$	$* \bullet * \bullet X \rightarrow Y \vdash \bullet * \bullet * X \rightarrow Y$
$.3'$	$X \rightarrow Y \quad \bullet X \rightarrow Y \quad * \bullet * X \rightarrow Y \vdash \bullet * \bullet * X \rightarrow Y$
$linf'$	$= .3'$
$linp'$	$X \rightarrow Y \quad \bullet X \rightarrow Y \quad * \bullet * X \rightarrow Y \vdash \bullet * \bullet * X \rightarrow Y$
V'	$X \rightarrow Y \vdash \bullet \mathbf{I} \rightarrow Y$
D_p'	$\bullet \mathbf{I} \rightarrow Y \vdash \mathbf{I} \rightarrow Y$
T_p'	$\bullet X \rightarrow Y \vdash X \rightarrow Y$
A_p'	$\bullet X \rightarrow Y \vdash \bullet \bullet X \rightarrow Y$
$\bar{5}_p'$	$\bullet X \rightarrow Y \vdash * \bullet \bullet \bullet X \rightarrow Y$
B_p'	$\bullet (X \circ \bullet Y) \rightarrow Z \vdash Y \circ \bullet X \rightarrow Z$
$AltI_p'$	$\bullet (X \circ Y) \rightarrow Z \vdash \bullet X \circ \bullet Y \rightarrow Z$
$T_p^{c'}$	$X \rightarrow Y \vdash \bullet X \rightarrow Y$
$4_p^{c'}$	$\bullet \bullet X \rightarrow Y \vdash \bullet X \rightarrow Y$
V_p'	$X \rightarrow Y \vdash * \bullet * \mathbf{I} \rightarrow Y$

Table 4. Structural rules corresponding to axiom schemata.

If A and B are only built up from propositional variables, \mathbf{f} , \wedge , \vee , $[F]$, and $[P]$, then by classical logic and distribution of $[F]$ and $[P]$ over conjunction, we have

$$A \equiv \bigwedge_{i \leq m} C_i \quad \text{and} \quad B \equiv \bigwedge_{j \leq n} D_j,$$

where every C_i and D_j is only built up from \mathbf{f} , \vee , $[F]$, and $[P]$. Therefore $A \supset B$ may be replaced by the rule schemata

$$\frac{X \rightarrow C_1 \quad \dots \quad X \rightarrow C_m}{X \rightarrow D_j}.$$

These schemata are translatable into purely structural sequent rules using the following translation η' from formulas of the fragment under consideration into structures:

$$\begin{aligned} \eta'(p) &= p & \eta'(\mathbf{f}) &= \mathbf{I} \\ \eta'([F]A) &= \bullet \eta'(A) & \eta'([P]A) &= * \bullet * \eta'(A) \\ \eta'(A \vee B) &= \eta'(A) \vee \eta'(B) \end{aligned}$$

The resulting structural rules

$$\frac{X \rightarrow \eta'(C_1) \ \dots \ X \rightarrow \eta'(C_m)}{X \rightarrow \eta'(D_j)}$$

again may still violate condition C3. In order to avoid the obstruction of proper display, it must be required that in the inducing schema $A \supset B$, the schematic formula B contains each formula variable only once. A tense logical formula schema is then said to be *dually primitive* if it has the form $A \supset B$, B contains each formula variable only once, and A, B are built up from \mathbf{f} , \wedge , \vee , $[F]$, and $[P]$.

THEOREM 35. *An axiomatic extension of \mathbf{Kt} can be properly displayed iff it is axiomatizable by a set of dually primitive axiom schemata.*

For instance, rule T' is equivalent to $X \rightarrow \bullet Y \vdash X \rightarrow Y$ and $4'$ with $X \rightarrow \bullet Y \vdash X \rightarrow \bullet \bullet Y$. Moreover, D' is equivalent to $\bullet X \circ \bullet Y \rightarrow \bullet \mathbf{I} \vdash X \rightarrow \bullet Y$, $AltI'$ with $X \rightarrow Y \vdash X \rightarrow \bullet \bullet \bullet Y$, and V' with $\vdash \bullet \mathbf{I} \rightarrow X$, see [Wansing, 1994].

The properly displayable modal and tense logics satisfy Došen's Principle. They are all based on the same set of left and right introduction rules, so that the logical operations indeed have the same proof-theoretic, operational meaning in each of these systems. Kracht's characterization results show that many interesting and important intensional logics admit a cut-free display sequent calculus presentation. In Sections 3.8 and 4 other applications of the display calculus are pointed out. Display sequent systems for various non-normal modal logics may be found in [Belnap, 1982].

3.5 Formulas-as-types for temporal logics

It is well-known that every derivation in Gentzen's natural deduction calculus for intuitionistic implicational logic can be encoded by a typed λ -term, and vice versa [Howard, 1980]. In particular, every natural deduction proof can be encoded by a closed term, and every closed term encodes a proof. It is also well-known that every pair of non-convertible typed λ -terms defines different functionals of finite type [Friedman, 1975]. Every type A is associated with an infinite set D^A , every term variable x^A of type A denotes an element from D^A , and every term $M^{(A \triangleright B)}$ of type $A \triangleright B$ denotes an element from the set $(D^B)^{D^A}$ of all functions from D^A to D^B . Together with the encoding, this interpretation results in a set-theoretic semantics of proofs in intuitionistic implicational logic. In this section, we shall develop a set-theoretic interpretation of sequent proofs in the $\{t, [F], \langle P \rangle, \triangleright, \wedge\}$ -fragment of the smallest normal temporal intuitionistic (or, for that purpose, minimal) logic \mathbf{IntKt} . The interpretation is based on the observation that the modalities $\langle P \rangle$ and $[F]$ form a residuated pair with respect to derivability. The encoding of proofs by typed terms should be such that

proof-simplification (or normalization) corresponds with a suitable reduction relation on terms, and therefore the set-theoretic semantics of terms has to validate the equalities underlying the reduction rules. The principal cut-elimination steps for $\langle P \rangle$ and $[F]$ reveal that two pairs of term forming operations o_1 and o_2 are needed such that $o_1(o_2(M)) = M$. We shall use the following identities:

$$\bigcup \mathcal{P}a = a \quad \text{and} \quad \bigcap \mathcal{S}a = a,$$

where \mathcal{P} is the familiar powerset operation and $\mathcal{S}a =_{\text{def}} \{b \mid a \subseteq b\}$. Since in general $\mathcal{S}a$ is a proper class, we shall restrict the denotations of terms to the universe V_{ω_1} . This is enough to accommodate the sets used as domains of the intended models in Section 3.7.

We shall first define a display sequent system **DIntKt** for the fragment of **IntKt** under consideration, and then present an extension λ_t of the typed λ -calculus. The set of types in λ_t is the set of all formulas in the language $\mathcal{L} = \{t, [F], \langle P \rangle, \triangleright, \wedge\}$ based on a denumerable set *Atom* of propositional variables. In Section 3.6 it is proved that term reduction is a homomorphic image of proof-simplification. Next, an encoding of terms by proofs is presented. A set-theoretic semantics of proofs in **DIntKt** is obtained in Section 3.7 by showing that every pair of non-convertible λ_t -terms defines different sets in the set-theoretic universe under consideration. In particular, every term $M^{[F]A}$ denotes an element from $\{\mathcal{P}a \mid a \in D^A\}$, and every term $M^{\langle P \rangle A}$ denotes an element from $\{\mathcal{S}a \mid a \in D^A\}$. Also the formulas-as-types notion of construction for various extensions of **DIntKt** is dealt with and remarks on some related work about formulas-as-types for modal logics are made.

First, we shall define the sequent system **DIntKt**. We assume the following language of structures:

$$X ::= A \mid \mathbf{I} \mid \bullet X \mid X \times Y.$$

A sequent now is an expression $X \rightarrow Y$, provided $Y \neq \mathbf{I}$. The declarative meaning of the structure connectives can be made explicit by a translation τ from the set of sequents into the set of \mathcal{L} -formulas:

$$\tau(X \rightarrow Y) := \tau_1(X) \triangleright \tau_2(Y),$$

where τ_i ($i = 1, 2$) is defined as follows:

$$\begin{array}{ll} \tau_i(A) &= A & \tau_1(\mathbf{I}) &= t \\ \tau_1(X \times Y) &= \tau_1(X) \wedge \tau_1(Y) & \tau_2(X \times Y) &= \tau_1(X) \triangleright \tau_2(Y) \\ \tau_1(\bullet X) &= \langle P \rangle \tau_1(X) & \tau_2(\bullet X) &= [F] \tau_2(X) \end{array}$$

Given this understanding of the structure connectives, the basic structural rules (4) and (5) from Section 3.1 are assumed. Clearly, the Display Theorem holds for this structural language and calculus.

DEFINITION 36. The display sequent calculus **DIntKt** is given by the logical rules (id) and (cut), the basic structural rules (4) and (5), the introduction rules for \mathbf{t} , \triangleright , $\langle P \rangle$, $[F]$, and the rules $(\rightarrow \wedge)'$ and $(\wedge \rightarrow)'$, together with the following structural rules:

$$\begin{array}{l}
 \text{(empty structure)} \quad X \rightarrow Y \vdash \mathbf{I} \times X \rightarrow Y, \quad X \rightarrow Y \vdash X \times \mathbf{I} \rightarrow Y \\
 \quad \quad \quad \mathbf{I} \times X \rightarrow Y \vdash X \rightarrow Y, \quad X \times \mathbf{I} \rightarrow Y \vdash X \rightarrow Y \\
 \text{(associativity)} \quad (X_1 \times X_2) \times X_3 \rightarrow Y \dashv\vdash X_1 \times (X_2 \times X_3) \rightarrow Y \\
 \text{(permutation)} \quad X \times Y \rightarrow Z \vdash Y \times X \rightarrow Z \\
 \text{(contraction)} \quad X \times X \rightarrow Y \vdash X \rightarrow Y \\
 \text{(expansion)} \quad X \rightarrow Y \vdash X \times X \rightarrow Y \\
 \text{(monotonicity)} \quad X \rightarrow Z \vdash X \times Y \rightarrow Z, \quad X \rightarrow Z \vdash Y \times X \rightarrow Z \\
 \text{(necessitation)} \quad \mathbf{I} \rightarrow X \vdash \bullet \mathbf{I} \rightarrow X.
 \end{array}$$

To show that **DIntKt** is a display calculus for **IntKt**, we define an axiomatic calculus **HIntKt**.

DEFINITION 37. The system **HIntKt** consists of the axiom schemata and rules of the $\{\mathbf{t}, \wedge, \triangleright\}$ -fragment of positive intuitionistic logic, together with

1. $([F]A \wedge [F]B) \triangleright [F](A \wedge B)$
2. $[F]\mathbf{t}$
3. $A \triangleright [F]\langle P \rangle A$
4. $\frac{\vdash A \triangleright B}{\vdash [F]A \triangleright [F]B}$
5. $\frac{\vdash A \triangleright B}{\vdash \langle P \rangle A \triangleright \langle P \rangle B}$

The relational semantics to be presented is a straightforward adaptation of the semantics developed by Bošić and Došen [1984]. A comprehensive survey of intuitionistic modal logics and their algebraic and relational semantics is [Wolter and Zakharyashev, 1999]. A temporal frame is defined as a structure $\langle W, R_I, R_T \rangle$, where W is a non-empty set (of states), R_I and R_T are binary relations on W , R_I is both reflexive and transitive, and, moreover, (i) $R_I R_T \subseteq R_T R_I$ (i.e. the composition of R_T and R_I is a subset of the composition of R_I and R_T) and (ii) $R_I^{-1} R_T^{-1} \subseteq R_T^{-1} R_I^{-1}$. If $\mathcal{F} = \langle W, R_I, R_T \rangle$ is a temporal frame, the temporal model based on \mathcal{F} is the structure $\langle \mathcal{F}, v \rangle$, where v is a function from $Atom \times W$ into $\{0, 1\}$ satisfying:

$$\text{(Heredity)} \quad (v(p, u) = 1 \text{ and } u R_I t) \text{ implies } v(p, t) = 1.$$

Let $\mathcal{M} = \langle W, R_I, R_T, v \rangle$ be a temporal model. Verification of a formula A at a state $u \in W$ ($\mathcal{M}, u \models A$) is inductively defined as follows:

$$\begin{aligned}
\mathcal{M}, u \models p & \quad \text{iff} \quad v(p, u) = 1 \\
\mathcal{M}, u \models t & \\
\mathcal{M}, u \models A \wedge B & \quad \text{iff} \quad \mathcal{M}, u \models A \text{ and } \mathcal{M}, u \models B \\
\mathcal{M}, u \models A \triangleright B & \quad \text{iff} \quad (\forall t \in W) uR_I t \text{ implies } [\mathcal{M}, t \not\models A \text{ or } \mathcal{M}, t \models B] \\
\mathcal{M}, u \models [F]A & \quad \text{iff} \quad (\forall t \in W) uR_T t \text{ implies } \mathcal{M}, t \models A \\
\mathcal{M}, u \models \langle P \rangle A & \quad \text{iff} \quad (\exists t \in W) tR_T u \text{ and } \mathcal{M}, t \models A
\end{aligned}$$

For every formula A , if A is verified at state u and $uR_I t$, then A is also verified at t . Condition (i) ensures this general heredity property for formulas $[F]A$, and condition (ii) ensures it for formulas $\langle P \rangle A$. A formula A is true in a model $\langle W, R_T, R_I, v \rangle$ if A is verified at every $u \in W$, and A is said to be true on a frame \mathcal{F} , if A is valid in every model based on \mathcal{F} . If \mathcal{K} is a class of models (frames), A is said to be valid in \mathcal{K} iff A is valid in every model (valid on every frame) in \mathcal{K} .

THEOREM 38. ***HIntKt** is sound and complete with respect to the class of all temporal frames, i.e. for every \mathcal{L} -formula A , A is provable in **HIntKt** iff A is valid in the class of all temporal frames.*

Proof. Soundness is shown by induction on proofs in **HIntKt**; for completeness see Appendix B. \blacksquare

LEMMA 39. (1) *If $\vdash A$ in **HIntKt**, then $\vdash \mathbf{I} \rightarrow A$ in **DIntKt**, and (2) *If $\vdash X \rightarrow Y$ in **DIntKt**, then $\vdash \tau(X \rightarrow Y)$ in **HIntKt**.**

Proof. (1) By induction on proofs in **HIntKt**. We shall consider only two example cases:

$$\begin{array}{c}
\frac{A \rightarrow A}{\bullet A \rightarrow \langle P \rangle A} \\
\frac{A \rightarrow [F] \langle P \rangle A}{A \times \mathbf{I} \rightarrow [F] \langle P \rangle A} \\
\frac{\mathbf{I} \rightarrow A \times [F] \langle P \rangle A}{\mathbf{I} \rightarrow A \triangleright [F] \langle P \rangle A}
\end{array}
\qquad
\begin{array}{c}
\frac{A \rightarrow A}{[F]A \rightarrow \bullet A} \qquad \frac{B \rightarrow B}{[F]B \rightarrow \bullet B} \\
\frac{[F]A \times [F]B \rightarrow \bullet A}{\bullet([F]A \times [F]B) \rightarrow A} \qquad \frac{[F]A \times [F]B \rightarrow \bullet B}{\bullet([F]A \times [F]B) \rightarrow B} \\
\frac{\bullet([F]A \times [F]B) \rightarrow A \quad \bullet([F]A \times [F]B) \rightarrow B}{\bullet([F]A \times [F]B) \rightarrow A \wedge B} \\
\frac{\bullet([F]A \times [F]B) \rightarrow A \wedge B}{([F]A \times [F]B) \rightarrow [F](A \wedge B)} \\
\frac{([F]A \times [F]B) \rightarrow [F](A \wedge B)}{([F]A \wedge [F]B) \rightarrow [F](A \wedge B)} \\
\frac{([F]A \wedge [F]B) \rightarrow [F](A \wedge B)}{([F]A \wedge [F]B) \times \mathbf{I} \rightarrow [F](A \wedge B)} \\
\frac{([F]A \wedge [F]B) \times \mathbf{I} \rightarrow [F](A \wedge B)}{\mathbf{I} \rightarrow ([F]A \wedge [F]B) \times [F](A \wedge B)} \\
\frac{\mathbf{I} \rightarrow ([F]A \wedge [F]B) \times [F](A \wedge B)}{\mathbf{I} \rightarrow ([F]A \wedge [F]B) \triangleright [F](A \wedge B)}
\end{array}$$

(2) By induction on proofs in **DIntKt**. \blacksquare

COROLLARY 40. In \mathbf{HIntKt} , $\vdash A$ iff $\vdash \mathbf{I} \rightarrow A$ in \mathbf{DIntKt} .

By induction on the complexity of X , one can prove the following

LEMMA 41. In every extension of \mathbf{DIntKt} by structural rules, it holds that $\vdash X \rightarrow \tau_1(X)$ and $\vdash \tau_2(X) \rightarrow X$.

THEOREM 42. In \mathbf{DIntKt} , $\vdash X \rightarrow Y$ iff $\vdash \tau(X \rightarrow Y)$ in \mathbf{HIntKt} .

Proof. Analogous to the proof of Theorem 20. ■

Since \mathbf{DIntKt} is a proper display calculus, we have the following

THEOREM 43. \mathbf{DIntKt} enjoys strong cut-elimination.

Take any terminating cut-elimination algorithm $elim_c$ for \mathbf{DIntKt} . We may also define a binary relation \rightsquigarrow_s on the set of proofs in \mathbf{DIntKt} by the following stipulations:

$$\frac{\frac{A \rightarrow A \quad B \rightarrow B}{A \times B \rightarrow A \wedge B}}{A \wedge B \rightarrow A \wedge B} \rightsquigarrow_s A \wedge B \rightarrow A \wedge B$$

$$\frac{\frac{A \rightarrow A \quad B \rightarrow B}{A \triangleright B \rightarrow A \times B}}{A \triangleright B \rightarrow A \triangleright B} \rightsquigarrow_s A \triangleright B \rightarrow A \triangleright B$$

If $\Pi \rightsquigarrow_s \Pi'$, we say that in Π' a redundant part of Π has been removed. Let $elim_r$ denote the terminating algorithm that removes redundant parts of a proof in top-down left to right order, so that a redundant part is removed only if it has no redundant part above it. Obviously, in any extension of \mathbf{DIntKt} , every proof of a sequent s can be converted into a proof of s containing no redundant part. Let $elim$ denote $elim_r \circ elim_c$, i.e. the composition of $elim_r$ and $elim_c$. The algorithm $elim$ is the process of proof simplification to be considered. We assume that $elim(\Pi) = \Pi$ if Π contains no application of (cut) and no redundant part.

3.6 The typed λ -calculus λ_t

The set T of type symbols (or just types) is the set of all \mathcal{L} -formulas. The set V of term variables is defined as $\{v_i^A \mid 0 < i \in \omega, A \in T\}$.

DEFINITION 44. The set Term of typed terms is defined as the smallest set Δ such that

1. $V \subseteq \Delta$;
2. if $M^A, N^B \in \Delta$, then $\langle M^A, N^B \rangle^{(A \wedge B)} \in \Delta$;
3. $M^{(A \wedge B)} \in \Delta$, then $(M^{(A \wedge B)})_0^A, (M^{(A \wedge B)})_1^B \in \Delta$;

4. if $x^A \in V$ and $M^B \in \Delta$, then $(\lambda x^A M^B)^{(A \triangleright B)} \in \Delta$;
5. if $M^{(A \triangleright B)}, N^A \in \Delta$, then $(M^{(A \triangleright B)}, N^A)^B \in \Delta$;
6. if $M^A \in \Delta$, then $(\mathcal{P}M)^{[F]A}, (\mathcal{S}M)^{\langle P \rangle A} \in \Delta$;
7. if $M^{[F]A} \in \Delta$, then $(\cup M^{[F]A})^A \in \Delta$;
8. if $M^{\langle P \rangle A} \in \Delta$, then $(\cap M^{\langle P \rangle A})^A \in \Delta$.

A term M^A is said to be a term of type A ; obviously, every term has a unique type. If confusion is unlikely to arise, we shall often write M instead of M^A and omit parentheses not needed for disambiguation. The set $fv(M)$ of free variables of M , the set of subterms of M , and $M[x^A := N^A]$, the result of substituting term N of type A for every occurrence of x^A in M are inductively defined in the obvious way. If a variable x in M is not an element of $fv(M)$, x is said to be a bound variable of M . The set of bound variables of M is denoted as $bv(M)$. We shall also write $M(x_1^{A_1}, \dots, x_n^{A_n})$ to express that $x_1, \dots, x_n \in fv(M)$. If $M(x_1^{A_1}, \dots, x_n^{A_n})$ and N_1, \dots, N_n are terms of types A_1, \dots, A_n , then $M(N_1, \dots, N_n)$ is the result of substituting in M the variables x_i by N_i . We shall use ‘ \equiv ’ to denote syntactic identity between term.

DEFINITION 45. The typed λ -calculus λ_t consists of the following rules and axiom schemata:

1. $\lambda x^A M = (\lambda y^A M[x := y])$, if $y \notin (fv(M) \cup bv(M))$;
2. $\lambda x(M, x) = M$, if $x \notin fv(M)$;
3. $(\lambda x M)N = M[x := N]$, if $bv(M) \cup fv(N) = \emptyset$;
4. $\langle (M_0, M_1) \rangle_i = M_i$;
5. $\langle (M)_0, (M)_1 \rangle = M$;
6. $\cup \mathcal{P}M = M$;
7. $\cap \mathcal{S}M = M$;
8. $M^A = M^A$;
9. $M = N \vdash N = M$; $M = N, N = G \vdash M = G$;
10. $M = N \vdash (G, M) = (G, N)$; $M = N \vdash (M, G) = (N, G)$;
11. $M = N \vdash \lambda x M = \lambda x N$;
12. $M = N \vdash \mathcal{P}M = \mathcal{P}N$; $M = N \vdash \cup M = \cup N$.

DEFINITION 46. The binary relations on Term, \rightarrow_r (one-step reduction), \rightarrow_r (reduction), and $=_r$ (equality) are defined as follows:

1.
 - $\lambda x(Mx) \rightarrow_r M$, if $x \notin fv(M)$;
 - $(\lambda xM)N \rightarrow_r M[x := N]$, if $bv(M) \cup fv(N) = \emptyset$;
 - $(\langle M, N \rangle)_0 \rightarrow_r M$; $(\langle M, N \rangle)_1 \rightarrow_r N$;
 - $\langle (M)_0, (M)_1 \rangle \rightarrow_r M$;
 - $\cup \mathcal{P}M \rightarrow_r M$; $\cap \mathcal{S}M \rightarrow_r M$;
 - if $M^{A \triangleright B} \rightarrow_r N^{A \triangleright B}$, then $(M, G^A) \rightarrow_r (N, G)$;
 - if $M^{A \wedge B} \rightarrow_r N^{A \wedge B}$, then $(M)_i \rightarrow_r (N)_i$;
 - if $M^A \rightarrow_r N^A$, then $\lambda xM \rightarrow_r \lambda xN$, $(G^{A \triangleright B}M) \rightarrow_r (GN)$, $\langle M, G \rangle \rightarrow_r \langle N, G \rangle$, $\langle G, M \rangle \rightarrow_r \langle G, N \rangle$, $\mathcal{P}M \rightarrow_r \mathcal{P}N$, $\mathcal{S}M \rightarrow_r \mathcal{S}N$, $\cap M \rightarrow_r \cap N$, $\cup M \rightarrow_r \cup N$.
2. \rightarrow_r is the reflexive transitive closure of \rightarrow_r ;
3. $=_r$ is the equivalence relation generated by \rightarrow_r .

DEFINITION 47. λ_t -terms $\lambda x(Mx)$ (where $x \notin fv(M)$), $(\lambda xM)N$ (where $bv(M) \cup fv(N) = \emptyset$), $(\langle M, N \rangle)_0$, $(\langle M, N \rangle)_1$, $\langle (M)_0, (M)_1 \rangle$, $\cup \mathcal{P}M$, and $\cap \mathcal{S}M$ are called redexes. A term M is a normal form (*nf*) if it has no redex as a subterm, and M has a *nf* if there is a *nf* N such that $M =_r N$. M is said to be strongly normalizable with respect to \rightarrow_r ($sn(M)$) if every sequence of reduction steps starting at M is finite.

THEOREM 48. *Every $M \in \text{Term}$ is strongly normalizable with respect to \rightarrow_r .*

Proof. See Appendix C. ■

Let $norm(M)$ refer to the iterated contraction of the leftmost redex in M . Since by the previous theorem, every reduction starting at M is finite, $norm$ is a terminating normalization algorithm with respect to \rightarrow_r .

We shall now encode proofs by giving recipes for building up constructions of sequents. Every formula occurring in an antecedent part of a sequent s is said to be an antecedent formula component of s .

DEFINITION 49. A construction of a sequent s is a term M^A such that an occurrence of A is the succedent part of s , and every type of a free variable of M is an antecedent formula component of s .

This notion of construction is a straightforward adaptation of the notion of construction for ordinary natural deduction and sequent calculi. The *set* of types of the free variables occurring in the term encoding a derivation Π is a subset of the set of assumptions on which Π depends. Therefore applications

of structural inference rules are not reflected by term modifications, and variations of structural rules are captured by imposing conditions on variable binding and occurrences of free variables in the encoding terms (see, for instance, [van Benthem, 1986, Chapter 7], [van Benthem, 1991], [Helman, 1977], [Wansing, 1992]).

OBSERVATION 50. Given a proof in *DIntKt* of a sequent s , one can find a construction M of s .

Proof. We define a function f from the set $\Pi\mathbf{DIntKt}$ of proofs in \mathbf{DIntKt} to *Term* such that $f(\Pi)$ is a construction of the conclusion sequent of Π . The pairs of sequent rules and terms or term construction rules in Table 5 amount to an inductive definition of f . The variables newly introduced into the conclusion of a term construction rule are the numerically first variables of the types indicated not occurring in the premise term. ■

Clearly, *norm* is a function on *Term*. Let $\Pi^+\mathbf{DIntKt}$ denote the set of all proofs in \mathbf{DIntKt} containing an application of (cut) or a redundant part, and let $\Pi^-\mathbf{DIntKt}$ denote the set of all cut-free proofs in \mathbf{DIntKt} containing no redundant part. Let $+Term$ denote the set of all terms that are not normal forms, and let $-Term$ denote the set of all terms that are normal forms.

THEOREM 51. *Let $\mathcal{A} = \langle \Pi\mathbf{DIntKt}, elim \rangle$ and $\mathcal{B} = \langle Term, norm \rangle$. The function f defined in the proof of Observation 50 is a homomorphism from \mathcal{A} to \mathcal{B} .*

Proof. See Appendix D. ■

Under the encoding of proofs by terms, surjective pairing ($\langle (M)_0, (M)_1 \rangle \rightarrow_r M$) and η -reduction ($\lambda x(Mx) \rightarrow_r M$, if $x \notin fv(M)$) correspond with replacing proofs

$$\frac{A \rightarrow A \quad B \rightarrow B}{A \times B \rightarrow A \wedge B} \quad \text{and} \quad \frac{A \rightarrow A \quad B \rightarrow B}{A \triangleright B \rightarrow A \times B}$$

$$\frac{}{A \wedge B \rightarrow A \wedge B} \quad \frac{}{A \triangleright B \rightarrow A \triangleright B}$$

by the axiomatic sequents $A \wedge B \rightarrow A \wedge B$ and $A \triangleright B \rightarrow A \triangleright B$, respectively. Note that there are no analogues of surjective pairing and η -reduction that correspond with a replacement of proofs of $[F]A \rightarrow [F]A$ and $\langle P \rangle A \rightarrow \langle P \rangle A$ from $A \rightarrow A$ by the axiomatic sequents $[F]A \rightarrow [F]A$ and $\langle P \rangle A \rightarrow \langle P \rangle A$. Moreover, since in the encoding applications of structural rules are not reflected by term formation steps, it is in general *not* the case that if $M = f(\Pi)$, Π can be uniquely reconstructed from M .

3.7 A denotational semantics of proofs

We shall now define models for λ_t . The completeness proof to be given straightforwardly extends H. Friedman's [1975] completeness proof for typed λ -calculus. The plan of the proof is as follows: first it is shown that λ_t is sound and complete with respect to the class of all models. This is achieved by defining a canonical model that itself characterizes λ_t . Then a notion of intended model is defined. In such models the typed terms have their intended set-theoretic interpretation. In order to characterize provable equality of terms in λ_t by validity in all intended models, it is shown that for every intended model \mathcal{M} , there exists a 'partial homomorphism' from \mathcal{M} onto the canonical model. Since such partial homomorphisms turn out to preserve validity, λ_t is sound and complete with respect to the class of all intended models.

DEFINITION 52. A structure $\mathcal{F} = \langle \{D^A\}, \{\text{AP}_{A,B}\}, \{\text{PRO}_{A,B}^0\}, \{\text{PRO}_{A,B}^1\}, \{\text{PAIR}_{A,B}\}, \{\text{P}_A\}, \{\text{S}_A\}, \{\text{P}\downarrow_A\}, \{\text{S}\downarrow_A\} \rangle$ is called a type structure frame (or just a frame) iff for all types A, B :

1. D^A (the domain of type A) is a non-empty set;
2. $\text{AP}_{A,B} : D^{(A \triangleright B)} \times D^A \longrightarrow D^B$,
 $\text{PRO}_{A,B}^0 : D^{(A \wedge B)} \longrightarrow D^A$,
 $\text{PRO}_{A,B}^1 : D^{(A \wedge B)} \longrightarrow D^B$,
 $\text{PAIR}_{A,B} : D^A \times D^B \longrightarrow D^{(A \wedge B)}$,
 $\text{P}_A : D^A \longrightarrow D^{[F]A}$,
 $\text{S}_A : D^A \longrightarrow D^{(P)A}$,
 $\text{P}\downarrow_A : D^{[F]A} \longrightarrow D^A$,
 $\text{S}\downarrow_A : D^{(P)A} \longrightarrow D^A$;
3. (*extensionality*) if $a, b \in D^{(A \triangleright B)}$ and $(\forall c \in D^A)$ we have $(\text{AP}_{A,B}(a, c) = \text{AP}_{A,B}(b, c))$, then $a = b$;
4. (*pro*) for all $a \in D^A, b \in D^B$:
 $\text{PRO}_{A,B}^0(\text{PAIR}_{A,B}(a, b)) = a$, $\text{PRO}_{A,B}^1(\text{PAIR}_{A,B}(a, b)) = b$;
5. (*pair*) for all $a \in D^{A \wedge B}$: $\text{PAIR}_{A,B}(\text{PRO}_{A,B}^0(a), \text{PRO}_{A,B}^1(a)) = a$;
6. (*future*) for all $a \in D^A$: $\text{P}\downarrow(\text{P}a) = a$;
7. (*past*) for all $a \in D^A$: $\text{S}\downarrow(\text{S}a) = a$.

An assignment in a frame $\langle \{D^A\}, \{\text{AP}_{A,B}\}, \{\text{PRO}_{A,B}^0\}, \{\text{PRO}_{A,B}^1\}, \{\text{PAIR}_{A,B}\}, \{\text{P}_A\}, \{\text{S}_A\}, \{\text{P}\downarrow_A\}, \{\text{S}\downarrow_A\} \rangle$ is a function f defined on the set V of term variables such that $f(x^A) \in D^A$. The set of all assignments in a given frame is denoted by Asg . If $y \in V$, then f_a^y is defined by $f_a^y(x) = f(x)$, if $x \neq y$, $f_a^y(y) = a$.

DEFINITION 53. Suppose that $\mathcal{F} = \langle \{D^A\}, \{\text{AP}_{A,B}\}, \{\text{PRO}_{A,B}^0\}, \{\text{PRO}_{A,B}^1\}, \{\text{PAIR}_{A,B}\}, \{\text{P}_A\}, \{\text{S}_A\}, \{\text{P}\downarrow_A\}, \{\text{S}\downarrow_A\} \rangle$ is a frame. Then $\langle \mathcal{F}, \text{val} \rangle$ is said to be a type structure model (or just a model) based on \mathcal{F} iff val is the valuation function from $\text{Term} \times \text{Asg}$ to $\bigcup_{A \in T} D^A$ such that:

1. $\text{val}(x, f) = f(x)$;
2. $\text{AP}_{A,B}(\text{val}((\lambda x M), f), a) = \text{val}(M, f_a^x), \forall a \in D^A$;
3. $\text{val}((M^{(A \triangleright B)}, N^B), f) = \text{AP}_{A,B}(\text{val}(M, f), \text{val}(N, f))$;
4. $\text{val}(\langle M^A, N^B \rangle, f) = \text{PAIR}_{A,B}(\text{val}(M, f), \text{val}(N, f))$;
5. $\text{val}((M^{(A \wedge B)})_i, f) = \text{PRO}_{A,B}^i(\text{val}(M, f)), i = 0, 1$;
6. $\text{val}((\mathcal{P}M^A)^{[F]A}, f) = \text{P}_A(\text{val}(M, f))$;
7. $\text{val}((\mathcal{S}M^A)^{\langle P \rangle A}, f) = \text{S}_A(\text{val}(M, f))$;
8. $\text{val}((\bigcup M^{[F]A})^A, f) = \text{P}\downarrow_A(\text{val}(M, f))$;
9. $\text{val}((\bigcap M^{\langle P \rangle A})^A, f) = \text{S}\downarrow_A(\text{val}(M, f))$.

Let $\mathcal{M} = \langle \mathcal{F}, \text{val} \rangle$ be a model.

LEMMA 54. (1) $\text{val}(M[x := N], f) = \text{val}(M, f_{\text{val}(N, f)}^x)$, if $\text{bv}(M) \cap \text{fv}(N) = \emptyset$. (2) $\text{val}(M[x := y], f_a^y) = \text{val}(M, f_a^x)$, if $y \notin \text{bv}(M) \cup \text{fv}(M)$.

Proof. (1) By induction on M , for fixed N ; (2) by (1). ■

The equality $M = N$ is said to hold in \mathcal{M} under assignment f ($\mathcal{M}, f \models M = N$) iff $\text{val}(M, f) = \text{val}(N, f)$. $M = N$ is called valid in \mathcal{M} ($\mathcal{M} \models M = N$) iff $\mathcal{M}, f \models M = N$, for all $f \in \text{Asg}$. $M = N$ is said to be valid in a class \mathcal{K} of models, if $\mathcal{M} \models M = N$, for each $\mathcal{M} \in \mathcal{K}$.

OBSERVATION 55. (Soundness) If $M = N$ is provable in λ_t , then $M = N$ is valid in the class of all models.

Proof. By induction on proofs in λ_t . We must show that every axiom is valid in every model, and that the rules of inference preserve validity. We shall consider two cases not already dealt with in [Friedman, 1975].

$$\begin{aligned}
& \langle (M)_0, (M)_1 \rangle = M: \\
& \text{val}(\langle (M, N) \rangle_0, \langle (M, N) \rangle_1, f) \\
= & \text{PAIR}(\text{val}(\langle (M, N) \rangle_0, f), \text{val}(\langle (M, N) \rangle_1, f)) \\
= & \text{PAIR}(\text{PRO}^0(\text{PAIR}(\text{val}(M, f), \text{val}(N, f))), \\
& \text{PRO}^1(\text{PAIR}(\text{val}(M, f), \text{val}(N, f)))) \\
= & \text{PAIR}(\text{val}(M, f), \text{val}(N, f)) = \text{val}(\langle M, N \rangle, f). \\
\\
& \cap SM = M: \\
& \text{val}(\cap SM, f) \\
= & \text{S}\downarrow(\text{val}(SM, f)) \\
= & \text{S}\downarrow(\text{S}(\text{val}(M, f))) \\
= & \text{val}(M, f) \quad \blacksquare
\end{aligned}$$

Next, we define the frame \mathcal{F}_0 on which the canonical model is based. Let $|M| = \{N \mid \vdash_{\lambda_t} M = N\}$; $|M|$ is the equivalence class of M with respect to provable equality in λ_t .

DEFINITION 56. $\mathcal{F}_0 = \langle \{D^A\}, \{\text{AP}_{A,B}\}, \{\text{PRO}_{A,B}^0\}, \{\text{PRO}_{A,B}^1\}, \{\text{PAIR}_{A,B}\}, \{\text{P}_A\}, \{\text{S}_A\}, \{\text{P}\downarrow_A\}, \{\text{S}\downarrow_A\} \rangle$ is defined as follows:

- $D^A = \{|M| \mid M \text{ is of type } A\}$;
- $\text{AP}_{A,B}(|M^{A \triangleright B}|, |N^A|) = |(M, N)|$;
- $\text{PRO}_{A,B}^0(|M^{A \wedge B}|) = |(M)_0|$;
- $\text{PRO}_{A,B}^1(|M^{A \wedge B}|) = |(M)_1|$;
- $\text{PAIR}_{A,B}(|M^A|, |N^B|) = |\langle M, N \rangle|$;
- $\text{P}_A(|M^A|) = |\mathcal{P}M|$;
- $\text{S}_A(|M^A|) = |SM|$;
- $\text{P}\downarrow_A(|M^A|) = |\cup M|$;
- $\text{S}\downarrow_A(|M^A|) = |\cap M|$.

LEMMA 57. \mathcal{F}_0 is a frame.

Proof. Clearly, D^A is a non-empty set, and $\text{AP}_{A,B}$, $\text{PRO}_{A,B}^0$, $\text{PRO}_{A,B}^1$, $\text{PAIR}_{A,B}$, P_A , S_A , $\text{P}\downarrow_A$, and $\text{S}\downarrow_A$ are functions with appropriate domain and range, for all types A and B . For (extensionality) see [Friedman, 1975]. For (pro), (pair), (future), and (past), use the obvious equalities. \blacksquare

A function $g : V \rightarrow \text{Term}$ is called a substitution, if $g(x)$ and x are of the same type. A substitution is called regular, if for pairwise distinct variables x, y , $fv(g(x)) \cap fv(g(y)) = \emptyset$. Let $M(g)$ denote the result of simultaneously

replacing in M every free occurrence of each variable x by $g(x)$. It can easily be shown that if $M \in \text{Term}$ and Γ is a finite set of variables, then there is an N such that $\vdash_{\lambda_t} M = N$, $fv(M) = fv(N)$, and $bv(N) \cap \Gamma = \emptyset$.

DEFINITION 58. Suppose f is an assignment in \mathcal{F}_0 and g is a regular substitution such that $f(x) = |g(x)|$, for every $x \in V$. For a given term M , choose a term N such that $\vdash_{\lambda_t} M = N$ and for every $x \in fv(N)$, $bv(N) \cap fv(g(x)) = \emptyset$. Then $val(M, f)$ is defined by $val(M, f) = |N(g)|$.

It can be shown that $val : \text{Term} \times \text{Asg} \rightarrow \bigcup_A D^A$, and $\vdash_{\lambda_t} M = N$ implies $val(M, f) = val(N, f)$, cf. [Friedman, 1975].

LEMMA 59. $\mathcal{M}_0 = \langle \mathcal{F}_0, val \rangle$ is a type structure model.

Proof. We consider those conditions not already assumed in Friedman's paper. Let g be a regular substitution and $f(x) = |g(x)|$, for $f \in \text{Asg}$. Choose M_1, N_1 such that $\vdash_{\lambda_t} M = M_1$, $\vdash_{\lambda_t} N = N_1$, and $bv(M_1) \cap fv(g(x)) = bv(N_1) \cap fv(g(x)) = \emptyset$, for every $x \in fv(M_1) \cup fv(N_1)$.

- 4 : $val(\langle M, N \rangle, f) = | \langle M_1, N_1 \rangle(g) | = \text{PAIR}(|M_1(g)|, |N_1(g)|) = \text{PAIR}(val(M, f), val(N, f))$.
- 5 : $val((M)_i, f) = |(M_1)_i(g)| = \text{PRO}^i(|M_1(g)|) = \text{PRO}^i(val(M, f))$.
- 6 : $val((\mathcal{P}M^A)^{[F]A}, f) = |\mathcal{P}M_1(g)| = \mathbf{P}_A(|M_1(g)|) = \mathbf{P}_A(val(M, f))$.
- 8 : $val((\cup M^{[F]A})^A, f) = |\cup M_1(g)| = \mathbf{P}\downarrow_A(|M_1(g)|) = \mathbf{P}\downarrow_A(val(M, f))$.
- 7 and 9 : analogous to the previous two cases. ■

THEOREM 60. (Completeness) *If $M = N$ is valid in the class of all models, then $\vdash_{\lambda_t} M = N$.*

Proof. Suppose $\not\vdash_{\lambda_t} M = N$. Choose M_1, N_1 such that $\vdash_{\lambda_t} M = N_1$, $\vdash_{\lambda_e} N = N_1$, and $bv(M_1) \cap fv(M_1) = bv(N_1) \cap fv(N_1) = \emptyset$. Then $val(M, f) = |M_1| \neq |N_1| = val(N, f)$, for $f(x) = |\text{id}(x)|$, for all $x \in V$, where id is the identity function on V . Thus, $\mathcal{M}_0 \not\models M = N$. ■

We now define the intended models. Following the terminology of Friedman, we shall call the frames underlying an intended model 'full temporal type structures over infinite sets'.

DEFINITION 61. A type structure frame $\mathcal{F} = \{\{\mathbf{D}^A\}, \{\mathbf{AP}_{A,B}\}, \{\mathbf{PRO}_{A,B}^0\}, \{\mathbf{PRO}_{A,B}^1\}, \{\mathbf{PAIR}_{A,B}\}, \{\mathbf{P}_A\}, \{\mathbf{S}_A\}, \{\mathbf{P}\downarrow_A\}, \{\mathbf{S}\downarrow_A\}\}$ is said to be a full temporal type structure over infinite sets, if

- \mathbf{D}^t is infinite, and for every $p \in \text{Atom}$, \mathbf{D}^p is infinite;
- $\mathbf{D}^{A \wedge B} = \mathbf{D}^A \times \mathbf{D}^B$;
- $\mathbf{D}^{A \triangleright B} = (\mathbf{D}^B)^{\mathbf{D}^A}$;

- $\mathbf{D}^{[F]A} = \{\mathcal{P}a \mid a \in \mathbf{D}^A\}$; $\mathbf{D}^{(P)A} = \{\mathcal{S}a \mid a \in \mathbf{D}^A\}$;
- $\mathbf{AP}_{A,B}(a, b) = a(b)$;
- $\mathbf{PRO}_{A,B}^0(\langle a, b \rangle) = a$; $\mathbf{PRO}_{A,B}^1(\langle a, b \rangle) = b$;
- $\mathbf{PAIR}_{A,B}(a, b) = \langle a, b \rangle$;
- $\mathbf{P}_A(a) = \mathcal{P}a$; $\mathbf{S}_A(a) = \mathcal{S}a$;
- $\mathbf{P}\downarrow_A(a) = \cup a$; $\mathbf{S}\downarrow_A(a) = \cap a$.

DEFINITION 62. Let $\mathcal{F} = \langle \{D^A\}, \{\mathbf{AP}_{A,B}\}, \{\mathbf{PRO}_{A,B}^0\}, \{\mathbf{PRO}_{A,B}^1\}, \{\mathbf{PAIR}_{A,B}\}, \{\mathbf{P}_A\}, \{\mathbf{S}_A\}, \{\mathbf{P}\downarrow_A\}, \{\mathbf{S}\downarrow_A\} \rangle$, $\mathcal{F}^* = \langle \{D^{*A}\}, \{\mathbf{AP}_{A,B}^*\}, \{\mathbf{PRO}_{A,B}^{*0}\}, \{\mathbf{PRO}_{A,B}^{*1}\}, \{\mathbf{PAIR}_{A,B}^*\}, \{\mathbf{P}_A^*\}, \{\mathbf{S}_A^*\}, \{\mathbf{P}\downarrow_A^*\}, \{\mathbf{S}\downarrow_A^*\} \rangle$ be frames, and let $\mathcal{M} = \langle \mathcal{F}, \text{val} \rangle$ and $\mathcal{M}^* = \langle \mathcal{F}^*, \text{val}^* \rangle$ be models. A family of functions $\{f_A\}$ is called a partial homomorphism from \mathcal{M} onto \mathcal{M}^* iff

1. for each type A , f_A is a partial function from D^A onto D^{*A} ;
2. if $f_{A \triangleright B}(a)$ exists, then $f_B(\mathbf{AP}_{A,B}(a, b)) = \mathbf{AP}_{A,B}^*(f_{A \triangleright B}(a), f_A(b))$, for all b in the domain of f_A ,
3. if $f_A(a), f_B(b)$ exist, then $f_{A \wedge B}(\mathbf{PAIR}_{A,B}(a, b)) = \mathbf{PAIR}_{A,B}^*(f_A(a), f_B(b))$;
4. if $f_{A \wedge B}(a)$ exists, then $f_A(\mathbf{PRO}_{A,B}^0(a)) = \mathbf{PRO}_{A,B}^{*0}(f_{A \wedge B}(a))$;
5. if $f_{A \wedge B}(a)$ exists, then $f_B(\mathbf{PRO}_{A,B}^1(a)) = \mathbf{PRO}_{A,B}^{*1}(f_{A \wedge B}(a))$;
6. if $f_A(a)$ exists, then $f_{[F]A}(\mathbf{P}_A(a)) = \mathbf{P}_A^*(f_A(a))$; $f_{(P)A}(\mathbf{S}_A(a)) = \mathbf{S}_A^*(f_A(a))$;
7. if $f_{[F]A}(a), f_{(P)A}(b)$ exist, then $f_A(\mathbf{P}\downarrow_A(a)) = \mathbf{P}\downarrow_A^*(f_{[F]A}(a))$; $f_A(\mathbf{S}\downarrow_A(b)) = \mathbf{S}\downarrow_A^*(f_{(P)A}(b))$.

LEMMA 63. Let $\mathcal{M}, \mathcal{M}^*$ be as in the previous definition, and let $\{f_A\}$ be a partial homomorphism from \mathcal{M} onto \mathcal{M}^* . If g, g^* are assignments in \mathcal{F} and \mathcal{F}^* respectively, and $f_A(g(x^A)) = g^*(x)$, then $f_A(\text{val}(M^A, g)) = \text{val}^*(M, g^*)$.

Proof. By induction on M . We consider the cases not already dealt with in [Friedman, 1975]. Note that we may assume $f_A(g(x^A)) = g^*(x)$, since f_A is onto.

- $M \equiv \langle N^A, G^B \rangle$: $f_{A \wedge B}(\text{val}(\langle N, G \rangle, g))$
 $= f_{A \wedge B}(\mathbf{PAIR}(\text{val}(N, g), \text{val}(G, g)))$
 $= \mathbf{PAIR}_{A,B}^*(f_A(\text{val}(N, g)), f_B(\text{val}(G, g)))$
 $= \mathbf{PAIR}_{A,B}^*(\text{val}^*(N, g^*), \text{val}^*(G, g^*))$ by the induction hypothesis
 $= \text{val}^*(\langle N, G \rangle, g^*)$.

- $M \equiv (N^{A \wedge B})_i$: $f(\text{val}((N)_i, g)) = f(\text{PRO}^i(\text{val}(N, g)))$
 $= \text{PRO}^{*i}(f_{A \wedge B}(\text{val}(N, g)))$
 $= \text{PRO}^{*i}(\text{val}^*(N, g^*))$ by the induction hypothesis
 $= \text{val}^*((N)_i, g^*)$.
- $M \equiv \mathcal{P}N^A$: $f_{[F]A}(\text{val}(\mathcal{P}N, g)) = f_{[F]A}(\mathbf{P}_A(\text{val}(N, g)))$
 $= \mathbf{P}_A^*(f_A(\text{val}(N, g))) = \mathbf{P}_A^*(\text{val}^*(N, g^*)) = \text{val}^*(\mathcal{P}N, g^*)$.
- $M \equiv \cup N^{[F]A}$: $f_A(\text{val}(\cup N, g)) = f_A(\mathbf{P}_{\downarrow A}(\text{val}(N, g)))$
 $= \mathbf{P}_{\downarrow A}^*(f_{[F]A}(\text{val}(N, g))) = \mathbf{P}_{\downarrow A}^*(\text{val}^*(N, g^*)) = \text{val}^*(\cup N, g^*)$.
- $M \equiv \mathcal{S}N, \cap N$: analogous to the previous two cases. ■

COROLLARY 64. *Let $\mathcal{M} = \langle \mathcal{F}, \text{val} \rangle$, $\mathcal{M}^* = \langle \mathcal{F}^*, \text{val}^* \rangle$ be models. If there is a partial homomorphism from \mathcal{M} onto \mathcal{M}^* , then $\mathcal{M} \models M = N$ implies $\mathcal{M}^* \models M = N$.*

Proof. Suppose $\mathcal{M} \models M^B = N^B$, $\{f_A\}$ is a partial homomorphism from \mathcal{M} onto \mathcal{M}^* , and g^* is an assignment in \mathcal{M}^* . We choose an assignment g in \mathcal{M} such that for every $A \in T$, $g^*(x) = f_A(g(x^A))$. By the previous lemma, $\text{val}^*(M, g^*) = f_B(\text{val}(M, g)) = f_B(\text{val}(N, g)) = \text{val}^*(N, g^*)$ ■

THEOREM 65. *Let \mathcal{M} be a model based on a full temporal type structure over infinite sets. Then $\vdash_{\lambda_t} M = N$ iff $\mathcal{M} \models M = N$.*

Proof. It suffices to show that $\mathcal{M} \models M = N$ implies $\mathcal{M}_0 \models M = N$. To prove this, we define by induction on A a partial homomorphism $\{f_A\}$ from \mathcal{M} onto \mathcal{M}_0 as follows:

- $A = p, A = t, p \in \text{Atom}$:
 f_A is any function from \mathbf{D}^A onto \mathcal{M}_0 's domain D^A .
 (Such a function exists, since \mathbf{D}^A is infinite and D^A is denumerable.)
- $A = (B \wedge C)$:
 If $f_B(b), f_C(c)$ exist, then $f_{B \wedge C}(\langle b, c \rangle) = f_{B \wedge C}(\mathbf{PAIR}(b, c))$ is defined as $\mathbf{PAIR}_{B,C}(f_B(b), f_C(c))$.
- $A = (B \triangleright C)$:
 $f_{B \triangleright C}(a)$ is defined as the unique member of $D^{(B \triangleright C)}$ (if it exists) such that $f_C(a(b)) = \mathbf{AP}_{B,C}(f_{B \triangleright C}(a), f_B(b))$, for all b in the domain of f_B .
- $A = [F]A$:
 $f_{[F]A}(a) = f_{[F]A}(\mathbf{P}_A(b))$ for some $b \in \mathbf{D}^A$ is defined as $\mathbf{P}_A(f_A(b))$ if $f_A(b)$ exists.
- $A = \langle P \rangle A$:
 $f_{\langle P \rangle A}(a) = f_{\langle P \rangle A}(\mathbf{S}_A(b))$ for some $b \in \mathbf{D}^A$ is defined as $\mathbf{S}_A(f_A(b))$ if $f_A(b)$ exists.

That $\{f_A\}$ is a partial homomorphism follows from the definition of $\{f_A\}$ and the following equations:

$$\begin{array}{ll}
f_A(\mathbf{PRO}_{A,B}^0(\langle a, b \rangle)) & = f_B(\mathbf{PRO}_{A,B}^1(\langle a, b \rangle)) \\
= f_A(a) & = f_B(b) \\
= \mathbf{PRO}_{A,B}^0(\mathbf{PAIR}_{A,B}(f_A(a), f_B(b))) & = \mathbf{PRO}_{A,B}^1(\mathbf{PAIR}_{A,B}(f_A(a), f_B(b))) \\
= \mathbf{PRO}_{A,B}^0(f_{A \wedge B}(\mathbf{PAIR}_{A,B}(a, b))) & = \mathbf{PRO}_{A,B}^1(f_{A \wedge B}(\mathbf{PAIR}_{A,B}(a, b))) \\
= \mathbf{PRO}_{A,B}^0(f_{A \wedge B}(\langle a, b \rangle)) & = \mathbf{PRO}_{A,B}^1(f_{A \wedge B}(\langle a, b \rangle)) \\
\\
f_A(\mathbf{P} \downarrow_A (\mathcal{P}a)) & = f_A(\mathbf{S} \downarrow_A (\mathcal{S}a)) \\
= f_A(a) & = f_A(a) \\
= \mathbf{P} \downarrow_A (f_{[F]A}(\mathcal{P}a)) & = \mathbf{S} \downarrow_A (f_{\langle P \rangle A}(\mathcal{S}a))
\end{array}$$

It remains to be shown that f_A is onto, for every type A . For $A = t$ and $A = p \in \mathit{Atom}$, this follows from the definitions of f_t , f_p and \mathcal{F}_0 . For the remaining cases we consider two examples. $A = [F]B$. Assume $d = |\mathcal{P}M| \in D^{[F]B}$. Choose $a \in \mathbf{D}^{[F]B}$ such that $a = \mathcal{P}b$ for $b \in \mathbf{D}^B$ and $b = f_B^{-1}(|M^B|)$. Since f_B is onto, such an element a from $\mathbf{D}^{[F]B}$ exists. Then $f_{[F]B}(a) = f_{[F]B}(\mathbf{P}_B(b)) = \mathbf{P}_B(f_B(b)) = |\mathcal{P}M| = d$. Consider now $A = (B \triangleright C)$, and assume $d \in D^{(B \triangleright C)}$. Choose $a \in \mathbf{D}^{(B \triangleright C)}$ such that for every b in the domain of f_B , $a(b) \in f_C^{-1}(\mathbf{Ap}(d, f_B(b)))$. Then $f_{(B \triangleright C)}(a) = d$. Since f_C and f_B may be assumed to be onto, the set of such $a \in \mathbf{D}^{(B \triangleright C)}$ is non-empty. \blacksquare

Whereas the encoding of substructural subsystems of \mathbf{DIntKt} obtained by giving up all or part of \mathbf{DIntKt} 's structural rules will require modifications of the notion of construction, in order to encode structural extensions of \mathbf{DIntKt} , the notion of construction need not be altered. Various extensions of \mathbf{HIntKt} can be presented as structural extensions of \mathbf{DIntKt} . The following axiom schemata are those schematic axioms from Table 3, which are in \mathcal{L} . Each axiom schema \mathbf{Ax} in this table corresponds with the associated structural rule \mathbf{Ax}' in the sense that an \mathcal{L} -formula A is provable in $\mathbf{HIntKt} + \mathbf{Ax}$ iff $\mathbf{I} \rightarrow A$ is provable in $\mathbf{DIntKt} + \mathbf{Ax}'$.

In the literature, several proposals have been made to extend the formulas-as-types notion of construction from positive logic to modal logics based on it. We shall here briefly point to five such approaches.

1. Gabbay and de Queiroz [1992] interpret the necessity modality \Box “as a sort of second-order universal quantification (quantification over structured collections of formulas)” [Gabbay and de Queiroz, 1992, p. 1359]. Using the framework of Labelled Natural Deduction [de Queiroz and Gabbay, 1999], proofs in various modal logics are encoded by imposing conditions on abstraction over possible-world variables [de Queiroz and Gabbay, 1997]. However, Gabbay and de Queiroz do not consider a Friedman-style completeness proof for the λ -calculus under consideration.

<i>name</i>	<i>axiom schema</i>	<i>name</i>	<i>structural rule</i>
T	$[F]A \triangleright A$	T'	$X \rightarrow \bullet Y \vdash X \rightarrow Y$
4	$[F]A \triangleright [F][F]A$	$4'$	$X \rightarrow \bullet Y \vdash X \rightarrow \bullet \bullet Y$
V	$[F]A$	V'	$X \rightarrow Y \vdash \bullet \mathbf{I} \rightarrow Y$
T^c	$A \triangleright [F]A$	$T^{c'}$	$X \rightarrow Y \vdash X \rightarrow \bullet Y$
4^c	$[F][F]A \triangleright [F]A$	$4^{c'}$	$X \rightarrow \bullet \bullet Y \vdash X \rightarrow \bullet Y$
D_p	$t \triangleright \langle P \rangle t$	D_p'	$\bullet \mathbf{I} \rightarrow Y \vdash \mathbf{I} \rightarrow Y$
T_p	$A \triangleright \langle P \rangle A$	T_p'	$\bullet X \rightarrow Y \vdash X \rightarrow Y$
4_p	$\langle P \rangle \langle P \rangle A \triangleright \langle P \rangle A$	$4_p'$	$\bullet X \rightarrow Y \vdash \bullet \bullet X \rightarrow Y$
B_p	$(A \wedge \langle P \rangle B) \triangleright \langle P \rangle (B \wedge \langle P \rangle A)$	B_p'	$\bullet (X \times \bullet Y) \rightarrow Z \vdash Y \times \bullet X \rightarrow Z$
$Alt1_p$	$\langle \langle P \rangle A \wedge \langle P \rangle B \rangle \triangleright \langle P \rangle (A \wedge B)$	$Alt1_p'$	$\bullet (X \times Y) \rightarrow Z \vdash \bullet X \times \bullet Y \rightarrow Z$
T_p^c	$\langle P \rangle A \triangleright A$	$T_p^{c'}$	$X \rightarrow Y \vdash \bullet X \rightarrow Y$
4_p^c	$\langle P \rangle A \triangleright \langle P \rangle \langle P \rangle A$	$4_p^{c'}$	$\bullet \bullet X \rightarrow Y \vdash \bullet X \rightarrow Y$

 Table 6. Axioms in \mathcal{L} .

2. Borghuis [1993; 1994; 1998] investigates the formulas-as-types-notion of construction for several normal modal propositional logics based on **CPL**. Fitch-style natural deduction proofs in these modal logics are interpreted in a second-order λ -calculus. In this approach, unary type-forming operators are introduced to encode applications of import and export rules for \square in Fitch-style natural deduction. The operations \hat{k} and \check{k} encoding the export and import rules for \square in the smallest normal modal logic **K**, for example, satisfy the following reduction rule: $\hat{k}(\check{k}M) \rightarrow_r M$. Borghuis proves strong normalization results for the modal typed λ -calculi under consideration. However, the term-forming operations used to encode applications of import and export rules for \square are not provided with a set-theoretic interpretation.

3. Martini and Masini [1996] consider formulas-as-types for 2-sequent calculi, cf. Section 2.2. They introduce two unary term-forming operations gen and ungen to encode applications of \square -introduction and \square -elimination rules. A strong normalization theorem is proved for the typed λ -calculus encoding proofs in the 2-sequent calculus for the modal logic **S4**. However, the typed terms do not receive a set-theoretic interpretation.

4. Recently, Sasaki [1999] suggested understanding a λ -term of type $\square A$ as either denoting an element from the domain associated with A , or being undefined. A term $M^{A \triangleright \square B}$ would then denote a partial function from D^A to D^B . Sasaki defines an extended typed λ -calculus with various formation rules for obtaining terms of type $\square A$. Moreover, natural deduction proofs in the extension of the intuitionistic modal logic **IntK** by the axiom schemata

$$T_c \quad A \triangleright \square A \quad \text{and} \quad 4_c \quad \square \square A \triangleright \square A$$

are encoded by terms in the extended typed λ -calculus. Unfortunately, no denotational semantics for this λ -calculus is developed.

5. The approach that comes closest to the one presented here is Restall's [1999, Chapter 7], who also applies Belnap's display calculus. Introductions of $[F]$ on the right (left) of the sequent arrow are encoded using a unary operator *up* (*down*), lifting (lowering) terms of type A ($[F]A$) to terms of type $[F]A$ (A), just like the operation \mathcal{P} (\cup). Backward-looking possibility is treated quite differently. Introductions of $\langle P \rangle$ (in Restall's notation \diamond) on the right are encoded using a unary type-lifting operation \bullet (not to be confused with the structure connective \bullet). Introductions on the left are encoded by a unary term-forming operation turning terms N^B , $M^{(P)A}$ into the term *let* M *be* $\bullet x$ *in* N of type B . Whereas the term *down up* N reduces in one step to N , *let* $\bullet G$ *be* $\bullet x$ *in* N reduces in one step to $N[x := G]$. Restall proves normalization for the extended typed λ -calculus under consideration, however, no set-theoretic interpretation of *up*, *down*, \bullet , and *let* M *be* $\bullet x$ *in* is suggested.

In the literature on functional programming there are various proposals for providing an *operational* semantics of proofs in modal logics, notably in intuitionistic **S4**. Natural deduction in the framework of Martin-Löf's type theory is considered in [Davis and Pfenning, 2000] and [Pfenning, 2000]. Also, further references can be found in these papers.

3.8 Bi-intuitionistic logic

Suppose a connective f_1 is introduced in a finite-set-to-formula sequent calculus, whereas another connective f_2 is introduced in a formula-to-finite-set sequent system. Then the right introduction rules for f_1 and the left introduction rules for f_2 satisfy the segregation condition. However, if we just combine the sets of rules of both sequent calculi, neither Af_1B nor Af_2B is introduced in the most general context, namely in an arbitrary finite set of formulas, because there are no structure operations like in display logic that allow keeping track of succedent (antecedent) formulas on the left (right) of \rightarrow . This leads to a problem encountered in formulating an ordinary sequent calculus for bi-intuitionistic logic **BiInt**, the combination of intuitionistic logic and dual-intuitionistic logic. It can be shown that in the ordinary finite-set-to-formula sequent calculus no binary operation \sharp is definable such that \sharp satisfies (in the finite-set-to-formula setting) the dual Deduction Theorem characteristic of coimplication: $A \rightarrow B$ iff $A\sharp B \rightarrow \emptyset$, see [Goré, 2000]. Bi-intuitionistic logic extends the language of intuitionistic logic by *coimplication*, the residual of disjunction, and *conegation*. The syntax of **BiInt** is given by:

$$A ::= p \mid \neg A \mid \sim A \mid A \wedge B \mid A \vee B \mid A \triangleright B \mid A \triangleleft B.$$

In the presence of a falsity constant \mathbf{f} , intuitionistic negation \neg can be defined by $\neg A := (A \triangleright \mathbf{f})$, and in the presence of a truth constant \mathbf{t} , conegation \smile can be defined by $\smile A := (\mathbf{t} \blacktriangleleft A)$.

Bi-intuitionistic logic has a natural algebraic and possible-worlds semantics, see [Rauszer, 1980]. The possible-worlds semantics adds to Kripke models for intuitionistic logic evaluation clauses for conegation and coimplication. A frame is a pair $\langle I, \sqsubseteq \rangle$, where I is a non-empty set (of states), and \sqsubseteq is a reflexive and transitive binary relation on I . A structure $\langle I, \sqsubseteq, v \rangle$ is a bi-intuitionistic model if v is a function assigning to every propositional variable p a subset $v(p)$ of I and, moreover, for every $t, u \in I$, if $t \sqsubseteq u$ and $t \in v(p)$, then $u \in v(p)$. Verification of a formula A in the model $\mathcal{M} = \langle I, \sqsubseteq, v \rangle$ at state t (in symbols $\mathcal{M}, t \models A$) is inductively defined as follows:

$$\begin{aligned}
 \mathcal{M}, t \models p & \quad \text{iff } t \in v(p), \text{ for every propositional variable } p; \\
 \mathcal{M}, t \models \neg A & \quad \text{iff for all } u \in I, t \sqsubseteq u \text{ implies } \mathcal{M}, u \not\models A \\
 \mathcal{M}, t \models \smile A & \quad \text{iff there exists } u \in I, u \sqsubseteq t, \text{ and } \mathcal{M}, u \not\models A \\
 \mathcal{M}, t \models A \wedge B & \quad \text{iff } \mathcal{M}, t \models A \text{ and } \mathcal{M}, t \models B; \\
 \mathcal{M}, t \models A \vee B & \quad \text{iff } \mathcal{M}, t \models A \text{ or } \mathcal{M}, t \models B; \\
 \mathcal{M}, t \models A \triangleright B & \quad \text{iff for all } u \in I, \text{ if } t \sqsubseteq u \text{ then } \mathcal{M}, u \not\models A \text{ or } \mathcal{M}, u \models B; \\
 \mathcal{M}, t \models A \blacktriangleleft B & \quad \text{iff there is a } u \in I, u \sqsubseteq t \text{ } \mathcal{M}, u \models A \text{ and } \mathcal{M}, u \not\models B;
 \end{aligned}$$

where $\mathcal{M}, t \not\models A$ is the (classical) negation of $\mathcal{M}, t \models A$. A formula A is valid in $\mathcal{M} = \langle I, \sqsubseteq, v \rangle$ if for every $t \in I$, $\mathcal{M}, t \models A$; and A is valid on a frame $\mathcal{F} = \langle I, \sqsubseteq \rangle$ if A is valid in every model $\langle \mathcal{F}, v \rangle$ based on \mathcal{F} . A formula A is said to be valid in a class \mathcal{K} of models (frames) if A is valid in every model (frame) from \mathcal{K} .

The axiomatic system **HBiInt** consists of axiom schemata for intuitionistic logic **Int**, modus ponens, the rule

$$\text{from } A \text{ infer } \neg \smile A$$

and the following axiom schemata:

1. $A \triangleright (B \vee (A \blacktriangleleft B))$
2. $(A \blacktriangleleft B) \triangleright \smile(A \triangleright B)$
3. $((A \blacktriangleleft B) \blacktriangleleft C) \triangleright (A \blacktriangleleft (B \vee C))$
4. $\neg(A \blacktriangleleft B) \triangleright (A \triangleright B)$
5. $(A \triangleright (B \blacktriangleleft B)) \triangleright \neg A$
6. $\neg A \triangleright (A \triangleright (B \blacktriangleleft B))$
7. $((B \triangleright B) \blacktriangleleft A) \triangleright \smile A$
8. $\smile A \triangleright ((B \triangleright B) \blacktriangleleft A)$

THEOREM 66. *A formula A in the language of \mathbf{BiInt} is valid in the class of all models iff A is provable in \mathbf{HBiInt} .*

In the present section, we shall apply the modal display calculus and use a modal translation of \mathbf{BiInt} into $\mathbf{S4t}$ to give a display sequent calculus for \mathbf{BiInt} based on the structure connectives \mathbf{I} , $*$, \circ , and \bullet , cf. [Goré, 1995], [Wansing, 1998, Chapter 10]. A direct display sequent system for \mathbf{BiInt} not relying on a modal translation has been presented in [Goré, 2000]. Sometimes making a detour via a modal translation may be useful. In [Wansing, 1999], a modal translation into $\mathbf{S4}$ has been used to give a cut-free display sequent calculus for a certain constructive modal logic of consistency, for which no other proof system is known. In view of the possible-worlds semantics for \mathbf{BiInt} and the familiar modal translation of \mathbf{Int} into $\mathbf{S4}$ (see [Gödel, 1933]), a faithful modal translation m of \mathbf{BiInt} into $\mathbf{S4t}$ can be straightforwardly defined as follows:

1. $m(p) = [F]p$, for every propositional variable p ;
2. $m(t) = t$;
3. $m(f) = f$;
4. $m(A\sharp B) = m(A)\sharp m(B)$, $\sharp \in \{\wedge, \vee\}$;
5. $m(A \triangleright B) = [F](m(A) \supset m(B))$;
6. $m(A \blacktriangleleft B) = \langle P \rangle \neg(m(A) \supset m(B))$.

THEOREM 67. ([Lukowski, 1996]) *A formula A in the language of \mathbf{BiInt} is provable in \mathbf{HBiInt} iff $m(A)$ is provable in $\mathbf{S4t}$.*

DEFINITION 68. The display sequent system \mathbf{DBiInt} consists of (id), (cut), the basic structural rules (1) – (4) of Section 1.3, rules $(\rightarrow t)$, $(t \rightarrow)$, $(\rightarrow f)$, $(f \rightarrow)$, $(\rightarrow \wedge)$, $(\wedge \rightarrow)$, $(\rightarrow \vee)$, $(\vee \rightarrow)$, the structural rules from Table 2 and:

$$\begin{array}{ll}
(\rightarrow \frown) & \bullet X \rightarrow *A \vdash X \rightarrow \frown A \\
(\frown \rightarrow) & *A \rightarrow X \vdash \frown A \rightarrow \bullet X \\
(\rightarrow \smile) & X \rightarrow *A \vdash \bullet X \rightarrow \smile A \\
(\smile \rightarrow) & *A \rightarrow \bullet X \vdash \smile A \rightarrow X \\
(\rightarrow \triangleright)^m & \bullet X \circ A \rightarrow B \vdash X \rightarrow A \triangleright B \\
(\triangleright \rightarrow)^m & X \rightarrow A \quad B \rightarrow Y \vdash A \triangleright B \rightarrow \bullet(*X \circ Y) \\
(\rightarrow \blacktriangleleft)^m & X \rightarrow A \quad B \rightarrow *X \vdash \bullet X \rightarrow A \blacktriangleleft B \\
(\blacktriangleleft \rightarrow)^m & * \bullet X \circ A \rightarrow B \vdash A \blacktriangleleft B \rightarrow X \\
(\text{persistence}) & p \rightarrow X \vdash \bullet p \rightarrow X \\
(\text{reflexivity}) & X \rightarrow \bullet Y \vdash X \rightarrow Y \\
(\text{transitivity}) & X \rightarrow \bullet Y \vdash X \rightarrow \bullet \bullet Y
\end{array}$$

It can be shown that the persistence rule for arbitrary formulas is an admissible rule of **DBiInt**. This can be used to prove weak completeness of **DBiInt** with respect to **HBiInt**.

LEMMA 69. *In **DBiInt**, $A \rightarrow X \vdash \bullet A \rightarrow X$.*

Proof. By induction on A ; for example:

$$\begin{array}{c}
 \frac{}{A \rightarrow A} \\
 \frac{}{*A \rightarrow *A} \\
 \frac{}{\wedge A \rightarrow \bullet * A} \\
 \frac{}{\wedge A \rightarrow \bullet \bullet * A} \\
 \frac{}{\bullet \wedge A \rightarrow \bullet * A} \\
 \frac{}{\bullet \bullet \wedge A \rightarrow *A} \\
 \frac{\bullet \wedge A \rightarrow \wedge A \quad \wedge A \rightarrow X}{\bullet \wedge A \rightarrow X} \text{ (cut)}
 \end{array}$$

$$\begin{array}{c}
 \frac{}{A \rightarrow A} \\
 \frac{}{*A \rightarrow *A} \\
 \frac{}{*A \rightarrow *A \circ B} \quad \frac{}{B \rightarrow B} \\
 \frac{}{*A \rightarrow *A \circ B} \quad \frac{}{B \rightarrow *A \circ B} \\
 \frac{}{*(A \circ B) \rightarrow A} \quad \frac{}{B \rightarrow **(*A \circ B)} \\
 \frac{}{\bullet **(*A \circ B) \rightarrow A \blacktriangleleft B} \\
 \frac{}{*(A \circ B) \rightarrow \bullet(A \blacktriangleleft B)} \\
 \frac{}{*(A \circ B) \rightarrow \bullet \bullet(A \blacktriangleleft B)} \\
 \frac{}{* \bullet \bullet(A \blacktriangleleft B) \rightarrow *A \circ B} \\
 \frac{}{A \circ * \bullet \bullet(A \blacktriangleleft B) \rightarrow B} \\
 \frac{}{* \bullet \bullet(A \blacktriangleleft B) \circ A \rightarrow B} \\
 \frac{}{A \blacktriangleleft B \rightarrow \bullet(A \blacktriangleleft B)} \\
 \frac{}{\bullet(A \blacktriangleleft B) \rightarrow A \blacktriangleleft B} \quad \frac{}{A \blacktriangleleft B \rightarrow X} \\
 \frac{}{\bullet(A \blacktriangleleft B) \rightarrow X}
 \end{array}$$

■

THEOREM 70. *In **DBiInt** $\vdash \mathbf{I} \rightarrow A$ iff in **HBiInt** $\vdash A$.*

Proof. \Leftarrow : By induction on proofs in **HBiInt**. As an example, we here consider only the proof of one axiom schema of **HBiInt**:

$$\begin{array}{c}
\frac{B \rightarrow B}{* \bullet * \bullet \mathbf{I} \circ B \rightarrow B} \\
\frac{A \rightarrow A \quad B \triangleleft B \rightarrow * \bullet \mathbf{I}}{A \triangleright (B \triangleleft B) \rightarrow \bullet (*A \circ * \bullet \mathbf{I})} \\
\frac{A \triangleright (B \triangleleft B) \rightarrow *A \circ * \bullet \mathbf{I}}{A \triangleright (B \triangleleft B) \rightarrow * \bullet \mathbf{I} \circ *A} \text{ (reflexivity)} \\
\frac{\bullet \mathbf{I} \circ (A \triangleright (B \triangleleft B)) \rightarrow *A}{\bullet \mathbf{I} \circ (A \triangleright (B \triangleleft B)) \rightarrow * \bullet * A} \text{ (persistence)} \\
\frac{\bullet (* \bullet \mathbf{I} \circ (A \triangleright (B \triangleleft B))) \rightarrow \bullet * A}{\bullet \mathbf{I} \circ (A \triangleright (B \triangleleft B)) \rightarrow \frown A} \\
\frac{\bullet \mathbf{I} \circ (A \triangleright (B \triangleleft B)) \rightarrow \frown A}{\mathbf{I} \rightarrow (A \triangleright (B \triangleleft B)) \triangleright \frown A}
\end{array}$$

\Rightarrow : We define the translations τ_1 and τ_2 from structures into tense logical formulas as in Section 1.3, except that now $\tau_1(A) = \tau_2(A) = m(A)$. By induction on proofs in **DBiInt**, it can be shown that $\vdash X \rightarrow Y$ in **DBiInt** implies $\vdash \tau_1(X) \supset \tau_2(Y)$ in **S4t**. Therefore, $\vdash \mathbf{I} \rightarrow A$ in **DBiInt** implies $\vdash m(A)$ in **S4t**. By the previous theorem we have $\vdash A$ in **HBiInt**. \blacksquare

THEOREM 71. *Strong cut-elimination holds for **DBiInt**.*

Proof. **DBiInt** is a proper display calculus. As to the fulfillment of condition C8, the derivation on the left, for example, reduces to the derivation on the right, using contraction:

$$\begin{array}{c}
\frac{X \rightarrow A \quad B \rightarrow *X \quad * \bullet Y \circ A \rightarrow B}{\bullet X \rightarrow A \triangleleft B \quad A \triangleleft B \rightarrow Y} \\
\frac{\bullet X \rightarrow A \triangleleft B \quad A \triangleleft B \rightarrow Y}{\bullet X \rightarrow Y} \\
\frac{* \bullet Y \circ A \rightarrow B}{A \rightarrow \bullet Y \circ B} \\
\frac{X \rightarrow A \quad A \rightarrow \bullet Y \circ B}{X \rightarrow \bullet Y \circ B} \\
\frac{* \bullet Y \circ X \rightarrow B \quad B \rightarrow *X}{* \bullet Y \circ X \rightarrow *X} \\
\frac{* \bullet Y \circ X \rightarrow *X}{X \rightarrow \bullet Y \circ *X} \\
\frac{X \circ X \rightarrow \bullet Y}{X \rightarrow \bullet Y} \\
\frac{X \rightarrow \bullet Y}{\bullet X \rightarrow Y}
\end{array}$$

\blacksquare

COROLLARY 72. ***DBiInt** \cup **DS4t** is a conservative extension of both **DBiInt** and **DS4t**.*

As in Section 3.1, let for modal formulas A the translations τ_i ($i = 1, 2$) be defined by $\tau_i(A) = A$.

LEMMA 73. *In **DBiInt** \cup **DS4t**, (i) $\vdash X \rightarrow \tau_1(X)$ and (ii) $\vdash \tau_2(X) \rightarrow X$.*

Proof. Both (i) and (ii) are proved simultaneously by induction on X . In particular we have to verify that for every formula of the language of **BiInt**, $\vdash A \rightarrow m(A)$ and $\vdash m(A) \rightarrow A$. But this is the case, see for example:

$$\begin{array}{c}
 \frac{A \rightarrow m(A) \quad m(B) \rightarrow B}{m(A) \supset m(B) \rightarrow *A \circ B} \\
 \frac{*(*A \circ B) \rightarrow *(m(A) \supset m(B))}{*(*A \circ B) \rightarrow \neg(m(A) \supset m(B))} \\
 \frac{\bullet *(*A \circ B) \rightarrow \langle P \rangle \neg(m(A) \supset m(B))}{*\bullet \langle P \rangle \neg(m(A) \supset m(B))} \\
 \frac{*\bullet \langle P \rangle \neg(m(A) \supset m(B)) \rightarrow *A \circ B}{*\bullet \langle P \rangle \neg(m(A) \supset m(B)) \rightarrow B \circ *A} \\
 \frac{*\bullet \langle P \rangle \neg(m(A) \supset m(B)) \circ A \rightarrow B}{A \blacktriangleleft B \rightarrow \langle P \rangle \neg(m(A) \supset m(B))} \\
 \\
 \begin{array}{cc}
 \frac{m(A) \rightarrow A}{m(A) \rightarrow A \circ m(B)} & \frac{B \rightarrow m(B)}{B \circ m(A) \rightarrow m(B)} \\
 \frac{*A \circ m(A) \rightarrow m(B)}{*A \rightarrow m(A) \supset m(B)} & \frac{B \rightarrow m(A) \supset m(B)}{*(m(A) \supset m(B)) \rightarrow *B} \\
 \frac{*(m(A) \supset m(B)) \rightarrow A}{\neg(m(A) \supset m(B)) \rightarrow A} & \frac{\neg(m(A) \supset m(B)) \rightarrow *B}{B \rightarrow *\neg(m(A) \supset m(B))} \\
 \frac{\bullet \neg(m(A) \supset m(B)) \rightarrow A \blacktriangleleft B}{\neg(m(A) \supset m(B)) \rightarrow \bullet(A \blacktriangleleft B)} & \\
 \frac{\neg(m(A) \supset m(B)) \rightarrow \bullet(A \blacktriangleleft B)}{\langle P \rangle \neg(m(A) \supset m(B)) \rightarrow A \blacktriangleleft B} &
 \end{array}
 \end{array}$$

■

THEOREM 74. *In **DBiInt** $\vdash X \rightarrow Y$ iff $\tau_1(X) \supset \tau_2(Y)$ is valid on every frame (understood as a frame for **S4t**).*

Proof. (\Rightarrow): This follows by induction on proofs in **DBiInt**. (\Leftarrow): Suppose that $\tau_1(X) \supset \tau_2(Y)$ is valid on every frame. Hence $\tau_1(X) \supset \tau_2(Y)$ is a theorem of **S4t** and hence $\vdash \tau_1(X) \rightarrow \tau_2(Y)$ in **DBiInt** \cup **DS4t**. By the previous lemma, $\vdash X \rightarrow Y$ in **DBiInt** \cup **DS4t** and by Corollary 72, $\vdash X \rightarrow Y$ in **DBiInt**. ■

One advantage of the translation-based sequent system **DBiInt** is that by abandoning combinations of the structural rules (*persistence*), (*reflexivity*), and (*transitivity*), one obtains cut-free sequent calculus presentations of the subsystems of **BiInt** that arise from giving up the corresponding semantic requirements: persistence of atomic information, reflexivity, and transitivity of the relation \sqsubseteq . Also seriality of \sqsubseteq , a weakening of reflexivity, is expressible by a purely structural sequent rule, see condition D' in Table 4.

4 INTERRELATIONS AND EXTENSIONS

While the existence of a rich inventory of types of proof systems for modal and other logics may be welcomed, for instance, from the point of view of designing and combining logics, there also exists the need of comparing different approaches and investigating their interrelations and their relative advantages and disadvantages. Mints [1997], for example, presents cut-free systems of indexed sequents for certain extensions of \mathbf{K} and defines a translation of these sequent systems into equivalent display calculi. In this final section a translation of multiple-sequent systems into higher-arity sequent systems and a translation of hypersequents into display sequents are defined, showing that multiple-sequent systems can be simulated within higher-arity proof systems and that the method of hypersequents can be simulated within display logic. Moreover, one interesting aspect of extending the sequent-style proof systems for modal and temporal *propositional* logics to sequent calculi for modal and temporal *predicate* logics is considered, namely avoiding the provability of the Barcan formula and its converse. We also briefly refer to recent work on display calculi for extended modal languages. Finally, the relation between display logic and Dunn's Gaggles Theory is pointed out.

4.1 Translation of multiple-sequent systems

The translation σ in Section 2.4 reveals a straightforward relation between Indrzejczak's multiple-sequent systems and higher-arity sequent systems for modal logics. The intended meaning of the multiple-sequents can be expressed by four-place sequents using a translation μ :

$$\begin{aligned}\mu(\Gamma \rightarrow \Delta) &= \delta(\Gamma) \rightarrow_{\emptyset}^{\emptyset} \delta(\Delta) \\ \mu(\Gamma \square \rightarrow \Delta) &= \delta(\Gamma) \rightarrow_{\emptyset}^{\bigvee \delta(\Delta)} \emptyset \\ \mu(\Gamma \diamond \rightarrow \Delta) &= \emptyset \rightarrow_{\emptyset}^{\neg \wedge \delta(\Gamma)} \delta(\Delta).\end{aligned}$$

If \mathbf{S} is a multiple-sequent system, then let $\mu(\mathbf{S})$ be the result of the μ -translation of the rules of \mathbf{S} . Let μ^* denote the translation of four-place sequents into modal formulas stated in Section 2.3. If $s_1, \dots, s_n/s$ is a rule of \mathbf{MC} , then $\mu^*(\mu(s_1)), \dots, \mu^*(\mu(s_n))/\mu^*(\mu(s))$ is validity preserving in \mathbf{C} . For the rule $[TR]$, for instance, we have $\mu^*(\mu([TR])) =$

$$\frac{\bigwedge \delta(\Delta) \supset \square \bigvee \delta(\Gamma)}{\diamond \neg \bigvee \delta(\Gamma) \supset \neg \bigwedge \delta(\Delta)} = \frac{\bigwedge \delta(\Delta) \supset \square \bigvee \delta(\Gamma)}{\diamond \bigwedge \delta(\Gamma^*) \supset \bigvee \delta(\Delta^*)}$$

Moreover, (RR) is derivable and \mathbf{CPL} is contained in $\mu(\mathbf{MC})$. Hence,

OBSERVATION 75. The system $\mu(\mathbf{MC})$ is sound and complete with respect to \mathbf{C} : $\vdash \Gamma \rightarrow \Delta$ in $\mu(\mathbf{MC})$ iff $\mu^*(\mu(\Gamma \rightarrow \Delta))$ is valid in \mathbf{C} .

The translation μ is also faithful for the extension of **MC** by the rules [nec], [D], [T], and [4] and extensions of **C** by the necessitation rule and the axiom schemata *D*, *T* and 4.

4.2 Translation of hypersequents

In order to characterize various non-classical logics by means of hypersequential calculi, Avron [1996] uses different semantical readings of hypersequents. Basically a distinction can be drawn between interpreting the sequent arrow of a component in a hypersequent as material implication or as a constructive implication not definable in terms of Boolean negation and disjunction. This difference in interpretation requires different translations of hypersequents into display sequents. If the sequent arrow is interpreted constructively, a suitable translation may, for example, exploit a faithful embedding of the logic under consideration into a normal modal or temporal logic. In such a case, the sequent arrow is interpreted as strict material implication. In [Wansing, 1998, Chapter 11] translations of hypersequents into display sequents are defined that simulate hypersequents in Avron's hypersequential calculi **GL3**, **GS5**, and **GLC** for Łukasiewicz 3-valued logic **L3**, **S5**, and Dummett's superintuitionistic logic **LC**, also called Gödel-Dummett logic. We shall here consider only the translations suitable for **S5** and **LC**. The treatment of **GL3** is slightly more involved, because **L3** comprises connectives from different 'families' of logical operations. To deal with this composite character of **L3** in display logic, the structure connective \circ is replaced by two binary structure operations \circ_c and \circ_i , see [Wansing, 1998]. If $\Delta = \{A_1, \dots, A_n\}$, let $*\Delta = \{*A_1, \dots, *A_n\}$. Since \circ is assumed to be associative and commutative, we may put $(\circ\Delta) = A_1 \circ \dots \circ A_n$. If $\Delta = \emptyset$, let $*\Delta = (\circ\Delta) = \mathbf{I}$. Recall the notion of hypersequent from Section 2.5.

DEFINITION 76. The translation η_0 of ordinary sequents into display structures is defined by

$$\eta_0(\Delta \rightarrow \Gamma) = \bullet((\circ * \Delta) \circ (\circ \Gamma)),$$

and the translation η of non-empty hypersequents into display sequents is defined by

$$\eta(s_1 \mid \dots \mid s_n) = \mathbf{I} \rightarrow \eta_0(s_1) \circ \dots \circ \eta_0(s_n).$$

THEOREM 77. *For every hypersequent H , $\vdash \eta(H)$ in **DS5** iff $\vdash H$ in **GS5**.*

In the hypersequential system **GLC** the components of a hypersequent are restricted to be ordinary Gentzen sequents with at most a single conclusion. Dummett's **LC** is the logic of linearly ordered intuitionistic Kripke

models. An axiomatization of **LC** is obtained from an axiomatization **HInt** of **Int** by adding the axiom schema $(A \triangleright B) \vee (B \triangleright A)$. It is well-known that the modal translation m defined in Section 3.8 (restricted to the language of intuitionistic logic, i.e. the language of **LC**) is a faithful embedding of **LC** into **S4.3**, the logic of linearly ordered modal Kripke models.

THEOREM 78. *For every formula A in the language of **LC**, $\vdash A$ in **LC** iff $\vdash m(A)$ in **S4.3**.*

DEFINITION 79. The translation ζ_0 of a single-conclusion ordinary sequent $s = A_1, \dots, A_n \rightarrow B$ is defined by

$$\zeta_0(s) = \bullet(*A_1 \circ \bullet(*A_2 \circ \dots \bullet(*A_n \circ B) \dots)).$$

If $s = A_1, \dots, A_n \rightarrow \emptyset$, then $\zeta(s) = \bullet(*A_1 \circ \bullet(*A_2 \circ \dots \bullet(*A_n \circ \mathbf{I}) \dots))$. If $s = \emptyset \rightarrow B$, then $\zeta(s) = \bullet(*\mathbf{I} \circ B)$, and if $s = \emptyset \rightarrow \emptyset$, $\zeta(s) = \bullet(*\mathbf{I} \circ \mathbf{I})$. The translation ζ of hypersequents with at most single-conclusion components into display sequents is defined by

$$\zeta(s_1 \mid \dots \mid s_n) = \mathbf{I} \rightarrow \zeta_0(s_1) \circ \dots \circ \zeta_0(s_n).$$

THEOREM 80. *For every hypersequent H with at most single-conclusion components, $\vdash \zeta(H)$ in **DLC** iff $\vdash H$ in **GLC**.*

4.3 Predicate logics and other logics

Modal predicate logic is still a largely unexplored area. As to sequent systems for modal predicate logics, one notorious problem is providing introduction rules for the modal operators and the quantifiers such that neither the Barcan formula (BF) $\forall x \Box A \supset \Box \forall x A$ nor its converse (BFc) $\Box \forall x A \supset \forall x \Box A$ are provable on the strength of only these rules. It is well-known that (BF) corresponds to the assumption of constant domains and (BFc) to the persistence of individuals along the accessibility relation; cf. for example [Fitting, 1993]. One way of avoiding the provability of the Barcan formula and its converse is described in [Wansing, 1998, Chapter 12]. The idea is to exploit the well-known similarity between $\Box [\diamond]$ and $\forall x [\exists x]$ to develop display introduction rules for $\forall x [\exists x]$; i.e., instead of thinking of the modal operators as quantifiers, one thinks of the quantifiers as modal operators, see also [Andreka *et al.*, 1998]. The addition of quantifiers to display logic is briefly discussed in [Belnap, 1982]:

Quantifiers may be added with the obvious rules:

$$(UQ) \quad \frac{Aa \vdash X}{(x)Ax \vdash X} \quad \frac{X \vdash Aa}{X \vdash (x)Ax}$$

provided, for the right rule, that a does not occur free in the conclusion. . . . The rule for the existential quantifier would be

dual. ... [A]s yet this addition provides no extra illumination. I think that is because these rules for quantifiers are “structure free” (no structure connectives are involved; ...). One upshot is that adding these quantifiers to modal logic brings along Barcan and its converse ... willy-nilly, which is an indication of an unrefined account; alternatives therefore need investigating. [Belnap, 1982, p. 408 f.]

Using the structure-independent rules (UQ), we would have the following proofs of (BF) and (BFc):

$$\begin{array}{l}
 \frac{A \rightarrow A}{\Box A \rightarrow \bullet A} \text{ (UQ)} \\
 \frac{\Box A \rightarrow \bullet A}{\forall x \Box A \rightarrow \bullet A} \\
 \frac{\forall x \Box A \rightarrow \bullet A}{\bullet \forall x \Box A \rightarrow A} \text{ (UQ)} \\
 \frac{\bullet \forall x \Box A \rightarrow A}{\bullet \forall x \Box A \rightarrow \forall x A} \\
 \frac{\bullet \forall x \Box A \rightarrow \forall x A}{\forall x \Box A \rightarrow \Box \forall x A} \\
 \frac{\forall x \Box A \rightarrow \Box \forall x A}{\mathbf{I} \circ \forall x \Box A \rightarrow \Box \forall x A} \\
 \mathbf{I} \rightarrow \forall x \Box A \supset \Box \forall x A
 \end{array}
 \qquad
 \begin{array}{l}
 \frac{A \rightarrow A}{\forall x A \rightarrow A} \text{ (UQ)} \\
 \frac{\forall x A \rightarrow A}{\Box \forall x A \rightarrow \bullet A} \\
 \frac{\Box \forall x A \rightarrow \bullet A}{\bullet \Box \forall x A \rightarrow A} \\
 \frac{\bullet \Box \forall x A \rightarrow A}{\Box \forall x A \rightarrow \Box A} \text{ (UQ)} \\
 \frac{\Box \forall x A \rightarrow \Box A}{\Box \forall x A \rightarrow \forall x \Box A} \\
 \frac{\Box \forall x A \rightarrow \forall x \Box A}{\mathbf{I} \circ \Box \forall x A \rightarrow \forall x \Box A} \\
 \mathbf{I} \rightarrow \Box \forall x A \supset \forall x \Box A
 \end{array}$$

Structure-dependent introduction rules for $\forall x$ and $\exists x$ are, however, available. For every binary relation \mathcal{R}_x on a non-empty set S of states, we may define the following functions on the powerset of S :

$$\begin{aligned}
 \forall x A &:= \{a \mid \forall b (a\mathcal{R}_x b \Rightarrow b \in A)\}, & \exists x^\checkmark A &:= \{a \mid \exists b (b\mathcal{R}_x a \ \& \ b \in A)\}, \\
 \forall x^\checkmark A &:= \{a \mid \forall b (b\mathcal{R}_x a \Rightarrow b \in A)\}, & \exists x A &:= \{a \mid \exists b (a\mathcal{R}_x b \ \& \ b \in A)\}.
 \end{aligned}$$

We then have

$$\exists x^\checkmark A \subseteq B \text{ iff } A \subseteq \forall x B, \quad \exists x A \subseteq B \text{ iff } A \subseteq \forall x^\checkmark B,$$

and for every individual variable x , we may introduce a structure connective \bullet_x , which in succedent position is to be understood as $\forall x$ and in antecedent position as a backward-looking existential quantifier $\exists x^\checkmark$. Semantically, what is required to account for these quantifiers is a generalization of the Tarskian semantics for first-order logic, see [Andreka *et al.*, 1998]. Let \mathcal{M} be any first-order model and let α, β, \dots range over variable assignments in \mathcal{M} . Tarski’s truth definition for the existential quantifier is:

$$\begin{aligned}
 \mathcal{M} \models \exists x A[\alpha] \text{ iff } & \text{for some assignment } \beta \text{ on } |\mathcal{M}|: \\
 & \alpha =_x \beta \text{ and } \mathcal{M} \models A[\beta],
 \end{aligned}$$

where $\alpha =_x \beta$ means that α and β differ at most with respect to the object assigned to x . In the more general semantics the concrete relations $=_x$ between variable assignments are replaced by abstract binary relations \mathcal{R}_x of ‘variable update’ between ‘states’ $\alpha, \beta, \gamma, \dots$ from a set of states S .

Assuming an interpretation of atoms containing free variables, the truth definition for the existential quantifier becomes:

$$\mathcal{M}, \alpha \models \exists x A \quad \text{iff for some } \beta \in S : \alpha \mathcal{R}_x \beta \text{ and } \mathcal{M}, \beta \models A$$

Thus, to every individual variable x there is associated a transition relation \mathcal{R}_x on states. The resulting minimal predicate logic, **KFOL**, is nothing but the ω -modal version of the minimal normal modal logic **K**. In order to obtain an axiomatization of **KFOL**, one may just take any axiomatic presentation of **K** and replace every occurrence of \diamond and \square by one of $\exists x$ and $\forall x$, respectively. The basic structural rules for the structure connective \bullet_x are:

$$X \rightarrow \bullet_x Y \dashv\vdash \bullet_x X \rightarrow Y.$$

In analogy to the case for \square and \diamond , we obtain the following structure-dependent introduction rules for $\forall x$ and $\exists x$:

$$\begin{array}{ll} (\rightarrow \forall x) & \bullet_x X \rightarrow A \vdash X \rightarrow \forall x A \quad (\rightarrow \exists x) \quad X \rightarrow A \vdash * \bullet_x * X \rightarrow \exists x A \\ (\forall x \rightarrow) & A \rightarrow X \vdash \forall x A \rightarrow \bullet_x X \quad (\exists x \rightarrow) \quad * \bullet_x * A \rightarrow X \vdash \exists x A \rightarrow X \end{array}$$

In addition to these introduction rules we need further structural assumption in order to take care of the necessitation rules in axiomatic presentations of normal modal and tense logics:

$$(MN\bullet_x) \quad \mathbf{I} \rightarrow X \vdash \mathbf{I} \rightarrow \bullet_x X \quad X \rightarrow \mathbf{I} \vdash X \rightarrow \bullet_x \mathbf{I}$$

The structural account of the quantifiers as modal operators blocks the above proofs of (BF) and (BFc). In the presence of additional structural sequent rules, however, these schemata become derivable:

OBSERVATION 81. BF and BFc correspond to the structural rules

$$\text{rBF} \quad X \rightarrow \bullet_x \bullet_x Y \vdash X \rightarrow \bullet_x Y; \quad \text{rBFc} \quad X \rightarrow \bullet_x X \vdash X \rightarrow \bullet_x Y.$$

The apparatus of display logic has also been applied to other extensions of normal modal propositional logic. A result of Kracht concerns the undecidability of decidability of display calculi. Consider the fusion or ‘independent sum’ of **Kf** and **Kf**, i.e. the bimodal logic **Kf** \otimes **Kf** of two functional accessibility relations $\mathcal{R}_1, \mathcal{R}_2$. In this system there are two pairs of modal operators, say, $[1], \langle 1 \rangle$ and $[2], \langle 2 \rangle$ each satisfying the *D* and the *Alt1* axiom schemata. The structural language of sequents for this logic comes with two unary operations \bullet_1 and \bullet_2 satisfying the display equivalence

$$\bullet_i X \rightarrow Y \dashv\vdash X \rightarrow \bullet_i Y,$$

$i = 1, 2$. Clearly, **Kf** \otimes **Kf** has many properly displayable extensions. Using an encoding of Thue-processes into frames of **Kf** \otimes **Kf**, Grefe and Kracht [1996] have proved a theorem about the undecidability of decidability.

THEOREM 82. (Grefe and Kracht) *It is undecidable whether or not a display calculus is decidable.*

According to Kracht, Theorem 82 indicates a serious weakness of display logic. In any case, the theorem provides insight into the expressive power of display logic; it shows that the subformula property and the strong cut-elimination theorem for displayable logics fail to guarantee decidability. Undecidability of the decidability of properly displayable extensions of $\mathbf{Kf} \otimes \mathbf{Kf}$ is a remarkable property of this particular family of bimodal logics, but is *not* a defect of the modal display calculus, at least insofar as the proof of the theorem also shows that it is undecidable whether or not a finite axiomatic calculus is decidable. Would it be desirable to have a proof-theoretic framework in which only decidable logics can be presented? A weakness of display logic is that it does not lend itself easily to obtain decidability proofs. Restall [1998] uses a display presentation to prove, among other things, decidability of certain relevance logics which are not known to have the finite model property. In [Wansing, 1998, Chapter 6] display logic is used to prove decidability of \mathbf{Kf} and deterministic dynamic propositional logic without Kleene star.

Display calculi for logics with relative accessibility relations can be found in [Demri and Goré, 2000] and for nominal tense logics in [Demri and Goré, 1999]. In both cases the calculi are obtained using modal translations.

4.4 Gaggle Theory

The generality of display logic has been highlighted by Restall [1995], who observes a close relation between display logic and J. Michael Dunn's *Gaggle Theory* [1990; 1993; 1995]. The relation between gaggle theory and display logic has also been investigated and worked out by Goré [1998]. A *gaggle* is an algebra $\mathcal{G} = \langle \mathbf{G}, \leq, OP \rangle$, where \leq is a distributive lattice ordering on \mathbf{G} , and OP is a founded family of operations. The latter means that there is an $f \in OP$ such that for every $g \in OP$, f and g satisfy the abstract law of residuation, see Section 3. If one only requires that \leq is a partial order, and every $f \in OP$ has a trace, then \mathcal{G} is said to be a *tonoid*. Restall defines the notion of *mimicing structure*. An n -place logical operation f mimics antecedent structure if there is a possibly complex n -place structure connective \sharp such that the following rules are admissible:

$$\begin{aligned} s = \sharp(A_1, \dots, A_n) \rightarrow X \vdash f(A_1, \dots, A_n) \rightarrow X \\ \mathcal{C}(X_1, A_1) \dots \mathcal{C}(X_n, A_n) \vdash \sharp(A_1, \dots, A_n) \rightarrow f(A_1, \dots, A_n) \end{aligned}$$

where $\sharp(A_1, \dots, A_n)$ is an antecedent part of s , $\mathcal{C}(X_i, A_i) = X_i \rightarrow A_i$, if A_i is an antecedent part of $\sharp(A_1, \dots, A_n)$, and $\mathcal{C}(X_i, A_i) = A_i \rightarrow X_i$, if A_i is a succedent part of $\sharp(A_1, \dots, A_n)$. Dually, f mimics succedent structure

if there is a possibly complex n -place structure connective \sharp such that the following rules are admissible:

$$\begin{aligned} s = X \rightarrow \sharp(A_1, \dots, A_n) \vdash X \rightarrow f(A_1, \dots, A_n) \\ \mathcal{C}(X_1, A_1) \dots \mathcal{C}(X_n, A_n) \vdash f(A_1, \dots, A_n) \rightarrow \sharp(A_1, \dots, A_n) \end{aligned}$$

where $\sharp(A_1, \dots, A_n)$ is a succedent part of s , $\mathcal{C}(X_i, A_i) = X_i \rightarrow A_i$, if A_i is an antecedent part of $\sharp(A_1, \dots, A_n)$, and $\mathcal{C}(X_i, A_i) = A_i \rightarrow X_i$, if A_i is a succedent part of $\sharp(A_1, \dots, A_n)$.

THEOREM 83. (Restall [1995]) *If a logical operation f in a display calculus presentation \mathbf{DA} of a logic Λ mimics structure, then f is a tonoid operator on the Lindenbaum algebra of Λ .*

If every logical operation of \mathbf{DA} mimics structure, mutual provability is a congruence relation and Λ has an algebraic semantics. Dunn's representation theorem for tonoids supplies also a Kripke-style relational semantics.

5 APPENDICES

5.1 Appendix A

The proof of Theorem 23 takes its pattern from the proof of strong normalization for typed λ -calculus (see for instance [Hindley and Seldin, 1986, Appendix 2]) and follows the argument given in [Roorda, 1991, Chapter 2, reprinted in [Troelstra, 1992]]. This proof has been extracted from the proof of strong cut-elimination for classical predicate logic in [Dragalin, 1988, Appendix B]. Suppose that Π is a proof containing an application of cut. A (one-step) reduction of Π is the proof Σ resulting by applying a primitive reduction to a subproof of Π . If Π reduces to Σ , this is denoted by $\Pi > \Sigma$ (or $\Sigma < \Pi$). Π is said to be reducible iff there is a Σ such that $\Pi > \Sigma$.

LEMMA 84. *If a proof cannot be reduced, then it is cut-free.*

Proof. Since the case distinction in the definition of primitive reductions is exhaustive, every proof that contains an application of cut is reducible. ■

DEFINITION 85. We inductively define the set of *inductive* proofs.

- a** Every instantiation of an axiomatic rule is an inductive proof.
- b** If Π ends in an inference *inf* different from cut, and every premise s_i of *inf* has an inductive proof Π_i in Π , then Π is inductive.
- c** $\Pi = \frac{\Pi_1 \quad \Pi_2}{(3)} \text{ cut}$ is inductive, if every Σ such that $\Pi > \Sigma$ is inductive.

LEMMA 86. *If Π is inductive, and $\Pi > \Sigma$, then Σ is inductive.*

Proof. By induction on the construction of Π . If Π is inductive by **a**, then no reduction can be performed. If Π is inductive by **b**, then every reduction on Π takes place in the Π_i 's, which are inductive. Hence, by the induction hypothesis, Σ is inductive due to **b**. If Π is inductive by **c**, then Σ is inductive by definition. ■

DEFINITION 87. Let Π be an inductive proof. The size $ind(\Pi)$ of Π is inductively defined as follows (the clauses correspond to those in the previous definition):

a $ind(\Pi) = 1$;

b $ind(\Pi) = \sum_i ind(\Pi_i) + 1$;

c $ind(\Pi) = \sum_{\Sigma < \Pi} ind(\Sigma) + 1$.

A proof Π is said to be *strongly normalizable* iff every sequence of reductions starting at Π terminates.

LEMMA 88. *Every inductive proof is strongly normalizable.*

Proof. By induction on $ind(\Pi)$. If $ind(\Pi) = 1$, no reduction is feasible. If Π is inductive by **b**, then every reduction is in the premises Π_i , and we can apply the induction hypothesis. If Π is inductive by **c**, then every proof to which Π reduces is inductive and therefore every such proof is strongly normalizable, by the induction hypothesis. But then Π is also strongly normalizable. ■

LEMMA 89. *Let Π be an inductive proof and let inf be the final inference of Π . If $\Pi > \Pi'$ by reducing a proof Π_j of a premise sequent of inf , then $ind(\Pi) > ind(\Pi')$.*

Proof. By induction on $ind(\Pi)$. If $ind(\Pi) = 1$, then Π cannot be reduced. Whence Π is inductive by **b** or **c**. If Π is inductive by **c**, then by definition, $ind(\Pi) > ind(\Pi')$. If Π is inductive by **b**, then Π_j is inductive by definition. If Π_j is inductive by **a**, it cannot be reduced. If Π_j is inductive by **b**, then the reduction of Π_j to Π'_j takes place in the proof of some premise sequent of the final inference of Π_j . By the induction hypothesis, $ind(\Pi_j) > ind(\Pi'_j)$. Hence $ind(\Pi) > ind(\Pi')$. If Π_j is inductive by **c**, then by definition, $ind(\Pi_j) > ind(\Pi'_j)$ and thus $ind(\Pi) > ind(\Pi')$. ■

LEMMA 90. *Suppose Π ends in an application inf of cut, and Π_1 and Π_2 are the proofs of the premises of inf . If Π_1 and Π_2 are inductive, then so is Π .*

Proof. We must show that every $\Sigma < \Pi$ is inductive. For this purpose, we define two complexity measures for Π : $r(\Pi)$, the rank of Π , and $h(\Pi)$, the height of Π . $r(\Pi)$ is the number of symbols in the cut-formula. $h(\Pi)$ is defined by:

$$h(\Pi) = \text{ind}(\Pi_1) + \text{ind}(\Pi_2).$$

We use induction on $r(\Pi)$ and, for fixed rank, induction on $h(\Pi)$.

Case 1. Σ is obtained by reduction in Π_1 or Π_2 , say $\Pi_1 > \Pi'_1$. It follows from Lemma 89 that $\text{ind}(\Pi'_1) < \text{ind}(\Pi_1)$. Then $h(\Sigma) < h(\Pi)$. Since Π_1 and Π_2 are inductive, by Lemma 86, Σ has inductive premises, and by the induction hypothesis for $h(\Pi)$, Σ is inductive.

Case 2. Σ is obtained by reducing *inf*. Then this reduction was either a principal or a parametric move.

Principal move.

Case 1. Since Σ proves one of (1) or (2), Σ is inductive by assumption.

Case 2. Since for every new proof Π' ending in an application of cut, $r(\Pi) > r(\Pi')$, Σ is inductive by the induction hypothesis for $r(\Pi)$.

Parametric move. Suppose A is parametric in the inference ending in (1) (the case for (2) is analogous). If the tree of parametric ancestors of the displayed occurrence of A in (1) contains at most one element A_u that is not parametric in *inf*, we have Figure 1, and we may assume that there is no application of cut on the path from (1) to $Z \rightarrow A$.

$$\text{Let } \Pi' = \frac{\frac{\Pi^1}{Z \rightarrow A} \quad \Pi_2}{Z \rightarrow Y} \quad \text{and } \Pi'' = \frac{\Pi^1}{Z \rightarrow A} .$$

Consider Π and Π' . Clearly, $r(\Pi) = r(\Pi')$, hence we use induction on the height. Since both Π_1 and Π'' are inductive by **b**, $\text{ind}(\Pi'') < \text{ind}(\Pi_1)$. Hence $h(\Pi') < h(\Pi)$. By the induction hypothesis for $h(\Pi)$, Π' is inductive, and thus Σ is inductive by definition. If the primitive reduction of Π to Σ requires cutting with Π_2 more than once, analogously every new Π' and hence Σ can be shown to be inductive.

If the tree of parametric ancestors of the displayed occurrence of A in (1) contains *more than one* element A_u that is not parametric in *inf*, $\Sigma = \Pi'^*$ or $\Sigma = \Pi'^{r*}$. Since for every new proof Π' ending in an application of cut, $r(\Pi) > r(\Pi')$, Σ is inductive by the induction hypothesis for $r(\Pi)$. ■

COROLLARY 91. *Every proof is inductive.*

Now Theorem 23 follows by Lemma 88 and Corollary 91, and cut is an admissible rule by Lemma 84.

5.2 Appendix B

To prove completeness of **HIntKt** with respect to the class of all temporal models we shall adopt completely standard methods as applied, for example, in [Schütte 1969, pp. 48–51]. Suppose Δ and Γ are finite sets of formulas, where Γ is empty or a singleton, and let p be a new propositional variable not already in *Atom*. The formula $\Delta \triangleright \Gamma$ is defined as follows:

$$\Delta \triangleright \Gamma = \begin{cases} \bigwedge \Delta \triangleright B & \text{if } \Delta \neq \emptyset, \Gamma = \{B\} \\ \mathbf{t} \triangleright B & \text{if } \Delta = \emptyset, \Gamma = \{B\} \\ \bigwedge \Delta \triangleright p & \text{if } \Delta \neq \emptyset, \Gamma = \emptyset \\ \mathbf{t} \triangleright p & \text{if } \Delta = \Gamma = \emptyset \end{cases}$$

The pair (Δ, Γ) is said to be consistent if $\Delta \triangleright \Gamma$ is unprovable in **HIntKt** based on $\mathcal{L}^+ = \mathcal{L} \cup \{p\}$. In what follows, let $A \in \mathcal{L}$. Let $\text{sub}(A)$ denote the finite set of all subformulas of A . If $C = (A_1 \triangleright \dots (A_{n-1} \triangleright A_n) \dots)$, then $\text{sub}^*(\{C\}) = (\bigcup_{1 \leq i \leq n} \text{sub}(A_i)) \setminus \{p\}$; $\text{sub}^*(\emptyset) = \emptyset$. The pair (Δ, Γ) is called *A*-complete, if $\Delta \cup \text{sub}^*(\Gamma) = \text{sub}(A)$. A pair (Δ^*, Γ^*) is called an expansion of (Δ, Γ) , if Δ^* is a finite superset of Δ , and either $\Gamma^* = \Gamma$ or Γ^* has the shape $(A_1 \triangleright \dots (A_{n-1} \triangleright A_n) \dots)$ and $n > 1$.

LEMMA 92. *If (Δ, Γ) is consistent, then so is $(\Delta \cup \{A\}, \Gamma)$ or $(\Delta, \{A \triangleright B\})$, where $B = p$ if $\Gamma = \emptyset$, and $\Gamma = \{B\}$ otherwise.*

Proof. Suppose neither $(\Delta \cup \{A\}, \Gamma)$ nor $(\Delta, \{A \triangleright B\})$ are consistent. Then both $(\bigwedge \Delta \wedge A) \triangleright B$ and $\bigwedge \Delta \triangleright (A \triangleright B)$ are derivable in **HIntKt** based on \mathcal{L}^+ . But then also $\bigwedge \Delta \triangleright B$ is derivable, and hence (Δ, Γ) is not consistent; a contradiction. ■

COROLLARY 93. *Every consistent pair (Δ, Γ) such that $\Delta, \text{sub}^*(\Gamma) \subseteq \text{sub}(A)$ can be expanded to an *A*-complete consistent pair.*

Let $\Delta \subseteq \text{sub}(A)$. Then Δ is said to be *A*-designated, if some *A*-complete pair (Δ, Γ) , where $\text{sub}^*(\Gamma) = \text{sub}(A) \setminus \Delta$ is consistent. By soundness of **HIntKt** based on \mathcal{L}^+ , the formula $\mathbf{t} \triangleright p$ fails to be provable. Therefore (\emptyset, \emptyset) is consistent. By the previous corollary, for every formula A , (\emptyset, \emptyset) can be expanded to an *A*-complete consistent pair. Hence, for every A , the set $\mathcal{D}(A)$ of all *A*-designated subsets of $\text{sub}(A)$ is non-empty.

LEMMA 94. *If $C \in \text{sub}(A)$, then C belongs to an *A*-designated set Δ iff $\Delta \triangleright \{C\}$ is provable in **HIntKt**.*

Proof. If $C \in \Delta$, then clearly $\Delta \triangleright \{C\}$ is provable in **HIntKt**. If $C \notin \Delta$, then $C \in \text{sub}(A) \setminus \Delta$, and since Δ is *A*-designated, $(\Delta, \{C\})$ is consistent. In other words, $\Delta \triangleright \{C\}$ is not provable in **HIntKt**. ■

DEFINITION 95. For every formula A , the structure $\mathcal{M}^A = \langle W^A, R_I^A, R_T^A, v^A \rangle$ is called the canonical model for A if

$$\begin{aligned} W^A &= \mathcal{D}(A) \\ R_I^A &= \subseteq \\ uR_T^A t &\text{ iff } [F]B \in u \text{ implies } B \in t \\ v^A(p, u) = 1 &\text{ iff } p \in u. \end{aligned}$$

As we have seen, the set W^A is non-empty, and it can easily be shown that \mathcal{M}^A is indeed a temporal model.

LEMMA 96. *Let $u, t \in \mathcal{D}(A)$. For every formula B , ($[F]B \in u$ implies $B \in t$) iff for every formula C , ($C \in u$ implies $\langle P \rangle C \in t$).*

Proof. First, suppose (i) for all B , $[F]B \in u$ implies $B \in t$ but (ii) there is a formula $C \in u$ such that $\langle P \rangle C \notin t$. By (i), $[F]\langle P \rangle C \notin u$. By the previous lemma, $u \triangleright [F]\langle P \rangle C$ is not provable in **HintKt**. Since $C \triangleright [F]\langle P \rangle C$ is provable, also $u \triangleright C$ fails to be provable. But then, by the previous lemma, $C \notin u$, which contradicts (ii). Suppose now (iii) for all C , $C \in u$ implies $\langle P \rangle C \in t$ but (iv) there is a formula $[F]B \in u$ such that $B \notin t$. By (iii), $\langle P \rangle [F]B \in t$, and by the previous lemma, $t \triangleright \langle P \rangle [F]B$ is provable in **HintKt**. Since $\langle P \rangle [F]B \triangleright B$ is provable, also $t \triangleright B$ is provable. Hence $B \in t$, a contradiction with (iv). \blacksquare

LEMMA 97. (Verification Lemma) *Consider $\mathcal{M}^A = \langle W^A, R_I^A, R_T^A, v^A \rangle$. For every $C \in \text{sub}(A)$ and every $u \in \mathcal{D}(A)$, $\mathcal{M}^A, u \models C$ iff $C \in u$.*

Proof. By induction on C . We shall consider only two cases. Let $\bigwedge u$ denote t , if $u = \emptyset$, and note that for all $B \in u$, $\vdash \langle P \rangle \bigwedge u \triangleright \langle P \rangle B$. Hence for every $u, t \in W^A$ we have: (*) if $\langle P \rangle \bigwedge u \in t$, then for every $B \in u$, $\langle P \rangle B \in t$.

1. $C = [F]B$.

\Rightarrow : Suppose $[F]B \notin u$. This is the case iff

$$\begin{aligned} &\bigwedge u \triangleright [F]B \text{ cannot be proved} \\ \text{iff} &\quad \langle P \rangle \bigwedge u \triangleright B \text{ cannot be proved} \\ \text{iff} &\quad (\langle P \rangle \bigwedge u, \{B\}) \text{ is consistent} \\ \text{iff} &\quad (\exists t \in \mathcal{D}(A)) u \subseteq t, \langle P \rangle \bigwedge u \in t, B \notin t \quad \text{by Corollary 93} \\ \text{only if} &\quad (\exists t \in \mathcal{D}(A)) uR_T^A t, B \notin t \quad \text{by Lemma 96 and (*)} \\ \text{iff} &\quad \mathcal{M}, u \not\models [F]B \quad \text{by the ind. hyp.} \end{aligned}$$

\Leftarrow : Suppose $[F]B \in u$. Then for all $t \in W^A$, $uR_T^A t$ implies $B \in t$. By the induction hypothesis, $\mathcal{M}^c, u \models [F]B$.

2. $C = \langle P \rangle B$.

\Rightarrow : Suppose $\mathcal{M}^A, u \models \langle P \rangle B$. This is the case iff

only if $(\exists t \in W^A) tR_T^A u$ and $\mathcal{M}^A, t \models B$
 $(\exists t \in W^A) (B \in t \text{ implies } \langle P \rangle B \in u), B \in t$ by Lem. 96,
 ind. hyp.
 only if $\langle P \rangle B \in u$.

\Leftarrow : Suppose $\langle P \rangle B \in u$. Put $t' := \{C \mid \langle P \rangle C \in u\}$. Clearly, the pair (t', \emptyset) is consistent. Hence

only if $(\exists t \in W^A) t' \subseteq t, \bigwedge t' \in t$ by Corollary 85
 $(\exists t \in W^A) tR_T^A u$ and $\mathcal{M}^A, t \models B$ by Lemma 88 and the
 ind. hyp.
 iff $\mathcal{M}^A, u \models \langle P \rangle B$

■

COROLLARY 98. *If A is valid in every temporal model, then A is provable in **HIntKt**.*

Proof. Suppose A is not provable in **HIntKt**. Then the pair $(\emptyset, \{A\})$ is consistent, and, by the previous corollary, there exists a $u \in \mathcal{D}(A)$ such that $A \notin u$. By the Verification Lemma, $\mathcal{M}^A, u \not\models A$. ■

COROLLARY 99. **HIntKt** is decidable.

Proof. This follows easily by the fact that $sub(A)$ is finite. ■

5.3 Appendix C

In order to prove strong normalization for λ_t , we shall follow R. de Vrijer's [1987] proof of strong normalization for typed λ -calculus with pairing and projections satisfying surjective pairing. Let $h(M)$ (the height of the reduction tree of M) be the length of a reduction sequence of M that has maximal length.

DEFINITION 100. $M^A \in Term$ is said to be computable iff

1. $sn(M)$;
2. if $A = B \triangleright C$, $M \rightarrow_r N_1$, and N_2^B is computable, then $(N_1, N_2)^C$ is computable;
3. if $A = B \wedge C$ and $M \rightarrow_r \langle N_1, N_2 \rangle$, then N_1^B, N_2^C are computable;
4. if $A = [F]B$ and $M \rightarrow_r \mathcal{P}N$, then N^B is computable;
5. if $A = \langle P \rangle B$ and $M \rightarrow_r \mathcal{S}N$, then N^B is computable.

The set of all computable terms is denoted by \mathbf{C} .

By this definition, every computable term is strongly normalizable. The aim is to show that every term is computable.

LEMMA 101.

- (a) If $M \in \mathbf{C}$ and $M \rightarrow_r N$, then $N \in \mathbf{C}$.
- (b) \mathbf{C} is closed under repeated formation of application terms (M, N) .
- (c) If $x \in V$, then $x \in \mathbf{C}$.
- (d) If for every $N^A \in \mathbf{C}$, $(M^{(A \triangleright B)}, N) \in \mathbf{C}$, then $M \in \mathbf{C}$.
- (e) If $(M^{A \wedge B})_0 \in \mathbf{C}$ and $(M^{A \wedge B})_1 \in \mathbf{C}$, then $M \in \mathbf{C}$.
- (f) If $N_1, N_2 \in \mathbf{C}$, and $G \in \mathbf{C}$, for every G such that $\langle N_1, N_2 \rangle \rightarrow_r G$, then $\langle N_1, N_2 \rangle \in \mathbf{C}$.
- (g) If $N \in \mathbf{C}$ and $G \in \mathbf{C}$, for all G such that $(N)_i \rightarrow_r G$, then $(N)_i \in \mathbf{C}$.
- (h) If $N \in \mathbf{C}$, and $G \in \mathbf{C}$, for all G such that $\mathcal{P}N \rightarrow_r G$, then $\mathcal{P}N \in \mathbf{C}$.
- (i) If $N \in \mathbf{C}$, and $G \in \mathbf{C}$, for all G such that $\mathcal{S}N \rightarrow_r G$, then $\mathcal{S}N \in \mathbf{C}$.
- (j) If $N \in \mathbf{C}$, and $G \in \mathbf{C}$, for all G such that $\cup N \rightarrow_r G$, then $\cup N \in \mathbf{C}$.
- (k) If $N \in \mathbf{C}$, and $G \in \mathbf{C}$, for all G such that $\cap N \rightarrow_r G$, then $\cap N \in \mathbf{C}$.

Proof. (a): By induction on $h(M)$. (b) By reflexivity of \rightarrow_r and Clause 2 in the definition of \mathbf{C} . (c): By induction on $A \in T$. If $A = B \triangleright C$, the claim follows by (b). (d): If for every $N^A \in \mathbf{C}$, $(M, N) \in \mathbf{C}$, then $sn(M)$, since by (c) and the assumption $(M, x^B) \in \mathbf{C}$. Now suppose $M \rightarrow_r N_1, N_2 \in \mathbf{C}$, and for every N , $(M, N) \in \mathbf{C}$. Then $(M, N_2) \rightarrow (N_1, N_2)$ and, by (a), $(N_1, N_2) \in \mathbf{C}$. Thus $M \in \mathbf{C}$. (e): Since $sn((M)_i)$, also $sn(M)$. Suppose $M \rightarrow_r \langle N_0, N_1 \rangle$. Then $(M)_i \rightarrow_r ((N_0, N_1))_i \rightarrow_r N_i$. Since $(M)_i \in \mathbf{C}$ and \mathbf{C} is closed under \rightarrow_r , also $N_i \in \mathbf{C}$. (f): Obviously, for every M , $sn(M)$ iff $sn(N)$, for each N such that $M \rightarrow_r N$. Moreover, suppose that $\langle N_1, N_2 \rangle \rightarrow_r \langle G_1, G_2 \rangle$. This is the case iff $\langle N_1, N_2 \rangle \equiv \langle G_1, G_2 \rangle$ or there is a term M^* such that $\langle N_1, N_2 \rangle \rightarrow_r M^*$, and $M^* \rightarrow_r \langle G_1, G_2 \rangle$. In both cases $G_1, G_2 \in \mathbf{C}$. (g): By induction on the type A of $(N)_i$. If A is atomic, Clauses 2–5 in the definition of \mathbf{C} hold trivially. $A = \langle P \rangle B$: Suppose $(N)_i \rightarrow_r SM$. If $N \equiv \langle M_1, M_2 \rangle$, then $(N)_i \rightarrow_r M_i$, and $M_i \in \mathbf{C}$. If $SM \neq M_i$, then $M_i \rightarrow_r SM$, and $SM \in \mathbf{C}$, by closure of \mathbf{C} under \rightarrow_r . If $N \not\equiv \langle M_1, M_2 \rangle$, then there is a term $M^* \in \mathbf{C}$ such that $(N)_i \rightarrow_r M^*$ and $M^* \rightarrow_r SM$. In each subcase, $M \in \mathbf{C}$. The cases $A = [F]B$ and $A = B \wedge C$ are analogous. If $A = B \triangleright C$, we may use closure of \mathbf{C} under application. (h): Suppose $\mathcal{P}N \rightarrow_r \mathcal{P}G$. This holds iff $N \equiv G$ or there is a term M^* such that $\mathcal{P}N \rightarrow_r M^*$ and $M^* \rightarrow_r \mathcal{P}G$. In both cases $G \in \mathbf{C}$. (i): Analogous to (h). (j): By induction

on the type A of $\cup N$. The only interesting case is $A = [F]B$. Suppose $\cup N \rightarrow_r \mathcal{P}M$. If $N \equiv \mathcal{P}N_1$, then $\cup N \rightarrow_r N_1$ and $N_1 \in \mathbf{C}$. If $\mathcal{P}M \not\equiv \mathcal{P}N_1$, then $N_1 \rightarrow_r \mathcal{P}M$, and $\mathcal{P}M \in \mathbf{C}$. In each case $M \in \mathbf{C}$. (k): Analogous to (j). ■

THEOREM 102. *If $M \in \text{Term}$ is λ -free, then $M \in \mathbf{C}$.*

Proof. By induction on M . (1): M is a variable: Lemma 101 (c). (2) $M \equiv \langle N_1, N_2 \rangle$: Lemma 101 (b) and the induction hypothesis. (3) $M \equiv \langle N_1^A, N_2^B \rangle$: In view of Lemma 101 (f), it is enough to show that $G \in \mathbf{C}$, for every G such that $\langle N_1, N_2 \rangle \rightarrow_r G$. There are two subcases. (i): $N_1 \equiv (G)_0$ and $N_2 \equiv (G)_1$. Then the claim follows by (e). (ii): $G \equiv \langle N_1, N^* \rangle$ and $N_2 \rightarrow_r N^*$ or $G \equiv \langle M^*, N_2 \rangle$ and $N_1 \rightarrow_r M^*$. We may use induction on $h(N_1) + h(N_2)$. (4) $M \equiv (N)_i$. In view of Lemma 101 (g), it is enough to show that $G \in \mathbf{C}$, for every G such that $M \rightarrow_r G$. There are two cases. (i) $N \equiv \langle N_0, N_1 \rangle$ and $G \equiv N_i$. Then we may use the induction hypothesis. (ii) $G \equiv (N^*)_i$, $N \rightarrow_r N^*$, and we may use induction on $h(N)$. (5) $M \equiv \mathcal{P}N$: In view of Lemma 101 (h), it is enough to show that $G \in \mathbf{C}$, for every G such that $M \rightarrow_r G$. If $M \rightarrow_r G$, then $G \equiv \mathcal{P}N^*$, $N \rightarrow_r N^*$, and we may use induction on $h(N)$. (6) $M \equiv \mathcal{S}N$: Analogous to (5), using Lemma 101 (i). (7) $M \equiv \cap N$: Given Lemma 101 (k), it suffices to show that $G \in \mathbf{C}$, for every G such that $M \rightarrow_r G$. There are two cases. (i) $N \equiv \mathcal{S}G_1$ and $G \equiv G_1$. Then we may use the induction hypothesis. (ii) $G \equiv \cap N^*$, $N \rightarrow_r N^*$, and we may use induction on $h(N)$. (8) $M \equiv \cup N$: Analogous to (7), using Lemma 101 (j). ■

Strong normalizability of all terms is derived from computability of all terms under substitution.

DEFINITION 103. $M^A \in \text{Term}$ is said to be computable under substitution iff any substitution of free variables in M by computable terms of suitable type results in a computable term.

Let \mathbf{C}^s denote the set of all terms computable under substitution.

THEOREM 104. *Every λ_t -term M is computable under substitution.*

Proof. By induction on M . For term variables the claim is obvious. Moreover, since \mathbf{C} is closed under application, \mathbf{C}^s is also closed under application. If $M \equiv \langle N_1, N_2 \rangle$, $M \equiv (N)_i$, $M \equiv \mathcal{P}N$, or $M \equiv \mathcal{S}N$, the claim follows by the induction hypothesis. If $M \equiv \lambda x^A N$, it must be shown that $\lambda x N \in \mathbf{C}^s$ if $N \in \mathbf{C}^s$. Suppose that $\lambda x N^*$ is the result of substituting a computable term for a free variable in $\lambda x N$, and suppose that G^A is a computable term such that (M, G) does not have a type $B \triangleright C$. Then, by Lemma 101 (f) – (k), $((\lambda x N^*)G) \in \mathbf{C}$, if for every term H , $((\lambda x N^*)G) \rightarrow_r H$ implies $H \in \mathbf{C}$. Since by assumption $N \in \mathbf{C}^s$, we have $N^* \in \mathbf{C}$. Therefore we may use induction on $h(N^*) + h(G)$ to show that $((\lambda x N^*)G) \in \mathbf{C}$. There are three

Figure 2. Normalization as a homomorphic image of proof-simplification.

subcases. (i) $H \equiv N^*[x := G]$ and $x \in fv(N^*)$. Then $N^* \in C^*$ implies $H \in C$. (ii) $H \equiv N^*[x := G]$ and $x \notin fv(N^*)$. Then $H \equiv N^* \in C$. (iii) H is obtained from $((\lambda x N^*)G)$ by executing one reduction step either in N^* or G . In this case we may use the induction hypothesis. ■

COROLLARY 105. *If M is a λ_t -term, then M is strongly normalizable.*

5.4 Appendix D

It has to be shown that f is a homomorphism from \mathcal{A} to \mathcal{B} , i.e., for every $\Pi \in \Pi^+ \mathbf{DIntKt}$, we have $f(\mathit{elim}(\Pi)) = \mathit{norm}(f(\Pi))$, see Figure 2. The proof is by induction on Π . If the rule applied to obtain the conclusion sequent s_c of Π is an axiomatic sequent $A \rightarrow A$, then $f(\mathit{elim}(\Pi)) = f(\Pi)$, and $f(\Pi)$ is a nf . If the rule applied to obtain s_c is such that the term construction step associated with it cannot generate a redex, we may apply the induction hypothesis. We shall consider the remaining cases.

$$\text{Case 1. } \Pi = \frac{\Pi' \quad A \times B \rightarrow X}{A \wedge B \rightarrow X}$$

A redex could be generated if the free variables x^A, y^B in the construction of $A \times B \rightarrow X$ occur in the context $\langle x, y \rangle$. But then $X = A \wedge B$, $A \times B \rightarrow X$ has been derived from $\{A \rightarrow A, B \rightarrow B\}$, and $\mathit{elim}(\Pi) = A \wedge B \rightarrow A \wedge B$. The claim holds, since $\langle (v_1^{A \wedge B})_0, (v_1^{A \wedge B})_1 \rangle \rightarrow_r v_1^{A \wedge B}$.

$$\text{Case 2. } \Pi = \frac{\Pi' \quad X \rightarrow A \times B}{X \rightarrow A \triangleright B}$$

A redex could be generated if the free variable x^A in the construction of $X \rightarrow A \times B$ occurs in the context $(N^{A \triangleright B}, x^A)$. But then $X = A \triangleright B$,

$X \rightarrow A \times B$ has been derived from $\{A \rightarrow A, B \rightarrow B\}$, and $\text{elim}(\Pi) = A \triangleright B \rightarrow A \triangleright B$. The claim holds, since $\lambda v_1^A(v_1^{A \triangleright B}, v_1^A) \rightarrow_r v_1^{A \triangleright B}$.

$$\text{Case 3. } \Pi = \frac{\frac{\Pi_1 \quad \Pi_2}{X \rightarrow A \quad A \rightarrow Y}}{X \rightarrow Y}$$

Suppose the exhibited application of cut in Π is not principal. If this application is reduced in one step, either the f -images of the resulting proof and Π are the same, or some principal cuts have been performed on subformulas of A . Thus, there are five remaining cases to be considered.

Case 3.1 (t):

$$\begin{array}{ccc} \frac{\frac{\Pi}{\frac{\frac{\mathbf{I} \rightarrow X}{\mathbf{I} \rightarrow t} \quad t \rightarrow X}}{\mathbf{I} \rightarrow X}} & \text{is converted into} & \frac{\Pi}{\mathbf{I} \rightarrow X} \\ \downarrow f & & \downarrow f \\ \frac{\frac{M}{v_1^t} \quad M}{M} & \rightarrow_r & M \end{array}$$

Case 3.2 (\wedge):

$$\begin{array}{ccc} \frac{\frac{\frac{\Pi_1 \quad \Pi_2}{X \rightarrow A \quad Y \rightarrow B} \quad \frac{\Pi_3}{A \wedge B \rightarrow Z}}{X \times Y \rightarrow A \wedge B} \quad \frac{A \wedge B \rightarrow Z}{A \wedge B \rightarrow Z}}{X \times Y \rightarrow Z} & \text{is conv. into} & \frac{\frac{\frac{\Pi_1 \quad \frac{\Pi_3}{A \times B \rightarrow Z}}{X \rightarrow A \quad A \rightarrow B \times Z}}{X \rightarrow B \times Z} \quad \frac{\Pi_2}{Y \rightarrow B}}{Y \rightarrow X \times Z} \quad \frac{B \rightarrow X \times Z}{B \rightarrow X \times Z}}{X \times Y \rightarrow Z} \\ \downarrow f & & \downarrow f \\ \frac{\frac{M_1^A \quad M_2^B}{\langle M_1, M_2 \rangle} \quad \frac{N(x^A, y^B)}{N((z^{A \wedge B})_0, (z^{A \wedge B})_1)}}{N(\langle \langle M_1, M_2 \rangle \rangle_0, \langle \langle M_1, M_2 \rangle \rangle_1)} & \rightarrow_r & \frac{\frac{M_1^A \quad \frac{N(x^A, y^B)}{N}}{N(M_1)} \quad \frac{M_2^B \quad N(M_1)}{N(M_1, M_2)}}{N(M_1, M_2)} \end{array}$$

Case 3.3 (\triangleright):

$$\begin{array}{ccc}
\frac{\frac{\Pi_1}{X \rightarrow A \times B} \quad \frac{\frac{\Pi_2}{Y \rightarrow A} \quad \frac{\Pi_3}{B \rightarrow Z}}{A \triangleright B \rightarrow Y \times Z}}{X \rightarrow Y \times Z} & \text{is conv. into} & \frac{\frac{\frac{\Pi_1}{X \rightarrow A \times B} \quad \frac{\Pi_3}{B \rightarrow Z}}{X \times A \rightarrow B} \quad \frac{\Pi_2}{Y \rightarrow A}}{X \times A \rightarrow Z} \\
\downarrow f & & \downarrow f \\
\frac{\frac{\frac{M^B(x^A)}{\lambda x^A M} \quad \frac{N_1^A \quad N_2(y^B)}{N_2(z^A \triangleright B), N_1}}{N_2(\lambda x^A M, N_1)}}{\rightarrow_r} & & \frac{\frac{\frac{M^B(x^A)}{M^B} \quad \frac{N_2(y^B)}{N_2(M)}}{N_2(M)} \quad \frac{N_1^A \quad \frac{N_2(M(x^A))}{N_2(M(N_1))}}{N_2(M(N_1))}}{N_2(M(N_1))}
\end{array}$$

Case 3.4 ($[F]$):

$$\begin{array}{ccc}
\frac{\frac{\Pi_1}{\bullet X \rightarrow A} \quad \frac{\Pi_2}{A \rightarrow Y}}{\frac{X \rightarrow [F]A \quad [F]A \rightarrow \bullet Y}{X \rightarrow \bullet Y}} & \text{is converted into} & \frac{\frac{\Pi_1}{\bullet X \rightarrow A} \quad \frac{\Pi_2}{A \rightarrow Y}}{\frac{\bullet X \rightarrow Y}{X \rightarrow \bullet Y}} \\
\downarrow f & & \downarrow f \\
\frac{\frac{M^A}{\mathcal{P}M} \quad \frac{N(x^A)}{N(\cup y[F]A)}}{N(\cup \mathcal{P}M)} & \rightarrow_r & \frac{\frac{M^A}{N(M)} \quad \frac{N(x^A)}{N(M)}}{N(M)}
\end{array}$$

Case 3.5 ($\langle P \rangle$): analogous to the previous case. ■

ACKNOWLEDGEMENT

I would like to thank Dov Gabbay for inviting me to contribute this chapter to the Second Edition of the Handbook of Philosophical Logic.

LENNART ÅQVIST

DEONTIC LOGIC

I. INTRODUCTION

1 THE PROTAGORAS PARADOX: AN EXERCISE IN ELEMENTARY LOGIC FOR LAWYERS AND MORALISTS

An ancient paradox is about the famous Greek law teacher Protagoras and goes like this: Protagoras and Euathlus agree that the former is to instruct the latter in rhetoric and is to receive a certain fee which is to be paid *if and only if* Euathlus wins his first court-case (in some versions: *as soon as* he has won his first case). Well, Euathlus completed his course but did not take any law cases. Some time elapsed and Protagoras sued his student for the sum. The following arguments were presented to the judge in court.

Protagoras: If I win this case, then Euathlus has to pay me by virtue of your verdict. On the other hand, if he wins the case, then he will win his first case, hence he has to pay me, this time by virtue of our agreement. In either case, he has to pay me. Therefore, he is obliged to pay me my fee.

Euathlus: If I win this case, then, by your verdict, I don't have to pay. If, however, Protagoras wins the case, then I will not yet have won my first case, so, by our agreement, I don't have to pay. Hence I am not obliged to pay the fee.

Let us now raise two questions:

Who was right?

Could deontic logic, in the sense of the logical theory of norms and normative systems, be helpful in providing a solution to this problem, or kind of problem?

In this chapter we shall not attempt to answer the first question, but just refer the reader to the attempts made by Lenzen [1977], Smullyan [1978] and Åqvist [1981]. But we shall indeed argue for an affirmative answer to the second question, agreeing with the following statement made by Bertrand Russell in 'On Denoting':

A logical theory may be tested by its capacity for dealing with puzzles, and it is a whole-some plan, in thinking about logic, to stock the mind with as many puzzles as possible, since these serve much the same purpose as is served by experiments in physical science.

As we shall see in Section 9 below, however, our affirmative answer will have to be carefully qualified as a result of the examination we undertake

in Part II of a number of paradoxes and dilemmas that have beset recent developments in deontic logic in the last thirty years. First of all, though, let us have a somewhat closer look at the subject as it stands nowadays.

2 THE IMPORTANCE OF VON WRIGHT'S AND ANDERSON'S WORK

What is deontic logic? It is tempting to answer with Rescher [1966], *à propos* the closely related area of the logic of imperatives and commands, that it is a field with the property that there is virtually no single issue in it upon which a settled consensus has been reached. Resisting that temptation, though, we say that deontic logic, broadly conceived, is the logical study of the normative use of language and that its subject matter is a variety of normative concepts, notably those of *obligation* (prescription), *prohibition* (forbiddance), *permission* and *commitment*. The first one among these concepts is often expressed by such words as 'shall', 'ought' and 'must', the second by 'shall not', 'ought not' and 'must not', and the third one by 'may'; the fourth notion amounts to an idea of *conditional obligation*, expressible by 'if..., then it shall (ought, must) be the case that ___'.

A powerful trend of research in the area was initiated by the famous contribution of Von Wright [1951], where the formal properties of *monadic* ('unconditional', 'absolute') normative concepts were systematically explored. Certain paradoxical results were seen to arise in Von Wright's monadic deontic logic, however, which led him to propose systems for and permission *dyadic* ('conditional', 'relative') normative concepts, where the notions of obligation, permission etc. are made relative to, or conditional on, certain circumstances. Thus, the dyadic deontic logic of Von Wright [1956] was proposed as a reaction to the Prior [1954] paradoxes of commitment ('derived obligation'), and that of Von Wright [1964; 1965] as a reaction to the Chisholm [1963] contrary-to-duty imperative paradox. One major problem-area, with which we shall deal in this chapter, concerns the mathematical structure and interpretation of the Von Wright-type deontic logics just mentioned, whether they be of the monadic kind or the dyadic one.

In Anderson [1956] the author interestingly argued that the study of normative concepts undertaken by deontic logic could profit a good deal from our considering their behavior in the context of *normative systems*, like systems of ethics (moral theories) and systems of positive law. He then, naturally, noticed and emphasized the role played by *sanctions* or *penalties* in actual normative systems, and went on to *define* the deontic or normative notions of obligation, forbiddance etc. along the following lines: letting S be a constant proposition, describing a situation which will count as a penalty or sanction relatively to the normative system under investigation, we say that a state-of-affairs p is obligatory if and only if (iff) the absence

of p entails the sanction S ; that p is forbidden iff p (itself) entails the sanction S ; and that p is permitted iff it is possible that p obtains without the sanction S being realized. (For graphic pictures of essentially these definitions, in the style of traditional ‘squares of opposition’, see Anderson [1968] and Åqvist [1987, Section 5.3].) Anderson [1956; 1958] then sets out to add these definitions to various systems of alethic modal logic (i.e. the logic of ‘ordinary’ necessity and possibility), whereby he achieves a kind of *reduction of monadic* deontic logic to alethic modal logic, provided only that the alethic system is supplemented with the constant S and (possibly) with some axiom governing S . Anderson [1956; 1959] also suggests a definition in terms of S and alethic modal notions of the *dyadic* concept of commitment.

A second major problem-area which will occupy us in the present work, concerns the mathematical structure and interpretation of Anderson-style systems of alethic modal logic with a propositional constant added to their basic machinery. Also, we shall be highly interested in the relation of such Anderson-style systems to Von Wright-type deontic logics of the two sorts mentioned above.

Let me now briefly say something about the current state of the subject of deontic logic. I think it is only fair to claim with Von Wright [1977] (his introduction to the proceedings of the international and interdisciplinary Bielefeld Colloquium in March 1975 — presumably the first one of its kind) that the widespread and intense interest aroused by deontic logic indicates that we have to deal with a new logical discipline, which has come to stay and is not just ‘*eine vorübergehende Erscheinung*’. On the other hand, he points out, it is still a relatively poorly developed branch of exact research for the following reasons:

- (i) The number of open problems is very big.
- (ii) There is a good deal of controversy and disagreement about fundamental matters in the area, e.g. about the interpretation and the validity of its basic principles.
- (iii) The high expectations as to the applicability of deontic logic to actual and potential normative systems, notably in the areas of ethics and legal theory, can hardly be said to have been satisfied to more than a very slight and modest degree.

The energy and dedication with which Von Wright himself has, since the ‘fifties, labored to improve and refine on his originally proposed systems, bear out conclusions (i) and (ii) very clearly in my opinion. And there is no doubt that the optimism in regard to applications — so characteristic of Anderson — has turned into pessimism.

My third main concern in this chapter will then be to do something to remove that pessimism. Suppose we want to achieve a *logical* analysis [Oppenheim, 1944] or a *rational reconstruction* [Wedberg, 1951] of some system

of positive law, say, some relevant part of any existing commercial or criminal code. It is then clear that the languages of the current systems of deontic logic, which we will encounter below, are almost totally inadequate for the formulation of even very simple rules of the system. A main reason for this being so is that these languages are just propositional and thus lack quantificational resources of expression. What is even worse, they lack explicit *temporal* resources, which fact makes them especially useless from the legal point of view. In Section 9 below, we follow Van Eck [1981] in arguing that, for any serious purposes of application, the expressive resources of deontic languages must be enriched so as to include temporal and quantificational ones. If this is done, the hope of deontic logicians and others concerned to be able to contribute substantively to ethical and legal theory might be regained. Maybe also to a linguistically important branch such as speech act theory.

Let me close this introductory section with a cursory historical note. Suggestions about a logic of normative concepts and sentences (including one for imperatives and commands) may be found in Aristotle, in the Stoics (see Rescher [1966]), in medieval philosophers (see Knuuttila [1981]), in Leibniz, as well as in Bentham and his followers in legal philosophy (see Lindahl [1977]). The first systematic attempt to build a formal theory of normative concepts is due to Mally [1926] (for a nice exposition of Mally's *Deontik*, see Føllesdal and Hilpinen [1971], who also cover later twentieth-century developments in an exemplary way).

3 PLAN OF THIS CHAPTER

The present work can be divided into two. The first deals with certain much-discussed difficulties in connection with the application of formal systems of deontic logic to a natural language such as English (Part II: Paradoxes and Dilemmas), and the other half is devoted to the purely mathematical presentation and elaboration of a number of formal systems of deontic logic (Parts III–VI).

In Part III we deal with ten systems of monadic deontic logic, which go back to the work of Timothy J. Smiley in [1963], to that of William H. Hanson in [1965], and, in the three cases of \mathbf{OM}^+ , $\mathbf{OS4}^+$ and $\mathbf{OS5}^+$, to the mixed alethic-deontic systems \mathbf{OM} , \mathbf{OM}' and \mathbf{OM}'' of Anderson [1956]; among other things, Smiley [1963] proved the three former systems to be identical with the deontic fragments of the three latter ones. The ten Smiley–Hanson systems, as I pertinently call them, are studied both from a *proof-theoretical* or *axiomatic* point of view (Section 10.2) and from that of *model-theoretical* ‘possible worlds’ *semantics* in a sense deriving from Hintikka [1957], Kanger [1957], Montague [1960] and, above all, Kripke [1963] (Section 10.3). In Section 11 we prove the semantic soundness and

completeness of the ten Smiley–Hanson systems, replacing the method of *semantic tableaux* used by Kripke [1963] and Hanson [1965] with the Henkin technique of *maximal consistent* (‘saturated’) sets, as transferred to modal logic by Makinson [1966] (see also Lemmon and Scott [1966]).

In Part IV we introduce ten Anderson-style systems of alethic modal logic with a propositional constant Q , interpreted as the negation of the Andersonian sanction S and due to Kanger [1957]. Each of these systems is supplemented by the famous Anderson-style definitions of monadic deontic operators, expressing *obligation*, *permission* and *prohibition*, respectively:

$$\begin{aligned} OA &= df & \Box(Q \rightarrow A) \\ PA &= df & \Diamond(Q \wedge A) \\ FA &= df & \Box(Q \rightarrow \neg A). \end{aligned}$$

Several of these ‘mixed’ alethic-deontic systems were considered by Smiley [1963], to whom, essentially, we owe what I take to be one of the main mathematical results on propositional monadic deontic logic: the Translation Theorem stated in Theorem 45 and proved (in very broad outline) in the proof thereafter. The gist of that result is that the ten Smiley–Hanson systems are, in the well defined sense of Definition 44, the *deontic fragments* of the corresponding alethic systems, as supplemented with Q and with the above definitions of O , P and F .

In Parts V and VI we try to pursue the very same line of thought in the area of propositional dyadic deontic logic, for which a good deal of motivation was provided in Part II, notably by Prior’s paradoxes of commitment and Chisholm’s contrary-to-duty imperative paradox (Sections 7 and 8). Thus, we are concerned about logics of *conditional obligation* and *permission*, expressed by such dyadic forms as $O_B A$ and $P_B A$ (Section 15), and also about the possibility of *representing* such dyadic logics in systems of alethic modal logic to which a *monadic*, or one-place, Q -connective is added as well as the definitions given in Section 15.1:

$$\begin{aligned} O_B A &= df & \Box(QB \rightarrow A) \\ P_B A &= df & \Diamond(QB \wedge A) \\ F_B A &= df & \Box(QB \rightarrow \neg A). \end{aligned}$$

We are then able, in Part V, to extend the Smileyan Translation Theorem to the following pairs of logical systems:

- (1) $\left. \begin{array}{ll} \mathbf{O}_{dy}\mathbf{S4} & \text{and } \mathbf{S4}_{Qmo} \\ \mathbf{O}_{dy}\mathbf{S5} & \text{and } \mathbf{S5}_{Qmo} \end{array} \right\}$ (Section 16)
- (2) $\mathbf{O}_{dy}\mathbf{S5}^N$ and $\mathbf{S5}_{Qmo}^N$ (Section 17)

where the first member in each pair is a system of (propositional) dyadic deontic logic and where the second one is a (propositional) alethic modal

logic supplemented with the monadic Q -operator and with the above Section 15.1 definitions of dyadic deontic operators.

In Part VI we consider certain axiomatic extensions of the systems $\mathbf{O}_{dy}\mathbf{S5}^N$ (Section 18) and $\mathbf{S5}_{Qmo}^N$ (Section 19). In Section 20 we then obtain a weakened version of the projected Smileyan Translation theorem, but have to leave open the problem of establishing it fully.

In Sections 21–22 we make an attempt to reconstruct and identify three dyadic deontic logics due to Bengt Hansson [1969] on the basis of certain further extensions of the calculi $\mathbf{O}_{dy}\mathbf{S5}^N$ and $\mathbf{S5}_{Qmo}^n$. A highly interesting feature of those extensions is that, in their semantics, we work with an explicitly specified *preference relation* with which we connect the remaining items in the models considered. Again, in Section 23, we deal with the completeness problem for the most important one among the extensions of $\mathbf{O}_{dy}\mathbf{S5}^N$, called the ‘strongly normal’ *core* system \mathbf{G} , and offer a positive solution to that problem. Finally, in three concluding sections (Sections 24–26) we present some further quite recent results on that ‘core’ system \mathbf{G} , which were obtained in Åqvist [1996; 1997].

The idea of basing Dyadic Deontic Logic, or the Logic of Conditional Obligation/Permission, on some kind of *preference* theory was proposed by several writers in the late 1960s and early 1970s. Pioneering contributions are due to Sven Danielsson [1968] and to Bengt Hansson [1969]; of these two, [Hansson, 1969] is more easily accessible from a mathematical standpoint, whence our aforementioned attempt to reconstruct his systems in our own framework. Danielsson’s work is considered in the Appendix of [Åqvist, 1987], where it is compared with that of Bas C. van Fraassen, Franz von Kutschera and David Lewis.

So much for the logical technicalities of various systems of formal deontic logic. Going back to Part II, then, we start out with certain preliminary considerations of the relation between formal languages (like that of the Smiley–Hanson systems of monadic deontic logic) and natural languages such as English. Thus, in Section 5, we explain in some detail how a system of formal deontic logic can be supplemented with *definitions of locutions in ordinary English* in much the same way as systems of alethic modal logic were extended with definitions of deontic modalities by Anderson; e.g. we stipulate the following:

- (D6) It is obligatory that $A = df \quad OA$
 (D7) It is permitted that $A = df \quad PA$
 (D8) You post the letter $= df \quad p$

where p is the first proposition letter in the formal language, which, on the basis of definition-theoretical considerations, we regard as a propositional *constant* and hence as a logical symbol. We then end up with a ‘mixed’ formal-English system which contains, on the basis of the definitions added,

certain expressions that count as reasonably good English sentences. In Section 5.1 and 5.2 we then show how our approach leads to (i) a *fragment* of normative English *generated* by those definitions, and (ii) a *translation* (formalization, symbolization) *of* that fragment *into* the original formal language — a translation which is in an obvious sense *induced* by those definitions. After having generalized these ideas in a straightforward way, we go on to introduce (in Section 5.3) the conception of a natural deontic logic *over* the English fragment just generated; this conception is based on an admittedly vague and imprecise notion of *logical validity (truth)*, which is supposedly applicable to some major part of the English language or, at the very least, to the sentences of the fragment. In Section 5.5 we consider *one* well known attempt to make such an intuitive notion of validity more precise, viz. the so called Bolzano criterion.

The whole argument of the crucially important Section 5 provides a basis for comparing and contrasting our natural deontic logic with systems of formal deontic logic, like the Smiley–Hanson ones. As appears from Section 5.3, such a comparison will, in general, lead to one of two results: *either* (i) the natural deontic logic is ‘perfectly matched’ by the formal one, *or* (ii) it is not so ‘perfectly matched’, because there are ‘clashes’, or ‘discrepancies’ between the two. In turn, such a clash may be of two different kinds, at least (as is explained under (I) and (II) in Section 5.3). All this leads up to the three notions of adequacy and faithful representation defined in Section 5.4. That section and its definitions are the main outcome of the discussion of formalization and translation in Section 5. We regard that preparatory discussion as indispensable to any orderly presentation of the deontic paradoxes: it gives us a framework, viz. *definitional extensions of formal theories*, which enables us to present those paradoxes with a sufficient degree of mathematical precision and, at the same time, is of some independent methodological interest to the study of the connections between natural and formal languages in general.

In Section 6–8 we proceed to an exposition of the familiar puzzles known respectively as Alf Ross’ paradox, Arthur N. Prior’s paradoxes of commitment, and Roderick M. Chisholm’s contrary-to-duty imperative paradox. A vital reason for dealing with the latter two is to show how the idea of dyadic deontic logic, originally proposed by Von Wright [1956], naturally suggests itself in any attempt to overcome them. In Section 9, however, we follow Van Eck [1981] in giving a survey of various problems which, as it seems, cannot be satisfactorily handled on the dyadic approach, nor, for that matter, on the monadic one. In Section 9.2 we diagnose the current state of the subject as a whole by agreeing with Van Eck [1981] that there is an urgent need in the area for explicitly temporal and quantificational resources in the basic languages of workable and useful deontic logics; as far as the latter sort of resources are concerned, the point has been made by quite a few writers, of course, e.g. Anderson [1956, p. 200]. In Section

9.2.1, we comment on a powerful research trend in present-day deontic logic, which combines our subject with the logic of action.

As for problems not dealt with in this essay, but which are nevertheless of a very fundamental nature, let us just mention the following two:

- (i) *The problem of truth-or-falsity of deontic (normative) sentences*: are there any true-or-false deontic sentences, expressing obligations, permissions or prohibitions? If not, why? If yes, what are the conditions under which such sentences are true/false, respectively? The discussion in the early twentieth century of this basic issue led some moral and legal philosophers as well as precursors of modern Von Wright-style deontic logic to emphasize a highly important distinction, which may be found in Bentham and which is nowadays usually credited to Ingemar Hedenius [1941]. So our second problem is:

- (ii) *The problem of explicating formally the Hedenius [1941] distinction between ‘genuine’ and ‘spurious’ deontic sentences*. According to Hedenius [1941], a sentence like ‘You shall not kill!’ normally directly expresses a prohibition against killing and is then a *genuine* deontic sentence. But the very same sentence, when uttered, e.g. by a Swedish lawyer, may well be interpreted as an elliptical formulation for ‘According to Swedish law in 1982 you shall not kill’ and function as a *spurious* deontic sentence, which just *asserts the existence of a norm* prohibiting killing *within* a specified legal *system* (without ‘directly expressing’ that prohibition, as it were). So the present problem concerns the formal explication of the Hedenius genuine vs. spurious distinction. We note here that Wedberg [1951] draws a similar distinction in dividing deontic sentences relatively to a given legal system into such as are *internal* and such as are *external* to the system. Again, Stenius [1963] stresses a *modal vs. factual* distinction applicable to interpretations of normative sentences, Hansson [1969] an analogous *imperative vs. descriptive* one. Finally, Von Wright [1963] distinguishes *norms* from *norm-propositions*.

As a quick reaction to this second problem, I recommend that deontic logicians consider more seriously the scarce attempts in the literature to construct logics of *commanding* as opposed to logics of *commands*, e.g. Fisher [1961a], Hanson [1966] and Bailhache [1981], where authorities and addressees are explicitly brought to the fore. These attempts look very promising indeed for future developments of our subject.

4 ELEMENTARY PROPERTIES OF SOME VON WRIGHT-TYPE DEONTIC LOGICS

In this section we shall first introduce two notions of a *normal* Von Wright-type deontic logic, secondly, comment on our suggested definition of those notions and, thirdly, list some obvious properties of these logics. Consider the formal language of the ten Smiley–Hanson systems of propositional monadic deontic logic studied in Parts III and IV below. Its set Σ of we formed *sentences* is defined as the smallest set which (i) has every proposition letter as an element, and (ii) is closed under the usual truth-functional connectives including the constants *verum* and *falsum* as well as under the two primitive monadic deontic operators **O** (for obligation) and **P** (for permission). We then propose the following:

DEFINITION 1.

Let \mathcal{L} be any subset of Σ . Then:

- (I) \mathcal{L} is a *normal propositional monadic Von Wright-type deontic logic* iff
 - (a) every thesis, i.e. provable sentence, of the system **OK** (Section 10.2) is a member of \mathcal{L} , and
 - (b) \mathcal{L} is closed under uniform substitution for proposition letters, detachment for material implication and the rule of *O*-necessitation (Section 10.2).
- (II) \mathcal{L} is a *strongly normal* (propositional monadic) Von Wright-type deontic logic iff
 - (a) every thesis of the system **OK**⁺ (Section 10.2) is a member of \mathcal{L} , and
 - (b) \mathcal{L} is closed under substitution, detachment and *O*-necessitation.

REMARK 2.

- (i) The system **OK** is determined as follows:

Axiom schemata:

- (A0) All tautologies over Σ
- (A1) $PA \Leftrightarrow \neg O\neg A$
- (A2) $O(A \rightarrow B) \rightarrow (OA \rightarrow OB)$.

Rules of proof:

$$(R1) \quad \frac{A, A \rightarrow B}{B} \quad (\text{modus ponens, detachment}).$$

$$(R2) \quad \frac{A}{OA} \quad (O\text{-necessitation}).$$

In the spirit of Section 10.2 we then define the set of **OK**-*provable* sentences (of **OK**-*theses*) as the smallest set which contains every instance of the schemata (A0)–(A2) as its member and which is closed under the rules (R1) and (R2). Since in this work we usually identify a logic(al system) with the set of its theses, we may even say that the system **OK** is identical to that set. Note also that our use of axiom *schemata* instead of single axioms guarantees that **OK** is closed under (uniform) substitution (for proposition letters), so no primitive rule of proof to that effect is needed.

The system **OK**⁺ results from **OK** by adding to the latter every instance of the schema

$$(A3) \quad OA \rightarrow PA \quad (\text{whatever is obligatory is also permitted})$$

as a new axiom; for sure, **OK**⁺ is to remain closed under (R1) and (R2).

- (ii) Our definition of ‘normality’ is meant to harmonize with the definition of a *normal* (alethic) *modal* logic given, e.g. by Makinson [1966], Segerberg [1971a] and Hansson and Gärdenfors [1973]. Many writers, including Von Wright [1951], Prior [1955] and Anderson [1956], are likely to regard this notion of normality (i.e. the one defined in (I)) as too weak, since not every instance of the schema (A3) is provable in **OK**; they are then likely to prefer, other things being equal, **OK**⁺ to **OK** and our concept of *strong* normality as the better notion. But quite a few authors, say, Erik Stenius [1963, (interesting argument on p. 254)] and Manfred Moritz [1963] (to mention just one specimen from a large production), have reacted against accepting (A3) (or its equivalent **OK**⁺**1** stated in Section 4.1 below) as a valid principle of deontic logic which is satisfied by every *existing* system of norms (at best, according to Stenius, (A3) is satisfied by every system of norms which is *possible to obey*); such authors are likely to prefer our weaker notion of normality.

Our definition of normality might still seem to be objectionable on the ground that every normal logic is required to be closed under the rule (R2) of *O*-necessitation. Roughly speaking, accepting this rule commits us to the position that every logically true proposition

(e.g. every tautology) is obligatory and, dually, every logical falsehood (contradictory state-of-affairs) is forbidden. Prior [1955] finds ‘no evident reasonableness’ in this position, and Von Wright [1951] explicitly rejects it when he proposes a *principle of deontic contingency* to the effect that such schemata as

$$O(A \vee \neg A) \quad \text{and} \quad \neg P(A \wedge \neg A)$$

should *not* be accepted as valid.

It seems to me, however, that the rule of *O*-necessitation (or something very much like it) has been successfully defended by Stenius [1963, p. 253], and by Anderson [1956, pp. 181–183]. Also, in Anderson [1956, Section IX], he outlines an interesting way of doing justice to the intuitions underlying Von Wright’s principle of deontic contingency. Essentially, his method amounts to this: we may accept a system admitting rule R2 as our *basic* (monadic) deontic logic; then, if such a system has resources for expressing alethic *contingency* in the sense of absence of necessity and of impossibility, we could define in it *new* concepts of obligation, permission and prohibition, which will apply only to contingent propositions (state-of-affairs). Clearly, the logic of these new concepts will not be normal in the sense of our definition above; but it may be developed *as a definitional extension of* a normal deontic logic in our sense. And this, I take it, is highly advantageous from a methodological standpoint.

- (iii) Somewhat cautiously, we speak in the definition above of normal (strongly normal) *propositional* monadic Von Wright-*type* deontic logics for the following reasons. Although our notions are ultimately inspired by the pioneering contribution of Von Wright [1951], the main difference between his original system and those discussed in this essay is that for Von Wright *O* and *P* are deontic *predicates*, which form sentences when applied to *names of acts* (in the sense of ‘act-types’), whereas for us, and many others, *O* and *P* are deontic *modalities* (modal operators or connectives), which form sentences when applied to *sentences* (which may possibly assert that such and such an act is performed, though). An advantage of viewing *O* and *P* as modalities is that questions concerning the status and acceptability of ‘mixed formulae’, like $OA \rightarrow A$, and of formulae involving iterated modalities, like $O(OA \rightarrow A)$, can be meaningfully raised and discussed; on Von Wright’s original approach, such questions were ruled out at the outset, since those kinds of formulae did not even count as well formed sentences.

(iv) Our proposed concepts of normality deviate from the Andersonian notion of a *normal deontic logic*, defined in Anderson [1956, p. 168], in the following respects:

- (a) Whereas we require closure under the rule of *O*-necessitation, Anderson only requires closure under a rule allowing for the intersubstitutability of provably equivalent expressions from the classical two-valued propositional calculus.
- (b) As was pointed out under (ii) above, he wants the schema (A3) to be provable in any normal deontic logic; we make this a condition of *strong* normality.
- (c) In addition to requiring certain schemata to be *provable* in any normal deontic logic Anderson also requires that certain schemata should *not* be provable in such logics, e.g..

$PA \rightarrow A$ (whatever is permitted is the case)

$A \rightarrow PA$ (whatever is the case is permitted).

Now, I think our considerations under (ii) above explain sufficiently well why we prefer to deviate from the Andersonian concept of normality in the respects (a) and (b). As far as (c) goes, I take his suggestion that certain schemata be *unprovable* in normal deontic logics to be perfectly sound; *negative requirements* of the sort may well be used to define new and stronger notions of normality, if properly defended, that is to say. Anderson's list of 'unprovables' could even be extended with a huge number of difficult items; let me just pick a few from the vast literature:

- (1) $OA \Leftrightarrow A$ (whatever is obligatory is the case and conversely).
- (2) $O(A \vee B) \rightarrow (OA \vee OB)$ (if *A-or-B* is obligatory, then *A* is obligatory or *B* is obligatory).
- (3) $(PA \wedge PB) \rightarrow P(A \wedge B)$ (if *A* is permitted and *B* is permitted, then *A-and-B* is permitted).
- (4) $(OA \wedge (A \rightarrow OB)) \rightarrow OB$ (if *A* is obligatory and if *A* then it is obligatory that *B*, then *B* is obligatory).

The strange result (1) is provable in the Mally [1926] system, see also Føllesdal and Hilpinen [1971, p. 4]. For interesting comments on the Mally system from the fresh standpoint of deontic *temporal*

logic, see Van Eck [1981, p. 81 f]. The unacceptable results 2 and 3 would seem to be provable in natural extensions of the Kalinowski [1953] systems \mathbf{K}_1 and \mathbf{K}_2 , which are based on a suggestive (2 + 3) valued matrix; see Prior [1956]. Again, (4), due to Prior [1955], is criticized by Hintikka [1957] and [1971]; but it receives an interesting vindication in terms of the Hintikka notion of *deontic* (as opposed to *logical*) *consequence*. Note that this notion of Hintikka's is very definitely based on a conception of O and P as modalities as opposed to predicates (see remark (iii) above).

- (v) We readily verify that the ten Smiley–Hanson systems (Section 10) are normal propositional monadic Von Wright-type deontic logics in the sense of clause (I) of our definition; and that the five +-systems (starting with \mathbf{OK}^+) are strongly normal ones. The question now arises: can we extend the notions of normality to the systems of dyadic deontic logic studied in Parts V and VI? My answer will be a bit tentative, because dyadic deontic logic does not yet appear to be a sufficiently well established discipline; as will be clear from the Appendix of Åqvist [1987], there is still too much controversy and disagreement about fundamentals to justify a firm answer. Nevertheless, I believe that our argument in Parts V and VI shows that the basic language of dyadic deontic logic must contain the operators N and M of *universal necessity* and *universal possibility* (for this terminology, see Scott [1970, p. 157]). The set of sentences of such a language will then be $\Sigma_{O,N}^2$ (Section 17) rather than Σ_O^2 (Section 15), and the weakest dyadic logic over $\Sigma_{O,N}^2$ is the system $\mathbf{O}_{dy}\mathbf{S5}^N$ (see again Section 17). So we propose to define a *normal propositional dyadic Von Wright-type deontic logic* as any subset of $\Sigma_{O,N}^2$ which contains every thesis of $\mathbf{O}_{dy}\mathbf{S5}^N$ and which is closed under its rules of inference (detachment and N -necessitation; as usual, closure under substitution is guaranteed by the use of axiom schemata). Again, a *strongly normal* dyadic logic of this sort will, we propose, have to contain the system \mathbf{G} (Sections 22 and 23) and to be closed under the above rules. Note that $\mathbf{O}_{dy}\mathbf{S5}^N$ and \mathbf{G} are much richer theories than, e.g. the Smiley–Hanson systems, in point of expressive and deductive power.

4.1 Theorems and rules of \mathbf{OK} and \mathbf{OK}^+

We now list some theorem-schemata, or thesis-schemata, of \mathbf{OK} , i.e. schemata of which each instance (in Σ) is provable in \mathbf{OK} . By our definition of normality, they will then be provable in every normal *monadic* deontic logic as well.

- OK1.** $OA \Leftrightarrow \neg P\neg A.$
OK2. $\neg OA \Leftrightarrow P\neg A.$
OK3. $O\neg A \Leftrightarrow \neg PA.$
OK4. $O\top.$
OK5. $O(A \wedge B) \Leftrightarrow (OA \wedge OB).$
OK6. $P(A \vee B) \Leftrightarrow (PA \vee PB).$
OK7. $OA \wedge PB \rightarrow P(A \wedge B).$
OK8. $OA \vee OB \rightarrow O(A \vee B).$
OK9. $P(A \wedge B) \rightarrow (PA \wedge PB).$
OK10. $(OA \wedge O(A \rightarrow B)) \rightarrow OB.$
OK11. $(PA \wedge O(A \rightarrow B)) \rightarrow PB.$
OK12. $(O\neg B \wedge O(A \rightarrow B)) \rightarrow O\neg A$
OK13. $(O(A \rightarrow (B \vee C)) \wedge (O\neg B \wedge O\neg C)) \rightarrow O\neg A.$
OK14. $OB \rightarrow O(A \rightarrow B).$
OK15. $O\neg A \rightarrow O(A \rightarrow B).$

Suggested readings of many of these items can be found in Anderson [1956, pp. 180 ff]. Note that the compound operator $O\neg$ may be read as ‘it is forbidden that’.

Furthermore, **OK** (and hence any normal monadic logic) is closed under the following rules of proof:

$$\mathbf{OKa.} \quad \frac{A \rightarrow B}{OA \rightarrow OB}.$$

$$\mathbf{OKb.} \quad \frac{A \Leftrightarrow B}{OA \Leftrightarrow OB}.$$

$$\mathbf{OKc.} \quad \frac{A \rightarrow B}{PA \rightarrow PB}.$$

$$\mathbf{OKd.} \quad \frac{A \Leftrightarrow B}{PA \Leftrightarrow PB}.$$

Again, the following schemata are provable in **OK**⁺ and, hence, in any *strongly* normal monadic calculus:

- OK⁺1.** $OA \rightarrow \neg O\neg A$.
OK⁺2. $\neg(OA \wedge O\neg A)$.
OK⁺3. $PA \vee P\neg A$.
OK⁺4. $P\top$.
OK⁺5. $\neg(O(A \vee B) \wedge (O\neg A \wedge O\neg B))$.

Schema **OK⁺5** may be taken to assert that it is impossible to be obliged to choose between forbidden alternatives (see, e.g. Von Wright [1951]). Note that **OK⁺5** is not a theorem-schema of **OK**; hence, it is not forthcoming in every normal monadic calculus.

Finally, **OK⁺** is closed under the following rule of proof:

$$\mathbf{OK}^+ \mathbf{a.} \quad \frac{A}{PA}$$

whereas **OK** fails to be closed under that rule.

II. PARADOXES AND DILEMMA'S

5 PRELIMINARIES ON FORMALIZATION AND TRANSLATION

Consider the *formal*, or *symbolic*, *language* common to the ten Smiley–Hanson systems of monadic deontic logic to be studied in Part III. That formal language can be conceived of as a structure

$$L = \langle \text{Bas}, \text{LogCon}, \text{Aux}, \text{Sent} \rangle$$

where:

- (i) Bas (= the set of *basic sentences* of L) is a denumerable set Prop of *proposition letters* p, q, r, p_1, p_2, \dots
- (ii) LogCon (= the set of primitive *logical connectives* or *constants* of L) is the set $\{\top, \perp, \neg, \wedge, \vee, \rightarrow, \Leftrightarrow, O, P\}$.
- (iii) Aux (= the set of *auxiliary* symbols of L) is the set consisting of the left parenthesis and the right parenthesis; thus, $\text{Aux} = \{(,)\}$.
- (iv) Sent (= the set of all well formed *sentences* of L) is identical to the set Σ as defined Section 10.1 i.e. the smallest set S such that
 - (a) every proposition letter in Prop is in S ,
 - (b) \top and \perp are in S ,
 - (c) if A is in S , then so are $\neg A, OA$ and PA ,

- (d) if A, B are in S , then so are $(A \wedge B)$, $(A \vee B)$, $(A \rightarrow B)$ and $(A \Leftrightarrow B)$.

This ‘recursive’ or ‘inductive’ definition of Σ may be summarized by saying that the set of sentences of L is the smallest set which (i) contains every basic sentence in Bas as an element, this according to clause (a), and (ii) is *closed* under every logical connective in LogCon , this being the joint effect of clauses (b)–(d). Note that these connectives are of different *degrees*, which are revealed, so to speak, by the way they are used to form new sentences : by clause (c), \neg , O and P do so when applied to *one single* sentence as their argument and, hence, are said to be of degree 1; by clause (d), \wedge , \vee , \rightarrow and \Leftrightarrow do so when applied to *any two* sentences as their arguments, and are, consequently, said to be of degree 2; finally, by clause (b), \top and \perp require *no* argument *at all* when used to form sentences, hence, they are said to be of degree 0 and to be *propositional constants* (as opposed to so called *propositional variables*).

Now, assume that we are interested in *theories*, or *logics*, formulated in the language L as just described; for instance, any of the Smiley–Hanson systems to be studied below. Generally speaking, such a logic is a subset of Σ determined by a finite number of *classes of axioms* having a common and peculiar form or *Gestalt* (these classes are usually known as ‘axiom schemata’) as well as by certain *rules of inference* (perhaps more appropriately: *rules of proof*). Now, why have deontic logicians and moral philosophers alike paid so much attention to systems of the Smiley–Hanson kind rather than to other subsets of Σ that might just as well have been selected for attention? An obvious reason appears to be this: certain definite *ordinary language readings* are associated with the logical connectives in L and, *on these readings*, the principles of these logics have more or less good claims to being true, valid, correct, acceptable, or whatnot, in a pre-systematic, informal or intuitive sense.

Which English readings are we then to associate with the connectives in LogCon ? Here is a familiar list:

- \neg : not (more fully: it is not the case that)
- \wedge : and (more fully: both _____, and...)
- \vee : or (more fully: either _____, or...)
- \rightarrow : if _____, then...
- \Leftrightarrow : if and only if (alternatively: if and only if _____, then...)
- O : it is obligatory that (alternatively: it ought to be that)
- P : it is permitted that (alternatively: it may be that).

Thus, \neg , \wedge , \vee , \rightarrow and \Leftrightarrow are to be symbols for the five best known so-called *truth-functions* of classical propositional logic, viz. negation, con-

junction, disjunction, material implication and material equivalence, respectively. Again, O and P are to symbolize the *normative* (or *deontic*) notions of obligation and permission. Finally, \top (*verum* in Latin) symbolizes some arbitrary, but fixed logical truth or tautology, and \perp (*falsum* in Latin) some arbitrary, but fixed logical falsehood, contradiction or absurdity; their precise reading in English is less important.

We may think of the list above as presenting items in a little logical dictionary or lexicon: they tell us both

- (i) how to translate connectives in LogCon into plain English, and
- (ii) how to translate certain English locutions, viz. those appearing to the right in the list, ‘back’ into the formal language L.

In this way, we suggest, we get an idea about the intended interpretation of the language L or, at least, of its logical connectives. But it still remains unclear how to understand the list of lexical items (the ‘logical dictionary’) itself; what is its status in a formal theory, like any one of the Smiley–Hanson systems of monadic deontic logic? What does it mean to assign an English reading to a connective in L on the basis of a lexical item in the list?

In answer to these questions, we propose to equate that list with the following series of *definitions*, applicable to any L-sentences A and B :

- (D1) It is not the case that $A = \text{df } \neg A$.
- (D2) Both A and $B = \text{df } (A \wedge B)$.
- (D3) Either A or $B = \text{df } (A \vee B)$.
- (D4) If A then $B = \text{df } (A \rightarrow B)$.
- (D5) If and only if A then $B = \text{df } (A \leftrightarrow B)$.
- (D6) It is obligatory that $A = \text{df } OA$.
- (D7) It is permitted that $A = \text{df } PA$.

Let us now distinguish some effects of adding this series D1–D7 to our language L or to any theory formulated in L.

- (I) We obtain a new language, call it L(D1–D7), which is *like* L in having (i) the same set Bas of basic sentences, viz. the set Prop, and (ii) the same set Aux consisting of the two brackets. But L(D1–D7) *differs from* L in having (i) a larger set LogCon than L and (ii) a larger set of sentences than L; because the seven defined English connectives ‘it is not the case that’, ‘both _____ and...’ etc. will be among the logical connectives of L(D1–D7), though not among those of L; and because

the set of sentences of $L(D1-D7)$, call it $\Sigma(D1-D7)$, will be closed, not only under the old, ‘symbolic’ connectives of L , but under the new, defined English ones as well. For example, the following strings:

$$(3) \quad \left. \begin{array}{l} \text{it is not the case that } p \\ \text{it is obligatory that } q \end{array} \right\} \quad (\text{where } p, q \text{ are in Prop})$$
