The middle part of this 'default' can be used to express consistency statements. Informally the default reads as 'If it is provable that Tweety is a bird, and it is not provable that Tweety cannot fly, then we may infer that Tweety can fly'. To see how this works, assume that in addition to this default we have a first-order theory

$$W = \{\text{Bird}(\text{Tweety}), \forall x. \text{Penguin}(x) \supset \neg \text{Canfly}(x)\}$$

Then (informally) since $\text{Canfly}(\text{Tweety})$ is consistent with what is known, we can apply the default to *Tweety* and defeasibly derive $\text{Canfly}(\text{Tweety})$ from W . That this inference is indeed defeasible becomes apparent if $\text{Penguin}(\text{Tweety})$ is also added to W : then $\neg \text{Canfly}(\text{Tweety})$ is classically entailed by what is known and the consistency check for applying the default fails, for which reason $\text{Canfly}(\text{Tweety})$ cannot be derived from $W \cup \{\text{Penguin}(\text{Tweety})\}$.

This example seems straightforward but the formal definition of default-logical consequence is tricky: in this approach, what is provable is determined by what is not provable, so the problem is how to avoid a circular definition. In default logic (as in related logics) this is solved by giving the definition a fixed-point appearance; see below in Section 5.4. Similar equilibrium-like definitions for argumentation systems will be discussed throughout this chapter.

Inconsistency handling

It has also been proposed to formalise defeasible reasoning as strategies for dealing with inconsistent information, e.g. by Brewka [1989]. In this approach defaults are formalised with ordinary material implications and without normality conditions, and their defeasible nature is captured in how they are used by the consistency handling strategies. In particular, in case of inconsistency, alternative consistent subsets (subtheories) of the premises give rise to alternative default conclusions, after which a choice can be made for the subtheory containing the exceptional rule.

In our birds example this works out as follows.

- (1) $\text{bird} \supset \text{canfly}$
- (2) $\text{penguin} \supset \neg \text{canfly}$
- (3) bird
- (4) penguin

The set $\{(1), (3)\}$ is a subtheory supporting the conclusion canfly , while $\{(2), (4)\}$ is a subtheory supporting the opposite. The exceptional nature of (2) over (1) can be captured by preferring the latter subtheory.

Systems for defeasible argumentation

Argumentation systems are yet another way to formalise nonmonotonic reasoning, viz. as the construction and comparison of arguments for and against certain conclusions. In these systems the basic notion is not that of a defeasible conditional but that of a defeasible argument. The idea is that the construction of arguments is monotonic, i.e., an argument stays an argument if more premises are added. Nonmonotonicity, or defeasibility, is not explained in terms of the interpretation of a defeasible conditional, but in terms of the interactions between conflicting arguments: in argumentation systems nonmonotonicity arises from the fact that new premises may give rise to stronger counterarguments, which defeat the original argument. So in case of Tweety we may construct one argument that Tweety flies because it is a bird, and another argument that Tweety does not fly because it is a penguin, and then we may prefer the latter argument because it is about a specific class of birds, and is therefore an exception to the general rule.

Argumentation systems can be combined with each of the above-discussed views on defaults. The ‘normality condition’ view can be formalised by regarding an argument as a standard derivation from a set of premises augmented with normality statements. Thus a counterargument is an attack on such a normality statement. A variant of this method can be applied to the use of consistency and nonprovability expressions. The ‘pragmatic’ view on defaults (as in inconsistency handling) can be formalised by regarding arguments as a standard derivation from a consistent subset of the premises. Here a counterargument attacks a premise of an argument. Finally, the ‘semantic’ view on defaults could be formalised by allowing the construction of arguments with inference rules (such as modus ponens) that are invalid in the semantics. In that case a counterargument attacks the use of such an inference rule.

It is important to note, however, that argumentation systems have wider scope than just reasoning with defaults. Firstly, argumentation systems can be applied to any form of reasoning with contradictory information, whether the contradictions have to do with rules and exceptions or not. For instance, the contradictions may arise from reasoning with several sources

of information, or they may be caused by disagreement about beliefs or about moral, ethical or political claims. Moreover, it is important that several argumentation systems allow the construction and attack of arguments that are traditionally called ‘ampliative’, such as inductive, analogical and abductive arguments; these reasoning forms fall outside the scope of most other nonmonotonic logics.

Most argumentation systems have been developed in artificial intelligence research on nonmonotonic reasoning, although Pollock’s work, which was the first logical formalisation of defeasible argumentation, was initially applied to the philosophy of knowledge and justification (epistemology). The first artificial intelligence paper on argumentation systems was [Loui, 1987]. One domain in which argumentation systems have become popular is legal reasoning [Loui *et al.*, 1993; Prakken, 1993; Sartor, 1994; Gordon, 1995; Loui & Norman, 1995; Prakken & Sartor, 1996; Freeman & Farley, 1996; Prakken & Sartor, 1997a; Prakken, 1997; Gordon & Karacapilidis, 1997]. This is not surprising, since legal reasoning often takes place in an adversarial context, where notions like argument, counterargument, rebuttal and defeat are very common. However, argumentation systems have also been applied to such domains as medical reasoning [Das *et al.*, 1996], negotiation [Parsons *et al.*, 1998] and risk assessment in oil exploration [Clark, 1990].

2.2 *Nonmonotonic reasoning: artificial intelligence or logic?*

Usually, nonmonotonic logics are studied as a branch of artificial intelligence. However, it is more than justified to regard these logics as also part of philosophical logic. In fact, several issues in nonmonotonic logic have come up earlier in philosophy. For instance, in the context of moral reasoning, Ross [1930] has studied the notion of *prima facie* obligations. According to Ross an act is *prima facie* obligatory if it has a characteristic that makes the act (by virtue of an underlying moral principle) *tend* to be a ‘duty proper’. Fulfilling a promise is a *prima facie* duty because it is the fulfillment of a promise, i.e., because of the moral principle that one should do what one has promised to do. But the act may also have other characteristics which make the act tend to be forbidden. For instance, if John has promised a friend to visit him for a cup of tea, and then John’s mother suddenly falls ill, then he also has a *prima facie* duty to do his mother’s shopping, based, say, on the principle that we ought to help our parents when they need it. To find out what one’s duty proper is, one should ‘consider all things’, i.e., compare all *prima facie* duties that can be based on any aspect of the factual circumstances and find which one is ‘more incumbent’ than any conflicting one. If we qualify the all-things-considered clause as ‘consider all things that you know’, then the reasoning involved is clearly nonmonotonic: if we are first only told that John has promised his friend to visit him, then we conclude that John’s duty proper is to visit his friend. But if we next also

hear that John's mother has become ill, we conclude instead that John's duty proper is to help his mother.

The term 'defeasibility' was first introduced not in logic but in legal philosophy, viz. by Hart [1949] (see the historical discussion in [Loui, 1995]). Hart observed that legal concepts are defeasible in the sense that the conditions for when a fact situation classifies as an instance of a legal concept (such as 'contract'), are only ordinarily, or presumptively, sufficient. If a party in a law suit succeeds in proving these conditions, this does not have the effect that the case is settled; instead, legal procedure is such that the burden of proof shifts to the opponent, whose turn it then is to prove additional facts which, despite the facts proven by the proponent, nevertheless prevent the claim from being granted (for instance, insanity of one of the contracting parties). Hart's discussion of this phenomenon stays within legal-procedural terms, but it is obvious that it provides a challenge for standard logic: an explanation is needed of how proving new facts without rejecting what was proven by the other party can reverse the outcome of a case.

Toulmin [1958], who criticised the logicians of his days for neglecting many features of ordinary reasoning, was aware of the implications of this phenomenon for logic. In his well-known pictorial scheme for arguments he leaves room for rebuttals of an argument. He also urges logicians to take the *procedural* aspect (in the legal sense) of argumentation seriously. In particular, Toulmin argues that (outside mathematics) an argument is valid if it can stand against criticism in a properly conducted dispute, and the task of logicians is to find criteria for when a dispute has been conducted properly.

The notion of burden of proof, and its role in dialectical inquiry, has also been studied by Rescher [1977], in the context of epistemology. Among other things, Rescher claims that a dialectical model of scientific reasoning can explain the rational force of inductive arguments: they must be accepted if they cannot be successfully challenged in a properly conducted scientific dispute. Rescher thereby assumes that the standards for *constructing* inductive arguments are somehow given by generally accepted practices of scientific reasoning; he only focuses on the dialectical interaction between conflicting inductive arguments.

Another philosopher who has studied defeasible reasoning is John Pollock. Although his work, to be presented below, is also well-known in the field of artificial intelligence, it was initially a contribution to epistemology, with, like Rescher, much attention for induction as a form of defeasible reasoning.

As this overview shows, a logical study of nonmonotonic, or defeasible reasoning fully deserves a place in philosophical logic. Let us now turn to the discussion of logics for defeasible argumentation.

3 SYSTEMS FOR DEFEASIBLE ARGUMENTATION: A CONCEPTUAL SKETCH

In this section we give a conceptual sketch of the general ideas behind logics for defeasible argumentation. These systems contain the following five elements (although sometimes implicitly): an underlying logical language, definitions of an argument, of conflicts between arguments and of defeat among arguments and, finally, a definition of the status of arguments, which can be used to define a notion of defeasible logical consequence.

Argumentation systems are built around an underlying logical language and an associated notion of logical consequence, defining the notion of an argument. As noted above, the idea is that this consequence notion is monotonic: new premises cannot invalidate arguments as arguments but only give rise to counterarguments. Some argumentation systems assume a particular logic, while other systems leave the underlying logic partly or wholly unspecified; thus these systems can be instantiated with various alternative logics, which makes them frameworks rather than systems. The notion of an argument corresponds to a proof (or the existence of a proof) in the underlying logic. As for the layout of arguments, in the literature on argumentation systems three basic formats can be distinguished, all familiar from the logic literature. Sometimes arguments are defined as a tree of inferences grounded in the premises, and sometimes as a sequence of such inferences, i.e., as a deduction. Finally, some systems simply define an argument as a premises - conclusion pair, leaving implicit that the underlying logic validates a proof of the conclusion from the premises. One argumentation system, viz. Dung [1995], leaves the internal structure of an argument completely unspecified. Dung treats the notion of an argument as a primitive, and exclusively focuses on the ways arguments interact. Thus Dung's framework is of the most abstract kind.

Figure 4. Rebutting attack (left) vs. undercutting attack (right).

The notions of an underlying logic and an argument still fit with the standard picture of what a logical system is. The remaining three elements are what makes an argumentation system a framework for defeasible argumentation.

Figure 5. Direct attack (left) vs. indirect attack (right).

The first is the notion of a *conflict* between arguments (also used are the terms ‘attack’ and ‘counterargument’). In the literature, three types of conflicts are discussed. The first type is when arguments have contradictory conclusions, as in ‘Tweety flies, because it is a bird’ and ‘Tweety does not fly because it is a penguin’ (cf. the left part of Fig. 4). Clearly, this form of attack, which is often called *rebutting* an argument, is symmetric. The other two types of conflict are not symmetric. One is where one argument makes a non-provability assumption (as in default logic) and another argument proves what was assumed unprovable by the first. For example, an argument ‘Tweety flies because it is a bird, and it is not provable that Tweety is a penguin’, is attacked by any argument with conclusion ‘Tweety is a penguin’. We shall call this *assumption attack*. The final type of conflict (first discussed by Pollock [1970]) is when one argument challenges, not a proposition, but a rule of inference of another argument (cf. the right part of Fig. 4). After Pollock, this is usually called *undercutting* an inference. Obviously, a rule of inference can only be undercut if it is not deductive. Non-deductive rules of inference occur in argumentation systems that allow inductive, abductive or analogical arguments. To consider an example, the inductive argument ‘Raven₁₀₁ is black since the observed ravens raven₁ ... raven₁₀₀ were black’ is undercut by an argument ‘I saw raven₁₀₂, which was white’. In order to formalise this type of conflict, the rule of inference that is to be undercut (in Fig. 4: the rule that is enclosed in the dotted box, in flat text written as $p, q, r, s/t$) must be expressed in the object language: $[p, q, r, s/t]$ and denied: $\neg[p, q, r, s/t]$.³

Note that all these senses of attack have a direct and an indirect version; indirect attack is directed against a subconclusion or a substep of an argument, as illustrated by Figure 5 for indirect rebutting.

The notion of conflicting, or attacking arguments does not embody any form of evaluation; evaluating conflicting pairs of arguments, or in other

³Ceiling brackets around a meta-level formula denote a conversion of that formula to the object language, provided that the object language is expressive enough to enable such a conversion.

words, determining whether an attack is successful, is another element of argumentation systems. It has the form of a binary relation between arguments, standing for ‘attacking and not weaker’ (in a weak form) or ‘attacking and stronger’ (in a strong form). The terminology varies: some terms that have been used are ‘defeat’ [Prakken & Sartor, 1997b], ‘attack’ [Dung, 1995; Bondarenko *et al.*, 1997] and ‘interference’ [Loui, 1998]. Other systems do not explicitly name this notion but leave it implicit in the definitions. In this chapter we shall use ‘defeat’ for the weak notion and ‘strict defeat’ for the strong, asymmetric notion. Note that the several forms of attack, rebutting vs. assumption vs. undercutting and direct vs. indirect, have their counterparts for defeat.

Argumentation systems vary in their grounds for the evaluation of arguments. In artificial intelligence the specificity principle, which prefers arguments based on the most specific defaults, is by many regarded as very important, but several researchers, e.g. Vreeswijk [1989], Pollock [1995] and Prakken & Sartor [1996], have argued that specificity is not a general principle of common-sense reasoning but just one of the many standards that might or might not be used. Moreover, some have claimed that general, domain-independent principles of defeat do not exist or are very weak, and that information from the semantics of the domain will be the most important way of deciding among competing arguments [Konolige, 1988; Vreeswijk, 1989]. For these reasons several argumentation systems are parametrised by user-provided criteria. Some, e.g. Prakken & Sartor, even argue that the evaluation criteria are debatable, just as the rest of the domain theory is, and that argumentation systems should therefore allow for defeasible arguments on these criteria. (Our example in the introduction contains such an argument, viz. *A*’s use of a priority rule (10) based on the expected consequences of certain events. This argument might, for instance, be attacked by an argument that in case of important officials even a small likelihood that the disease affects the official’s functioning justifies publication, or by an argument that the negative consequences of publication for the official are small.)

The notion of defeat is a binary relation on the set of arguments. It is important to note that this relation does not yet tell us with what arguments a dispute can be won; it only tells us something about the relative strength of two individual conflicting arguments. The ultimate status of an argument depends on the interaction between all available arguments: it may very well be that argument *B* defeats argument *A*, but that *B* is in turn defeated by a third argument *C*; in that case *C* ‘reinstates’ *A* (see Figure 6).⁴ Suppose, for instance, that the argument *A* that Tweety flies because it is a bird is regarded as being defeated by the argument *B* that

⁴While in figures 4 and 5 the arrows stood for attack relations, from now on they will depict defeat relations.

Figure 6. Argument C reinstates argument A .

Tweety does not fly because it is a penguin (for instance, because conflicting arguments are compared with respect to specificity). And suppose that B is in turn defeated by an argument C , attacking B 's intermediate conclusion that Tweety is a penguin. C might, for instance, say that the penguin observation was done with faulty instruments. In that case C reinstates argument A .

Therefore, what is also needed is a definition of the status of arguments on the basis of all the ways in which they interact. Besides reinstatement, this definition must also capture the principle that an argument cannot be justified unless all its subarguments are justified (by Vreeswijk [1997] called the 'compositionality principle'). There is a close relation between these two notions, since reinstatement often proceeds by indirect attack, i.e., attacking a subargument of the attacking argument. (Cf. Fig. 5 on page 231.) It is this definition of the status of arguments that produces the output of an argumentation system: it typically divides arguments in at least two classes: arguments with which a dispute can be 'won' and arguments with which a dispute should be 'lost'. Sometimes a third, intermediate category is also distinguished, of arguments that leave the dispute undecided. The terminology varies here also: terms that have been used are justified vs. defensible vs. defeated (or overruled), defeated vs. undefeated, in force vs. not in force, preferred vs. not preferred, etcetera. Unless indicated otherwise, this chapter shall use the terms 'justified', 'defensible' and 'overruled' arguments.

These notions can be defined both in a 'declarative' and in a 'procedural' form. The declarative form, usually with fixed-point definitions, just declares certain sets of arguments as acceptable, (given a set of premises and evaluation criteria) without defining a procedure for testing whether an argument is a member of this set; the procedural form amounts to defining just such a procedure. Thus the declarative form of an argumentation system can be regarded as its (argumentation-theoretic) semantics, and the procedural form as its proof theory. Note that it is very well possible that, while an argumentation system has an argumentation-theoretic semantics, at the same time its underlying logic for constructing arguments has a model-theoretic semantics in the usual sense, for instance, the semantics of standard first-order logic, or a possible-worlds semantics of some modal logic.

In fact, this point is not universally accepted, and therefore we devote a separate subsection to it.

Semantics: model-theoretic or not?

A much-discussed issue is whether logics for nonmonotonic reasoning should have a model-theoretic semantics or not. In the early days of this field it was usual to criticise several systems (such as default logic) for the lack of a model-theoretic semantics. However, when such semantics were provided, this was not always felt to be a major step forward, unlike when, for instance, possible-worlds semantics for modal logic was introduced. In addition, several researchers argued that nonmonotonic reasoning needs a different kind of semantics than a model theory, viz. an argumentation-theoretic semantics. It is here not the place to decide the discussion. Instead we confine ourselves to presenting some main arguments for this view that have been put forward.

Traditionally, model theory has been used in logic to define the meaning of logical languages. Formulas of such languages were regarded as telling us something about reality (however defined). Model-theoretic semantics defines the meaning of logical symbols by defining how the world looks like if an expression with these symbols is true, and it defines logical consequence, entailment, by looking at what else must be true if the premises are true. For defaults this means that their semantics should be in terms of how the world normally, or typically looks like when defaults are true; logical consequence should, in this approach, be determined by looking at the most normal worlds, models or situations that satisfy the premises.

However, others, e.g. Pollock [1991, p. 40], Vreeswijk [1993a, pp. 88–9] and Loui [1998], have argued that the meaning of defaults should not be found in a correspondence with reality, but in their role in dialectical inquiry. That a relation between premises and conclusion is defeasible means that a certain burden of proof is induced. In this approach, the central notions of defeasible reasoning are notions like attack, rebuttal and defeat among arguments, and these notions are not ‘propositional’, for which reason their meaning is not naturally captured in terms of correspondence between a proposition and the world. This approach instead defines ‘argumentation-theoretic’ semantics for such notions. The basic idea of such a semantics is to capture sets of arguments that are as large as possible, and adequately defend themselves against attacks on their members.

It should be noted that this approach does not deny the usefulness of model theory but only wants to define its proper place. Model theory should not be applied for things for which it is not suitable, but should be reserved for the initial components of an argumentation system, the notions of a logical language and a consequence relation defining what an argument is.

It should also be noted, however, that some have proposed argumentation systems as proof theories for model-theoretic semantics of preferential entailment (in particular Geffner & Pearl [1992]). In our opinion, one criterion for success of such model-theoretic semantics of argumentation systems

is whether *natural* criteria for model preference can be defined. For certain restricted cases this seems possible, but whether this approach is extendable to more general argumentation systems, for instance, those allowing inductive, analogical or abductive arguments, remains to be investigated.

4 GENERAL FEATURES OF ARGUMENT-BASED SEMANTICS

Let us now, before looking at some systems in detail, become more formal about some of the notions that these systems have in common. We shall focus in particular on the semantics of argumentation systems, i.e., on the conditions that sets of justified arguments should satisfy. In line with the discussion at the end of Section 3, we can say that argumentation systems are not concerned with truth of propositions, but with justification of accepting a proposition as true. In particular, one is justified in accepting a proposition as true if there is an argument for the proposition that one is justified in accepting. Let us concentrate on the task of defining the notion of a justified argument. Which properties should such a definition have?

Let us assume as background a set of arguments, with a binary relation of ‘defeat’ defined over it. Recall that we read ‘ A defeats B ’ in the weak sense of ‘ A conflicts with B and is not weaker than B ’; so in some cases it may happen that A defeats B and B defeats A . For the moment we leave the internal structure of an argument unspecified, as well as the precise definition of defeat.⁵ Then a simple definition of the status of an argument is the following.

DEFINITION 1. Arguments are either justified or not justified.

1. An argument is *justified* if all arguments defeating it (if any) are not justified.
2. An argument is *not justified* if it is defeated by an argument that is justified.

This definition works well in simple cases, in which it is clear which arguments should emerge victorious, as in the following example.

EXAMPLE 2. Consider three arguments A , B and C such that B defeats A and C defeats B :

$$A \longleftarrow B \longleftarrow C$$

⁵This style of discussion is inspired by Dung [1995]; see further Subsection 5.1 below.

A concrete version of this example is

$A =$ ‘Tweety flies because it is a bird’

$B =$ ‘Tweety does not fly because it is a penguin’

$C =$ ‘The observation that Tweety is a penguin is unreliable’

C is justified since it is not defeated by any other argument. This makes B not justified, since B is defeated by C . This in turn makes A justified: although A is defeated by B , A is reinstated by C , since C makes B not justified.

In other cases, however, Definition 1 is circular or ambiguous. Especially when arguments of equal strength interfere with each other, it is not clear which argument should remain undefeated.

EXAMPLE 3. (Even cycle.) Consider the arguments A and B such that A defeats B and B defeats A .

A concrete example is

$A =$ ‘Nixon was a pacifist because he was a quaker’

$B =$ ‘Nixon was not a pacifist because he was a republican’

Can we regard A as justified? Yes, we can, if B is not justified. Can we regard B as not justified? Yes, we can, if A is justified. So, if we regard A as justified and B as not justified, Definition 1 is satisfied. However, it is obvious that by a completely symmetrical line of reasoning we can also regard B as justified and A as not justified. So there are two possible ‘status assignments’ to A and B that satisfy Definition 1: one in which A is justified at the expense of B , and one in which B is justified at the expense of A . Yet intuitively, we are not justified in accepting either of them.

In the literature, two approaches to the solution of this problem can be found. The first approach consists of changing Definition 1 in such a way that there is always precisely one possible way to assign a status to arguments, and which is such that with ‘undecided conflicts’ as in our example both of the conflicting arguments receive the status ‘not justified’. The second approach instead regards the existence of multiple status assignments not as a problem but as a feature: it allows for multiple assignments and defines an argument as ‘genuinely’ justified if and only if it receives this status in all possible assignments. The following two subsections discuss the details of both approaches.

First, however, another problem with Definition 1 must be explained, having to do with self-defeating arguments.

EXAMPLE 4. (Self-defeat.) Consider an argument L , such that L defeats L . Suppose L is not justified. Then all arguments defeating L are not

Figure 7. A self-defeating argument.

justified, so by clause 1 of Definition 1 L is justified. Contradiction. Suppose now L is justified. Then L is defeated by a justified argument, so by clause 2 of Definition 1 L is not justified. Contradiction.

Thus, Definition 1 implies that there are no self-defeating arguments. Yet the notion of self-defeating arguments seems intuitively plausible, as is illustrated by the following example.

EXAMPLE 5. (The Liar.) An elementary self-defeating argument can be fabricated on the basis of the so-called *paradox of the Liar*. There are many versions of this paradox. The one we use here, runs as follows:

Dutch people can be divided into two classes: people who always tell the truth, and people who always lie. Hendrik is a Dutch monk, and of Dutch monks we know that they tend to be consistent truth-tellers. Therefore, it is reasonable to assume that Hendrik is a consistent truth-teller. However, Hendrik *says* he is a liar. Is Hendrik a truth-teller or a liar?

The Liar-paradox is a paradox, because either answer leads to a contradiction.

1. Suppose that Hendrik tells the truth. Then what Hendrik says must be true. So, Hendrik is a liar. Contradiction.
2. Suppose that Hendrik lies. Then what Hendrik says must be false. So, Hendrik is not a liar. Because Dutch people are either consistent truth-tellers or consistent liars, it follows that Hendrik always tells the truth. Contradiction.

From this paradox, a self-defeating argument L can be made out of (1):

	Dutch monks tend to be consistent truth-tellers	Hendrik is a Dutch monk
	<hr style="width: 100%;"/>	Hendrik is a consistent truth-teller
Hendrik says: “I lie”	<hr style="width: 100%;"/>	
	Hendrik lies	
	<hr style="width: 100%;"/>	
	Hendrik is not a consistent truth-teller	

If the argument for “Hendrik is *not* a consistent truth-teller” is as strong as its subargument for “Hendrik is a consistent truth-teller,” then L defeats one of its own sub-arguments, and thus is a self-defeating argument.

In conclusion, it seems that Definition 1 needs another revision, to leave room for the existence of self-defeating arguments. Below we shall not discuss this in general terms since, perhaps surprisingly, in the literature it is hard to find generally applicable solutions to this problem. Instead we shall discuss for each particular system how it deals with self-defeat.

4.1 *The unique-status-assignment approach*

The idea to enforce unique status assignments basically comes in two variants. The first defines status assignments in terms of some fixed-point operator, and the second involves a recursive definition of a justified argument, by introducing the notion of a subargument of an argument. We first discuss the fixed-point approach.

Fixed-point definitions

This approach, followed by e.g. Pollock [1987; 1992], Simari & Loui [1992] and Prakken & Sartor [1997b], can best be explained with the notion of ‘reinstatement’ (see above, Section 3). The key observation is that an argument that is defeated by another argument can only be justified if it is reinstated by a third argument, viz. by a justified argument that defeats its defeater. This idea is captured by Dung’s [1995] notion of *acceptability*.

DEFINITION 6. An argument A is *acceptable* with respect to a set S of arguments iff each argument defeating A is defeated by an argument in S .

The arguments in S can be seen as the arguments capable of reinstating A in case A is defeated.

However, the notion of acceptability is not sufficient. Consider in Example 3 the set $S = \{A\}$. It is easy to see that A is acceptable with respect to S , since all arguments defeating A (viz. B) are defeated by an argument in S , viz. A itself. Clearly, we do not want that an argument can reinstate itself, and this is the reason why a fixed-point operator must be used. Consider the following operator from [Dung, 1995], which for each set of arguments returns the set of all arguments that are acceptable to it.

DEFINITION 7. (Dung's [1995] grounded semantics.) Let $Args$ be a set of arguments ordered by a binary relation of defeat,⁶ and let $S \subseteq Args$. Then the operator F is defined as follows:

- $F(S) = \{A \in Args \mid A \text{ is acceptable with respect to } S\}$

Dung proves that the operator F has a least fixed point. (The basic idea is that if an argument is acceptable with respect to S , it is also acceptable with respect to any superset of S , so that F is monotonic.) Self-reinstatement can then be avoided by defining the set of justified arguments as that least fixed point. Note that in Example 3 the sets $\{A\}$ and $\{B\}$ are fixed points of F but not its least fixed point, which is the empty set. In general we have that if no argument is undefeated, then $F(\emptyset) = \emptyset$.

These observations allow the following definition of a justified argument.

DEFINITION 8. An argument is *justified* iff it is a member of the least fixed point of F .

It is possible to reformulate Definition 7 in various ways, which are either equivalent to, or approximations of the least fixed point of F . To start with, Dung shows that it can be approximated from below, and when each argument has at most finitely many defeaters even be obtained, by iterative application of F to the empty set.

PROPOSITION 9. Consider the following sequence of arguments.

- $F^0 = \emptyset$
- $F^{i+1} = \{A \in Args \mid A \text{ is acceptable with respect to } F^i\}$.

The following observations hold [Dung, 1995].

1. All arguments in $\cup_{i=0}^{\infty}(F^i)$ are justified.
2. If each argument is defeated by at most a finite number of arguments, then an argument is justified iff it is in $\cup_{i=0}^{\infty}(F^i)$

⁶As remarked above, Dung uses the term 'attack' instead of 'defeat'.

In the iterative construction first all arguments that are not defeated by any argument are added, and at each further application of F all arguments that are reinstated by arguments that are already in the set are added. This is achieved through the notion of acceptability. To see this, suppose we apply F for the i th time: then for any argument A , if all arguments that defeat A are themselves defeated by an argument in F^{i-1} , then A is in F^i .

It is instructive to see how this works in Example 2. We have that

$$\begin{aligned} F^1 &= F(\emptyset) = \{C\} \\ F^2 &= F(F^1) = \{A, C\} \\ F^3 &= F(F^2) = F^2 \end{aligned}$$

Dung [1995] also shows that F is equivalent to double application of a simpler operator G , i.e. $F = G \circ G$. The operator G returns for each set of arguments all arguments that are not defeated by any argument in that set.

DEFINITION 10. Let $Args$ be a set of arguments ordered by a binary relation of defeat. Then the operator G is defined as follows:

- $G(S) = \{A \in Args \mid A \text{ is not defeated by any argument in } S\}$

The G operator is in turn very similar to the one used by Pollock [1987; 1992]. To see this, we reformulate G in Pollock's style, by considering the sequence obtained by iterative application of G to the empty set, and defining an argument A to be justified if and only if at some point (or "level") m in the sequence A remains in G_n for all $n \geq m$.

DEFINITION 11. (Levels in justification.)

- All arguments are *in at level 0*.
- An argument is *in at level $n + 1$* iff it is not defeated by any argument in at level n .
- An argument is *justified* iff there is an m such that for every $n \geq m$, the argument is in at level n .

As shown by Dung [1995], this definition stands to Definition 10 as the construction of Proposition 9 stands to Definition 7. Dung also remarks that Definition 11 is equivalent to Pollock's [1987; 1992] definition, but as we shall see below, this is not completely accurate.

In Example 2, Definition 11 works out as follows.

level	in
0	A, B, C
1	C
2	A, C
3	A, C
.	...

C is in at all levels, while A becomes in at 2 and stays in at all subsequent levels.

And in Example 3 both A and B are in at all even levels and out at all odd levels.

level	in
0	A, B
1	
2	A, B
3	
4	A, B
.	...

The following example, with an infinite chain of defeat relations, gives another illustration of Definitions 7 and 11.

EXAMPLE 12. (Infinite defeat chain.) Consider an infinite chain of arguments A_1, \dots, A_n, \dots such that A_1 is defeated by A_2 , A_2 is defeated by A_3 , and so on.

$$A_1 \longleftarrow A_2 \longleftarrow A_3 \longleftarrow A_4 \longleftarrow A_5 \longleftarrow \dots$$

The least fixed point of this chain is empty, since no argument is undefeated. Consequently, $F(\emptyset) = \emptyset$. Note that this example has two other fixed points, which also satisfy Definition 1, viz. the set of all A_i where i is odd, and the set of all A_i where i is even.

Defensible arguments

A final peculiarity of the definitions is that they allow a distinction between two types of arguments that are not justified. Consider first again Example 2 and observe that, although B defeats A , A is still justified since it is reinstated by C . Consider next the following extension of Example 3.

EXAMPLE 13. (Zombie arguments.) Consider three arguments A , B and C such that A defeats B , B defeats A , and B defeats C .

A concrete example is

- $A =$ ‘Dixon is no pacifist because he is a republican’
 $B =$ ‘Dixon is a pacifist because he is a quaker, and he has no gun
because he is a pacifist’
 $C =$ ‘Dixon has a gun because he lives in Chicago’

According to Definitions 8 and 11, neither of the three arguments are justified. For A and B this is since their relation is the same as in Example 3, and for C this is since it is defeated by B . Here a crucial distinction between the two examples becomes apparent: unlike in Example 2, B is, although not justified, not defeated by any justified argument and therefore B retains the potential to prevent C from becoming justified: there is no justified argument that reinstates C by defeating B . Makinson & Schlechta [1991] call arguments like B ‘zombie arguments’:⁷ B is not ‘alive’, (i.e., not justified) but it is not fully dead either; it has an intermediate status, in which it can still influence the status of other arguments. Following Prakken & Sartor [1997b], we shall call this intermediate status ‘defensible’. In the unique-status-assignment approach it can be defined as follows.

DEFINITION 14. (Overruled and defensible arguments.)

- An argument is *overruled* iff it is not justified, and defeated by a justified argument.
- An argument is *defensible* iff it is not justified and not overruled.

Self-defeating arguments

Finally, we must come back to the problem of self-defeating arguments. How does Definition 7 deal with them? Consider the following extension of Example 4.

EXAMPLE 15. Consider two arguments A and B such that A defeats A and A defeats B .

Intuitively, we want that B is justified, since the only argument defeating it is self-defeating. However, we have that $F(\emptyset) = \emptyset$, so neither A nor B are justified. Moreover, they are both defensible, since they are not defeated by any justified argument.

How can Definitions 7 and 11 be modified to obtain the intuitive result that A is overruled and B is justified? Here is where Pollock’s deviation from the latter definition becomes relevant. His version is as follows.

⁷Actually, they talk about ‘zombie paths’, since their article is about inheritance systems.

DEFINITION 16. (Pollock, [1992])

- An argument is *in at level 0* iff it is not self-defeating.
- An argument is *in at level $n + 1$* iff it is in at level 0 and it is not defeated by any argument in at level n .
- An argument is *justified* iff there is an m such that for every $n \geq m$, the argument is in at level n .

The additions *iff it is not self-defeating* in the first condition and *iff it is in at level 0* in the second make the difference: they render all self-defeating arguments out at every level, and incapable of preventing other arguments from being out.

Another solution is provided by Prakken & Sartor [1997b] and Vreeswijk [1997], who distinguish a special ‘empty’ argument, which is not defeated by any other argument and which by definition defeats any self-defeating argument. Other solutions are possible, but we shall not pursue them here.

Recursive definitions

Sometimes a second approach to the enforcement of unique status assignments is employed, e.g. by Prakken [1993] and Nute [1994]. The idea is to make explicit that arguments are usually constructed step-by-step, proceeding from intermediate to final conclusions (as in Example 13, where A has an intermediate conclusion ‘Dixon is a pacifist’ and a final conclusion ‘Dixon has no gun’). This approach results in an explicitly recursive definition of justified arguments, reflecting the basic intuition that an argument cannot be justified if not all its subarguments are justified. At first sight, this recursive style is very natural, particularly for implementing the definition in a computer program. However, the approach is not so straightforward as it seems, as the following discussion aims to show.

To formalise the recursive approach, we must make a first assumption on the structure of arguments, viz. that they have subarguments (which are ‘proper’ iff they are not identical to the entire argument). Justified arguments are then defined as follows. (We already add how self-defeating arguments can be dealt with, so that our discussion can be confined to the issue of avoiding multiple status assignments. Note that the explicit notion of a subargument makes it possible to regard an argument as self-defeating if it defeats one of its subarguments, as in Example 5.)

DEFINITION 17. (Recursively justified arguments.) An argument A is *justified* iff

1. A is not self-defeating; and
2. All proper subarguments of A are justified; and

3. All arguments defeating A are self-defeating, or have at least one proper subargument that is not justified.

How does this definition avoid multiple status assignments in Example 3? The ‘trick’ is that for an argument to be justified, clause (2) requires that it have no (non self-defeating) defeaters of which all proper subarguments are justified. This is different in Definition 1, which leaves room for such defeaters, and instead requires that these themselves are not justified; thus this definition implies in Example 3 that A is justified if and only if B is not justified, inducing two status assignments. With Definition 17, on the other hand, A is prevented from being justified by the existence of a (non-selfdefeating) defeater with justified subarguments, viz. B (and likewise for B).

The reader might wonder whether this solution is not too drastic, since it would seem to give up the property of reinstatement. For instance, when applied to Example 2, Definition 17 says that argument A is not justified, since it is defeated by B , which is not self-defeating. That B is in turn defeated by C is irrelevant, even though C is justified.

However, here it is important that Definition 17 allows us to distinguish between two kinds of reinstatement. Intuitively, the reason why C defeats B in Example 2, is that it defeats B ’s proper subargument that Tweety is a penguin. And if the subarguments in the example are made explicit as follows, Definition 17 yields the intuitive result. (As for notation, for any pair of arguments X and X^- , the latter is a proper subargument of the first.)

EXAMPLE 18. Consider four arguments A , B , B^- and C such that B defeats A and C defeats B^- .

According to Definition 17, A and C are justified and B and B^- are not justified. Note that B is not justified by Clause 2. So C reinstates A not by directly defeating B but by defeating B ’s subargument B^- .

The crucial difference between the Examples 2 and 3 is that in the latter example the defeat relation is of a different kind, in that A and B are in conflict on their final conclusions (respectively that Nixon is, or is not a pacifist). The only way to reinstate, say, the argument A that Nixon was a

pacifist is by finding a defeater of B 's proper subargument that Nixon was a republican (while making the subargument relations explicit).

So the only case in which Definition 17 does not capture reinstatement is when all relevant defeat relations concern the final conclusions of the arguments involved. This might even be regarded as a virtue of the definition, as is illustrated by the following modification of Example 2 (taken from [Nute, 1994]).

EXAMPLE 19. Consider three arguments A , B and C such that B defeats A and C defeats B . Read the arguments as follows.

A = 'Tweety flies because it is a bird'

B = 'Tweety does not fly because it is a penguin'

C = 'Tweety might fly because it is a genetically altered penguin'

Note that, unlike in Example 2, these three arguments are in conflict on the same issue, viz. on whether Tweety can fly. According to Definitions 7 and 11 both A and C are justified; in particular, A is justified since it is reinstated by C . However, according to Definition 17 only C is justified, since A has a non-self-defeating defeater, viz. B . The latter outcome might be regarded as the intuitively correct one, since we still accept that Tweety is a penguin, which blocks the 'birds fly' default, and C allows us at most to conclude that Tweety *might* fly.

So does this example show that Definitions 7 and 11 must be modified? We think not, since it is possible to represent the arguments in such a way that these definitions give the intuitive outcome. However, this solution requires a particular logical language, for which reason its discussion must be postponed (see Section 5.2, p. 269).

Nevertheless, we can at least conclude that while the indirect form of reinstatement (by defeating a subargument) clearly seems a basic principle of argumentation, Example 19 shows that with direct reinstatement this is not so clear.

Unfortunately, Definition 17 is not yet fully adequate, as can be shown with the following extension of Example 3. It is a version of Example 13 with the subarguments made explicit.

EXAMPLE 20. (Zombie arguments 2.) Consider the arguments A^- , A , B and C such that A^- and B defeat each other and A defeats C .

A concrete example is

- A^- = ‘Dixon is a pacifist because he is a quaker’
- B = ‘Dixon is no pacifist because he is a republican’
- A = ‘Dixon has no gun because he is a pacifist’
- C = ‘Dixon has a gun because he lives in Chicago’

According to Definition 17, C is justified since its only defeater, A , has a proper subargument that is not justified, viz. A^- . Yet, as we explained above with Example 13, intuitively A should retain its capacity to prevent C from being justified, since the defeater of its subargument is not justified.

There is an obvious way to repair Definition 17: it must be made explicitly ‘three-valued’ by changing the phrase ‘not justified’ in Clause 3 into ‘overruled’,⁸ where the latter term is defined as follows.

DEFINITION 21. (Defensible and overruled arguments 2.)

- An argument is *overruled* iff it is not justified and either it is self-defeating, or it or one of its proper subarguments is defeated by a justified argument.
- An argument is *defensible* iff it is not justified and not overruled.

This results in the following definition of justified arguments.

DEFINITION 22. (Recursively justified arguments—revised.) An argument A is *justified* iff

1. A is not self-defeating; and
2. All proper subarguments of A are justified; and
3. All arguments defeating A are self-defeating, or have at least one proper subargument that is overruled.

In Example 20 this has the following result. Note first that none of the arguments are self-defeating. Then to determine whether C is justified, we must determine the status of A . A defeats C , so C is only justified if A is overruled. Since A is not defeated, A can only be overruled if its proper subargument A^- is overruled. No proper subargument of A^- is defeated, but A^- is defeated by B . So if B is justified, A^- is overruled. Is B justified? No, since it is defeated by A^- , and A^- is not self-defeating and has no overruled proper subarguments. But then A is not overruled, which means that C is not justified. In fact, all arguments in the example are defensible, as can be easily verified.

⁸Makinson & Schlechta [1991] criticise this possibility and recommend the approach with multiple status assignments.

Comparing fixed-point and recursive definitions

Comparing the fixed-point and recursive definitions, we have seen that in the main example where their outcomes differ (Example 19), the intuitions seem to favour the outcome of the recursive definitions (but see below, p. 269). We have also seen that the recursive definition, if made ‘three-valued’, can deal with zombie arguments just as well as the fixed-point definitions. So must we favour the recursive form? The answer is negative, since it also has a problem: Definitions 17 and 22 do not always enforce a unique status assignment. Consider the following example.

EXAMPLE 23. (Crossover defeat.)⁹ Consider four arguments A^- , A , B^- , B such that A defeats B^- while B defeats A^- .

Definition 17 allows for two status assignments, viz. one in which only A^- and A are justified, and one in which only B^- and B are justified. In addition, Definition 22 also allows for the status assignment which makes all arguments defensible. Clearly, the latter status assignment is the intuitively intended one. However, without fixed-point constructions it seems hard to enforce it as the unique one.

Note, finally, that in our discussion of the non-recursive approach we implicitly assumed that when a proper subargument of an argument is defeated, thereby the argument itself is also defeated (see e.g. Example 2). In fact, any particular argumentation system that has no explicitly recursive definition of justified arguments should satisfy this assumption. By contrast, systems that have a recursive definition, can leave defeat of an argument independent from defeat of its proper subarguments. Furthermore, if a system has no recursive definition of justified arguments, but still distinguishes arguments and subarguments for other reasons (as e.g. [Simari & Loui, 1992] and [Prakken & Sartor, 1997b]), then a proof is required that Clause 2 of Definition 17 holds. Further illustration of this point must be postponed to the discussion of concrete systems in Section 5.

⁹The name ‘crossover’ is taken from Hunter [1993].

Unique status assignments: evaluation

Evaluating the unique-status-assignment approach, we have seen that it can be formalised in an elegant way if fixed-point definitions are used, while the, perhaps more natural attempt with a recursive definition has some problems. However, regardless of its precise formalisation, this approach has inherent problems with certain types of examples, such as the following.

EXAMPLE 24. (Floating arguments.) Consider the arguments A , B , C and D such that A defeats B , B defeats A , A defeats C , B defeats C and C defeats D .

Since no argument is undefeated, Definition 8 tells us that all of them are defensible. However, it might be argued that for C and D this should be otherwise: since C is defeated by both A and B , C should be overruled. The reason is that as far as the status of C is concerned, there is no need to resolve the conflict between A and B : the status of C ‘floats’ on that of A and B . And if C should be overruled, then D should be justified, since C is its only defeater.

A variant of this example is the following piece of default reasoning. To analyse this example, we must again make an assumption on the structure of arguments, viz. that they have a conclusion.

EXAMPLE 25. (Floating conclusions.)¹⁰ Consider the arguments A^- , A , B^- and B such that A^- and B^- defeat each other and A and B have the same conclusion.

An intuitive reading is

¹⁰The term ‘floating conclusions’ was coined by Makinson & Schlechta [1991].

- A^- = Brygt Rykkje is Dutch because he was born in Holland
- B^- = Brygt Rykkje is Norwegian because he has a Norwegian name
- A = Brygt Rykkje likes ice skating because he is Dutch
- B = Brygt Rykkje likes ice skating because he is Norwegian

The point is that whichever way the conflict between A^- and B^- is decided, we always end up with an argument for the conclusion that Brygt Rykkje likes ice skating, so it seems that it is justified to accept this conclusion as true, even though it is not supported by a justified argument. In other words, the status of this conclusion floats on the status of the arguments A^- and B^- .

While the unique-assignment approach is inherently unable to capture floating arguments and conclusions, there is a way to capture them, viz. by working with multiple status assignments. To this approach we now turn.

4.2 *The multiple-status-assignments approach*

A second way to deal with competing arguments of equal strength is to let them induce two alternative status assignments, in both of which one is justified at the expense of the other. Note that both these assignments will satisfy Definition 1. In this approach, an argument is ‘genuinely’ justified iff it receives this status in all status assignments. To prevent terminological confusion, we now slightly reformulate the notion of a status assignment.

DEFINITION 26. A *status assignment* to a set X of arguments ordered by a binary defeat relation is an assignment to each argument of either the status ‘in’ or the status ‘out’ (but not both), satisfying the following conditions:

1. An argument is *in* if all arguments defeating it (if any) are out.
2. An argument is *out* if it is defeated by an argument that is in.

Note that the conditions (1) and (2) are just the conditions of Definition 1. In Example 3 there are precisely two possible status assignments:

Recall that an argumentation system is supposed to define when it is justified to accept an argument. What can we say in case of A and B ? Since both of them are ‘in’ in one status assignment but ‘out’ in the other, we must conclude that neither of them is justified. This is captured by redefining the notion of a justified argument as follows:

DEFINITION 27. Given a set X of arguments and a relation of defeat on X , an argument is *justified* iff it is ‘in’ in all status assignments to X .

However, this is not all; just as in the unique-status-assignment approach, it is possible to distinguish between two different categories of arguments that are not justified. Some of those arguments are in no extension, but others are at least in some extensions. The first category can be called the *overruled*, and the latter category the *defensible* arguments.

DEFINITION 28. Given a set X of arguments and a relation of defeat on X

- An argument is *overruled* iff it is ‘out’ in all status assignments to X ;
- An argument is *defensible* iff it is ‘in’ in some and ‘out’ in some status assignments to X .

It is easy to see that the unique-assignment and multiple-assignments approaches are not equivalent. Consider again Example 24. Argument A and B form an even loop, thus, according to the multiple-assignments approach, either A and B can be assigned ‘in’ but not both. So the above defeat relation induces two status assignments:

While in the unique-assignment approach all arguments are defensible, we now have that D is justified and C is overruled.

Multiple status assignments also make it possible to capture floating conclusions. This can be done by defining the status of formulas as follows.

DEFINITION 29. (The status of conclusions.)

- φ is a *justified conclusion* iff every status assignment assigns ‘in’ to an argument with conclusion φ ;
- φ is a *defensible conclusion* iff φ is not justified, and a conclusion of a defensible argument.
- φ is an *overruled conclusion* iff φ is not justified or defensible, and a conclusion of an overruled argument.

Changing the first clause into ‘ φ is a justified conclusion iff φ is the conclusion of a justified argument’ would express a stronger notion, not recognising floating conclusions as justified.

There is reason to distinguish several variants of the multiple-status-assignments approach. Consider the following example, with an ‘odd loop’ of defeat relations.

EXAMPLE 30. (Odd loop.) Let A, B and C be three arguments, represented in a triangle, such that A defeats C , B defeats A , and C defeats B .

In this situation, Definition 27 has some problems, since this example has no status assignments.

1. Assume that A is ‘in’. Then, since A defeats C , C is ‘out’. Since C is ‘out’, B is ‘in’, but then, since B defeats A , A is ‘out’. Contradiction.
2. Assume next that A is ‘out’. Then, since A is the only defeater of C , C is ‘in’. Then, since C defeats B , B is ‘out’. But then, since B is the only defeater of A , A is ‘in’. Contradiction.

Note that a self-defeating argument is a special case of Example 30, viz. the case where B and C are identical to A . This means that sets of arguments containing a self-defeating argument might have no status assignment.

To deal with the problem of odd defeat cycles, several alternatives to Definition 26 have been studied in the literature. They will be discussed in Section 5, in particular in 5.1 and 5.2.

4.3 Comparing the two approaches

How do the unique- and multiple-assignment approaches compare to each other? It is sometimes said that their difference reflects a difference between a ‘sceptical’ and ‘credulous’ attitude towards drawing defeasible conclusions: when faced with an unresolvable conflict between two arguments, a sceptic would refrain from drawing any conclusion, while a credulous reasoner would choose one conclusion at random (or both alternatively) and further explore its consequences. The sceptical approach is often defended by saying that since in an unresolvable conflict no argument is stronger than the other, neither of them can be accepted as justified, while the credulous approach

has sometimes been defended by saying that the practical circumstances often require a person to act, whether or not s/he has conclusive reasons to decide which act to perform.

In our opinion this interpretation of the two approaches is incorrect. When deciding what to accept as a justified belief, what is important is not whether one or more possible status assignments are considered, but how the arguments are evaluated given these assignments. And this evaluation is captured by the qualifications ‘justified’ and ‘defensible’, which thus capture the distinction between ‘sceptical’ and ‘credulous’ reasoning. And since, as we have seen, the distinction justified vs. defensible arguments can be made in both the unique-assignment and the multiple-assignments approach, these approaches are independent of the distinction ‘sceptical’ vs. ‘credulous’ reasoning.

Although both approaches can capture the notion of a defensible argument, they do so with one important difference. The multiple-assignments approach is more convenient for identifying *sets* of arguments that are compatible with each other. The reason is that while with unique assignments the defensible arguments are defensible on an individual basis, with multiple assignments they are defensible because they belong to a set of arguments that are ‘in’ and thus can be defended simultaneously. Even if two defensible arguments do not defeat each other, they might be incompatible in the sense that no status assignment makes them both ‘in’, as in the following example.

EXAMPLE 31. *A* and *B* defeat each other, *B* defeats *C*, *C* defeats *D*.

This example has two status assignments, viz. $\{A, C\}$ and $\{B, D\}$. Accordingly, all four arguments are defensible. Note that, although *A* and *D* do not defeat each other, *A* is in iff *D* is out. So *A* and *D* are in some sense incompatible. In the unique-assignment approach this notion of incompatibility seems harder to capture.

As we have seen, the unique-assignment approach has no inherent difficulty to recognise ‘zombie arguments’; this problem only occurs if this approach uses a recursive two-valued definition of the status of arguments.

As for their outcomes, the approaches mainly differ in their treatment of floating arguments and conclusions. With respect to these examples, the question easily arises whether one approach is the right one. However, we prefer a different attitude: instead of speaking about the ‘right’ or ‘wrong’ definition, we prefer to speak of ‘senses’ in which an argument or conclusion

can be justified. For instance, the sense in which the conclusion that Brygt Rykkje likes ice skating in Example 25 is justified is different from the sense in which, for instance, the conclusion that Tweety flies in Example 2 is justified: only in the second case is the conclusion supported by a justified argument. And the status of D in Example 24 is not quite the same as the status of, for instance, A in Example 2. Although both arguments need the help of other arguments to be justified, the argument helping A is itself justified, while the arguments helping D are merely defensible. In the concluding section we come back to this point, and generalise it to other differences between the various systems.

4.4 General properties of consequence notions

We conclude this section with a much-discussed issue, viz. whether any nonmonotonic consequence notion, although lacking the property of monotonicity, should still satisfy other criteria. Many argue that this is the case, and much research has been devoted to formulating such criteria and designing systems that satisfy them; see e.g. [Gabbay, 1985; Makinson, 1989; Kraus *et al.*, 1990]. We, however, do not follow this approach, since we think that it is hard to find any criterion that should really hold for any argumentation system, or nonmonotonic consequence notion, for that matter. We shall illustrate this with the condition that is perhaps most often defended, called *cumulativity*. In terms of argumentation systems this principle says that if a formula φ is justified on the basis of a set of premises T , then any formula ψ is justified on the basis of T if and only if ψ is also justified on the basis of $T \cup \{\varphi\}$. We shall in particular give counterexamples to the ‘if’ part of the biconditional, which is often called *cautious monotony*. This condition in fact says that adding justified conclusions to the premises cannot make other justified conclusions unjustified.

At first sight, this principle would seem uncontroversial. However, we shall now (quasi-formally) discuss reasonably behaving argumentation systems, with plausible criteria for defeat, and show by example that they do not satisfy cautious monotony and are therefore not cumulative. These examples illustrate two points. First they illustrate Makinson & Schlechta’s [1991] remark that systems that do not satisfy cumulativity assign facts a special status. Second, since the examples are quite natural, they illustrate that argumentation systems *should* assign facts a special status and therefore should not be cumulative.

Below, the \longrightarrow symbols stand for unspecified reasoning steps in an argument, and the formulas stand for the conclusion drawn in such a step.

EXAMPLE 32. Consider two (schematic) arguments

$$\begin{aligned} A : p &\longrightarrow q \longrightarrow r \longrightarrow \neg q \longrightarrow s \\ B : &\longrightarrow \neg s \end{aligned}$$

Suppose we have a system in which self-defeating arguments have no capacity to prevent other arguments from being justified. Assume also that A is self-defeating, since a subconclusion, $\neg q$, is based on a subargument for a conclusion q . Assume, finally, that the system makes A 's subargument for r justified (since it has no non-selfdefeating counterarguments). Then B is justified. However, if r is now added to the 'facts', the following argument can be constructed:

$$A' : r \longrightarrow \neg q \longrightarrow s$$

This argument is not self-defeating, and therefore it might have the capacity to prevent B from being justified.

EXAMPLE 33. Consider next the following arguments.

$$A \text{ is a two-step argument } p \longrightarrow q \longrightarrow r$$

$$B \text{ is a three-step argument } s \longrightarrow t \longrightarrow u \longrightarrow \neg r$$

And assume that conflicting arguments are compared on their length (the shorter, the better). Then A strictly defeats B , so A is justified. Assume, however, also that B 's subargument

$$s \longrightarrow t \longrightarrow u$$

is justified, since it has no counterarguments, and assume that u is added to the facts. Then we have a new argument for $\neg r$, viz.

$$B' : u \longrightarrow \neg r$$

which is shorter than A and therefore strictly defeats A .

Yet another type of example uses numerical assessments of arguments.

EXAMPLE 34. Consider the arguments

$$A : p \longrightarrow q \longrightarrow r$$

$$B : s \longrightarrow \neg r$$

Assume that in A the strength of the derivation of q from p is 0.7 and that the strength of the derivation of r from q is 0.85, while in B the strength of the derivation of $\neg r$ from s is 0.8. Consider now an argumentation system where arguments are compared with respect to their weakest links. Then B strictly defeats A , since B 's weakest link is 0.8 while A 's weakest link is 0.7. However, assume once more that A 's subargument for q is justified because it has no counterargument, and then assume that q is added as a fact. Then a new argument

$$A' : q \longrightarrow r$$

can be constructed, with as weakest link 0.85, so that it strictly defeats B .

The point of these examples is that reasonable argumentation systems with plausible criteria for defeat are conceivable which do not satisfy cumulativity, so that cumulativity cannot be required as a minimum requirement for justified belief. Vreeswijk [1993a, pp. 82–8] has shown that other

properties of nonmonotonic consequence relations also turn out to be counterintuitive in a number of realistic logical scenario's.

5 SOME ARGUMENTATION SYSTEMS

Let us, after our general discussions, now turn to individual argumentation systems and frameworks. We shall present them according to the conceptual sketch of Section 3, and also evaluate them in the light of Section 4.

5.1 *The abstract approach of Bondarenko, Dung, Kowalski and Toni*

Introductory remarks

We first discuss an abstract approach to nonmonotonic logic developed in several articles by Bondarenko, Dung, Toni and Kowalski (below called the 'BDKT approach'). Historically, this work came after the development by others of a number of argumentation systems (to be discussed below). The major innovation of the BDKT approach is that it provides a framework and vocabulary for investigating the general features of these other systems, and also of nonmonotonic logics that are not argument-based.

The latest and most comprehensive account of the BDKT approach is Bondarenko *et al.* [1997]. In this account, the basic notion is that of a set of "assumptions". In their approach the premises come in two kinds: 'ordinary' premises, comprising a *theory*, and *assumptions*, which are formulas (of whatever form) that are designated (on whatever ground) as having default status. Inspired by Poole [1988], Bondarenko *et al.* [1997] regard nonmonotonic reasoning as adding sets of assumptions to theories formulated in an underlying monotonic logic, provided that the contrary of the assumptions cannot be shown. What in their view makes the theory argumentation-theoretic is that this provision is formalised in terms of sets of assumptions attacking each other. In other words, according to Bondarenko *et al.* [1997] an argument is a set of assumptions. This approach has especially proven successful in capturing existing nonmonotonic logics.

Another version of the BDKT approach, presented by Dung [1995], completely abstracts from both the internal structure of an argument and the origin of the set of arguments; all that is assumed is the existence of a set of arguments, ordered by a binary relation of 'defeat'.¹¹ This more abstract point of view seems more in line with the aims of this chapter, and therefore we shall below mainly discuss Dung's version of the BDKT approach. As remarked above, it inspired much of our discussion in Section 4. The

¹¹BDKT use the term 'attack', but to maintain uniformity we shall use 'defeat'.

assumption-based version of Bondarenko *et al.* [1997] will be briefly outlined at the end of this subsection.

Basic notions

As just remarked, Dung's [1995] primitive notion is a set of arguments ordered by a binary relation of defeat. Dung then defines various notions of so-called argument extensions, which are intended to capture various types of defeasible consequence. These notions are declarative, just declaring sets of arguments as having a certain status. Finally, Dung shows that many existing nonmonotonic logics can be reformulated as instances of the abstract framework.

Dung's basic formal notions are as follows.

DEFINITION 35. An *argumentation framework* (AF) is a pair $(Args, \text{defeat})$, where $Args$ is a set of arguments, and defeat a binary relation on $Args$.

- An AF is *finitary* iff each argument in $Args$ is defeated by at most a finite number of arguments in $Args$.
- A set of arguments is *conflict-free* iff no argument in the set is defeated by an argument in the set.

One might think of the set $Args$ as all arguments that can be constructed in a given logic from a given set of premises (although this is not always the case; see the discussions below of 'partial computation'). Unless stated otherwise, we shall below implicitly assume an arbitrary but fixed AF.

Dung interprets *defeat*, like us, in the weak sense of 'conflicting and not being weaker'. Thus in Dung's approach two arguments can defeat each other. Dung does not explicitly use the stronger (and asymmetric) notion of strict defeat, but we shall sometimes use it below.

A central notion of Dung's framework is acceptability, already defined above in Definition 6. We repeat it here. It captures how an argument that cannot defend itself, can be protected from attacks by a set of arguments.

DEFINITION 36. An argument A is *acceptable* with respect to a set S of arguments iff each argument defeating A is defeated by an argument in S .

As remarked above, the arguments in S can be seen as the arguments capable of reinstating A in case A is defeated. To illustrate acceptability, consider again Example 2, which in terms of Dung has an AF (called 'TT' for 'Tweety Triangle') with $Args = \{A, B, C\}$ and $\text{defeat} = \{(B, A), (C, B)\}$ (B strictly defeats A and C strictly defeats B). A is acceptable with respect to $\{C\}$, $\{A, C\}$, $\{B, C\}$ and $\{A, B, C\}$, but not with respect to \emptyset and $\{B\}$.

Another central notion is that of an admissible set.

DEFINITION 37. A conflict-free set of arguments S is *admissible* iff each argument in S is acceptable with respect to S .

Intuitively, an admissible set represents an admissible, or defensible, point of view. In Example 2 the sets \emptyset , $\{C\}$ and $\{A, C\}$ are admissible but all other subsets of $\{A, B, C\}$ are not admissible.

Argument extensions

In terms of the notions of acceptability and admissibility several notions of ‘argument extensions’ can be defined, which are what we above called ‘status assignments’. The following notion of a stable extension is equivalent to Definition 26 above.

DEFINITION 38. A conflict-free set S is a *stable extension* iff every argument that is not in S , is defeated by some argument in S .

In Example 2, TT has only one stable extension, viz. $\{A, C\}$. Consider next an AF called ND (the Nixon Diamond), corresponding to Example 3, with $Args = \{A, B\}$, and $defeat = \{(A, B), (B, A)\}$. ND has two stable extensions, $\{A\}$ and $\{B\}$.

Since a stable extension is conflict-free, it reflects in some sense a coherent point of view. It is also a maximal point of view, in the sense that every possible argument is either accepted or rejected. In fact, stable semantics is the most ‘aggressive’ type of semantics, since a stable extension defeats every argument not belonging to it, whether or not that argument is hostile to the extension. This feature is the reason why not all AF’s have stable extensions, as Example 30 has shown.

To give such examples also a multiple-assignment semantics, Dung defines the notion of a preferred extension.

DEFINITION 39. A conflict-free set is a *preferred extension* iff it is a maximal (with respect to set inclusion) admissible set.

Let us go back to Definition 26 of a status assignment and define a *partial status assignment* in the same way as a status assignment, but without the condition that it assigns a status to all arguments. Then it is easy to verify that preferred extensions correspond to maximal partial status assignments.

Dung shows that every AF has a preferred extension. Moreover, he shows that stable extensions are preferred extensions, so in the Nixon Diamond and the Tweety Triangle the two semantics coincide. However, not all preferred extensions are stable: in Example 30 the empty set is a (unique) preferred extension, which is not stable. Preferred semantics leaves all arguments in an odd defeat cycle out of the extension, so none of them is defeated by an argument in the extension.

Preferred and stable semantics are an instance of the multiple-status-assignments approach of Section 4.2: in cases of an irresolvable conflict as

in the Nixon diamond, two incompatible extensions are obtained. Dung also explores the unique-status-assignment approach, with his notion of a *grounded* extension, already presented above as Definition 7. To build a bridge between the various semantics, Dung also defines ‘complete semantics’.

DEFINITION 40. An admissible set of arguments is a *complete extension* iff each argument that is acceptable with respect to S belongs to S .

This definition implies that a set of arguments is a complete extension iff it is a fixed point of the operator F defined in Definition 7. According to Dung, a complete extension captures the beliefs of a rational person who believes everything s/he can defend.

Self-defeating arguments

How do Dung’s various semantics deal with self-defeating arguments? It turns out that all semantics have some problems. For stable semantics they are the most serious, since an AF with a self-defeating argument might have no stable extensions. For preferred semantics this problem does not arise, since preferred extensions are guaranteed to exist. However, this semantics still has a problem, since self-defeating arguments can prevent other arguments from being justified. This can be illustrated with Example 15 (an AF with two arguments A and B such that A defeats A and A defeats B). The set $\{B\}$ is not admissible, so the only preferred extension is the empty set. Yet intuitively it seems that instead $\{B\}$ should be the only preferred extension, since B ’s only defeater is self-defeating. It is easy to see that the same holds for complete semantics. In Section 4.1 we already saw that this example causes the same problems for grounded semantics, but that for finitary AF’s Pollock [1987] provides a solution. Both Dung [1995] and Bondarenko *et al.* [1997] recognise the problem of self-defeating arguments, and suggest that solutions in the context of logic programming of Kakas *et al.* [1994] could be generalised to deal with it. Dung also acknowledges Pollock’s [1995] approach, to be discussed in Subsection 5.2.

Formal results

Both Dung [1995] and Bondarenko *et al.* [1997] establish a number of results on the existence of extensions and the relation between the various semantics. We now summarise some of them.

1. Every stable extension is preferred, but not vice versa.
2. Every preferred extension is a complete extension, but not vice versa.
3. The grounded extension is the least (with respect to set inclusion) complete extension.

4. The grounded extension is contained in the intersection of all preferred extensions (Example 24 is a counterexample against ‘equal to’.)
5. If an AF contains no infinite chains A_1, \dots, A_n, \dots such that each A_{i+1} defeats A_i then AF has exactly one complete extension, which is grounded, preferred and stable. (Note that the even loop of Example 3 and the odd loop of Example 30 form such an infinite chain.)
6. Every AF has at least one preferred extension.
7. Every AF has exactly one grounded extension.

Finally, Dung [1995] and Bondarenko *et al.* [1997] identify several conditions under which preferred and stable semantics coincide.

Assumption-based formulation of the framework

As mentioned above, Bondarenko *et al.* [1997] have developed a different version of the BDKT approach. This version is less abstract than the one of Dung [1995], in that it embodies a particular view on the structure of arguments. Arguments are seen as sets of assumptions that can be added to a theory in order to (monotonically) derive conclusions that cannot be derived from the theory alone. Accordingly, Bondarenko *et al.* [1997] define a more concrete version of Dung’s [1995] argumentation frameworks as follows:

DEFINITION 41. Let \mathcal{L} be a formal language and \vdash a monotonic logic defined over \mathcal{L} . An *assumption-based framework* with respect to (\mathcal{L}, \vdash) is a tuple $\langle T, Ab, \bar{\ } \rangle$ where

- $T, Ab \subseteq \mathcal{L}$
- $\bar{\ }$ is a mapping from Ab into \mathcal{L} , where $\bar{\alpha}$ denotes the *contrary* of α .

The notion of *defeat* is now defined for sets of assumptions (below we leave the assumption-based framework implicit).

DEFINITION 42. A set of assumptions A *defeats* an assumption α iff $T \cup A \vdash \bar{\alpha}$; and A *defeats* a set of assumptions Δ iff A *defeats* some assumption $\alpha \in \Delta$.

The notions of argument extensions are then defined in terms of sets of assumptions. For instance,

DEFINITION 43. A set of assumptions Δ is *stable* iff

- Δ is closed, i.e., $\Delta = \{\alpha \in Ab \mid T \cup \Delta \vdash \alpha\}$
- Δ does not defeat itself

- Δ defeats each assumption $\alpha \notin \Delta$

A *stable extension* is a set $Th(T \cup \Delta)$ for some stable set Δ of assumptions.

As remarked above, Bondarenko *et al.*'s [1997] main aim is to reformulate existing nonmonotonic logics in their general framework. Accordingly, what an assumption is, and what its contrary is, is determined by the choice of nonmonotonic logic to be reformulated. For instance, in applications of preferential entailment where abnormality predicates ab_i are to be minimised (see Section 2.1), the assumptions will include expressions of the form $\neg \text{ab}_i(c)$, where $\overline{\neg \text{ab}_i(c)} = \text{ab}_i(c)$. And in default logic (see also Section 2.1), an assumption is of the form $M\varphi$ for any 'middle part' φ of a default, where $\overline{M\varphi} = \neg\varphi$; moreover, all defaults $\varphi:\psi/\chi$ are added to the rules defining \vdash as monotonic inference rules $\varphi, M\psi/\chi$.

Procedure

The developers of the BDKT approach have also studied procedural forms for the various semantics. Dung *et al.* [1996; 1997] propose two abstract proof procedures for computing admissibility (Definition 37), where the second proof procedure is a computationally more efficient refinement of the first. Both procedures are based upon a proof procedure originally intended for computing stable semantics in logic programming. And they are both formulated as logic programs that are derived from a formal specification. The derivation guarantees the correctness of the proof procedures. Further, Dung *et al.* [1997] show that both proof procedures are complete. Here, the first procedure is discussed.

It is defined in the form of a meta-level logic program, of which the top-level clause defines admissibility. This concept is captured in a predicate *adm*:

$$(1) \quad \text{adm}(\Delta_0, \Delta) \longleftrightarrow [\Delta_0 \subseteq \Delta \text{ and } \Delta \text{ is admissible}]$$

Δ and Δ_0 are sets of assumptions, where ' Δ is admissible' is a low-level concept that is defined with the help of auxiliary clauses. In this manner, (1) provides a specification for the proof procedure. Similarly, a top-level predicate *defends* is defined

$$\text{defends}(D, \Delta) \longleftrightarrow [D \text{ defeats } \Delta' - \Delta, \text{ for every } \Delta' \text{ that defeats } \Delta]$$

The proof procedure that Dung *et al.* propose can be understood in procedural terms as repeatedly adding defences to the initially given set of assumptions Δ_0 until no further defences need to be added. More precisely,

given a current set of assumptions Δ , initialised as Δ_0 , the proof procedure repeatedly

1. finds a set of assumptions D such that $\text{defends}(D, \Delta)$;
2. replaces Δ by $\Delta \cup D$

until $D = \Delta$, in which case it returns Δ .

Step (1) is non-deterministic, since there might be more than one set of assumptions D defending the current Δ . The proof procedure potentially needs to explore a search tree of alternatives to find a branch which terminates with a self-defending set. The logic-programming formulation of the proof procedure is:

$$\begin{aligned} \text{adm}(\Delta, \Delta) &\leftarrow \text{defends}(\Delta, \Delta) \\ \text{adm}(\Delta, \Delta') &\leftarrow \text{defends}(D, \Delta), \text{adm}(\Delta \cup D, \Delta') \end{aligned}$$

The procedural characterisation of the proof procedure is obtained by applying SLD resolution to the above clauses with a left-to-right selection rule, with an initial query of the form $\leftarrow \text{adm}(\Delta_0, \Delta)$ with Δ_0 as input and Δ as output.

The procedure is proved correct with respect to the admissibility semantics, but it is shown to be incorrect for stable semantics in general. According to Dung *et al.*, this is due to the above-mentioned ‘epistemic aggressiveness’ of stable semantics, viz. the fact that a stable extension defeats every argument not belonging to it. Dung *et al.* remark that, besides being counterintuitive, this property is also computationally very expensive, because it necessitates a search through the entire space of arguments to determine, for every argument, whether or not it is defeated. Subsequent evaluation by Dung *et al.* of the proof procedure has suggested that it is the semantics, rather than the proof procedure, which was at fault, and that preferred semantics provides an improvement. This insight is also formulated by Dung [1995].

Finally, it should be noted that recently, Kakas & Toni [1999] have developed proof procedures in dialectical style (see Section 6 below) for the various semantics of Bondarenko *et al.* [1997] and for Kakas *et al.* [1994]’s acceptability semantics.

Evaluation

As remarked above, the abstract BDKT approach was a major innovation in the study of defeasible argumentation, in that it provided an elegant general framework for investigating the various argumentation systems. Moreover, the framework also applies to other nonmonotonic logics, since Dung and Bondarenko *et al.* extensively show how many of these logics can be translated into argumentation systems. Thus it becomes very easy to formulate alternative semantics for nonmonotonic logics. For instance, default logic, which was shown by Dung [1995] to have a stable semantics, can very easily

be given an alternative semantics in which extensions are guaranteed to exist, like preferred or grounded semantics. Moreover, the proof theories that have been or will be developed for the various argument-based semantics immediately apply to the systems that are an instance of these semantics. Because of these features, the BDKT framework is also very useful as guidance in the development of new systems, as, for instance, Prakken & Sartor have used it in developing the system of Subsection 5.7 below.

On the other hand, the level of abstractness of the BDKT approach (especially in Dung's version) also leaves much to the developers of particular systems. In particular, they have to define the internal structure of an argument, the ways in which arguments can conflict, and the origin of the defeat relation. Moreover, it seems that at some points the BDKT approach needs to be refined or extended. We already mentioned the treatment of self-defeating arguments, and Prakken & Sartor [1997b] have extended the BDKT framework to let it cope with reasoning about priorities (see Subsection 5.7 below).

5.2 *Pollock*

John Pollock was one of the initiators of the argument-based approach to the formalisation of defeasible reasoning. Originally he developed his theory as a contribution to philosophy, in particular epistemology. Later he turned to artificial intelligence, developing a computer program called OSCAR, which implements his theory. Since the program falls outside the scope of this handbook, we shall only discuss the logical aspects of Pollock's system; for the architecture of the computer program the reader is referred to e.g. Pollock [1995]. The latter also discusses other topics, such as practical reasoning, planning and reasoning about action.

Reasons, arguments, conflict and defeat

In Pollock's system, the underlying logical language is standard first-order logic, but the notion of an argument has some nonstandard features. What still conforms to accounts of deductive logic is that arguments are sequences of propositions linked by inference rules (or better, by instantiated inference schemes). However, Pollock's formalism begins to deviate when we look at the kinds of inference schemes that can be used to build arguments. Let us first concentrate on linear arguments; these are formed by combining so-called *reasons*. Technically, reasons connect a set of propositions with a proposition. Reasons come in two kinds, conclusive and *prima facie* reasons.

Conclusive reasons still adhere to the common standard, since they are reasons that logically entail their conclusions. In other words, a conclusive reason is any valid first-order inference scheme (which means that Pollock's system includes first-order logic). Thus, examples of conclusive reasons are

$\{p, q\}$ is a conclusive reason for $p \wedge q$
 $\{\forall xPx\}$ is a conclusive reason for Pa

Prima facie reasons, by contrast have no counterpart in deductive logic; they only create a presumption in favour of their conclusion, which can be defeated by other reasons, depending on the strengths of the conflicting reasons. Based on his work in epistemology, Pollock distinguishes several kinds of *prima facie* reasons: for instance, principles of perception, such as¹²

$[x \text{ appears to me as } Y]$ is a *prima facie* reason for believing $[x \text{ is } Y]$.

(For the objectification-operator $[\cdot]$ see page 231 and page 265.)

Another source of *prima facie* reasons is the statistical syllogism, which says that:

If $(r > 0.5)$ then $[x \text{ is an } F \text{ and } \text{prob}(G/F) = r]$ is a *prima facie* reason of strength r for believing $[x \text{ is a } G]$.

Here $\text{prob}(G/F)$ stands for the conditional probability of G given F .

Prima facie reasons can also be based on principles of induction, for example,

$[X \text{ is a set of } m \text{ } F\text{'s and } n \text{ members of } X \text{ have the property } G \text{ (} n/m > 0.5\text{)}]$ is a *prima facie* reason of strength n/m for believing $[\text{all } F\text{'s have the property } G]$.

Actually, Pollock adds to these definitions the condition that F is *projectible* with respect to G . This condition, introduced by Goodman, 1954, is meant to prevent certain ‘unfounded’ probabilistic or inductive inferences. For instance, the first observed person from Lanikai, who is a genius, does not permit the prediction that the next observed Lanikaian will be a genius. That is, the predicate ‘intelligence’ is not projectible with respect to ‘birthplace’. Projectibility is of major concern in probabilistic reasoning.

To give a simple example of a linear argument, assume the following set of ‘input’ facts $\text{INPUT} = \{A(a), \text{prob}(B/A) = 0.8, \text{prob}(C/B) = 0.7\}$. The following argument uses reasons based on the statistical syllogism, and the first of the above-displayed conclusive reasons.

¹²When a reason for a proposition is a singleton set, we drop the brackets.

- | | |
|---|--|
| 1. $\langle A(a), \infty \rangle$ | $(A(a) \text{ is in INPUT})$ |
| 2. $\langle [\text{prob}(B/A) = 0.8], \infty \rangle$ | $([\text{prob}(B/A) = 0.8] \text{ is in INPUT})$ |
| 3. $\langle A(a) \wedge [\text{prob}(B/A) = 0.8], \infty \rangle$ | (1,2 and $\{p, q\}$ is a conclusive reason
for $p \wedge q$) |
| 4. $\langle B(a), 0.8 \rangle$ | (3 and the statistical syllogism) |
| 5. $\langle [\text{prob}(C/B) = 0.7], \infty \rangle$ | $(\text{lceilprob}(C/B) = 0.7] \text{ is in INPUT})$ |
| 6. $\langle B(a) \wedge [\text{prob}(C/B) = 0.7], 0.8 \rangle$ | (4,5 and $\{p, q\}$ is a conclusive reason
for $p \wedge q$) |
| 7. $\langle C(a), 0.7 \rangle$ | (6 and the statistical syllogism) |

So each line of a linear argument is a pair, consisting of a proposition and a numerical value that indicates the strength, or degree of justification of the proposition. The strength ∞ at lines 1,2 and 5 indicates that the conclusions of these lines are put forward as absolute facts, originating from the epistemic base 'INPUT'. At line 4, the *weakest link* principle is applied, with the result that the strength of the argument line is the minimum of the strength of the reason for $B(a)$ (0.8) and the argument line 3 from which $C(a)$ is derived with this reason (∞). At lines 6 and 7 the weakest link principle is applied again.

Besides linear arguments, Pollock also studies *suppositional* arguments. In suppositional reasoning, we 'suppose' something that we have not inferred from the input, draw conclusions from the supposition, and then 'discharge' the supposition to obtain a related conclusion that no longer depends on the supposition. In Pollock's system, suppositional arguments can be constructed with inference rules familiar from natural deduction. Accordingly, the propositions in an argument have sets of propositions attached to them, which are the *suppositions* under which the proposition can be derived from earlier elements in the sequence.

The following definition (based on [Pollock, 1995]) summarises this informal account of argument formation.

DEFINITION 44. In OSCAR, an *argument* based on INPUT is a finite sequence $\sigma_1, \dots, \sigma_n$, where each σ_i is a line of argument. A *line of argument* σ_i is a triple $\langle X_i, p_i, \nu_i \rangle$, where X_i , a set of propositions, is the set of *suppositions* at line i , p_i is a proposition, and ν_i is the *degree of justification* of σ at line i . A line of argument is obtained from earlier lines of argument according to one of the following rules of argument formation.

Input. If p is in INPUT and σ is an argument, then for any X it holds that $\sigma, \langle X, p, \infty \rangle$ is an argument.

Reason. If σ is an argument, $\langle X_1, p_1, \eta_1 \rangle, \dots, \langle X_n, p_n, \eta_n \rangle$ are members of σ , and $\{p_1, \dots, p_n\}$ is a reason of strength ν for q , and for each i , $X_i \subset X$, then $\sigma, \langle X, q, \min\{\eta_1, \dots, \eta_n, \nu\} \rangle$ is an argument.

Supposition. If σ is an argument, X a set of propositions and $p \in X$, then $\sigma, \langle X, p, \infty \rangle$ is also an argument.

Conditionalisation. If σ is an argument and some line of σ is $\langle X \cup \{p\}, q, \nu \rangle$, then $\sigma, \langle X, (p \supset q), \nu \rangle$ is also an argument.

Dilemma. If σ is an argument and some line of σ is $\langle X, p \vee q, \nu \rangle$, and some line of σ is $\langle X \cup \{p\}, r, \mu \rangle$, and some line of σ is $\langle X \cup \{q\}, r, \xi \rangle$, then $\sigma, \langle X, r, \min\{\nu, \mu, \xi\} \rangle$ is also an argument.

Pollock [1995] notes that other inference rules could be added as well.

It is the use of *prima facie* reasons that makes arguments defeasible, since these reasons can be defeated by other reasons. This can take place in two ways: by *rebutting* defeaters, which are at least as strong reasons with the opposite conclusion, and by *undercutting* defeaters, which are at least as strong reasons of which the conclusion denies the connection that the undercut reason states between its premises and its conclusion. A typical example of rebutting defeat is when an argument using the reason ‘Birds fly’ is defeated by an argument using the reason ‘Penguins don’t fly’. Pollock’s favourite example of an undercutting defeater is when an object looks red because it is illuminated by a red light: knowing this undercuts the reason for believing that this object is red, but it does not give a reason for believing that the object is not red.

Before we can explain how Pollock formally defines the relation of defeat among arguments, some extra notation must be introduced. In the definition of defeat among arguments, Pollock uses a, what may be called, *objectification* operator, $[\cdot]$. (This operator was also used in Fig. 4 on page 230 and in the *prima facie* reasons on page 263.) With this operator, expressions in the meta-language are transformed into expressions in the object language. For example, the meta-level rule

$$\{p, q\} \text{ is a conclusive reason for } p$$

may be transformed into the object-level expression

$$[\{p, q\} \text{ is a conclusive reason for } p].$$

If the object language is rich enough, then the latter expression is present in the object language, in the form $(p \wedge q) \supset p$. Evidently, a large fraction of the meta-expressions cannot be conveyed to the object language, because the object language lacks sufficient expressibility. This is the case, for example, if corresponding connectives are missing in the object language.

Pollock formally defines the relation of defeat among arguments as follows.

Defeat among arguments. An argument σ defeats another argument η if and only if:

1. η ’s last line is $\langle X, q, \alpha \rangle$ and is obtained by the argument formation rule *Reason* from some earlier lines $\langle X_1, p_1, \alpha_1 \rangle, \dots, \langle X_n, p_n, \alpha_n \rangle$ where $\{p_1, \dots, p_n\}$ is a *prima facie* reason for q ; and

2. σ 's last line is $\langle Y, r, \beta \rangle$ where $Y \subseteq X$ and either:

- (a) r is $\neg q$ and $\beta \geq \alpha$; or
- (b) r is $\neg[\{p_1, \dots, p_n\} \gg q]$ and $\beta \geq \alpha$.

(1) determines the weak spot of η , while (2) determines whether that weak spot is (2a) a conclusion (in this case q), or (2b) a reason (in this case $\{p_1, \dots, p_n\} \gg q$). For Pollock, (2a) is a case of *rebutting defeat*, and 2b is a case of *undercutting defeat*: if σ undercuts the last reason of η , it blocks the derivation of q , without supporting $\neg q$ as alternative conclusion. The formula $[\{p_1, \dots, p_n\} \gg q]$ stands for the translation of ‘ $\{p_1, \dots, p_n\}$ is a *prima facie* reason for q ’ into the object language.

Pollock leaves the notion of conflicting arguments implicit in this definition of defeat. Note also that a defeater of an argument always defeats the last step of an argument; Pollock treats ‘subargument defeat’ by a recursive definition of a justified argument, i.e., in the manner explained above in Section 4.1.

Suppositional reasoning

As noted above, the argument formation rules *supposition*, *conditionalisation* and *dilemma* can be used to form suppositional arguments. OSCAR is one of the very few nonmonotonic logics that allow for suppositional reasoning. Pollock finds it necessary to introduce suppositional reasoning because, in his opinion, this type of reasoning is ubiquitous not only in deductive, but also in defeasible reasoning. Pollock mentions, among other things, the reasoning form ‘reasoning by cases’, which is notoriously hard for many non-monotonic logics. An example is ‘presumably, birds fly, presumably, bats fly, Tweety is a bird or a bat, so, presumably, Tweety flies’. In Pollock’s system, this argument can be formalised as follows.

EXAMPLE 45. Consider the following reasons.

- (1) $\text{Bird}(x)$ is a *prima facie* reason of strength ν for $\text{Flies}(x)$
- (2) $\text{Bat}(x)$ is a *prima facie* reason of strength μ for $\text{Flies}(x)$

And consider $\text{INPUT} = \{\text{Bird}(t) \vee \text{Bat}(t)\}$. The conclusion $\text{Flies}(t)$ can be defeasibly derived as follows.

- 1. $\langle \emptyset, \text{Bird}(t) \vee \text{Bat}(t), \infty \rangle$ ($\text{Bird}(t) \vee \text{Bat}(t)$ is in INPUT)
- 2. $\langle \{\text{Bird}(t)\}, \text{Bird}(t), \infty \rangle$ (Supposition)
- 3. $\langle \{\text{Bird}(t)\}, \text{Flies}(t), \nu \rangle$ (2 and *prima facie* reason (1))
- 4. $\langle \{\text{Bat}(t)\}, \text{Bat}(t), \infty \rangle$ (Supposition)
- 5. $\langle \{\text{Bat}(t)\}, \text{Flies}(t), \mu \rangle$ (4 and *prima facie* reason (2))
- 6. $\langle \emptyset, \text{Flies}(t), \min\{\nu, \mu\} \rangle$ (3,5 and Dilemma)

At line 1, the proposition $\text{Bird}(t) \vee \text{Bat}(t)$ is put forward as an absolute fact. At line (2), the proposition $\text{Bird}(t)$ is temporarily supposed to be true. From this assumption, at the following line the conclusion $\text{Flies}(t)$ is defeasibly derived with the first *prima facie* reason. Line (4) is an alternative continuation of line 1. At line (4), $\text{Bat}(t)$ is supposed to be true, and at line (5) it is used to again defeasibly derive $\text{Flies}(t)$, this time from the second *prima facie* reason. Finally, at line (6) the Dilemma rule is applied to (3) and (5), discharging the assumptions in the alternative suppositional arguments, and concluding to $\text{Flies}(t)$ under no assumption.

According to Pollock, another virtue of his system is that it validates the defeasible derivation of a material implication from a *prima facie* reason. Consider again the ‘birds fly’ reason (1), and assume that INPUT is empty.

1. $\langle \{\text{Bird}(t)\}, \text{Bird}(t), \infty \rangle$ (Supposition)
2. $\langle \{\text{Bird}(t)\}, \text{Flies}(t), \nu \rangle$ (1 and *prima facie* reason (1))
3. $\langle \emptyset, \text{Bird}(t) \supset \text{Flies}(t), \nu \rangle$ (2 and Conditionalisation)

Pollock regards the validity of these inferences as desirable. On the other hand, Vreeswijk has argued that suppositional defeasible reasoning, in the way Pollock proposes it, sometimes enables incorrect inferences. Vreeswijk’s argument is based on the idea that the strength of a conclusion obtained by means of conditionalisation is incomparable to the reason strength of the implication occurring in that conclusion. For a discussion of this problem the reader is further referred to Vreeswijk [1993a, pp. 184–7].

Having seen how Pollock defines the notions of arguments, conflicting arguments, and defeat among arguments, we now turn to what was the main topic of Section 4 and the main concern of Dung [1995], defining the status of arguments.

The status of arguments

Over the years, Pollock has more than once changed his definition of the status of arguments. One change is that while earlier versions (e.g. Pollock, 1987) dealt with (successful) attack on a subargument in an implicit way via the definition of defeat, the latest version makes this part of the status definition, by explicitly requiring that all subarguments of an ‘undefeated’ argument are also undefeated (cf. Section 4.1). Another change is in the form of the status definition. Earlier Pollock took the unique-status-assignment approach, in particular, the fixed-point variant of Definition 16 which, as shown by Dung [1995], (almost) corresponds to the grounded semantics of Definition 7. However, his most recent work is in terms of multiple status assignments, and very similar to the preferred semantics of Definition 39. Pollock’s thus combines the recursive style of Definition 17 with the multiple-status-assignments approach. We present the most recent definition, of [Pollock, 1995]. To maintain uniformity in our terminology, we

state it in terms of arguments instead of, as Pollock, in terms of an ‘inference graph’. To maintain the link with inference graphs, we make the definition relative to a *closed* set of arguments, i.e., a set of arguments containing all subarguments of all its elements.

Since we deviate from Pollock’s inference graphs, we must be careful in defining the notion of subarguments. Sometimes a later line of an argument depends on only some of its earlier lines. For instance, in Example 45 line (5) only depends on (4). In fact, the entire argument (1-6) has three independent, or parallel subarguments, viz. a linear subargument (1), and two suppositional subarguments (2,3) and (4,5). Pollock’s inference graphs nicely capture such dependencies, since their nodes are argument lines and their links are inferences. However, with our sequential format of an argument this is different, for which reason we cannot define a subargument as being any subsequence of an argument. Instead, they are only those subsequences of A that can be transformed into an inference tree.

DEFINITION 46 (subarguments). An argument A is a *subargument* of an argument B iff A is a subsequence of B and there exists a tree T of argument lines such that

1. T contains all and only lines from A ; and
2. T ’s root is A ’s last element; and
3. l is a child of l' iff l was inferred from a set of lines one of which was l' .

A *proper* subargument of A is any subargument of A unequal to A .

Now we can give Pollock’s [1995] definition of a status assignment.

DEFINITION 47. An assignment of ‘defeated’ and ‘undefeated’ to a closed set S of arguments is a *partial defeat status assignment* iff it satisfies the following conditions.

1. All arguments in S with only lines obtained by the *input* argument formation rule are assigned ‘undefeated’;
2. $A \in S$ is assigned ‘undefeated’ iff:
 - (a) All proper sub-arguments of A are assigned ‘undefeated’; and
 - (b) All arguments in S defeating A are assigned ‘defeated’.
3. $A \in S$ is assigned ‘defeated’ iff:
 - (a) One of A ’s proper sub-arguments is assigned ‘defeated’;
 - or
 - (b) A is defeated by an argument in S that is assigned ‘undefeated’.

A *defeat status assignment* is a maximal (with respect to set inclusion) partial defeat status assignment.

Observe that the conditions (2a) and (3a) on the sub-arguments of A make the weakest link principle hold by definition.

The similarity of defeat status assignments to Dung's preferred extensions of Definition 39 shows itself as follows: the conditions (2b) and (3b) on the defeaters of A are the analogues of Dung's notion of acceptability, which make a defeat status assignment an admissible set; then the fact that a defeat status assignment is a maximal partial assignment induces the similarity with preferred extensions.

It is easy to verify that when two arguments defeat each other (Example 3), an input has more than one status assignment. Since Pollock wants to define a sceptical consequence notion, he therefore has to consider the intersection of all assignments. Pollock does so in a variant of Definitions 27 and 28.

DEFINITION 48. (The status of arguments.) Let S be a closed set of arguments based on INPUT. Then, relative to S , an argument is *undefeated* iff every status assignment to S assigns 'undefeated' to it; it is *defeated outright* iff no status assignment to S assigns 'undefeated' to it; otherwise it is *provisionally defeated*.

In our terms, 'undefeated' is 'justified', 'defeated outright' is 'overruled', and 'provisionally defeated' is 'defensible'.

Direct vs. indirect reinstatement

It is now the time to come back to the discussion in Section 4.1 on reinstatement. Example 19 showed that there is reason to invalidate the direct version of this principle, viz. when the conflicts are about the same issue. We remarked that the explicitly recursive Definition 17 of justified arguments indeed invalidates direct reinstatement while preserving its indirect version. However, we also promised to explain that both versions of reinstatement can be retained if Example 19 is represented in a particular way. In fact, Pollock (personal communication) would represent the example as follows:

- (1) Being a bird is a prima facie reason for being able to fly
- (2a) Being a penguin is an undercutting reason for (1)
- (2b) Being a penguin is a defeasible reason for not being able to fly
- (3) Being a genetically altered penguin is an undercutting reason for (2b)
- (4) Tweety is a genetically altered penguin

It is easy to verify that Definitions 47 and 48, which validate both direct and indirect of reinstatement, yield the intuitive outcome, viz. that it is neither justified that Tweety can fly, nor that it cannot fly. A similar representation

is possible in systems that allow for abnormality or exception clauses, e.g. in [Geffner & Pearl, 1992; Bondarenko *et al.*, 1997; Prakken & Sartor, 1997b].

Self-defeating arguments

Pollock has paid much attention to the problem of self-defeating arguments. In Pollock's system, an argument defeats itself iff one of its lines defeats another of its lines. Above in Section 4.1 we already discussed Pollock's treatment of self-defeating arguments within the unique-status-assignment approach. However, he later came to regard this treatment as incorrect, and he now thinks that it can only be solved in the multiple-assignment approach (personal communication).

Let us now see how Pollock's Definitions 47 and 48 deal with the problem. Two cases must be distinguished. Consider first two defeasible arguments A and B rebutting each other. Then A and B are 'parallel' subarguments of a deductive argument $A+B$ for any proposition. Then (if no other arguments interfere with A or B) there are two status assignments, one in which A is assigned 'undefeated' and B assigned 'defeated', and one the other way around. Now $A+B$ is in both of these assignments assigned 'defeated', since in both assignments one of its proper subarguments is assigned 'defeated'. Thus the self-defeating argument $A+B$ turns out to be defeated outright, which seems intuitively plausible.

A different case is the following, with the following reasons

- (1) p is a *prima facie* reason of strength 0.8 for q
- (2) q is a *prima facie* reason of strength 0.8 for r
- (3) r is a conclusive reason for $[\neg(p \gg q)]$

and with INPUT = $\{p\}$. The following (linear) argument can be constructed.

- | | | |
|----|--------------------------------------|--|
| 1. | $\langle p, \infty \rangle$ | $(p \text{ is in INPUT})$ |
| 2. | $\langle q, 0.8 \rangle$ | $(1 \text{ and } \textit{prima facie} \text{ reason (1)})$ |
| 3. | $\langle r, 0.8 \rangle$ | $(2 \text{ and } \textit{prima facie} \text{ reason (2)})$ |
| 4. | $\langle \neg(p \gg q), 0.8 \rangle$ | $(3 \text{ and conclusive reason (3)})$ |

Let us call this argument A , with proper subarguments A_1, A_2, A_3 and A_4 , respectively. Observe first that, according to Pollock's definition of self-defeat, A_4 is self-defeating. Further, according to Pollock's earlier approach with Definition 16, A_4 is, as being self-defeating, overruled, or 'defeated', while A_1, A_2 and A_3 are justified, or 'undefeated'. Pollock now regards this outcome as incorrect: since A_4 is a deductive consequence of A_3 , A_3 should also be 'defeated'.

This result is obtained with Definitions 47 and 48. Firstly, A_1 is clearly undefeated. Consider next A_2 . This argument is undercut by A_4 , so if A_4 is assigned 'undefeated', then A_2 must be assigned 'defeated'. But then A_4

must also be assigned ‘defeated’, since one of its proper subarguments is assigned ‘defeated’. Contradiction. If, on the other hand, A_4 is assigned ‘defeated’, then A_2 and so A_3 must be assigned ‘undefeated’. But then A_4 must be assigned ‘undefeated’. Contradiction. In conclusion, no partial status assignment will assign a status to A_4 and, consequently, no status assignment will assign a status to A_2 or A_3 either. And since this implies that no status assignment assigns the status ‘undefeated’ to any of these arguments, they are by Definition 48 all defeated outright.

Two remarks about this outcome can be made. Firstly, it might be doubted whether A_2 should indeed be defeated outright, i.e., overruled. It is not self-defeating, its only defeater is self-defeating, and this defeater is not a deductive consequence of A_2 ’s conclusion. Other systems, e.g. those of Vreeswijk (Section 5.5) and Prakken & Sartor (Section 5.7), regard A_2 as justified. In these systems Pollock’s intuition about A_3 is formalised by regarding A_3 as self-defeating because its conclusion deductively, not just defeasibly, implies a conclusion incompatible with itself. This makes it possible to regard A_3 as overruled but A_2 as justified.

Furthermore, even if Pollock’s outcome is accepted, the situation is not quite the same as with the previous example. Consider another defeasible argument B which rebuts and is rebutted by A_3 . Then no assignment assigns a status to B either, for which reason B is also defeated outright. Yet this shows that the ‘defeated outright’ status of A_2 is not the same as the ‘defeated outright’ status of an argument that has an undefeated defeater: apparently, A_2 is still capable of preventing other arguments from being undefeated. In fact, the same holds for arguments involved in an odd defeat cycle (as in Example 30).

In conclusion, Pollock’s definitions leave room for a fourth status of arguments, which might be called ‘seemingly defeated’. This status holds for arguments that according to Definition 48 are defeated outright but still have the power to prevent other arguments from being ultimately defeated. The four statuses can be partially ordered as follows: ‘undefeated’ is better than ‘provisionally defeated’ and than ‘seemingly defeated’, which both in turn are better than ‘defeated outright’. This observation applies not only to Pollock’s definition, but to all approaches based on partial status assignments, like Dung [1995] preferred semantics.

However, this is not yet all: even if the notion of seeming defeat is made explicit, there still is an issue concerning floating arguments (cf. Example 24). To see this, consider the following extension of Example 30 (formulated in terms of [Dung, 1995]).

EXAMPLE 49. Let A, B and C be three arguments, represented in a triangle, such that A defeats C , B defeats A , and C defeats B . Furthermore, let D and E be arguments such that all of A, B and C defeat D , and D defeats E .

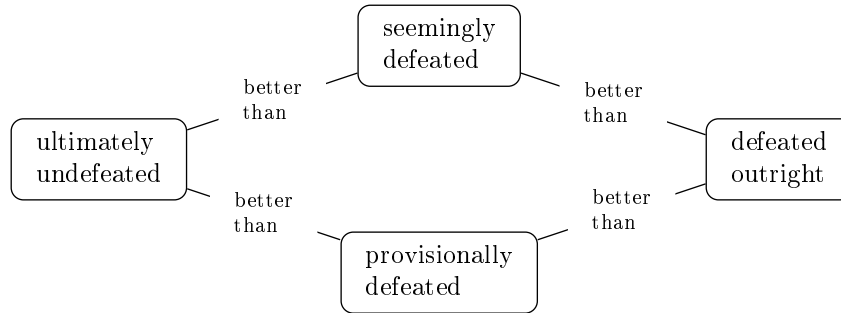

Figure 8. Partial ordering of defeat statuses.

The difference between Example 24 and this example is that the even defeat loop between two arguments is replaced by an odd defeat loop between three arguments. One view on the new example is that this difference is inessential and that, for the same reasons as why in Example 24 the argument D is justified, here the argument E is ultimately undefeated: although E is strictly defeated by D , it is reinstated by all of A , B and C , since all these arguments strictly defeat D . On this account Definitions 47 and 48 are flawed since they render all five arguments defeated outright (and in our terms seemingly defeated). However, an alternative view is that odd defeat loops are of an essentially different kind than even defeat loops, so that our analysis of Example 24 does not apply here and that the outcome in Pollock's system reflects a flaw in the available input information rather than in the system.

Ideal and resource-bounded reasoning

We shall now see that Definition 48 is not yet all that Pollock has to say on the status of arguments. In the previous section we saw that the BDKT approach leaves the origin of the set of 'input' arguments unspecified. At

this point Pollock develops some interesting ideas. At first sight it might be thought that the set S of the just-given definitions is just the set of all arguments that can be constructed with the argument formation rules of Definition 44. However, this is only one of the possibilities that Pollock considers, in which Definition 48 captures so-called *ideal warrant*.

DEFINITION 50. (Ideal warrant.) Let S be the set of all arguments based on INPUT. Then an argument A is *ideally warranted* relative to INPUT iff A is undefeated relative to S .

Pollock wants to respect that in actual reasoning the construction of arguments takes time, and that reasoners have no infinite amount of time available. Therefore, he also considers two other definitions, both of which have a computational flavour. To capture an actual reasoning process, Pollock makes them relative to a sequence \mathcal{S} of closed finite sets $S_0 \subseteq \dots \subseteq S_i \dots$ of arguments. Let us call this an *argumentation sequence*. Such a sequence contains all arguments constructed by a reasoner, in the order in which they are produced. It (and any of its elements) is based on INPUT if all its arguments are based on INPUT.¹³

Now the first ‘computational’ status definition determines what a reasoner must believe at any given time.

DEFINITION 51. (Justification.) Let \mathcal{S} be an argumentation sequence based on INPUT, and S_i an element of \mathcal{S} . Then an argument A is *justified* relative to INPUT at stage i iff A is undefeated relative to S_i .

In this definition the set S_i contains just those arguments that have actually been constructed by a reasoner. Thus this definition captures the *current* status of a belief; it may be that further reasoning (without adding new premises) changes the status of a conclusion.

This cannot happen for the other ‘computational’ consequence notion defined by Pollock, called *warrant*. Intuitively, an argument A is warranted iff eventually in an argumentation sequence a stage is reached where A remains justified at every subsequent stage. To define this, the notion of a ‘maximal’ argumentation sequence is needed, i.e., a sequence that cannot be extended. Thus it contains all arguments that a reasoner with unlimited resources would construct (in a particular order).

DEFINITION 52. (Warrant.) Let \mathcal{S} be a maximal argumentation sequence $S_0 \subseteq \dots \subseteq S_i \dots$ based on INPUT. Then an argument A is *warranted* (relative to INPUT) iff there is an i such that for all $j > i$, A is undefeated relative to S_j .

The difference between warrant and ideal warrant is subtle: it has to do with the fact that, while in determining warrant every set $S_j \supseteq S_i$ that

¹³Note that we again translate Pollock’s inference graphs into (structured) sets of arguments.

is considered is *finite*, in determining ideal warrant the set of all possible arguments has to be considered, and this set can be infinite.

EXAMPLE 53. (Warrant does not entail ideal warrant.) Suppose A_1, A_2, A_3, \dots are arguments such that every A_i is defeated by its successor A_{i+1} . Further, suppose that the arguments are produced in the order $A_2, A_1, A_4, A_3, A_6, A_5, A_8, \dots$. Then

Stage	Produced	Justified
1	A_2	A_2
2	A_2, A_1	A_2
3	A_2, A_1, A_4	A_2, A_4
4	A_2, A_1, A_4, A_3	A_2, A_4
5	A_2, A_1, A_4, A_3, A_6	A_2, A_4, A_6
6	$A_2, A_1, A_4, A_3, A_6, A_5$	A_2, A_4, A_6
7	$A_2, A_1, A_4, A_3, A_6, A_5, A_8$	A_2, A_4, A_6, A_8
\vdots	\vdots	\vdots

From stage 1, A_2 is justified and stays justified. Thus, A_2 is warranted. At the same time, however, A_2 is not ideally warranted, because there exist two status assignments for all A_i 's. One assignment in which all and only all odd arguments are 'in', and one assignment in which all and only all odd arguments are 'out'. Hence, according to ideal warrant, every argument is only provisionally defeated. In particular, A_2 is provisionally defeated. A remarkable aspect of this example is that, eventually, every argument will be produced, but without reaching the right result for A_2 .

EXAMPLE 54. (Ideal warrant does not imply warrant.) Suppose that A, B_1, B_2, B_3, \dots and C_1, C_2, C_3, \dots are arguments such that A is defeated by every B_i , and every B_i is defeated by C_i . Further, suppose that the arguments are produced in the order $A, B_1, C_1, B_2, C_2, B_3, C_3, \dots$. Then

Stage	Produced	Justified
1	A	A
2	A, B_1	B_1
3	A, B_1, C_1	A, C_1
4	A, B_1, C_1, B_2	C_1, B_2
5	A, B_1, C_1, B_2, C_2	A, C_1, C_2
6	$A, B_1, C_1, B_2, C_2, B_3$	C_1, C_2, B_3
\vdots	\vdots	\vdots

Thus, in this sequence, A is provisionally defeated. However, according to the definition of ideal warrant, every B_i is defeated by C_i , so that A remains undefeated.

Although the notion of warrant is computationally inspired, as Pollock observes there is no automated procedure that can determine of any war-

ranted argument that it is warranted: even if in fact a warranted argument stays undefeated after some finite number n of computations, a reasoner can in state n not *know* whether it has reached a point where the argument stays undefeated, or whether further computation will change its status.

Pollock's reasoning architecture

We now discuss Pollock's reasoning architecture for computing the ideally warranted propositions, i.e. the propositions that are the conclusion of an ideally warranted argument. (According to Pollock, ideal warrant is what every reasoner should ultimately strive for.) In deductive logic such an architecture would be called a 'proof theory', but Pollock rejects this term. The reason is that one condition normally required of proof theories, viz. that the set of theorems is recursively enumerable, cannot in general be satisfied for a defeasible reasoner. Pollock assumes that a reasoner reasons by constantly updating its beliefs, where an update is an elementary transition from one set of propositions to the next set of propositions. According to this view, a reasoner would be adequate if the resulting sequence is a recursively enumerable approximation of ideal warrant. However, this is impossible. Ideal warrant contains all theorems of predicate logic, and it is known that all theorems of predicate logic form a set that is not recursive. And since in defeasible reasoning some conclusions depend on the failure to derive other conclusions, the set of defeasible conclusions is not recursively enumerable. Therefore, Pollock suggests an alternative criterion of adequacy. A reasoner is called *defeasibly adequate* if the resulting sequence is a defeasibly enumerable approximation of ideal warrant.

DEFINITION 55. A set A is *defeasibly enumerable* if there is a sequence of sets $\{A_i\}_{1 \leq i}$ such that for all x

1. If $x \in A$, then there is an N such that $x \in A_i$ for all $i > N$.
2. If $x \notin A$, then there is an M such that $x \notin A_i$ for all $i > M$.

If A is recursively enumerable, then a reasoner who updates his beliefs in Pollock's way can approach A 'from below': the reasoner can construct sets that are all supersets of the preceding set and subsets of A . However, when A is only defeasibly enumerable, a reasoner can only approach A from below and above simultaneously, in the sense that the sets A_i the reasoner constructs may contain elements not contained in A . Every such element must eventually be taken out of the A_i 's, but there need not be any point at which they have *all* been removed.

To ensure defeasible adequacy, Pollock introduces the following three operations:

1. The reasoner must adopt beliefs in response to constructing arguments, provided no counterarguments have already been adopted for

any step in the argument. If a defeasible inference occurs, a check must be made whether a counterargument for it has not already been adopted as a belief.

2. The reasoner must keep track of the bases upon which its beliefs are held. When a new belief is adopted that is a defeater for a previous inference step, then the reasoner must retract that inference step and all beliefs inferred from it.
3. The reasoner must keep track of defeated inferences, and when a defeater is itself retracted (2), this should reinstate the defeated inference.

To achieve the functions just described, Pollock introduces a so-called *flag-based* reasoner. A flag-based reasoner consists of an inference engine that produces all arguments eventually, and a component computing the defeat status of arguments.

```

LOOP   BEGIN
        make-an-inference
        recompute-defeat-statuses
      END

```

The procedure `recompute-defeat-statuses` determines which arguments are defeated outright, undefeated and provisionally defeated at each iteration of the loop. That is, at each iteration it determines justification.

Pollock then identifies certain conditions under which a flag-based reasoner is defeasibly adequate. For these conditions, the reader is referred to [Pollock, 1995, ch. 4].

Evaluation

Pollock's theory of defeasible reasoning is based on more than thirty years of research in logic and epistemology. This large time span perhaps explains the richness of his theory. It includes both linear and suppositional arguments, and deductive as well as non-deductive (mainly statistical and inductive) arguments, with a corresponding distinction between two types of conflicts between arguments. Pollock's definition of the status of arguments takes the multiple-status-assignments approach, being related to Dung's preferred semantics. This semantics can deal with certain types of floating statuses and conclusions, but we have seen that certain other types are still ignored. In fact, this seems one of the main unsolved problems in argument-based semantics. An interesting aspect of Pollock's work is his study of the resource-bounded nature of practical reasoning, with the idea of partial computation embodied in the notions of warrant and especially

justification. And for artificial intelligence it is interesting that Pollock has implemented his system as a computer program.

Since Pollock focuses on epistemological issues, his system is not immediately applicable to some specific features of practical (including legal) reasoning. For instance, the use of probabilistic notions seems to make it difficult to give an account of reasoning with and about priority relations between arguments (see below in Subsection 5.7). Moreover, it would be interesting to know what Pollock would regard as suitable reasons for normative reasoning. It would also be interesting to study how, for instance, analogical and abductive arguments can be analysed in Pollock's system as giving rise to *prima facie* reasons.

5.3 Inheritance systems

A forerunner of argumentation systems is work on so-called inheritance systems, especially of Horty *et al.*, e.g. [1990], which we shall briefly discuss. Inheritance systems determine whether an object of a certain kind has a certain property. Their language is very restricted. The network is a directed graph. Its initial nodes represent individuals and its other nodes stand for classes of individuals. There are two kinds of links, \rightarrow and \nrightarrow , depending on whether something does or does not belong to a certain class. Links from an individual to a class express class membership, and links between two classes express class inclusion.

A path through the graph is an *inheritance path* iff its only negative link is the last one. Thus the following are examples of inheritance paths.

P_1 : Tweety \rightarrow Penguin \rightarrow Bird \rightarrow Canfly
 P_2 : Tweety \rightarrow Penguin \nrightarrow Canfly

Another basic notion is that of an *assertion*, which is of the form $x \rightarrow y$ or $x \nrightarrow y$, where y is a class. Such an assertion is *enabled* by an inheritance path if the path starts with x and ends with the same link to y as the assertion. Above, an assertion enabled by P_1 is Tweety \rightarrow Canfly, and an assertion enabled by P_2 is Tweety \nrightarrow Canfly.

As the example shows, two paths can be conflicting. They are compared on specificity, which is read off from the syntactic structure of the net, resulting in relations of *neutralisation* and *preemption* between paths. The assignment of a status to a path (whether it is *permitted*) is similar to the recursive variant of the unique-status-assignment approach of Definition 17. This means that the system has problems with Zombie paths and floating conclusions (as observed by Makinson & Schlechta [1991]).

Although Horty *et al.* present their system as a special-purpose formalism, it clearly has all the elements of an argumentation system. An inheritance path corresponds to an argument, and an assertion enabled by a path to a conclusion of an argument. Their notion of conflicting paths

corresponds to rebutting attack. Furthermore, neutralisation and preemption correspond to defeat, while a permitted path is the same as a justified argument.

Because of the restricted language and the rather complex definition of when an inheritance path is permitted, we shall not present the full system. However, Horty *et al.* should be credited for anticipating many distinctions and discussions in the field of defeasible argumentation. In particular, their work is a rich source of benchmark examples. We shall discuss one of them.

EXAMPLE 56. Consider four arguments A, B, C and D such that B strictly defeats A , D strictly defeats C , A and D defeat each other and B and C defeat each other.

Here is a natural-language version (due to Horty, personal communication), in which the defeat relations are based on specificity considerations.

- A = Larry is rich because he is a public defender, public defenders are lawyers, and lawyers are rich;
- B = Larry is not rich because he is a public defender, and public defenders are not rich;
- C = Larry is rich because he lives in Brentwood, and people who live in Brentwood are rich;
- D = Larry is not rich because he rents in Brentwood, and people who rent in Brentwood are not rich.

If we apply the various semantics of the BDKT approach to this example, we see that since no argument is undefeated, none of them is in the grounded extension. Moreover, there are preferred extensions in which Larry is rich, and preferred extensions in which Larry is not rich. Yet it might be argued that since both arguments that Larry is rich are strictly defeated by an argument that Larry is not rich, the sceptical conclusion should be that Larry is not rich. This is the outcome obtained by Horty *et al.* [1990]. We note that if this example is represented in the way Pollock proposes for Example 19 (see page 269 above), this outcome can also be obtained in the BDKT approach.

5.4 *Lin and Shoham*

Before the BDKT approach, an earlier attempt to provide a unifying framework for nonmonotonic logics was made by Lin & Shoham [1989]. They show how any logic, whether monotonic or not, can be reformulated as a system for constructing arguments. However, in contrast with the other theories in this section, they are not concerned with comparing incompatible arguments, and so their framework cannot be used as a theory of defeat among arguments.

The basic elements of Lin & Shoham's abstract framework are an unspecified logical language, only assumed to contain a negation symbol, and an also unspecified set of inference rules defined over the assumed language. Arguments can be constructed by chaining inference rules into trees.

Inference rules are either monotonic or nonmonotonic. For instance,

$$\begin{aligned} & \text{Penguin}(a) \rightarrow \text{Bird}(a) \\ & \text{Penguin}(a), \neg \text{ab}(\text{penguin}(a)) \rightarrow \neg \text{Fly}(a) \end{aligned}$$

are monotonic rules, and

$$\begin{aligned} & \text{True} \Rightarrow \neg \text{ab}(\text{penguin}(a)) \\ & \text{True} \Rightarrow \neg \text{ab}(\text{bird}(a)) \end{aligned}$$

are nonmonotonic rules. Note that these inference rules are, as in default logic, domain specific. In fact, Lin & Shoham do not distinguish between general and domain-dependent inference rules, as is shown by their reconstruction of default logic, to be discussed below.

Although the lack of a notion of defeat is a severe limitation, in capturing nonmonotonic consequence Lin & Shoham introduce a notion which for defeasible argumentation is very relevant viz. that of an *argument structure*.

DEFINITION 57. (argument structures) A set T of arguments is an *argument structure* if T satisfies the following conditions:

1. The set of 'base facts' (which roughly are the premises) is in T ;
2. Of every argument in T all its subarguments are in T ;
3. The set of conclusions of arguments in T is deductively closed and consistent.

Note that the notion of a 'closed' set of arguments that we used above in Pollock's Definition 47 satisfies the first two but not the third of these conditions. Note also that, although argument structures are closed under monotonic rules, they are not closed under defeasible rules.

Lin & Shoham then reformulate existing nonmonotonic logics in terms of monotonic and nonmonotonic inference rules, and show how the alternative

sets of conclusions of these logics can be captured in terms of argument structures with certain completeness properties. Bondarenko *et al.* [1997] remark that structures with these properties are very similar to their stable extensions.

The claim that existing nonmonotonic logics can be captured by an argument system is an important one, and Lin & Shoham were among the first to make it. The remainder of this section is therefore devoted to showing with an example how Lin & Shoham accomplish this, viz. for default logic [Reiter, 1980].

In default logic (see also Subsection 2.1), a *default theory* is a pair $\Delta = (W, D)$, where W is a set of first-order formulas, and D a set of defaults. Each default is of the form $A : B_1, \dots, B_n / C$, where A , B_i and C are first-order formulas. Informally, a default reads as ‘If A is known, and B_1, \dots, B_n are consistent with what is known, then C may be inferred’. An *extension* of a default theory is any set of formulas E satisfying the following conditions. $E = \bigcup_{i=0}^{\infty} E_i$, where

$$\begin{aligned} E_0 &= W, \\ E_{i+1} &= Th(E_i) \cup \{C \mid A : B_1, \dots, B_n / C \in D \\ &\quad \text{where } A \in E_i \text{ and } \neg B_1, \dots, \neg B_n \notin E_i\} \end{aligned}$$

We now discuss the correspondence between default logic and argument systems by providing a global outline of the translation and proof. Lin & Shoham perform the translation as follows. Let $\Delta = (W, D)$ be a closed default theory. Define $R(\Delta)$ to be the set of the following rules:

1. **True** is a base fact.
2. If $A \in W$, then A is a base fact of $R(\Delta)$.
3. If A_1, \dots, A_n , and B are first-order sentences and B is a consequence of A_1, \dots, A_n in first-order logic, then $A_1, \dots, A_n \rightarrow B$ is a monotonic rule.
4. If A is a first-order sentence, then $\neg A \rightarrow \text{ab}(A)$ is a monotonic rule.
5. If $A : B_1, \dots, B_n / C$ is a default in D , then

$$A, \neg \text{ab}(B_1), \dots, \neg \text{ab}(B_n) \rightarrow C$$

is a monotonic rule.

6. If B is a first-order sentence, then $\text{True} \Rightarrow \neg \text{ab}(B)$ is a nonmonotonic rule.

Lin & Shoham proceed by introducing the concept of DL-complete argument structures.

DEFINITION 58. An argument structure T of $R(\Delta)$ is said to be *DL-complete* if for any first-order sentence A , either $\text{ab}(A)$ or $\neg\text{ab}(A)$ is in $\text{Wff}(T)$.

Thus, a DL-complete argument structure is explicit about the abnormality of every first-order sentence. For DL-complete argument structures, the following lemma is established.

LEMMA 59. *If T is a DL-complete argument structure of $R(\Delta)$, then for any first-order sentence A , $\text{ab}(A) \in \text{Wff}(T)$ iff $\neg A \in \text{Wff}(T)$.*

On the basis of this result, Lin & Shoham are able to establish the following correspondence between default logic and argument systems.

THEOREM 60. *Let E be a consistent set of first-order sentences. E is an extension of Δ iff there is a DL-complete argument structure T of $R(\Delta)$ such that E is the restriction of $\text{Wff}(T)$ to the set of first-order sentences.*

This theorem is proven by constructing extensions for given argument structures and *vice versa*. If E is an extension of Δ , Lin & Shoham define T as the set of arguments with all nodes in E' , where

$$E' = E \cup \{\text{ab}(B) \mid \neg B \in E\} \cup \{\neg\text{ab}(B) \mid \neg B \notin E\}$$

and prove that $\text{Wff}(T) = E'$. Conversely, for a DL-complete argument structure T of $R(\Delta)$, Lin & Shoham prove that the first-order restriction E of $\text{Wff}(T)$ is a default extension of Δ . This is proven by induction on the definition of an extension.

Two features in the translation are worth noticing. First, default logic makes a distinction between meta-logic default rules and first-order logic, while argument systems do not. Second, the notion of groundedness of default extensions corresponds to that of an argument in argument systems, and the notion of fixed points in default logic corresponds to that of DL-completeness of argument structures.

Lin & Shoham further show that, for normal default theories, the translation can be performed without second-order predicates, such as ab . This result however falls beyond the scope of this chapter.

5.5 Vreeswijk's Abstract Argumentation Systems

Like the BDKT approach and Lin & Shoham [1989], Vreeswijk [1993a; 1997] also aims to provide an abstract framework for defeasible argumentation. His framework builds on the one of Lin & Shoham, but contains the main elements that are missing in their system, namely, notions of conflict and defeat between arguments. As Lin & Shoham, Vreeswijk also assumes an unspecified logical language \mathcal{L} , only assumed to contain the symbol \perp , denoting 'falsum' or 'contradiction,' and an unspecified set of monotonic and

nonmonotonic inference rules (which Vreeswijk calls ‘strict’ and ‘defeasible’). This also makes his system an abstract framework rather than a particular system. A point in which Vreeswijk’s work differs from Lin & Shoham is that Vreeswijk’s inference rules are not domain specific but general logical principles.

DEFINITION 61. (Rule of inference.) Let \mathcal{L} be a language.

1. A *strict rule of inference* is a formula of the form $\phi_1, \dots, \phi_n \rightarrow \phi$ where ϕ_1, \dots, ϕ_n is a finite, possibly empty, sequence in \mathcal{L} and ϕ is a member of \mathcal{L} .
2. A *defeasible rule of inference* is a formula of the form $\phi_1, \dots, \phi_n \Rightarrow \phi$ where ϕ_1, \dots, ϕ_n is a finite, possibly empty, sequence in \mathcal{L} and ϕ is a member of \mathcal{L} .

A *rule of inference* is a strict or a defeasible rule of inference.

Another aspect taken from Lin & Shoham is that in Vreeswijk’s framework, arguments can also be formed by chaining inference rules into trees.

DEFINITION 62. (Argument.) Let R be a set of rules. An argument has *premises*, a *conclusion*, *sentences* (or propositions), *assumptions*, *subarguments*, *top arguments*, a *length*, and a *size*. These are abbreviated by corresponding prefixes. An *argument* σ is

1. A member of \mathcal{L} ; in that case,

$$\begin{aligned} \text{prem}(\sigma) &= \{\sigma\}, \text{conc}(\sigma) = \sigma, \text{sent}(\sigma) = \{\sigma\}, \text{asm}(\sigma) = \emptyset, \\ \text{sub}(\sigma) &= \{\sigma\}, \text{top}(\sigma) = \{\sigma\}, \text{length}(\sigma) = 1, \text{and } \text{size}(\sigma) = \\ &1; \end{aligned}$$

or

2. A formula of the form $\sigma_1, \dots, \sigma_n \rightarrow \phi$ where $\sigma_1, \dots, \sigma_n$ is a finite, possibly empty, sequence of arguments, such that $\text{conc}(\sigma_1) = \phi_1, \dots, \text{conc}(\sigma_n) = \phi_n$ for some rule $\phi_1, \dots, \phi_n \rightarrow \phi$ in R , and $\phi \notin \text{sent}(\sigma_1) \cup \dots \cup \text{sent}(\sigma_n)$ —in that case,

$$\begin{aligned} \text{prem}(\sigma) &= \text{prem}(\sigma_1) \cup \dots \cup \text{prem}(\sigma_n), \\ \text{conc}(\sigma) &= \phi, \\ \text{sent}(\sigma) &= \text{sent}(\sigma_1) \cup \dots \cup \text{sent}(\sigma_n) \cup \{\phi\}, \\ \text{asm}(\sigma) &= \text{asm}(\sigma_1) \cup \dots \cup \text{asm}(\sigma_n), \\ \text{sub}(\sigma) &= \text{sub}(\sigma_1) \cup \dots \cup \text{sub}(\sigma_n) \cup \{\sigma\}, \\ \text{top}(\sigma) &= \{\tau_1, \dots, \tau_n \rightarrow \phi \mid \tau_1 \in \text{top}(\sigma_1), \dots, \tau_n \in \text{top}(\sigma_n)\} \cup \\ &\{\phi\}, \\ \text{length}(\sigma) &= \max\{\text{length}(\sigma_1), \dots, \text{length}(\sigma_n)\} + 1, \text{and} \\ \text{size}(\sigma) &= \text{size}(\sigma_1) + \dots + \text{size}(\sigma_n) + 1; \end{aligned}$$

or

3. A formula of the form $\sigma_1, \dots, \sigma_n \Rightarrow \phi$ where $\sigma_1, \dots, \sigma_n$ is a finite, possibly empty, sequence of arguments, such that $\text{conc}(\sigma_1) = \phi_1, \dots, \text{conc}(\sigma_n) = \phi_n$ for some rule $\phi_1, \dots, \phi_n \Rightarrow \phi$ in R , and $\phi \notin \text{sent}(\sigma_1) \cup \dots \cup \text{sent}(\sigma_n)$; for assumptions we have

$$\text{asm}(\sigma) = \text{asm}(\sigma_1) \cup \dots \cup \text{asm}(\sigma_n) \cup \{\phi\};$$

premises, conclusions, and other attributes are defined as in (2).

Arguments of type (1) are *atomic* arguments; arguments of type (2) and (3) are *composite* arguments. Thus, atomic arguments are language elements. An argument σ is said to be *in contradiction* if $\text{conc}(\sigma) = \perp$. An argument is *defeasible* if it contains at least one defeasible rule of inference; else it is *strict*.

Unlike Lin & Shoham, Vreeswijk assumes an ordering on arguments, indicating their difference in strength (on which more below).

As for conflicts between arguments, a difference from all other systems of this section (except [Verheij, 1996]; see below in subsection 5.10) is that a counterargument is in fact a *set* of arguments: Vreeswijk defines a set Σ of arguments *incompatible* with an argument τ iff the conclusions of $\Sigma \cup \{\tau\}$ give rise to a strict argument for \perp . Sets of arguments are needed because the language in Vreeswijk's framework is unspecified and therefore lacks the expressive power to 'recognise' inconsistency. The consequence of this lack of expressiveness is that a set of arguments $\sigma_1, \dots, \sigma_n$ that is incompatible with τ , cannot be joined to one argument σ that contradicts, or is inconsistent, with τ . Therefore, it is necessary to take sets of arguments into account.

Vreeswijk has no explicit notion of undercutting attacks; he claims that this notion is implicitly captured by his notion of incompatibility, viz. as arguments for the denial of a defeasible conditional used by another argument. This requires some extra assumptions on the language of an abstract argumentation system, viz. that it is closed under negation (\neg), conjunction (\wedge), material implication (\supset), and defeasible implication (\triangleright). For the latter connective Vreeswijk defines the following defeasible inference rule.

$$\varphi, \varphi \triangleright \psi \Rightarrow \psi$$

With these extra language elements, it is possible to express rules of inference (which are meta-linguistic notions) in the object language. Meta-level rules using \rightarrow (strict rule of inference) and \Rightarrow (defeasible rule of inference) are then represented by corresponding object language implication symbols \supset and \triangleright . Under this condition, Vreeswijk claims to be able to define rebutting and undercutting attackers in a formal fashion. For example, let σ and τ be arguments in Vreeswijk's system with conclusions φ and ψ , respectively. Let $\varphi_1, \dots, \varphi_n \Rightarrow \varphi$ be the top rule of σ .

Rebutting attack. If $\psi = \neg\varphi$, then Vreeswijk calls τ a *rebutting* attacker of σ . Thus, the conclusion of a rebutting attacker contradicts the conclusion of the argument it attacks.

Undercutting attack. If $\psi = \neg(\varphi_1 \wedge \dots \wedge \varphi_n > \varphi)$, i.e. if ψ is the negation of the last rule of σ stated in the object language, then τ is said to be an *undercutting* attacker of σ . Thus, the conclusion of an undercutting attacker contradicts the last inference of the argument it attacks.

Vreeswijk's notion of defeat rests on two basic concepts, viz. the above-defined notion of incompatibility and the notion of undermining. An argument is said to *undermine* a set of arguments, if it dominates at least one element of that set. Formally, a set of arguments Σ is *undermined* by an argument τ if $\sigma < \tau$ for some $\sigma \in \Sigma$. If a set of arguments is undermined by another argument, it cannot uphold or maintain all of its members in case of a conflict.

Vreeswijk then defines the notion of a defeater as follows:

DEFINITION 63. (Defeater.) Let P be a base set, and let σ be an argument. A set of arguments Σ is a *defeater* of σ if it is incompatible with σ and not undermined by it; in this case σ is said to be *defeated* by Σ , and Σ *defeats* σ . Σ is a *minimal defeater* of σ if all its proper subsets do not defeat σ .

As for the assessment of arguments, Vreeswijk's declarative definition, (which he says is about "warrant") is similar to Pollock's definition of a defeat status assignment: both definitions have an explicit recursive structure and both lead to multiple status assignments in case of irresolvable conflicts. However, Vreeswijk's status assignments cannot be partial, for which reason Vreeswijk's definition is closer to stable semantics than to preferred semantics.

DEFINITION 64. (Defeasible entailment.) Let P be a base set. A relation \sim between P and arguments based on P is a *defeasible entailment relation* if, for every argument σ based on P , we have $P \sim \sigma$ (σ is in force on the basis of P) if and only if

1. The set P contains σ ; or
2. For some arguments $\sigma_1, \dots, \sigma_n$ we have $P \sim \sigma_1, \dots, \sigma_n$ and $\sigma_1, \dots, \sigma_n \rightarrow \sigma$; or
3. For some arguments $\sigma_1, \dots, \sigma_n$ we have $P \sim \sigma_1, \dots, \sigma_n$ and $\sigma_1, \dots, \sigma_n \Rightarrow \sigma$ and every set of arguments Σ such that $P \sim \Sigma$ does not defeat σ .

In the Nixon Diamond of Example 3 this results in 'the Quaker argument is in force iff the Republican argument is not in force'. To deal with such

circularities Vreeswijk defines for every \sim satisfying the above definition an extension

$$(1) \quad \Sigma = \{\phi \mid P \sim \phi\}$$

On the basis of Definition 64 it can be proven that (1) is stable, i.e., it can be proven that $\phi \notin \Sigma$ iff Σ' defeats ϕ for some $\Sigma' \subseteq \Sigma$. With equally strong conflicting arguments, as in the Nixon Diamond, this results in multiple stable extensions (cf. Definition 38).

Just as in Dung's stable semantics, in Vreeswijk's system examples with odd defeat loops might have no extensions. However, an exception holds for the special case of self-defeating arguments, since Definition 63 implies that every argument of which the conclusion strictly implies \perp is defeated by the empty set.

Argumentation sequences

Vreeswijk extensively studies various other characterisations of defeasible argumentation. Among other things, he develops the notion of an 'argumentation sequence'. An argumentation sequence can be regarded as a sequence

$$\Sigma_1 \longrightarrow \Sigma_2 \longrightarrow \dots \longrightarrow \Sigma_n \longrightarrow \dots$$

of Lin & Shoham's [1989] argument structures, but without the condition that these structures are closed under deduction. Each following structure is constructed by applying an inference rule to the arguments in the preceding structure. An important addition to Lin & Shoham's notion is that a newly constructed argument is only appended to the sequence if it survives all counterattacks from the argument structure developed thus far. Thus the notion of an argumentation sequence embodies, like Pollock's notion of 'justification', the idea of partial computation, i.e., of assessing arguments relative to the inferences made so far. Vreeswijk's argumentation sequences also resemble BDKT's procedure for computing admissible semantics. The difference is that BDKT adopt arguments that are defended (admissible semantics), while Vreeswijk argumentation sequences adopt arguments that are not defeated (stable semantics).

Vreeswijk also develops a procedural version of his framework in dialectical style. It will be discussed below in Section 6.

Plausible reasoning

Vreeswijk further discusses a distinction between two kinds of nonmonotonic reasoning, 'defeasible' and 'plausible' reasoning. According to him, the above definition of defeasible entailment captures defeasible reasoning, which is unsound (i.e., defeasible) reasoning from firm premises, like in 'typically birds fly, Tweety is a bird, so presumably Tweety flies'. Plausible

reasoning, by contrast, is sound (i.e., deductive) reasoning from uncertain premises, as in ‘all birds fly (we think), Tweety is a bird, so Tweety flies (we think)’ [Rescher, 1976]. The difference is that in the first case a default proposition is accepted categorically, while in the second case a categorical proposition is accepted by default. In fact, Vreeswijk would regard reasoning with ordered premises, as studied in many nonmonotonic logics, not as defeasible but as plausible reasoning.

One element of this distinction is that for defeasible reasoning the ordering on arguments is not part of the input theory, reflecting priority relations between, or degrees of belief in premises, but a general ordering of *types* of arguments, such as ‘deductive arguments prevail over inductive arguments’ and ‘statistical inductive arguments prevail over generic inductive arguments’. Accordingly, Vreeswijk assumes that the ordering on arguments is the same for all sets of premises (although relative to a set of inference rules). Vreeswijk formalises plausible reasoning independent of defeasible reasoning, with the possibility to define input orderings on the premises, and he then combines the two formal treatments. To our knowledge, Vreeswijk’s framework is unique in treating these two types of reasoning in one formalism as distinct forms of reasoning; usually the two forms are regarded as alternative ways to look at the same kind of reasoning.

Evaluating Vreeswijk’s framework, we can say that it has little attention for the details of comparing arguments and that, as Pollock but in contrast to BDKT, it formalises only one type of defeasible consequence, but that it is philosophically well-motivated, and quite detailed with respect to the structure of arguments and the process of argumentation.

5.6 Simari & Loui

Simari & Loui [1992] present a declarative system for defeasible argumentation that combines ideas of Pollock [1987] on the interaction of arguments with ideas of Poole [1985] on specificity and ideas of Loui [1987] on defaults as twoplace meta-linguistic rules. Simari & Loui divide the premises into sets of contingent first-order formulas \mathcal{K}_C , and necessary first-order formulas \mathcal{K}_N , and one-directional default rules Δ , e.g.

$$\begin{aligned}\mathcal{K}_C &= \{P(a)\} \\ \mathcal{K}_N &= \{\forall x.P(x) \supset B(x)\} \\ \Delta &= \{B(x) \succ F(x), P(x) \succ \neg F(x)\}.\end{aligned}$$

Note that Simari & Loui’s default rules are not threeplace as Reiter’s defaults, but twoplace. The set of *grounded instances* of Δ , i.e., of defeasible rules without variables, is denoted by Δ^\downarrow . The notion of argument that Simari & Loui maintain is somewhat uncommon:

DEFINITION 65. (Arguments.) Given a context $\mathcal{K} = \mathcal{K}_N \cup \mathcal{K}_C$ and a set Δ of defeasible rules we say that a subset T of Δ^\downarrow is an *argument* for $h \in \text{Sent}_C(\mathcal{L})$ in the context \mathcal{K} , denoted by $\langle T, h \rangle_{\mathcal{K}}$ if and only if

1. $\mathcal{K} \cup T \vdash h$
2. $\mathcal{K} \cup T \not\vdash \perp$
3. $\nexists T' \subset T : \mathcal{K} \cup T' \vdash h$

An argument $\langle T, h_1 \rangle_{\mathcal{K}}$ is a subargument of an argument $\langle S, h_2 \rangle_{\mathcal{K}}$ iff $T \subseteq S$.

That $\mathcal{K} \cup T \vdash h$ means that h is derivable from $\mathcal{K} \cup T$ with first-order inferences applied to first-order formulas and modus ponens applied to defaults. Thus, an argument T is a set of grounded instances of defeasible rules containing sufficient rules to infer h (1), containing no rules irrelevant for inferring h (3), and not making it possible to infer \perp (2). This notion of argument is somewhat uncommon because it does not refer to a tree or chain of inference rules. Instead, Definition 65 merely demands that an argument is a unordered collection of rules that together imply a certain conclusion.

Simari & Loui define conflict between arguments as follows. An argument $\langle T, h_1 \rangle_{\mathcal{K}}$ *counterargues* an argument $\langle S, h_2 \rangle_{\mathcal{K}}$ iff the latter has a subargument $\langle S', h \rangle_{\mathcal{K}}$ such that $\langle T, h_1 \rangle_{\mathcal{K}}$ *disagrees* with $\langle S', h \rangle_{\mathcal{K}}$, i.e., $\mathcal{K} \cup \{h_1, h\} \vdash \perp$.

Arguments are compared with Poole's [1985] definition of specificity: an argument A *defeats* an argument B iff A disagrees with a subargument B^- of B and A is more specific than B^- . Note that this allows for subargument defeat: this is necessary since Simari & Loui's definition of the status of arguments is not explicitly recursive. In fact, they use Pollock's theory of level- n arguments. Since they exclude self-defeating arguments by definition, they can use the version of Definition 11.

An important component of Simari & Loui's system is the Σ^k -operator. Of all the conclusions that can be argued, the Σ^k -operator returns the conclusions that are supported by level- k arguments. Simari & Loui prove that arguments for which $\Sigma^k = \Sigma^{k+1}$, are justified. The main theorem of the paper states that the set of justified conclusions is uniquely determined, and that a repeated application of the Σ -operator will bring us to that set.

A strong point of Simari & Loui's approach is that it combines the ideas of specificity (Poole) and level- n arguments (Pollock) into one system. Another strong point of the paper is that it presents a convenient calculus of arguments, that possesses elegant mathematical properties. Finally, Simari & Loui sketch an interesting architecture for implementation, which has a dialectical form (see below, Section 6 and, for a full description, [Simari *et al.*, 1994; Garcia *et al.*, 1998]). However, the system also has some limitations. Most of them are addressed by Prakken & Sartor [1996; 1997b], to be discussed next.

5.7 Prakken & Sartor

Inspired by legal reasoning, Prakken & Sartor [1996; 1997b] have developed an argumentation system that combines the language (but not the rest) of default logic with the grounded semantics of the BDKT approach.¹⁴ Actually, Prakken & Sartor originally used the language of extended logic programming, but Prakken [1997] generalised the system to default logic's language. Below we present the latter version. The main contributions to defeasible argumentation are a study of the relation between rebutting and assumption attack, and a formalisation of argumentation about the criteria for defeat. The use of default logic's language and grounded semantics make Prakken & Sartor's system rather similar to Simari & Loui's. However, as just noted, they extend and revise it in a number of respects, to be indicated in more detail below.

As for the logical language, the premises are divided into factual knowledge \mathcal{F} , a set of first-order formulas subdivided into the necessary facts \mathcal{F}_n and the contingent facts \mathcal{F}_c , and defeasible knowledge Δ , consisting of Reiter-defaults. The set \mathcal{F} is assumed consistent. Prakken & Sartor write defaults as follows.

$$d: \varphi_1 \wedge \dots \wedge \varphi_j \wedge \sim \varphi_k \wedge \dots \wedge \sim \varphi_n \Rightarrow \psi$$

where d , a term, is the informal name of the default, and each φ_i and ψ is a first-order formula. The part $\sim \varphi_k \wedge \dots \wedge \sim \varphi_n$ corresponds to the middle part of a Reiter-default. The symbol \sim can be informally read as 'not provable that'. For each $\sim \varphi_i$ in a default, $\neg \varphi_i$ is called an *assumption* of the default. The language is defined such that defaults cannot be nested, nor combined with other formulas.

Arguments are, as in [Simari & Loui, 1992], chains of defaults 'glued' together by first-order reasoning. More precisely, consider the set \mathcal{R} consisting of all valid first-order inference rules plus the following rule of *defeasible modus ponens (DMP)*:

$$\frac{d: \quad \varphi_0 \wedge \dots \wedge \varphi_j \wedge \sim \varphi_k \wedge \dots \wedge \sim \varphi_m \Rightarrow \varphi_n, \quad \varphi_0 \wedge \dots \wedge \varphi_j}{\varphi_n}$$

where all φ_i are first-order formulas. Note that *DMP* ignores a default's assumptions; the idea is that such an assumption is untenable, this will be reflected by a successful attack on the argument using the default.

An argument is defined as follows.

DEFINITION 66. (Arguments.) Let Γ be any default theory ($\mathcal{F}_c \cup \mathcal{F}_n \cup \Delta$). An *argument based on* Γ is a sequence of distinct first-order formulas and/or ground instances of defaults $[\varphi_1, \dots, \varphi_n]$ such that for all φ_i :

¹⁴A forerunner of this system was presented in [Prakken, 1993].

- $\varphi_i \in \Gamma$; or
- There exists an inference rule $\psi_1, \dots, \psi_m / \varphi_i$ in \mathcal{R} such that $\psi_1, \dots, \psi_m \in \{\varphi_1, \dots, \varphi_{i-1}\}$

For any argument A

- $\varphi \in A$ is a *conclusion* of A iff φ is a first-order formula;
- $\varphi \in A$ is an *assumption* of A iff φ is an assumption of a default in A ;
- A is *strict* iff A does not contain any default; A is *defeasible* otherwise.

The set of conclusions of an argument A is denoted by $CONC(A)$ and the set of its assumptions by $ASS(A)$.

Note that unlike in Simari & Loui, arguments are not assumed consistent. Here is an example of an argument:

$$[a, r_1: a \wedge \sim \neg b \Rightarrow c, c, a \wedge c, r_2: a \wedge c \Rightarrow d, d, d \vee e]$$

$CONC(A) = \{a, c, a \wedge c, d, d \vee e\}$ and $ASS(A) = \{b\}$.

The presence of assumptions in a rule gives rise to two kinds of conflicts between arguments, conclusion-to-conclusion attack and conclusion-to-assumption attack.

DEFINITION 67. (Attack.) Let A and B be two arguments. A *attacks* B iff

1. $CONC(A) \cup CONC(B) \cup \mathcal{F}_n \vdash \perp$; or
2. $CONC(A) \cup \mathcal{F}_n \vdash \neg\varphi$ for any $\varphi \in ASS(B)$.

Prakken & Sartor's notion of defeat among arguments is built up from two other notions, 'rebutting' and 'undercutting' an argument. An argument A *rebutts* an argument B iff A conclusion-to-conclusion attacks B and either A is strict and B is defeasible, or A 's default rules involved in the conflict have no lower priority than B 's defaults involved in the conflict. Identifying the involved defaults and applying the priorities to them requires some subtleties for which the reader is referred to Prakken & Sartor [1996; 1997b] and Prakken [1997]. The source of the priorities will be discussed below.

An argument A *undercuts* an argument B precisely in case of the second kind of conflict (attack on an assumption). Note that it is not necessary that the default(s) responsible for the attack on the assumption has/have no lower priority than the default containing the assumption. Note also that Prakken & Sartor's undercutters capture a different situation than Pollock's: their undercutters attack an explicit non-provability assumption of another argument (in Section 3 called 'assumption attack'), while Pollock's undercutters deny the relation between premises and conclusion in a non-deductive argument.

Prakken & Sartor's notion of defeat also differs from that of Pollock [1995]. An inessential difference is that their notion allows for 'subargument defeat';

this is necessary since their definition of the status of arguments is not explicitly recursive (cf. Subsection 4.1). More importantly, Prakken & Sartor regard undercutting defeat as prior to rebutting defeat.

DEFINITION 68. (Defeat.) An argument A *defeats* an argument B iff $A = \square$ and B attacks itself, or else if

- A undercuts B ; or
- A rebuts B and B does not undercut A .

As mentioned above in Subsection 4.1, the empty argument serves to adequately deal with self-defeating arguments. By definition the empty argument is not defeated by any other argument.

The rationale for the precedence of undercutters over rebutters is explained by the following example.

EXAMPLE 69. Consider

$$\begin{aligned} r_1 : & \sim \neg \textit{Brutus is innocent} \Rightarrow \textit{Brutus is innocent} \\ r_2 : & \varphi \Rightarrow \neg \textit{Brutus is innocent} \end{aligned}$$

Assume that for some reason r_2 has no priority over r_1 and consider the arguments $[r_1]$ and $[\dots, r_2]$.¹⁵ Then, although $[r_1]$ rebuts $[\dots, r_2]$, $[r_1]$ does not defeat $[\dots, r_2]$, since $[\dots, r_2]$ undercuts $[r_1]$. So $[\dots, r_2]$ strictly defeats $[r_1]$.

Why should this be so? According to Prakken & Sartor, the crux is to regard the assumption of a rule as one of its conditions (albeit of a special kind) for application. Then the only way to accept both rules is to believe that Brutus is not innocent: in that case the condition of r_1 is not satisfied. By contrast, if it is believed that Brutus is innocent, then r_2 has to be rejected, in the sense that its conditions are believed but its consequent is not ('believing an assumption' here means not believing its negation). Note that this line of reasoning does not naturally apply to undercutters Pollock-style, which might explain why in Pollock's [1995] rebutting and undercutting defeaters stand on equal footing.

Finally, we come to Prakken & Sartor's definition of the status of arguments. As remarked above, they use the grounded semantics of Definition 7. However, they change it in one important respect. This has to do with the origin of the default priorities with which conflicting arguments are compared.

In artificial intelligence research the question where these priorities can be found is usually not treated as a matter of common-sense reasoning. Either a fixed ordering is simply assumed, or use is made of a specificity ordering, read off from the syntax or semantics of an input theory. However, Prakken

¹⁵We abbreviate arguments by omitting their conclusions and only giving the names of their defaults. Furthermore, we leave implicit that r_2 's antecedent φ is derived by a subargument of possibly several steps.

& Sartor want to capture that in many domains of common-sense reasoning, like the law or bureaucracies, priority issues are part of the domain theory. This even holds for specificity; although checking which argument is more specific may be a logical matter, deciding to prefer the most specific argument is an extra-logical decision. Besides varying from domain to domain, the priority sources can also be incomplete or inconsistent, in the same way as ‘ordinary’ domain information can be. In other words, reasoning about priorities is defeasible reasoning. (This is why our example of the introduction contains a priority argument, viz. A ’s use of (9) and (10).) For these reasons, Prakken & Sartor want that the status of arguments does not only *depend* on the priorities, but also *determines* the priorities. Accordingly, priority conclusions can be defeasibly derived within their system in the same way as conclusions like ‘Tweety flies’.¹⁶

To formalise this, Prakken & Sartor need a few technicalities. First the first-order part of the language is extended with a special twoplace predicate \prec . That $x \prec y$ means that y has priority over x . The variables x and y can be instantiated with default names. This new predicate symbol should denote a strict partial order on the set of defaults that is assumed by the metatheory of the system. For this reason, the set \mathcal{F}_n must contain the axioms of a strict partial order:

$$\begin{aligned} \textit{transitivity:} \quad & \forall x, y, z. x \prec y \wedge y \prec z \supset x \prec z \\ \textit{asymmetry:} \quad & \forall x, y. x \prec y \supset \neg y \prec x \end{aligned}$$

For simplicity, some restrictions on the syntactic form of priority expressions are assumed. \mathcal{F}_c may not contain any priority expressions, while in the defaults priority expressions may only occur in the consequent, and only in the form of conjunctions of literals (a literal is an atomic formula or a negated atomic formula). This excludes, for instance, disjunctive priority expressions.

Next, the rebut and defeat relations must be made relative to an ordering relation that might vary during the reasoning process.

DEFINITION 70. For any set S of arguments

- $\prec_S = \{r \prec r' \mid r \prec r' \text{ is a conclusion of some } A \in S\}$
- A (strictly) S -defeats B iff, assuming the ordering \prec_S on Δ , A (strictly) defeats B .

The idea is that when it must be determined whether an argument is acceptable with respect to a set S of arguments, the relevant defeat relations are verified relative to the priority conclusions drawn by the arguments in S .

¹⁶For some non-argument-based nonmonotonic logics that deal with this phenomenon, see Grosz [1993], Brewka [1994a; 1996], Prakken [1995] and Hage [1997]; see also Gordon’s [1995] use of [Geffner & Pearl, 1992].

DEFINITION 71. An argument A is *acceptable* with respect to a set S of arguments iff all arguments S -defeating A are strictly S -defeated by some argument in S .

Note that this definition also replaces the second occurrence of defeat in Definition 6 with strict defeat. This is because otherwise it cannot be proven that no two justified arguments are in conflict with each other.

Prakken & Sartor then apply the construction of Proposition 9 with Definition 71. They prove that the resulting set of justified arguments is unique and conflict-free and that, when S is this set, the ordering $<_S$ is a strict partial order. They also prove that if an argument is justified, all its sub-arguments are justified.

We illustrate the system with the following example.

EXAMPLE 72. Consider an input theory with empty \mathcal{F}_c , \mathcal{F}_n containing the above axioms for \prec , and Δ containing the following defaults.

$$\begin{array}{ll} r_0: \Rightarrow a & r_4: \Rightarrow r_0 \prec r_3 \\ r_1: a \Rightarrow b & r_5: \Rightarrow r_3 \prec r_0 \\ r_2: \sim b \Rightarrow c & r_6: \Rightarrow r_5 \prec r_4 \\ r_3: \Rightarrow \neg a & \end{array}$$

The set of justified arguments is constructed as follows (for simplicity we ignore combinations of the listed arguments).

$$\begin{array}{ll} F^0 = \emptyset & <_0 = \emptyset \\ F^1 = \{\emptyset, [r_6]\} & <_1 = \{r_5 < r_4\} \\ F^2 = F^1 \cup \{[r_4]\} & <_2 = \{r_5 < r_4, r_0 < r_3\} \\ F^3 = F^2 \cup \{[r_3]\} & <_3 = <_2 \\ F^4 = F^3 \cup \{[r_2]\} & <_4 = <_3 \\ F^5 = F^4 & <_5 = <_4 \end{array}$$

Kowalski & Toni [1996] propose an alternative formalisation of reasoning about priorities, which does not require a change of the logic. They show how within the BDKT approach priority statements can be encoded with assumptions. This method requires that the notion of conflicting rules is expressed in the logical language of the system. Similar methods in non-argument-based approaches have been proposed by Gordon [1995] and Hage [1997].

Procedural form

Like several other systems, Prakken & Sartor define a procedural version of their system in dialectical form. Compared to the other systems, its main feature is that it also covers debates about priorities. It will be discussed in some detail in Section 6.

Comparison with Simari & Loui [1992]

As remarked above, Prakken & Sartor's system is (in the version of [Prakken, 1997]) similar to Simari & Loui's. They both use the language of default logic, and their notions of an argument are quite similar: in particular, both systems use a modus ponens rule for defaults. Finally, both systems use grounded semantics and both have a procedural version in dialectical form. However, we have also seen that Prakken & Sartor extend Simari & Loui's system in a number of respects: their defaults are not twoplace but threeplace, which makes it possible to distinguish rebutting from assumption attack; they allow for comparing arguments on any ground, and they allow for debates on these grounds.

5.8 Nute's Defeasible Logic

A development closely related to defeasible argumentation is so-called 'defeasible logic', initiated by Donald Nute, e.g. [1994].¹⁷ In both fields the notion of defeat is central. However, while in defeasible argumentation defeat is among arguments, in defeasible logic it happens between rules. Nevertheless, the approaches are sufficiently similar to warrant a discussion of defeasible logic in this chapter.

In several publications Nute has developed a family of such logics. For explanatory purposes we discuss the simplest version, described in [Nute & Erk, 1995]. In a way this is unfair, since this version has a problem that is absent in the other versions. However, it is instructive to see what the problem is, and we shall indicate how Nute deals with it in his other work.

Nute's systems are based on the idea that defaults are not propositions but inference licenses. Thus Nute's defeasible rules are, like Reiter's defaults, one-directional. However, unlike Reiter's defaults they are twoplace; assumption attacks are dealt with by an explicit category of defeater rules, which are comparable to Pollock's undercutting defeaters, although in Nute's case they are, like his defeasible rules, not intended to express general principles of inference but, as in default logic, domain specific generalisations.

As for the underlying logical language, since Nute's aim is to develop a logic that is efficiently implementable, he keeps the language as simple as possible. It has three categories of one-direction rules, viz. *strict* rules $A \rightarrow p$, *defeasible rules* $A \Rightarrow p$ and *defeaters* $A \rightsquigarrow p$. In all three cases p is a strong literal, i.e., an atomic proposition or a classically negated atomic proposition, and A is a finite set of strong literals. Defeaters must be read as 'if A then it might be that p '. Defeaters cannot be used to derive formulas; they can only be used to block an application of a rule $B \Rightarrow \neg p$. An example

¹⁷In fact, Nute [1994] also counts systems for defeasible argumentation as defeasible logics.

is ‘Genetically altered penguins might fly’, which undercuts ‘Penguins don’t fly’. Thus Nute has, like Pollock, both rebutting and undercutting conflicts between arguments.

Arguments can be formed by chaining rules into trees, and conflicting arguments are compared with the help of an ordering on the rules. Actually, Nute does not work with an explicit notion of argument; instead he incorporates it in two notions of derivability, strict (\vdash) and defeasible ($\vdash\sim$) derivability, to be explained below. To capture non-derivability, Nute does not use the familiar notions \nmid (meaning ‘not \vdash ’) and $\nmid\sim$ (meaning ‘not $\vdash\sim$ ’). Instead, his aim of designing a tractable system leads him to define two notions of *demonstrable* non-derivability \dashv and $\dashv\sim$, which require that a proof of a formula fails after finitely many steps.

As just stated, Nute’s assessment of arguments is implicit in his definitions of derivability. Nute has two core definitions, depending on when the last rule of the tree is strict or defeasible. (He has similar rules for \dashv and $\dashv\sim$.) The first definition detaches consequences of strict rules.

DEFINITION 73. (Strict derivability.) $T \vdash p$ if

1. $p \in T$, or
2. There is a $A \rightarrow p \in T$ such that for every $a \in A$, $T \vdash a$.

The second definition detaches consequences of defeasible rules, taking into account all nonmonotonic proofs that derive the contrary:

DEFINITION 74. (Defeasible derivability.) $T \vdash\sim p$ if there is a rule $A \Rightarrow p \in T$ such that

1. $T \dashv \neg p$, and
2. for each $a \in A$, $T \vdash\sim a$, and
3. for each $B \rightarrow \neg p \in T$ there is $b \in B$ such that $T \dashv\sim b$, and
4. for each $C \Rightarrow \neg p \in T$ or $C \rightsquigarrow \neg p \in T$, either
 - (a) there is a $c \in C$ such that $T \dashv\sim c$ or
 - (b) $A \Rightarrow p$ has higher priority than $C \rightarrow \neg p$ (or than $C \rightsquigarrow \neg p$).

Condition (1) says that the opposite of p must demonstrably be not strictly derivable. This gives strict arguments priority over defeasible arguments. For the rest, this definition has the recursive structure discussed above in Section 4.1. There must be a defeasible rule for p which, firstly, ‘fires’, i.e., of which all antecedents are themselves defeasibly derivable (condition 2) and which, secondly, is of higher priority than any conflicting rule which also fires: for any rule which is not lower, at least one antecedent must

be demonstrably non-derivable (conditions 3–4). As a special case, condition (3) implicitly gives priority to strict rules over defeasible rules; for the rest these priorities must be defined by the user (condition 4), although Nute pays much attention to the specificity criterion. Note that like Pollock [1995], Nute applies priorities to decide whether undercutting attack succeeds.

A literal can also be derived defeasibly from a strict rule, namely, when one of its antecedents is itself derived defeasibly. When there is a strict rule for p , the definition of defeasible derivability is simpler: since strict rules have priority over the other two categories, condition 4 can be dropped. In consequence, defeasible derivability from a strict rule can only be blocked by derivability from a conflicting strict rule.

Since Definitions 73 and 74 have the recursive structure of Definition 17, they share with this definition the problem that multiple assignments are not always avoided. Consider the following variant of Example 23.

EXAMPLE 75. Assume we have the following rules

1. $\Rightarrow p$
2. $p \Rightarrow q$
3. $\Rightarrow \neg q$
4. $\neg q \Rightarrow \neg p$

Three status assignments satisfy the above definitions.

- Status assignment 1:* $T \mid\sim p, T \mid\sim q, T \not\sim \neg p, T \not\sim \neg q$;
Status assignment 2: $T \mid\sim \neg p, T \mid\sim \neg q, T \not\sim p, T \not\sim q$
Status assignment 3: $T \not\sim p, T \not\sim q, T \not\sim \neg p, T \not\sim \neg q$

Only the third assignment is intended by Nute. In his other work, e.g. [Nute, 1994], he reformulates Definitions 73 and 74, and also the rules for $\not\sim$, as conditions on finite proof trees for a formula. This solves the problem, since for the unintended status assignments no proof trees can be constructed. The crux is that $\not\sim$ must also be established by constructing a finite proof tree (being a finite proof that a formula cannot be derived). And in the above example this is impossible.

Another problem inherited from Definition 17 is that Nute's system cannot capture floating conclusions (cf. Example 24). This is since an inference of p can only be blocked by a rule for $\neg p$ if all antecedents for that rule are derivable. Since Nute has no third category 'defensible' in between '(demonstrably) derivable' and '(demonstrably) not derivable', two rules that are in an irresolvable conflict do not give rise to conclusions and thus cannot block other inferences.

Finally, Nute's system behaves in a somewhat peculiar way when a conflict involves strict rules, as in the following example:

1. x has children $\Rightarrow x$ is married
2. x lives alone $\Rightarrow x$ is a bachelor
3. x is married $\rightarrow \neg x$ is a bachelor

In Nute's system only rules with directly contradicting heads are compared, and since strict rules prevail over defeasible rules, the outcome is that x is a bachelor, even if the first defeasible rule has priority over the second. This seems counterintuitive. In [Simari & Loui, 1992] and [Prakken & Sartor, 1997b] this problem does not occur, since there (3) is in the necessary facts \mathcal{F}_n , which count in testing whether conclusions contradict each other, for which reason the conflict is recognised as being between (1) and (2). It should be noted that in his most recent work Nute deals with this problem [Nute, 1997].

Evaluation

Evaluating Nute's defeasible logic, we see that it is an instance of the recursive-definition variant of the multiple-status-assignments approach, without an intermediate notion of defensible arguments. Consequently, his system has some problems with zombie arguments and floating conclusions. On the positive side, Nute's system gives intuitive results for a large class of benchmark examples and is, due to its simple language and its transparent definitions, very suitable for implementation.

As for the relation with defeasible argumentation, although Nute never introduced 'argument' as a concept in his defeasible logics, his theory can easily be recast in terms of arguments. One way to do this is to chain Nute's rules into trees (analogously to Lin & Shoham or Vreeswijk) and call them arguments (these trees must not be confused with the above-mentioned proof trees, which are proofs that a formula is defeasibly derivable). With this definition of arguments, Definition 74 can be stated alternatively in the way Vreeswijk defines defeat among arguments. A first conclusion that may be drawn from such a translation is that Nute's logic for defeasible reasoning is closely related to other approaches discussed here. This close relation justifies the discussion of defeasible logic in this chapter. For work on formalising this relation see [Governatori & Maher, 2000]. Another conclusion is that arguments in Nute's logic defeat each other on the basis of information in top-rules only. This is due to the fact that a strong literal in Nute's system is defeasibly derivable only if the antecedent of the last rule applied is defeasibly derivable. This is in contrast with Vreeswijk's theory, in which arguments are compared and defeated in their entirety.

5.9 Defeasible argumentation in reasoning about events (Konolige, 1988)

Konolige's [1988] system ARGH (Argumentation with Hypotheses) was presented as a solution to the Yale Shooting Problem (YSP) [Hanks & McDermott, 1987]. Although the resulting formalism is still rather rudimentary, Konolige's discussion anticipates many issues and distinctions of later work, so that ARGH can be regarded as one of the forerunners of the field of defeasible argumentation.

The YSP concerns reasoning about events. The main problem to be dealt with is that sometimes the tendency of facts to 'persist' over time conflicts with the change of these facts by certain events. Konolige uses argumentation to allow various types of arguments based on considerations of persistence or change, and to adjudicate between conflicting arguments by means of principles of defeat. One such principle says that arguments based on change caused by events defeat arguments based on persistence.

The logical language of ARGH resembles McCarthy's [1969] situation calculus, where properties are attached to situations and events bring us in new situations, with new properties. This language is used for giving *world descriptions*. An example of a world-description is

$$W = \left\{ \begin{array}{lll} p, q, \neg r, s \mid s_0, & s_0 \rightarrow_{\alpha} s_1, & p, \neg q \mid s_1 \\ \text{The propositions} & \text{At situation} & \text{At situation} \\ p, q, \neg r \text{ and } s \text{ hold} & s_0, \text{ action } \alpha & s_1, \text{ the propo-} \\ \text{at situation } s_0. & \text{brings us to} & \text{situation } p \text{ still} \\ & \text{situation } s_1. & \text{holds, but } q \\ & & \text{does not.} \end{array} \right\}$$

This scheme forms a single world description, consisting of three statements. The second statement is an *event description*, connecting the two *situation descriptions* that are stated on the first and the third line. Thus, typically, the letters s_0, s_1, \dots denote *situations*, the letters p, q, r, \dots denote propositions or *properties* that hold at situations, the letters α, β, \dots denote actions or *events*. In ARGH, a world description can be partial: in the example above, neither $\neg r, s$, nor their negations are specified at s_1 .

The purpose of argumentation in ARGH is to fill in partially described worlds as much as possible, by drawing conclusions regarding missing propositional values. Konolige considers three elementary types of inference rules for constructing arguments (which because of their generality are comparable to Pollock's notion of defeasible reasons).

	<i>Notation</i>	<i>Meaning</i>
Forward persis- tence:	$p s_i \rightarrow_{\text{persist}} p s_i + 1$	If p holds at s_i , then it is likely that p holds at the next situation s_{i+1} .
Backward per- sistence:	$p s_i + 1 \rightarrow_{\text{persist}} p s_i$	If p holds at s_{i+1} , then it is likely that p is inherited from the previous situation s_i .
A p -establishing action:	$ s_i \rightarrow_{\alpha} p s_i + 1$	Doing α in s_i results in p at $s_i + 1$, defeasibly.

Labels such as ‘persist’, α and β , are not typed, that is, do not belong to a certain class of actions or propositions.

The above notation is used as a basis for constructing compound arguments and for performing defeasible reasoning. For example, the world

$W =$	$p s_1$	Proposition p holds at s_1
	$s_1 \rightarrow_{\text{wait}} s_2 \rightarrow_{\beta} s_3$	At s_1 , waiting brings us in s_2 ; then, performing β in s_2 , brings us in s_3 .

enables a number of arguments such as

	<i>Argument</i>	<i>For</i>
A	$p s_1 \rightarrow_{\text{persist}} p s_2$	$p s_2$
B	$p s_2 \rightarrow_{\text{persist}} p s_3$	$p s_3$
$A; B$	A followed by B	$p s_3$
B'	$p s_2 \rightarrow_{\beta} \neg p s_3$	$\neg p s_3$
$A; B'$	A followed by B'	$\neg p s_3$
C	$\neg p s_3 \rightarrow_{\text{persist}} \neg p s_2$	$\neg p s_2$
$A; B'; C$	A, B' followed by C	$\neg p s_2$

$A; B$ and $A; B'$ are conflicting arguments. An argument for $\neg p | s_2$ is $A; B'$, followed by C (backward persistence). In this way, the arguments A and $A; B'; C$ compete for p .

To adjudicate among competing arguments, Konolige formulates a number of *rules of defeat*, such as the rule that event arguments have priority over persistence arguments. However, he also observes that this priority rule is defeasible, by giving an example in which backwards persistence is stronger than that change-by-event. In fact, one of Konolige’s main observations is that any general, domain-independent priority principle will be very weak, and that information from the semantics of the domain will be the most important way of deciding among competing arguments. Such semantic information could, for instance, express the strength of the tendency of certain facts to persist over time. For example, the fact that a house will remain at its place is more likely to persist over time than the fact that a car will remain at its place. Thus Konolige anticipates later research on reasoning with and about domain specific priorities (see above, Section 5.7).

Evaluation

Evaluating Konolige's formalism, we can say that it is tailored to one particular problem, viz. reasoning about a changing world. However, for defeasible argumentation the main value of Konolige's system is not this application but the fact that it was one of the earliest argument-based accounts of defeasible reasoning, anticipating many of the issues arising in later work.

5.10 A brief overview of other work

We end this section with a brief overview of other work on logics for defeasible argumentation.

Loui [1987]

One of the initiators of the field of defeasible argumentation was Loui [1987]. On the basis of the same language as later used in [Simari & Loui, 1992], Loui defines arguments as graphs in which the links are formed by first-order inferences or default applications. Since defaults are twoplace, Loui only has rebutting attack. In particular, an argument A is a counterargument of an argument B if the root of A is inconsistent with some node in B . Loui orders conflicting arguments in terms of four syntactic specificity criteria, and then defines an argument A to be justified iff it is undefeated (with respect to its top node) and all its counterarguments (i.e., all argument attacking another node of A) are defeated by a counterargument.

As this brief description shows, Loui's [1987] system already has all the elements of an argumentation system. The ideas of this paper have been very influential, but the formalism has some technical flaws, for which reason it has not survived. His paper with Simari was Loui's own attempt to overcome the flaws. Loui's most recent work (e.g. [Loui & Norman, 1995; Loui, 1998]) addresses the procedural aspects of argumentation.

Connection with truth-maintenance systems

Systems for defeasible argumentation are related to so-called truth-maintenance systems (TMSs). A TMS is a bookkeeping system for a reasoning system, in which logical dependencies among propositional beliefs, or assertions, are represented and maintained to preserve consistency of the reasoning system. There exists several TMSs, such as Justification-Based [Doyle, 1979], Assumption-Based, [De Kleer, 1986] and Logic-Based TMSs. Basically, in all TMSs all assertions are connected via a network of dependencies and all TMSs do some form of dependency-directed backtracking. In Justification-Based TMSs, for example,

- The structure of the assertions themselves is left unspecified. Each supported belief (assertion) has a so-called *justification*.

- Each justification has two parts:
 1. An IN-List which supports beliefs held.
 2. An OUT-List which supports beliefs not held.
- An assertion is connected to its justification by an arrow; one assertion can feed another justification thus creating the network.
- Assertions may be labelled with a belief status.
- An assertion is valid if every assertion in its IN-List is believed and none in its OUT-List are believed.
- An assertion is *non-monotonic* if the OUT-List is not empty or if any assertion in the IN-List is *non-monotonic*.

Thus, the concepts and ideas are similar in spirit to those underlying argumentation systems. For instance, the issues of multiple and nonexisting status assignments have been studied in the literature on Justification-Based TMSs as the issues of multiple and nonexisting labellings of a dependency network. Since [Doyle, 1979], a variety of TMSs have been developed as a means of implementing nonmonotonic reasoning. The relation between TMSs and nonmonotonic reasoning is further discussed in [Martins & Reinfrank, 1991]. Baker & Ginsberg [1989] establish a connection with argument and debate.

Krause et al. [1995]

Recently, the system of Krause *et al.* [1995], further explored by Elvang-Gøransson & Hunter [1995], has attracted some attention in the multi-agent community, as a component of models of negotiation; cf. [Parsons *et al.*, 1998]. In this system, arguments are essentially a (Premises, Conclusion) pair, where the conclusion follows from the set Premises according to a system of intuitionistic logic. The conclusion of an argument can, as in Pollock's system, have a degree of belief, which allows arguments to be ordered using numerical (e.g. probabilistic) information. The only type of conflict is conclusion-to-conclusion attack. However, Krause *et al.* distinguish two subtypes, "rebutting" and "undercutting" conflict, with a deviating use of the term 'undercutter': in their terms, A undercuts B iff A rebuts (i.e., conclusion-to-conclusion-attacks) a subargument of B . (An argument (S, φ) is a subargument of an argument (T, ψ) iff $S \subseteq T$.)

The main feature that sets this system apart from other systems, is the definition of the status of arguments. Given rebutting and undercutting relations between arguments, arguments are divided into the following categories (relative to a certain input theory Δ).

DEFINITION 76. (Argument classes.)

- A1 is the class of all arguments that can be made from Δ .
- A2 is the class of all consistent arguments that can be made from Δ .
- A3 is the class of all consistent arguments from Δ without rebutting arguments.
- A4 is the class of all consistent arguments from Δ without undercutting arguments.
- A5 is the class of all arguments with empty set of Premises.

Observe that $A5 \subseteq A4 \subseteq A3 \subseteq A2 \subseteq A1$. (Note that rebutting an argument implies undercutting it.) Accordingly, arguments in smaller classes are regarded as better than arguments in larger classes. Krause *et al.* also consider a refinement of this ordering in terms of the degrees of belief of arguments.

In our opinion, a drawback of this definition is that it does not capture reinstatement.

Argument-based proof theories for preferential entailment

Two argumentation-theoretic proof theories have been proposed for a preferred-model semantics. As explained in Section 2, in preferential entailment defaults are represented as first-order material implications with special ‘normality conditions’, as in

- (1) $\forall x. \text{Bird}(x) \wedge \neg \text{ab}_1(x) \supset \text{Canfly}(x)$
- (2) $\forall x. \text{Penguin}(x) \wedge \neg \text{ab}_2(x) \supset \neg \text{Canfly}(x)$

First-order theories containing such defaults are then semantically interpreted by only looking at those models where the extension of the ab_i predicates are minimal (with respect to set inclusion), which captures the assumption that the world is as normal as possible.

The proof-theoretic idea is that arguments are (in their simplest form) a set of normality statements that can be added to a certain theory to derive certain conclusions. (This is essentially a special case of Bondarenko *et al.*'s [1997] assumption-based definition of an argument.) For instance, suppose that the defaults (1) and (2) are part of a first-order theory

$$T = \{1, 2\} \cup \{\text{Penguin}(\text{Tweety}), \forall x. \text{Penguin}(x) \supset \text{Bird}(x)\}$$

Then $A = \{\neg \text{ab}_1(\text{Tweety})\}$ is an argument for the conclusion $\text{Canfly}(\text{Tweety})$, since $T \cup A \vdash \text{Canfly}(\text{Tweety})$, and $B = \{\neg \text{ab}_2(\text{Tweety})\}$ is an argument for $\neg \text{Canfly}(\text{Tweety})$, since $T \cup B \vdash \neg \text{Canfly}(\text{Tweety})$. In order to capture floating conclusions (cf. Example 25), the general form of an argument is

not that of a set but of a collection of sets of normality assumptions (an alternative form is that of a disjunction of conjunctions of such assumptions). Conflicting arguments can be compared in terms of an ordering of the normality assumptions.

Baker & Ginsberg [1989]

Baker & Ginsberg [1989] have applied this idea to the semantics of so-called prioritised circumscription. In their proof theory, an argument A *rebuts* another argument B if A and B have contradictory conclusions, and if A 's least default is not inferior to B 's least default, while A *refutes* B if in addition its least default has priority over the least default of B . A defeasible proof then has a dialectical form, which form will be discussed in detail in Section 6. Baker & Ginsberg prove that this proof theory is sound and complete with respect to the model theory of prioritised circumscription.

Geffner & Pearl [1992]

Geffner & Pearl [1992] have proposed similar ideas, in a proof theory for their “conditional entailment” (see also [Geffner, 1991], for an application to logic programming’s negation as failure). When representing default rules, a minor difference with Baker & Ginsberg is that they use positive ‘applicability’ atoms δ_i instead of negated abnormality atoms. In their preferred model semantics they then prefer those models which make as few applicability atoms false as possible. In ordering applicability atoms, Geffner and Pearl define a class of “admissible orderings” which, if respected by the preference relation on models, reflects the notion of specificity. Although this notion is the only source of priorities that Geffner & Pearl consider, their formalism seems not to exclude orderings on the δ_i 's based on other standards.

Geffner & Pearl’s proof theory is sound and complete with respect to conditional entailment. They also define an architecture for (incompletely) implementing the proof theory as a computer program, which has the dialectical flavour that will be the topic of Section 6. Bondarenko *et al.* [1997] conjecture that it computes the grounded semantics of Definition 7.

Evaluation

The idea of providing a model-theoretic foundation for defeasible argumentation is interesting, but as we remarked at the end of Section 3, a critical test for such approaches is whether the resulting criteria for model preference are sufficiently natural. For certain restricted applications this test might succeed, but it remains to be seen to what extent this approach can be generalised; for instance, to argumentation systems that allow for inductive, analogical or abductive arguments.

Verheij [1996]

Verheij combines ideas of Lin & Shoham and Vreeswijk on the structure of arguments with Pollock's partial status assignments into a formalism called CumulA. This system has three distinctive features. The first is a new type of argument called 'coordinated argument', which combines two arguments for the same conclusion. For instance, from the arguments '*The sun is shining. So, it is a beautiful day*' and '*The sky is blue. So, it is a beautiful day*' it is possible to construct a new argument '*The sun is shining; the sky is blue. So, it is a beautiful day*'. Verheij stresses that this is not the same as an ordinary argument with two premises: the semicolon expresses that each premise on its own also supports the conclusion. With coordinated arguments Verheij wants to capture the 'accrual of arguments', i.e., the phenomenon that a combination of arguments that are individually defeated by another argument, possibly defeats that argument.

EXAMPLE 77. (Accrual of arguments.) Consider the arguments

- A: Peter robbed a person, therefore Peter should be punished.
- B: Peter injured a person, therefore Peter should be punished.
- C: Peter is a minor offender and should therefore not be punished.
- D: Peter robbed a person. He injured that person too. Therefore, Peter should be punished.

According to Verheij, it is conceivable that the coordination *D* of *A* and *B* prevails over *C*, even if *C* would prevail over *A* and *B* when these are considered individually. Accordingly, Verheij allows that a status assignment makes a coordinated argument 'in' even when any of its components would be 'out' when present without the others. On the other hand, any status assignment should make a coordinated argument 'in' if already one of its components is 'in'.

A second feature of CumulA is that it generalises other argumentation systems by making defeat a relation between *sets* of arguments. According to Verheij this enables a more natural formalisation of certain types of defeat. Verheij also argues that several types of defeat, such as Pollock's undercutters, cannot be defined in terms of inconsistency between conclusions of arguments. For this reason, in CumulA the relation of 'defeat' is, as in [Dung, 1995], a primitive notion and can be further defined in various ways, which may but need not be triggered by inconsistency of conclusions. Verheij claims that his treatment of defeaters is able to capture a wide range of types of defeat proposed in the literature.

A final feature of CumulA is its further development of Lin & Shoham's and Vreeswijk's notions of argument structures and sequences. In particular,

Cumula models the replacement of a premise with an argument that has this premise as conclusion. Such a move is very common in actual debates but has not yet received much attention in the field of defeasible argumentation (but see Loui, 1998). Verheij also develops an elegant notation that shows how the status of arguments can change when more arguments are taken into account (Figure 9).

Figure 9. Stages of argumentation when C defeats A , C defeats B , but $\{A, B\}$ defeats C . Each node represents a partial defeat status assignment (cf. Definition 47), and reflects a ‘stage’ in the argumentation process. Arguments between parentheses have the status ‘defeated’, the other arguments have the status ‘undefeated’.

Other work

Finally, we mention other relevant work on logics for defeasible argumentation.

Marek *et al.* [1990; 1992] aim to capture the main existing nonmonotonic logics in a general framework of so-called ‘nonmonotonic rule systems’. The basic notion is not that of an argument but that of a (one-direction) rule. They define a notion of extensions of a given rule system as a set of formulas that has certain closure and completeness properties with regard to rule application. Bondarenko *et al.* [1997] prove that these extensions correspond to stable semantics. Marek *et al.*’s ideas bear some resemblance to Lin & Shoham’s system. Both systems aim to be a general framework for capturing nonmonotonic logics, both work with one-direction rules, and Marek *et al.*’s notion of extensions is related to Lin & Shoham’s notion of a complete argument structure. Finally, neither have a mechanism of defeat among arguments (or proofs).

Benferhat *et al.* [1993] study argumentative reasoning with inconsistent databases. An argument for a formula is a consistent subset of a database (which is a set of logical formulas) that classically entails the formula. Conflicts between arguments are resolved with an ordering on the elements of

the database. The approach and its relation with inconsistency handling approaches (cf. Section 2.1) and other argumentation systems is further investigated by Benferhat *et al.* [1995], Cayrol [1995] and Amgoud & Cayrol [1997].

The BDKT framework has triggered further work in the area of logic programming. For instance, Dung [1993] has applied his own framework to the semantics of extended logic programming. Thielscher [1996] has defined a semantics and proof theory for drawing sceptical conclusions from multiple status assignments, based on an adapted version of Dung's [1995] framework. And Jakobovits [Jakobovits & Vermeir, 1999; Jakobovits, 2000] has generalised Dung's version of the BDKT framework by defining several weak notions of argument extensions, and examining the relation with the various BDKT semantics.

Finally, Starmans [1996] carries the ideas of defeasible argumentation to a multi-agent environment, where more than two parties participate in a dispute. Part of this endeavour is to show that n -party disputes, where $n \geq 3$, involve a richer arsenal of speech acts (question, demand for clarification, refusal of adduced evidence) and other types of attack than just rebutting or undercutting counterarguments (such as such as just refusing to accept a certain claim). As debate proceeds, on the basis of the individual theories a so-called *aggregated* theory is formed, which contains the claims that are supported collectively by the group of disputants. This process can be constrained by so-called *principles of preservation*. Starmans discusses a number of such principles analogous to choice principles in the theory of social choice.

6 DIALECTICAL FORMS OF ARGUMENTATION SYSTEMS

So far mainly semantical aspects have been discussed, where the main focus was on properties of *sets* of arguments. In this section we shall go deeper into proof-theoretical, or procedural aspects of argumentation, where the chief concern is to establish the status of *individual* arguments. Several argumentation systems have been formulated in dialectical style [Baker & Ginsberg, 1989; Simari & Loui, 1992; Vreeswijk, 1993b; Simari *et al.*, 1994; Dung, 1994; Brewka, 1994b; Prakken & Sartor, 1996; Loui, 1998; Garcia *et al.*, 1998; Prakken, 1999; Kakas & Toni, 1999; Jakobovits, 2000]. (It should be noted that Loui [1998] does not regard the dialectical style merely as a reformulation of declarative nonmonotonic logics, but as a formalism in its own right, capturing the “essentially constructive” nature of defeasible reasoning, which, Loui argues, cannot be captured by declarative formalisms.)

The common idea can be explained in terms of a dialogue game between two players, a proponent and an opponent of an argument. A dialogue is an alternating series of moves by the two players. The proponent starts with an

argument to be tested, and each following move consists of an argument that attacks the last move of the other party with a certain minimum force. The initial argument provably has a certain status if the proponent has a winning strategy, i.e., if he can make the opponent run out of moves whatever moves the opponent makes. The exact rules of the game depend on the semantics it is meant to capture. A natural idea here is that of dialectical asymmetry. For instance, if the game reflects sceptical reasoning, i.e., if it is meant to test whether an argument is justified, the proponent's arguments can be required to be strictly defeating while the opponent's moves may be just defeating. If, on the other hand, the game reflects credulous reasoning, these rules can be reversed (as suggested by Prakken [1999]).

Let us introduce the concept of dispute more formally by making use of an adapted version of what is called a 'dialogue' in [Prakken & Sartor, 1996] and 'argument game' in [Loui, 1998]. It is meant to capture sceptical reasoning.

DEFINITION 78. (Disputes.) A *dispute* on an argument A is a non-empty sequence of arguments $move_i = (Player_i, A_i)$ ($i > 0$) with $A_1 = A$, in which one player, denoted by **PRO**, uses odd-numbered moves to try to establish A and another player, denoted by **CON**, uses even-numbered moves to try to prevent $Player_1$'s success.

1. $Player_i = \mathbf{PRO}$ iff i is odd; and $Player_i = \mathbf{CON}$ iff i is even;
2. If $Player_i = Player_j = \mathbf{PRO}$ and $i \neq j$, then $A_i \neq A_j$;
3. If $Player_i = \mathbf{PRO}$ ($i > 1$), then A_i strictly defeats A_{i-1} ;
4. If $Player_i = \mathbf{CON}$, then A_i defeats A_{i-1} .

The first condition stipulates that **PRO** begins and then the players take turns, while the second condition prevents the proponent from repeating its attacks. The remaining two conditions form the heart of the definition: they state the burdens of proof for **PRO** and **CON**. Thus, **PRO** is required to establish A while **CON** need only provide nuisance defeaters.

The various authors format their disputes in different ways. Vreeswijk [1993b; 1995] uses a format that displays the depth of the proof tree and is able to represent exhaustive disputes. (See below.) Here we have instead used a simplified version of the format used by [Dung, 1994; Prakken & Sartor, 1997b; Loui, 1998]. This format is simple and compact, but does not represent the depth of the proof tree.

EXAMPLE 79. Let A, B, C and D be arguments such that B and D defeat A , and C defeats B . Then a dispute on A may run as follows:

PRO: A , **CON**: B , **PRO**: C

In this dispute **PRO** advances A as an argument supporting the main thesis. (Arguments are conceived as primitive concepts here, so that the main thesis is left unspecified.) Both B and D defeat A , which means that **CON** has two choices in response to A . **CON** chooses to respond with B in the second move. Then C is the only argument defeating B , so that **PRO** has no choice than to respond with C in the third move. There are no arguments against C , so that **CON** cannot move and loses the dispute. As a result, A and C are established, and B is overruled by C .

A dispute in which **CON** follows an optimal strategy is

PRO: A , **CON**: D

So in this game, under these rules, there is no winning strategy for player 1, **PRO**. The only reason why **PRO** wins the first dispute is that **CON** chooses the wrong argument, viz. B , in response to A . In fact, **CON** is in the position to win every game, provided it chooses the right moves. In other words, **CON** possesses a winning strategy.

The concept of dispute presently discussed can be characterised as a so-called *argument game*. An argument game is a ‘one-dimensional’ dispute in which each player may respond only once to each argument advanced by the opponent, and if that argument turns out to be ineffective, that player may not try a second reply to the same argument. Thus, no backtracking is allowed. This fact makes argument games into what is officially known as *two-player zero-sum games*, including the concepts that come with it, the most important of which is strategy.

Exhaustive dispute

The opposite of an argument game is a so-called *exhaustive dispute*. An exhaustive dispute is a dialogue in which each player is allowed to try out every possible rebuttal in reply to the arguments of its opponent. If a player discovers that it has put forward the wrong argument, it can recover from its mistake by trying another argument, provided there are such alternatives.

In displaying exhaustive disputes, we follow the format of Vreeswijk [1993b; 1995], in which the depth of the proof tree is represented by vertical bars in the left column:

- | | | |
|----|--|---------------------------|
| 1. | PRO : argument 1 | [justification] |
| 2. | CON : reply | [justification for reply] |
| 3. | PRO : reply to reply | ... |
| 4. | CON : 2nd reply to argument 1 | ... |
| 5. | PRO : reply to 2nd reply | ... |
| 6. | CON : reply to reply to 2nd reply | ... |
| ⋮ | ⋮ | ⋮ |

With the arguments presented in Example 79, **CON** has two strategies: one employing *B* and one employing *D*; let us refer to these strategies as *strategy B* and *strategy D*, respectively. As remarked above, when the players are engaged in an argument game, **CON** must choose between strategy *B* and strategy *D*. What **CON** cannot do is deploying *B* and *D* one after the other. In an exhaustive dispute, on the other hand, **CON** has the opportunity to try both strategies in succession:

1. | **PRO** : *A* [A]
2. || **CON** : *B* [*B* defeats *A*]
3. ||| **PRO** : *C* [*C* defeats *B*]
4. ||| **CON** : *D* [*D* defeats *A*]

At line 1, **PRO** advances *A* as an argument supporting the main thesis. (The main thesis is left unspecified here.) Both *B* and *D* defeat *A*, so that **CON** has two choices in response to *A*. **CON** chooses to respond with *B* at line 2. *C* is the only argument defeating *B*, so that **PRO** responds with *C* at line 3. There are no counterarguments to *C*, so that **CON** backtracks and searches new counterarguments to *A*. **CON** finds *D* as a new counterargument to *A*. At line 4, **CON** advances *D* in reply to *A*. There are no arguments against *D*, so that **PRO** cannot move and loses the dispute. As a result, we know that *A* cannot be established as justified.

Had **CON** responded with *D* instead of *B* at line 2, then the dispute would be settled within 2 moves:

1. | **PRO** : *A* [A]
2. || **CON** : *D* [*D* defeats *C*]

The choice and order of moves is determined by the players.

In the above definition as well as in most approaches a move consists of a complete argument. This means that the search for an individual argument is conducted in a ‘monological’ fashion, determined by the nature of the underlying logic; only the process of considering counterarguments is modelled dialectically. A notable exception is [Loui, 1998], in which arguments are constructed piecewise (beginning with the top-rule) and dialogue moves consist of

- attacking the conclusion of an unfinished argument,
- challenging an unfinished argument, or
- extending an unfinished argument in a top-down fashion on request of the opponent.

Another feature of Loui’s protocol is that, to reflect the idea of resource-bounded reasoning, every move consumes resources except requests to the opponent to extend unfinished arguments.

Completeness results

An important objective in the dialectic approach is a correspondence between the various argument-based semantics and the different forms of dispute.

Dung [1994] establishes a correspondence between the semantics defined in Definition 7 (grounded semantics) and his notion of argument game. Dung's game is similar to the one of Definition 78, but it is different in two respects: it does not have the nonrepetition rule (2), and it allows that **PRO**'s moves are, like **CON**'s moves, just defeating. On the other hand, Prakken & Sartor [1997b] show that Dung's result also holds for Definition 78. Thus they give a justification to the nonrepetition rule and the dialectical asymmetry, in the sense that these features make debate more efficient while preserving semantical soundness of the game. Intuitively, this is since the only effect of these features is the termination of dialogues that could otherwise go on forever: thus they do not deny **PRO** any chance of winning the debate.

As for some details, Dung's idea is to establish a mapping for which

- arguments in the set F^{2i} map to arguments for which **PRO** has a winning strategy that results in an argument game of at most $2i$ moves
- arguments *not* in F^{2i+1} map to arguments for which **CON** has a winning strategy that results in an argument game of at most $2i + 1$ moves

Another completeness result is established by Vreeswijk [1995], between a particular form of exhaustive dispute and a variant of his argumentation system with grounded instead of stable semantics (in the 'levelled' form of Definition 11). Furthermore, Kakas & Toni [1999] define dialectical versions of most of the assumption-based semantics proposed by Bondarenko *et al.* [1997], while Jakobovits [2000] does the same for several of her generalisations of the BDKT semantics. Finally, Vreeswijk & Prakken [2000] define a dialectical version of preferred semantics, both for sceptical and for credulous reasoning.

Disputes with defeasible priorities

Prakken & Sartor [1997b] extend their dialectical proof theory (see Definition 78) to the case with defeasible priorities. The main problem is on the basis of which priorities the defeating force of the moves should be determined. In fact, a few very simple conditions suffice. **CON** may completely ignore priorities: it suffices that its moves \emptyset -defeat **PRO**'s previous move. And for **PRO** only those priorities count that are stated by **PRO**'s move itself, i.e., moving with an argument A is allowed for **PRO** if A strictly A -defeats **CON**'s previous move; in addition, **PRO** has a new move available,

viz. moving a priority argument A such that **CON**'s last move does not A -defeat **PRO**'s previous move.

This results in the following change of conditions (3) and (4) of Definition 78.

- (3) If $Player_i = \mathbf{PRO}$ ($i > 1$), then
- Arg_i strictly Arg_i -defeats Arg_{i-1} ; or
 - Arg_{i-1} does not Arg_i -defeat A_{i-2} .
- (4) If $Player_i = \mathbf{CON}$ then Arg_i \emptyset -defeats Arg_{i-1} .

Prakken & Sartor [1997b] show that their correctness and completeness results also hold for this definition (although in this case dialectical asymmetry is necessary). The main feature of their system that ensures this is the following property of the defeat relation: if A S -defeats B and $S' \subseteq S$, then A S' -defeats B .

Consider by way of illustration the dialectical version of Example 72.

$$\begin{array}{ll} \mathbf{PRO}_1 : [r_2 : \sim b \Rightarrow c] & \mathbf{CON}_1 : [r_0 : \Rightarrow a, r_1 : a \Rightarrow b] \\ \mathbf{PRO}_2 : [r_3 : \Rightarrow \neg a, r_4 : \Rightarrow r_0 \prec r_3] & \mathbf{CON}_2 : [r_5 : \Rightarrow r_3 \prec r_0] \\ \mathbf{PRO}_3 : [r_6 : \Rightarrow r_5 \prec r_4] & \end{array}$$

Here, **PRO**₂ uses the first available type of move, while **PRO**₃ uses the second type.

7 FINAL REMARKS

As we remarked in the introduction, the field of defeasible argumentation is still young, with a proliferation of systems and disagreement on many issues. Nevertheless, we have also observed many similarities and connections between the various systems, and we have seen that a formal meta-theory is emerging. In particular the BDKT approach has shown that a unifying account is possible; not only has it shown that many differences between argument-based systems are variations on just a few basic themes, but also has it shown how many nonmonotonic logics can be reformulated in argument-based terms. And Pollock's work on partial computation and adequacy criteria for defeasible reasoners paves the way for more meta-theoretical research. This also holds for the work of Lin & Shoham, Vreeswijk and Verheij on argumentation sequences, and for the just-discussed work on argument games and disputes.

In addition, several differences between the various systems appear to be mainly a matter of design, i.e., the systems are, to a large extent, translatable into each other. This holds, for instance, for the conceptions of arguments as sets (Simari & Loui), sequences (Prakken & Sartor) or trees (Lin & Shoham, Nute, Vreeswijk), and for the implicit (BDKT, Simari &

Loui, Prakken & Sartor), or explicit (Pollock, Nute, Vreeswijk) stepwise assessment of arguments. Moreover, other differences result from different levels of abstraction, notably with respect to the underlying logical language, the structure of arguments and the grounds for defeat. And some systems extend other systems: for example, Vreeswijk extends Lin & Shoham by adding the possibility to compare conflicting arguments, and Prakken & Sartor extend Simari & Loui with priorities from any source and with assumption attack, and they extend both Simari & Loui and Dung [1995] with reasoning about priorities. Finally, the declarative form of some systems and the procedural form of other systems are two sides of the same coin, as are the semantics and proof theory of standard logic.

The main substantial differences between the systems are probably the various notions of defeasible consequence described in Section 4, often reflecting a clash of intuitions in particular examples. Although the debate on the best definitions will probably continue for some time, in our opinion the BDKT approach has nevertheless shown that to a certain degree a unifying account is possible here also. Moreover, as already explained at the end of Section 4, some of the different consequence notions are not mutually exclusive but can be used in parallel, as capturing different senses in which belief in a proposition can be supported by a body of information. And each of these notions may be useful in a different context or for different purposes. Of course, in some cases this is otherwise. For instance, we would regard a definition as flawed if it does not capture indirect reinstatement (cf. p. 245). However, in general the existence of different definitions is not a problem for, but a feature of the field of defeasible argumentation. An important consequence of this is that the choice between the notions might depend on pragmatic considerations, as is, for instance, the case in legal procedure for the standards of proof. For example, the distinction in Anglo-Saxon jurisdictions between ‘beyond reasonable doubt’ in criminal cases and ‘on the balance of probabilities’ in civil cases is of a pragmatic nature; there are no intrinsic reasons to prefer one standard over the other as being ‘the’ standard of rational belief.

Another important difference is that while some systems formalise ‘logically ideal’ reasoners, other systems embody the idea of partial computation, i.e., of evaluating arguments not with respect to all possible arguments but only with respect to the arguments that have actually been constructed by the reasoner (Pollock, Loui, Vreeswijk, Verheij). However, here, too, we can say that these notions are not rivals, but capture different senses of support for beliefs, perhaps useful in different contexts.

We end with listing some of the main open problems in defeasible argumentation.

- Some examples do not receive a fully adequate treatment in any of the semantics that we have discussed. This holds, for instance, for

the ‘seemingly defeated’ arguments discussed in Section 5.2, and for Horty’s example discussed in Section 5.3. And perhaps other ‘critical’ examples can be discovered.

- Verheij’s work raises the question whether the conflict types that have been discussed in this chapter are all types of conflict that can exist between arguments.
- Another question raised by Verheij is what the best treatment is of accrual of arguments.
- Our informal remarks on the relation between the various systems should, where possible, be turned into a formal meta-theory of defeasible argumentation, making use of the work that has already been done.
- The procedural form of defeasible argumentation must be further developed; most current systems only have a semantic form.
- The notion of partial computation should be further studied. This notion is not only relevant for artificial intelligence but also for philosophy. The essence of defeasible reasoning is that it is reasoning under less than perfect conditions, where it is difficult or even impossible to obtain complete and reliable information. Since these conditions are very common in daily life, the correctness conditions for reasoning in such circumstances should be of interest to any logician who wants to study the formal structure of ordinary reasoning.
- Finally, it would be interesting to connect argumentation systems with research in so-called ‘formal dialectics’, which studies formal systems of procedural rules for dialogues; see e.g. Hamblin [1971], MacKenzie [1979] and Walton & Krabbe [1995]. Both fields would be enriched by such a connection. The argument games discussed in Section 6 are, unlike those of formal dialectics, not rules for real discussions between persons, but just serve as a proof theory for a (nonmonotonic) logic, i.e. they determine the (defeasible) consequences of a given set of premises. The ‘players’ of these argument games are not real actors but stand for the alternate search for arguments and counterarguments that is required by the proof theory. An embedding of argumentation systems in formal dialectics would yield an account of how their input theories are constructed dynamically during disputes between real discussants, instead of given in advance and fixed. On the other hand, argumentation systems could also enrich formal dialectics, which lacks notions of counterargument and defeat; its underlying logic is still deductive and its main dialectical speech act is

asking for premises that support a certain claim; ‘real’ counterarguments are impossible. Defeasible argumentation can provide formal dialectics with stronger dialectical features.

Some work of this nature has already been done, much of it in the area of artificial intelligence and law [Loui, 1998; Hage *et al.*, 1994; Gordon, 1995; Loui & Norman, 1995; Starmans, 1996; Prakken & Sartor, 1998; Lodder, 1999; Vreeswijk, 1999; Prakken, 2000]. Such work could provide a key in meeting Toulmin’s [1958] challenge to logicians to study how the properties of disputational procedures influence the validity of arguments. Perhaps in 1958 Toulmin’s challenge seemed odd, but 40 years of work in logic, philosophy, artificial intelligence and argumentation theory have brought an answer within reach.

ACKNOWLEDGEMENTS

We thank all those with whom over the years we have had fruitful discussions on the topic of defeasible argumentation. Useful comments on an earlier version of this chapter were given by Jaap Hage, Simon Parsons, John Pollock and Bart Verheij.

SVEN OVE HANSSON

PREFERENCE LOGIC

1 INTRODUCTION

The study of general principles for preferences can, if we so wish, be traced back to Book III of Aristotle's *Topics*. Since the early twentieth century several philosophers have approached the subject of preferences with logical tools, but it is probably fair to say that the first complete systems of preference logic were those proposed by Sören Halldén in 1957 and Georg Henrik von Wright in 1963. [Rescher, 1968, pp. 287–288; Halldén, 1967; von Wright, 1963]. The subject also has important roots in utility theory and in the theory of games and decisions.

Preferences and their logical properties have a central role in rational choice theory, a subject that in its turn permeates modern economics, as well as other branches of formalized social science. Some of the most important recent developments in moral philosophy make essential use of preference logic [Fehige and Wessels, 1998]. At the same time, preference logic has turned out to be an indispensable tool in studies of belief revision and non-monotonic logic [Rott, 1999]. Preference logic has become so integrated into both philosophy and social science that we run the risk of taking it for granted and not noticing its influence.

This chapter is devoted to the philosophical foundations, rather than the applications, of preference logic. The emphasis is on fundamental results and their interpretation. Section 2 treats the basic case in which the objects of preferences form a set of mutually exclusive alternatives. In Section 3, such preferences are related to choice functions. In Section 4, the requirement of mutual exclusivity is relaxed. In Section 5, preferences are related to monadic concepts such as 'best', 'good', and 'ought'.

2 PREFERENCES OVER INCOMPATIBLE ALTERNATIVES

In most applications of preference logic, the objects that preferences refer to are assumed to be mutually exclusive. This assumption will also be made in the present section.

2.1 Preference, indifference, and other value concepts

From a logical point of view, the major value concepts of ordinary language can be divided into two major categories. The *monadic* (classificatory) value concepts, such as 'good', 'very bad', and 'worst' report how we evaluate a

single referent. The *dyadic* (comparative) value concepts, such as ‘better’, ‘worse’, and ‘equal in value to’, indicate a relation between two referents. In less colloquial contexts we can also find three-termed value predicates, such as ‘if x , then y is better than z ’ (conditional preferences) and even four-termed ones, such as ‘ x is preferred to y more than z is preferred to w ’ [Packard, 1987]. This chapter is primarily devoted to the dyadic value concepts.

There are two fundamental comparative value concepts, namely ‘better’ (strict preference) and ‘equal in value to’ (indifference) [Halldén, 1957, p. 10]. The relations of preference and indifference between alternatives are usually denoted by the symbols $>$ and \equiv or by the symbols P and I . Here, the former notation will be used.

There is a long-standing philosophical tradition to take $A > B$ to represent ‘ B is worse than A ’ as well as ‘ A is better than B ’. [Brogan, 1919, p. 97]. This is not in exact accordance with ordinary English. We tend to use ‘better’ when focusing on the goodness of the higher-ranked of the two alternatives, and ‘worse’ when emphasizing the badness of the lower-ranked one [Halldén, p. 13; von Wright, 1963, p. 10; Chisholm and Sosa, 1966, p. 244]. However, the distinction between betterness and converse worseness can only be made at the price of a much more complex formal structure. The distinction does not seem to have enough philosophical significance to be worth this complexity, at least not in a general-purpose treatment of the subject.

When describing the preferences of others, we tend to use the word ‘preferred’. The word ‘better’ is used when we express our own preferences and also when we refer to purportedly impersonal evaluations. Although these are important distinctions, not very much has been made of them in preference logic. ‘Logic of preference’ and ‘logic of betterness’ are in practice taken as synonyms.

The preferences studied in preference logic are the preferences of rational individuals. Since none of us is fully rational, this means that we are dealing with an idealization. If a proposed principle for preference logic does not correspond to how we actually think and behave, the reason may be either that the principle is wrong or that we are not fully rational when our behaviour runs into conflicts with it.

The objects of preference are represented by the relata of the preference relation. (A and B in $A > B$.) In order to make the formal structure determinate enough, every preference relation is assumed to range over a specified set of relata. As already indicated, in this section, the relata are assumed to be mutually exclusive, i.e. none of them is compatible with, or included in, any of the others. No further assumptions are made about their internal structure. They may be physical objects, types or properties of such objects, states of affairs, possible worlds—just about anything.

Preferences over a set of mutually exclusive relata will be referred to as *exclusionary* preferences.

The following four properties of the two exclusionary comparative relations will be taken to be part of the meaning of the concepts of (strict) preference and of indifference:

- (1) If A is better than B , then B is not better than A .
- (2) If A is equal in value to B , then is B equal in value to A .
- (3) A is equal in value to A .
- (4) If A is better than B , then A is not equal in value to B .

It follows from (1) that preference is irreflexive, i.e. that A is not better than A . The following is a restatement of the four properties in formal language.

DEFINITION 1. A (*triplex*) *comparison structure* is a triple $\langle \mathcal{A}, >, \equiv \rangle$, in which \mathcal{A} is a set of alternatives, and $>$ and \equiv are relations in \mathcal{A} such that for all $A, B \in \mathcal{A}$:

- (1) $A > B \rightarrow \neg(B > A)$ (*asymmetry of preference*)
- (2) $A \equiv B \rightarrow B \equiv A$ (*symmetry of indifference*)
- (3) $A \equiv A$ (*reflexivity of indifference*)
- (4) $A > B \rightarrow \neg(A \equiv B)$ (*incompatibility of preference and indifference*)

Furthermore:

$$A \geq B \leftrightarrow (A > B) \vee (A \equiv B) \text{ (weak preference)}$$

The intended reading of \geq is 'at least as good as' (or more precisely: 'better than or equal in value to'). As an alternative to \geq , it can also be denoted ' R '. Weak preference can replace (strict) preference and indifference as primitive relations in comparison structures:

OBSERVATION 2. Let $\langle \mathcal{A}, >, \equiv \rangle$ be a triplex comparison structure, and let \geq be the union of $>$ and \equiv . Then:

- (1) $A > B \leftrightarrow (A \geq B) \ \& \ \neg(B \geq A)$
- (2) $A \equiv B \leftrightarrow (A \geq B) \ \& \ (B \geq A)$

Proof.

Part 1: Left-to-right: From $A > B$ it follows by the definition of \geq that $A \geq B$. Furthermore, it follows from the asymmetry of preference that $\neg(B > A)$ and from the incompatibility of preference and indifference that $\neg(A \equiv B)$, i.e., by the symmetry of indifference, $\neg(B \equiv A)$. Thus $\neg((B > A) \vee (B \equiv A))$, i.e., by the definition of \geq , $\neg(B \geq A)$. *Right-to-left:* It follows from $A \geq B$, according to the definition of \geq , that either $A > B$ or $A \equiv B$. By the same definition, it follows from $\neg(B \geq A)$ that $\neg(B \equiv A)$. By the symmetry of indifference, $\neg(A \equiv B)$, so that $A > B$ may be concluded.

Part 2: Left-to-right: It follows from $A \equiv B$, by the definition of \geq , that $A \geq B$. By the symmetry of indifference, $A \equiv B$ yields $B \equiv A$ so that, by the definition of \geq , $B \geq A$. *Right-to-left:* It follows from the definition of \geq and $(A \geq B) \& (B \geq A)$ that $((A > B) \vee (A \equiv B)) \& ((B > A) \vee (B \equiv A))$. By the symmetry of indifference, $((A > B) \vee (A \equiv B)) \& ((B > A) \vee (A \equiv B))$. By the asymmetry of preference, $A > B$ is incompatible with $B > A$. We may conclude that $A \equiv B$. ■

The choice of primitives (either \geq or both $>$ and \equiv) is a fairly inconsequential choice between formal simplicity (\geq) and conceptual clarity ($>$ and \equiv). (Cf. [Burros, 1976].) The following is an alternative to Definition 1.

DEFINITION 3. A (*duplex*) *comparison structure* is a pair $\langle A, \geq \rangle$, in which A is a set of alternatives and \geq a reflexive relation on A . The derived relations $>$ and \equiv are defined as follows:

$$\begin{aligned} A > B & \text{ if and only if } A \geq B \text{ and } \neg(B \geq A) \\ A \equiv B & \text{ if and only if } A \geq B \text{ and } B \geq A \end{aligned}$$

It will be seen that the defined relation \geq of Definition 1 is reflexive and that the defined relations $>$ and \equiv of Definition 3 satisfy conditions (1)–(4) of Definition 7. It follows that the two definitions are interchangeable. Given our definitions, the four conditions of Definition 1 are in combination equivalent to the reflexivity of weak preference.

The relations $>$ and \equiv that are defined from \geq in the manner of Definition 3 are called the *strict part*, respectively the *symmetric part*, of \geq .

NOTATIONAL CONVENTIONS N1:

- (1) Chains of relations can be contracted. Hence, $A \geq B \geq C$ abbreviates $(A \geq B) \& (B \geq C)$, and $A > B > C \equiv D$ abbreviates $(A > B) \& (B > C) \& (C \equiv D)$.
- (2) $>^*$ stands for $>$ repeated any finite non-zero number of times (and similarly for the other relations). Thus $A >^* C$ denotes that either $A > C$ or there are B_1, \dots, B_n such that $(A > B_1) \& (B_1 > B_2) \& \dots \& (B_{n-1} > B_n) \& (B_n > C)$.

2.2 Completeness

In most applications of preference logic, it is taken for granted that the following property, called *completeness* or *connectedness*, should be satisfied:

$$(A \geq B) \vee (B \geq A), \text{ or equivalently:} \\ (A > B) \vee (A \equiv B) \vee (B > A)$$

As we will see later on, the assumption of completeness is often extremely helpful in terms of simplifying the formal structure. In terms of interpretation, however, it is much more problematic. In many everyday cases, we do not have, and do not need, complete preferences. In the choice between three brands of canned soup, A , B , and C , I clearly prefer A to both B and C . As long as A is available I do not need to make up my mind whether I prefer B to C , prefer C to B or consider them to be of equal value. Similarly, a voter in a multi-party or multi-candidate election can do without ranking the parties or candidates that she does not vote for.

From the viewpoint of interpretation, we can distinguish between three major types of preference incompleteness. First, incompleteness may be *uniquely resolvable*, i.e. resolvable in exactly one way. The most natural reason for this to be the case is that incompleteness is due to lack of knowledge or reflection. Behind what we perceive as an incomplete preference relation there may be a complete preference relation that we can arrive at through observation, logical inference, or some other means of discovery.

Secondly, incompleteness may be *multiply resolvable*, i.e. possible to resolve in several different ways. In this case it is genuinely undetermined what will be the outcome of extending the relation to cover the previously uncovered cases.

Thirdly, incompleteness may be *irresolvable*. The most natural reason for this is that the alternatives differ in terms of advantages or disadvantages that we are unable to put on the same footing. I may be unable to say which I prefer—the death of two specified acquaintances or the death of a specified friend [Hansson, 1998a]. I may be unable to say which I prefer—the destruction of the pyramids in Giza or the extinction of the giant panda. I may also be unable in many cases to compare monetary costs to environmental damage.

It is established terminology to call two alternatives ‘incomparable’ whenever the preference relation is incomplete with respect to them. The term ‘incommensurable’ ‘can be reserved for cases when the incompleteness is irresolvable.

2.3 Transitivity and acyclicity

By far the most discussed logical property of preferences is the following:

$$A \geq B \geq C \rightarrow A \geq C \text{ (transitivity of weak preference)}$$

The corresponding properties of the other two relations are defined analogously:

$$\begin{aligned} A \equiv B \equiv C &\rightarrow A \equiv C \text{ (transitivity of indifference)} \\ A > B > C &\rightarrow A > C \text{ (transitivity of strict preference)} \end{aligned}$$

A weak preference relation \geq is called *quasi-transitive* if its strict part $>$ is transitive.

'Mixed' transitivity properties can be also defined. The most important of these are:

$$\begin{aligned} A \equiv B > C &\rightarrow A > C \text{ (IP-transitivity)} \\ A > B \equiv C &\rightarrow A > C \text{ (PI-transitivity)} \end{aligned}$$

The relation \geq is *acyclic* if its strict part $>$ satisfies the following property:

$$\text{There is no series } A_1, \dots, A_n \text{ of alternatives such that } A_1 > \dots > A_n > A_1.$$

These properties are logically related as follows:

OBSERVATION 4. Let $\langle \mathcal{A}, \geq \rangle$ be a comparison structure such that \geq satisfies transitivity (of weak preference). Then it also satisfies:

1. Transitivity of indifference.
2. Transitivity of strict preference.
3. IP-transitivity.
4. PI-transitivity.

Proof.

Part 1: Let $A \equiv B$ and $B \equiv C$. Then $A \geq B$ and $B \geq C$, and \geq -transitivity yields $A \geq C$. Similarly, $C \geq B$ and $B \geq A$, so that $C \geq A$. Hence $A \equiv C$.

Parts 2 and 3: Let $A \geq B$ and $B > C$. Then $A \geq B$ and $B \geq C$, and \geq -transitivity yields $A \geq C$. Suppose that $A > C$ is not the case. It then follows from $A \geq C$ that $A \equiv C$, hence $C \geq A$. From this and $A \geq B$ we obtain that $C \geq B$, contrary to $B > C$. It follows from this contradiction that $A > C$.

Part 4: Let $A > B$ and $B \equiv C$. Then $A \geq B$ and $B \geq C$, and \geq -transitivity yields $A \geq C$. Suppose that $A > C$ is not the case. It then follows from $A \geq C$ that $A \equiv C$, hence $C \geq A$. From this and $B \geq C$ we obtain that $B \geq A$, contrary to $A > B$. It follows from this contradiction that $A > C$. ■

OBSERVATION 5. Let $\langle \mathcal{A}, \geq \rangle$ be a comparison structure such that \geq satisfies quasi-transitivity (transitivity of $>$). Then it also satisfies acyclicity.

Proof. Let $>$ be transitive and suppose that $A_1 > \dots A_n > A_1$. It follows by repeated use of $>$ -transitivity that $A_1 > A_1$, contrary to the asymmetry of $>$. ■

2.4 Anti-cyclic properties

Acyclicity implies each member of the following series of properties that are specified with respect to the number of elements of the prohibited cycles:

- 1-acyclicity prohibits $A_1 > A_1$
- 2-acyclicity prohibits $A_1 > A_2 > A_1$
- 3-acyclicity prohibits $A_1 > A_2 > A_3 > A_1$
- etc.

1-acyclicity is better known as irreflexivity and 2-acyclicity as asymmetry. Furthermore, just like the mixed transitivity properties referred to in the previous subsection, we can introduce mixed variants of acyclicity. The term *anti-cyclic properties* can be used for this more general category of properties. The definition is as follows:

DEFINITION 6 (Hansson, 1993b). Let π_1, \dots, π_n be binary relations with the common domain \mathcal{A} . Then π_1, \dots, π_n -anticyclicity, denoted $[\pi_1 \dots \pi_n]$, is the property that there is no series A_1, \dots, A_n of elements of \mathcal{A} such that $A_1 \pi_1 \dots A_n \pi_n A_1$.

Hence, irreflexivity of a relation π can be written $[\pi]$, and asymmetry can be written $[\pi\pi]$. The following notation is convenient:

NOTATIONAL CONVENTIONS N2:

- (1) Π and Ψ denote series of relation symbols.
- (2) π^n , with π a relation symbol and $n \geq 1$, denotes the repetition of π n times. Similarly, Π^n denotes the repetition of Π n times.
- (3) In the notation of anti-cyclic properties, \geq is replaced by R , $>$ by P , and \equiv by I .

Hence, $[P^3]$ denotes 3-acyclicity, and $[P^2I^2]$ denotes that there are no A_1, A_2, A_3, A_4 , such that $A_1 > A_2 > A_3 \equiv A_4 \equiv A_1$.

Anticyclic properties are useful in preference logic. A major reason for their usefulness is that if the weak preference relation is complete, then the common transitivity properties are all equivalent to an anti-cyclic property. To begin with, consider transitivity of weak preference. When \geq is complete, then $A \geq C$ is equivalent with $\neg(C > A)$, and we have the following equivalences:

For all A, B, C : $(A \geq B) \& (B \geq C) \rightarrow A \geq C$
iff: For all A, B, C : $(A \geq B) \& (B \geq C) \rightarrow \neg(C > A)$
iff: For all A, B, C : $\neg((A \geq B) \& (B \geq C) \& (C > A))$
iff: $[RRP]$

Hence, transitivity of a complete relation is equivalent to the anticyclic property $[RRP]$. The following more general translation rules can be used to replace transitivity-related properties of a complete preference relation by equivalent anticyclic properties.

OBSERVATION 7 (Hansson, 1993b). Let $\langle \mathcal{A}, \geq \rangle$ be a comparison structure such that \geq satisfies completeness. Then:

- (T1) $A \Pi C \rightarrow A \geq C$ is equivalent to $[\Pi P]$
(T2) $A \Pi C \rightarrow A > C$ is equivalent to $[\Pi R]$
(T3) $A \equiv^n C \rightarrow A \equiv C$ is equivalent to $[I^n P]$
(T4) $A \Pi C \rightarrow (A > B) \vee (B > C)$ is equivalent to $[RR\Pi]$
(T5) $(A \Pi B) \& (C \Psi D) \rightarrow (A > D) \vee (C > B)$ is equivalent to $[R\Pi R\Psi]$

Proof. *T1* follows in the same way as the translation of \geq -transitivity that was given in the text. So does *T2*; note that $A > C$ is equivalent with $\neg(C \geq A)$.

For *T3*, we have the following series of equivalent statements:

For all A_1, \dots, A_n : $A_1 \equiv A_2 \equiv \dots \equiv A_n \rightarrow A_1 \equiv A_n$.
For all A_1, \dots, A_n : $A_1 \equiv A_2 \equiv \dots \equiv A_n \rightarrow \neg(A_1 > A_n) \& \neg(A_n > A_1)$.
For all A_1, \dots, A_n : $\neg(A_1 \equiv A_2 \equiv \dots \equiv A_n \& (A_1 > A_n))$ and
 $\neg(A_1 \equiv A_2 \equiv \dots \equiv A_n \& (A_n > A_1))$.
For all A_1, \dots, A_n : $\neg(A_n \equiv A_{n-1} \equiv \dots \equiv A_1 > A_n)$ and
 $\neg(A_1 \equiv A_2 \equiv \dots \equiv A_n > A_1)$
 $[I^n P]$

For *T4*:

For all A, B, C : $A \Pi C \rightarrow (A > B) \vee (B > C)$
For all A, B, C : $A \Pi C \rightarrow \neg((B \geq A) \& (C \geq B))$
For all A, B, C : $\neg((A \Pi C) \& (B \geq A) \& (C \geq B))$
For all A, B, C : $\neg(C \geq B \geq A \Pi C)$
 $[RR\Pi]$

For *T5*:

For all A, B, C, D : $(A \Pi B) \& (C \Psi D) \rightarrow (A > D) \vee (C > B)$
For all A, B, C, D : $(A \Pi B) \& (C \Psi D) \rightarrow \neg((D \geq A) \& (B \geq C))$
For all A, B, C, D : $\neg((A \Pi B) \& (C \Psi D) \& (D \geq A) \& (B \geq C))$
For all A, B, C, D : $\neg((D \geq A) \& (A \Pi B) \& (B \geq C) \& (C \Psi D))$
 $[R\Pi R\Psi]$ ■

One important instance of T4 refers to the following property:

$$A > C \rightarrow (A > B) \vee (B > C) \text{ (virtual connectivity)}$$

It follows directly from T4 that virtual connectivity is equivalent to $[RRP]$, or in other words to transitivity of \geq . Another important instance of T4 is the translation of the following property:

$$A > B > C \rightarrow (A > D) \vee (D > C) \text{ (semi-transitivity)}$$

to $[RRPP]$. The following property:

$$(A > B) \& (C > D) \rightarrow (A > D) \vee (C > B) \text{ (interval order property)}$$

can be translated to $[RPRP]$, using T5. In summary, some of the major transitivity-related properties can be translated as follows:

$$[RRP] \quad A \geq B \geq C \rightarrow A \geq C \text{ (transitivity of weak preference)}$$

$$[IIP] \quad A \equiv B \equiv C \rightarrow A \equiv C \text{ (transitivity of indifference)}$$

$$[PPR] \quad A > B > C \rightarrow A > C \text{ (transitivity of strict preference)}$$

$$[IPR] \quad A \equiv B > C \rightarrow A > C \text{ (IP-transitivity)}$$

$$[PIR] \quad A > B \equiv C \rightarrow A > C \text{ (PI-transitivity)}$$

$$[RRPP] \quad A > B > C \rightarrow (A > D) \vee (D > C) \text{ (semi-transitivity)}$$

$$[RPRP] \quad (A > B) \& (C > D) \rightarrow (A > D) \vee (C > B) \text{ (interval order property)}$$

$$[P^n] \quad \text{n-acyclicity}$$

$$[P^*] \quad \text{acyclicity}$$

The major reason for undertaking these translations is that a series of simple derivation rules are available for proving the logical interrelations of anticyclic properties.

OBSERVATION 8 (Hansson, 1993b). Let $\langle \mathcal{A}, \geq \rangle$ be a comparison structure such that \geq satisfies completeness. Then the following derivation rules hold for anticyclic properties of \geq .

$$(DR1) \quad [\Pi\Psi] \text{ iff } [\Psi\Pi].$$

$$(DR2) \quad [\Pi R] \text{ iff } [\Pi P] \& [\Pi I].$$

$$(DR3) \quad \text{If } [\Pi^n], \text{ then } [\Pi]. \text{ (} n \geq 1 \text{)}$$

$$(DR4) \quad \text{If } [\Pi I], \text{ then } [\Pi].$$

(DR5) If $[\Pi R]$ & $[\Psi P]$, then $[\Pi\Psi]$.

Proof. The validity of DR1, DR2, and DR3 is obvious. For DR4, note that $A\Pi A \equiv A$ follows from $A\Pi A$.

For DR5, suppose that $[\Pi R]$ holds. We need to show that if $[\Pi\Psi]$ is violated, then so is $[\Psi P]$. Suppose that $(A\Pi B)$ & $(B\Psi A)$. From $A\Pi B$ it follows by $[\Pi R]$ that $B \geq A$ does not hold, thus $A > B$. We therefore have $(B\Psi A)$ & $(A > B)$, violating $[\Psi P]$. ■

Derivation rules DR1–DR5 have turned out to be sufficient to prove the major connections between the common transitivity-related properties. However, it remains an open issue how to construct a complete set of rules, i.e. a set of rules that is sufficient to prove all valid logical connections between anticyclic properties involving a reflexive relation \geq and its strict and symmetric parts.

The proofs of the standard logical connections between the transitivity-related properties of complete preference relations are quite simple:

OBSERVATION 9 (Sen 1969). Let $\langle \mathcal{A}, \geq \rangle$ be a comparison structure such that \geq satisfies completeness, and let $>$ and \equiv be the strict and symmetric parts of \geq . Then:

- (1) IP-transitivity and PI-transitivity are equivalent.
- (2) IP-transitivity implies \equiv -transitivity.
- (3) $>$ -transitivity and \equiv -transitivity together imply PI-transitivity.
- (4) $>$ -transitivity and PI-transitivity together imply \geq -transitivity.

Proof.

Part 1: We can use DR1 and DR2 to show that $[PIR]$ iff $[PII]$ & $[PIP]$, iff $[IPI]$ & $[IPP]$, iff $[IPR]$.

Part 2: From $[IPR]$ we obtain $[IPI]$ by DR2 and $[IIP]$ by DR1.

Part 3: Let $[PPR]$ and $[IIP]$. It follows from $[PPR]$ by DR2 that $[PPI]$, hence by DR1 $[PIP]$. Applying DR1 to $[IIP]$ we obtain $[PII]$, and applying DR2 to $[PIP]$ and $[PII]$ we obtain $[PIR]$.

Part 4: Let $[PPR]$ and $[PIR]$. Applying DR1 to both of them we obtain $[RPP]$ and $[RPI]$. From this we obtain $[RPR]$ by DR2 and $[RRP]$ by DR1. ■

The following results refer to longer cycles:

OBSERVATION 10 (Hansson, 1993b). Let $\langle \mathcal{A}, \geq \rangle$ be a comparison structure such that \geq satisfies completeness. Then:

- (1) If $[\Pi PR]$ then $[\Pi^n PR]$ for all $n \geq 1$.

- (2) If $[\Pi RP]$ then $[\Pi^n RP]$ for all $n \geq 1$.
- (3) If $[\Pi PR]$ and $[\Psi R]$, then $[\Pi^n \Psi R]$ for all $n \geq 1$.
- (4) If $[\Pi RP]$ and $[\Psi P]$, then $[\Pi^n \Psi P]$ for all $n \geq 1$.
- (5) For all $n \geq 2$: $[R^n P]$ iff $[RRP]$.
- (6) If Π contains at least one instance of P , then: If $[RRP]$ then $[\Pi]$
- (7) If $[PPR]$ then $[P^n R]$ for all $n \geq 2$.
- (8) If $[I^n P]$ with $n \geq 2$, then $[IIP]$.
- (9) If $[IPP]$ and $[IIP]$, then $[I^n PP]$ and $[I^{n+1} P]$ for all $n \geq 1$.
- (10) If $[PPP]$ and $[IPP]$, then $[IP^n]$ and $[P^{n+1}]$ for all $n \geq 2$.
- (11) If $[RPRP]$, then $[(RP)^n]$ for all $n \geq 1$.
- (12) If $[RRPP]$, then $[R^m P^n]$ for all m, n such that $m \leq n$ and $n \geq 2$.
- (13) If $[RPRP]$ and $[RRPP]$, then $[R^k P^l R^m P^n]$ for all $k, l, m, n \geq 1$ such that $k + m \leq l + n$.

Proof.

Part 1: The proof is by induction. Let $[\Pi PR]$ and $[\Pi^k PR]$. We are going to show that $[\Pi^{k+1} PR]$. Through DR1, $[\Pi PR]$ yields $[R\Pi P]$. We can then apply DR5 to $[\Pi^k PR]$ and $[R\Pi P]$ and obtain $[\Pi^k PR\Pi]$, hence through DR1 $[\Pi^{k+1} PR]$.

Part 2. This proof is similar to the previous one. Let $[\Pi RP]$ and $[\Pi^k RP]$. We use DR1 to obtain $[P\Pi R]$, DR5 to obtain $[P\Pi\Pi^k R]$, and finally DR1 to obtain $[\Pi^{k+1} RP]$.

Part 3: Let $[\Pi PR]$ and $[\Psi R]$. DR1 yields $[R\Pi P]$, and then DR5 can be used to obtain $[\Psi R\Pi]$ and DR1 to obtain $[\Pi\Psi R]$. For induction, let $[\Pi^k \Psi R]$. We can apply DR5 to $[\Pi^k \Psi R]$ and $[R\Pi P]$ to obtain $[\Pi^k \Psi R\Pi]$, and then use DR1 to obtain $[\Pi^{k+1} \Psi R]$.

Part 4: Let $[\Pi RP]$ and $[\Psi P]$. We can use DR1 to obtain $[P\Pi R]$, DR5 to obtain $[P\Pi\Psi]$ and then DR1 to obtain $[\Pi\Psi P]$. For induction, let $[\Pi^k \Psi P]$. We can apply DR5 to $[P\Pi R]$ and $[\Pi^k \Psi P]$ to obtain $[P\Pi\Pi^k \Psi]$ and then DR1 to obtain $[\Pi^{k+1} \Psi P]$.

Part 5: For one direction, let $[R^n P]$ with $n \geq 2$. Then DR1 yields $[R^{n-1} PR]$, and DR2 and DR4 yield $[R^{n-1} P]$. By repetition, $[R^2 P]$ will be obtained. For the other direction, let $[R^2 P]$ and $[R^k P]$ with $k \geq 2$. DR1 yields $[RPR]$, and DR5 can be applied to $[RPR]$ and $[R^k P]$ to obtain $[RPR^k]$. We can use DR1 to obtain $[R^{k+1} P]$.

Part 6: We are first going to show that if $[RRP]$ then $[\Pi RP]$ where Π is a possibly empty sequence. To see that this holds if Π is empty, use DR1 to obtain $[RPR]$ and then DR2 and DR4 to obtain $[RP]$. Next suppose that $[\Psi RP]$ holds for all sequences with n elements, and let Ψ' be a sequence with $n+1$ elements. Then Ψ' has one of the three forms ΨR , ΨI , and ΨP , where Ψ has n elements.

We can apply DR1 to $[\Psi RP]$ and obtain $[P\Psi R]$. Applying DR5 to this and $[RRP]$ we obtain $[P\Psi RR]$. From DR1 follows $[RP\Psi R]$ and then from DR2 $[RP\Psi I]$ and $[RP\Psi P]$. DR1 yields $[\Psi RRP]$, $[\Psi IRP]$, and $[\Psi PRP]$, hence $[\Psi' RP]$ in all three cases. Hence, if $[RRP]$ then $[\Pi RP]$.

It follows by DR1 from $[\Pi RP]$ that $[P\Pi R]$. DR2 and DR4 can be used to obtain $[P\Pi]$. Since every sequence that contains at least one instance of P is equivalent in the sense of DR1 to a sequence of the form $[P\Pi]$, this concludes the proof.

Part 7: The proof will be by induction. Let $[PPR]$ and $[P^k R]$ with $k \geq 2$. We can use DR1 to obtain $[PRP]$ and then DR5 to obtain $[P^k PR]$, i.e. $[P^{k+1} R]$.

Part 8: Let $[I^n P]$. We can use DR1 to obtain $[IIP I^{n-2}]$ and then DR4 $n-2$ times to obtain $[IIP]$.

Part 9: Let $[IPP]$ and $[IIP]$. We are first going to show by induction that $[I^n PP]$. Let $[I^n PP]$ with $n \geq 1$. We can use DR1 to obtain $[PIP]$ and $[PII]$ and then DR2 to obtain $[PIR]$. From this and $[I^n PP]$ we obtain $[PII^n P]$ with DR5 and $[I^{n+1} PP]$ with DR1.

Next, let $[I^{n+1} P]$ with $n \geq 1$. We can use DR5 and combine this with $[PIR]$ to obtain $[PII^{n+1}]$, and DR1 yields $[I^{n+2} P]$.

Part 10: Let $[PPP]$ and $[IPP]$. We are first going to show by induction that $[IP^n]$ for all $n \geq 2$. Let $[IP^n]$ and $n \geq 2$. DR1 yields $[PPI]$ and DR2 $[PPR]$, that can be combined with $[IP^n]$ to obtain, through DR5, $[PPI P^{n-1}]$, and then through DR1, $[IP^{n+1}]$.

Next, we are going to show that $[P^{n+1}]$ for all $n \geq 2$. Let $[P^{n+1}]$ and $n \geq 2$. Equivalently, $[P^n P]$. Since we also have $[PPR]$, DR5 yields $[PPP^n]$, or equivalently $[P^{n+2}]$.

Part 11: The proof proceeds by induction. It follows from DR3 that $[RP]$. Let $[(RP)^n]$ with $n \geq 2$. Equivalently, $[(RP)^{n-1} RP]$. From $[RPRP]$ it follows, via DR1, that $[PRPR]$. We can use DR5 and combine this with $[(RP)^{n-1} RP]$ to obtain $[PRP(RP)^{n-1} R]$, and DR1 yields $[RPRP(RP)^{n-1}]$ or equivalently $[(RP)^{n+1}]$.

Part 12: Let $[RRPP]$. We are first going to show by induction that $[R^n P^n]$ for all $n \geq 2$. Let $[R^n P^n]$ and $n \geq 2$. From $[RRPP]$ follows by DR1 that $[PPRR]$. DR5 yields $[PPRR^n P^{n-1}]$, and then DR1 yields $[R^{n+1} P^{n+1}]$.

Next, we are going to show that if $[R^n P^n]$ and $m \leq n$, then $[R^m P^n]$. Let $[R^n P^n]$. It follows from DR1 that $[P^n R^n]$, from repeated use of DR2 and DR4 that $[P^n R^m]$ and then from DR1 that $[R^m P^n]$.

Part 13: Let $[RPRP]$ and $[RRPP]$. We are first going to show that $[R^k P^l R^m P^n]$ for all $k, l, m, n \geq 1$ such that $k + m = l + n$. The proof will be by induction. We have $[RPRP]$, and for the induction step we need to show that if $[R^k P^l R^m P^n]$, then (A) $[R^{k+1} P^l R^m P^{n+1}]$ and (B) $[R^k P^l R^{m+1} P^{n+1}]$. (There are two additional cases, but they can be excluded due to DR1.) For (A), use DR1 to obtain $[PPRR]$. We can use DR5 to combine $[PPRR]$ and $[R^k P^l R^m P^n]$, and obtain $[PPRR^k P^l R^m P^{n-1}]$. DR1 yields $[R^{k+1} P^l R^m P^{n+1}]$. For (B), apply DR1 to $[R^k P^l R^m P^n]$ to obtain $[P^n R^k P^l R^m]$. Then use DR5 to combine this with $[RRPP]$ and obtain $[P^n R^k P^l R^{m-1} RRP]$. DR1 yields $[R^k P^l R^{m+1} P^{n+1}]$.

To complete the proof it is sufficient to show that if $[R^k P^l R^m P^n]$, then $[R^{k-1} P^l R^m P^n]$ and $[R^k P^l R^{m-1} P^n]$. Due to DR1 it is sufficient to prove one of these. Let $[R^k P^l R^m P^n]$. DR1 yields $[P^l R^m P^n R^k]$, DR2 and DR4 yield $[P^l R^m P^n R^{k-1}]$ and then DR1 yields $[R^{k-1} P^l R^m P^n]$. ■

2.5 Preference cycles exemplified

Part 6 of Observation 10 is particularly interesting since it shows that $[RRP]$, transitivity of weak preference, implies all anticyclic properties that can hold if \geq is reflexive and has a non-empty domain. (Let π_1, \dots, π_n be a series, each element of which is either \geq or \equiv . Then $A\pi_1 A \dots A\pi_n A\pi_1$ holds for any $A \in \mathcal{A}$ due to the reflexivity of \geq and consequently of \equiv . It follows that $[\pi_1 \dots \pi_n]$ does not hold.)

Should transitivity of weak preference hold, or at least some of the weaker transitivity-related properties mentioned above? This is probably the most debated issue in preference logic. Since completeness has mostly been assumed to hold, this controversy can also be expressed in terms of anticyclic properties: What types of cycles are acceptable? As we have just seen, the controversial cycles are those that contain at least one instance of P . Therefore, this is more precisely a matter of which if any P -containing cycles should be allowed. All P -containing cycles contradict transitivity of weak preference. In addition, IIP-cycles contradict transitivity of indifference, PPR-cycles contradict transitivity of strict preference, etc. In what follows, preferences with a P -containing cycle will be called *cyclic preferences*.

Quite a few examples of preference cycles have been proposed in the literature for various philosophical purposes. Most of these examples belong to the following four categories: $I^n P$ -cycles with $n \geq 2$, IPIP-cycles, IPP-cycles, and P^n -cycles with $n \geq 3$.

$I^n P$ -cycles, with $n \geq 2$, are often used as arguments against transitivity. The classic construction employs a series of objects that are so arranged that we cannot distinguish between two adjacent members of the series, whereas we can distinguish between members at greater distance [Armstrong, 1939; Armstrong, 1948; Luce, 1954]. Let us think of 1000 cups of coffee, numbered C_0, C_1, C_2, \dots up to C_{999} . Cup C_0 contains no sugar, cup C_1 one grain of

sugar, cup C_2 two grains etc. Since I cannot taste the difference between C_{999} and C_{998} , they are equally good (or rather equally terrible) in my taste, $C_{999} \equiv C_{998}$. For the same reason, we have $C_{998} \equiv C_{997}$, etc. all the way up to $C_1 \equiv C_0$, but clearly $C_0 > C_{999}$, so that we have an $I^{999}P$ -cycle.

With suitably adjusted thresholds of discrimination, it is also possible to construct shorter cycles of the same kind, including IIP-cycles. Michael Dummett [1984, p. 34] proposed that a subject may be incapable of distinguishing between wine A and wine B or between wine B and wine C , but able to distinguish between A and C , and likes A better. A somewhat different construction of IIP-cycles has been ascribed to W. Armstrong [Lehrer and Wagner, 1985]: A boy may be indifferent between receiving a bicycle or a pony, and also between receiving a bicycle with a bell and a pony, whereas he prefers receiving a bicycle with a bell to receiving just a bicycle. The reason is of course that the bell is too small an advantage to be significant in the uncertain choice between a bicycle and a horse. A similar example was proposed by Frank Restle [1961, pp. 62–63]: replace the pony by a trip to Florida, the bicycle by a trip to California and the bell by a very small amount of money.

An IPIP-cycle was constructed by Sven Danielsson [1998] through the addition of one more alternative to Restle's example:

- X A trip to California plus an apple
- Y A trip to California
- Z A trip to Florida
- U A trip to Florida plus an apple

We can then have $Z \equiv X > Y \equiv U > Z$, i.e. an IPIP-cycle.

Next, let us turn to IPP-cycles. A simple way to construct an IPP-cycle is to combine two IIP-cycles in different dimensions. This was done by Ng [1977], whose (unusually undramatic example) refers to three samples of paper, x , y , and z . It can be observed that x is thicker than y , but no difference in thickness can be observed between x and z (which is intermediate in thickness) or between z and y . Similarly, y is perceptibly whiter than z , but there is no noticeable difference in whiteness between y and x or between x and z . Assuming that I prefer thick white paper, 'I prefer x to y as I can observe that x is thicker than y but cannot observe any difference in whiteness. Similarly, I prefer y to z . But I am indifferent to the choice between x and z ' [Ng, 1977, p. 52].

Our next category is P^n -cycles with $n > 3$. To construct them, we can make use of an IP^n -cycle with $n > 2$. The construction method is exemplified by the 'lawn-crossing example' that has been much discussed in the literature on utilitarianism [Harrison, 1953, p. 107; Österberg, 1989]. Let c_0, \dots, c_{1000} denote the number of times that you cross a particular lawn. A single crossing makes no (perceptible) difference in the condition of the lawn, but it results in a perceptible time gain. Therefore, $c_{1000} > c_{999} >$

... $> c_2 > c_1 > c_0$. However, a large number of crossings will cause a complete damage of the lawn that is not outweighed by the total time gain. Therefore, $c_0 > c_{1000}$, and we have a P^{1001} -cycle (based on the $I^{1000}P$ -cycle for the condition of the lawn).

A famous example by Warren S. Quinn [Quinn 1990] has the same structure. He assumed that a medical device has been implanted in the body of a person (the self-torturer). The device has 1001 settings, from 0 (off) to 1000. Each increase leads to a negligible increase in pain. Each week, the self-torturer 'has only two options—to stay put or to advance the dial one setting. But he may advance only one step each week, and he may never retreat. *At each advance he gets \$ 10,000.*' In this way he may 'eventually reach settings that will be so painful that he would then gladly relinquish his fortune and return to 0' [Quinn, 1990, p. 79].

Our final category of cycles is PPP-cycles. They differ from IPP-cycles in being direct arguments against acyclicity. One way to construct a PPP-cycle is to combine three IIP-cycles in the same way that two such cycles were used to obtain an IPP-cycle. This was done by George Schumm [1987], who invites us to consider a Mr. Smith who chooses between three boxes of Christmas tree ornaments. Each box contains one red, one blue, and one green ball. The balls of box 1 are denoted R_1 , B_1 , and G_1 , etc. in the obvious way. 'Suppose that any difference in color between R_1 and R_3 falls below Smith's threshold of discrimination, as does that between R_3 and R_2 . But he can see a difference between R_1 and R_2 , and he prefers the former. Likewise, suppose that while Smith sees no difference between B_3 and B_2 , or between B_2 and B_1 , he prefers the hue of B_3 to that of B_1 . Finally, although being unable to detect any difference between G_2 and G_1 , or between G_1 and G_3 , he prefers G_2 to G_3 ... Smith prefers Box 1 to Box 2 since, to his eye, they contain equally attractive blue balls and green balls, while Box 1 contains the prettier red ball. Analogously, he prefers Box 2 to Box 3, and Box 3 to Box 1.'

Schumm argued that 'given any proposed counterexample to the transitivity of indifference... one can always construct, on the foregoing model, an equally compelling counterexample to the transitivity of strict preference. Thus, those who would have us shun the transitivity of indifference should have the courage of their convictions to forsake both principles.'

R. G. Hughes [1980] constructed a PPP-cycle in a quite different but not less plausible way. In his example, a voter assesses three political candidates A , B , and C , as follows: In terms of political views, A is better than the other two, and B is better than C . In terms of honesty, C is better than the other two, and B is better than A . A difference in corruptibility is important to this voter only when it exceeds a critical level, but when it does so, this issue becomes more important than all other considerations. The difference between A and B and that between B and C are below this critical level, but that between A and C is above it. (The voter therefore

acts as if she were indifferent between A and B , and also between B and C , but prefers C to A , in terms of honesty.) Thus, the voter, both aspects considered, prefers A to B , B to C , and C to A . (An example with the same structure, that Hughes does not seem to have been aware of, can be found in [Tversky, 1969, p. 321].)

2.6 *Why cycles are problematic*

At least some of the examples cited in the foregoing subsection can be used to show that actual human beings may have cyclic preferences. It does not necessarily follow, however, that the same applies to the idealized *rational* agents of preference logic. Perhaps such patterns are due to irrationality or to factors, such as lack of knowledge or discrimination, that prevent us from being rational. There is a strong tradition, not least in economic applications, to regard full \geq -transitivity as a necessary prerequisite of rationality.

Some authors have argued for transitivity through direct appeal to intuition. According to Savage, whenever I find a PPP-cycle among my own preferences, 'I feel uncomfortable in much the same way that I would do when it is brought to my attention that some of my beliefs are logically contradictory. Whenever I examine such a triple of preferences on my own part, I find that it is not at all difficult to reverse one of them. In fact, I find on contemplating the three alleged preferences side by side that at least one of them is not a preference at all, at any rate not any more' [Savage, 1954, p. 21]. There is also some empirical evidence that when people are faced with their own intransitivities, they tend to modify their preferences to make them transitive [Tversky, 1969].

Two other, somewhat more substantial types of argument have been put forward in favour of transitivity: The money-pump argument and the choice-guidance argument.

The money-pump argument originates with F. P. Ramsey [1931, p. 182]. Ramsey pointed out that if a subject's relation of preference violates transitivity, then '[h]e could have a book made against him by a cunning better and would then stand to lose in any event'. The non-probabilistic version of this argument, the 'money-pump', runs as follows:

'Suppose an individual prefers y to x , z to y , and x to z . It is reasonable to assume that he is willing to pay a sum of money to replace x by y . Similarly, he should be willing to pay some amount of money to replace y by z and still a third amount to replace z by x . Thus, he ends up with the alternative he started with but with less money.'

[Tversky, 1969, p. 45]

In order to see more in detail how the argument works, consider the following example [Hansson, 1993a]. A certain stamp-collector has cyclic preferences with respect to three stamps, denoted a , b , and c . She prefers a to b , b to c ,

and c to a . Following Ramsey, we may assume that there is an amount of money, say 10 cents, that she is prepared to pay for exchanging b for a , c for b , or a for c . She comes into a stamp shop with stamp a . The stamp-dealer offers her to trade in a for c , if she pays 10 cents. She accepts the deal.

For a precise notation, let $\langle x, v \rangle$ denote that the collector owns stamp x and has paid v cents to the dealer. She has now moved from the state $\langle a, 0 \rangle$ to the state $\langle c, 10 \rangle$.

Next, the stamp-dealer takes out stamp b from a drawer, and offers her to swap c for b , against another payment of 10 cents. She accepts, thus moving from the state $\langle c, 10 \rangle$ to $\langle b, 20 \rangle$.

When she is just on her way out of the shop, the dealer calls her back, and advises her that it only costs 10 cents to change back to a , the very stamp that she had in her pocket when she entered the shop. Since she prefers it to b , she pulls out a third dime, thus moving from $\langle b, 20 \rangle$ to $\langle a, 30 \rangle$. Since her original state was $\langle a, 0 \rangle$, this does not seem to be much of an achievement.

To summarize the argument, the following sequence of preferences caused the trouble:

$$\begin{aligned} \langle c, 10 \rangle &> \langle a, 0 \rangle \\ \langle b, 20 \rangle &> \langle c, 10 \rangle \\ \langle a, 30 \rangle &> \langle b, 20 \rangle \end{aligned}$$

The trouble does not end here. Presumably, the sequence continues:

$$\begin{aligned} \langle c, 40 \rangle &> \langle a, 30 \rangle \\ \langle b, 50 \rangle &> \langle c, 40 \rangle \\ \langle a, 60 \rangle &> \langle b, 50 \rangle \\ \dots \end{aligned}$$

If the poor customer stays long enough in the stamp shop, she will be bereft of all her money, to no avail.

The money-pump argument relies on the following two assumptions: (1) The primary alternatives (the stamps) can be combined with some other commodity (money) to form composite alternatives. (2) For every preferred change of primary alternatives, there is some non-zero loss of the auxiliary commodity (money) that is worth that change. The money-pump can be used to extract money from a subject with cyclic preferences only if these two conditions are satisfied.

The money-pump presented above requires a P^n -cycle. There is also another type of money-pump that can operate on any type of cyclic preferences. Let's go back to the stamp shop.

A new customer enters the shop. She is indifferent between stamps a and b , and also between stamps b and c , but prefers c to a . Contrary to the first customer, she only has an IIP-cycle (intransitive indifference). Strangely enough, just like the first customer she enters the shop carrying stamp a .

Can the stamp-dealer extract money from this customer as well? It turns out that he can, but he must apply a modified strategy. The first move is identical. He offers her to exchange stamp a for stamp c against a modest fee of 10 cents (or whatever sum is small enough to make her accept the deal). In this way, he makes her move from $\langle a, 0 \rangle$ to $\langle c, 10 \rangle$. Next, he offers to pay her 1 cent if she is willing to take stamp b instead of stamp c . Since, presumably, the customer is absolutely indifferent between b and c , she is—or so we may expect—willing to accept this bid, thus moving from $\langle c, 10 \rangle$ to $\langle b, 9 \rangle$. After that he offers her another cent for changing to a , thus bringing her to $\langle a, 8 \rangle$. Just like the previous customer, she has given away money to no avail. The vicious sequence of preferences was:

$$\begin{aligned}\langle c, 10 \rangle &> \langle a, 0 \rangle \\ \langle b, 9 \rangle &> \langle c, 10 \rangle \\ \langle a, 8 \rangle &> \langle b, 9 \rangle.\end{aligned}$$

Presumably, the sequence continues:

$$\begin{aligned}\langle c, 18 \rangle &> \langle a, 8 \rangle \\ \langle b, 17 \rangle &> \langle c, 18 \rangle \\ \langle a, 16 \rangle &> \langle b, 17 \rangle \\ \dots\end{aligned}$$

In this way, the second customer, just like the first, will be ruined unless her dealings with the cunning stamp-dealer are interrupted. In order for this type of money-pump to operate we only need an R*P-cycle. Therefore, this combination can be used as a fully general argument against all types of cyclic preferences.

But how convincing are the money-pumps? It should be noted that they rely on a particular way to combine preferences in two dimensions. A critic can argue that the construction of preferences for the combined alternative set $(\{\langle a, 0 \rangle, \langle c, 10 \rangle, \langle b, 20 \rangle, \langle a, 30 \rangle, \langle c, 40 \rangle, \langle b, 50 \rangle \dots\})$ in our first example) out of preferences over the primary alternative set $(\{a, b, c\})$ should not be performed in the straightforward simple way that was indicated in the examples. When forming their preferences over the new alternative sets created by the cunning dealer, the collectors must consider the totality of the situation, and therefore—according to the critic—they must construct these preferences in a way that avoids the absurd result. Most of us would prefer $\langle b, 20 \rangle$ to $\langle a, 30 \rangle$ in the first example, even if we would have preferred $\langle a, 10 \rangle$ to $\langle b, 0 \rangle$. Arguably, the example only works if the agent (the stamp-collector) can be brought to make each decision in isolation, without taking into account the total situation. What the example shows, it can be argued, is only that a rational subject's preference-guided behaviour can be 'manipulated' by persons, institutions or impersonal conditions that control her agenda (decision horizon). This may be seen as an extension of the well-known result

from social decision theory that '[a] clever agenda setter, with knowledge of all voters' preferences could design an agenda to reach virtually any point in the alternative space' [McKelvey, 1979, p. 1087]; cf. [McKelvey, 1976; McKelvey and Wendell, 1976; Plott, 1967]. Even if the logical structure of our preferences is rational, agenda-setting mechanisms may very well drive us to irrational behaviour.

The second major argument in favour of transitivity is the choice-guidance argument. It is based on the assumption that the logical properties of preferences should be compatible with their use as guides to choice or action. It is easy to find examples of how cycles make preferences unsuitable as guides for choices. Our first stamp-collector, who prefers stamp a to stamp b , stamp b to stamp c , and stamp c to stamp a , cannot use these preferences as a guide to choose one of these stamps.

However, the choice-guidance argument cannot be used directly against all forms of cyclic preferences. Suppose that there is also a fourth stamp d , that she prefers to all the other three. Then her preference relation can be used without problem to guide a choice among the set $\{a, b, c, d\}$, in spite of the cycle. Cycles among defeated elements do not prevent rational choice.

For a preference relation to be choice-guiding, it must supply at least one alternative that is eligible, i.e. can reasonably be chosen. The minimal formal criterion for eligibility is that the chosen alternative is no worse than any other alternative:

Weak eligibility

There is at least one alternative A such that for all B , $\neg(B > A)$.

Let A be a weakly eligible alternative, and let B be an alternative that is *not* (weakly) eligible. Furthermore, suppose that A and B are comparable, i.e. that either $A > B$, $A \equiv B$, or $B > A$. Then, by the definition of weak eligibility, $B > A$ does not hold. It would also be very strange for A and B to be equal in value, i.e., for $A \equiv B$ to hold. If preferences are choice-guiding, then two alternatives should not be considered to be of equal value if one of them is eligible and the other is not. We may therefore conclude, as a consequence of the principle of choice-guidance, that if A but not B is weakly eligible, then A and B are not equal in value. In an equivalent formulation:

Top-transitivity of weak eligibility

If $A \equiv B$, and $\neg(C > A)$ for all C , then $\neg(C > B)$ for all C .

If the preference relation \geq is complete, then weak eligibility is equivalent with the following condition:

Strong eligibility

There is at least one alternative A such that for all B , $A \geq B$.

Top-transitivity can be rewritten as follows:

Top-transitivity of strong eligibility:

If $A \equiv B$, and $A \geq C$ for all C , then $B \geq C$ for all C .

The sets of alternatives that our preferences refer to are not immutable. To the contrary, new alternatives can become available, and old ones can be lost. If no alternative is considered to be exempt from possibly being lost in the future, then it may be a cost-minimizing strategy to pursue one's deliberations until (weak or strong) eligibility holds for all non-empty subsets of the original alternative set. A rationality criterion will be said to hold *restrictably* for a set of alternatives if and only if it holds for all its non-empty subsets. It must be emphasized that restrictability does not always hold for rational preferences. The preference relation best suited for guiding choices among a certain set of alternatives need not be a suitable guide for choosing among a particular subset of that set. (For a counterexample, see Subsection 3.1.)

As will be seen from the following theorem, if the eligibility properties are required to hold restrictably, then we obtain rationality criteria of the more well-known types, such as completeness, acyclicity, and various types of transitivity.

THEOREM 11 (Hansson, 1997a). *Let \geq be a relation over some finite set A with at least two elements.*

1. *It satisfies restrictable weak eligibility if and only if it satisfies $[P^*]$ (acyclicity).*
2. *It satisfies restrictable strong eligibility if and only if it satisfies completeness and $[P^*]$ (acyclicity).*
3. *It satisfies restrictable top-transitive weak eligibility if and only if it satisfies $[P^*]$ (acyclicity) and $[PIR]$ (PI-transitivity).*
4. *It satisfies restrictable top-transitive strong eligibility if and only if it satisfies completeness and $[RRP]$ (transitivity).*

Proof.

Part 1: For one direction, suppose that acyclicity does not hold. Then there are $A_1, \dots, A_n \in \mathcal{A}$ such that $A_1 > A_2 > \dots > A_{n-1} > A_n$ and $A_n > A_1$. Weak eligibility is not satisfied for the subset $\{A_1, \dots, A_n\}$ of \mathcal{A} .

For the other direction, suppose for *reductio* that acyclicity but not restrictable weak eligibility is satisfied. We are going to show that \mathcal{A} is infinite, contrary to the assumptions. Since restrictable weak eligibility is violated, there is some subset \mathcal{B} of \mathcal{A} for which weak eligibility does not hold. Let $A_1 \in \mathcal{B}$. Since weak eligibility is not satisfied, there is some $A_2 \in \mathcal{B}$ such

that $A_2 > A_1$. Similarly, there is some A_3 such that $A_3 > A_2$, etc... If any two elements on the list A_1, A_2, A_3, \dots are identical, then acyclicity is violated. Thus, \mathcal{B} is infinite, and consequently so is \mathcal{A} , contrary to the conditions.

Part 2: For one direction, suppose that \geq satisfies restrictable strong eligibility. To see that it satisfies completeness let $A, B \in \mathcal{A}$. Since strong eligibility holds restrictably for \mathcal{A} , strong eligibility holds for the subset $\{A, B\}$ of \mathcal{A} , so that either $A \geq B$ or $B \geq A$. Since restrictable strong eligibility implies restrictable weak eligibility, acyclicity follows from part 1.

For the other direction, suppose for *reductio* that \geq is complete and acyclic but violates restrictable strong eligibility. There must be some subset \mathcal{B} of \mathcal{A} for which strong eligibility does not hold. Let $A_1 \in \mathcal{B}$. There is then some $A_2 \in \mathcal{B}$ such that $\neg(A_1 \geq A_2)$. By completeness, $A_2 > A_1$. Similarly, there is some $A_3 \in \mathcal{B}$ such that $\neg(A_2 \geq A_3)$ and consequently $A_3 > A_2$, etc. Suppose that any two elements of the list A_1, A_2, A_3, \dots are identical. Then acyclicity is violated. Thus \mathcal{B} is infinite, and so is \mathcal{A} , contrary to the conditions.

Part 3: First suppose that \geq satisfies restrictable top-transitive weak eligibility. Acyclicity follows from part 1. For PI-transitivity, let A, B , and C be three elements of \mathcal{A} such that $A > B$ and $B \equiv C$. Suppose that $\neg(A > C)$. Then $\neg(X > C)$ for all $X \in \{A, B, C\}$, and by top-transitive weak eligibility for that set $B \equiv C$ yields $\neg(X > B)$ for all $X \in \{A, B, C\}$, contrary to $A > B$. We may conclude that $A > C$.

For the other direction, suppose that acyclicity and PI-transitivity are satisfied. It follows from part 1 that \geq satisfies restrictable weak eligibility. For top-transitivity, let \mathcal{B} be a subset of \mathcal{A} and A and B two elements of \mathcal{B} such that $A \equiv B$ and that for all $X \in \mathcal{B}$, $\neg(X > B)$. For *reductio*, suppose that for some $C \in \mathcal{B}$, $C > A$. Then it follows from $A \equiv B$ and PI-transitivity that $C > B$, contrary to the conditions. We may conclude that $\neg(X > A)$ holds for all $X \in \mathcal{B}$, so that top-transitivity of weak eligibility holds for \geq in \mathcal{B} . Since this applies to all subsets \mathcal{B} of \mathcal{A} , top-transitivity of weak eligibility holds restrictably in \mathcal{A} .

Part 4: First suppose that restrictable top-transitive strong eligibility is satisfied. Completeness follows from part 2. For transitivity, let $A \geq B$ and $B \geq C$. Since top-transitivity of strong eligibility holds restrictably for \mathcal{A} , top-transitive strong eligibility holds for $\{A, B, C\}$. There are three cases:

Case i, $A \equiv B$: By completeness, $B \geq B$, so that $B \geq X$ for all $X \in \{A, B, C\}$. It follows from top-transitivity of strong eligibility, as applied to $\{A, B, C\}$, that $A \geq X$ for all $X \in \{A, B, C\}$, so that $A \geq C$.

Case ii, $A > B > C$: Suppose that $C > A$. Then strong eligibility does not hold for $\{A, B, C\}$, contrary to the conditions. It follows that $\neg(C > A)$ and by completeness that $A \geq C$.

Case iii, $A > B \equiv C$: Suppose that $C \geq A$. By completeness $C \geq C$, so that $C \geq X$ for all $X \in \{A, B, C\}$. By top-transitivity and $B \equiv C$,

$B \geq X$ for all $X \in \{A, B, C\}$, so that $B \geq A$, contrary to $A > B$. By this contradiction, $\neg(C \geq A)$. By completeness, $A \geq C$.

For the other direction, suppose that completeness and transitivity are satisfied. Transitivity implies acyclicity, so that restrictable strong eligibility follows from part 2. For top-transitivity, let \mathcal{B} be a subset of \mathcal{A} with $A, B \in \mathcal{B}$ and such that $A \equiv B$ and that $A \geq C$ for all $C \in \mathcal{B}$. Then for all $C, B \geq A$ and $A \geq C$ yield $B \geq C$, so that top-transitivity of strong eligibility holds in \mathcal{B} . Since this applies to all subsets \mathcal{B} of \mathcal{A} , top-transitivity of strong eligibility holds restrictably in \mathcal{A} . ■

In summary, the two major anticyclic (and protransitive) arguments, money-pumps and choice-guidance, both depend on manipulations of the alternative set. Money-pumps require the construction of composite alternative sets and the choice-guidance argument depends on the restriction of alternative sets. Since neither of these manipulations is uncontroversial, we do not have an uncontroversial argument in favour of preference transitivity.

2.7 Numerical representation

Preferences can be interpreted as expressions of value. $A > B$ then means that more value is assigned to A than to B , and $A \equiv B$ that the same value is assigned to the two. Values, we may assume, can be adequately expressed in numerical terms. Let u (as in *utility*) be a value function, that assigns a real number to each element of the alternative set. We can then construct a model of preference logic in the following way: (\mathfrak{R} is the set of real numbers.)

Exact value representation

$A > B$ iff $u(A) > u(B)$, where u is a function from \mathcal{A} to \mathfrak{R} .

Since completeness is assumed to hold, $A \geq B$ is defined to hold if and only if $\neg(B > A)$. This construction has been characterized in terms of postulates as follows:

THEOREM 12 (Roberts, 1979). *Let $\langle \mathcal{A}, \geq \rangle$ be a comparison structure such that \mathcal{A} is countable. Then the following two conditions are equivalent:*

1. \geq is satisfies completeness and transitivity ($[RRP]$).
2. There is a function u from \mathcal{A} to \mathfrak{R} such that $A > B$ iff $u(A) > u(B)$.

Proof. See [Roberts, 1979, pp. 109–110]. ■

As can be seen from I^nP -cycles such as the ‘cups of coffee’ example mentioned in Subsection 2.5, the exact value representation of preferences is for some purposes too demanding. If $u(A) > u(B)$, but $u(A) - u(B)$ is so small

that it cannot be discerned, then we should not expect $A > B$ to hold. One interesting way to represent this feature is to introduce a fixed limit of indiscernibility, such that $A > B$ holds if and only if $u(A) - u(B)$ is larger than that limit. Such a limit is commonly called a *just noticeable difference* (JND).

JND representation

$A > B$ iff $u(A) - u(B) > \delta$, where δ is a positive real number.

THEOREM 13 (Scott and Suppes, 1958). *Let $\langle \mathcal{A}, \geq \rangle$ be a comparison structure such that \mathcal{A} is finite. Then the following two conditions are equivalent:*

1. \geq satisfies completeness and the two properties

$A > B > C \rightarrow (A > D) \vee (D > C)$ ([RRPP], semi-transitivity)

$(A > B) \ \& \ (C > D) \rightarrow (A > D) \vee (C > B)$ ([RPRP], interval order property)

2. There is a function u from \mathcal{A} to \mathfrak{R} and a positive real number δ such that $A > B$ iff $u(A) - u(B) > \delta$.

Proof. See [Scott and Suppes, 1958; Suppes and Zinnes, 1963] or [Roberts, 1979, p. 260–264]. ■

A relation \geq that satisfies condition 1 of this theorem is called a *semiorder*. Semiorders were introduced in [Luce, 1954]. The present axioms and the above representation theorem were given in [Scott and Suppes, 1958]. The theorem cannot in general be extended to infinite alternative sets; for the infinite case see [Manders, 1981].

Semiorders can be generalized by relaxing the condition that the threshold of discrimination be the same for all comparisons of alternatives:

Variable threshold representation

$A > B$ iff $u(A) - u(B) > \sigma(A)$, where $\sigma(A) > 0$ for all A .

Another interesting construction is to assign to each alternative an interval instead of a single number. We then need two functions from \mathcal{A} to \mathfrak{R} , u_{\max} and u_{\min} , such that for all $A \in \mathcal{A}$, $u_{\max}(A) \geq u_{\min}(A)$. Here, u_{\max} represents, of course, the upper limit of the interval assigned to A , and u_{\min} its lower limit. $A > B$ holds if and only if all elements of the interval assigned to A have higher value than all elements of the B interval:

Interval representation:

$A > B$ iff $u_{\min}(A) > u_{\max}(B)$

It is easy to see that the variable threshold representation and the interval representation are equivalent. Just let:

$$u(A) = u_{\max}(A) \text{ and } \sigma(A) = u_{\max}(A) - u_{\min}(A).$$

The following representation theorem has been obtained for these constructions:

THEOREM 14 (Fishburn, 1970a). *Let $\langle \mathcal{A}, \geq \rangle$ be a comparison structure. Then the following two conditions are equivalent:*

1. \geq satisfies completeness and:
 $(A > B) \ \& \ (C > D) \rightarrow (A > D) \vee (C > B)$ ($\lceil RPRP \rceil$, interval order property)
2. There is a function u from \mathcal{A} to \mathfrak{R} and a function σ from \mathcal{A} to the positive part of \mathfrak{R} such that for all A and B in \mathcal{A} , $A > B$ iff $u(A) - u(B) > \sigma(A)$.
3. There are two functions u_{\max} and u_{\min} from \mathcal{A} to \mathfrak{R} such that for all A and B in \mathcal{A} , $u_{\max}(A) \geq u_{\min}(A)$ and $A > B$ iff $u_{\min}(A) > u_{\max}(B)$.

Proof. See [Fishburn, 1970a]. ■

A relation \geq is called an *interval order* if it satisfies the conditions of Theorem 14. Interval orders were introduced by Fishburn as a generalization of semiorders [Fishburn, 1970a]. One further step of generalization can be taken: We can let the threshold of discrimination depend on both relata.

Doubly variable threshold representation

$A > B$ iff $u(A) - u(B) > \sigma(A, B)$, with $\sigma(A, B) > 0$ for all A and B .

THEOREM 15 (Abbas, 1995). *Let $\langle \mathcal{A}, \geq \rangle$ be a comparison structure such that \mathcal{A} is finite. Then the following two conditions are equivalent:*

1. \geq satisfies acyclicity ($\lceil P^* \rceil$)
2. There is a function u from \mathcal{A} to \mathfrak{R} and a function σ from $\mathcal{A} \times \mathcal{A}$ to the positive part of \mathfrak{R} such that $A > B$ iff $u(A) - u(B) > \sigma(A, B)$.

Proof. See [Abbas, 1995]. ■

Relations satisfying acyclicity, the condition referred to in Theorem 15, are often called *suborders* [Fishburn, 1970b].

3 PREFERENCE AND CHOICE

There is a strong tradition, particularly in economics, to equate preference with choice. Preference is considered to be hypothetical choice, and choice to be revealed preference. Given an alternative set \mathcal{A} , we can represent (hypothetical) choice as a function C that, for any given subset \mathcal{B} of \mathcal{A} , turns out the chosen ('preferred') elements of \mathcal{B} .

Subsection 3.1 introduces some rationality criteria for choice functions. In Subsection 3.2 these are related to properties of the preference relation.

3.1 Postulates for choice functions

The formal definition of choice functions is as follows:

DEFINITION 16. C is a choice function for \mathcal{A} if and only if it is a function from and to $\wp(\mathcal{A})$, such that for all $\mathcal{B} \in \wp(\mathcal{A})$:

- (1) $C(\mathcal{B}) \subseteq \mathcal{B}$, and
- (2) if $\mathcal{B} \neq \emptyset$, then $C(\mathcal{B}) \neq \emptyset$.

A large number of rationality properties for preferences have been proposed. Only three of the most important of these will be discussed here.

Chernoff (property α) [Chernoff 1954]
If $\mathcal{B}_1 \subseteq \mathcal{B}_2$ then $\mathcal{B}_1 \cap C(\mathcal{B}_2) \subseteq C(\mathcal{B}_1)$.

Amartya Sen has called Chernoff 'a very basic requirement of rational choice' [Sen, 1969, p. 384]. It 'states that if the world champion in some game is Pakistani, then he must also be the champion in Pakistan'. However, it is far from self-evident that this property should hold on all occasions. Two types of examples showing this are well-known from the literature. First, the alternative set may carry information, as in Amartya Sen's example: '[G]iven the choice between having tea at a distant acquaintance's home (x), and not going there (y), a person who chooses to have tea (x) may nevertheless choose to go away (y), if offered—by that acquaintance—a choice over having tea (x), going away (y), and having some cocaine (z)' [Sen, 1993, p. 502]. See also [Kirchsteiger and Puppe, 1996]. Secondly, choice may be positional. In a choice between a big apple, a small apple, and an orange, you may choose the big apple, but in a choice between only the two apples you may nevertheless opt for the smaller one [Anand, 1993, p. 344], cf. [Gärdenfors, 1973].

Property β
If $\mathcal{B}_1 \subseteq \mathcal{B}_2$ and $X, Y \in C(\mathcal{B}_1)$, then $X \in C(\mathcal{B}_2)$ iff $Y \in C(\mathcal{B}_2)$

According to Sen, property β is ‘also appealing, though... perhaps somewhat less intuitive than Property α ’. It ‘states that if some Pakistani is a world champion, then *all* champions of Pakistan must be champions of the world’ [Sen, 1969, p. 384]. Property β is not either unproblematic, as can be seen from a modification of Sen’s cocaine example. I may be indifferent between staying for tea and going away ($C(\{x, y\}) = \{x, y\}$), but prefer to leave if cocaine is offered ($C(\{x, y, z\}) = \{y\}$).

$$\begin{aligned} & \text{Expansion (property } \gamma) \\ & C(\mathcal{B}_1) \cap \dots \cap C(\mathcal{B}_n) \subseteq C(\mathcal{B}_1 \cup \dots \cup \mathcal{B}_n) \end{aligned}$$

To see that expansion does not always hold, let $\mathcal{B}_1 = \{\text{small apple, big apple}\}$ and $\mathcal{B}_2 = \{\text{small apple, orange}\}$. It may very well be that $C(\mathcal{B}_1) = C(\mathcal{B}_2) = \{\text{small apple}\}$ whereas $C(\mathcal{B}_1 \cup \mathcal{B}_2) = \{\text{big apple}\}$.

3.2 Connecting choice and preference

The most obvious way to construct a choice function out of a preference relation \geq is to have the function always choose the elements that are best according to \geq :

$$\begin{aligned} & \text{The best choice connection} \\ & C(\mathcal{B}) = \{X \in \mathcal{B} \mid (\forall Y \in \mathcal{B})(X \geq Y)\} \end{aligned}$$

A choice function is *relational* if it is based on some preference relation \geq in this way. It can be seen from the definition that \geq must then be complete. (If it is incomplete, then there are elements X and Y such that neither $X \geq Y$ nor $Y \geq X$. It follows that $C(\{X, Y\}) = \emptyset$, contrary to Definition 16.) It can also be seen that the connection does not work if \geq violates acyclicity ($[P^*]$). Let $X_1 > X_2 > \dots > X_n > X_1$. Then it holds for each X_k that there is some X_m such that $X_m > X_k$, so that $X_k \notin C(\{X_1, X_2, \dots, X_n\})$. Hence $C(\{X_1, X_2, \dots, X_n\}) = \emptyset$, again contrary to Definition 16. Indeed, these two conditions can also be shown to be sufficient for the workability of the best choice connection. The following theorems show how various properties of choice functions correspond to properties of underlying preference relations.

THEOREM 17. *Let $\langle \mathcal{A}, \geq \rangle$ be a comparison structure, and let C be the function constructed from \geq according to the best choice connection. Then:*

1. *C is a choice function if and only if \geq satisfies completeness and acyclicity.*

Furthermore, if C is a relational choice function, then:

2. *C satisfies Chernoff [Sen 1969 p. 384]*

3. C satisfies property β if and only if \geq satisfies PI -transitivity ($[PIR]$).
[Sen 1969 p. 384]
4. C satisfies property β if and only if \geq satisfies \geq -transitivity ($[RRP]$).
[Sen 1969 p. 385]

Proof.

Part 1: This is essentially a restatement of Theorem 11, part 2.

Part 2: Let $\mathcal{B}_1 \subseteq \mathcal{B}_2$ and $X \in \mathcal{B}_1 \cap C(\mathcal{B}_2)$. Then it holds for all $Y \in \mathcal{B}_2$ that $X \geq Y$, hence this holds for all Y in \mathcal{B}_1 , hence $X \in C(\mathcal{B}_1)$.

Part 3: For one direction, let $[PIR]$ be violated. Then there are X, Y , and Z such that $X > Y \equiv Z \geq X$. It follows that $C(\{Y, Z\}) = \{Y, Z\}$, $Z \in C(\{X, Y, Z\})$ and $Y \notin C(\{X, Y, Z\})$, contrary to property β .

For the other direction, let property β be violated. Then there are alternatives X and Y and sets \mathcal{B}_1 and \mathcal{B}_2 such that $\mathcal{B}_1 \subseteq \mathcal{B}_2$, $X, Y \in C(\mathcal{B}_1)$, $X \in C(\mathcal{B}_2)$ and $Y \notin C(\mathcal{B}_2)$. It follows from $X, Y \in C(\mathcal{B}_1)$ that $Y \equiv X$, from $Y \notin C(\mathcal{B}_2)$ that there is some $Z \in \mathcal{B}_2$ such that $Z > Y$, and from $X \in C(\mathcal{B}_2)$ that $X \geq Z$. Hence, $Z > Y \equiv X \geq Z$, contrary to $[PIR]$.

Part 4: Due to Part 1 of the present theorem, it is sufficient to show that if R is complete and satisfies $[P^*]$, then $[PIR]$ and $[RRP]$ are equivalent. It follows from part 6 of Observation 10 that $[RRP]$ implies $[PIR]$. For the other direction, apply DR2 to $[PIR]$ to obtain $[PIP]$, and then DR1 to obtain $[PPI]$. $[P^*]$ yields $[PPP]$ that we can combine with $[PPI]$, using DR2, to obtain $[PPR]$. Applying DR1 to $[PPR]$ and $[PIR]$ we obtain $[RPP]$ and $[RPI]$, and DR2 yields $[RPR]$. Finally, through DR1 we obtain $[RRP]$. ■

THEOREM 18 (Sen, 1971). *Let C be a choice function for \mathcal{A} . Then the following two conditions are equivalent:*

- (1) C satisfies Chernoff and Expansion.
- (2) There is a relation \geq on \mathcal{A} such that C coincides with the function constructed from \geq via the best choice connection.

Proof.

1-to-2: Let \geq be the relation such that $X \geq Y$ iff $X \in C(\{X, Y\})$. For one direction, let $X \in C(\mathcal{B})$ and $\mathcal{B} \subseteq \mathcal{A}$. We need to show that $X \geq Y$ for all $Y \in \mathcal{B}$. Suppose to the contrary that for some Y , $\neg(X \geq Y)$. Then $X \notin C(\{X, Y\})$, and according to Chernoff, $C(\mathcal{B}) \cap \{X, Y\} \subseteq C(\{X, Y\}) = \{Y\}$. Contradiction.

For the other direction, let $X \in C(\{X, Y\})$ for all $Y \in \mathcal{B}$. It follows from Expansion that $X \in C(\mathcal{B})$.

2-to-1. To prove that Chernoff holds, let $\mathcal{B}_1 \subseteq \mathcal{B}_2$ and $X \in \mathcal{B}_1 \cap C(\mathcal{B}_2)$. Then it holds for all $Y \in \mathcal{B}_2$ that $X \geq Y$, hence this holds for all $Y \in \mathcal{B}_1$,

hence $X \in C(\mathcal{B}_1)$. To prove that Expansion holds, let $X \in C(\mathcal{B}_1) \cap \dots \cap C(\mathcal{B}_n)$. Then it holds for all $Y \in \mathcal{B}_1 \cup \dots \cup \mathcal{B}_n$ that $X \geq Y$. Hence, $X \in C(\mathcal{B}_1 \cup \dots \cup \mathcal{B}_n)$. ■

For a more extensive review of connections between choice and preference, the reader is referred to [Moulin, 1985]. For applications to epistemic choice and preference, see [Rott, 1993; Rott, 1999].

The results that connect choice functions with preference relations are so elegant that it may be somewhat unwelcome to question their meaningfulness. Nevertheless, the very idea of regarding choice as based on preference is quite problematic. This can be seen in two ways. First, as we saw above, the Chernoff property holds for all relational choice functions, but it nevertheless has counterintuitive consequences in realistic cases. Secondly, on a more basic, conceptual level, choices and preferences are entities of quite different categories. Preferences are *states of mind*. That I prefer x to y means that I consider x to be better than y . Choices are *actions*. That I have chosen x means that I have actually selected x (irrespective of whether I consider myself or anyone else to be better off through this choice).

Obviously, examples can easily be found in which choice and preference coincide, but there are also situations in which they clearly do *not* coincide. (Cf. [Sen, 1973].) We can, for instance, make choices that are not guided by preferences. A person may be indifferent between two alternatives, but still have to choose between them. This is exemplified by my recent choice between a match with a red head and one with a black head. Although I actually chose the red one, this does not mean that I prefer it, other than in some technical sense of ‘prefer’ that has been constructed to conciliate it with choice. A similar situation obtains when we have to choose between incommensurable alternatives. As was noted by Sen, it is particularly odd in this latter case to claim that choice reveals preference [Sen, 1973].

Clearly, preference can be defined (technically) as binary choice, but then difficulties arise in ‘interpreting preference thus defined as preference in the usual sense with the property that if a person prefers x to y then he must regard himself to be better off with x than with y ’ [Sen, 1973, p. 15].

4 PREFERENCES WITH COMPATIBLE RELATA

In the previous sections, we have studied preferences that refer to a set of mutually exclusive alternatives that are taken as primitive units (exclusionary preferences). In actual discourse on preferences, we often make statements that transgress these limitations. In a discussion on musical pieces, someone may express preferences for orchestral music over chamber music, and also for Baroque over Romantic music. We may then ask her how she rates Baroque chamber music versus orchestral music from the Romantic

period. Assuming that these comparisons are all covered by one and the same preference relation, some of the relata of this preference relation are not mutually exclusive. Preferences with compatible relata may be called *combinative preferences*.

In Subsection 4.1, the use of sentential representation for the relata of combinative preferences is introduced, and in Subsection 4.2 some postulates for this type of preferences are discussed. Subsections 4.3–4.7 are devoted to the stepwise construction of a model in which preferences with compatible relata are based on exclusionary preferences. Some logical properties emerging from this construction are discussed in Subsection 4.8. An alternative construction of combinative preferences is discussed in Subsection 4.9.

4.1 Sentential representation

In non-regimented language, all sorts of abstract and concrete entities can serve as the relata of preference relations. Thus, one may prefer butter to margarine, democracy to tyranny, or Bartok's fourth string quartet to his third. In spite of this, logical analyses of combinative preferences have been almost exclusively concerned with relata that represent states of affairs.

This practice is based on the assumption that combinative preferences over other types of entities can be adequately expressed as preferences over states of affairs. R. Lee went as far as to saying that 'all preferences can be understood in terms of preference among states of affairs or possible circumstances. A preference for bourbon, for example, may be a general preference that one drink bourbon instead of drinking scotch' [von Wright, 1963, p. 12; von Wright, 1972, pp. 143–144; Trapp, 1985, p. 303]. It is probably not quite as simple as that, but no other general-purpose representation of combinative preferences seems to be available. Therefore, combinative preferences will be taken to have states of affairs as relata. States of affairs, in their turn, will be represented in the usual way by sentences in sentential logic. The logical relationships among these sentences are assumed to include classical sentential logic. These choices are in line with tradition in philosophical logic.

Furthermore, it will be assumed that logically equivalent expressions can be substituted for each other. This assumption makes way for certain counter-intuitive inferences. Let p denote that you receive \$100 tomorrow, q that you receive \$50 tomorrow, and r that you are robbed of all the money that you own the day after tomorrow. Presumably, you prefer p to q . By intersubstitutivity, you then also prefer $(p \& r) \vee (p \& \neg r)$ to q . However, the direct translation of $(p \& r) \vee (p \& \neg r)$ into natural language does not seem to be preferable to the direct translation of q into natural language. The reason for this is that the disjunctive formulation of the comparison gives the impression that each of the disjuncts is preferred to q [Hansson, 1998b].

This and other counter-intuitive inferences can only be avoided by giving up intersubstitutivity, thereby losing much of the simplicity and logical strength of the formal structure. It is, on balance, better for most purposes to endure the somewhat strange consequences of intersubstitutivity than to pay the high price for getting rid of them.

Sentences will be denoted by lower-case letters p, q, \dots . The relations of weak preference, strict preference, and indifference will be denoted $\geq, >, \equiv$ as before, with indices added to distinguish between different relations whenever needed.

4.2 *Preference postulates for sentences*

The postulates for exclusionary preferences discussed in Subsections 2.2–2.4 can also be applied to combinative preferences. We therefore have the following properties:

$$\begin{aligned} p &\geq p \text{ (reflexivity)} \\ (p &\geq q) \vee (q \geq p) \text{ (completeness)} \\ p &\geq q \geq r \rightarrow p \geq r \text{ (transitivity)} \end{aligned}$$

and the various anticyclic properties discussed in Subsection 2.4. Reflexivity is clearly a desirable property. Everything that we can compare—not only complete alternatives—should be equal in value to itself. Completeness, on the other hand, is even more problematic for combinative than for exclusionary preferences. Even if your preferences are sufficiently developed to cover all possible comparisons between complete alternatives, they do not in general also cover all other possible comparisons. To see this, consider the four meals that can be composed out of the two dishes and the two drinks served at a small market stand. Suppose that you like each of the meals on the following list better than all those below it:

hamburger and beer
sandwich and coffee
sandwich and beer
hamburger and coffee

It does not follow that you, in this context, prefer a meal with coffee to a meal with beer, or a meal with beer to a meal with coffee, or that you are indifferent between these two (incomplete) alternatives. You may very well lack a determinate preference between the two.

Some of the logical issues that arise in connection with combinative preferences do not arise for exclusionary preferences, for the simple reason that they are not defined for the latter. In particular, this applies to logical principles that refer to negated or disjunctive states of affairs.

Sören Halldén introduced the postulates $(p \equiv q) \rightarrow (\neg q \equiv \neg p)$ and $(p > q) \rightarrow (\neg q > \neg p)$ [Halldén, 1957, pp. 27–29 and 36]. von Wright used

the phrase ‘the principle of contraposition’ for the latter of the two principles [von Wright, 1972, pp. 147–149]. A similar postulate, $(p \geq q) \rightarrow (\neg q \geq \neg p)$, can be formed for weak preference. The term ‘contraposition’ can be used as a common term for all postulates of this general form. Thus, $(p \geq q) \rightarrow (\neg q \geq \neg p)$ is contraposition of weak preference, $(p \equiv q) \rightarrow (\neg q \equiv \neg p)$ is contraposition of indifference, etc.

The principles of contraposition have a clear intuitive appeal. If you prefer playing the piano to playing football, then not playing the piano should be worse for you than not playing football. But convincing counterexamples are not either difficult to find. Bengt Hansson provided an example against contraposition of strict preference [Hansson, 1968, pp. 428–429]. Let p denote that you win the first prize and q that you win some prize. Then $p > q$ may reasonably hold, but it does not hold that $\neg q > \neg p$. To the contrary, $\neg p$ is preferable to $\neg q$, since it leaves open the possibility of winning some other prize than the first prize. The same example can also be used against contraposition of weak preference. ($p \geq q$ holds, but not $\neg q \geq \neg p$.)

The following example can be used against contraposition of indifference [Hansson, 1996a]. Let p denote that I have at least two copies of Rousseau’s *Du contrat social* on my bookshelf and q that I have at least one copy of it. Since I need the book, but cannot use more than one copy, p and q are of equal value, i.e. $p \equiv q$. However, it does not hold that $\neg q \equiv \neg p$. To the contrary, $\neg q$ is worse than $\neg p$, since it means that I am in the precarious situation of not having access to *Du contrat social*.

The most widely quoted argument against contraposition was provided by Chisholm and Sosa. They claimed that ‘although that state of affairs consisting of there being happy egrets (p) is better than that one that consists of there being stones (q), that state of affairs that consists of there being no stones ($\neg q$) is no better, nor worse, than that state of affairs consisting of there being no happy egrets ($\neg p$)’ [Chisholm and Sosa, 1966, p. 245]. More will be said about this example in Subsection 4.5.

Halldén also introduced the two principles $(p > q) \leftrightarrow ((p \& \neg q) > (q \& \neg p))$ and $(p \equiv q) \leftrightarrow ((p \& \neg q) \equiv (q \& \neg p))$ [Halldén, 1957, p. 28]. They have been accepted by von Wright. [von Wright 1963, pp. 24–25, 40, and 60.] The postulate $(p > q) \leftrightarrow ((p \& \neg q) > (q \& \neg p))$ has been called conjunctive expansion’ [Jennings, 1967]. This term can be used for all relationships of the same form. (Thus, $(p \equiv q) \leftrightarrow ((p \& \neg q) \equiv (q \& \neg p))$ is conjunctive expansion of indifference, etc.)

Conjunctive expansion is based on the reasonable assumption that ‘when one is to decide between two situations p and q , one does not actually compare these alternatives, but the situation that p is true while q is not on one hand and that q is true while p is not on the other’ [Hansson, 1968, p. 428]. However, as has been pointed out by several authors, conjunctive expansion cannot hold unrestrictedly since it would involve preferences with contradictory relata [Castañeda, 1958; Chisholm and Sosa, 1966; Quinn,

1974]. For concreteness, let p denote that a certain person is blind in her left eye and q that she is blind in two eyes. It is clearly worse to be blind in two eyes (q) than to be blind in the left eye (p). However, it does not follow that being blind only in the left eye ($p \& \neg q$) is better than contradiction ($q \& \neg p$).

Chisholm and Sosa chose to reject conjunctive expansion altogether, and so did Quinn [Chisholm and Sosa, 1966, p. 245; Quinn, 1974, p. 125]. It should be noted, however, that the arguments that led up to this conclusion refer to examples in which one of the relata implies the other. This was pointed out by Saito, who therefore claimed that conjunctive expansion of indifference and strict preference hold ‘only when both $p \& \neg q$ and $\neg p \& q$ are logically possible, i.e., p and q do not imply each other’ [Saito, 1973, p. 388]. Cf. [Trapp, 1985, p. 318].

Intuitively, we would expect $p \vee q$ to be intermediate in value between p and q . Suppose that I prefer that the painter paints the house white rather than that she paints it yellow. Then the information that she painted it either white or yellow should be at most as welcome as the information that she painted it white, and at least as welcome as the information that she painted it yellow. More generally speaking, the following should hold:

$$(p \geq q) \rightarrow (p \geq (p \vee q) \geq q) \text{ (disjunctive interpolation)}$$

von Wright argued that ‘[d]isjunctive preferences are conjunctively distributive’ in the sense that preferring $p \vee q$ to r is essentially the same as preferring p to r and also q to r [von Wright, 1963, p. 26]. See also [Hansson, 1968, pp. 433–439]. This standpoint is expressed in the following two distributive axioms:

$$\begin{aligned} ((p \vee q) \geq r) &\leftrightarrow ((p \geq r) \& (q \geq r)) \text{ (left disjunctive distribution of } \geq) \\ (p \geq (q \vee r)) &\leftrightarrow ((p \geq q) \& (p \geq r)) \text{ (right disjunctive distribution of } \geq) \end{aligned}$$

Close connections hold between disjunctive distribution principles for \geq and $>$:

OBSERVATION 19 (Bengt Hansson, 1968). Let \geq be a relation over a set \mathcal{L} of sentences that is closed under truth-functional operations. Let $>$ be the strict part of \geq . Furthermore, let \geq be complete. Then

- (1) $(p \vee q) \geq r \rightarrow (p \geq r) \& (q \geq r)$ is valid iff $(p > q) \vee (p > r) \rightarrow p > (q \vee r)$ is valid.
- (2) $(p \geq r) \& (q \geq r) \rightarrow (p \vee q) \geq r$ is valid iff $p > (q \vee r) \rightarrow (p > q) \vee (p > r)$ is valid.
- (3) $p \geq (q \vee r) \rightarrow (p \geq q) \& (p \geq r)$ is valid iff $(p > r) \vee (q > r) \rightarrow (p \vee q) > r$ is valid.

(4) $(p \geq q) \& (p \geq r) \rightarrow p \geq (q \vee r)$ is valid iff $(p \vee q) > r \rightarrow (p > r) \vee (q > r)$ is valid.

If \geq is both complete and transitive, then:

(5) If $(p \geq r) \& (q \geq r) \rightarrow (p \vee q) \geq r$ is valid, then so is $p \geq (q \vee r) \rightarrow (p \geq q) \vee (p \geq r)$

(6) If $(p \geq q) \& (p \geq r) \rightarrow p \geq (q \vee r)$ is valid, then so is $(p \vee q) \geq r \rightarrow (p \geq r) \vee (q \geq r)$

Proof.

Part 1:

$(p \vee q) \geq r \rightarrow (p \geq r) \& (q \geq r)$

iff $\neg((p \geq r) \& (q \geq r)) \rightarrow \neg((p \vee q) \geq r)$

iff $\neg(p \geq r) \vee \neg(q \geq r) \rightarrow \neg((p \vee q) \geq r)$

iff $(r > p) \vee (r > q) \rightarrow r > (p \vee q)$

Substitution yields $(p > q) \vee (p > r) \rightarrow p > (q \vee r)$.

Parts 2-4 are proved in the same way as part 1.

Part 5: Suppose to the contrary that $p \geq (q \vee r) \rightarrow (p \geq q) \vee (p \geq r)$ does not hold. Then we have $p \geq (q \vee r)$ and, due to completeness, $q > p$ and $r > p$. Transitivity yields $q > (q \vee r)$ and $r > (q \vee r)$.

Due to part (2), since $(p \geq r) \& (q \geq r) \rightarrow (p \vee q) \geq r$ is valid, so is $p > (q \vee r) \rightarrow (p > q) \vee (p > r)$. Applying the appropriate substitution instance to $q > (q \vee r)$ we obtain $(q > q) \vee (q > r)$, and since $>$ is irreflexive it follows that $q > r$. In the same way, $r > (q \vee r)$ yields $r > q$. Since $>$ is asymmetric, this is impossible, and we can conclude from the contradiction that $p \geq (q \vee r) \rightarrow (p \geq q) \vee (p \geq r)$.

Part 6: Suppose to the contrary that $(p \vee q) \geq r \rightarrow (p \geq r) \vee (q \geq r)$ does not hold. Then we have $(p \vee q) \geq r$ and, due to completeness, $r > p$ and $r > q$. Transitivity yields $(p \vee q) > p$ and $(p \vee q) > q$.

Due to part (4), since $(p \geq q) \& (p \geq r) \rightarrow p \geq (q \vee r)$ is valid, so is $(p \vee q) > r \rightarrow (p > r) \vee (q > r)$. Applying the appropriate substitution instance to $(p \vee q) > p$ we obtain $(p > p) \vee (q > p)$, hence $q > p$. In the same way, $(p \vee q) > q$ yields $p > q$. This contradiction concludes the proof. ■

The following argument against $(p \geq q) \& (p \geq r) \rightarrow p \geq (q \vee r)$ was proposed by Sven Danielsson and reported by Bengt Hansson [1968, p. 439]: A person who is away from home receives a letter. The following are statements about the letter:

- p the letter says that the family's dog is feeling well
- q the letter says that his son is feeling well
- r the letter says that his daughter is feeling well
- s the letter says that his wife has been killed in an accident

We can then reasonably expect to have $p \geq (q \vee (r \& s))$ and $p \geq ((q \& s) \vee r)$. It follows from the postulate under discussion that $p \geq (q \vee (r \& s) \vee (q \& s) \vee r)$, or equivalently $p \geq (q \vee r)$, which is much less plausible. It should be observed, though, that this argument depends on the substitution of $q \vee r$ for the logically equivalent sentence $q \vee (r \& s) \vee (q \& s) \vee r$. This substitution, rather than the application of disjunctive distribution, is the problematic step.

A close connection has been shown to hold between disjunctive interpolation and one direction of the disjunctive distribution principles:

OBSERVATION 20 (Bengt Hansson, 1968). Let \geq be a relation over a set \mathcal{L} of sentences that is closed under truth-functional operations. Consider the following postulates:

- (i) $(p \geq r) \& (q \geq r) \rightarrow ((p \vee q) \geq r)$
- (ii) $(p \geq q) \& (p \geq r) \rightarrow (p \geq (q \vee r))$
- (iii) If $p \geq q$ then $p \geq (p \vee q) \geq q$ (*disjunctive interpolation*)

(1) If \geq is complete, and (i) and (ii) both hold, then so does (iii).
If \geq is complete and transitive, then (iii) holds if and only if both (i) and (ii) hold.

Proof.

Part 1: Suppose to the contrary that (iii) does not hold. Then $p \geq q$, and it follows from completeness that either $q > (p \vee q)$ or $(p \vee q) > p$. In the former case, it follows from (i) and part (2) of Observation 19 that $(q > p) \vee (q > q)$, and by the irreflexivity of $>$ that $q > p$, contrary to $p \geq q$. In the latter case, it follows from (ii) and part (4) of Observation 19 that $(p > p) \vee (q > p)$, which is contradictory in the same way.

Part 2: Due to part 1, only one direction of the equivalence remains to prove.

In order to prove (i), let $(p \geq r) \& (q \geq r)$. Due to completeness, either $p \geq q$ or $q \geq p$. In the former case, (iii) yields $(p \vee q) \geq q$, and with $q \geq r$ and transitivity we obtain $(p \vee q) \geq r$. In the latter case, (iii) yields $(p \vee q) \geq p$, and with $p \geq r$ and transitivity we again obtain $(p \vee q) \geq r$.

In order to prove (ii), let $(p \geq q) \& (p \geq r)$. Due to completeness, either $q \geq r$ or $r \geq q$. In the former case, (iii) yields $q \geq (q \vee r)$, and with $p \geq q$ transitivity yields $p \geq (q \vee r)$. In the latter case, (iii) yields $r \geq (q \vee r)$, and with $p \geq r$ transitivity again yields $p \geq (q \vee r)$. ■

4.3 Connecting the two levels

We can expect strong connections to hold between the preferences that refer to a set of (mutually exclusive) alternatives and the preferences that

refer to incomplete relata that are associated with those same alternatives. In the formal representation, there are two major ways to construct these connections.

One of these is the *holistic* approach, that takes preferences over wholes for basic and uses them to derive combinative preferences. The other may be called the *aggregative* approach. It takes smaller units (expressible as incomplete relata) to be the fundamental bearers of value, and the values of complete alternatives are obtained by aggregating these units. A precise aggregative model was developed by Warren Quinn, on the basis of a proposal by Gilbert Harman. In Quinn's model, (intrinsic) values are assigned to certain basic propositions, which come in groups of mutually exclusive propositions. A conjunction of basic propositions is assigned the sum of the intrinsic values of its conjuncts. Various proposals have been made for the calculation of other truth-functional combinations of basic propositions [Harman, 1967; Quinn, 1974; Oldfield, 1977; Carlson, 1997; Danielsson, 1997].

The aggregative approach requires that there be isolable units of value and that these can be aggregated in some exact way, such as arithmetic addition. These conditions are satisfied in some utilitarian theories of moral betterness. This was indeed what Quinn had in mind; he considered it 'natural to suppose that the most evaluatively prior of all states of affairs are those which locate a specific sentient individual at a specific point along an evaluatively relevant dimension such as happiness, virtue, wisdom, etc. Thus for each pair consisting of an individual and a dimension there will be a distinct basic proposition for each point on that dimension which that individual may occupy' [Quinn, 1974, p. 131]. Cf. [Harman, 1967, p. 799].

The forms of utilitarianism that lend themselves to this mathematization are not the only reasonable theories of moral value. Furthermore, there are non-moral preference relations for which the aggregative approach does not seem at all suitable. Although many different factors may influence our judgment of the overall aesthetic value of a theatre performance, we cannot expect its overall value to be derivable in a mechanical way (such as addition) from these factors. The aesthetic value of the whole cannot be reduced in a summative way into isolable constituents. An analogous argument can be made against applying the aggregative approach to moral value according to intuitionist moral theories. 'The value of a whole must not be assumed to be the same as the sum of the values of its parts' [Moore, 1903, p. 28].

The holistic approach avoids these difficulties. Furthermore, it allows us to make use of the results already obtained for exclusionary preferences. An underlying exclusionary preference relation for (complete) alternatives can be used to derive preferences over the incomplete relata associated with these alternatives. Due to this, and to the implausibility in many cases of the decomposition required in aggregative models, the holistic approach

will be followed here. In other words, exclusionary preferences over a set of (mutually exclusive) alternatives are taken to be basic, and from them preferences over other relata can be derived.

This is not an unusual choice; the holistic approach has been chosen by most philosophical logicians dealing with combinative preferences. It must be borne in mind that it is a logical reconstruction rather than a faithful representation of actual deliberative or evaluative processes. In everyday life, combinative preferences do not seem to need the support of underlying exclusionary preferences. I prefer chess to boxing *simpliciter*. Only as a result of philosophical reflection do I prefer certain alternatives in which I watch or take part in chess to certain other such alternatives in which I watch or take part in pugilism. [Pollock, 1983, esp pp. 413–414; Beck, 1941, esp. p. 12]. This assumption, and the additional assumption that preferences over combinative relata can be reconstructed from the exclusionary preference relation (although, of course, they did not originate that way) have been made since they provide us with the basis for a series of fruitful formal explications of preference.

4.4 *Constructing the alternatives*

What is the nature of the underlying alternatives that are used as a basis for modelling combinative preferences? Clearly, to each such alternative should be assigned a set of sentences, namely those sentences that hold in that alternative. This can be achieved through the introduction of a function that assigns a set of sentences to each alternative. However, an even simpler construction is possible. We may assume that if two alternatives support the same sentences, then they are treated in the same way by the preference relation. Under this assumption, we can dispense with the function that was just mentioned, and simplify the notation by identifying alternatives with their supported sets of sentences.

We will therefore assume that there is a non-empty language \mathcal{L} that is closed under the truth-functional operations \neg (negation), \vee (disjunction), $\&$ (conjunction), \rightarrow (implication), and \leftrightarrow (equivalence). In order to express the logical relations between sentences in the formal language, an operator of logical consequence (Cn) will be used, such that for any set X of sentences, $\text{Cn}(X)$ is the set of logical consequences of X . Cn includes classical sentential logic. (On consequence operators, see [Hansson, 1999a].)

Logically equivalent sets represent the same states of affairs, i.e., if $\text{Cn}(S) = \text{Cn}(S')$ for some $S, S' \subseteq \mathcal{L}$, then S and S' represent the same state of affairs. Therefore, nothing is lost by requiring that all alternatives be logically closed, i.e. that if $A \in \mathcal{A}$, then $A = \text{Cn}(A)$. Clearly, the set of alternatives should be non-empty (and arguably, it should have at least two elements). This gives rise to the following definition:

DEFINITION 21. A subset \mathcal{A} of $\wp(\mathcal{L})$ is a *sentential alternative set* (a set of *sentential alternatives*) if and only if:

- (1) $\mathcal{A} \neq \emptyset$, and
- (2) If $A \in \mathcal{A}$, then A is consistent and logically closed ($A = \text{Cn}(A)$).

A comparison structure $\langle \mathcal{A}, \geq \rangle$ is a *sentential comparison structure* if and only if \mathcal{A} is a sentential alternative set.

This definition allows for alternative sets such as $\{\text{Cn}(\{p\}), \text{Cn}(\{p, q\})\}$ in which one alternative is a proper subset of another. Such sets should be excluded, and we also have reasons to exclude alternative sets such as $\{\text{Cn}(\{p\}), \text{Cn}(\{q\})\}$ in which two alternatives are logically compatible. Mutual exclusivity is a characteristic feature of complete alternatives that distinguishes them from *relata* in general. These requirements can be summarized as follows:

DEFINITION 22. A subset \mathcal{A} of $\wp(\mathcal{L})$ is a *set of mutually exclusive alternatives* if and only if:

- (1) $\mathcal{A} \neq \emptyset$,
- (2) If $A \in \mathcal{A}$, then A is consistent and logically closed ($A = \text{Cn}(A)$), and
- (3) If $A, A' \in \mathcal{A}$ and $A \neq A'$, then $A \cup A'$ is inconsistent. (*mutual exclusivity*)

This definition still allows for an alternative set such as the following:

$$\{\text{Cn}(\{p, q\}), \text{Cn}(\{p, \neg q\}), \text{Cn}(\{\neg p\})\}$$

For concreteness, consider the alternative set containing the following three alternatives, referring to possible ways of spending an evening:

- (1) Eating out (p) and going to the theatre (q).
- (2) Eating out (p) and not going to the theatre ($\neg q$).
- (3) Not eating out ($\neg p$).

This is a somewhat strange set of alternatives, since the third alternative is less specified than the other two. If neither $\text{Cn}(\{\neg p, q\})$ nor $\text{Cn}(\{\neg p, \neg q\})$ has to be excluded from consideration, then the two of them should replace $\text{Cn}(\{\neg p\})$. If only one of them is available, then that one alone should replace $\text{Cn}(\{\neg p\})$. The outcome of amending the set of alternatives in either of these ways is a new alternative set in which all alternatives have been specified in the same respects. This makes it possible to compare them in a more uniform way. In the above case, such uniformity seems to be a

prerequisite for exhaustiveness in deliberation. On the other hand, there are also cases in which such exhaustiveness is not needed. This can be seen from an alternative interpretation of the above example that was proposed by Wlodek Rabinowicz. Let p denote that I go out and q that I wear a tie. Then $\{\text{Cn}(\{p, q\}), \text{Cn}(\{p, \neg q\}), \text{Cn}(\{\neg p\})\}$ is an adequate alternative set, provided that q is value-relevant in the presence of p but not of $\neg p$. When exhaustiveness of deliberation is required, then the alternative set should satisfy the following condition:

DEFINITION 23. A subset \mathcal{A} of $\wp(\mathcal{L})$ is a *set of contextually complete alternatives* if and only if:

- (1) $\mathcal{A} \neq \emptyset$,
- (2) If $A \in \mathcal{A}$, then A is consistent and logically closed ($A = \text{Cn}(A)$), and
- (3) If $p \in A \in \mathcal{A}$ and $A' \in \mathcal{A}$, then either $p \in A'$ or $\neg p \in A'$. (*relative negation-completeness* [Hansson, 1992])

OBSERVATION 24. Any set of contextually complete alternatives is also a set of mutually exclusive alternatives.

Proof. Conditions (1) and (2) of Definition 23 coincide with the equally numbered conditions of Definition 22. To see that condition (3) of Definition 22 is satisfied, let $A, A' \in \mathcal{A}$ and $A \neq A'$. Without loss of generality, we can assume that there is some $p \in A \setminus A'$. It follows from condition (3) of Definition 23 that $\neg p \in A'$. Hence, $\{p, \neg p\} \subseteq A \cup A'$, so that condition (3) of Definition 22 is satisfied. ■

In most applications of the holistic approach to combinative preferences, the underlying alternatives have been possible worlds, represented by maximal consistent subsets of the language [Rescher, 1967; Åqvist, 1968; Cresswell, 1971; von Wright, 1972; van Dalen, 1974; von Kutschera, 1975; Trapp, 1985; Hansson, 1989; Hansson, 1996a].

DEFINITION 25. A subset \mathcal{A} of $\wp(\mathcal{L})$ is a *set of possible worlds* if and only if:

- (1) $\mathcal{A} \neq \emptyset$,
- (2) If $A \in \mathcal{A}$, then A is a maximal consistent subset of \mathcal{L} .

OBSERVATION 26. Any set of possible worlds is a set of contextually complete alternatives.

Proof. We need to show that if A is a maximal consistent subset of \mathcal{L} , then it is logically closed and satisfies relative negation-completeness. Both are standard results. For logical closure, suppose to the contrary that $p \in \text{Cn}(A)$

and $p \notin A$. Then $A \cup \{p\}$ is a superset of A and a consistent subset of \mathcal{L} , contrary to the assumption that A is a maximal consistent subset of \mathcal{L} . Relative negation-completeness, follows from the well-known fact that if $p \in \mathcal{L}$ and $A' \in \mathcal{A}$, then either $p \in A'$ or $\neg p \in A'$. (Suppose not. Then due to the logical closure of A , $p \notin \text{Cn}(A')$, hence $A' \cup \{\neg p\}$ is a superset of A' and a consistent subset of \mathcal{L} .) ■

Possible world modelling has the advantages of generality and logical beauty, but it also has the disadvantage of cognitive unrealism. In practice, we are not capable of deliberating on anything approaching the size of completely determinate possible worlds. Instead, we restrict our deliberations to objects of manageable size. It can therefore be argued that a more realistic holism should be based on smaller wholes, namely alternatives that cover all the aspects under consideration—but not all the aspects that might have been considered. This approach may be seen as an application of Simon’s ‘bounded rationality view’. Alternatives smaller than possible worlds are referred to in decision theory as ‘small worlds’ [Savage, 1954; Simon, 1957; Toda and Shuford, 1965; Toda, 1976; Schoemaker, 1982; Humphreys, 1983; Mendola, 1987; Hansson, 1993c; Hansson, 1996b].

In summary, we have the following series of increasingly general representations of (holistic) alternatives:

The following notation will turn out to be useful:

DEFINITION 27. Let \mathcal{A} be a set of sentential alternatives in \mathcal{L} . The subset $\mathcal{L}_{\mathcal{A}}$ of \mathcal{L} is the set consisting exactly of (1) $\cup\mathcal{A}$, and (2) the truth-functional combinations of elements of $\cup\mathcal{A}$.

$\mathcal{L}_{\mathcal{A}}$ is called the \mathcal{A} -language. Its elements are the \mathcal{A} -sentences.

DEFINITION 28. Let \mathcal{A} be a set of sentential alternatives, and let p and q be elements of $\cup\mathcal{A}$. Then:

- $\models_{\mathcal{A}} q$ denotes that $q \in A$ for all $A \in \mathcal{A}$.
- $p \models_{\mathcal{A}} q$ denotes that $q \in A$ for all $A \in \mathcal{A}$ such that $p \in A$.
- p and q are \mathcal{A} -incompatible if and only if $\models_{\mathcal{A}} \neg(p \& q)$

4.5 Comparing compatible alternatives

We have now constructed the holistic preference structure. Before connecting it with combinative preferences, we need to have a closer look at the

characteristic feature of combinative preferences—namely that they allow for comparisons of compatible relata.

There is nothing strange or unusual with an utterance such as ‘It is better to have a cat than to have a dog’—although it is possible to have both a cat and a dog. We need to make the conventions explicit that guide our understanding of such utterances. A child may very well protest against the quoted sentence, saying: ‘No, it is better to have a dog, if you have a cat too.’ This we perceive as a sign that the child has misunderstood what it means to make this comparison. But why is it so, and what is a correct analysis?

There are at least two plausible answers to this question. According to one approach, that we may call the *adjustment account*, having both a cat and a dog is not under consideration. The sentence expresses a comparison between cat-and-no-dog and dog-and-no-cat. As proposed by Castañeda, ‘[w]hen St. Paul said “better to marry than to burn” he meant “it is better to marry and not to burn than not to marry and to burn” ’ [Castañeda, 1958, Cf. 1 Cor 7:9].

According to the other approach, that we may call the *totality account*, the comparison is between all-ways-to-have-a-dog and all-ways-to-have-a-cat. Since the alternatives in which one has both a dog and a cat are elements of both these sets of alternatives, their influence is cancelled out.

At first view, the difference between the adjustment and the totality account may seem rather inconsequential. In the first approach, the cat-and-dog cases are excluded for both relata, and in the second approach they are included in both relata but their effects are cancelled out. The difference will be more clearly seen when a third option is included in the comparison, such as ‘having a canary’. First consider the totality account. When we compare having a cat to having dog, the former alternative is represented by all-ways-to-have-a-cat. Similarly, when we compare having a cat to having canary, it is represented by all-ways-to-have-a-cat. The representation of having a cat is unaffected by what we compare it to. Next, consider the adjustment account. When we compare having a cat to having dog, the former alternative is represented by cat-and-no-dog alternatives. Similarly, when we compare having a cat to having canary, the former alternative is represented by cat-and-no-canary alternatives. Hence, the representation of cat-owning alternatives is constant according to the totality view, but according to the adjustment account it differs depending on what comparison is being made.

It has been argued that the adjustment account is better suited to express *ceteris paribus* preferences, whereas the totality view is better suited for decision-theoretical applications. The two approaches require different constructions and give rise to different logical properties. The adjustment approach will be developed in the rest of this subsection and in Subsections 4.6–4.8. We will return to the totality approach in Subsection 4.9.

Probably the first statement of the adjustment approach was given by

Halldén in his pioneering work on preference logic. He observed: ‘If we say that it would be better if p than if q , then we mean that it would be better if $p \& \neg q$ than if $q \& \neg p$ ’ [Halldén, 1957, p. 28]. (Cf. Subsection 4.2.) The same standpoint was taken by von Wright in his analysis of *ceteris paribus* preference [von Wright, 1963, pp. 24–25; von Wright, 1972, pp. 146–147]. The following has become a standard procedure in preference logic:

TRANSLATION PROCEDURE 1 (Halldén): The informal statement ‘ p is better than q ’ is translated into $(p \& \neg q) > (q \& \neg p)$, and ‘ p is equal in value to q ’ is translated into $(p \& \neg q) \equiv (q \& \neg p)$.

This is by no means bad as a first approximation. It works in cases such as the one just cited, when the alternatives are compatible and neither of them logically implies the other. It also works when the alternatives are logically incompatible. (Then $p \& \neg q$ is equivalent to p and $q \& \neg p$ to q .)

Halldén’s translation procedure runs into serious trouble when at least one of p and q logically implies the other. Then it forces us to compare a state of affairs to a contradictory state of affairs. This problem was observed by Kron and Milovanovic, who decided to accept the translation procedure but left as an open question ‘what it could mean to prefer a contradiction to something else or to prefer a state of affairs to a contradiction’ [Kron and Milovanovic, 1975, p. 187]. Cf. [Trapp, 1985, pp. 314–318]. The translation procedure breaks down completely when a sentence p is compared to itself; this comparison will be reduced to comparing logical contradiction to itself. Arguably, logical contradiction is equal in value to itself, but this does not seem to be the right reason why a non-contradictory statement p should be equal in value to itself. The right reason must be concerned with comparing p to itself, not contradiction to itself.

A remedy for this breakdown can be found simply by observing how the problematic cases are treated in informal discourse. Let p denote ‘I work hard and earn a lot of money’ and q ‘I work hard’. A case can be made for the viewpoint that p and q are incomparable. However, it should be clear that *if the comparison can be made in a meaningful way*, then it does not invoke the contradictory state of affairs $p \& \neg q$. Rather, the actual comparison takes place between p and $q \& \neg p$. It would seem correct to say that since $p \& \neg q$ is contradictory, it is not used to replace p .

Similarly, a comparison between p and itself does not involve a comparison between $p \& \neg p$ and itself. Since $p \& \neg p$ is contradictory, it is not used to replace p . We are thus led to the following definition and translation procedure:

DEFINITION 29 (Hansson, 1989). p/q (‘ p and if possible not q ’) is equal to p if $p \& \neg q$ is logically contradictory, and otherwise it is equal to $p \& \neg q$.

TRANSLATION PROCEDURE 2: [Hansson 1989] The informal statement ‘ p is better than q ’ is translated into $(p/q) > (q/p)$, and ‘ p is equal in value to q ’ is translated into $(p/q) \equiv (q/p)$.

This procedure yields the same result as Halldén’s in the two cases when the latter turns out to be satisfactory, namely when p and q are incompatible and when they are compatible and neither of them implies the other. In the remaining cases, namely when one or both of p and q implies the other, the second procedure yields an intuitively more reasonable result than Halldén’s procedure.

However, we are not yet finished. The use of logical contradiction in the definition of $/$ leads to undesired results. Let p denote ‘I go to the moon’ and q ‘I travel by spaceship’. A comparison between p and q will, according to translation procedure 2, be conceived as a comparison between $p \& \neg q$ and $q \& \neg p$. However, $p \& \neg q$ is not a serious possibility, although it is clearly *logically* possible. The only reasonable way to perform this comparison (outside of certain science fiction contexts) is to compare p to $q \& \neg p$. More generally, p/q should be defined as p not only when $p \& \neg q$ is logically impossible but also when it is for other reasons not to be counted as possible, or more precisely: not included in any element of the alternative set.

DEFINITION 30. p/Aq (‘ p and if A -possible not q ’) is equal to $p \& \neg q$ if $p \not\vdash_A q$. If $p \vdash_A q$, then p/Aq is equal to p .

TRANSLATION PROCEDURE 3: The informal statement ‘ p is better than q ’ is translated into $(p/Aq) > (q/AP)$, and ‘ p is equal in value to q ’ is translated into $(p/Aq) \equiv (q/AP)$.

This is the translation procedure that will be used in what follows.

We can now return to Chisholm’s and Sosa’s argument against contraposition, that was referred to in Subsection 4.2. They argued that ‘although that state of affairs consisting of there being happy egrets (p) is better than that one that consists of there being stones (q), that state of affairs that consists of there being no stones ($\neg q$) is no better, nor worse, than that state of affairs consisting of there being no happy egrets ($\neg p$)’ [Chisholm and Sosa, 1966, p. 245].

Since stones and happy egrets can coexist, this is a comparison between compatible alternatives. Therefore, we can apply translation procedure 3. In other words, when comparing the existence of happy egrets with that of stones, we should compare alternatives in which there are happy egrets but no stones to alternatives in which there are stones but no happy egrets, i.e., $p \& \neg q$ to $q \& \neg p$. Next, let us compare $\neg q$ to $\neg p$. By the same argument, this should be a comparison between, on the one hand, there being no stones and not being no happy egrets and, on the other hand, there being no happy egrets and not being no stones. This is, hidden behind double negations, the same comparison between $p \& \neg q$ and $q \& \neg p$ that we have just

made. Thus, from a logical point of view, it is unavoidable—once we have accepted translation procedure 3—that $p > q$ holds if and only if $\neg q > \neg p$. What makes the example seem strange is that although we apply translation procedure 3 spontaneously to p and q , unaided intuition halts before the negated statements and does not perform the same operation.

4.6 Representation functions

As we have just seen, an informal comparison between the relata p and q should be translated into a formal comparison between the relata $p/\mathcal{A}q$ and $q/\mathcal{A}p$. Therefore, it should be derivable from a comparison between alternatives in which $p/\mathcal{A}q$ is true and alternatives in which $q/\mathcal{A}p$ is true. A pair $\langle A_1, A_2 \rangle$ of alternatives, such that $p/\mathcal{A}q$ is true in A_1 and $q/\mathcal{A}p$ is true in A_2 will be called a *representation* of the pair $\langle p/\mathcal{A}q, q/\mathcal{A}p \rangle$.

DEFINITION 31. Let \mathcal{A} be a set of sentential alternatives. An element A of \mathcal{A} is a *representation* in \mathcal{A} of a sentence x if and only if $x \in A$.

An element $\langle A, B \rangle$ of $\mathcal{A} \times \mathcal{A}$ is a *representation* in \mathcal{A} of the pair $\langle x, y \rangle$ of sentences if and only if $x \in A$ and $y \in B$.

A sentence x or a pair $\langle x, y \rangle$ of sentences is *representable* in \mathcal{A} if and only if it has a representation in \mathcal{A} .

More concisely, x is representable in \mathcal{A} if and only if $x \in \cup \mathcal{A}$, and $\langle x, y \rangle$ if and only if $x, y \in \cup \mathcal{A}$.

Not all representations of $\langle p/\mathcal{A}q, q/\mathcal{A}p \rangle$ need to be relevant to the comparison between p and q . Those that are relevant will be picked out by a *representation function*.

DEFINITION 32 (Hansson, 1989). A *representation function* for a set \mathcal{A} of sentential alternatives is a function f such that:

- (1) If $\langle x, y \rangle$ is representable in \mathcal{A} , then $f(\langle x, y \rangle)$ is a non-empty set of representations of $\langle x, y \rangle$ in \mathcal{A} .
- (2) Otherwise, $f(\langle x, y \rangle) = \emptyset$.

Representation functions provide a general format for deriving combinative preference relations from exclusionary preference relations:

DEFINITION 33 (Hansson, 1989). Let \geq be a relation on the set \mathcal{A} of sentential alternatives, and f a representation function for \mathcal{A} . The weak preference relation \geq_f , the *f-extension* of \geq , is defined as follows:

$$p \geq_f q \text{ if and only if } A \geq B \text{ for all } \langle A, B \rangle \in f(\langle p/\mathcal{A}q, q/\mathcal{A}p \rangle).$$

$>_f$ is the strict part of \geq_f , and \equiv_f its symmetric part.

For most purposes it can be assumed that a comparison between p and q and one between q and p are based on comparisons between the same

pairs of complete alternatives. This assumption corresponds to the following symmetry property of representation functions:

DEFINITION 34. A representation function f for a set \mathcal{A} of sentential alternatives is *symmetric* if and only if for all sentences $x, y \in \cup\mathcal{A}$ and all elements A and B of \mathcal{A} :

$$\langle A, B \rangle \in f(\langle x, y \rangle) \text{ if and only if } \langle B, A \rangle \in f(\langle y, x \rangle)$$

Another plausible property of a representation function is that reflexive comparisons of states of affairs (comparisons of a state of affairs to itself) should only be represented by reflexive comparisons of complete alternatives (comparisons of such an alternative to itself). This can also be required for comparisons between states of affairs that are coextensive, i.e. hold in exactly the same alternatives:

DEFINITION 35. A representation function f for a set \mathcal{A} of sentential alternatives satisfies *weak centering* if and only if for all sentences $x \in \cup\mathcal{A}$ and all elements A_1 and A_2 of \mathcal{A} :

$$\text{If } \langle A_1, A_2 \rangle \in f(\langle x, x \rangle), \text{ then } A_1 = A_2.$$

Furthermore, it satisfies *centering* if and only if for all sentences $x, y \in \cup\mathcal{A}$:

$$\text{If } \models_{\mathcal{A}} x \leftrightarrow y, \text{ and } \langle A_1, A_2 \rangle \in f(\langle x, y \rangle), \text{ then } A_1 = A_2.$$

We should expect a derived combinative preference relation to say about the complete alternatives exactly what the underlying exclusionary preference relation says about them. If there is a sentence a that has A as its only representation, and a sentence b that has B as its only representation, then $a \geq_f b$ should hold if and only if $A \geq B$ holds. Indeed, this condition holds for all representation functions.

OBSERVATION 36 (Hansson, 1989). Let \geq be a relation on the set \mathcal{A} of sentential alternatives and f a representation function for \mathcal{A} . Furthermore, let A and B be elements of \mathcal{A} , and a and b sentences such that A is the only representation of a in \mathcal{A} , and B the only representation of b in \mathcal{A} . Then:

$$a \geq_f b \text{ if and only if } A \geq B.$$

COROLLARY: If \mathcal{A} is a mutually exclusive alternative set, and $A = \text{Cn}(\{a\})$ and $B = \text{Cn}(\{b\})$, then $a \geq_f b$ if and only if $A \geq B$.

Proof. Since A is the only representation of a in \mathcal{A} , it is also the only representation of $a/\mathcal{A}b$ in \mathcal{A} . Similarly, B is the only representation of $b/\mathcal{A}a$ in \mathcal{A} . Definition 32 yields $f(\langle a/\mathcal{A}b, b/\mathcal{A}a \rangle) = \{\langle A, B \rangle\}$. According to Definition 33, $a \geq_f b$ iff $A \geq B$. ■

4.7 *Ceteribus paribus preferences*

The more precise construction of a representation function will have to depend on the type of preferences that we aim at representing. This subsection is devoted to the construction of representation functions for *ceteris paribus* preferences.

A recipe for this construction can be extracted from von Wright's early work. He defined *ceteris paribus* preferences as follows:

‘[A]ny given total state of the world, which contains p but not q , is preferred to a total state of the world, which differs from the first in that it contains q but not p , but otherwise is identical with it.’ [von Wright, 1963, p. 31]. Cf. [Quinn, 1974, p. 124; von Wright, 1972, pp 140 and 147].

This recipe needs some modifications before it can be put to use. Where von Wright refers to ‘ p but not q ’, i.e. to $p \& \neg q$, we should instead refer to $p/\Delta q$, as explained in Subsection 4.5. Furthermore, von Wright's concept of ‘identity’ is problematic. It is more reasonable to require that the alternatives are, given the differences required for them to represent the respective sentences, as similar as possible in all other respects.

With these modifications, the quoted passage can be rephrased as follows:

Any given alternative which contains $p/\Delta q$ is preferred to an alternative which differs from the first in that it contains $q/\Delta p$, but is otherwise as similar as possible it.

Before this recipe can be formalized, we need to operationalize ‘as similar as possible’. In a follow-up article, von Wright attempted to solve this problem (under another description) by means of an arithmetical count of differences in terms of logically independent atomic states of the world [von Wright, 1972, pp. 146–147]. He assumed that there are n logically independent states of affairs p_1, \dots, p_n , and 2^n possible states of the world w_1, \dots, w_{2^n} that can be compared in terms of the n atomic states. If two states of affairs q and r are molecular combinations of in all m out of the n atomic states, then a *ceteris paribus* comparison of q and r keeps the other $n - m$ states constant.

Unfortunately, this simple construction is not as promising as it might seem at first sight. Its major weakness is that the choice of atomic states can be made in different ways that give rise to different relations of similarity. For an example of this, consider the following four sentential alternatives:

(1a) $\text{Cn}(\{p, q_1, q_2, q_3, q_4, q_5, q_6, q_7, q_8, q_9, q_{10}\})$

(1b) $\text{Cn}(\{\neg p, q_1, q_2, q_3, q_4, q_5, q_6, q_7, q_8, q_9, q_{10}\})$

(2a) $\text{Cn}(\{p, r_1, r_2, r_3, r_4, r_5, r_6, r_7, r_8, r_9, r_{10}\})$

$$(2b) \text{ Cn}(\{\neg p, \neg r_1, \neg r_2, \neg r_3, \neg r_4, \neg r_5, \neg r_6, \neg r_7, \neg r_8, \neg r_9, \neg r_{10}\})$$

Intuitively, (1a) and (1b) seem to represent a *ceteris paribus* comparison between p and $\neg p$, whereas (2a) and (2b) do not. But suppose that r_1, \dots, r_{10} are definable in terms of p, q_1, \dots, q_{10} as follows:

$$\begin{aligned} r_1 &\leftrightarrow (p \leftrightarrow q_1) \\ \dots & \\ r_{10} &\leftrightarrow (p \leftrightarrow q_{10}) \end{aligned}$$

Then, in going from (1a) and (1b) to (2a) and (2b), we shift to another, expressively equivalent set of atomic sentences. Since there are no objectively given logical atoms, there is in general ample scope for choosing among sets of atomic sentences that are equivalent in terms of what can be expressed in the language, but not in terms of von Wright's similarity measure.

It seems inescapable that a non-trivial explication of similarity will have to make use of more information than what is inherent in the logic. Probably the most transparent way to represent similarity is by means of a similarity relation, as follows:

DEFINITION 37 (Williamson, 1988). For any set Ψ , the four-place relation T is a similarity relation over Ψ if and only if, for all $U, V, W, X, Y, Z \in \Psi$:

$$(T1) \quad T(W, X, Y, Z) \vee T(Y, Z, W, X) \quad (\text{completeness})$$

$$(T2) \quad T(U, V, W, X) \ \& \ T(W, X, Y, Z) \rightarrow T(U, V, Y, Z) \quad (\text{transitivity})$$

$$(T3) \quad T(X, X, Y, Z)$$

$$(T4) \quad T(X, Y, Y, Y) \rightarrow X = Y$$

$$(T5) \quad T(X, Y, Y, X) \quad (\text{symmetry})$$

The strict part of T is defined as follows:

$$\hat{T}(W, X, Y, Z) \leftrightarrow T(W, X, Y, Z) \ \& \ \neg T(Y, Z, W, X)$$

$T(W, X, Y, Z)$ should be read 'W is at least as similar to X as is Y to Z', and $\hat{T}(W, X, Y, Z)$ 'W is more similar to X than is Y to Z'. This axiomatization of the four-termed similarity relation was proposed by T. Williamson [1988], see also [Hansson, 1992]. It is a generalization of a three-termed similarity relation that was introduced earlier by David Lewis [Lewis, 1973a, pp. 48ff; 1973b, p. 560; 1981]. Lewis's relation $S(X, Y, Z)$ should be read 'X is more similar to Y than is Z'. It can be defined from the four-termed relation through the relationship $S(X, Y, Z) \leftrightarrow T(X, Y, Z, Y)$.

(T1) and (T2) combine to say that similarity is a weak ordering (complete and transitive). (T3) and (T4) combine to say that maximal similarity obtains between two arguments if and only if they are identical, and (T5)

states that the degree of similarity between two arguments does not depend on the order in which they are taken.

How can similarity be used to explicate *ceteris paribus* preferences? Two proposals are available in the literature. One of these is based on the intuition that when comparing p and q we should look for pairs of alternatives $\langle A_1, A_2 \rangle$ that satisfy the following two conditions:

(1) *The representation condition*

A_1 is a representation of p , and A_2 a representation of q .

(2) *The unfocused similarity condition*

A_1 and A_2 are maximally similar to each other, as compared to other pairs of alternatives that satisfy the representation condition.

These assumptions give rise to the following definition of *ceteris paribus* preferences. It can be seen as a formalized version of the basic ideas behind von Wright's explication of *ceteris paribus* preferences, as quoted above.

DEFINITION 38. Let \mathcal{A} be a set of sentential alternatives and T a similarity relation over \mathcal{A} . Then f is the *unfocused similarity-maximizing* representation function that is based on T , if and only if it is a representation function and, for all $x, y \in \cup \mathcal{A}$ and $A, B \in \mathcal{A}$:

$\langle A, B \rangle \in f(\langle x, y \rangle)$ if and only if $x \in A, y \in B$, and $T(A, B, A', B')$ holds for all $A', B' \in \mathcal{A}$ such that $x \in A'$ and $y \in B'$.

Furthermore, if \geq is a reflexive relation on \mathcal{A} , then \geq_f is an *unfocused similarity-maximizing* preference relation if and only if it is based on an unfocused similarity-maximizing representation function.

The adequacy criteria introduced in Subsection 4.6 are satisfied by unfocused similarity-maximizing representation functions.

OBSERVATION 39. Let \mathcal{A} be a set of sentential alternatives and f an unfocused similarity-maximizing representation function over \mathcal{A} . Then f satisfies centring and symmetry.

Proof.

Centring: Suppose to the contrary that centring does not hold for f . Then, according to Definition 35, there are $A_1, A_2 \in \mathcal{A}$ and $x, y \in \cup \mathcal{A}$ such that $\models_{\mathcal{A}} x \leftrightarrow y$, $\langle A_1, A_2 \rangle \in f(\langle x, y \rangle)$, and $A_1 \neq A_2$. It follows from $A_1 \neq A_2$, using (T4), that $\neg T(A_1, A_2, A_2, A_2)$. On the other hand, according to Definition 38, it follows from $x, y \in A_2$ that $T(A_1, A_2, A_2, A_2)$. Contradiction.

Symmetry: Suppose to the contrary that symmetry is not satisfied. Then there are $x, y \in \cup \mathcal{A}$ and $A, B \in \mathcal{A}$ such that $\langle A, B \rangle \in f(\langle x, y \rangle)$ and $\langle B, A \rangle \notin$

$f(\langle y, x \rangle)$. It follows by Definition 38 from $\langle B, A \rangle \notin f(\langle y, x \rangle)$ that there are $A', B' \in \mathcal{A}$ such that $x \in A', y \in B'$, and $\neg T(B, A, B', A')$.

On the other hand, it follows according to Definition 38 from $\langle A, B \rangle \in f(\langle x, y \rangle)$, $x \in A'$, and $y \in B'$, that $T(A, B, A', B')$. We can use (T5) to obtain $T(B, A, A, B)$ and $T(A', B', B', A')$. Two applications of (T2) to $T(B, A, A, B)$, $T(A, B, A', B')$, and $T(A', B', B', A')$ provide us with $T(B, A, B', A')$, contrary to what was just shown. This contradiction concludes the proof. ■

The other similarity-based approach to *ceteris paribus* preferences is based on the assumption that there is a privileged alternative A_0 that can serve as a reference point. If the alternative set consists of possible worlds, then the actual world can be used as such a reference point. This amounts to the following alternative to (2):

(2') *The focused similarity condition*

A_1 is maximally similar to A_0 , as compared to other alternatives that satisfy the representation condition with respect to p . In the same way, A_2 is maximally similar to A_0 , as compared to other alternatives that satisfy the representation condition with respect to q .

This is an approach with some tradition in the literature on preference logic [von Kutschera, 1975; Trapp, 1985; Hansson, 1989]. In the present formal framework it can be expressed as follows:

DEFINITION 40. Let \mathcal{A} be a set of sentential alternatives, A_0 an element of \mathcal{A} , and T a similarity relation over \mathcal{A} . Then f is the A_0 -*focused similarity-maximizing* representation function that is based on T , if and only if it is a representation function f such that, for all $x, y \in \cup \mathcal{A}$ and $A, B \in \mathcal{A}$:

$$\begin{aligned} \langle A, B \rangle \in f(\langle x, y \rangle) & \text{ if and only if } x \in A, y \in B, \\ T(A, A_0, A', A_0) & \text{ holds for all } A' \text{ such that } x \in A' \in \mathcal{A}, \text{ and} \\ T(B, A_0, B', A_0) & \text{ holds for all } B' \text{ such that } y \in B' \in \mathcal{A}. \end{aligned}$$

Furthermore, if \geq is a reflexive relation on \mathcal{A} , then \geq_f is an A_0 -*focused similarity-maximizing* preference relation if and only if it is based on an A_0 -focused similarity-maximizing representation function.

Perhaps surprisingly, from a formal point of view the focused approach can be subsumed under the unfocused approach.

OBSERVATION 41 (Hansson, 1998b). Let $\langle \mathcal{A}, \geq \rangle$ be a sentential comparison structure such that \mathcal{A} is finite and that \geq is complete and transitive. Then:

1. If \geq_f is a focused similarity-maximizing preference relation, based on $\langle \mathcal{A}, \geq \rangle$ and a similarity relation T , then it is also an unfocused

similarity-maximizing preference relation, based on $\langle \mathcal{A}, \geq \rangle$ and another similarity relation T' .

2. The converse relationship does not hold in general.

Proof.

Part 1: Let \geq_f be focused on A_0 . For each $X \in \mathcal{A}$, let $\delta(X)$ be the number of elements of Y in \mathcal{A} such that $\hat{T}(Y, A_0, X, A_0)$. Let $T'(X, Y, Z, W)$ hold if and only if *either* $X = Y$ *or* $\delta(X) + \delta(Y) \leq \delta(Z) + \delta(W)$ and $Z \neq W$. Then T' satisfies conditions (T1)-(T5) of Definition ???. Furthermore, if x and y are \mathcal{A} -incompatible, then:

$$\begin{aligned} &T'(A, B, A', B') \text{ whenever } x \in A' \in \mathcal{A} \text{ and } y \in B' \in \mathcal{A}, \\ &\text{iff } \delta(A) + \delta(B) \leq \delta(A') + \delta(B') \text{ whenever } x \in A' \in \mathcal{A} \text{ and } y \in B' \in \mathcal{A}, \\ &\text{iff } \delta(A) \leq \delta(A') \text{ whenever } x \in A' \in \mathcal{A} \text{ and } \delta(B) \leq \delta(B') \\ &\quad \text{whenever } y \in B' \in \mathcal{A}, \\ &\text{iff } T(A, A_0, A', A_0) \text{ whenever } x \in A' \in \mathcal{A} \text{ and } T(B, A_0, B', A_0) \\ &\quad \text{whenever } y \in B' \in \mathcal{A}. \end{aligned}$$

It follows that T' gives rise to the same preference relation via Definition 38 as does T via Definition 40.

Part 2: We are going to exhibit an unfocused similarity-maximizing preference relation that cannot be reconstructed as a focused similarity-maximizing preference relation. For that purpose, let \geq be transitive and complete, and let $p, q,$ and r be mutually exclusive relata. Let $\mathcal{A} = \{A, B, C, D\}$ be contextually complete, with $r \in A, p \in B, q \in C,$ and $r \in D$. Furthermore, let \geq be a weak ordering (complete and transitive) over \mathcal{A} , such that $A > B > C > D$. Let T be a similarity relation over \mathcal{A} such that similarity coincides with closeness in the following diagram:

(The distances $A - B, B - C,$ and $C - D$ are the same.) Let f be the unfocused representation function based on T in the manner of Definition 38. Then $p \geq_f q$ and $q \geq_f r$ but not $p \geq_f r$. It is easy to show that a focused similarity-maximizing preference relation always satisfies transitivity for mutually exclusive relata, if the underlying exclusionary preference relation is transitive. Therefore, \geq_f cannot be reconstructed as focused. ■

Due to its greater generality, the unfocused approach will be used in what follows. To simplify the terminology, it will be called ‘similarity-maximizing’ rather than ‘unfocused similarity-maximizing’.

4.8 Logical properties of combinative preferences

It is natural to ask to what extent various logical properties of the underlying exclusionary preference relation \geq are reflected in the logic of the derived preference relation \geq_f . More precisely, a logical property is *transmitted* by f if and only if: If \geq has this property, then so does \geq_f [Hansson, 1996a].

Reflexivity is not transmitted by all representation functions, but it is transmitted by a wide range of representation functions, including those that are similarity-maximizing.

OBSERVATION 42 (Hansson, 1998b). Let \geq be a reflexive relation on the sentential alternative set \mathcal{A} , and let f be a representation function for \mathcal{A} . Then \geq_f is reflexive if and only if for all sentences x and all elements A_1 and A_2 of \mathcal{A} : If $\langle A_1, A_2 \rangle \in f(\langle x, x \rangle)$, then $A_1 \geq A_2$.

COROLLARY. If f satisfies weak centring, then \geq_f is reflexive.

Proof. Immediate from Definitions 33 and 35. ■

Completeness of the exclusionary preference relation $((A \geq B) \vee (B \geq A))$ is not transmitted to similarity-maximizing preference relations. Indeed, a fairly strong negative result can be obtained that holds for all types of representation functions.

OBSERVATION 43 (Hansson, 1998b). Let f be a representation function for the sentential alternative set \mathcal{A} , such that there are two elements p and q of $\cup \mathcal{A}$ and four pairwise distinct elements $A_1, A_2, B_1,$ and B_2 of \mathcal{A} such that $\langle A_1, B_1 \rangle \in f(\langle p/\mathcal{A}q, q/\mathcal{A}p \rangle)$ and $\langle B_2, A_2 \rangle \in f(\langle q/\mathcal{A}p, p/\mathcal{A}q \rangle)$. Then there is a complete relation \geq over \mathcal{A} such that $(p \geq_f q) \vee (q \geq_f p)$ does not hold.

Proof. Let \geq be complete and such that $A_2 > B_2$ and $B_1 > A_1$. Then it follows from $\langle B_2, A_2 \rangle \in f(\langle q/\mathcal{A}p, p/\mathcal{A}q \rangle)$ and $\neg(B_2 \geq A_2)$ that $\neg(q \geq_f p)$. Similarly, it follows from $\langle A_1, B_1 \rangle \in f(\langle p/\mathcal{A}q, q/\mathcal{A}p \rangle)$ and $\neg(A_1 \geq B_1)$ that $\neg(p \geq_f q)$. ■

Transitivity is not in general transmitted by similarity-maximizing representation functions, not even for pairwise incompatible relations.

OBSERVATION 44 (Hansson, 1998b). Let \geq be a transitive and complete relation on the contextually complete alternative set \mathcal{A} , and let f be a representation function on \mathcal{A} . Then $p \geq_f q \geq_f r \rightarrow p \geq_f r$ does not hold in general if \geq_f is similarity-maximizing, not even if $p, q,$ and r are pairwise incompatible.

Proof. See part 2 of the proof of Observation 41. ■

We can now turn to such logical properties of combinative preferences that cannot be transmitted since they are not defined for exclusionary preferences. The principles of contraposition and conjunctive expansion hold for

\geq_f , \equiv_f , and $>_f$ in the principal case when neither of the relata contextually implies the other. These results apply to all preference relations that are based on a representation function in the manner of Definition 33.

OBSERVATION 45 (Hansson 1998b). Let \geq be a reflexive relation on the sentential alternative set \mathcal{A} and f a representation function for \mathcal{A} . Furthermore, let p and q be elements of $\cup\mathcal{A}$ such that $p \not\leq_{\mathcal{A}} q$ and $q \not\leq_{\mathcal{A}} p$. Then:

- (1) $p \geq_f q \rightarrow \neg q \geq_f \neg p$,
- (2) $p \equiv_f q \rightarrow \neg q \equiv_f \neg p$, and
- (3) $p >_f q \rightarrow \neg q >_f \neg p$.

Proof.

Part 1: Let $p \geq_f q$, and let $\langle A, B \rangle \in f(\langle \neg q /_{\mathcal{A}} \neg p, \neg p /_{\mathcal{A}} \neg q \rangle)$. It follows from $p \not\leq_{\mathcal{A}} q$ that $\neg q /_{\mathcal{A}} \neg p$ is equivalent to $p /_{\mathcal{A}} q$, and from $q \not\leq_{\mathcal{A}} p$ that $\neg p /_{\mathcal{A}} \neg q$ is equivalent to $q /_{\mathcal{A}} p$. Thus, $\langle A, B \rangle \in f(\langle p /_{\mathcal{A}} q, q /_{\mathcal{A}} p \rangle)$. It follows from $p \geq_f q$ that $A \geq B$. Since this holds for all $\langle A, B \rangle \in f(\langle \neg q /_{\mathcal{A}} \neg p, \neg p /_{\mathcal{A}} \neg q \rangle)$, we may conclude that $\neg q \geq_f \neg p$.

Part 2: From part 1.

Part 3: Suppose that $p >_f q$, i.e., $p \geq_f q$ and $\neg(q \geq_f p)$. It follows from $p \geq_f q$, in the same way as in part 1, that $\neg q \geq_f \neg p$.

It follows from $\neg(q \geq_f p)$ that there is some A and some B such that $\langle B, A \rangle \in f(\langle q /_{\mathcal{A}} p, p /_{\mathcal{A}} q \rangle)$ and $\neg(B \geq A)$. Then, $\langle B, A \rangle \in f(\langle \neg p /_{\mathcal{A}} \neg q, \neg q /_{\mathcal{A}} \neg p \rangle)$. From this and $\neg(B \geq A)$ follows $\neg(\neg p \geq_f \neg q)$.

From $\neg q \geq_f \neg p$ and $\neg(\neg p \geq_f \neg q)$ it follows that $\neg q >_f \neg p$. ■

OBSERVATION 46 (Hansson, 1998b). Let \geq be a reflexive relation on the sentential alternative set \mathcal{A} and f a representation function for \mathcal{A} . Furthermore, let p and q be elements of $\cup\mathcal{A}$ such that $p \not\leq_{\mathcal{A}} q$ and $q \not\leq_{\mathcal{A}} p$. Then:

- (1) $p \geq_f q \leftrightarrow (p \& \neg q) \geq_f (q \& \neg p)$,
- (2) $p \equiv_f q \leftrightarrow (p \& \neg q) \equiv_f (q \& \neg p)$, and
- (3) $p >_f q \leftrightarrow (p \& \neg q) >_f (q \& \neg p)$.

Proof. For all $\langle A, B \rangle \in \mathcal{A} \times \mathcal{A}$, $\langle A, B \rangle \in f(p /_{\mathcal{A}} q, q /_{\mathcal{A}} p)$ iff $\langle A, B \rangle \in f(p \& \neg q /_{\mathcal{A}} q \& \neg p, q \& \neg p /_{\mathcal{A}} p \& \neg q)$. The proof proceeds as that of Observation 45. ■

Disjunctive interpolation does not hold in general for similarity-maximizing preference relations, but if p and q are \mathcal{A} -incompatible then it holds for all preference relations that are based on representation functions.

OBSERVATION 47 (Hansson, 1998b). Let \mathcal{A} be a sentential alternative set, \geq a reflexive relation on \mathcal{A} and f a representation function on \mathcal{A} . Let p and q be \mathcal{A} -incompatible elements of $\cup\mathcal{A}$. Then:

- (1) $(p \geq_f (p \vee q)) \leftrightarrow (p \geq_f q)$
- (2) $((p \vee q) \geq_f p) \leftrightarrow (q \geq_f p)$
- (3) $(p \geq_f q) \rightarrow (p \geq_f (p \vee q) \geq_f q)$

Proof. For *part 1*, we have: $f(\langle p/\mathcal{A}(p \vee q), (p \vee q)/\mathcal{A}p \rangle) = f(\langle p, q \rangle) = f(\langle p/\mathcal{A}q, q/\mathcal{A}p \rangle)$. *Part 2* is proved in the same way, and *part 3* follows from parts 1 and 2. ■

OBSERVATION 48 (Hansson, 1998b). Let \geq be a transitive and complete relation on the contextually complete alternative set \mathcal{A} . Let \geq_f be a similarity-maximizing extension of \geq . Then:

- (1) $(p \geq_f q) \rightarrow (p \geq_f (p \vee q))$ does not hold in general.
- (2) $(p \geq_f q) \rightarrow ((p \vee q) \geq_f q)$ does not hold in general.

Proof.

Part 1: Let $\mathcal{A} = \{A, B, C\}$, with $p, \neg q \in A$, $\neg p, q \in B$, and $p, q \in C$. Let $A > B > C$. Let f be based on a similarity relation T such that for all X, Y, Z , and W , if $X \neq Y$ and $Z \neq W$ then $T(X, Y, Z, W)$. Then $f(\langle p/\mathcal{A}q, q/\mathcal{A}p \rangle) = \{\langle A, B \rangle\}$ and $A \geq B$, so that $p \geq_f q$. However, it follows from $\langle C, B \rangle \in f(\langle p/\mathcal{A}p \vee q, p \vee q/\mathcal{A}p \rangle)$ and $B > C$ that $\neg(p \geq_f (p \vee q))$.

Part 2: Let $\mathcal{A} = \{A, B, C\}$, with $p, q \in A$, $p, \neg q \in B$, and $\neg p, q \in C$. Let $A > B > C$. Let f be based on a similarity relation T such that for all X, Y, Z , and W , if $X \neq Y$ and $Z \neq W$ then $T(X, Y, Z, W)$. Then $f(\langle p/\mathcal{A}q, q/\mathcal{A}p \rangle) = \{\langle B, C \rangle\}$ and $B \geq C$, so that $p \geq_f q$. However, it follows from $\langle B, A \rangle \in f(\langle p \vee q/\mathcal{A}q, q/\mathcal{A}p \vee q \rangle)$ and $A > B$ that $\neg((p \vee q) \geq_f q)$. ■

The properties of disjunctive distribution referred to in Subsection 4.2 do not hold in general for similarity-maximizing preference relations [Hansson, 1998b]. However, the following much weaker properties for pairwise incompatible relata can be shown to hold:

OBSERVATION 49. Let \geq be a transitive and complete relation on the contextually complete alternative set \mathcal{A} . Let $p, q, r \in \cup\mathcal{A}$, and let \geq_f be a similarity-maximizing extension of \geq . Then:

- (1) $((p \vee q) \geq_f r) \rightarrow (p \geq_f r) \vee (q \geq_f r)$ holds if p , q , and r are pairwise \mathcal{A} -incompatible elements of \mathcal{A} .

(2) $(p \geq_f (q \vee r)) \rightarrow (p \geq_f q) \vee (p \geq_f r)$ holds if $p, q,$ and r are pairwise \mathcal{A} -incompatible elements of \mathcal{A} .

Proof.

Part 1: Let $(p \vee q) \geq_f r$. Then there is at least one pair $\langle X, Y \rangle$ of elements of \mathcal{A} such that $p \vee q \in X, r \in Y,$ and $T(X, Y, X', Y')$ for all $X', Y' \in \mathcal{A}$ such that $p \vee q \in X'$ and $r \in Y'$. Clearly, either $p \in X$ or $q \in X$.

If $p \in X,$ let $\langle X'', Y'' \rangle$ be any pair such that $p \in X''$ and $r \in Y''$. Then $p \vee q \in X'',$ and it follows that $T(X, Y, X'', Y'')$. Since this holds for all pairs $\langle X'', Y'' \rangle$ with $p \in X''$ and $r \in Y'', p \geq_f r$.

If $q \in X,$ then $q \geq_f r$ follows in the same way.

Part 2: Let $p \geq_f (q \vee r)$. Then there is at least one pair $\langle X, Y \rangle$ of elements of \mathcal{A} such that $p \in X, q \vee r \in Y,$ and $T(X, Y, X', Y')$ for all $X', Y' \in \mathcal{A}$ such that $p \in X'$ and $q \vee r \in Y'$. Clearly, either $q \in Y$ or $r \in Y$.

If $q \in Y,$ let $\langle X'', Y'' \rangle$ be a pair such that $p \in X''$ and $q \in Y''$. Then $q \vee r \in Y'',$ and it follows that $T(X, Y, X'', Y'')$. Since this holds for all pairs $\langle X'', Y'' \rangle$ with $p \in X''$ and $q \in Y'', p \geq_f q$.

If $r \in Y,$ then $p \geq_f r$ follows in the same way. ■

In summary, similarity-maximizing preference relations have very weak, perhaps disappointingly weak, logical properties. However, it does not follow that they are inadequate to represent *ceteris paribus* preferences. Counterexamples to several of the rejected principles were given in Subsection 4.2, and it can reasonably be argued that an adequate logic for *ceteris paribus* preferences should be quite weak.

4.9 The totality approach

In this subsection, we are going to return to the alternative approach to combinative preferences that was mentioned in Subsection 4.5, namely the totality approach. It is based on the representation of (single) sentences rather than of pairs of sentences. Each sentence is represented by the set of alternatives to which it is applied.

DEFINITION 50. Let $p \in \mathcal{L}_{\mathcal{A}}$. Then:

$$repr_{\mathcal{A}}(p) = \{X \in \mathcal{A} \mid p \in X\}$$

The index of $repr_{\mathcal{A}}$ is deleted whenever convenient.

Preferences over sentences can be derived from preferences over sets of alternatives, according to the simple principle that $p \geq' q$ holds if and only if $repr(p) \geq' repr(q)$ holds. More precisely:

DEFINITION 51. Let $\langle \mathcal{A}, \geq \rangle$ be a comparison structure. Then a relation \geq' over $\wp(\mathcal{A}) \setminus \{\emptyset\}$ is a *subset-extension* of \geq if and only if it holds for all $A, B \in \mathcal{A}$ that $\{A\} \geq' \{B\}$ iff $A \geq B$.

If $\langle \mathcal{A}, \geq \rangle$ is a sentential comparison structure, then $p \geq' q$ is an abbreviated notation for $\text{repr}_{\mathcal{A}}(p) \geq' \text{repr}_{\mathcal{A}}(q)$.

Several types of subset-extensions have been investigated. Among the simplest are those that are based on the decision-theoretical principles of maximin and maximax. To express them we need some additional notation and terminology.

DEFINITION 52. Let $\emptyset \neq \mathcal{B} \subseteq \mathcal{A}$, let $p \in \cup \mathcal{A}$, and let \geq be a relation on \mathcal{A} . Then:

$$\begin{aligned} \max(\mathcal{B}) &= \{X \in \mathcal{B} \mid (\forall Y \in \mathcal{B})(X \geq Y)\} \\ \min(\mathcal{B}) &= \{X \in \mathcal{B} \mid (\forall Y \in \mathcal{B})(Y \geq X)\} \end{aligned}$$

The elements of $\max(\mathcal{B})$ are the (\geq -)maximal elements of \mathcal{B} , and those of $\min(\mathcal{B})$ are its (\geq -)minimal elements.

$\max(p)$ is an abbreviation of $\max(\text{repr}(p))$, and $\min(p)$ an abbreviation of $\min(\text{repr}(p))$. Furthermore:

$$\begin{aligned} \max(\mathcal{B}) \geq \max(\mathcal{D}) &\text{ holds if and only if } X \geq Y \\ &\text{ for all } X \in \max(\mathcal{B}) \text{ and } Y \in \max(\mathcal{D}). \\ \min(\mathcal{B}) \geq \min(\mathcal{D}) &\text{ holds if and only if } X \geq Y \\ &\text{ for all } X \in \min(\mathcal{B}) \text{ and } Y \in \min(\mathcal{D}). \end{aligned}$$

DEFINITION 53. Let $\langle \mathcal{A}, \geq \rangle$ be a sentential comparison structure. The *maximin preference relation* that is based on \geq is the relation $\geq_{\mathbf{i}}$ on $\cup \mathcal{A}$ such that:

$$\mathcal{B} \geq_{\mathbf{i}} \mathcal{D} \text{ if and only if } \min(\mathcal{B}) \geq \min(\mathcal{D}).$$

Furthermore, the *maximax preference relation* based on \geq is the relation $\geq_{\mathbf{x}}$ on $\cup \mathcal{A}$ such that:

$$\mathcal{B} \geq_{\mathbf{x}} \mathcal{D} \text{ if and only if } \max(\mathcal{B}) \geq \max(\mathcal{D}).$$

$\mathcal{B} >_{\mathbf{i}} \mathcal{D}$ is an abbreviation of $(\mathcal{B} \geq_{\mathbf{i}} \mathcal{D}) \ \& \ \neg(\mathcal{D} \geq_{\mathbf{i}} \mathcal{B})$, and $\mathcal{B} \equiv_{\mathbf{i}} \mathcal{D}$ of $(\mathcal{B} \geq_{\mathbf{i}} \mathcal{D}) \ \& \ (\mathcal{D} \geq_{\mathbf{i}} \mathcal{B})$. $\mathcal{B} >_{\mathbf{x}} \mathcal{D}$ and $\mathcal{B} \equiv_{\mathbf{x}} \mathcal{D}$ are defined analogously.

In the indices, \mathbf{x} refers to maximization of the maximum and \mathbf{i} to maximization of the minimum.

Neither completeness nor transitivity is transmitted from an exclusionary preference relation \geq to $\geq_{\mathbf{i}}$ and $\geq_{\mathbf{x}}$. However, the combined property of being both complete and transitive is transmitted.

OBSERVATION 54 (Hansson, 1998b). Let \mathcal{A} be a finite and sentential alternative set.

- (1) Let \geq be a complete relation on \mathcal{A} . It does not follow in general that $\geq_{\mathbf{i}}$ and $\geq_{\mathbf{x}}$ are complete.

- (2) Let \geq be a reflexive and transitive relation on \mathcal{A} . It does not follow in general that \geq_i and \geq_x are transitive.
- (3) Let \geq be a complete and transitive relation on \mathcal{A} . Then \geq_i and \geq_x are complete and transitive.

Proof.

Part 1: Let $\mathcal{A} = \{X, Y, Z\}$ and let $\text{repr}(p) = \{X, Y\}$, $\text{repr}(q) = \{Z\}$, and $Z > X \equiv Y > Z$. Then $\text{min}(p) = \{X, Y\}$ and $\text{min}(q) = \{Z\}$. It follows from $Z > X$ that $p \geq_i q$ does not hold and from $Y > Z$ that $q \geq_i p$ does not hold. The same example can be used to prove the incompleteness of \geq_x .

Part 2: Let $\mathcal{A} = \{X, Y_1, Y_2, Z\}$, $\text{repr}(p) = \{X\}$, $\text{repr}(q) = \{Y_1, Y_2\}$, $\text{repr}(r) = \{Z\}$, and $\geq = \{\langle X, X \rangle, \langle Y_1, Y_1 \rangle, \langle Y_2, Y_2 \rangle, \langle Z, Z \rangle, \langle Z, X \rangle\}$. Then $\text{min}(p) = \{X\}$, $\text{min}(q) = \emptyset$, and $\text{min}(r) = \{Z\}$. Since $\text{min}(q) = \emptyset$, $p \geq_i q$ and $q \geq_i r$ hold vacuously, whereas $p \geq_i r$ does *not* hold. The same example can be used to show that \geq_x is not transitive.

Part 3: For completeness of \geq_i , it is sufficient to note that due to the completeness and transitivity of \geq , either $\text{min}(p) \geq \text{min}(q)$ or $\text{min}(q) \geq \text{min}(p)$. For the transitivity of \geq_i , let $p \geq_i q \geq_i r$. Let $X \in \text{min}(p)$ and $Z \in \text{min}(r)$. Since $q \in \cup \mathcal{A}$, $\text{repr}(q)$ is non-empty. Since \mathcal{A} is finite and \geq is complete and transitive, so is $\text{min}(q)$. Let $Y \in \text{min}(q)$. Then $X \geq Y$ follows from $p \geq_i q$ and $Y \geq Z$ from $q \geq_i r$. Due to the transitivity of \geq , $X \geq Z$. Since this holds for all elements X of $\text{min}(p)$ and Z of $\text{min}(r)$, we may conclude that $p \geq_i r$.

The completeness and transitivity of \geq_x follows in the same way. ■

Contraposition does not hold for either maximin nor maximax preferences, but conjunctive expansion of strict preference holds in both cases.

OBSERVATION 55. Let \geq be a transitive and complete relation on the contextually complete alternative set \mathcal{A} , and let $p, \neg p, q, \neg q \in \cup \mathcal{A}$. Then:

- (1a) $p \geq_i q \rightarrow \neg q \geq_i \neg p$ does not hold in general.
- (1b) $p \equiv_i q \rightarrow \neg q \equiv_i \neg p$ does not hold in general.
- (1c) $p >_i q \rightarrow \neg q >_i \neg p$ does not hold in general.
- (2a) $p \geq_x q \rightarrow \neg q \geq_x \neg p$ does not hold in general.
- (2b) $p \equiv_x q \rightarrow \neg q \equiv_x \neg p$ does not hold in general.
- (2c) $p >_x q \rightarrow \neg q >_x \neg p$ does not hold in general.

Proof.

Parts 1a, 1b, 2a, and 2b: Let $\mathcal{A} = \{A, B, C, D\}$, $p, q \in A$, $\neg p, q \in B$, $p, \neg q \in C$, and $p, q \in D$. Let $A \equiv B > C \equiv D$.

Part 1c and 2c: Let $\mathcal{A} = \{A, B, C, D\}$, $\neg p, \neg q \in A$, $p, \neg q \in B$, $\neg p, q \in C$, and $\neg p, \neg q \in D$. Let $A \equiv B > C \equiv D$. ■

OBSERVATION 56. Let \geq be a transitive and complete relation on the contextually complete alternative set \mathcal{A} , and let $p \& \neg q, q \& \neg p \in \cup \mathcal{A}$. Then:

(1a) $(p \geq_i q) \rightarrow ((p \& \neg q) \geq_i (q \& \neg p))$ does not hold in general.

(1b) $(p \equiv_i q) \rightarrow ((p \& \neg q) \equiv_i (q \& \neg p))$ does not hold in general.

(1c) $(p >_i q) \rightarrow ((p \& \neg q) >_i (q \& \neg p))$

(2a) $(p \geq_x q) \rightarrow ((p \& \neg q) \geq_x (q \& \neg p))$ does not hold in general.

(2b) $(p \equiv_x q) \rightarrow ((p \& \neg q) \equiv_x (q \& \neg p))$ does not hold in general.

(2c) $(p >_x q) \rightarrow ((p \& \neg q) >_x (q \& \neg p))$

Proof.

Parts 1a, 1b, 2a, and 2b: Let $\mathcal{A} = \{A, B, C, D\}$, $p, q \in A$, $\neg p, q \in B$, $p, \neg q \in C$, and $p, q \in D$. Let $A \equiv B > C \equiv D$.

Part 1c: Let $p >_i q$. Then $\min(p) > \min(q)$. Clearly $\min(p \& \neg q) \geq \min(p)$. Furthermore, it follows from $\min(p) > \min(q)$ that $\neg p \in \min(q)$, hence $q \& \neg p \in \min(q)$, hence $\min(q) \equiv \min(q \& \neg p)$. We can apply transitivity to $\min(p \& \neg q) \geq \min(p)$, $\min(p) > \min(q)$, and $\min(q) \equiv \min(q \& \neg p)$, and obtain $\min(p \& \neg q) > \min(q \& \neg p)$, so that $(p \& \neg q) >_i (q \& \neg p)$.

Part 2c: Let $p >_x q$. Then $\max(p) > \max(q)$. Clearly $\max(q) \geq \max(q \& \neg p)$. Furthermore, it follows from $\max(p) > \max(q)$ that $\neg q \in \max(p)$, hence $p \& \neg q \in \max(p)$, hence $\max(p \& \neg q) \equiv \max(p)$. We can apply transitivity to $\max(p \& \neg q) \equiv \max(p)$, $\max(p) > \max(q)$, and $\max(q) \geq \max(q \& \neg p)$, and obtain $\max(p \& \neg q) > \max(q \& \neg p)$, so that $(p \& \neg q) >_x (q \& \neg p)$. ■

Disjunctive interpolation holds for both \geq_i and \geq_x .

OBSERVATION 57. Let \geq be a transitive and complete relation on the contextually complete alternative set \mathcal{A} , and let $p, q \in \cup \mathcal{A}$. Then:

(1) $(p \geq_i q) \rightarrow (p \geq_i (p \vee q) \geq_i q)$

(2) $(p \geq_x q) \rightarrow (p \geq_x (p \vee q) \geq_x q)$

Proof.

Part 1: Let $p \geq_i q$. Then $\min(p) \geq \min(p \vee q)$ and $\min(p \vee q) \equiv \min(q)$.

Part 2: Let $p \geq_x q$. Then $\max(p) \equiv \max(p \vee q)$ and $\max(p \vee q) \geq \max(q)$. ■

Fairly strong principles of disjunctive distribution can be obtained for \geq_i and \geq_x :

OBSERVATION 58. Let \geq be a transitive and complete relation over the contextually complete alternative set \mathcal{A} . Then:

$$(1a) ((p \vee q) \geq_i r) \leftrightarrow (p \geq_i r) \& (q \geq_i r)$$

$$(1b) (p \geq_i (q \vee r)) \leftrightarrow (p \geq_i q) \vee (p \geq_i r)$$

$$(2a) ((p \vee q) \geq_x r) \leftrightarrow (p \geq_x r) \vee (q \geq_x r)$$

$$(2b) (p \geq_x (q \vee r)) \leftrightarrow (p \geq_x q) \& (p \geq_x r)$$

Proof.

Part 1a: Left to right: Let $(p \vee q) \geq_i r$. Then $\min(p \vee q) \geq \min(r)$. Since $\min(p) \geq \min(p \vee q)$, transitivity yields $\min(p) \geq \min(r)$, hence $p \geq_i r$. We can prove $q \geq_i r$ in the same way.

Right to left: Let $p \geq_i r$ and $q \geq_i r$. Then $\min(p) \geq \min(r)$ and $\min(q) \geq \min(r)$. Since either $\min(p \vee q) \equiv \min(p)$ or $\min(p \vee q) \equiv \min(q)$, we can use transitivity to obtain $\min(p \vee q) \geq \min(r)$, hence $(p \vee q) \geq_i r$.

Part 1b: Left to right: Let $p \geq_i (q \vee r)$. Then $\min(p) \geq \min(q \vee r)$. Since either $\min(q \vee r) \equiv \min(q)$ or $\min(q \vee r) \equiv \min(r)$, transitivity yields either $\min(p) \geq \min(q)$ or $\min(p) \geq \min(r)$, hence either $p \geq_i q$ or $p \geq_i r$.

Right to left: For symmetry reasons, we may assume that $p \geq_i q$. Then $\min(p) \geq \min(q)$. Since $\min(q) \geq \min(q \vee r)$, transitivity yields $\min(p) \geq \min(q \vee r)$, hence $p \geq_i (q \vee r)$.

Part 2a: Left to right: Let $(p \vee q) \geq_x r$, i.e. $\max(p \vee q) \geq \max(r)$. Since either $\max(p) \equiv \max(p \vee q)$ or $\max(q) \equiv \max(p \vee q)$, we can use transitivity to obtain either $\max(p) \geq \max(r)$ or $\max(q) \geq \max(r)$, hence either $p \geq_x r$ or $q \geq_x r$.

Right to left: Let $p \geq_x r$, i.e. $\max(p) \geq \max(r)$. We have $\max(p \vee q) \geq \max(p)$, and transitivity yields $\max(p \vee q) \geq \max(r)$, i.e. $(p \vee q) \geq_x r$. If $q \geq_x r$, then $(p \vee q) \geq_x r$ follows in the same way.

Part 2b: Left to right: Let $p \geq_x (q \vee r)$. Then $\max(p) \geq \max(q \vee r)$. Since $\max(q \vee r) \geq \max(q)$, transitivity yields $\max(p) \geq \max(q)$, so that $p \geq_x q$. We can obtain $p \geq_x r$ in the same way.

Right to left: Let $p \geq_x q$ and $p \geq_x r$. Then $\max(p) \geq \max(q)$ and $\max(p) \geq \max(r)$. Furthermore, either $\max(q) \equiv \max(q \vee r)$ or $\max(r) \equiv \max(q \vee r)$. In either case it follows by transitivity that $\max(p) \geq \max(q \vee r)$, hence $p \geq_x (q \vee r)$. ■

The following observation introduces a couple of fairly problematic properties for maximin and maximax preferences.

OBSERVATION 59. Let \geq be a relation on the sentential alternative set \mathcal{A} , and let $p, q \in \cup \mathcal{A}$. Then:

- (1) If $\models_{\mathcal{A}} p \rightarrow q$, then $p \geq_i q$.
- (2) If $\models_{\mathcal{A}} p \rightarrow q$, then $q \geq_x p$.

COROLLARY: Let \geq be a relation on the sentential alternative set \mathcal{A} , and let $p, q \in \cup \mathcal{A}$. Then:

- (1) $p \geq_i (p \vee q)$
- (2) $(p \vee q) \geq_x p$

Proof.

Part 1: It follows from $\models_{\mathcal{A}} p \rightarrow q$ that $\min(p) \geq \min(q)$, hence $p \geq_i q$.

Part 2: It follows from $\models_{\mathcal{A}} p \rightarrow q$ that $\max(q) \geq \max(p)$, hence $q \geq_x p$. ■

Part (1) of this observation has been called the ‘Nobel peace prize postulate’. [Hansson 1998b] Let q denote that a certain statesman stops a war, and p that he first starts a war and then stops it. Let \mathcal{A} be an alternative set that contains representations of p and q . Then $\models_{\mathcal{A}} p \rightarrow q$ is satisfied, and we can conclude that $p \geq_i q$, i.e. p is (in the maximin sense) at least as good a behaviour as q . It is not difficult, either, to find examples that bring out the strangeness of part (2). We may, for instance, let q denote some violent action and p the same action, performed in self-defence.

The properties listed in the Corollary of Observation 59 were used by Packard in axiomatic characterizations. Maximin preference is characterized by transitivity, completeness, $p \geq_i (p \vee q)$, and $(p \geq_i r) \ \& \ (q \geq_i r) \rightarrow ((p \vee q) \geq_i r)$. Maximax preference is characterized by transitivity, completeness, $(p \vee q) \geq_x p$, and $(p \geq_x q) \ \& \ (p \geq_x r) \rightarrow (p \geq_x (q \vee r))$. [Packard 1979]

Maximin and maximax preferences are not they only subset-extended preference relations of interest. To begin with, they are not the only such relations that are determined exclusively by the best and worst elements of a set. (On such relations, see [Barbera *et al.*, 1984].) Two other such preference relations are the interval maximin and interval maximax relations:

DEFINITION 60 (Hansson, 1998b). Let \geq be a relation on the sentential alternative set \mathcal{A} . The *interval maximin preference relation* \geq_{ix} based on \geq is the relation on $\wp(\mathbf{A}) \setminus \emptyset$ such that for all $\mathcal{B}, \mathcal{D} \in \wp(\mathbf{A}) \setminus \emptyset$:

- (1) If $\min(\mathcal{B}) > \min(\mathcal{D})$, then $\mathcal{B} >_{ix} \mathcal{D}$.
- (2) If $\min(\mathcal{B}) \equiv \min(\mathcal{D})$, then $\mathcal{B} \geq_{ix} \mathcal{D}$ if and only if $\max(\mathcal{B}) \geq \max(\mathcal{D})$.

$\mathcal{B} >_{ix} \mathcal{D}$ is an abbreviation of $(\mathcal{B} \geq_{ix} \mathcal{D}) \ \& \ \neg(\mathcal{D} \geq_{ix} \mathcal{B})$, and $\mathcal{B} \equiv_{ix} \mathcal{D}$ of $(\mathcal{B} \geq_{ix} \mathcal{D}) \ \& \ (\mathcal{D} \geq_{ix} \mathcal{B})$.

DEFINITION 61 (Hansson, 1998b). Let \geq be a relation on the sentential alternative set \mathcal{A} . The *interval maximax preference relation* \geq_{xi} based on \geq is the relation on $\wp(\mathbf{A}) \setminus \emptyset$ such that for all $\mathcal{B}, \mathcal{D} \in \wp(\mathbf{A}) \setminus \emptyset$:

- (1) If $\max(\mathcal{B}) > \max(\mathcal{D})$, then $\mathcal{B} >_{xi} \mathcal{D}$.
- (2) If $\max(\mathcal{B}) \equiv \max(\mathcal{D})$, then $\mathcal{B} \geq_{xi} \mathcal{D}$ if and only if $\min(\mathcal{B}) \geq \min(\mathcal{D})$.

$\mathcal{B} >_{xi} \mathcal{D}$ is an abbreviation of $(\mathcal{B} \geq_{xi} \mathcal{D}) \ \& \ \neg(\mathcal{D} \geq_{xi} \mathcal{B})$, and $\mathcal{B} \equiv_{xi} \mathcal{D}$ of $(\mathcal{B} \geq_{xi} \mathcal{D}) \ \& \ (\mathcal{D} \geq_{xi} \mathcal{B})$.

\geq_{ix} maximizes first the minimum and after that the maximum, whereas \geq_{xi} does this in the reverse order.

Interval maximin preference is a modification of the maximin preference relation. The latter not only gives precedence to the avoidance of bad worst outcomes (which is an expression of cautiousness), but also refrains from making any difference between two relata that both satisfy this criterion. In contrast, the interval maximin preference relation maximizes both worst and best alternatives, but gives maximization of the former absolute priority over maximization of the latter. Similarly, the interval maximax preference relation maximizes both worst and best alternatives, but gives maximization of the latter absolute priority over maximization of the former.

Another interesting group of subset-extensions are those that rank sets of alternatives according to their medians. If a set has an odd number of elements, then the set consisting of the element in the middle according to the \geq -ranking is the median according to \geq . If there is an even number of elements, then the two elements closest to the middle form the median [Nitzan and Prasanta, 1984]. Hence, in this case as well, one or two elements determine the value of the whole set.

A good case can be made that all elements of a set of alternatives should have an influence on the value of the set as a whole. This can easily be achieved if a numerical value (utility) is assigned to each element of \mathcal{A} . Fishburn has provided an axiomatic characterization of preferences over $\wp(\mathcal{A}) \setminus \emptyset$ that are derived from utility assignments to \mathcal{A} by means of even-chance lotteries [Fishburn, 1972].

5 PREFERENCES AND MONADIC CONCEPTS

In addition to the comparative notions, ‘better’ and ‘of equal value’, informal discourse on values contains monadic (one-place) value predicates, such as ‘good’, ‘best’, ‘very bad’, ‘fairly good’, etc. It also contains monadic normative concepts such as ‘ought’, ‘may’, ‘forbidden’, etc. This section

is devoted to the connection between preference relations and some major types of monadic predicates. Throughout this section, \geq' denotes a (weak) combinative preference relation that operates on the union $\cup\mathcal{A}$ of some contextually complete alternative set \mathcal{A} . $>'$ and \equiv' are its strict and symmetric parts, respectively. The construction of \geq' will be left open, but the constructions discussed in Section 4 are obvious candidates.

Subsection 5.1 introduces two general categories of monadic predicates. Subsections 5.2–5.3 are devoted to ‘good’ and ‘bad’, Subsection 5.4 to some other monadic value predicates, and Subsection 5.5 to normative predicates.

5.1 Positive and negative predicates

What is better than something good is itself good. Many other value predicates—such as ‘best’, ‘not worst’, ‘very good’, ‘excellent’, ‘not very bad’, ‘acceptable’, etc.—have the same property. If one of these predicates holds for p , then it also holds for everything that is better than p or equal in value to p . This property will be called ‘ \geq' -positivity’, or (when there is no risk of confusion), simply ‘positivity’.

DEFINITION 62 (Hansson, 1990). A monadic predicate H is \geq' -positive if and only if for all p and q :

$$Hp \ \& \ (q \geq' p) \rightarrow Hq.$$

Similarly, ‘bad’ has the converse property that if p is bad, then whatever is worse than or equal in value to p , is also bad. Other predicates that share this property are ‘very bad’, ‘worst’, and ‘not best’. This property will be called ‘(\geq' -)negativity’.

DEFINITION 63 (Hansson, 1990). A monadic predicate H is \geq' -negative if and only if for all p and q :

$$Hp \ \& \ (p \geq' q) \rightarrow Hq.$$

Intuitively, we expect the negation ‘not good’ of the positive predicate ‘good’ to be negative. Indeed, this can easily be shown to be a general pattern that holds for all positive and negative predicates.

OBSERVATION 64 (Hansson, 1990). A monadic predicate H satisfies \geq' -positivity if and only if its negation $\neg H$ satisfies \geq' -negativity.

Proof.

Left-to-right: Let H be a \geq' -positive predicate. Suppose that $\neg H$ does not satisfy \geq' -negativity. Then there are relata p and q such that $\neg Hp$, $p \geq' q$, and $\neg(\neg Hq)$. Hence, Hq , $p \geq' q$, and $\neg Hp$, contrary to the positivity of H .

Right-to-left: Let $\neg H$ be a \geq' -negative predicate. Suppose that H does not satisfy \geq' -positivity. Then there are relata p and q such that $Hp, q \geq' p$, and $\neg(Hq)$. Hence, $\neg Hq, q \geq' p$, and $\neg(\neg Hp)$, contrary to the negativity of $\neg H$. ■

An important class of positive predicates are those that represent ‘best’. They are mirrored at the other end of the value-scale by negative predicates that represent ‘worst’:

DEFINITION 65. Let \geq' be a combinative preference relation. The following are monadic predicates defined from \geq' :

$$\begin{aligned} Hp &\leftrightarrow (\forall q)(p \geq' q) \text{ (strongly best)} \\ Hp &\leftrightarrow \neg(\exists q)(q >' p) \text{ (weakly best)} \\ Hp &\leftrightarrow (\forall q)(q \geq' p) \text{ (strongly worst)} \\ Hp &\leftrightarrow \neg(\exists q)(p >' q) \text{ (weakly worst)} \end{aligned}$$

The first two of these definitions correspond to the notions of strong and weak eligibility, that were introduced in Subsection 2.6. The first of them also corresponds to the best choice connection discussed in Subsection 3.2.

5.2 Good and bad: definitions

Definitions of ‘good’ and ‘bad’ in terms of a preference relation are a fairly common theme in the value-logical literature. There are two major traditions. One of these may be called *indifference-related* since it bases the definitions of ‘good’ and ‘bad’ on a set of indifferent or neutral propositions. Goodness is predicated of everything that is better than something neutral, and badness of everything that is worse than something neutral.

This construction requires a sentence that represents neutral value. Such a sentence can of course be introduced as a primitive notion, but it would be more interesting to identify it among the sentences already available.

Some authors have made use of tautologies or contradictions as neutral propositions. Tautologies have been used for this purpose by Danielsson [1968, p. 37] and contradictions by von Wright [1972, p. 164]. However, it is far from clear how something contingent can be compared in terms of value to a tautology or a contradiction. It would be more intuitively appealing to have neutral sentences that represent contingent states of affairs. Such an approach was proposed by Chisholm and Sosa. According to these authors, a state of affairs is indifferent if and only if it is neither better nor worse than its negation. Then ‘a state of affairs is *good* provided it is better than some state of affairs that is indifferent, and... a state of affairs is *bad* provided some state of affairs that is indifferent is better than it’ [Chisholm and Sosa, 1966, p. 246]. (These authors distinguish between indifference and neutrality. To be neutral means, in their terminology, to be equal in

value to something that is indifferent.) The definitions of ‘good’ and ‘bad’ proposed by Chisholm and Sosa can be introduced into the present formal framework as follows:

DEFINITION 66.

$$\begin{aligned} G_I p &\leftrightarrow (\exists q)(p >' q \equiv' \neg q) \text{ (indifference-related good)} \\ B_I p &\leftrightarrow (\exists q)(\neg q \equiv' q >' p) \text{ (indifference-related bad)} \end{aligned}$$

For the definitions of G_I and B_I to be at all useful, there should be at least one indifferent element, i.e., at least one q such that $q \equiv' \neg q$. Furthermore, it can be required that all indifferent elements should be interchangeable in comparisons. This amounts to the following requirement on the preference relation:

DEFINITION 67 (Hansson, 1990). \geq' satisfies *calibration* if and only if:

- (1) There is some q such that $q \equiv' \neg q$, and
- (2) If $q \equiv' \neg q$ and $s \equiv' \neg s$, then for all p : $p \geq' q \leftrightarrow p \geq' s$ and $q \geq' p \leftrightarrow s \geq' p$.

The other major approach to defining ‘good’ and ‘bad’ has no need for neutral propositions. According to this definition, ‘good’ means ‘better than its negation’ and ‘bad’ means ‘worse than its negation’. The first clear statement of this idea seems to be due to Brogan [1919]. It has been accepted by many other authors [Mitchell, 1950, pp. 103–105; Halldén, 1957, p. 109; von Wright, 1963, p. 34; von Wright, 1972, p. 162; Åqvist, 1968]. We can express it in the present framework as follows:

DEFINITION 68.

$$\begin{aligned} G_N p &\leftrightarrow p >' \neg p \text{ (negation-related good)} \\ B_N p &\leftrightarrow \neg p >' p \text{ (negation-related bad)} \end{aligned}$$

This definition has a strong intuitive appeal, but unfortunately G_N and B_N do not always satisfy positivity, respectively negativity. For an example, let $q \equiv' \neg q \geq' p >' \neg p$. Then $G_N p$, $q \geq' p$ and $\neg G_N q$, contrary to positivity. In order to avoid this deficiency, a modified version of the negation-related definition has been proposed.

DEFINITION 69 (Hansson, 1990).

$$\begin{aligned} G_C p &\leftrightarrow (\forall q)(q \geq'^* p \rightarrow q >' \neg q) \text{ (canonical good)} \\ B_C p &\leftrightarrow (\forall q)(p \geq'^* q \rightarrow \neg q >' q) \text{ (canonical bad)} \end{aligned}$$

It is easy to show that G_C satisfies \geq' -positivity and B_C \geq' -negativity. Since the positivity of ‘good’ and the negativity of ‘bad’ are indispensable properties of these predicates, G_N and B_N can be plausible formalizations

of ‘good’ and ‘bad’ only if \geq' is such they satisfy positivity, respectively negativity. It turns out that this is so exactly when G_N coincides with G_C and B_N with B_C .

OBSERVATION 70 (Hansson, 1990). Let \geq' satisfy ancestral reflexivity ($p \geq'^* p$). Then G_N coincides with G_C and B_N with B_C if and only if G_N satisfies positivity and B_N satisfies negativity.

Proof. For one direction, note that if G_N and B_N do not satisfy positivity respectively negativity, then they cannot be identical with G_C and B_C that satisfy these conditions.

For the other direction, let G_N and B_N satisfy positivity and negativity. It follows from Part 2 of Theorem 73 (to be proved in the next subsection) that $G_N p \rightarrow G_C p$ and $B_N p \rightarrow B_C p$. It follows directly from Definitions 68 and 69 that $G_C p \rightarrow G_N p$ and $B_C p \rightarrow B_N p$. ■

Hence, G_C and B_C may be seen as extentions of G_N and B_N that coincide with the latter in all cases when the latter provide a reasonable account of ‘good’ and ‘bad’.

5.3 Good and bad: The axiomatic approach

Another approach to defining ‘good’ and ‘bad’ is to identify a set of reasonable axioms that a pair of predicates representing these notions should satisfy. The following are such axioms:

DEFINITION 71 (Hansson, 1990). Let $\langle G, B \rangle$ be a pair of monadic predicates.

- (1) It satisfies *positivity – negativity* (PN) with respect to \geq' if and only if G satisfies \geq' -positivity and B satisfies \geq' -negativity.
- (2) It satisfies *negation-comparability* (NC) with respect to \geq' if and only if, for all p :

$$\begin{aligned} Gp &\rightarrow (p \geq' \neg p) \vee (\neg p \geq' p) \\ Bp &\rightarrow (p \geq' \neg p) \vee (\neg p \geq' p) \end{aligned}$$

- (3) It satisfies *mutual exclusiveness* (ME) if and only if for all p : $\neg(Gp \ \& \ Bp)$.
- (4) It satisfies *non-duplcity* (ND) if and only if for all p : $\neg(Gp \ \& \ G\neg p)$ and $\neg(Bp \ \& \ B\neg p)$.
- (5) It satisfies *closeness* if and only if for all p and q , $p >' q \rightarrow Gp \vee Bq$.

These postulates are fairly self-explanatory. Perhaps it should be mentioned that NC can be seen as a (much) weakened form of completeness. In favour

of this postulate it can be argued that a sentence that is not comparable to its negation is deficient in determinate value information. Therefore, predicates such as ‘good’ and ‘bad’ are not applicable to such states of affairs.

According to closeness, ‘good’ and ‘bad’ come so close to each other that they only have ‘neutral’ values between them. One way to express this is that ‘if two things are of unequal value, then at least one of them must be good or at least one of them bad’ [von Wright, 1972, p. 161].

As the following observation shows, ME is redundant in the presence of three of the other postulates:

OBSERVATION 72. If $\langle G, B \rangle$ satisfies PN, ND, and NC, then it also satisfies ME.

Proof. Suppose to the contrary that $\langle G, B \rangle$ satisfies PN, ND, and NC, but not ME. Then, since ME does not hold, there is some p such that $Gp \& Bp$. It follows from NC that $(p \geq' \neg p) \vee (\neg p \geq' p)$. From PN follows $(\neg p \geq' p) \& Gp \rightarrow G\neg p$ and $(p \geq' \neg p) \& Bp \rightarrow B\neg p$. By sentential logic, $(Gp \& G\neg p) \vee (Bp \& B\neg p)$, contrary to ND. This contradiction completes the proof. ■

We have already seen that $\langle G_N, B_N \rangle$ does not always satisfy PN. It is easy to check that it satisfies ND, NC, and ME. $\langle G_C, B_C \rangle$ satisfies all these postulates, and it can also be shown to be maximal among the predicate pairs that satisfy them.

THEOREM 73 (Hansson, 1990). *Let \geq' be a relation that satisfies ancestral reflexivity ($p \geq'^* p$). Let $\langle G_C, B_C \rangle$ be as in Definition 69. Then:*

- (1) $\langle G_C, B_C \rangle$ satisfies PN, ND and NC.
- (2) Let $\langle G, B \rangle$ be a pair of monadic predicates that satisfies PN, ND and NC. Then for all p :

$$Gp \rightarrow G_C p \text{ and } Bp \rightarrow B_C p.$$

- (3) If there is a pair $\langle G, B \rangle$ of predicates that satisfies PN, ND, NC, and closeness, then $\langle G_C, B_C \rangle$ satisfies (PN, ND, NC, and) closeness.

Proof.

Part 1: That PN holds follows directly from Definition 69. To see that ND is satisfied, suppose to the contrary that $G_C p$ and $G_C \neg p$. Due to ancestral reflexivity, $p \geq'^* p$, and since $G_C p$, Definition 69 yields $p >' \neg p$. In the same way it follows from $G_C \neg p$ that $\neg p >' p$. This contradiction is sufficient to ensure that $\neg(G_C p \& G_C \neg p)$. The proof that $\neg(B_C p \& B_C \neg p)$ is similar.

To see that NC is satisfied, note that due to ancestral reflexivity, $G_C p$ implies $p >' \neg p$ and $B_C p$ implies $\neg p >' p$.

Part 2: Let Gp and $q \geq'^* p$. Then there is a series of sentences s_0, \dots, s_n , such that $s_0 \leftrightarrow p$, $s_n \leftrightarrow q$ and for all integers k , if $0 \leq k < n$, then $s_{k+1} \geq' s_k$. Clearly, Gs_0 . From Gs_k and $s_{k+1} \geq' s_k$ it follows by PN that Gs_{k+1} . Thus, by induction, Gs_n , i.e. Gq .

From Gq it follows by NC that $(q >' \neg q) \vee (\neg q \geq' q)$. Suppose that $\neg q \geq' q$. Then by PN follows $G\neg q$, so that $Gq \ \& \ G\neg q$, contrary to ND. It follows that $q >' \neg q$.

Thus, if Gp , then for all q , if $q \geq'^* p$, then $q >' \neg q$. The corresponding property for Bp can be proved in the same way.

Part 3: Let $\langle G, B \rangle$ satisfy PN, ND, NC, and closeness. Due to part 1, it remains to show that $\langle G_C, B_C \rangle$ satisfies closeness. Let $p >' q$. Since $\langle G, B \rangle$ satisfies closeness, we have $Gp \vee Bp$, and by part (2) of the present theorem we have $G_C p \vee B_C p$. ■

The indifference-related approach fares worse with respect to the postulates.

OBSERVATION 74. Let \geq' be a relation that satisfies ancestral reflexivity ($p \geq'^* p$). Let $\langle G_I, B_I \rangle$ be as in Definition 66. Then:

- (1) If \geq' satisfies calibration, then $\langle G_I, B_I \rangle$ satisfies ME.
- (2) If \geq' satisfies transitivity, then $\langle G_I, B_I \rangle$ satisfies PN.
- (3) If \geq' satisfies completeness, then $\langle G_I, B_I \rangle$ satisfies NC.
- (4) ND does not follow even if calibration, transitivity, and completeness are all satisfied.

Proof.

Part 1: Let ME be violated. Then there is some p such that $G_I p$ and $B_I p$, i.e. there are q and r such that $p >' q \equiv' \neg q$ and $\neg s \equiv' s >' p$. It follows from $p >' q \equiv' \neg q$ and $s \equiv' \neg s$, due to calibration, that $p >' s$. Contradiction.

Part 2: For the positivity of G_I , let $G_I p$ and $q \geq' p$. Then there is some s such that $p >' s \equiv' \neg s$. Transitivity yields $q >' s$, hence $G_I q$. The negativity of B_I is proved in the same way.

Part 3: Directly from the definition of NC.

Part 4: Let \geq' be transitive and complete, and such that $p >' \neg p >' s \equiv' \neg s$ and that calibration is satisfied. Then $Gp \ \& \ G\neg p$. ■

ND is an essential property of ‘good’ and ‘bad’, and $\langle G_I, B_I \rangle$ can hardly be a satisfactory account of these concepts unless this property holds. Fairly strong additional conditions are needed to ensure that it holds [Hansson 1990]. In the light of this, the axiomatic analysis is much more favourable to $\langle G_N, B_N \rangle$ and, in particular to its generalization $\langle G_C, B_C \rangle$, than to $\langle G_I, B_I \rangle$.

5.4 *Some other value predicates*

Common language contains many value predicates in addition to ‘best’, ‘worst’, ‘good’, and ‘bad’, as defined above. For a couple of these, precise definitions have been proposed:

very good = good among those that are good [Wheeler, 1972]
 very bad = bad among those that are bad
 fairly good = good but not very good [Wheeler, 1972]
 fairly good = good among those that are not very good [Klein, 1980, pp. 24–25]
 almost worst = very bad but not worst [Hansson, 1998b]

The last three of these are neither positive nor negative predicates, but belong to a third category of predicates, namely those that are, intuitively speaking, bounded both upwards and downwards. From a formal point of view, they can be defined as the meets of one positive and one negative predicate. Thus, as indicated above, ‘ p is almost worst’ may be defined as ‘ p is very bad and p is not worst’, employing the negative predicate ‘very bad’ and the positive predicate ‘not worst’.

DEFINITION 75 (Hansson, 1998b). A monadic predicate H is \geq' -circumscriptive if and only if there is a \geq' -positive predicate H^+ and a \geq' -negative predicate H^- such that for all p :

$$Hp \leftrightarrow H^+p \ \& \ H^-p.$$

A \geq' -circumscriptive predicate is *properly* \geq' -circumscriptive if and only if it is neither \geq' -positive nor \geq' -negative.

5.5 *Deontic concepts*

It is generally recognized that there are three major groups of normative expressions in ordinary language, namely prescriptive, prohibitive, and permissive expressions. In the formal language, they are represented by the corresponding three types of predicates. Here, prescriptive predicates will be denoted by ‘ O ’, permissive predicates by ‘ P ’, and prohibitive predicates by ‘ W ’. (These are abbreviations of ‘ought’, ‘permitted’, and ‘wrong’.) The arguments of these predicates are in general taken to be sentences that represent states of affairs or actions. The three categories of predicates are also generally taken to be interdefinable: Oq holds if and only if $W\neg q$, and it also holds if and only if $\neg P\neg q$.

Modern deontic logic began with a seminal paper by Georg Henrik von Wright in 1951 [von Wright, 1951]. (On the origins of deontic logic, see also [Føllesdal and Hilpinen, 1970; von Wright, 1998].) The literature in this area is at least as extensive as that on preference logic. The purpose of this subsection is not to give an overview of this vast subject, but only

to point out two alternative ways in which deontic logic can be connected with preference logic. (For an overview of deontic logic, see [Åqvist, 1987].)

The first of these is the standard semantical construction that dominates the subject [Føllesdal and Hilpinen, 1970]. It is assumed that there is a subset of the set of possible worlds (the ‘ideal worlds’) such that for any sentence p , Op holds if and only if p holds in all these worlds. Although there is some leeway in the meaning of the term *standard deontic logic* (SDL), the following definition seems to capture the gist of the matter:

DEFINITION 76. A model $\langle \mathcal{A}, \mathcal{I} \rangle$ for *non-iterative standard deontic logic* (non-iterative SDL) consists of a set \mathcal{A} of possible worlds and a non-empty subset \mathcal{I} of \mathcal{A} .

A *non-iterative deontic sentence* in $\langle \mathcal{A}, \mathcal{I} \rangle$ is a truth-functional combination of sentences of the form $O\alpha$, with $\alpha \in \mathcal{L}_{\mathcal{A}}$. Such a sentence is *true* in $\langle \mathcal{A}, \mathcal{I} \rangle$ if and only if it follows by classical truth-functional logic from the set $\{O\alpha \mid \alpha \in \cap \mathcal{I}\} \cup \{\neg O\alpha \mid \alpha \notin \cap \mathcal{I}\}$. It is *valid* if and only if it is true in all models.

No explicit preference relation is involved here, but \mathcal{I} can be interpreted as consisting of the best alternatives according to some preference relation. An explicit preference relation is used in corresponding accounts of conditional obligation. A sentence such as ‘If you borrow his lawn-mower then you ought to return it’ is held to be true if and only if you return the lawn-mower in all those worlds that are best among the worlds in which you borrow the lawn-mower in question.

The valid sentences of non-iterative SDL coincide with the theorems that are derivable from the following three axioms [Føllesdal and Hilpinen, 1970]:

$$\begin{aligned} Op &\rightarrow \neg O\neg p, \\ Op \ \& \ Oq &\leftrightarrow O(p\&q), \text{ and} \\ O(p \vee \neg p) &. \end{aligned}$$

The term ‘non-iterative’ in Definition 76 refers to the fact that sentences containing iterations of the deontic predicate (such as OOp and $\neg O(Op \vee Oq)$) have been excluded. To cover them, modal semantics (with an accessibility relation) can be used [Føllesdal and Hilpinen, 1970, pp. 15–19].

Unfortunately, it is an immediate consequence of the basic semantic idea of SDL—that of identifying obligatory status with presence in all elements of a certain subset of the alternative set—that the following property will hold:

$$\text{If } \vdash p \rightarrow q, \text{ then } \vdash Op \rightarrow Oq$$

This property may be called *necessitation* since it says that whatever is necessitated by a moral requirement is itself a moral requirement. (It has also been called ‘the inheritance principle’ [Vermazen, 1977, p. 14], ‘Becker’s law’

[McArthur, 1981, p. 149], ‘transmission’ [Routley and Plumwood, 1984], ‘the consequence principle’ [Hilpinen, 1985, p. 191], and ‘entailment’ [Jackson, 1985, p. 178].) As an example, suppose that I am morally required to take a boat without the consent of its owner and use it to rescue a drowning person. Let p denote this composite action that I am required to perform, and let q denote the part of it that consists in taking the boat without leave. Since q follows logically from p , I am logically necessitated to perform q in order to perform p . According to the postulate of necessitation, I then also have an obligation to q . This is contestable, since it can be argued that I have no obligation to q in isolation.

Necessitation is the source of all the major deontic paradoxes. We may call them the *necessitation paradoxes*. Four of the most prominent are Ross’s paradox, the paradox of commitment, the Good Samaritan, and the Knower. Ross’s paradox is based on the instance $Op \rightarrow O(p \vee q)$ of necessitation. (‘If you ought to mail the letter, then you ought to either mail or burn it.’) [Ross, 1941, p. 62] The paradox of commitment is based on the instance $O\neg p \rightarrow O(p \rightarrow q)$, which is interpreted as saying that if you do what is forbidden, then you are required to do anything whatsoever. (‘If it is forbidden for you to steal this car, then if you steal it you ought to run over a pedestrian’) [Prior, 1954]. The Good Samaritan operates on two sentences p and q , such that q denotes some atrocity and p some good act that can only take place if q has taken place. We then have $\vdash p \rightarrow q$, and it follows by necessitation that if Op then Oq . (‘You ought to help the assaulted person. Therefore, there ought to be an assaulted person’) [Prior, 1958, p. 144]. Åqvist’s Knower paradox makes use of the epistemic principle that only that which is true can be known. Here, q denotes some wrongful action, and p denotes that q is known by someone who is required to know it. Again, we have $\vdash p \rightarrow q$ and Op , and it follows by necessitation that Oq . (‘If the police officer ought to know that Smith robbed Jones, then Smith ought to rob Jones’) [Åqvist, 1967].

A quite different approach, introduced in [Hansson, 1993c] and further developed in [Hansson, 1997b; Hansson, 1998b; Hansson, 1999b] is based on the assumption that prescriptive predicates (ought-predicates) should satisfy the following property:

DEFINITION 77. A (monadic) predicate H is *contranegative* with respect to a given relation \geq' if and only if the following holds for all p and q :

$$Hp \ \& \ (\neg p \geq' \neg q) \rightarrow Hq.$$

OBSERVATION 78. Let O , P , and W be predicates with a common domain that is closed under negation, and such that for all p , Op if and only if $\neg P\neg p$, and Op if and only if $W\neg p$. Let \geq' be a relation over this domain. Then the following three conditions are equivalent:

- (1) O satisfies \geq' -contranegativity,

- (2) P satisfies \geq' -positivity, and
- (3) W satisfies \geq' -negativity.

Proof. Left to the reader. ■

Since both \geq' -positivity of P and \geq' -negativity of W are reasonable properties, we have good reasons to accept the equivalent requirement that \geq' be contranegative. At first sight, one might also wish to require that O be \geq' -positive, but it is easy to show with examples that this is not a plausible property. For instance, let q denote that you give your hungry visitor something to eat and p that you serve her a gourmet meal. It is quite plausible to claim both that p is better than q and that q is morally required whereas p is not.

In a deontic logic based on contranegativity of O , the logical properties of O will depend on those of the underlying preference relation. The more implausible properties of SDL turn out to correspond to rather implausible properties of the preference relation. In particular, this applies to necessitation.

OBSERVATION 79. Let \mathcal{A} be a set of contextually complete alternatives. The following are two conditions on a relation \geq' in $\mathcal{L}_{\mathcal{A}}$:

- (1) If $\models_{\mathcal{A}} q \rightarrow p$, then $p \geq'^* q$.
- (2) Every \geq' -contranegative predicate O on $\mathcal{L}_{\mathcal{A}}$ satisfies necessitation (If $\models_{\mathcal{A}} p \rightarrow q$, then $Op \rightarrow Oq$.)

If (1) holds, then so does (2). If \geq' satisfies ancestral reflexivity ($p \geq'^* p$) then (1) and (2) are equivalent.

Proof.

From (1) to (2): Let (1) hold. Let O be a predicate that is contranegative with respect to \geq' , and such that $\models_{\mathcal{A}} p \rightarrow q$ and Op . Then, equivalently: $\models_{\mathcal{A}} \neg q \rightarrow \neg p$ and Op . It follows from (1) that $\neg p \geq'^* \neg q$ and from the contranegativity of O that Oq .

From ancestral reflexivity and (2) to (1): We are going to assume that ancestral reflexivity holds, but (1) does not hold, and prove that then (2) is violated. Since (1) is not satisfied there are p and q such that $\models_{\mathcal{A}} q \rightarrow p$ and $\neg(p \geq'^* q)$.

Let W be the predicate such that for all $r \in \mathcal{L}_{\mathcal{A}}$, Wr holds if and only if $p \geq'^* r$. Then W is \geq' -negative. Since \geq' satisfies ancestral reflexivity, we have $p \geq'^* p$ and thus Wp . It follows from $\neg(p \geq'^* q)$ that $\neg Wq$. We therefore have $\models_{\mathcal{A}} q \rightarrow p$, Wp , and $\neg Wq$, or equivalently for the corresponding \geq' -contranegative predicate O : $\models_{\mathcal{A}} \neg p \rightarrow \neg q$, $O(\neg p)$, and $\neg O(\neg q)$. This is sufficient to show that (2) is violated. ■

On the other hand, some of the more plausible properties of deontic predicates turn out to correspond to more plausible preference postulates [Hansson, 1997b; Hansson, 1998b]. The following postulate was proposed by von Wright [1972, p. 44].

$$P(p \& q) \ \& \ P(p \& \neg q) \ \rightarrow \ Pp$$

It has been called *permissive cancellation* since it allows for the cancellation of q and $\neg q$ from the two permissions [Hansson, 1998b]. As the following observation shows, permissive cancellation holds for a wide range of contranegative predicates. (Note that a permissive predicate P is \geq' -positive if and only if the corresponding prescriptive predicate O is \geq' -contranegative.)

OBSERVATION 80. Let \mathcal{A} be a set of contextually complete alternatives. The following are two conditions on a relation \geq' in $\mathcal{L}_{\mathcal{A}}$:

- (1) $(p \geq'^* (p \& q)) \vee (p \geq'^* (p \& \neg q))$
- (2) Every \geq' -positive predicate P on $\mathcal{L}_{\mathcal{A}}$ satisfies permissive cancellation $(P(p \& q) \ \& \ P(p \& \neg q) \ \rightarrow \ Pp)$.

If (1) holds, then so does (2). Furthermore, if \geq' satisfies completeness, then (1) and (2) are equivalent.

Proof.

From (1) to (2): If $p \geq'^* (p \& q)$, then we can use $P(p \& q)$ and the positivity of P to obtain Pp . If $p \geq'^* (p \& \neg q)$, then we can use $P(p \& \neg q)$ and the positivity of P to obtain Pp .

From (2) and completeness to (1): Let \geq' satisfy completeness. We are going to assume that (1) does not hold, and prove that then neither does (2). Since (1) does not hold, there are p and q such that $\neg(p \geq'^* (p \& q))$ and $\neg(p \geq'^* (p \& \neg q))$. Due to completeness, there are two cases.

Case *i*, $(p \& q) \geq' (p \& \neg q)$: Let P be the predicate such that for all r , Pr iff $r \geq' (p \& \neg q)$. Then P is \geq' -positive, and it follows directly that $P(p \& q)$ and $P(p \& \neg q)$. It follows from $\neg(p \geq'^* (p \& \neg q))$ that $\neg Pp$.

Case *ii*, $(p \& \neg q) \geq' (p \& q)$: The proof proceeds in the same way as in case *i*. ■

The condition $(p \geq'^* (p \& q)) \vee (p \geq'^* (p \& \neg q))$ used in the observation follows from completeness and disjunctive interpolation:

$$\begin{aligned} & ((p \& \neg q) \geq' (p \& q)) \vee ((p \& q) \geq' (p \& \neg q)) && \text{(completeness)} \\ & (((p \& q) \vee (p \& \neg q)) \geq' (p \& q)) \vee (((p \& q) \vee (p \& \neg q)) \geq' (p \& \neg q)) \\ & && \text{(disjunctive interpolation)} \\ & (p \geq' (p \& q)) \vee (p \geq' (p \& \neg q)) && \text{(intersubstitutivity)} \\ & (p \geq'^* (p \& q)) \vee (p \geq'^* (p \& \neg q)) && \text{(definition of ancestral)} \end{aligned}$$

More details on contranegative logic can be found in [Hansson, 1998b; Hansson, 1999b]. This is probably only one of many examples of how new applications of preference logic can lead to new insights in other branches of philosophical logic.

DIAGRAMMATIC LOGIC

The many diagrammatic systems in use include Euler circles, Venn diagrams, state diagrams, control-flow diagrams, line graphs, circuit diagrams, category-theory diagrams, Hasse diagrams, and geometry diagrams. A *diagrammatic logic* seeks to describe the syntax, semantics, proof theory, etc., of some such diagrammatic system.

The diagrams of a diagrammatic system have a (typically two-dimensional) syntactic structure that can be described using concepts such as labeling, connectedness, inclusion, direction, etc. They also have a meaning that can be described using techniques from model theory or algebra. Thus, a diagrammatic logic differs from an ordinary logic only in the type of well-formed representations it describes (though these may well have properties not common to more familiar logics).

Diagrams can have unusual properties that distinguish them from expressions of many languages, properties that might motivate the formulation and analysis of a diagrammatic logic. The structure of a diagram might have a close correspondence with what they represent. Its meaning might be invariant under certain topological transformations. It might be unusually easy to understand. A diagrammatic logic *need* illuminate none of these matters (though some of them may be connected to the system's logical properties and hence addressed by the logic). In particular, philosophical and psychological questions about the nature of the diagrammatic system that is the target of a logic could be left to philosophy and psychology.

To reveal the typical characteristics of diagrammatic logics more directly, several examples will be presented. These include Venn diagrams, a variation due to Peirce that will be called *Peirce-Venn diagrams*, and a historically important system developed by Peirce called *existential graphs*. Other diagrammatic logics that have been developed include logics of state transition diagrams,¹ blocks world diagrams,² circuit diagrams,³ conceptual graphs,⁴ and geometry diagrams.⁵ Relevant collections include Allwein and Barwise [1996] and Glasgow, Narayanan, and Chandrasekaran [1995].

1 FOUNDATIONS

Venn diagrams and Peirce-Venn diagrams (covered in the next two sections) are constructed from circles or, more generally, closed curves, that overlap in

¹Harel [1988].

²Barwise and Etchemendy [1995].

³Johnson, Barwise and Allwein [1996].

⁴Sowa [1984].

⁵Luengo [1995].

all combinations. Some simple syntactic and semantic concepts are common to both of these systems and so are handled jointly in this section.

The circles of Venn diagrams represent sets, and the overlapping combinations of the circles represent combinations of the sets. For example, in the case of two circles the four combinations of circles represent the intersection, the two differences, and the complement of the union.

In particular, this diagram consists of four *minimal regions*⁶ which can be described by four corresponding combinations of the two labels:

Term	Corresponds to minimal region
AB	within both
$A\bar{B}$	within A, not B
$\bar{A}B$	within B, not A
$\bar{A}\bar{B}$	within neither

A term such as $A\bar{B}$ is said to *correspond* to the minimal region of the diagram within left one circle but outside of the right circle.⁷ Likewise, $\bar{A}\bar{B}$ corresponds to the minimal region outside of both circles, AB corresponds to the minimal region within both circles, and $B\bar{A}$ corresponds to the minimal region within the right but not the left circle. A three-circle diagram such as

has eight corresponding terms:

$$ABC \quad \bar{A}BC \quad AB\bar{C} \quad \bar{A}B\bar{C} \quad A\bar{B}C \quad \bar{A}\bar{B}C \quad A\bar{B}\bar{C} \quad \bar{A}\bar{B}\bar{C}$$

The term $A\bar{B}C$ corresponds to the minimal region within both A and C but outside of B, etc. More generally, with an n -circle diagram labeled by n

⁶Minimal regions are described in Shin [1994], p. 51.

⁷Correspondence is described in Hammer [1994], pp. 77–78.

letters, there should be a minimal region and a corresponding term for each of the 2^n combinations of circles. One way to think of this is that there should be a term for each row of an n -variable truth table, the variables of which are the letters labeling the circles, with truth indicating that the region falls within the circle and falsity indicating that it falls outside of the circle.

For the purposes of logic, minimal regions are entirely described by which of the circles they fall within (and hence also which they fall outside of). So any subset of the n circles should describe a minimal region: that minimal region falling within all the circles in the subset and outside of the rest of the circles of the diagram.

Given n circles, the following are the conditions desired for a Venn-type diagram:

1. For each of the 2^n terms, there is a minimal region corresponding to it.
2. There is no more than one region corresponding to any term.

The first condition ensures that every Boolean combination of the n sets is represented in the diagram. The second prevents any redundancy by ensuring that each combination is represented only once.

For logical purposes, these two conditions are really the only desiderata of a (formal or informal) syntax of the circles of a system of Venn-type diagrams. All that is relevant is that there is exactly one minimal region for each term representing each combination of circles.⁸

A *region* of a diagram consists of one or more minimal regions. Hence, a region can be entirely represented as a set of one or more of the terms corresponding to the minimal regions of a diagram.⁹ In the case of a two-circle diagram with labels A and B , the set $\{A\bar{B}, \bar{A}B\}$ represents the region outside of the circle labeled by B .

Since a region consists of any one or more minimal regions, there are as many regions as there are sets of minimal region, minus the empty set. So there are $2^{(2^n)} - 1$ regions.

If two regions of two diagrams are represented by the same set of terms, they are said to be *counterparts*.¹⁰ Because regions that are counterparts have to be assigned the same set by any model, for convenience below they are sometimes spoken of as though they were the same region. This makes some discussions and proofs easier to read.

⁸Formal models of the syntax of overlapping circles have been provided for which these two conditions are satisfied for any finite number of circles, though the concept of circle must be extended to include non-convex closed curves. An example of such a model is presented in More [1959].

⁹See Shin [1994], p. 51.

¹⁰The counterpart relation is defined in Shin [1994], pp. 53–57.

A *model* has a domain of discourse which can be an arbitrary set, and assigns subsets of the domain to the circles of the diagrams in question, assigning the same subset to circles labeled by the same letter. For example, a model might assign $\{x, y\}$ to the domain, assign $\{x\}$ to one circle of a diagram and $\{x, y\}$ to the other circle.

A model can also be understood as assigning subsets of the domain to minimal regions. A minimal region such as $\overline{A}BC\overline{D}E$ would be assigned $\overline{A} \cap B \cap C \cap \overline{D} \cap E$ (where \overline{A} is the domain minus the set assigned to the circle labeled by A , B is the set assigned to the circle labeled B , etc.).¹¹ Likewise, a region can be understood as being assigned the union of the sets assigned to the minimal regions composing it.

Just as a model determines the sets assigned to minimal regions, conversely, an assignment to minimal regions can be used to specify a model. For example, suppose the four minimal regions of the following diagram are assigned sets x , y , z , and w , as shown:

This specifies the model:

$$\left\{ \begin{array}{l} A = y \cup z \\ B = z \cup w \\ \text{domain} = x \cup y \cup z \cup w \end{array} \right.$$

The two systems, Venn diagrams and Peirce-Venn diagrams, discussed in the next two sections build on the basic diagrams described here by adding additional syntactic devices that can be used to mark various regions and thereby make assertions about the sets they represent.

2 VENN DIAGRAMS

This section presents the logical theory of Venn diagrams. Venn diagrams were introduced by John Venn in 1880 for the purpose of clearly representing categorical sentences and syllogistic reasoning.¹² Venn's system is a modification of a previous, incompleting system of Leonhard Euler's developed in 1761.¹³

¹¹This definition of model is given in Hammer and Danner [1996]. A similar concept is defined in Shin [1994], pp. 64–68.

¹²See Venn [1880] and Venn [1894].

¹³Euler [1846]. For an analysis of Euler's system see Hammer and Shin [1996].

The particular version of Venn diagrams presented here is based on modifications made by Peirce in 1903¹⁴ and Shin in 1994.¹⁵ Peirce provided syntactic rules of inference for manipulating his variation on Venn diagrams while Shin formulated a coherent fragment of Peirce's system and reconstructed and analyzed it in modern form.

Venn diagrams are based on the syntax and semantics developed in the previous section. In addition, the system allows any region of a diagram to be marked as either representing an empty set or a non-empty set (more briefly: to be marked as empty or non-empty).

To assert that a region (rather, the set it represents) is empty is simply to assert that each of the minimal regions that make it up is empty. A minimal region is marked as empty by adding the symbol 'o' to it. This is Peirce's notation replacing Venn's shading of the minimal region.

For example, the following diagram asserts that A is empty (that both \overline{AB} and AB are empty):

It is redundant to mark a minimal region with more than one 'o'. If the region is empty it's empty. Therefore well-formed diagrams will be required to have at most one 'o' in each minimal region.

To assert that a region is non-empty (rather, the set it represents) is not the same as asserting that each of the minimal regions composing it is empty. Rather, it is to assert that at least one of them is non-empty. With Venn diagrams, this is done by adding a chain of 'x's connected by lines to the region, with one 'x' falling in each of its minimal regions. For example, the following diagram asserts that A is non-empty (that either \overline{AB} or AB is non-empty):

The region consisting of all the minimal regions with 'x's of the chain is said to *have* the chain. In particular, larger regions will not be said to have a chain falling in some proper subregion of it. For example in the

¹⁴Peirce [1958], pp. 294-319.

¹⁵Shin [1994].

above diagram the region $\{\overline{AB}, AB\}$ has the 'x'-chain but the larger region $\{\overline{AB}, AB, \overline{AB}\}$ does not.

Because it is redundant for any one chain to have more than one 'x' in a minimal region, all chains of a well-formed diagram are required to have no more than one 'x' in each minimal region.

Likewise, because it is redundant to have two chains in the same region, a well-formed diagram is allowed to have no more than one 'x'-chain in each region.

Thus, the well-formed Venn diagrams can be summarized by the following four constructions:

1. Any n circles drawn to overlap in all combinations as described in the previous section and labeled by n names is a well-formed Venn diagrams.
2. Given any Venn diagram, the result of adding an 'o' to any minimal region not already containing an 'o' results in a well-formed Venn diagram.
3. Given any Venn diagram, the result of adding an 'x'-chain to any region not already having an 'x'-chain results in a well-formed Venn diagram.
4. Nothing else is a well-formed Venn diagram.

A Venn diagram is *consistent* just in case no minimal region has both an 'o' and an unconnected 'x' in it.

For logical purposes, the syntactic granularity that is relevant for defining diagrams is at the level of which regions have x-chains and which minimal regions have an 'o'. Thus, a diagram is entirely determined by (i) the set of letters labeling the circles, (ii) the minimal regions with an 'o', and (iii) the sets of minimal regions constituting a region with an 'x'-chain. For example, the following diagram is specified by (i) the set $\{A, B\}$ of letters labeling the circles, (ii) the minimal regions with an 'o' \overline{AB} and \overline{AB} , and (iii) the regions with 'x'-chains $\{\overline{AB}, AB, \overline{AB}\}$ and $\{\overline{AB}\}$.¹⁶

¹⁶This type of approach to the identity conditions between diagram is presented in Hammer and Danner [1996].

Any other diagram having the same such descriptions is just another instance of the same diagram.

Consider the number of distinct syntactically correct diagrams there are having n curves and some fixed set of n predicates. A diagram can have an ‘o’ in any number of its minimal regions, so there are 2^n possibilities for adding o’s to each diagram. A diagram can have a chain of ‘x’s in any number of its regions, so there are $2^{(2^n)} - 1$ possible chains to consider. This leaves a choice of $2^n + 2^{(2^n)} - 1$ ‘o’s and chains of ‘x’s to choose from for each diagram. Since a diagram can include any combination of these, there are $2^{(2^n + 2^{(2^n)} - 1)}$ distinct diagrams possible. In the case of $n = 1$ there are 16 distinct diagrams possible, with $n = 2$ there are 524,288 diagrams possible, and with $n = 3$ and up the number is huge but finite.¹⁷ A more difficult task is that of specifying the precise number of logically distinct diagrams that can be constructed from n curves and some fixed set of n labels, that is, the number of equivalence classes (the relation being logical equivalence) of diagrams constructible from the n curves and labels.

The definition of the conditions under which a model satisfies a Venn diagram are as was intuitively described:

DEFINITION 1 (Satisfies).

1. A model *satisfies* an ‘x’ occurring in some minimal region just in case the set assigned to that minimal region is non-empty.
2. A model *satisfies* an ‘o’ occurring in some minimal region just in case the set assigned to that minimal region is empty.
3. A model *satisfies* an ‘x’-chain occurring in some region just in case the set satisfies at least one ‘x’ in the chain.
4. A model *satisfies* a Venn diagram just in case it satisfies each ‘x’-chain and each ‘o’ in the diagram.¹⁸

A diagram is a *logical consequence* of a set of diagrams just in case the diagram is satisfied by every model satisfying each diagram in the set. A diagram is *logically equivalent* to another diagram just in case the two are satisfied by the same models.

The following rules of inference govern the manipulation of ‘x’-chains and ‘o’s.

RULE 2 (Addition). An ‘x’-chain can be extended with an additional ‘x’ in a new minimal region.¹⁹

¹⁷Various calculations of this sort are given in Peirce [1960], pp. 306–307 and analyzed in Hammer [1995b], pp. 811–813.

¹⁸This definition is given in Hammer [1995b], pp. 817–818.

¹⁹Peirce [1958], p. 310.

The validity of Addition can be seen from the fact that if a region is assigned a non-empty set any region containing it will be assigned a superset, and hence will be non-empty.

RULE 3 (Contraction). If an 'x'-chain has an 'x' in a region also having an 'o', that 'x' can be erased. If the 'x' does not occur on an end, the two halves of the chain must be reconnected.²⁰

The validity of Contraction can be seen from the fact that if a minimal region is empty and some region containing it is non-empty, then some other minimal region of the larger region must be non-empty.

RULE 4 (Simplification). Any 'o' can be erased. Any entire 'x'-chain can be erased.²¹

The validity of Simplification can be seen from the fact that the various 'o's and 'x'-chains of a diagram must all be satisfied for a diagram to be satisfied.

RULE 5 (Contradiction). Any diagram can be inferred from a diagram having a minimal region with both an 'o' and an unconnected 'x'.²²

The validity of Contradiction can be seen from the fact that no diagram of this type can be satisfied.

PROPOSITION 6. Addition, Simplification, and Contradiction result in diagrams that are logical consequences of the diagrams they are applied to. Contraction results in a logically equivalent diagram.

For two diagrams having the same labels, logical equivalence can be characterized in terms of the two rules of Contraction and Addition. Define the *summary* of a diagram to be the result of applying Contraction as many times as possible, then erasing any chain that could be obtained by Addition. For example, the summary of the diagram

is the diagram:

²⁰Peirce [1958], pp. 310–311.

²¹Peirce [1958], p. 310.

²²Shin [1994], pp. 87–88.

The two chains are shortened, and then the remaining 2-link chain is erased because it could be obtained from the unconnected 'x' by Addition. A summary is said to be *inconsistent* if the result is an inconsistent diagram.

THEOREM 7. Two Venn diagrams having the same labels (and number of circles) are logically equivalent if and only if they either have the same summary or else both have inconsistent summaries.

Proof. The right-to-left direction of the theorem follows from the fact that Contraction results in a logically equivalent diagram and Addition is a valid rule of inference. For the contrapositive of the other direction, suppose that two diagrams have distinct (consistent) summaries d and e . Then some minimal region has an 'o' in one but not the other summary, or else some region has an 'x'-chain in one but not the other. The 'x'-chain case is handled.

Case 1: A region of d has an 'x'-chain but no subregion of e has one. Assign the empty set to each minimal region of the chain. Because e does not have an 'x' in any of those regions, it can still be satisfied by extending this model. The result satisfies e but not d . Likewise with d and e reversed.

Case 2: A region of d has an 'x'-chain and some proper subregion of e has an 'x'-chain. Let r be a minimal region with an 'x' of the chain in d but not e . Assign to r a non-empty set, but to all other regions of the 'x'-chain the empty set. Extend this model to satisfy d . The model does not satisfy the 'x'-chain of e in the subregion and so does not satisfy e . Likewise with d and e reversed. ■

The following completeness result for Venn diagrams shows that if a diagram e is a consequence of a diagram d with the same labels, then e can be obtained from d by applying Contraction a number of times followed by either one application of Contradiction or else a number of applications of Addition and Simplification.

THEOREM 8 (Completeness). If diagram e is a logical consequence of d and both have the same labels (and number of circles), then e is provable from d .²³

Proof. Assume e is a logical consequence of d . Apply Contraction to d as many times as possible. It can be assumed that at no time during this process is an inconsistent diagram obtained. For if one were, e would be immediately obtainable by Contradiction, establishing e 's provability. By applying Contraction a number of times, it can be assumed without loss of generality that no minimal region of d has both an 'x' and an 'o'.

²³This result is essentially a special case of the completeness result proved in Shin [1994], pp. 98–110.

First note that every minimal region with an ‘o’ in e has an ‘o’ in d . Suppose otherwise for some minimal region r . Construct a model which assigns

$$\begin{cases} \text{the empty set} & \text{to any minimal region of } d \text{ with an ‘o’} \\ \text{a non-empty set} & \text{to all other minimal regions of } d \end{cases}$$

Such a model satisfies d . Because r is assigned the empty set, the model does not satisfy e , a contradiction.

Next note that for every region with an ‘x’-chain in e , some subregion has an ‘x’-chain in d . Suppose otherwise for some region r . Construct a model which assigns

$$\begin{cases} \text{the empty set} & \text{to region } r \\ \text{the empty set} & \text{to any minimal region of } d \text{ with an ‘o’} \\ \text{a non-empty set} & \text{to all other minimal regions of } d \end{cases}$$

Because no subregion of r has an ‘x’-chain, this model satisfies d . However, because r is assigned the empty set, the model does not satisfy e , a contradiction.

These two observations imply that e can now be obtained from d by several applications of Addition and Simplification. ■

More general completeness results extending Theorem 8 can be proved by formulating rules of Merge, Add Circle, and Remove Circle. This section concludes with a formulation of these three rules of inference.

RULE 9 (Merge). Two diagrams having the same labels may be combined into a single diagram as follows:

1. A new diagram is drawn with circles labeled by each of the letters occurring in the two premises.
2. For each minimal region of either premise with an ‘o’, add an ‘o’ to each of its counterparts in the conclusion to which an ‘o’ has not already been added.²⁴
3. For each region of either premise with an ‘x’-chain, add an ‘x’-chain to its counterpart in the conclusion if one has not already been added to that region.²⁵

²⁴The formulation of this rule uses the more general concept of any two regions being counterparts. This is defined as follows: (i) If two circles are labeled by the same letter, the two regions within the circles are counterparts. (ii) If two regions are counterparts then their two ‘complements’ are counterparts, where the ‘complement’ of a region is the combination of minimal region of the diagram that are not a part of the region. (iii) If two pairs of regions are counterparts, then the two ‘unions’ of the two pairs are counterparts, where the ‘union’ of a pair of regions is the combination of all minimal regions that are a part of either region. (iv) No other two regions are counterparts.

²⁵Examples of this rule are given in Peirce [1958], e.g., p. 312, however the rule is not stated explicitly. It is stated in essentially this form in Shin [1994], pp. 88–92.

Next is addition of new circles to Venn diagrams. First, the new circle must be drawn so that the well-formedness of the overlapping circles is preserved, that is, so that all Boolean combinations of the circles are represented. In doing this, any minimal region of the original diagram is broken into two parts, one within the new circle and the other outside of the new circle. Hence, any ‘o’ occurring in a minimal region needs to be replaced by two connected ‘o’s, one in each of the two new subregions. Similarly, any ‘x’ occurring in a minimal region needs to be split into two parts, one within the new circle and the other outside of the new circle, with the two being connected by a line.

RULE 10 (Add Circle). A new circle may be added to a Venn diagram in such a way that well-formedness is preserved, provided all ‘x’s and ‘o’s are split as described.²⁶

The following is an example of an application of Add Circle:

The ‘o’ is replaced by two ‘o’s, and the two ‘x’s are each replaced by two ‘x’s that are connected by lines.

The final rule is that allowing the removal of a circle. The removal of a circle from a diagram throws pairs of *adjoining* minimal regions together: one within the circle and one outside of the new circle.

RULE 11 (Remove Circle). A circle may be erased provided any two ‘o’s in adjoining minimal regions are replaced by a single ‘o’ when the two regions are thrown together, and any ‘o’s without an ‘o’ in the adjoining region are erased.²⁷

The following is an example of Remove Circle:

²⁶Peirce [1958], p. 311 and Shin [1994], pp. 86–87.

²⁷Peirce [1958], p. 311 and Shin [1994], pp. 82–85.

The two ‘o’s in the two regions that are thrown together when the circle is erased are replaced by a single ‘o’ while the ‘o’ without an adjoining ‘o’ is erased. The ‘x’-chain is left as is.

The repeated application of Merge allows any finite set of diagrams to be combined into a single, logically equivalent ‘conjunction’. Add Circle allows new circles to be added to any diagram, the result being logically equivalent. Remove Circle has the property that if e is a logical consequence of d but a circle in e is labeled by a letter not occurring in d , then the result of removing that circle using Remove Circle is a diagram that still implies e . The earliest general completeness result using these additional rules is due to Shin.²⁸ Another is in Hammer and Danner [1996].

3 PEIRCE–VENN DIAGRAMS

This section presents the logic of *Peirce–Venn diagrams*, Peirce’s variation and extension of Venn diagrams developed in 1903.²⁹ Peirce’s system is equivalent to the monadic fragment of first-order logic in expressive power. It also is based on what amounts to a conjunctive normal form. In fact, the key rules of inference formulated by Peirce are practically identical to the resolution proof procedure for propositional logic.

All Venn diagrams are also Peirce–Venn diagrams. However, Peirce–Venn diagrams allow any combination of ‘x’s and ‘o’s to be connected by lines to form a disjunctive chain. For example, the following is a Peirce–Venn diagram with two chains:

It asserts that either some A are not B or no A is B (by means of the upper chain) and something is either A or B (by means of the lower chain).

Because it is redundant to have a single chain with more than one ‘x’ in one minimal region or more than one ‘o’ in one minimal region, well-formed Peirce–Venn diagrams are required to have at most one ‘x’ and at most one ‘o’ in each minimal region. This rules out the following diagram as not well-formed:

²⁸ Shin[1994], pp. 98–110.

²⁹ Peirce [1958], pp. 294–319.

Likewise, well-formed Peirce–Venn diagrams may not have two chains in the same region that have ‘x’s and ‘o’s in the same minimal regions. This rules out the following diagram:

However, the following diagram is not ruled out:

The syntax of well-formed Peirce–Venn diagrams can be summarized by the following conditions:

1. Any n circles drawn to overlap in all combinations as described above and labeled by n names is a well-formed Peirce–Venn diagrams.
2. Given any Venn diagram, the result of adding a chain of ‘x’s and ‘o’s to any region not already having such a chain results in a well-formed Peirce–Venn diagram.
3. Nothing else is a well-formed Peirce–Venn diagram.

A Peirce–Venn diagram is *consistent* just in case no minimal region has both an unconnected ‘o’ and an unconnected ‘x’ in it.

The semantics for Peirce–Venn diagrams are given by the following conditions:³⁰

DEFINITION 12 (Satisfies).

1. A model *satisfies* an ‘x’ occurring in some minimal region just in case the set assigned to that minimal region is non-empty.

³⁰Hammer [1995b], pp. 817–818.

2. A model *satisfies* an ‘o’ occurring in some minimal region just in case the set assigned to that minimal region is empty.
3. A model *satisfies* a chain occurring in some region just in case the set satisfies at least one of the ‘x’s or ‘o’s in the chain.
4. A model *satisfies* a Peirce–Venn diagram just in case it satisfies each chain in the diagram.

There is a very close similarity between Peirce–Venn diagram and propositional sentences in conjunctive normal form. A Peirce–Venn diagram is interpreted as a conjunction of disjunctions, each of the distinct chains being a ‘conjunct’ and each link of such a chain being a ‘disjunct’.

For some purposes, it is convenient to represent Peirce–Venn diagrams in tabular form. Lower-case letters are used to represent the minimal regions of a diagram having either an ‘x’ or an ‘o’. One row of a table represents one chain of the diagram. The left side of a row consists the minimal regions that have an ‘x’ from the chain while the right side consists of the minimal regions that have an ‘o’ from the chain.

As an example, the following table could be used to represent a Peirce–Venn diagram with two chains, the various links of which fall in five different minimal regions (temporarily referred to as a , b , c , d , and e):

‘x’	‘o’
a, b	c, d
c, e	b

The first chain has two ‘x’s in regions a and b and two ‘o’s in regions c and d . The second chain has ‘x’s in c and e and an ‘o’ in b .

Notice that the conditions on well-formed diagram prevent such a table from having two duplicate rows. They also prevent a table from having any row where the same letter appears twice on the left or twice on the right.

The two rows of the above table can also be expressed as the two propositional sentences

$$a \vee b \vee \neg c \vee \neg d$$

and

$$c \vee e \vee \neg b$$

where $\neg b$ represents an ‘o’ in minimal region b and b represents an ‘x’ in region b , and a disjunction of such literals represents a chain of such ‘x’s and ‘o’s in those minimal regions.

The first task is to show that Peirce–Venn diagrams are equivalent in expressive power to the monadic fragment of first-order logic.³¹ The sentences

³¹An extension of Venn diagrams is formulated in Shin [1994], pp. 111–152, with the same expressive power. That system allows any finite disjunction of Venn diagrams to qualify as a well-formed diagram.

of *monadic logic* are those sentences of first-order logic without identity constructible from languages involving only one-place predicate symbols.

THEOREM 13. Peirce–Venn diagrams are equivalent to monadic logic.

Proof. It is clear how to derive an equivalent monadic sentence from a given Peirce–Venn diagram, so only the converse will be shown. Let ϕ be a monadic sentence and let $\mathcal{L}(\phi)$ be the set of all predicates occurring in ϕ . First, the quantifiers of ϕ are driven inwards so that the scope of each quantifier is a truth function of atomic formulas each involving the quantified variable.³² It can be assumed that only existential quantifiers occur. Consider such a subformula $\exists x\psi$. The truth-function ψ can be put into disjunctive normal form, resulting in

$$\exists x(\phi_1 \vee \dots \vee \phi_n)$$

which is equivalent to

$$\exists x\phi_1 \vee \dots \vee \exists x\phi_n$$

Thus the scope of each quantifier is a conjunction of atomic formulas and negated atomic formulas. Notice that each such conjunction, say $A(x) \wedge \neg B(x) \wedge C(x)$, can be written as a term such as $A\overline{B}C$, the notation used above. Now expand each such existentially quantified term into a disjunction of existentially quantified terms each of which involves every predicate in $\mathcal{L}(\phi)$. For example, if the subformula is $\exists xA\overline{B}C$ and D is the only other predicate in $\mathcal{L}(\phi)$, the result would be

$$\exists xA\overline{B}CD \vee \exists xA\overline{B}C\overline{D}$$

Call each such disjunct a *complete atom*. Thus, complete atoms are existentially quantified conjunction of atomic formulas and negated atomic formulas in which each predicates in $\mathcal{L}(\phi)$ occurs once. Now put the entire sentence into conjunctive normal form using the complete atoms as atomic elements. Each conjunct of the resulting sentence corresponds to one chain, and each disjunct of a conjunct corresponds to one ‘x’ or ‘o’ of the chain, depending on whether the disjunct is negated or not. The minimal region the ‘x’ or ‘o’ should be drawn in depends on which region corresponds to the quantified term. Thus, a Peirce–Venn diagram can be drawn for ϕ by drawing one circle for each predicate in $\mathcal{L}(\phi)$ and adding one chain for each conjunct of the derived sentence. ■

The rules of inference for Peirce–Venn diagrams include parallels of the rules of Addition, Simplification, Contraction, and Contradiction from Venn diagrams. The primary rule, Peirce’s Rule, is new.

³²A procedure for this deriving from Behmann [1922] is described in Quine [1982].

RULE 14 (Addition). A chain can be extended with an additional ‘x’ or ‘o’ in a new minimal region.

RULE 15 (Simplification). Any entire chain can be erased.

RULE 16 (Contradiction). Any diagram can be inferred from a diagram having a minimal region with both an unconnected ‘o’ and an unconnected ‘x’.

RULE 17 (Contraction).

Case 1: If a chain has an ‘x’ in a minimal region having an unconnected ‘o’, the ‘x’ and the two halves reconnected.

Case 2: If a chain has an ‘o’ in a minimal region having an unconnected ‘x’, the ‘o’ can be erased and the two halves reconnected.

RULE 18 (Peirce’s Rule). If a chain has an ‘x’ in a minimal region and another chain has an ‘o’ in that same region, the ‘x’ and the ‘o’ can be that ‘x’ can be erased provided the four halves of the remaining chains are all connected to each other.³³

Expressed in terms of tables, Peirce’s Rule states that two rows that share a letter that is on the right in one and on the left in the other can be combined into a larger row, with the two letters in common erased (unless they were the only letter on that side of the row). As an example, a Peirce–Venn diagram represented as

$$\begin{array}{c|c} \text{‘x’} & \text{‘o’} \\ \hline a, b & c \\ d & b, e \end{array}$$

implies

$$\begin{array}{c|c} \text{‘x’} & \text{‘o’} \\ \hline a, d & c, e \end{array}$$

In minimal region B , one chain has an ‘x’ and the other has an ‘o’. The ‘x’ and ‘o’ are erased, and the resulting pieces from the two chains are connected together.

Peirce’s Rule is essentially identical to the Resolution Rule of the Resolution proof procedure for propositional logic, which operates on propositional sentences in conjunctive normal form.

The following lemma shows that a trivial test determines whether or not a Peirce–Venn diagram is satisfiable.

DEFINITION 19 (Peirce Closure). The *Peirce closure* of a diagram is the result of applying Peirce’s Rule and Contraction to it as many times as possible.

³³ Peirce [1958], pp. 310–311.

LEMMA 20. A Peirce–Venn diagram is satisfiable if and only if its Peirce closure is consistent.

Proof. One direction follows from the validity of Peirce’s Rule. For the other direction, note first that a consistent Peirce closure is satisfiable because no minimal region has both an ‘x’ and an ‘o’. Next note that an application of Peirce’s Rule on two chains that conflict in some minimal region results in two subchains of the original chains. Therefore any model satisfying the new chains must also satisfy the two original chains. Hence, by induction, any model satisfying the Peirce closure also satisfies the original diagram. ■

Lemma 20 provides a simple decision procedure for propositional logic. Given a propositional sentence ϕ , construct the conjunctive normal form of $\neg\phi$. Draw a Peirce–Venn diagram with at least as many minimal regions as propositional variables in ϕ . Assign each variable P to a fixed minimal region and let P translate to an ‘x’ in that region, $\neg P$ translate to an ‘o’ in that region, and each conjunct of the CNF translate to a connected chain of these ‘x’s and ‘o’s. Let the assignment of a non-empty set to a minimal region translates to the assignment of truth to the variable corresponding to it, and the empty set to false. The resulting Peirce–Venn diagram is unsatisfiable if and only if ϕ is valid. Hence ϕ is valid if and only if the Peirce closure of the diagram is inconsistent.

Next a completeness result for Peirce’s diagrammatic logic is proved. A somewhat different completeness result for a natural deduction formulation of Peirce’s system is given in Hammer [1995b].³⁴

THEOREM 21 (Completeness). If diagram e is a logical consequence of d and both have the same labels (and number of circles), then e is provable from d .

Proof. Assume that e is not provable from d . Take the Peirce closure of d , which we can assume is consistent. Some chain

$$p \vee q \vee \neg r \vee \neg s$$

occurs in e but no subchain of it occurs in the Peirce closure. (The same argument will work for other types of chains). We construct a model satisfying d but not e . Add the two unconnected ‘o’s $\neg p, \neg q$ and the two unconnected ‘x’s r, s to the Peirce closure, obtaining d' . We construct a model of d' using Lemma 20. Suppose the Peirce closure of d' were inconsistent, say resulting in an ‘x’ and ‘o’ z and $\neg z$. The presence of $\neg p, \neg q, r, s$ allow chains having any of $p, q, \neg r$, or $\neg s$ as links to be shortened by Contraction. Consider now the same proof with all uses of the added ‘x’s and ‘o’s $\neg p, \neg q, r, s$ removed (this is a proof from the Peirce closure of d .) The result is two chains

³⁴pp. 821–825.

$p \vee q \vee \neg r \vee \neg s \vee z$ and $p \vee q \vee \neg r \vee \neg s \vee \neg z$, including at least the last link but possibly not all of the other links, depending on which of $\neg p, \neg q, r, s$ were used in the original proof. One application of Peirce's Rule to these two chains results in either $p \vee q \vee \neg r \vee \neg s$ or a subchain of $p \vee q \vee \neg r \vee \neg s$ (from which $p \vee q \vee \neg r \vee \neg s$ is obtainable by Addition). This contradicts that $p \vee q \vee \neg r \vee \neg s$ is not provable from d . Hence the Peirce closure of d' is consistent, and so by Lemma 20 e is not a logical consequence of d . ■

As with the Venn system, rules of Merge, Add Circle, and Remove Circle can be formulated that allow more general completeness results to be proved for Peirce–Venn diagrams.

4 EXISTENTIAL GRAPHS

This section describes the logic of *existential graphs* developed by Peirce.³⁵ Existential graphs, a system arising from Peirce's work on the calculus of relations and predicate logic, is a graphical system for representing logical sentences and inferences.

Peirce wavered somewhat on the purpose of existential graphs. In 1911 he describes the system as a 'system of logical symbols' whose 'purpose and end is simply and solely the investigation of the theory of logic, and not at all the construction of a calculus to aid the drawing of inferences'.³⁶ Likewise, in 1903 he writes of the system that 'the whole effort has been to dissect the operations of inference into as many distinct steps as possible'.³⁷ The system is presented in these statements as an analytical device rather than a practical tool. On the other hand, in 1906 Peirce describes the system as a practical reasoning tool: 'The system of Existential Graphs which I have now sufficiently described - or, at any rate, have described as well as I know how, leaving the further perfection of it to others - greatly facilitates the solution of problems of Logic...'.³⁸ This statement describes the system as a practical tool designed to assist in logical reasoning.

The system of existential graphs was divided by Peirce into several natural fragments. The *alpha* fragment is equivalent to propositional logic, and forms a very elegant and workable substitute. The *beta* fragment is equivalent to first-order logic with identity. Its rules are much more complex than those of the alpha fragment, and is a system that is not readily analyzable. These are the two most polished fragments of the system of existential graphs, and are the two examined here. The *gamma* fragment allows expressions of modality, abstraction, higher-order quantification, and state-

³⁵ Peirce [1958].

³⁶ Peirce [1958], p. 320.

³⁷ Peirce [1958], p. 343.

³⁸ Peirce [1958], pp. 458–459.

ments about existential graphs themselves.³⁹ A good description of Peirce's entire system is Roberts [1973].

Graphs are drawn on the *sheet of assertion*: a blank, empty area of the page on which is drawn all that is asserted. The blank sheet of assertion is logically true, since nothing is, in that case, being asserted.

Several graphs drawn on the sheet of assertion are interpreted conjunctively. Thus,

is equivalent to $A \wedge B \wedge C$.

A closed curve (as with the circles of Venn diagrams) called a *cut* negates the subgraph that it encloses. Thus,

is equivalent to $A \wedge B \wedge \neg(C \wedge D)$.

A cut that encloses no subgraph other than a part of the sheet of assertion is logically false because it denies the empty subgraph consisting of no assertion.

A common idiom is used frequently by Peirce to graph implications. To graph an implication, first two concentrically nested cuts are drawn. Then the antecedent is drawn in the area within the outer cut but outside of the inner cut, and the consequent drawn within the inner cut. Thus, the following graph is equivalent to 'if A then B '.

The first rule of inference allows a double negation to be added or removed from any subgraph.

RULE 22 (Double Cut). Two concentrically nested cuts may be erased or added around any subgraph.

³⁹See Peirce [1958], pp. 401–410.

RULE 23 (Insertion in Odd). Any graph may be drawn on an area of the sheet of assertion that is enclosed by an odd number of cuts.

Insertion in Odd can be thought of as allowing additional assumptions to be added to subproofs.⁴⁰

RULE 24 (Erasure in Even). Any subgraph drawn on an area of the sheet of assertion that is enclosed by an even number of cuts may be erased.

Erasure in Even can be thought of as a generalized version of simplification, the rule allowing any conjunct to be eliminated from a conjunction.

RULE 25 (Iteration). A subgraph may be copied to any other area on the sheet of assertion that falls within all of the cuts enclosing the original subgraph.

Iteration can be understood as allowing one to reiterate or use assumptions or facts in subproofs within their scope.

RULE 26 (Deiteration). Any subgraph that could have been drawn as a result of the rule of Iteration may be erased.

Conversely, Deiteration encodes the principle that if a previously established fact occurs in a subproof, there is no need to reestablish it in the subproof and so any such redundant occurrence can be eliminated.

The *alpha* fragment of Peirce's system is equivalent to propositional logic. Completeness results for various formulations of the system have been provided by Zeman [1964], Roberts [1964], Roberts [1973], White [1984], and Hammer [1995a].

The following is an example of a proof that uses all five inference rules. The conclusion is a graph of 'if A and D , then C '. The premises are graphs of 'if A then B ' and 'if not- C , then not- B ':

By Double Cut:

⁴⁰The connection between the rules of existential graphs and natural deduction proofs is made in Roberts [1964].

By Iteration of the right graph into the left graph and then Erasure of the right graph:

By Deiteration:

By Double Cut:

Finally, by Erasure in Even (of B) and then Insertion in Odd (of D):

Peirce's next fragment of existential graphs, the *beta* system, is much more complicated. Peirce uses what he calls *lines of identity* instead of variables. The formula x knows y would be approximated by the graph:

Actually, lines of identity also have quantificational import, so the graph is really the equivalent of $\exists x \exists y (x \text{ knows } y)$.

The next graph is equivalent to $\exists x \neg \exists y (x \text{ knows } y)$, or equivalently, 'Someone knows nobody.'

As this example shows, the scope of quantification associated with a line of identity is determined by the portion of the line that is the least deeply enclosed within cuts. In particular, the order in which the elements of a graph are interpreted is (i) lines of identity on the sheet of assertion (i.e., with parts enclosed by no cuts), (ii) cuts on the sheet of assertion, (iii) lines of identity on the sheet of assertion (i.e., with parts enclosed by no cuts), (iv) cuts on the sheet of assertion, etc.

The next graph is equivalent to ‘someone knows everyone’.

Notice that lines of identity enclosed by an odd number of cuts are naturally interpreted as universally quantified.

Cross-reference (indicated in first-order logic by the same variable occurring more than once) is accomplished in the system of existential graphs by allowing lines of identity to branch. For example, the following graph is equivalent to ‘everyone knows a millionaire’.

The following is a selection of most of the rules of inference for the beta fragment.⁴¹ For a more complete list see Peirce [1958], Zeman [1964], Roberts [1973] and Roberts [1992]. Most of the rules are generalizations of the alpha rules, now taking into account lines of identity.

RULE 27 (Double Cut). Concentrically nested cuts may be added or removed around any subgraph as long as no graphs occur in the area within the outer cut but outside of the inner cut except possibly lines of identity that pass directly from within the inner cut to outside of the other cut.

This is the same rule as in the alpha system, with the only exception being that lines of identity are allowed to pass directly through the two cuts.

RULE 28 (Erasure). Any subgraph occurring within an even number of cuts may be erased, including an evenly enclosed portion of a line of identity.

⁴¹See Peirce [1958], pp. 395–396.

RULE 29 (Iteration). A subgraph of a graph can be copied to any other part of the graph which falls within the same or additional cuts.⁴²

This rule is not stated in its entirety, which allows lines of identity to be connected to their iterated counterparts.

RULE 30 (Deiteration). A subgraph that could be the result of an application of Iteration can be erased.

RULE 31 (Connect in Odd). Two loose ends of lines of identity that occur in the same, oddly enclosed area can be connected.

Graphs in oddly enclosed areas behave like assumptions. Connecting two loose ends in such an area has something of the effect of making a stronger assumption, namely that the two objects are identical.

RULE 32 (Retraction Outwards). A loose end of a line of identity can be retracted as long as the only cuts it is retracted across are in the direction of within the cut to outside of the cut.

RULE 33 (Extension Inwards). A loose end can be extended inwards through zero or more additional cuts.

RULE 34 (Branch). A branch can be added to any portion of a line of identity.

Here is an example of a non-trivial proof in the beta system. The conclusion is a graph of ‘everyone is known by someone’:

The two premises are graphs of ‘someone is known by everyone’ and ‘if someone knows another, that person also knows the first’ (or ‘knows is symmetric’):

To begin the proof, an application of Iteration to the graph of ‘knows is symmetric’ (and then an application of Erasure to the original) gives:

⁴²Peirce [1958], p. 396.

The effect of this is to bring the premise 'knows is symmetric' within the scope of the other premise so that the two can be combined.

The next step is to connect the two lines of identity of each premise to a line of the other premise, thereby identifying the variables of the two premises. This is done using Branch, Extension Inwards, and Connect in Odd. First, four applications of Branch gives:

Second, two applications of Extension Inwards to the two new outer branches gives:

Finally, two applications of Connect in Odd gives:

The effect of these operations is that the two pairs of 'variables' of the two premises have been identified, allowing the lines of identity of the two premises to interact.

Eventually, the innermost occurrence of 'knows' will be the predicate of the conclusion, the other two being eliminated once they have been used. An application of Deiteration (to the subgraph 'knows') gives:

Two applications of Retraction to the loose ends results in:

Then, by Double Cut:

Because the outermost 'knows' occurs within an even number of cuts it can be eliminated. Thus, an application of Erasure and then two applications of Retraction on the loose ends yields:

Restructuring this graph for readability gives:

This graph says that the person who was known by everyone knows everybody. To get the conclusion, an application of Erasure gives:

Finally, an application of Retraction Outwards to the unconnected line of identity and then Erasure yields the conclusion:

Analysis of the beta system of existential graphs remains uncompleted at this time partly because the system's unusual topological syntax resists many standard techniques. However, completeness results have been reported in Zeman [1964] and Roberts [1973], and consistency results have been reported in Zeman [1964] and Roberts [1973, 1992].

5 CONCLUSION

A diagrammatic logic is simply a logic whose target objects are diagrams rather than sentences. Other than this, diagrammatic logics and logics involving expressions of some language are not different in kind. In either case, the logic should provide an adequate description of the class of representations being studied, their meaning, and the principles behind their use and purpose within the system of which they are a part. The reasons for formulating and analyzing a diagrammatic logic are also the same as for a language-based logic. If for any reason the grammatical, semantical, or inferential properties of a diagrammatic system need to be determined precisely, say for computational or psychological purposes, a diagrammatic logic will do exactly that.

PREFACE TO THE SECOND EDITION

It is with great pleasure that we are presenting to the community the second edition of this extraordinary handbook. It has been over 15 years since the publication of the first edition and there have been great changes in the landscape of philosophical logic since then.

The first edition has proved invaluable to generations of students and researchers in formal philosophy and language, as well as to consumers of logic in many applied areas. The main logic article in the Encyclopaedia Britannica 1999 has described the first edition as ‘the best starting point for exploring any of the topics in logic’. We are confident that the second edition will prove to be just as good.!

The first edition was the second handbook published for the logic community. It followed the North Holland one volume *Handbook of Mathematical Logic*, published in 1977, edited by the late Jon Barwise. The four volume *Handbook of Philosophical Logic*, published 1983–1989 came at a fortunate temporal junction at the evolution of logic. This was the time when logic was gaining ground in computer science and artificial intelligence circles.

These areas were under increasing commercial pressure to provide devices which help and/or replace the human in his daily activity. This pressure required the use of logic in the modelling of human activity and organisation on the one hand and to provide the theoretical basis for the computer program constructs on the other. The result was that the *Handbook of Philosophical Logic*, which covered most of the areas needed from logic for these active communities, became their bible.

The increased demand for philosophical logic from computer science and artificial intelligence and computational linguistics accelerated the development of the subject directly and indirectly. It directly pushed research forward, stimulated by the needs of applications. New logic areas became established and old areas were enriched and expanded. At the same time, it socially provided employment for generations of logicians residing in computer science, linguistics and electrical engineering departments which of course helped keep the logic community thriving. In addition to that, it so happens (perhaps not by accident) that many of the Handbook contributors became active in these application areas and took their place as time passed on, among the most famous leading figures of applied philosophical logic of our times. Today we have a handbook with a most extraordinary collection of famous people as authors!

The table below will give our readers an idea of the landscape of logic and its relation to computer science and formal language and artificial intelligence. It shows that the first edition is very close to the mark of what was needed. Two topics were not included in the first edition, even though

they were extensively discussed by all authors in a 3-day Handbook meeting. These are:

- a chapter on non-monotonic logic
- a chapter on combinatory logic and λ -calculus

We felt at the time (1979) that non-monotonic logic was not ready for a chapter yet and that combinatory logic and λ -calculus was too far removed.¹ Non-monotonic logic is now a very major area of philosophical logic, alongside default logics, labelled deductive systems, fibring logics, multi-dimensional, multimodal and substructural logics. Intensive re-examinations of fragments of classical logic have produced fresh insights, including at time decision procedures and equivalence with non-classical systems.

Perhaps the most impressive achievement of philosophical logic as arising in the past decade has been the effective negotiation of research partnerships with fallacy theory, informal logic and argumentation theory, attested to by the Amsterdam Conference in Logic and Argumentation in 1995, and the two Bonn Conferences in Practical Reasoning in 1996 and 1997.

These subjects are becoming more and more useful in agent theory and intelligent and reactive databases.

Finally, fifteen years after the start of the Handbook project, I would like to take this opportunity to put forward my current views about logic in computer science, computational linguistics and artificial intelligence. In the early 1980s the perception of the role of logic in computer science was that of a specification and reasoning tool and that of a basis for possibly neat computer languages. The computer scientist was manipulating data structures and the use of logic was one of his options.

My own view at the time was that there was an opportunity for logic to play a key role in computer science and to exchange benefits with this rich and important application area and thus enhance its own evolution. The relationship between logic and computer science was perceived as very much like the relationship of applied mathematics to physics and engineering. Applied mathematics evolves through its use as an essential tool, and so we hoped for logic. Today my view has changed. As computer science and artificial intelligence deal more and more with distributed and interactive systems, processes, concurrency, agents, causes, transitions, communication and control (to name a few), the researcher in this area is having more and more in common with the traditional philosopher who has been analysing

¹I am really sorry, in hindsight, about the omission of the non-monotonic logic chapter. I wonder how the subject would have developed, if the AI research community had had a theoretical model, in the form of a chapter, to look at. Perhaps the area would have developed in a more streamlined way!

such questions for centuries (unrestricted by the capabilities of any hardware).

The principles governing the interaction of several processes, for example, are abstract and similar to principles governing the cooperation of two large organisations. A detailed rule based effective but rigid bureaucracy is very much similar to a complex computer program handling and manipulating data. My guess is that the principles underlying one are very much the same as those underlying the other.

I believe the day is not far away in the future when the computer scientist will wake up one morning with the realisation that he is actually a kind of formal philosopher!

The projected number of volumes for this Handbook is about 18. The subject has evolved and its areas have become interrelated to such an extent that it no longer makes sense to dedicate volumes to topics. However, the volumes do follow some natural groupings of chapters.

I would like to thank our authors and readers for their contributions and their commitment in making this Handbook a success. Thanks also to our publication administrator Mrs J. Spurr for her usual dedication and excellence and to Kluwer Academic Publishers for their continuing support for the Handbook.

Logic	IT			
	Natural language processing	Program control specification, verification, concurrency	Artificial intelligence	Logic programming
Temporal logic	Expressive power of tense operators. Temporal indices. Separation of past from future	Expressive power for recurrent events. Specification of temporal control. Decision problems. Model checking.	Planning. Time dependent data. Event calculus. Persistence through time—the Frame Problem. Temporal query language. temporal transactions.	Extension of Horn clause with time capability. Event calculus. Temporal logic programming.
Modal logic. Multi-modal logics	generalised quantifiers	Action logic	Belief revision. Inferential databases	Negation by failure and modality
Algorithmic proof	Discourse representation. Direct computation on linguistic input	New logics. Generic theorem provers	General theory of reasoning. Non-monotonic systems	Procedural approach to logic
Non-monotonic reasoning	Resolving ambiguities. Machine translation. Document classification. Relevance theory	Loop checking. Non-monotonic decisions about loops. Faults in systems.	Intrinsic logical discipline for AI. Evolving and communicating databases	Negation by failure. Deductive databases
Probabilistic and fuzzy logic	logical analysis of language	Real time systems	Expert systems. Machine learning	Semantics for logic programs
Intuitionistic logic	Quantifiers in logic	Constructive reasoning and proof theory about specification design	Intuitionistic logic is a better logical basis than classical logic	Horn clause logic is really intuitionistic. Extension of logic programming languages
Set theory, higher-order logic, λ-calculus, types	Montague semantics. Situation semantics	Non-well-founded sets	Hereditary finite predicates	λ -calculus extension to logic programs

Imperative vs. declarative languages	Database theory	Complexity theory	Agent theory	Special comments: A look to the future
Temporal logic as a declarative programming language. The changing past in databases. The imperative future	Temporal databases and temporal transactions	Complexity questions of decision procedures of the logics involved	An essential component	Temporal systems are becoming more and more sophisticated and extensively applied
Dynamic logic	Database updates and action logic	Ditto	Possible actions	Multimodal logics are on the rise. Quantification and context becoming very active
Types. Term rewrite systems. Abstract interpretation	Abduction, relevance	Ditto	Agent's implementation rely on proof theory.	
	Inferential databases. Non-monotonic coding of databases	Ditto	Agent's reasoning is non-monotonic	A major area now. Important for formalising practical reasoning
	Fuzzy and probabilistic data	Ditto	Connection with decision theory	Major area now
Semantics for programming languages. Martin-Löf theories	Database transactions. Inductive learning	Ditto	Agents constructive reasoning	Still a major central alternative to classical logic
Semantics for programming languages. Abstract interpretation. Domain recursion theory.		Ditto		More central than ever!

Classical logic. Classical frag- ments	Basic back- ground lan- guage	Program syn- thesis	A basic tool	
Labelled deductive systems	Extremely use- ful in modelling		A unifying framework. Context theory.	Annotated logic programs
Resource and substructural logics	Lambek calcu- lus		Truth maintenance systems	
Fibring and combining logics	Dynamic syn- tax	Modules. Combining languages	Logics of space and time	Combining fea- tures
Fallacy theory				
Logical Dynamics	Widely applied here			
Argumentation theory games		Game seman- tics gaining ground		
Object level/ metalevel			Extensively used in AI	
Mechanisms: Abduction, default relevance			ditto	
Connection with neural nets				
Time-action- revision mod- els			ditto	

	Relational databases	Logical complexity classes	The workhorse of logic	The study of fragments is very active and promising.
	Labelling allows for context and control.		Essential tool.	The new unifying framework for logics
Linear logic			Agents have limited resources	
	Linked databases. Reactive databases		Agents are built up of various fibred mechanisms	The notion of self-fibring allows for self-reference
				Fallacies are really valid modes of reasoning in the right context.
			Potentially applicable	A dynamic view of logic
				On the rise in all areas of applied logic. Promises a great future
			Important feature of agents	Always central in all areas
			Very important for agents	Becoming part of the notion of a logic
				Of great importance to the future. Just starting
			A new theory of logical agent	A new kind of model

DIRK VAN DALEN

INTUITIONISTIC LOGIC

INTRODUCTION

Among these logics that deal with the familiar connectives and quantifiers two stand out as having a solid philosophical–mathematical justification. On the one hand there is a classical logic with its ontological basis and on the other hand intuitionistic logic with its epistemic motivation. The case for other logics is considerably weaker; although one may consider intermediate logics with more or less plausible principles from certain viewpoints none of them is accompanied by a comparably compelling philosophy. For this reason we have mostly paid attention to pure intuitionistic theories.

Since Brouwer, and later Heyting, considered intuitionistic reasoning, intuitionistic logic has grown into a discipline with a considerable scope. The subject has connections with almost all foundational disciplines, and it has rapidly expanded.

The present survey is just a modest cross-section of the presently available material. We have concentrated on a more or less semantic approach at the cost of the proof theoretic features. Although the proof theoretical tradition may be closer to the spirit of intuitionism (with its stress on *proofs*), even a modest treatment of the proof theory of intuitionistic logic would be beyond the scope of this chapter. The reader will find ample information on this particular subject in the papers of, e.g. Prawitz and Troelstra.

For the same reason we have refrained from going into the connection between recursion theory and intuitionistic logic. Section 8 provides a brief introduction to realizability.

Intuitionistic logic is, technically speaking, just a subsystem of classical logic; the matter changes, however, in higher-order logic and in mathematical theories. In those cases specific intuitionistic principles come into play, e.g. in the theory of choice sequences the meaning of the prefix $\forall\xi\exists x$ derives from the nature of the mathematical objects concerned. Topics of the above kind are dealt with in Section 9.

The last sections touch on the recent developments in the area of categorical logic. We do not mention categories but consider a very special case. There has been an enormous proliferation in the semantics of intuitionistic second-order and higher-order theories. The philosophical relevance is quite often absent so that we have not paid attention to the extensive literature on independence results. For the same reason we have not incorporated the intuitionistic ZF-like systems.

Intuitionistic logic can be arrived at in many ways—e.g. physicalistic or materialistic—we have chosen to stick to the intuitionistic tradition in considering mathematics and logic as based on human mental activities. Not surprisingly, intuitionistic logic plays a role in constructive theories that do not share the basic principles of intuitionism, e.g. Bishop’s constructive mathematics. There was no room to go into the foundations of these alternatives to intuitionism. In particular we had to leave out Feferman’s powerful and elegant formalisations of operations and classes. The reader is referred to Beeson [1985] and Troelstra and van Dalen [1988] for this and related topics.

We are indebted for discussions and comments to C.P.J. Koymans, A.S. Troelstra and A. Visser.

1 A SHORT HISTORY

Intuitionism was conceived by Brouwer in the early part of the twentieth century when logic was still in its infancy. Hence we must view Brouwer’s attitude towards logic in the light of a rather crude form of theoretical logic. It is probably a sound conjecture that he never read Frege’s fundamental expositions and that he even avoided Whitehead and Russell’s *Principia Mathematica*. Frege was at the time mainly known in mathematical circles for his polemics with Hilbert and others, and one could do without the *Principia Mathematica* by reading the fundamental papers in the journals. Taking into account the limited amount of specialised knowledge Brouwer had of logic, one might well be surprised to find an astute appraisal of the role of logic in Brouwer’s Dissertation [Brouwer, 1907]. Contrary to most traditional views, Brouwer claims that logic does not precede mathematics, but, conversely, that logic depends on mathematics. The apparent contradiction with the existing practice of establishing strings of ‘logical’ steps in mathematical reasoning, is explained by pointing out that each of these steps represents a sequence of mathematical constructions. The logic, so to speak, is what remains if one takes away the specific mathematical constructions that lead from one stage of insight to the next.

Here it is essential to make a short excursion into the mathematical and scientific views that Brouwer held and that are peculiar to intuitionism. Mathematics, according to Brouwer, is a mental activity, sometimes described by him as the exact part of human thought. In particular, mathematical objects are mental constructions, and properties of these objects are established by, again, mental constructions. Hence, in this view, something holds for a person if he has a construction (or proof) that establishes it. Language does not play a role in this process but may be (and in practice: is) introduced for reasons of communication. ‘People try by means of sounds and symbols to originate in other copies of mathematical constructions and

reasonings which they have made themselves; by the same means they try to aid their own memory. In this way *mathematical language* comes into being, and as its special case *the language of logical reasoning*. The next step taken by man is to consider the language of logical reasoning mathematically, i.e. to study its mathematical properties. This is the birth of *theoretical logic*.

Brouwer's criticism of logic is two-fold. In the first place, logicians are blamed for giving logic precedence over mathematics, and in the second place, logic is said to be unreliable (Brouwer [1907; 1908]). In particular, Brouwer singled out the *principle of the excluded third* as incorrect and unjustified. The criticism of this principle is coupled to the criticism of Hilbert's famous dictum that 'each particular mathematical problem can be solved in the sense that the question under consideration can either be affirmed, or refuted' [Brouwer, 1975, pp. 101 and 109].

Let us, by way of example, consider Goldbach's Conjecture, G , which states that each even number is the sum of two odd primes. A quick check tells us that for small numbers the conjecture is borne out: $12 = 5 + 7$, $26 = 13 + 13$, $62 = 3 + 59$, $300 = 149 + 151$. Since we cannot perform an infinite search, this simple method of checking can at best provide, with luck, a counter example, but not a proof of the conjecture. At the present stage of mathematical knowledge no proof of Goldbach's conjecture, or of its negation, has been provided. So can we affirm $G \vee \neg G$? If so, we should have a construction that would decide which of the two alternatives holds and provide a proof for it. Clearly we are in no position to exhibit such a construction, hence we have no grounds for accepting $G \vee \neg G$ as correct.

The undue attention paid to the principle of the excluded third, had the unfortunate historical consequence that the issues of the foundational dispute between the Formalists and the Intuitionists were obscured. An outsider might easily think that the matter was a dispute of two schools—one with, and one without, the *principle of the excluded third* (or *middle*), PEM for short. Brouwer himself was in no small degree the originator of the misunderstanding by choosing the far too modest and misleading title of 'Begründung der Mengenlehre unabhängig vom logischen Satz vom ausgeschlossenen Dritten' for his first fundamental paper on intuitionistic mathematics. For the philosophical-mystical background of Brouwer's views, see [van Dalen, 1999a]; a foundational exposition can be found in [van Dalen, 2000].

The logic of intuitionism was not elaborated by Brouwer, although he proved its first theorem: $\neg\varphi \leftrightarrow \neg\neg\neg\varphi$.

The first mathematicians to consider the logic of intuitionism in a more formal way were Glivenko and Kolmogorov.

The first presented a fragment of propositional logic and the second a fragment of predicate logic. In 1928 Heyting independently formalised intuitionist predicate logic and the fundamental theories of arithmetic and 'set

theory' [Heyting, 1930]. For historical details, cf. Troelstra [1978; 1981]. Heyting's formalization opened up a new field to adventurous logicians, but it did not provide a 'standard' or 'intended' interpretation, thus lacking the inner coherence of a conceptual explanation. In a couple of papers (cf. [Heyting, 1934]), Heyting presented from 1931 on the interpretation that we have come to call the *proof-interpretation* (cf. [Heyting, 1956, Chapter VII]). The underlying idea traces back to Brouwer: the truth of a mathematical statement is established by a proof, hence the meaning of the logical connective has to be explained in terms of proofs and constructions (recall that a proof is a kind of construction). Let us consider one connective, by way of example: A proof of $\varphi \rightarrow \psi$ is a construction which converts any proof of φ into a proof of ψ .

Note that this definition is in accord with the conception of mathematics (and hence logic) as a mental constructive activity. Moreover it does not require statements to be bivalent, i.e. to be either true or false. For example, $\varphi \rightarrow \varphi$ is true independent of our knowledge of the truth of φ . The proof-interpretation provided at least an informal insight into the mysteries of intuitionistic truth, but it lacked the formal clarity of the notion of truth in classical logic with its completeness property.

An analogue of the classical notion of truth value was discovered by Tarski, Stone and others who had observed the similarities between intuitionistic logic and the closure operation of topology (cf. [Rasiowa and Sikorski, 1963]). This so-called *topological interpretation* of intuitionistic logic also covers a number of interpretations that at first sight might seem to be totally devoid of topological features. Among these are the lattice (like) interpretations of Jaskowski, Rieger and others, but also the more recent interpretations of Beth and Kripke. All these interpretations are grouped together as semantical interpretations, in contrast to interpretations that are based on algorithms, one way or another.

A breakthrough in intuitionistic logic was accomplished by Gentzen in 1934 in his system of *Natural Deduction* (and also his *calculus of sequents*), which embodied the meaning of the intuitionistic connectives far more accurately than the existing Hilbert-type formalizations. The eventual recognition of Gentzen's insights is to a large extent due to the efforts of Prawitz who reintroduced Natural Deduction, and considerably extended Gentzen's work [1965; 1971].

In the beginning of the thirties the first meta-logical results about intuitionistic logic and its relation to existing logics appeared. Gödel, and independently Gentzen, formulated a translation of classical predicate logic into a fragment of intuitionistic predicate logic, thus extending early work of Glivenko [Glivenko, 1929; Gentzen, 1933; Gödel, 1932].

Gödel also established the connection between the modal logic **S4** and intuitionistic logic [Gödel, 1932].

The period after the Second World War brought new researchers to intuitionistic logic and mathematics. In particular Kleene, who based an ‘effective’ interpretation of intuitionistic arithmetic on the notion of recursive function. His interpretation is known as *realizability* (Kleene [1952; 1973]). In 1956 Beth introduced a new semantic interpretation with a better foundational motivation than the earlier topological interpretations, and Kripke presented a similar, but more convenient interpretation in 1963 [Kripke, 1965]. These new semantics showed more flexibility than the earlier interpretations and lent themselves better to the model theory of concrete theories. General model theory in the lattice and topological tradition had already been undertaken by the Polish school (cf. [Rasiowa and Sikorski, 1963]).

In the meantime Gödel had presented his Dialectica Interpretation [1958], which like Kleene’s realizability, belongs to the algorithmic type of interpretations. Both the realizability and the Dialectica Interpretation have shown to be extremely fruitful for the purpose of Proof Theory.

Another branch at the tree of semantic interpretations appeared fairly recently, when it was discovered that sheaves and topoi present a generalisation of the topological interpretations [Goldblatt, 1979; Troelstra and van Dalen, 1988].

The role of a formal semantics will be expounded in Section 3. Its most obvious and immediate use is the establishing of underivability results in a logical calculus. However, even before a satisfactory semantics was discovered, intuitionists used to show that certain classical theorems were not valid by straightforward intuitive methods. We will illustrate the naive approach for two reasons. In the first place it is direct and the first thing one would think of, in the second place it has its counterparts in formal semantics and can be useful as a heuristics.

The traditional counterexamples are usually formulated in terms of a particular unsolved problem. The problem in the following example goes back to Brouwer. Consider the decimal expansion of $\pi : 3,14\dots$, hardly anything is known about regularities in this expansion, e.g. it is not known if it contains a sequence of 9 nines. Let $A(n)$ be the statement ‘the n th decimal of π is a nine and it is preceded by 8 nines’.

1. The principle of the excluded third is not valid.
Suppose $\exists xA(x) \vee \neg\exists xA(x)$, then we would have a proof that either provides us with a natural number n such that $A(n)$, or that shows us that no such n exists. Since there is no such evidence available we cannot accept the principle of the excluded third.
2. The double negation principle is not valid. Observe that $\neg\neg(\exists xA(x) \vee \neg\exists xA(x))$ holds. In general the double negation of the principle of the excluded third holds, since $\neg\neg(\varphi \vee \neg\varphi)$ is equivalent to $\neg(\neg\varphi \wedge \neg\neg\varphi)$ and the latter is correct on the intuitive interpretations.

Since $\exists xA(x) \vee \neg\exists xA(x)$ does not hold, we see that $\neg\neg\varphi \rightarrow \varphi$ is not valid.

3. One version of De Morgan's Law fails.

The suspect case is $\neg(\varphi \wedge \psi) \rightarrow \neg\varphi \vee \neg\psi$, since its conclusion is strong and its premise is weak. Consider $\neg(\neg\exists xA(x) \wedge \exists xA(x)) \rightarrow \neg\neg\exists xA(x) \vee \neg\exists xA(x)$. The premise is true, but the conclusion cannot be asserted, since we do not know if it is impossible that there is no sequence of 9 nines or it is impossible that there is such a sequence.

Counterexamples of the above kind show that our present state of knowledge does not permit us to affirm certain logical statements that are classically true. They represent evidence of implausibility, all the same it is not the strongest possible result. Of course we cannot expect to establish the negation of the principle of the excluded third because that is a downright contradiction. By means of certain strong intuitionistic, or alternatively algorithmic, principles one can establish a strongly non-classical theorem like $\neg\forall x(\varphi(x) \vee \neg\varphi(x))$ for a suitable $\varphi(x)$.

We will now present an informal version of the proof interpretation. For convenience we will suppose that the variables of our language range over natural numbers. This is not strictly necessary, but it suffices to illustrate the working of the interpretation. Recall that we understand the primitive notion 'a is a proof of φ ', where a proof is a particular kind of (mental) construction. We will now proceed to explain what it means to have a proof of a non-atomic formula φ in terms of proofs of its components.

- (i) a is a proof of $\varphi \wedge \psi$ iff a is a pair (a_1, a_2) such that a_1 is a proof of φ and a_2 is a proof of ψ .
- (ii) a is a proof of $\varphi \vee \psi$ iff a is a pair (a_1, a_2) such that $a_1 = 0$ and a_2 is a proof of φ or $a_1 = 1$ and a_2 is a proof of ψ .
- (iii) a is a proof of $\varphi \rightarrow \psi$ iff a is a construction that converts each proof b of φ into a proof $a(b)$ of ψ .
- (iv) nothing is a proof of \perp (falsity).
- (v) a is a proof of $\exists x\varphi(x)$ iff a is a pair (a_1, a_2) such that a_1 is a proof of $\varphi(a_2)$.
- (vi) a is a proof of $\forall x\varphi(x)$ iff a is a construction such that for each natural number n , $a(n)$ is a proof of $\varphi(\bar{n})$.

Note that intuitionists consider $\neg\varphi$ as an abbreviation for $\varphi \rightarrow \perp$. The clause that a trained logician will immediately look for is the one dealing with the atomic case. We cannot provide a definition for that case since it

must essentially depend on the specific theory under consideration. In the case of ordinary arithmetic the matter is not terribly important as the closed atoms are decidable statements of the form $5 = 7 + 6$, $23.16 = 5(3 + 2.8)$, etc. We can ‘start’ the definition in a suitable fashion.

REMARK. If one wishes to preserve the feature that from a proof one can read off the result, then some extra care has to be taken, e.g. according to clause (iii) $(0, p)$ proves $\varphi \vee \psi$ for all possible ψ , where φ is a proof of φ . One may beef up the ‘proof’ by adding the disjunction to it: replace $(0, p)$ by $(0, p, \varphi \vee \psi)$, etc.

The above version is due to Heyting (cf. [Heyting, 1956; Troelstra, 1981]). Refinements have been added by Kreisel for the clauses involving the implication and universal quantification [Kreisel, 1965]. His argument being: the definition contains a part that is not immediately seen to be of the ultimate simple and lucid form we wish it to be. In particular one could ask oneself ‘does this alleged construction do what it purports to do?’ For this reason Kreisel modified clause (iii) as follows: a is a proof of $\varphi \rightarrow \psi$ iff a is a pair (a_1, a_2) such that a_1 is a construction that converts any proof b of φ into a proof $a_1(b)$ of ψ , and a_2 is a proof of the latter fact. A similar modification is provided for (vi). The situation is akin to that of the correctness of computer programs. In particular we use Kreisel’s clause if we want the relation ‘ a is a proof of φ ’ to be decidable. Clauses (iii) and (vi) clearly do not preserve decidability, moreover they do not yield ‘logic free’ conditions.

It must be pointed out however that the decidability of the proof-relations has been criticised and that the ‘extra clauses’ are not universally accepted.

Sundholm [1983] contains a critical analysis of the various presentations of the ‘proof interpretation’. In summing up the views of Brouwer, Heyting and Kreisel, he notes a certain confusion in terminology. In particular he points out that constructions (in particular proofs) can be viewed as *processes* and differ from the resulting construction-object. The latter is a mathematical object, and can be operated upon, not so the former. The judgements at the right-hand side, explaining the meaning of the logical constants, are taken by Kreisel to be mathematical objects, a procedure that is objected to by Sundholm. indeed, on viewing the judgement ‘ a converts each proof of φ into a proof of ψ ’ as extra-mathematical, the need for a second clause disappears.

In Beeson [1979] a theory of constructions and proofs is presented violating the decidability of the proof relation. Troelstra and Diller [1982] study the relation between the proof interpretation and Martin-Löf’s type theory.

The proofs inductively defined above are called *canonical* by Martin-Löf, Prawitz and others. Of course there are also non-canonical proofs, and some of them are preferable to canonical ones. Consider, e.g. $10^{11} + 11^{10} = 11^{10} + 10^{11}$ in arithmetic. One knows how to get a canonical proof: by simply carrying out the addition according to the basic rules $(x + 0 = x$

and $x + Sy = S(x + y)$, where S is the successor function). An obvious non-canonical (and shorter) proof would be: first show $\forall xy(x + y = y + x)$ by mathematical induction and then specialise.

We will now proceed to illustrate the rules in use.

$$(1) \quad (\varphi \wedge \psi \rightarrow \sigma) \rightarrow (\varphi \rightarrow (\psi \rightarrow \sigma)).$$

Let a be a proof of $\varphi \wedge \psi \rightarrow \sigma$, i.e. a is a construction that converts any proof (b, c) of $\varphi \wedge \psi$ into a proof $a((b, c))$ of σ . We want a proof of $\varphi \rightarrow (\psi \rightarrow \sigma)$. So let p be a proof of φ and q a proof of ψ .

Define a construction k such that $k(p)$ is a proof of $\psi \rightarrow \sigma$, i.e. $(k(p))(q)$ is a proof of σ . Evidently we should put $(k(p))(q) = a((p, q))$; so, using the functional abstraction operator, $k(p) = \lambda q.a((p, q))$ and $k = \lambda p.\lambda q.a((p, q))$. The required proof is a construction that carries a into k , i.e. $\lambda apq.a((p, q))$.

$$(2) \quad \neg(\varphi \vee \psi) \rightarrow (\neg\varphi \wedge \neg\psi).$$

Let a be a proof of $\neg(\varphi \vee \psi)$, a construction that carries a proof of $\varphi \vee \psi$ into a proof of \perp . Suppose now that p is a proof of φ , then $(0, p)$ is a proof of $\varphi \vee \psi$, and hence $a((0, p))$ is a proof of \perp . So $\lambda p.a((0, p))$ is a proof of $\neg\varphi$. Likewise $\lambda q.a((1, q))$ is a proof of $\neg\psi$. By definition $(\lambda p.a((0, p)), \lambda q.a((1, q)))$ is a proof of $\neg\varphi \wedge \neg\psi$. So the construction that carries a into $(\lambda p.a((0, p)), \lambda q.a((1, q)))$, i.e. $\lambda a.(\lambda p.a((0, p)), \lambda q.a((1, q)))$, is the required proof.

$$(3) \quad \exists x\neg\varphi(x) \rightarrow \neg\forall x\varphi(x).$$

Let (a_1, a_2) be a proof of $\exists x\neg\varphi(x)$, i.e. a_1 is a proof of $\varphi(\bar{a}_2) \rightarrow \perp$. Suppose p is a proof of $\forall x\varphi(x)$, then in particular $p(a_2)$ is a proof of $\varphi(\bar{a}_2)$, and hence $a_1(p(a_2))$ is a proof of \perp . So $\lambda p.a_1(p(a_2))$ is a proof of $\neg\forall x\varphi(x)$. Therefore $\lambda(a_1, a_2)\lambda p.a_1(p(a_2))$ is the required proof.

The history of intuitionistic logic is not as stirring as the history of intuitionism itself. The logic itself was not controversial, Heyting's formalization showed it to be a subsystem of classical logic. Moreover, it convinced logicians that there was a coherent notion of 'constructive reasoning'. In the following sections we will show some of the rich structure of this logic. One problem in intuitionistic logical theories is how to codify and exploit typically intuitionistic principles. These are to be found in particular in the second-order theories where the concepts of set (species) and function play a role.

Despite Brouwer's scorn for logic, some of the finer distinctions that are common today were introduced by him. In his thesis we can already find the fully understood notions of language, logic, metalanguage, metalogic, etc. (cf. Brouwer [1907; 1975]).

The Brouwer–Hilbert controversy seems from our present viewpoint to be one of those deplorable misunderstandings. Hilbert wanted to justify by

metamathematical means the mathematics of infinity with all its idealizations. He considered mathematics as based on the bedrock of its finitistic part, which is just a very concrete part of intuitionistic mathematics. The latter transcends finitism by its introduction of abstract notions, such as *set* and *sequence*.

2 PROPOSITIONAL AND PREDICATE LOGIC

The syntax of intuitionistic logic is identical to that of classical logic (cf. Wilfrid Hodges' chapter in Volume 1 of this *Handbook*). As in classical logic, we have the choice between a formalisation in a Hilbert-type system or in a Gentzen-type system. Heyting's original formalisation used the first kind. We will exhibit a Hilbert-type system first.

2.1 An Axiom System for Intuitionistic Logic

Axioms

1. $\varphi \rightarrow (\psi \rightarrow \varphi)$
2. $(\varphi \rightarrow \psi) \rightarrow ((\varphi \rightarrow (\psi \rightarrow \sigma)) \rightarrow (\varphi \rightarrow \sigma))$
3. $\varphi \rightarrow (\psi \rightarrow \varphi \wedge \psi)$
4. $\varphi \wedge \psi \rightarrow \varphi \quad \varphi \wedge \psi \rightarrow \psi$
5. $\varphi \rightarrow \varphi \vee \psi \quad \psi \rightarrow \varphi \vee \psi$
6. $(\varphi \rightarrow \sigma) \rightarrow ((\psi \rightarrow \sigma) \rightarrow (\varphi \vee \psi \rightarrow \sigma))$
7. $(\varphi \rightarrow \psi) \rightarrow ((\varphi \rightarrow \neg\psi) \rightarrow \neg\varphi)$
8. $\varphi(t) \rightarrow \exists x\varphi(x)$
9. $\forall x\varphi(x) \rightarrow \varphi(t)$
10. $\varphi \rightarrow (\neg\varphi \rightarrow \psi)$

Rules

Modus Ponens

$$\frac{\varphi \quad \varphi \rightarrow \psi}{\psi}$$

Quantifier rules

$$\frac{\varphi \rightarrow \psi(x)}{\varphi \rightarrow \forall x\psi(x)}$$

$$\frac{\varphi(x) \rightarrow \psi}{\exists x\varphi(x) \rightarrow \psi}$$

The quantifier axioms and rules are subject to the usual variable conditions: t is free for x and x does not occur free in ψ .

The deducibility relation, \vdash , is defined as in Hodges' chapter (Vol. 1) of the *Handbook*. As in classical logic, we have the *Deduction theorem*:

$$\psi_1, \dots, \psi_n \vdash \varphi \Leftrightarrow \psi_1, \dots, \psi_{n-1} \vdash \psi_n \rightarrow \varphi.$$

If we add to the axioms the principle of the excluded third, $\varphi \vee \neg\varphi$, or the double negation principle, $\neg\neg\varphi \rightarrow \varphi$, we obtain the familiar classical logic.

We should note that the axioms contain all connectives, and not, as in classical logic, just \vee , \neg and \exists (or whatever your favourite choice may be). The reason is that the definability of the connectives in terms of some of them (Hodges Chapter in Volume 1 of this *Handbook*) fails, as we will see later.

Since intuitionistic logic is more of an epistemic than of an ontological nature, we will study it mainly by means of Gentzen's Natural Deduction, as this latter system reflects the specific constructive reasoning of the intuitionist best.

This particular system has only rules and no axioms. The simplest rules have the form $\frac{\dots}{\varphi}$, and are to be read as φ follows (immediately) from the premises above the line. Some of the rules, however, involve manipulations with the so-called *assumptions*. The prime example is the rule that corresponds to the deduction theorem in Hilbert-type systems. Suppose we can derive ψ by means of a derivation \mathcal{D} from a number of assumptions among which is a formula φ , then we can derive $\varphi \rightarrow \psi$ from the mentioned assumptions *without* φ . We denote this by

$$\frac{\begin{array}{c} [\varphi] \\ \mathcal{D} \\ \psi \end{array}}{\varphi \rightarrow \psi}$$

we say that the assumption φ is *cancelled*, this is indicated by the use of square brackets.

It appears to be convenient to employ a choice of connectives that includes \perp and excludes \neg . Of course $\neg\varphi$ can be introduced as an abbreviation for $\varphi \rightarrow \perp$. We will also use the traditional abbreviation $\varphi \leftrightarrow \psi$.

The rules come in two kinds, *Introduction rules* and *Elimination rules*.

<i>Introduction rules</i>	<i>Elimination rules</i>
$\wedge I$ $\frac{\varphi \quad \psi}{\varphi \wedge \psi}$	$\wedge E$ $\frac{\varphi \wedge \psi}{\varphi} \quad \frac{\varphi \wedge \psi}{\psi}$
$\vee I$ $\frac{\varphi}{\varphi \vee \psi} \quad \frac{\psi}{\varphi \vee \psi}$	$\vee E$ $\frac{\begin{array}{c} [\varphi] \\ \mathcal{D}_1 \end{array} \quad \begin{array}{c} [\psi] \\ \mathcal{D}_2 \end{array}}{\varphi \vee \psi} \quad \frac{\sigma \quad \sigma}{\sigma}$
$\rightarrow I$ $\frac{\begin{array}{c} [\varphi] \\ \mathcal{D} \\ \psi \end{array}}{\varphi \rightarrow \psi}$	$\rightarrow E$ $\frac{\varphi \quad \varphi \rightarrow \psi}{\psi}$
$\forall I$ $\frac{\varphi(x)}{\forall x\varphi(x)}$	$\forall E$ $\frac{\forall x\varphi(x)}{\varphi(t)}$
$\exists I$ $\frac{\varphi(t)}{\exists x\varphi(x)}$	$\exists E$ $\frac{\begin{array}{c} [\varphi(y)] \\ \mathcal{D} \end{array} \quad \sigma}{\exists x \quad \sigma}$
	\perp $\frac{\perp}{\varphi}$

For the quantifier rules we have to add a few conditions: in the rules $\exists I$ and $\forall E$, t has to be ‘free for x ’. An application of $\forall I$ is allowed only if the variable x does not occur in any of the assumptions in the derivation of $\varphi(x)$. Similarly the free variable y in the cancelled formula $\varphi(y)$ may not occur free in σ or any of the assumptions in the right-hand derivation of σ (in $\exists E$).

The rules of Gentzen’s system of Natural Deduction are intended to represent the meaning of connectives as faithfully as possible (cf. [Gentzen, 1935] or [Szabo, 1969, p. 74]). Gentzen’s goals have recently been made more precise in [Dummett, 1973] and [Prawitz, 1977]. We will set ourselves a specific goal by showing that the natural deduction rules are in accordance with the meaning of the logical connectives as put forward in Heyting’s proof interpretation.

We will consider a few representative cases.

$$\wedge I : \frac{\varphi_1 \quad \varphi_2}{\varphi_1 \wedge \varphi_2}.$$

Let proofs p_i of φ_i be given. Then we can form the ordered pair (p_1, p_2) which is a proof of $\varphi_1 \wedge \varphi_2$. This is the step that, given canonical proofs of the conjuncts, provides the canonical proof of the conjunction.

$$\wedge E : \frac{\varphi_1 \wedge \varphi_2}{\varphi_i}.$$

Given a canonical proof p of $\varphi_1 \wedge \varphi_2$, we know that it must be an ordered pair (p_1, p_2) . The projection π_i yields the required canonical proof of φ_i .

$$\rightarrow I : \frac{\begin{array}{c} [\varphi] \\ \mathcal{D} \\ \psi \end{array}}{\varphi \rightarrow \psi}.$$

Suppose that we have a proof of ψ under a number of assumptions, including φ . Then this proof, when supplemented by a proof of φ yields a proof of ψ , i.e. we have a construction that transforms any proof of φ into a proof of ψ , but that means that we have a proof of $\varphi \rightarrow \psi$.

$$\forall I : \frac{\varphi(x)}{\forall x \varphi(x)}.$$

Suppose that we have a proof of $\varphi(x)$, i.e. a proof schema, that for each instance $\varphi(n)$ of $\varphi(x)$ yields a proof of it. Since x does not occur in the assumptions, the proof is uniform in x , i.e. it is a method for converting n into a proof of $\varphi(n)$. Again we have found a proof of $\forall x \varphi(x)$, along the lines of Heyting's interpretation.

The reader will now be able to continue this line of argument. We will only dwell for a moment on the *ex falso* rule.

$$\perp : \frac{\perp}{\varphi}.$$

The justification in terms of constructions is not universally accepted, e.g. [Johansson, 1936] rejected the rule and formulated his so-called minimal logic, which has the same rules as intuitionistic logic with deletion of the *ex falso* rule.

Now, \perp has, in the intuitionistic conception, no proof. What we have to provide is a construction that automatically yields for every proof of \perp a

proof of φ . Nothing is simpler; take for example the identity construction $i : p \mapsto p$, i promises to give a proof of φ as output as soon as it gets a proof of \perp as input. Obviously, i keeps its promise because it is never asked to fulfill it.

Note that there is an alternative way of looking at the Natural Deduction system, we could consider it as a concrete illustration of Heyting's proof interpretation. For instance, the actual formal derivations *are* the proofs and/or constructions. In that sense they realized Heyting's clauses.

Let us, by way of illustration, make a few derivations.

1. $(\varphi \rightarrow \psi) \rightarrow ((\psi \rightarrow \sigma) \rightarrow \varphi \rightarrow \sigma)$

$$\begin{array}{c}
 \frac{{}^1[\varphi] \quad [\varphi \rightarrow \psi]^3}{\psi \quad [\psi \rightarrow \sigma]^2} \rightarrow E \\
 \frac{\sigma}{\varphi \rightarrow \sigma} \rightarrow I \\
 (1) \quad \frac{\sigma}{\varphi \rightarrow \sigma} \rightarrow I \\
 (2) \quad \frac{\quad}{(\psi \rightarrow \sigma) \rightarrow (\varphi \rightarrow \sigma)} \rightarrow I \\
 (3) \quad \frac{(\psi \rightarrow \sigma) \rightarrow (\varphi \rightarrow \sigma)}{(\varphi \rightarrow \psi) \rightarrow ((\psi \rightarrow \sigma) \rightarrow (\varphi \rightarrow \sigma))} \rightarrow I
 \end{array}$$

2. By substitution of \perp for σ we obtain the law of contraposition $(\varphi \rightarrow \psi) \rightarrow (\neg\psi \rightarrow \neg\varphi)$.

3. $\varphi \rightarrow \neg\neg\varphi$

$$\begin{array}{c}
 \frac{{}^1[\neg\varphi] \quad [\varphi]^2}{\perp} \rightarrow E \quad (\text{recall that } \neg\varphi \text{ stands for } \varphi \rightarrow \perp) \\
 (1) \quad \frac{\perp}{\neg\neg\varphi} \\
 (2) \quad \frac{\quad}{\varphi \rightarrow \neg\neg\varphi} \rightarrow I
 \end{array}$$

4. $\neg\neg\neg\varphi \rightarrow \neg\varphi$

$$\begin{array}{c}
 \frac{{}^1[\neg\varphi] \quad [\varphi]^2}{\perp} \\
 (1) \quad \frac{\perp}{\neg\neg\neg\varphi} \quad [\neg\neg\neg\varphi]^3 \\
 (2) \quad \frac{\perp}{\neg\varphi} \\
 (3) \quad \frac{\quad}{\neg\neg\neg\varphi \rightarrow \neg\varphi}
 \end{array}$$

5. From 3. we get $\neg\varphi \rightarrow \neg\neg\neg\varphi$, combining this with 4. we have $\neg\varphi \leftrightarrow \neg\neg\neg\varphi$.
6. $\neg\neg\forall x\varphi(x) \rightarrow \forall x\neg\neg\varphi(x)$

$$\frac{\frac{^1[\forall x\varphi(x)]}{\varphi(x)} \quad [\neg\varphi(x)]^2}{\perp}$$

$$(1) \frac{\perp}{\neg\neg\forall x\varphi(x) \quad [\neg\neg\forall x\varphi(x)]^3}$$

$$(2) \frac{\perp}{\neg\neg\varphi(x)}$$

$$(3) \frac{\forall x\neg\neg\varphi(x)}{\neg\neg\forall x\varphi(x) \rightarrow \forall x\neg\neg\varphi(x)}$$

7. $\neg(\varphi \vee \psi) \leftrightarrow (\neg\varphi \wedge \neg\psi)$

$$\frac{\frac{[\varphi]^1}{\varphi \vee \psi} \quad [\neg(\varphi \vee \psi)]^3}{\neg\varphi} \quad \frac{\frac{[\psi]^2}{\varphi \vee \psi} \quad [\neg(\varphi \vee \psi)]^3}{\neg\psi}$$

$$(1) \quad (2)$$

$$(3) \frac{\neg\varphi \wedge \neg\psi}{\neg(\varphi \vee \psi) \rightarrow \neg\varphi \wedge \neg\psi}$$

The arrow from right to left is trivial.

8. $\varphi \vee \neg\varphi$ and $\neg\neg\varphi \rightarrow \varphi$ are equivalent as schema's, i.e. all instances of PEM follow from all instances of the double negation principle and vice versa. We will consider one direction. the proof requires a number of derivations, each of which is simple.

(a) $\vdash \neg\neg(\varphi \vee \neg\varphi)$ (use (7))

$$(b) \frac{\neg\neg(\varphi \vee \neg\varphi) \rightarrow (\varphi \vee \neg\varphi) \quad \mathcal{D}}{\varphi \vee \neg\varphi} \quad \frac{\mathcal{D}}{\neg\neg(\varphi \vee \neg\varphi)}$$

where \mathcal{D} is a derivation obtained in (a).

The other direction is left to the reader.

The following list of provable statements will come in handy (relevant variables are shown)

1. $\varphi \rightarrow \neg\neg\varphi$
2. $\neg\varphi \leftrightarrow \neg\neg\neg\varphi$
3. $\neg(\varphi \wedge \neg\varphi)$

4. $\neg\neg(\varphi \vee \neg\varphi)$
5. $\neg(\varphi \vee \psi) \leftrightarrow \neg\varphi \wedge \neg\psi$
6. $(\varphi \vee \neg\varphi) \rightarrow (\neg\neg\varphi \rightarrow \varphi)$
7. $(\varphi \rightarrow \psi) \rightarrow \neg(\varphi \wedge \neg\psi)$
8. $(\varphi \rightarrow \neg\psi) \leftrightarrow \neg(\varphi \wedge \psi)$
9. $(\neg\neg\varphi \wedge \neg\neg\psi) \leftrightarrow \neg\neg(\varphi \wedge \psi)$
10. $(\neg\neg\varphi \rightarrow \neg\neg\psi) \leftrightarrow \neg\neg(\varphi \rightarrow \psi)$
11. $(\neg\neg\varphi \rightarrow \psi) \rightarrow (\neg\psi \rightarrow \neg\varphi)$
12. $\exists x\neg\varphi(x) \rightarrow \neg\forall x\varphi(x)$
13. $\neg\exists x\varphi(x) \leftrightarrow \forall x\neg\varphi(x)$
14. $\varphi \vee \forall x\psi(x) \rightarrow \forall x(\varphi \vee \psi(x))$
15. $\forall x(\varphi \rightarrow \psi(x)) \leftrightarrow (\varphi \rightarrow \forall x\psi(x))$
16. $\forall x(\varphi(x) \rightarrow \psi) \leftrightarrow (\exists\varphi(x) \rightarrow \psi)$
17. $\exists x(\varphi \rightarrow \psi(x)) \rightarrow (\varphi \rightarrow \exists x\psi(x))$
18. $\neg\neg\forall x\varphi(x) \rightarrow \forall x\neg\neg\varphi(x)$.

Furthermore, conjunction and disjunction have the familiar associative, commutative and distributive properties.

For counterexamples to invalid propositions and sentences see Section 3.11.

The systems of intuitionistic *propositional* and *predicate* (or *quantificational*) logic are, without consideration of their formalisations, denoted by **IPC** and **IQC**.

Derivability will pedantically be denoted by $\Gamma \vdash_{\text{IPC}} \varphi$ (resp. $\Gamma \vdash_{\text{IQC}} \varphi$), or **IPC** $\vdash \varphi$ (resp. **IQC** $\vdash \varphi$), for empty Γ . When no confusion arises, we will however delete the subscripts. The derivations are in tree form, but one can easily represent them in linear form (cf. [Prawitz, 1965, p. 89 ff]). The present form, however, is more suggestive and since there is nothing sacrosanct about linearity we will stick to Gentzen's notation.

There is, nonetheless, a good reason for a more complete notation that makes the cancellation of assumptions explicit.

As usual, we write $\Gamma \vdash \varphi$ for 'there is a derivation of φ from uncanceled assumptions that belong to the set Γ '. The rules of natural deduction can be formulated in terms of \vdash . For convenience we write $\Gamma, \varphi_1, \dots, \varphi_n$ for $\Gamma \cup \{\varphi_1, \dots, \varphi_n\}$ and Γ, Δ for $\Gamma \cup \Delta$.

The following facts follow immediately from our rules:

1. $\Gamma \vdash \varphi$ if $\varphi \in \Gamma$
2. $\Gamma \vdash \varphi$ and $\Delta \vdash \psi \Rightarrow \Gamma, \Delta \vdash \varphi \wedge \psi$
3. $\Gamma \vdash \varphi \wedge \psi \Rightarrow \Gamma \vdash \varphi$
 $\Gamma \vdash \varphi \wedge \psi \Rightarrow \Gamma \vdash \psi$
4. $\Gamma \vdash \varphi \Rightarrow \Gamma \vdash \varphi \vee \psi$
 $\Gamma \vdash \psi \Rightarrow \Gamma \vdash \varphi \vee \psi$
5. $\Gamma \vdash \varphi \vee \psi$ and $\Delta, \varphi \vdash \sigma$ and $\Delta', \psi \vdash \sigma \Rightarrow \Gamma, \Delta, \Delta' \vdash \sigma$
6. $\Gamma, \varphi \vdash \psi \Rightarrow \Gamma \vdash \varphi \rightarrow \psi$
7. $\Gamma \vdash \varphi$ and $\Delta \vdash \varphi \rightarrow \psi \Rightarrow \Gamma, \Delta \vdash \psi$
8. $\Gamma \vdash \perp \Rightarrow \Gamma \vdash \varphi$
9. $\Gamma \vdash \varphi(x) \Rightarrow \Gamma \vdash \forall x\varphi(x)$, where x is not free in Γ
10. $\Gamma \vdash \forall x\varphi(x) \Rightarrow \Gamma \vdash \varphi(t)$
11. $\Gamma \vdash \varphi(t) \Rightarrow \Gamma \vdash \exists x\varphi(x)$
12. $\Gamma \vdash \exists x\varphi(x)$ and $\Delta, \varphi(y) \vdash \sigma \Rightarrow \Gamma, \Delta \vdash \sigma$, where y is not free in Δ and σ .

The above presentation of natural deduction can be viewed as a kind of sequent calculus, cf. [Troelstra and Schwichtenberg, 1996, §2.1.4]

We can now turn the tables and define $\Gamma \vdash \varphi$ inductively by the preceding clauses. D is the least class of pairs (Γ, φ) (denoted by $\Gamma \vdash \varphi$) such that

$$\begin{aligned}
&\Gamma \vdash \varphi \in D \text{ if } \varphi \in \Gamma \\
&\Gamma \vdash \varphi \in D; \Delta \vdash \psi \in D \Rightarrow \Gamma, \Delta \vdash \varphi \wedge \psi \in D \\
&\quad \vdots \\
&\Gamma \vdash \exists x\varphi(x) \in D; \Delta, \varphi(y) \vdash \sigma \in D \Rightarrow \Gamma, \Delta \vdash \sigma \in D, \\
&\quad \text{where } y \text{ is not free in } \Delta \text{ and } \sigma.
\end{aligned}$$

Observe that a derivation in D corresponds to a derivation in tree form, as presented before. The linearisation of natural deduction derivations that some authors have practised obscures the perspicuity of the derivations and we will stick to the tree form (remember what Frege said about ‘the convenience of the printer’).

EXAMPLE 1. Take the string

$$\begin{aligned}
\varphi, \psi, \sigma \vdash \varphi &\quad (\text{by 1}) \\
\psi, \sigma \vdash \varphi \rightarrow \varphi &\quad (\text{by 6}) \\
\psi \vdash \sigma \rightarrow (\varphi \rightarrow \varphi) &\quad (\text{by 6})
\end{aligned}$$

It shows that $\psi \vdash \sigma \rightarrow (\varphi \rightarrow \varphi)$ and we can recover the derivation in tree form from it:

$$\begin{array}{lcl}
 \text{first derivation} & \varphi & \text{second derivation} \quad \frac{[\varphi]}{\varphi \rightarrow \varphi} \\
 \\
 \text{third derivation} & \frac{[\varphi]}{\varphi \rightarrow \varphi} & \\
 & \frac{\quad}{\sigma \rightarrow (\varphi \rightarrow \varphi)} &
 \end{array}$$

All this calls for some clarification.

1. The matter of cancellation is somewhat delicate, you don't have to cancel *all* occurrences of the relevant formula, not even *any* occurrence. This is made explicit in, e.g. rule 6, $\Gamma, \varphi \vdash \psi \Rightarrow \Gamma \vdash \varphi \rightarrow \psi$. Γ may still contain φ .
2. The tree derivation shows only the assumptions that actually play a role, but in $\Gamma \vdash \varphi$ there may be lots of superfluous assumptions (infinitely many if you wish!).

It is for example quite simple to show, on the basis of the rules 1–12 $\Gamma \vdash \varphi \Rightarrow \Gamma, \Delta \vdash \varphi$.

Natural Deduction, or for that matter its sister system of the *Sequent Calculus*, lends itself well to study derivations for their own sake. This particular branch of logic has in the case of Natural Deduction been rigorously practised and promoted by Dag Prawitz, who established the main facts of the system and who demonstrated its flexibility and usefulness (cf. Prawitz [1965; 1971]).

The fundamental theorem in the subject is concerned with derivations without superfluous parts. The following is evidently awkward.

$$\frac{\frac{\frac{\sigma \quad \sigma \rightarrow \varphi}{\varphi \quad [\psi]} \rightarrow E}{\varphi \wedge \psi} \wedge I}{\varphi} \wedge E}{\psi \rightarrow \varphi} \rightarrow I$$

We have introduced the superfluous conjunction $\varphi \wedge \psi$ only in order to eliminate it again. A more efficient proof is

$$\frac{\frac{\sigma \quad \sigma \rightarrow \varphi}{\varphi} \rightarrow E}{\psi \rightarrow \varphi} \rightarrow I$$

We have eliminated the introduction followed by an elimination, thus simplifying the derivation. A derivation in which an introduction is never followed by an elimination is called *normal*. Here it has to be explained what ‘follow’ means. For this purpose a special partial ordering is introduced; e.g. in $\rightarrow I$ $\varphi \rightarrow \psi$ follows after ψ , in $\forall E$ φ follows after $\varphi \forall \psi$, etc. See [van Dalen, 1997, p. 199,203].

Prawitz proved the

THEOREM 2 (Normal Form Theorem). *If $\Gamma \vdash \varphi$, then there is a normal derivation of φ from Γ (cf. [Prawitz, 1965]).*

There is a better result called the

THEOREM 3 (Normalisation Theorem). *Any derivation reduces to a normal derivation.*

Here a reduction step consists in the removal of a superfluous introduction followed by an elimination (cf. [Prawitz, 1971]).

There is even a still stronger form, the

THEOREM 4 (Strong Normalisation Theorem). *Every sequence of reduction steps terminates in a normal form.*

The whole tradition of normalisation and reduction is traditionally a part of combinatory logic and λ -calculus, a systematic account is given in [Klop, 1980] and [Barendregt, 1984].

There is an interesting interplay between natural deduction derivations and λ -terms, and hence between normalisation in natural deduction and in λ -calculus (cf. [Gallier, 1995; Howard, 1980; Pottinger, 1976; Troelstra and van Dalen, 1988]).

One of the pleasant corollaries of the normal form of a derivation is the

PROPERTY 5 (Subformula property). *In a normal derivation of $\Gamma \vdash \varphi$ only subformulas of Γ and φ occur.*

In particular only connectives from Γ and φ can occur. As a consequence we have

THEOREM 6. *Intuitionistic predicate logic is conservative over intuitionistic propositional logic.*

Proof. Let $\Gamma \vdash \varphi$ where φ is a proposition. Consider a normal derivation π of φ . By the subformula property only propositional connectives can occur, hence we have a derivation using only propositional rules. ■

Natural deduction was given an interesting extension by Schroeder-Heister, [1984]; an exposition and applications can be found in [Negri and von Plato, 2001].

3 PROOF TERMS AND THE CURRY–HOWARD ISOMORPHISM

Since natural deduction is so close in nature to the proof interpretation, it is perhaps not surprising that a formal correspondence between a term calculus and natural deduction can be established.

We will first demonstrate this for a small fragment, containing only the connective ‘ \rightarrow ’. Consider an \rightarrow introduction:

$$\frac{[\varphi] \quad \mathcal{D} \quad \psi}{\varphi \rightarrow \psi} \qquad \frac{[x : \varphi] \quad \mathcal{D} \quad t : \psi}{\lambda x \cdot t : \varphi \rightarrow \psi}$$

We assign in a systematic way proof-terms to formulas in the derivation. Since φ is an assumption, it has a hypothetical proof term, say x . On cancelling the hypotheses; we introduce a λx in front of the (given) term t for ψ . By binding x , the proof term for $\varphi \rightarrow \psi$ no longer depends on the hypothetical proof x of φ . Note that this corresponds exactly to our intuitive proof interpretation.

The elimination runs as follows:

$$\frac{\varphi \rightarrow \psi \quad \varphi}{\psi} \qquad \frac{t : \varphi \rightarrow \psi \quad s : \varphi}{t(s) : \psi}$$

Observe the analogy to the proof interpretation. Let us consider a particular derivation.

$$\frac{[\varphi] \quad \psi \rightarrow \varphi}{\varphi \rightarrow (\psi \rightarrow \varphi)} \qquad \frac{[x : \varphi] \quad \lambda y \cdot x : \psi \rightarrow \varphi}{\lambda x \cdot \lambda y \cdot x : \varphi \rightarrow (\psi \rightarrow \varphi)}$$

Thus the proof term of $\varphi \rightarrow (\psi \rightarrow \varphi)$ is $\lambda xy.x$, this is Curry combinator K .

A cut elimination conversion now should give us information about the conversion of the proof term.

$$\frac{\frac{x : \psi \quad \mathcal{D} \quad t : \varphi}{\lambda x \cdot t : \psi \rightarrow \varphi} \quad \frac{\mathcal{D}' \quad s : \psi}{s : \psi}}{(\lambda x \cdot t)(s) : \varphi} \quad \text{reduces to} \quad \frac{\mathcal{D}' \quad s : \psi}{\mathcal{D}[s/x] \quad t[s/x] : \varphi}$$

The proof theoretic conversion corresponds to the β -reduction of the λ -calculus.

In order to deal with full predicate logic we have to introduce specific operations in order to render the meaning of the connectives and their derivation rules:

$$\begin{cases} p & \text{--- pairing} \\ p_0, p_1 & \text{--- projections} \end{cases}$$

$$\begin{cases} D & \text{--- discriminator ("case dependency")} \\ k & \text{--- case obliteration} \end{cases}$$

E – witness extractor

\perp – ex falso operator

$$\begin{array}{ll} \wedge I & \frac{t_0 : \varphi_0 \quad t_1 : \varphi_1}{p(t_0, t_1) : \varphi_0 \wedge \varphi_1} & \wedge E & \frac{t : \varphi_0 \wedge \varphi_1}{p_i(t) : \varphi_i} \quad (i = 0, 1) \\ \vee I & \frac{t : \varphi_i}{k_i(t) : \varphi_0 \vee \varphi_1} \quad (i = 0, 1) & \vee E & \frac{t : \varphi \vee \psi \quad t_0[x^\varphi] : \sigma \quad t_1[x^\psi] : \sigma}{D_{u,v}(t, t_0[u], t_1[v]) : \sigma} \\ \rightarrow I & \frac{t[x^\varphi] : \psi}{\lambda y^\varphi \cdot t[y^\varphi] : \varphi \rightarrow \psi} & \rightarrow E & \frac{t : \varphi \rightarrow \psi \quad t' : \varphi}{t(t') : \psi} \\ \forall I & \frac{t[x] : \varphi(x)}{\lambda y \cdot t[y] : \forall y \varphi(y)} & \forall E & \frac{t : \forall x \varphi(x)}{t(t') : \varphi(t')} \\ \exists I & \frac{t_1 : \varphi(t_0)}{p(t_0, t_1) : \exists x \varphi(x)} & \exists E & \frac{t : \exists x \varphi(x) \quad t_1[y, z^{\varphi(y)}] : \sigma}{E_{u,v}(t, t_1[u, v]) : \sigma} \end{array}$$

There are a number of details that we have to mention.

- (i) In $\rightarrow I$ the dependency on the hypothesis has to be made explicit in the term. We do this by assigning to each hypothesis its own variable. E.g. $x^\varphi : \varphi$.
- (ii) In $\forall E$ (and similarly $\exists E$) the dependency on the particular (auxilliary) hypotheses φ and ψ disappears. This is done by a variable binding technique. In $D_{u,v}$ the variables u and v are bound.
- (iii) In the falsum rule the result, of course, depends on the conclusion φ . So φ has its own ex falso operator \perp_φ .

Now the conversion rules for the derivation automatically suggest the conversion for the term.

We have seen that the term calculus corresponds with the natural deduction system. This suggests a correspondence between proofs and propositions on the one hand and elements (given by the terms) and types (the spaces where these terms are to be found). This correspondence was first observed for a simple case (the implication fragment) by Haskell Curry, [Curry and Feys, 1958], ch. 9, § E, and extended to full intuitionistic logic by W. Howard, [Howard, 1980]. Let us first look at a simple case, the one considered by Curry.

Since the meaning of proposition is expressed in terms of possible proofs — we know the meaning of φ if we know what things qualify as proofs — one may take an abstract view and consider a proposition as its collection of proofs. From this viewpoint there is a striking analogy between propositions and sets. A set has elements, and a proposition has proofs. As we have seen, proofs are actually a special kind of constructions, and they operate on each other. E.g. if we have a proof $p : \varphi \rightarrow \psi$ and a proof $q : \varphi$ then $p(q) : \psi$. So proofs are naturally typed objects.

Similarly one may consider sets as being typed in a specific way. If φ and ψ are typed sets then the set of all mappings from φ to ψ is of a higher type, denoted by $\varphi \rightarrow \psi$ or ψ^φ . Starting from certain basic sets with types, one can construct higher types by iterating this ‘function space’-operation. Let us denote ‘ a is in type φ ’ by $a \in \varphi$.

Now there is this striking parallel.

Propositions	Types
$a : \varphi$	$a \in \varphi$
$p : \varphi \rightarrow \psi, q : \varphi$ $\Rightarrow p(q) : \psi$	$p \in \varphi \rightarrow \psi, q \in \varphi$ $\Rightarrow p(q) \in \psi$
$x : \varphi \Rightarrow t(x) : \psi$ then $\lambda x \cdot t : \varphi \rightarrow \psi$	$x : \varphi \Rightarrow t(x) \in \psi$ then $\lambda x \cdot t \in \varphi \rightarrow \psi$

It now is a matter of finding the right types corresponding to the remaining connectives. For \wedge and \vee we introduce a product type and a disjoint sum type. For the quantifiers generalizations are available. The reader is referred to the literature, cf. [Howard, 1980], [Gallier, 1995].

The main aspect of the Curry-Howard isomorphism, (also known as “proofs as types”), is the faithful correspondence:

$$\frac{\text{proofs}}{\text{propositions}} = \frac{\text{elements}}{\text{types}}$$

with their conversion and normalization properties.

The importance of the connection between intuitionistic logic and type theory was fully grasped and exploited by Per Martin-Löf. Indeed, in his approach the two are actually merge into one master system. His type systems are no mere technical innovations, but they intend to capture the foundational meaning of intuitionistic logic and the corresponding mathematical universe. Expositions of ‘proofs as types’ and the Martin-Löf type theories can be found in e.g. [Gallier, 1995], [Girard *et al.*, 1989], [Martin-Löf, 1977], [Martin-Löf, 1984], [Troelstra and van Dalen, 1988], [Sommaruga, 2000].

4 SEMANTICS

The intended interpretation of intuitionistic logic as presented by Heyting, Kreisel and others so far has proved to be rather elusive, in as much that the completeness properties that are on every logicians shopping list, have not (yet) been established. Even in the case of the interpretation of arithmetic the results are far from final. The Curry–Howard isomorphism, also known by the name ‘formulas as types’, in a sense fulfills the promise of the proof interpretation for intuitionistic logic, in the sense that there is a precise correspondence between natural deductions and proof terms, [Troelstra and van Dalen, 1988, p. 556].

However, ever since Heyting’s formalisation, various, more or less artificial, semantics have been proposed. In the thirties the topological interpretation was introduced by Tarski, and in the fifties and sixties Beth and Kripke formulated two closely related semantics.

We will first consider the topological interpretation.

DEFINITION 7. A *topological space* is a pair $\langle X, \mathcal{O} \rangle$ where $\mathcal{O} \subseteq \mathcal{P}(X)$ such that

1. $\emptyset, X \in \mathcal{O}$
2. $U, V \in \mathcal{O} \rightarrow U \cap V \in \mathcal{O}$
3. $U_i \in \mathcal{O} (i \in I) \rightarrow \cup \{U_i \mid i \in I\} \in \mathcal{O}$.

In plain words, a topological space is a set that comes with a family \mathcal{O} of open subsets that is closed under arbitrary unions and finite intersections and that contains \emptyset and X . A familiar example is the Euclidean plane, where \mathcal{O} consists of unions of open discs.

In general we can define a topological space when a *basis* is given, i.e. a collection \mathcal{B} of subsets such that

1. $A_i \in \mathcal{B}, p \in A_i (i = 1, 2) \Rightarrow \exists A \in \mathcal{B} (p \in A \subseteq A_1 \cap A_2)$
2. $\forall p \in X \exists A \in \mathcal{B} (p \in A)$.

We now define open sets as arbitrary unions of basis-elements. It is a simple exercise to show that the open sets, thus introduced, indeed satisfy the condition of Definition 7. The open discs of the Euclidean plane evidently form a basis for the natural topology.

We call U a *neighbourhood* of a point p if U is open and $p \in U$, and if, for a given basis $\mathcal{B}, U \in \mathcal{B}$, we say that U is a basic neighbourhood of p .

Now we will interpret sentences as open subsets (*opens*, for short) of a topological space. In order to motivate the interpretation we recall that, when a fixed basis \mathcal{B} is given, the evidence for $p \in U$ is a basic neighbourhood A of p such that $A \subseteq U$.

Let us now assign to each statement φ an open subset $\llbracket \varphi \rrbracket$ of X . We will try to motivate the topological operations that accompany the connectives.

Let us say that a basic neighbourhood U *proves* φ if $U \subseteq \llbracket \varphi \rrbracket$. Suppose that U_i proves φ_i then by the definition of basis we can find $U \in \mathcal{B}$ such that $U \subseteq U_1 \cap U_2$, U proves both φ_1 and φ_2 . The union of all those U 's that prove both φ_1 and φ_2 is $\llbracket \varphi_1 \rrbracket \cap \llbracket \varphi_2 \rrbracket$, so let us put $\llbracket \varphi_1 \wedge \varphi_2 \rrbracket := \llbracket \varphi_1 \rrbracket \cap \llbracket \varphi_2 \rrbracket$. Similarly we put $\llbracket \varphi_1 \vee \varphi_2 \rrbracket := \llbracket \varphi_1 \rrbracket \cup \llbracket \varphi_2 \rrbracket$. Since \perp should not have a proof, we put $\llbracket \perp \rrbracket := \emptyset$. Note that this leaves \emptyset as a proof of \perp , therefore we consider \emptyset as the empty proof (or a kind of degenerate proof that carries no evidence). The interesting case is the implication.

A proof of $\varphi_1 \rightarrow \varphi_2$ should give us a method to convert a proof of φ_1 into a proof of φ_2 . Therefore we take a basic neighbourhood U in $\llbracket \varphi_1 \rrbracket^c \cup \llbracket \varphi_2 \rrbracket$, now for any proof U_1 that intersects U we can find a proof U_2 of φ_2 in $U \cap U_1$: So U indeed provides the required method.

The U 's with that property make up the largest open subset of $\llbracket \varphi_1 \rrbracket^c \cup \llbracket \varphi_2 \rrbracket$, which we call the interior of that set. So let us put

$$\llbracket \varphi_1 \rightarrow \varphi_2 \rrbracket := \text{Int} (\llbracket \varphi_1 \rrbracket^c \cup \llbracket \varphi_2 \rrbracket) \quad (= \text{Int}\{x \mid x \in \llbracket \varphi_1 \rrbracket \Rightarrow x \in \llbracket \varphi_2 \rrbracket\}).$$

In order to interpret quantified statements we assume that a domain A of individuals is given. Then we put

$$\begin{aligned} \llbracket \exists x\varphi(x) \rrbracket &:= \cup \{ \llbracket \varphi(a) \rrbracket \mid a \in A \} \\ \llbracket \forall x\varphi(x) \rrbracket &:= \text{Int} \cap \{ \llbracket \varphi(a) \rrbracket \mid a \in A \}.^1 \end{aligned}$$

Let us now accept the above as an inductive definition of the *value* $\llbracket \varphi \rrbracket_X$ of φ in X under a given assignment of open sets to atomic sentences. When no confusion arises we will delete the index X . The notation suppresses \mathcal{O} , a better notation would be $\llbracket \varphi \rrbracket_{\mathcal{O}}$, but the reader will have no difficulty finding the correct meaning. A formula φ is said to be *true in the topological space* X , notation $\models_X \varphi$, if for all valuations $\llbracket \text{cl}(\varphi) \rrbracket = X$, where $\text{cl}(\varphi)$ is the universal closure of φ . φ is true, $\models \varphi$, if φ is true in all topological spaces.

For the consequence relation, \vDash , we define $\Gamma \vDash_X \varphi := \text{Int} \cap \{ \llbracket \psi \rrbracket_X \mid \psi \in \Gamma \} \subseteq \llbracket \varphi \rrbracket_X$ and $\Gamma \vDash \varphi$ iff $\Gamma \vDash_X \varphi$ for all X . Observe that for finite $\Gamma (= \{ \psi_1, \dots, \psi_n \})$, $\Gamma \vDash \varphi \Leftrightarrow \vDash \psi_1 \wedge \dots \wedge \psi_n \rightarrow \varphi$. Observe that nothing has been said about the topological space X , in particular X could be the one-point space with a resulting two-valued, classical logic! This shows that the above motivation has not enough special assumptions on ‘constructions’, or ‘evidence’ to lead to a specifically intuitionistic logic. The explanation is too liberal.

The topological interpretation is complete in the following sense:

THEOREM 8. $\Gamma \vdash \varphi \Leftrightarrow \Gamma \vDash \varphi$.

The implication from left to right (the soundness with respect to the topological interpretation) is easily verified by the reader. Just check all the axioms of the Hilbert-type system and show that the derivation rules preserve truth, or do the latter for the rules of natural deduction.

¹For convenience we will abuse notation and use the same symbol for the individual and its name.

We will treat the $\rightarrow I$ rule.

Let us abbreviate $\llbracket \Gamma \rrbracket_X$, $\llbracket \varphi \rrbracket_X$ and $\llbracket \psi \rrbracket_X$ as U, V, W (where $\llbracket \Gamma \rrbracket_X = \bigcup \{ \llbracket \sigma \rrbracket_X \mid \sigma \in \Gamma \}$). Then the induction hypothesis is $U \cap V \subseteq W$ (note that we use the formulation of p. 20). Since U is open, $U \subseteq \text{Int}(V^c \cup W) \Leftrightarrow U \subseteq V^c \cup W$. Now it is a matter of elementary set theory to show $U \cap V \subseteq W \Leftrightarrow U \subseteq V^c \cup W$.

The implication from right to left will follow from a later result.

EXAMPLE 9. $\llbracket \neg \varphi \rrbracket = \llbracket \varphi \rightarrow \perp \rrbracket = \text{Int} \llbracket \varphi \rrbracket^c$. Let φ be an atom and assign to it the complement of a point p (in the plane), then $\llbracket \neg \varphi \rrbracket = \emptyset$ and $\llbracket \varphi \vee \neg \varphi \rrbracket = X - \{p\} \neq X$. By the soundness of the logic we have $\not\vdash \varphi \vee \neg \varphi$.

The topological interpretation is extensively studied in [Rasiowa and Sikorski, 1963] (cf. also [Schütte, 1968; Dummett, 1977]).

We will move on to a semantics that belongs to the same family as the topological interpretation but that has certain advantages. Beth and Kripke have each introduced a semantics for intuitionistic logic and shown its completeness. The semantics that we present here is a common generalisation introduced for metamathematical purposes in [van Dalen, 1984].

The underlying heuristics is based on the conception of mathematics (and hence logic) as a mental activity of an (idealised) mathematician (or logician if you like). Consider the mental activity of this person, S , as structured in linear time of type ω , i.e. time t runs through $0, 1, 2, 3, \dots$. At each time t S has acquired a certain body of facts, knowledge. It seems reasonable to assume that S has perfect memory, so that the body of facts increases monotone in time. Furthermore S has at each time t , in general, a number of possibilities to increase his knowledge in the transition to time $t+1$. So if we present 'life' graphically for S , it turns out to fork. However, S not only collects, experiences or establishes truths, but he also constructs objects, the elements of his universe. Here also is considerable freedom of choice for S , going from time t to $t+1$ he may decide to construct the next prime, or to construct $\sqrt{2}$. This yields a treelike picture of S 's possible histories.

Each node of the tree represents a stage of knowledge of S and a stage in his construction of his universe. So to each node α_i we have assigned a set of sentences S_i and a set of objects A_i , subject to the condition that S_i and A_i increase, i.e.

$$\alpha_i \leq \alpha_j \Rightarrow S_i \subseteq S_j \text{ and } A_i \subseteq A_j.$$

Given this picture of S 's activity, let us find out how he interprets the logical constants. First, two auxiliary notions: a *path* through α is a maximal linearly ordered subset, a *bar* for α is a subset B such that each path through α intersects B .

It is suggestive to picture bars above α_i , i.e. to situate them in the future. It is no restriction to restrict ourselves to this kind of bars we will see. Now let φ be an atomic sentence. How can S know φ at state α ? He could

require that φ were then and there given to him. That however seems a bit restrictive. He might know how to establish φ , but need more time to do so. In that case we say that S knows φ at stage α if for each path through α (so to speak each ‘research’) there is a stage β such that at β φ is actually established (or, maybe, experienced). In other words, if there is a bar B for α such that at each $\beta \in B$ φ is given. The following clauses fix the knowledge of S concerning composite statements.

CONJUNCTION. S knows $\varphi \wedge \psi$ at stage α if he knows both φ and ψ at stage α .

DISJUNCTION. For S to know that $\varphi \vee \psi$ holds at stage α he need not know right away which one holds, he may again need a bit more time. All he needs to know is that eventually φ or ψ will hold. To be precise, that there is a bar B for α such that for each $\beta \in B$ S knows φ at stage β or he knows ψ at stage β .

IMPLICATION. For S to know $\varphi \rightarrow \psi$ at stage α , he need not know anything about φ or ψ at stage α , all he must be certain of is that if he comes to know φ in any later stage β , he must also know ψ at that stage.

FALSITY. S , being an idealised person, never establishes a falsity.

UNIVERSAL QUANTIFICATION. For S to know $\forall x\varphi(x)$ at stage α it does not suffice to know $\varphi(a)$ for al objects a that exist at stage α , but also for all objects that will be constructed in the future.

EXISTENTIAL QUANTIFICATION. S knows $\exists x\varphi(x)$ at stage α if eventually he will construct an element a such that he knows $\varphi(a)$. To be precise, if there is a bar B for α such that for each $\beta \in B$ there exists an element a at stage β such that S knows $\varphi(a)$ at that stage.

Examples.

* knows $\varphi \rightarrow \psi$ at α

* knows $\exists x\varphi(x)$ at α

We will now give a formal definition of a model for a given similarity type (without functions).

DEFINITION 10.

1. A model is a quadruple $\mathcal{M} = \langle M, \leq, D, \Vdash \rangle$ where M is partially ordered by \leq , and D is a function that assigns to each element of M a structure of the given type, such that for $\alpha, \beta \in M, \alpha \leq \beta \Rightarrow D(\alpha) \subseteq D(\beta)$. *Warning:* we mean literally ‘subset’, not ‘substructure’. $D(\alpha) \subseteq D(\beta)$ is used as a shorthand for ‘the universe of $D(\alpha)$ is a subset of that of $D(\beta)$, and the relations of $D(\alpha)$ are subsets of the corresponding relations of $D(\beta)$ ’. We write $a \in D(\alpha)$ for ‘ a is in the universe of $D(\alpha)$ ’.
2. The relation \Vdash between elements of M and sentences, called the *forcing relation* is inductively defined by
 - (a) $\alpha \Vdash \varphi$, for φ atomic, if there is a bar B for α such that $\forall \beta \in B, D(\beta) \models \varphi$
 - (b) $\alpha \Vdash \varphi \wedge \psi$ if $\alpha \Vdash \varphi$ and $\alpha \Vdash \psi$
 - (c) $\alpha \Vdash \varphi \vee \psi$ if there is a bar B for α such that $\forall \beta \in B, \beta \Vdash \varphi$ or $\beta \Vdash \psi$
 - (d) $\alpha \Vdash \varphi \rightarrow \psi$ if $\forall \beta \geq \alpha, \beta \Vdash \varphi \Rightarrow \beta \Vdash \psi$
 - (e) $\alpha \Vdash \forall x\varphi(x)$ if $\forall \beta \geq \alpha \forall b \in D(\beta), \beta \Vdash \varphi(b)$
 - (f) $\alpha \Vdash \exists x\varphi(x)$ if there is a bar B for α such that $\forall \beta \in B, \exists b \in D(\beta), \beta \Vdash \varphi(b)$.

Observe that for no $\alpha, \alpha \Vdash \perp$, so by defining $\neg\varphi := \varphi \rightarrow \perp$ we get

3. $\alpha \Vdash \neg\varphi$ if $\forall \beta \geq \alpha, \beta \not\Vdash \varphi$ (where $\beta \not\Vdash \varphi$ stands for $\beta \Vdash \varphi$).

Our definition used the approach with auxiliary names for elements of the structures $D(\alpha)$. The alternative approach with assignments works just as well.

We say that a formula φ holds (is true) in a model \mathcal{M} if $\alpha \Vdash \text{cl}(\varphi)$ for all $\alpha \in M$. If we also allow for the language to contain proposition letters, then the interpretation of propositional logic is contained as a special case.

The following lemma is rather convenient for practical purposes

LEMMA 11.

1. $\alpha \leq \beta, \alpha \Vdash \varphi \Rightarrow \beta \Vdash \varphi$
2. $\alpha \not\Vdash \varphi \Leftrightarrow$ *there is a path P through α such $\forall \beta \in P(\beta \not\Vdash \varphi)$*
3. $\alpha \Vdash \varphi \Leftrightarrow$ *there is a bar B for α such that $\forall \beta \in B(\beta \Vdash \varphi)$.*

Proof. Induction on φ . Note that (2) is obtained from (3) by negating both sides. ■

For sentences we have

LEMMA 12 (Soundness). $\Gamma \vdash \varphi \Rightarrow \Gamma \Vdash \varphi$.

Proof. $\Gamma \Vdash \varphi$ stands for ‘for each \mathcal{M} and each $\alpha \in M, \alpha \Vdash \psi$ for all $\psi \in \Gamma \Rightarrow \alpha \Vdash \varphi$ ’. The proof proceeds by induction on the derivation of $\Gamma \vdash \varphi$. We consider one case: $\Gamma, \varphi \vdash \psi \rightarrow \Gamma \vdash \varphi \rightarrow \psi$. Let, in a model $\mathcal{M}, \alpha \Vdash \sigma$ for all $\sigma \in \Gamma$. Suppose that $\alpha \not\Vdash \varphi \rightarrow \psi$, then there is a $\beta \geq \alpha$ such that $\beta \Vdash \varphi$ but $\beta \not\Vdash \psi$. This conflicts with the induction hypothesis $\Gamma, \varphi \Vdash \psi$. Hence $\Gamma \Vdash \varphi \rightarrow \psi$. ■

We obtain the Beth models and Kripke models by specialisation:

DEFINITION 13.

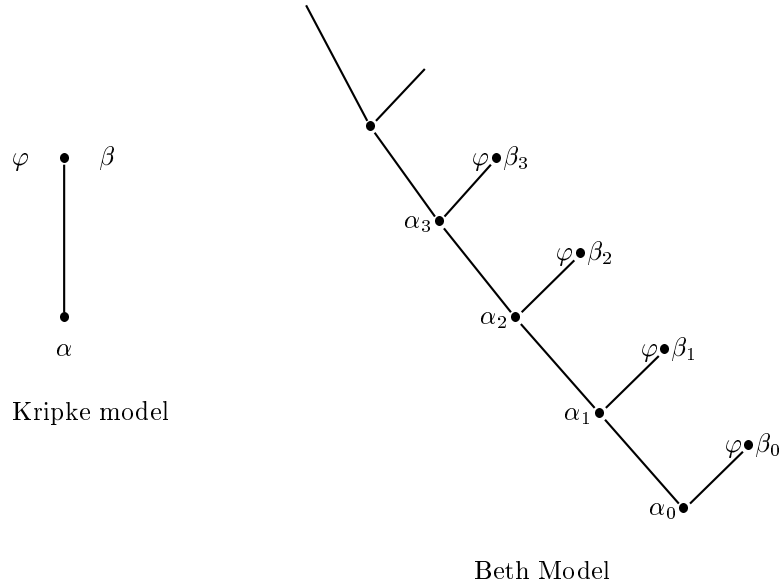

1. \mathcal{M} is a *Beth model* if $|D(\alpha)|$ is a fixed set D for all α .
2. \mathcal{M} is a *Kripke model* if in (a), (c) and (f) $B = \{\alpha\}$. To spell it out:
 - (a') $\alpha \Vdash \varphi$ if $D(\alpha) \vDash \varphi$
 - (c') $\alpha \Vdash \varphi \vee \psi$ if $\alpha \Vdash \varphi$ or $\alpha \Vdash \psi$
 - (f') $\alpha \Vdash \exists x \varphi(x)$ if $\exists a \in D(\alpha), \alpha \Vdash \varphi(a)$.

For a Beth model we can simplify clause 5:

- (a') $\forall x \varphi(x) \Leftrightarrow \forall a \in D, \alpha \Vdash \varphi(a)$ (repeat the proof of Lemma 11(a)).

Generally speaking, Kripke models are somewhat superior to Beth models. A small example may serve to illustrate this.

We will summarily present models by a simple diagram. For each node we list the propositions that are forced by it.

The Kripke model is a counter-example to $\varphi \vee \neg\varphi$, and so is the Beth model. Note that the Beth model has to be infinite in order to refute a classical tautology, since in a well-founded model all classical tautologies are true. One sees this by observing that in a well-founded model (i.e. there are no infinite *ascending* sequences; if we had turned the model upside down, we would have had the proper well-foundedness) there is a bar of maximal nodes.

Now consider a maximal node α , if $\alpha \not\vdash \varphi$, then $\alpha \Vdash \neg\varphi$. So $\alpha \Vdash \varphi \vee \neg\varphi$. So $\varphi \vee \neg\varphi$ is forced on the bar B and hence in each node of the model.

So, as a rule, we have simpler Kripke models for our logical purposes than Beth models.

A Beth model is a special case of our model, so we automatically have soundness for Beth models. For Kripke models, however, we have to show soundness separately.

Each class of models is complete for intuitionistic logic. This can be shown as follows, first show the Model Existence Lemma for Kripke semantics, then modify a Kripke model into a model and finally a model into a Beth model.

LEMMA 14 (Model Existence Lemma for Kripke Semantics). *If $\Gamma \not\vdash \varphi$ then there is a Kripke model \mathcal{K} with a bottom node α_0 such that $\alpha_0 \Vdash \psi$ for all $\psi \in \Gamma$ and $\alpha_0 \not\vdash \varphi$.*

Proof. We'll use a Henkin-style proof after Aczel, Fitting and Thomason. For simplicity's sake we'll treat the case of a denumerable language, i.e. we have denumerably many individual variables and individual constants. A set Γ of sentences is called a *prime* (also, saturated) *theory* if

1. it is closed under derivability
2. $\varphi \vee \psi \in \Gamma \Rightarrow \varphi \in \Gamma$ or $\psi \in \Gamma$
3. $\exists x\varphi(x) \in \Gamma \Rightarrow \varphi(c) \in \Gamma$ for some constant c . ■

The fundamental fact about prime theories is the following:

LEMMA 15. *If $\Gamma \not\vdash \varphi$ then there is a prime theory $\Gamma^p \supseteq \Gamma$ such that $\varphi \notin \Gamma^p$.*

Proof. We have to make a harmless little assumption, namely that there are enumerably many constants c_i , not in Γ . We approximate the Γ^p , as in the case of the Hintikka sets. To start, we add enumerably many new constants to the language of Γ, φ . Since we have a countable language, we may assume that the sentences are given in some fixed enumeration. We will treat these sentences one by one. This 'treatment' consists of adding witnesses (as in the case of the Hintikka set) and deciding disjunctions. We, so to speak, approximate the required Γ^p .

step 0 $\Gamma_0 = \Gamma$

step $k + 1$ *k is even.* Let $\exists x\psi(x)$ be the first existential sentence such that $\Gamma_k \vdash \exists x\psi(x)$, that has not been treated, and let c be the first fresh constant not in Γ_k . then put $\Gamma_{k+1} = \Gamma_k, \psi(c)$.

k is odd. Let $\psi_1 \vee \psi_2$ be the first disjunction that has not been treated, such that $\Gamma_k \vdash \psi_1 \vee \psi_2$. Pick an i such that $\Gamma_k, \psi_i \not\vdash \varphi$, then put $\Gamma_{k+1} = \Gamma_k, \psi_i$. By 2. below, at least one of ψ_1, ψ_2 will do.

The prime theory we are looking for is

$$\Gamma^p = \bigcup_{k \geq 0} \Gamma_k.$$

We will check the properties.

1. $\Gamma \subseteq \Gamma^p$, trivially.

2. $\Gamma^p \not\vdash \varphi$. This amounts to $\Gamma_k \not\vdash \varphi$ for all k . We use induction on k .

Case 1. $\Gamma_{2k+1} = \Gamma_{2k}, \psi(c)$. Assume $\Gamma_{2k} \not\vdash \varphi$. If $\Gamma_{2k+1} \vdash \varphi$ then by $\exists E, \Gamma_{2k} \vdash \varphi$. Contradiction.

Case 2. We have to show that $\Gamma_{2k+1}, \psi_1 \not\vdash \varphi$ or $\Gamma_{2k+1}, \psi_2 \not\vdash \varphi$. Suppose both are false, then by $(\forall E)$ $\Gamma_{2k+1} \vdash \varphi$. Contradiction.

So, we proved $\Gamma_k \not\vdash \varphi$ for all k .

3. Γ^p is a prime theory.

(a) Let $\psi_1 \vee \psi_2 \in \Gamma^p$, then $\psi_1 \vee \psi_2 \in \Gamma_k$ for some k , and hence $\Gamma_h \vdash \psi_1 \vee \psi_2$ for all $h \geq k$. Now look for the first h such that $\psi_1 \vee \psi_2$ is treated at step h ; then by definition $\psi_1 \in \Gamma_{h+1}$ or $\psi_2 \in \Gamma_{h+1}$. And so at least one of the ψ_i 's is in Γ^p .

(b) $\exists x\psi(x) \in \Gamma^p$ implies by a similar argument that $\psi(c) \in \Gamma^p$ for some c .

(c) If $\Gamma^p \vdash \psi$, then $\Gamma^p \vdash \psi \vee \psi$ and, as in (1), $\psi \in \Gamma^p$. ■

We now can construct the required Kripke model. In order to obtain elements for the various domains we consider denumerably many disjoint sets V_i of denumerably many constants $\{c_m^i \mid m \geq 0\}$. By joining these V_i 's we get a denumerable family of languages L_i partially ordered by inclusion. The nodes of our Kripke model are prime theories $\Gamma \supseteq \Gamma_0$, which are prime with respect to some L_i , and the partial ordering is the inclusion relation. The domain of such a Γ is the set of constants of its language L_i . The forcing relation is defined by

$$\Gamma \Vdash \psi \Leftrightarrow \psi \in \Gamma \text{ for atomic } \psi.$$

Claim: $\Gamma \Vdash \psi \Leftrightarrow \psi \in \Gamma$ holds for all sentences ψ .

We use induction on ψ . For $\psi_1 \vee \psi_2, \exists x\psi(x)$ we apply the prime property of Γ . Consider $\Gamma \Vdash \psi_1 \rightarrow \psi_2$, if $\psi_1 \rightarrow \psi_2 \notin \Gamma$, then $\Gamma, \psi_1 \not\vdash \psi_2$, so we can find $\Delta \supseteq \Gamma, \psi_1$ such that $\Delta \not\vdash \psi_2$ and Δ is prime with respect to L_{i+1} (where L_i belongs to Γ). So, by induction hypothesis, $\Delta \Vdash \psi_1$ and $\Delta \not\vdash \psi_2$. Contradiction. Hence $\psi_1 \rightarrow \psi_2 \in \Gamma$. The converse is simple.

A similar argument is used for $\forall x\psi(x)$. Let $\Gamma \Vdash \forall x\psi(x)$, i.e. $\forall \Delta \supseteq \Gamma, \forall c \in D(\Delta), \Delta \Vdash \psi(c)$, and by induction hypothesis $\psi(c) \in \Delta$. Now if

$\forall x\psi(x) \notin \Gamma$, then $\Gamma \not\vdash \forall x\psi(x)$ and hence $\Gamma \not\vdash \psi(c)$ for a fresh constant c of the next language L_i . But then we can find a prime theory Δ with respect to L_i that contains Γ and $\Delta \not\vdash \psi(c)$, so $\psi(c) \notin \Delta$. Contradiction. So $\forall x\psi(x) \in \Gamma$. Again the converse is simple.

We now finally can finish our proof: the model that we have constructed satisfies the requirements. To be precise, we first extend Γ to a prime theory Γ_0 and then construct the model with Γ_0 as bottom node.

As a corollary we have the

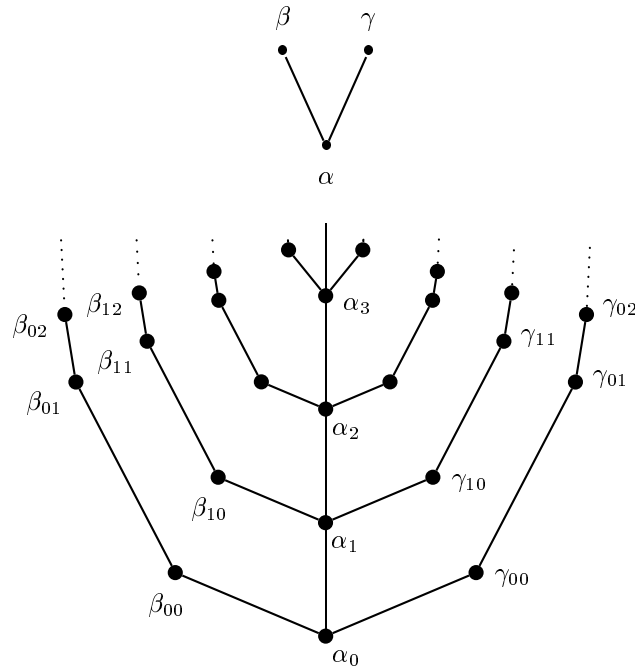

THEOREM 16 (Strong Completeness Theorem for Kripke Semantics).
 $\Gamma \vdash \varphi \Leftrightarrow \Gamma \Vdash \varphi$.

Proof. \Rightarrow is the soundness property.

\Leftarrow If $\Gamma \not\vdash \varphi$, then we have a Kripke model such that its bottom node $\alpha_0 \not\vdash \varphi$ and $\alpha_0 \Vdash \psi$ for all $\psi \in \Gamma$. Hence $\Gamma \not\vdash \varphi$. ■

In order to carry the result over to the other two semantics it suffices to modify a Kripke model so that we obtain a (Beth) model that does the trick of Lemma 14.

Kripke has indicated how to do this. In one step we obtain a general model, and in one more step a Beth model. We will indicate only the first modification

We basically repeat each node infinitely often, complete with its domain. If we look at the Kripke model and its modification below, then we see that

each α_i forces the same atoms as α in the Kripke model, since any bar intersects the path $\alpha_0\alpha_1\alpha_2\dots$.

An inductive argument shows that

$$\delta \Vdash_K \varphi \Leftrightarrow \delta' \Vdash \varphi,$$

where $\delta = \alpha, \beta, \gamma$ and δ' is one of the indexed δ 's below and where \Vdash_K stands for Kripke-forcing, and \Vdash for general forcing. In order to make the procedure general, we introduce finite sequences $\langle \alpha_1, \alpha_2, \dots, \alpha_n \rangle$ of nodes of the Kripke model, with $\alpha_i \leq \alpha_{i+1}$, as nodes of the new model. Put $D(\langle \alpha_1, \dots, \alpha_n \rangle) = D(\alpha_n)$. It is a simple exercise to show that the new model serves to establish Lemma 14. This suffices to show the completeness of our semantics. In order to obtain a Beth model we have to collect everything into one domain. This is worked out in [Kripke, 1965, p. 112 ff] or [Schütte, 1968].

As a result we have

$$\Gamma \vdash \varphi \Leftrightarrow \Gamma \Vdash_K \varphi \Leftrightarrow \Gamma \Vdash \varphi \Leftrightarrow \Gamma \Vdash_B \varphi,$$

where \Vdash_K and \Vdash_B stand for Kripke and Beth forcing.

Let us finally return to the topological interpretation. We will show that each Beth model can be viewed as a topological model. Consider a Beth model $\langle B, \leq, D, \Vdash \rangle$, the poset B gives rise to a topological space as follows: the points of T_B are paths in B . We define a topology by indicating the basic open sets U_α , where $U_\alpha = \{P \mid \exists \beta \geq \alpha, P \text{ passes through } \beta\}$. The opens (short for 'open sets') of T_B are unions of U_α 's. In the terminology of topology: $\{U_\alpha \mid \alpha \in B\}$ is a basis for the topology on T_B . We check the properties of a basis 4:

1. $P \in U_\alpha \cap U_\beta$, then there are $\gamma \geq \alpha$ and $\delta \geq \beta$ such that $\gamma, \delta \in P$. Let $\delta \geq \gamma$ then $P \in U_\delta$ and $U_\delta \subseteq U_\alpha \cap U_\beta$.
2. For any path P and any $\alpha \in P$ we have $P \in U_\alpha$.

We next turn to the definition of the truth values. Put $\llbracket \varphi \rrbracket = \cup\{U_\alpha \mid \alpha \Vdash \varphi\}$ for atomic φ . We thus obtain a canonical topological model T_B .

THEOREM 17. *For the topological model T_B the identity $\llbracket \varphi \rrbracket = \cup\{U_\alpha \mid \alpha \Vdash \varphi\}$ holds for all sentences φ .*

Proof. Induction on φ .

For atoms the identity holds by definition. \vee and \wedge are simple.

Consider \rightarrow . We must show $U_\alpha \subseteq \llbracket \varphi \rightarrow \psi \rrbracket \Leftrightarrow \alpha \Vdash \varphi \rightarrow \psi$.

We use a small topological lemma: $U \subseteq \text{Int}(V^c \cup W) \Leftrightarrow U \cap V \subseteq W$, cf. the proof of Theorem 8.

$$\text{So, } U_\alpha \subseteq \llbracket \varphi \rightarrow \psi \rrbracket \Leftrightarrow U_\alpha \subseteq \text{Int}(\llbracket \varphi \rrbracket^c \cup \llbracket \psi \rrbracket) \Leftrightarrow U_\alpha \cap \llbracket \varphi \rrbracket \subseteq \llbracket \psi \rrbracket.$$

We want to show $\beta \Vdash \varphi \Rightarrow \beta \Vdash \psi$ for all $\beta \geq \alpha$. So let $\beta \Vdash \varphi$. then by induction hypothesis, $U_\beta \subseteq \llbracket \varphi \rrbracket$, and by $\beta \geq \alpha$ $U_\beta \subseteq U_\alpha$. Therefore $U_\beta \cap \llbracket \varphi \rrbracket = U_\beta \subseteq \llbracket \psi \rrbracket$, i.e. $\beta \Vdash \psi$. Conversely we have to show $U_\alpha \cap \llbracket \varphi \rrbracket \subseteq \llbracket \psi \rrbracket$. since the U_α 's form a basis it suffices to show $U_\beta \subseteq U_\alpha \cap \llbracket \varphi \rrbracket \rightarrow U_\beta \subseteq \llbracket \psi \rrbracket$, but $U_\beta \subseteq \llbracket \varphi \rrbracket$ implies $\beta \Vdash \varphi$, and hence $\beta \Vdash \psi$, which in turn implies, $U_\beta \subseteq \llbracket \psi \rrbracket$.

The quantifier cases are simple, we leave them to the reader. \blacksquare

COROLLARY 18. *For the topological interpretation the completeness theorem holds, i.e. $\Gamma \vdash \varphi \Leftrightarrow \Gamma \Vdash \varphi$.*

Proof. Soundness is shown by a routine induction. Completeness follows from the completeness of the Beth semantics and Theorem 17. \blacksquare

We have introduced a number of semantics each of which has certain drawbacks. For designing counterexamples and straightforward theoretical applications the Kripke semantics is the most convenient one. We will demonstrate this below in a few examples.

EXAMPLE 19. The following, classically valid, sentences are not derivable.

1. $\varphi \vee \neg\varphi$ (principle of the excluded middle, PEM)
2. $\neg\neg\varphi \rightarrow \varphi$ (double negation principle)
3. $\neg(\varphi \wedge \psi) \rightarrow \neg\varphi \vee \neg\psi$ (De Morgan's Law)
4. $\neg\varphi \vee \neg\neg\varphi$
5. $(\varphi \rightarrow \psi) \vee (\psi \rightarrow \varphi)$ (Dummett's axiom)
6. $(\neg\neg\varphi \rightarrow \varphi) \rightarrow \varphi \vee \neg\varphi$
7. $(\neg\varphi \rightarrow \neg\psi) \rightarrow (\psi \rightarrow \varphi)$
8. $(\varphi \rightarrow \psi) \rightarrow \neg\varphi \vee \psi$
9. $\neg\forall x\varphi(x) \rightarrow \exists x\neg\varphi(x)$
10. $\forall x\neg\neg\varphi(x) \rightarrow \neg\neg\forall x\varphi(x)$ (double negation shift, DNS)
11. $\forall x(\varphi \vee \psi(x)) \rightarrow \varphi \vee \forall x\psi(x)$ (constant domain axiom)
12. $(\varphi \rightarrow \exists x\psi(x)) \rightarrow \exists x(\varphi \rightarrow \psi(x))$ (independence of premiss principle, IP)
13. $(\forall x\varphi(x) \rightarrow \psi) \rightarrow \exists x(\varphi(x) \rightarrow \psi)$
14. $\forall x(\varphi(x) \vee \neg\varphi(x)) \wedge \neg\neg\exists x\varphi(x) \rightarrow \exists x\varphi(x)$

15. $\neg\neg\forall xy(x = y \vee x \neq y)$

16. $\neg\neg\forall xy(\neg x \neq y \rightarrow x \neq y)$

Proof. Consider the following Kripke models (where the nodes are labelled with the forced atoms and forced formulas).

1 and 2 are refuted by model a.
 4 and 6 are refuted by model b. (forget about the ψ).
 3 and 5 are refuted by model b.
 7 is refuted by model c.
 8 is refuted by model a (take $\psi := \varphi$).

For the quantified sentences we need to indicate universes.

9 and 13 are refuted in model a.
 10 is refuted in model e.
 11 is refuted in model b.

- 12 is refuted in model c.
- 14 is refuted in model d.
- 15 and 16 are refuted in model f.

The identity relation satisfies the obvious axioms of reflexivity, symmetry, transitivity and compatibility with basic relations. Model f clearly satisfies these axioms.

Observe that we could have refuted 9, 11, 12, 13, 14 by the familiar reduction of a quantified statement to a proposition mimicking a finite domain. Sentence 10 is of a different ilk, we can even show that 10 is true in all finite Kripke models (i.e. with a finite tree).

In a finite tree each node is dominated by an end (or top) node. Suppose that $\forall x \neg \neg \varphi(x)$ holds, then in an end node α we have $\alpha \Vdash \forall x \neg \neg \varphi(x)$, i.e. $\forall a \in D\alpha, \alpha \Vdash \neg \neg \varphi(a)$. But, since α is an end node, this implies $\alpha \Vdash \varphi(a)$ hence $\alpha \Vdash \forall x \varphi(x)$. As a result we get $\alpha_0 \Vdash \neg \neg \forall x \varphi(x)$ for the bottom node.

As we will show in the next section, **IPC** is complete for finite Kripke models, so **IQC** essentially needs a wider class of partially ordered sets for its Kripke semantics. ■

Heyting algebras, the common generalization of the preceding semantics.

Boole's discovery of the algebraic nature of the logical laws and operations was repeated for the case of intuitionistic logic by McKinsey, Stone, Tarski and others. The resulting algebra has been called *closure algebra*, *Brouwerian algebra*, *pseudo-Boolean algebra*, but nowadays the term *Heyting algebra* is generally accepted.

There are various axiomatisations for the theory of Heyting algebras (cf. [Rasiowa and Sikorski, 1963; Johnstone, 1982]), we will use one that stays very close to the axioms of **IPC**.

For the formulation it is convenient to use the notion of lattice.

DEFINITION 20. $\langle A, \leq \rangle$ is a lattice if it is a poset in which each pair of elements has a sup and an inf.

We denote the sup and inf of x and y by $x \sqcup y$ and $x \sqcap y$. by definition \sqcap and \sqcup satisfy

$$\begin{aligned} x \sqcap y &\leq x, \quad y \leq x \sqcup y \\ x, y &\leq z \rightarrow x \sqcup y \leq z \\ z &\leq x, y \rightarrow z \leq x \sqcap y. \end{aligned}$$

We can alternatively obtain a lattice from a structure $\langle A, \sqcup, \sqcap \rangle$ satisfying

$$\begin{aligned} x \sqcup y &= y \sqcup x & x \sqcap y &= y \sqcap x \\ x \sqcup (y \sqcup z) &= (x \sqcup y) \sqcup z & x \sqcap (y \sqcap z) &= (x \sqcap y) \sqcap z \\ x \sqcap (x \sqcup y) &= x & x \sqcup (x \sqcap y) &= x. \end{aligned}$$

We define the relation ‘ \leq ’ by $x \leq y := x \sqcap y = x$. It is a simple exercise to show that \leq defines a lattice (cf. [Rasiowa and Sikorski, 1963, pp. 35,36]). A lattice with top \top and bottom \perp is a lattice with two elements \top and \perp satisfying $\perp \leq x \leq \top$ for all x .

Note that we can show $x \sqcap y = x \Leftrightarrow x \leq y \Leftrightarrow x \sqcup y = y$, so the ordering can also be expressed by \sqcup .

DEFINITION 21. A Heyting-algebra is a structure $\langle A, \sqcap, \sqcup, \Rightarrow, \top, \perp \rangle$ such that

1. it is a distributive lattice with respect to \sqcap, \sqcup and with top and bottom.
2. $x \sqcap (x \Rightarrow y) = x \sqcap y$
3. $(x \Rightarrow y) \sqcap y = y$
4. $(x \Rightarrow y) \sqcap (x \Rightarrow z) \Rightarrow (x \Rightarrow (y \sqcap z))$
5. $\perp \sqcap x = \perp$
6. $\perp \Rightarrow \perp = \top$.

Any Boolean algebra obviously is a Heyting algebra. The paradigm of a Heyting algebra is $\mathcal{O}(X)$, the set of opens of a topological space X , where $U \Rightarrow V$ is defined as in Section 3: $\text{Int}(U^c \cup V)$.

We have the following key properties

LEMMA 22.

1. $x \Rightarrow x = \top$
2. $x \sqcap y \leq z \leftrightarrow x \leq y \Rightarrow z$.

We define the complement by $-x := x \Rightarrow \perp$.

The obvious connection with logic is via the *Lindenbaum algebra* of a theory. Consider some theory T in **IPC**, then

$$\varphi \sim \psi := T \vdash_{\mathbf{IPC}} \varphi \leftrightarrow \psi$$

is a congruence relation, as one easily shows.

On the equivalence classes we define a Heyting algebra, by putting

$$\begin{aligned} \varphi / \sim \sqcap \psi / \sim &:= (\varphi \wedge \psi) / \sim \\ \varphi / \sim \sqcup \psi / \sim &:= (\varphi \vee \psi) / \sim \\ \varphi / \sim \Rightarrow \psi / \sim &:= (\varphi \rightarrow \psi) / \sim \\ \perp &:= \perp / \sim \\ \top &:= (\perp \rightarrow \perp) / \sim. \end{aligned}$$

It is a routine matter to show that one thus obtains a Heyting algebra, the so-called Lindenbaum algebra of T .

Examples of Heyting algebras

1.

$$\begin{array}{ccccccc} 0 & 1 & 2 & 3 & \dots & \dots & \omega \\ \bullet & \bullet & \bullet & \bullet & \dots & \dots & \bullet \end{array}$$

Consider the set of natural numbers with a sup ω (i.e. the ordinal $\omega + 1$) and define $n \sqcap m := \min(n, m)$, $n \sqcup m := \max(n, m)$,

$$\begin{aligned} n \Rightarrow m &:= \begin{cases} m & \text{if } n > m \\ \omega & \text{if } n \leq m, \text{ for } n, m \leq \omega \end{cases} \\ \perp &:= 0, \top := \omega. \end{aligned}$$

The ordering is the natural one. In this Heyting algebra the excluded third fails:

$$-n = n \Rightarrow \perp = \begin{cases} \perp & \text{if } n \neq 0 \\ \top & \text{else.} \end{cases}$$

For $n \neq \perp, \top$ we get $n \sqcup -n = n \sqcup \perp = n \neq \top$.

2. From the diagram below we can read off the operations. The non-trivial one is the ‘implication’ (relative complement).

The relation $x \leq y \Rightarrow z \Leftrightarrow x \sqcap y \leq z$ tells us that $y \Rightarrow z$ is the greatest element x such that $x \sqcap y \leq z$, so we can write down the table for \Rightarrow .

\Rightarrow	\perp	a	b	c	\top
\perp	\top	\top	\top	\top	\top
a	b	\top	b	\top	\top
b	a	a	\top	\top	\top
c	\perp	a	b	\top	\top
\top	\perp	a	b	c	\top

The first column yields the negation. One can view the Heyting algebras as a suitable generalisation of the classical truth table. In this form Heyting algebras occur already in Heyting’s paper of 1930. Truth tables also occur in [Jaskowski, 1936].

3. *The Rieger–Nishimura lattice* [Nishimura, 1966]

In the diagram below one of the two points immediately above the bottom, is the complement of the other. If we call the right hand one p , we can compute the remaining elements. We enumerate the points as indicated. We put

$$\begin{aligned}
 \varphi_0 &:= \perp \\
 \varphi_1 &:= p \\
 \varphi_2 &:= \neg p \\
 \varphi_{2n+3} &:= \varphi_{2n+1} \sqcup \varphi_{2n+2} \\
 \varphi_{2n+4} &:= \varphi_{2n+2} \Rightarrow \varphi_{2n+1}.
 \end{aligned}$$

The operations on the lattice follow from its order. The Rieger–Nishimura lattice is the free Heyting algebra with one generator, i.e. in logical terms it is the Lindenbaum algebra of **IPC** with just one atom.

There are two things to be shown:

- (a) each proposition in p is one of the φ_i 's;
- (b) the dependencies between the φ_i 's are as shown in the diagram.

(a) is shown by induction on φ . We'll do one case. Let $\varphi = \psi \wedge \sigma$. By induction hypothesis $\vdash \psi \leftrightarrow \varphi_i, \vdash \sigma \leftrightarrow \varphi_j$ for some i, j . If the elements i, j are comparable, then we immediately see that φ is a φ_k . So the interesting cases are $i = 2n + 1, j = 2n + 2$ and $i = 2n + 3, j = 2n + 4$. In the first case $\vdash \varphi \leftrightarrow \varphi_{2n-1}$, in the second case $\vdash \varphi \leftrightarrow \varphi_{2n+1}$.

The proof of (b) is a matter of tedious bookkeeping. Given the dependencies between $\varphi_0, \varphi_1, \varphi_2$, one checks the dependencies for higher φ_n 's inductively. Consider for example φ_{2n+3} and φ_{2n+4} .

$$\begin{aligned}
 &(\varphi_{2n+3} \rightarrow \varphi_{2n+4}) \leftrightarrow \\
 &[(\varphi_{2n+1} \vee \varphi_{2n+2}) \rightarrow \\
 &(\varphi_{2n+2} \rightarrow \varphi_{2n+1})] \leftrightarrow \\
 &\varphi_{2n+2} \rightarrow \varphi_{2n+1}.
 \end{aligned}$$

So, from the induction hypothesis $\not\vdash \varphi_{2n+2} \rightarrow \varphi_{2n+1}$, we obtain $\not\vdash \varphi_{2n+3} \rightarrow \varphi_{2n+4}$, i.e. $\varphi_{2n+3}/\sim \Rightarrow \varphi_{2n+4}/\sim \neq \top$, i.e. $\varphi_{2n+3}/\sim \not\leq \varphi_{2n+4}/\sim$.

An interpretation of **IPC** in a Heyting algebra A is given by a mapping h from the atoms into A . h is then extended to all propositions in the canonical way i.e. $h(\varphi \wedge \psi) = h(\varphi) \sqcap h(\psi)$, $h(\varphi \vee \psi) = h(\varphi) \sqcup h(\psi)$, $h(\varphi \rightarrow \psi) = h(\varphi) \Rightarrow h(\psi)$; φ is true in A if for all interpretations h , $h(\varphi) = \top$. A simple inductive proof shows the

SOUNDNESS THEOREM IPC $\vdash \varphi \Rightarrow \varphi$ is true in all Heyting algebras.

The converse also holds, for consider the Lindenbaum algebra of **IPC** and interpret each proposition canonically: $h(\sigma) = \sigma/\sim$, then **IPC** $\vdash \sigma \Leftrightarrow h(\sigma) = \top$. So φ is true in the Lindenbaum algebra.

Hence we have the

COMPLETENESS THEOREM FOR HEYTING ALGEBRAS. IPC $\vdash \varphi \Leftrightarrow \varphi$ is true in all Heyting algebras.

There is a simple connection between Kripke models and Heyting algebras. We can associate to a Kripke model a topological space as follows. The points of the space are the nodes of the poset; the opens are the sets U with the property $\alpha \in U \wedge \beta \geq \alpha \Rightarrow \beta \in U$. As in the case of the topological model associated to a Beth model over a tree, the sets $U_\alpha = \{\beta \mid \beta \geq \alpha\}$ form a basis for this topology.

For atoms we define $\llbracket \varphi \rrbracket = \{\alpha \mid \alpha \Vdash \varphi\} (*)$.

One shows by induction on φ that $(*)$ holds for all propositions (cf. also [Fitting, 1969, p.23]). Thus we have associated to each Kripke model an interpretation in the Heyting algebra of the opens of the associated topological space.

Instead of considering Kripke or Beth models with a prescribed interpretation (forcing) of the atoms, we can also consider the underlying poset only. We then speak of a *Kripke (Beth) frame*. A frame is thus turned into a model by assigning structures to the nodes.

There is an alternative formulation of Kripke (Beth, etc.) models, that sticks closer to the language. Instead of assigning classical structures to nodes, one can just as well assign sets of atoms to nodes, e.g. think of $V(\alpha)$ as the set of atomic sentences that are true in $D(\alpha)$. So V is a function from M to the power set of the set of closed atoms, subject to the condition that $\alpha \leq \beta \Rightarrow V(\alpha) \subseteq V(\beta)$.

Alternatively one can define a binary interpretation function $i : At \times M \rightarrow \{0, 1\}$ (where At is the set of closed atoms), such that $\alpha \leq \beta$ and $i(\varphi, \alpha) = 1 \Rightarrow i(\varphi, \beta) = 1$ (think of $i(\varphi, \alpha) = 1$ as $D(\alpha) \models \varphi$).

4.1 An External View of Kripke Models

If one looks at a Kripke model from the outside, then it appears as a complicated concoction of classical structures, and hence as a classical structure itself. Such a structure has its own language and we can handle it by ordinary, classical, model-theoretical means.

What is involved in this ‘master structure’ of \mathcal{K} ? (i) the partially ordered set of nodes, (ii) the relations between these structures. We can simply describe this master structure \mathcal{K}^* by a language, containing two sorts of individuals (or alternatively one sort, but two predicates $N(x)$ and $E(x)$, for ‘ x is a node’ and ‘ x is an element’). Let us use $\alpha, \beta, \gamma, \dots$ for the ‘node-sort’ and x, y, z, \dots for the ‘element sort’. Then we add \leq to the original language, and replace each predicate symbol P by P^* with one more argument than P and add a domain predicate symbol. The structure \mathcal{K}^* validates the following laws (referred to by Σ):

$$\begin{aligned} \alpha \leq \beta \wedge \beta \leq \gamma &\rightarrow \alpha \leq \gamma \\ \alpha \leq \beta \wedge \beta \leq \alpha &\rightarrow \alpha = \beta \\ \forall \alpha \beta \vec{x} (\alpha \leq \beta \wedge P^*(\alpha, \vec{x}) &\rightarrow P^*(\beta, \vec{x})) \\ \forall \alpha \beta x (D(\alpha, x) &\rightarrow D(\beta, x)) \end{aligned}$$

Now we can mimic the forcing clauses in the extended language. Consider the translation of $\alpha \Vdash \varphi$ given by the inductive definition:

1. $(\alpha \Vdash P(\vec{t}))^* := P^*(\alpha, \vec{t})$ and $(\alpha \Vdash \perp)^* := \perp$.
2. $(\alpha \Vdash \varphi \wedge \psi)^* := (\alpha \Vdash \varphi)^* \wedge (\alpha \Vdash \psi)^*$.
3. $(\alpha \Vdash \varphi \vee \psi)^* := (\alpha \Vdash \varphi)^* \vee (\alpha \Vdash \psi)^*$.
4. $(\alpha \Vdash \varphi \rightarrow \psi)^* := \forall \beta \geq \alpha ((\beta \Vdash \varphi)^* \rightarrow (\beta \Vdash \psi)^*)$.
5. $(\alpha \Vdash \exists x \varphi(x))^* := \exists x (D(\alpha, x) \wedge (\alpha \Vdash \varphi(x))^*)$.
6. $(\alpha \Vdash \forall x \varphi(x))^* := \forall \beta \geq \alpha \forall x (D(\beta, x) \rightarrow (\beta \Vdash \varphi(x))^*)$.

It is obvious that:

1. $\alpha \Vdash \varphi \Leftrightarrow \mathcal{K}^* \models (\alpha \Vdash \varphi)^*$
2. each model of Σ corresponds uniquely to a Kripke model.

Now we can apply the full force of classical model theory to the models of Σ in order to obtain results about Kripke models. For example, one gets for free the ultraproduct theorem and the Hilbert–Bernays completeness theorem (consistent RE theories have Δ_2^0 models, cf. [Kleene, 1952, Ch XIV]).

Similar ‘translations’ can be applied to Beth semantics or the general semantics (cf. [van Dalen, 1978] for an application to lawless sequences).

4.2 Model theory of intuitionistic logic in an intuitionistic setting

If one is willing to give up the strong results of all the artificial semantics (completeness, Skolem–Löwenheim, etc.), there is no reason why one should not practise model theory of intuitionistic theories as an ordinary part of intuitionistic mathematics. That is to say, to adopt an intuitionistic variant of the Tarskian semantics. A number of interesting results have been obtained for specific theories and structures, e.g., the continuum and the irrationals are elementarily equivalent for the theories of equality, apartness and linear order. Note that even a seemingly trivial theory, such as that of equality, turns out to be highly complicated—in contrast to the classical case. Also, strong classical theorems cannot always be upheld in an intuitionistic setting. e.g. the existence of winning strategies for Ehrenfeucht–Fraïssé games implies elementary equivalence (cf. [van Dalen, 1993]), but the converse fails (cf. [Veldman and Waaldijk, 1996]). The last mentioned paper contains a wealth of interesting methods and results, it is recommended for getting acquainted with the field.

5 SOME METALOGICAL PROPERTIES OF IPC AND IQC

Intuitionistic logic is in a sense richer in metalogical properties than classical logic. There are common properties, such as completeness, compactness and deduction theorem, but soon the logics start to diverge. Classical logic has phenomena such as prenex normal forms, Skolem form, and Herbrand’s theorem which are absent in intuitionistic logic. Intuitionistic logic on the other hand is more blessed with derived rules.

The first example is the

DISJUNCTION PROPERTY, DP. $\Gamma \vdash \varphi \vee \psi \Rightarrow \Gamma \vdash \varphi$ or $\Gamma \vdash \psi$.

Clearly, the nature of Γ is relevant, for if Γ contains all instances of PEM, then DP is false, since in **CPC** $\varphi \vee \neg\varphi$ is a tautology, but neither φ , nor $\neg\varphi$ needs to be a tautology.

A sufficient condition on Γ is that it exists of *Harrop formulas*, i.e. formulas without dangerous occurrences of \vee or \exists . To be precise, the class of Harrop formulas is inductively defined by

1. $\varphi \in H$ for atomic φ
2. $\varphi, \psi \in H \rightarrow \varphi \wedge \psi \in H$
3. $\varphi \in H \Rightarrow \forall x\varphi \in H$
4. $\psi \in H \Rightarrow \varphi \rightarrow \psi \in H$.

THEOREM 23. *The disjunction property holds for sets Γ of Harrop formulas.*

For a proof using natural deduction, see [Prawitz, 1965, p. 55], [van Dalen, 1997, p. 209]. In Aczel [1968] a proof is given using a metamathematical device ‘Aczel’s slash’. See also [Gabbay, 1981, Ch. 2, Section 3].

The intuitionistic reading of the disjunction property is: given a proof of $\varphi \vee \psi$ we can effectively find a proof of φ or a proof of ψ . The proof theoretical demonstrations of DP have this intuitionistic character, not however the model-theoretic proof below. The proof uses classical meta-theory, to be specific, it uses *reductio ad absurdum*.

To demonstrate the use of Kripke models, we give the proof for a simple case, $\Gamma = \emptyset$.

Let $\vdash \varphi \vee \psi$ and suppose $\not\vdash \varphi$ and $\not\vdash \psi$. Then there are Kripke models \mathcal{K}_1 and \mathcal{K}_2 with bottom node α_1 and α_2 such that $\alpha_1 \not\vdash \varphi$ and $\alpha_2 \not\vdash \psi$. We construct a new Kripke model \mathcal{K} by taking the disjoint union of \mathcal{K}_1 and \mathcal{K}_2 and placing an extra node α_0 at the bottom, see figure above. We stipulate that nothing is forced at α_0 . Clearly, the result is a Kripke model.

$\alpha_0 \Vdash \varphi \vee \psi$, so $\alpha_0 \Vdash \varphi$ or $\alpha_0 \Vdash \psi$. If $\alpha_0 \Vdash \varphi$, then $\alpha_1 \Vdash \varphi$. Contradiction. And if $\alpha_0 \Vdash \psi$, then $\alpha_2 \Vdash \psi$. Contradiction. Hence we have $\vdash \varphi$ or $\vdash \psi$.

For predicate logic we can also establish the *Existence Property*: $\Gamma \vdash \exists x\varphi(x) \Rightarrow \Gamma \vdash \varphi(t)$ for a chosen term t , where Γ consists of Harrop formulas ($\exists x\varphi(x)$ is closed). See [Prawitz, 1965; Aczel, 1968; Gabbay, 1981; van Dalen, 1997].

Since the only closed terms in our present approach are constants, we can replace the conclusion of EP by ‘ $\Gamma \vdash \varphi(c)$ for a constant c ’.

In the case that there are no constants at all the conclusion is rather surprising: $\Gamma \vdash \forall x\varphi(x)$.

Like its classical counterpart **IPC** is decidable; there are various proofs for this fact. In [Kleene, 1952, Section 80], [Troelstra and van Dalen, 1988, p. 541] and [Szabo, 1969, p. 103], a sequent calculus is used. The use of normal derivations in natural deduction likewise yields a decision procedure. In [Rasiowa, 1974, p. 266] decidability is derived from the completeness of **IPC** for finite Heyting algebras. We will use a similar argument based on Kripke models.

Our first step is to reduce Kripke models for **IPC** to finite models, following [Smoryński, 1973].

We consider a Kripke model \mathcal{K} with a tree as its underlying poset such that $K \not\vdash \varphi$; a suitable refining will yield a ‘submodel’ \mathcal{K}^* , such that

1. \mathcal{K}^* is finite
2. $\alpha \Vdash^* \psi \Leftrightarrow \alpha \Vdash \psi$, for all subformulas of φ .

Let S be the set of subformulas of φ , and put $S_\beta = \{\psi \in S \mid \beta \Vdash \psi\}$. We define a sequence of sets $K_n : K_0 = \{\alpha_0\}$ (α_0 is the bottom node of \mathcal{K}).

Let K_n be defined, and $\beta \in K_n$. We consider sets $\{\delta_1, \dots, \delta_k\} \subseteq K$ such that

1. $\beta \leq \delta_i$
2. $S_\beta \neq S_{\delta_i}$
3. the S_δ jumps only once between β and δ_i , i.e. $S_\delta = S_\beta$ or $S_\delta = S_{\delta_i}$ for $\beta \leq \delta \leq \delta_i$
4. $S_{\delta_i} \neq S_{\delta_j}$ for $i \neq j$.

Since there are only finitely many S_δ ’s we can find a maximal such set say $\{\beta'_1, \dots, \beta'_k\}$, if there are such δ ’s at all.

Define

$$\begin{aligned} K_1 &= \{\alpha'_{0,1}, \dots, \alpha'_{0,k}\} \cup \{\alpha_0\} \\ K_{n+1} &= K_n \cup \bigcup \{ \{\beta'_2, \dots, \beta'_k\} \mid \beta \in K_n - K_{n-1} \}, n \geq 1. \end{aligned}$$

As the S_β ’s increase, and there are only finitely many subformulas, the sequence K_n stops eventually. Clearly each K_n is finite, hence $K^* = \bigcup K_n$ is finite.

Claim: K^* with its inherited \Vdash^* is the required finite submodel. Property (2) is shown by induction on ψ . For atomic ψ (2) holds by definition. For \vee and \wedge the result follows immediately. Let us consider $\psi_1 \rightarrow \psi_2$. Suppose that for $\beta \in K^*$, $\beta \not\vdash \psi_1 \rightarrow \psi_2$, then there is a $\gamma \geq \beta$ in K such that $\gamma \Vdash \psi_1$ and $\gamma \not\vdash \psi_2$. If $\psi_1 \in S_\beta$ we are done. Else we find by our construction a $\delta \in K^*$ with $\beta < \delta \leq \gamma$ such that $\psi_1 \in S_\delta$ and $\psi_2 \notin S_\delta$, hence $\beta \not\vdash^* \psi_1 \rightarrow \psi_2$. The converse is simple.

We now may conclude.

THEOREM 24. *IPC is complete for finite Kripke models over trees.*

Proof. By the above and Lemma 14. ■

As a consequence we get

COROLLARY 25. *IPC is decidable.*

Proof. We can effectively enumerate all finite Kripke models over trees, and hence effectively enumerate all refutable propositions. By enumerating all proofs in **IPC** we also obtain an effective enumeration of all provable propositions. By performing these enumerations simultaneously we obtain an effective test for provability in **IPC**. ■

Theorem 24 is also paraphrased as ‘**IPC** has the Finite Model Property (FMP)’, i.e. **IPC** $\not\vdash \varphi \Rightarrow \varphi$ is false in a finite model. The FMP is the key concept in our decidability proof. Note that the decision procedure of Corollary 25 is horribly inefficient. The procedures based on sequent calculus or natural deduction are much more practical.

Corollary 25 can be considerably improved, in the sense that narrower classes of Kripke models can be indicated for which **IPC** is complete.

EXAMPLES.

1. **IPC** is complete for the Jaskowski sequence J_n . The sequence J_n is defined inductively. J_1 is the one point tree.

J_{n+1} is obtained from J_n by taking $n+1$ disjoint copies J_n and adding an extra bottom node.

Cf. [Gabbay, 1981, p. 70 ff.]. The Jaskowski sequence is the Kripke model version of Jaskowski’s original sequence of truth tables, [Jaskowski, 1936].

2. **IPC** is complete for the full binary tree (cf. [Gabbay, 1981, p. 72]).

Strictly speaking we have given classes of Kripke frames, where completeness with respect to a class **K** of frames means ‘completeness with respect to all Kripke models over frames from **K**’.

During the early childhood of intuitionism and its logic it was put forward by some mathematicians that intuitionistic logic actually is a three-valued logic with values true, false, undecided. This proposal is wrong on two counts, it is philosophically wrong and by a result of Gödel no finite truth table completely characterizes intuitionistic logic (see Section 5).

Our comments on the failure of the *double negation shift*, DNS, (Section 3.11-10) have already made it clear that **IQC** is not complete for finite

Kripke frames. The usual refinement of the completeness proof tells us that (for a countable language) **IQC** is complete for countable Kripke models over trees.

Intuitionistic predicate calculus differs in a number of ways from its classical counterpart. Although both **IQC** and **CQC** are undecidable, monadic **IQC** is undecidable (Kripke) (cf. [Gabbay, 1981, p. 234]), whereas the monadic fragment of **CQC** is decidable (Behmann). Another remarkable result is the decidability of the prenex fragment of **IQC**, which implies that not every formula has a prenex normal form to which it is equivalent in **IQC**.

We will consider the class of prenex formulas below.

LEMMA 26. $\mathbf{IQC} \vdash \exists y\varphi(x_1, \dots, x_n, y) \Rightarrow \mathbf{IQC} \vdash \forall x_1, \dots, x_n\varphi(x_1, \dots, x_n, t)$, where all variables in φ are shown, and where t is either a constant or one of the variables x_1, \dots, x_n .

Proof. Add new constants a_1, \dots, a_n , then $\mathbf{IQC} \vdash \exists y\varphi(a_1, \dots, a_n, y)$ and apply EP. ■

We now get the following intuitionistic version of the Herbrand Theorem.

THEOREM 27. Let $Q_1x_1, \dots, Q_nx_n\varphi$ be a prenex sentence, then $\mathbf{IQC} \vdash Q_1x_1, \dots, Q_nx_n\varphi$ iff $\mathbf{IPC} \vdash \varphi'$, where φ' is obtained from φ by replacing the universally quantified variables by distinct new constants, and the existentially quantified variables by suitable old or new constants.

Proof. Induction on n . Use EP and Lemma 26. ■

As a corollary of Theorem 27 and Corollary 25 we get

THEOREM 28. The prenex fragment of **IQC** is decidable.

and

COROLLARY 29. There is not for every φ a prenex ψ such that $\mathbf{IQC} \vdash \varphi \leftrightarrow \psi$.

Among the properties that classical and intuitionistic logic share is the so-called

THEOREM 30 (Interpolation Theorem). If $\mathbf{IQC} \vdash \varphi \rightarrow \psi$, then there exists a σ , called an interpolant of $\varphi \rightarrow \psi$, such that

1. $\mathbf{IQC} \vdash \varphi \rightarrow \sigma$ and $\mathbf{IQC} \vdash \sigma \rightarrow \psi$
2. all non-logical symbols in σ occur in φ and in ψ .

The interpolation theorem was established by proof theoretical means by [Schütte, 1962] and [Prawitz, 1965]. Gabbay [1971] proved the theorem by

model theory, he also established a suitable form of Robinson’s consistency theorem.

For proofs and refinements the reader is referred to [Gabbay, 1981, Chapter 8], and [Troelstra and Schwichtenberg, 1996, §4.3], whereas in **CPC** the interpolation theorem holds in all fragments. Zucker has shown this not to be the case for **IPC** (cf. [Renardel de Lavalette, 1981]).

5.1 Independence of the Propositional Connectives

Whereas in classical logic the propositional connectives are interdefinable, this is not the case in **IPC**, a fact already known to McKinsey [1939]. There are a number of ways to show the independence of the intuitionistic connectives. A proof theoretical argument, based on the normal form theorem, is given by [Prawitz, 1965, p. 59 ff]. We will use some *ad hoc* considerations.

1. The independence of \vee from $\rightarrow, \wedge, \neg, \perp$ is clear, since $\rightarrow, \wedge, \neg, \perp$ are preserved under the double negation translation (up to provable equivalence), but \vee is not.
2. \neg is independent from $\vee, \rightarrow, \wedge$ already in **CPC**, so let alone in **IPC**.
3. \rightarrow is independent from \wedge, \vee, \neg . We use the simple fact that for \rightarrow -free $\varphi, \vdash (p \rightarrow q) \rightarrow \varphi \Rightarrow \vdash (p \rightarrow \neg\neg q) \rightarrow \varphi$. Definability of \rightarrow would yield $\vdash (p \rightarrow \neg\neg q) \rightarrow (p \rightarrow q)$.
4. \wedge is independent of $\vee, \rightarrow, \neg, \perp$. Consider the Kripke model

A simple inductive argument shows that the \wedge -free formulas are either equivalent to \perp or are forced in at least one of the lower nodes.

Although even the traditional definability result fail in intuitionistic logic, there is a completeness of the sets $\{\rightarrow, \wedge, \vee, \perp\}$ for **IPC** or $\{\rightarrow, \wedge, \vee, \perp, =, \exists, \forall\}$ for **IQC** under special assumptions. Zucker and Tragesser [1978] showed that logical constants, given by Natural Deduction rules are definable in the above sets. A similar result is to be found in [Prawitz, 1979].

In view of the incompleteness of the intuitionistic connectives there have been a number of definitions of new connectives, e.g. by model theoretic means (cf. Gabbay [1977; 1981, p. 130 ff], Goad [1978] and de Jongh [1980]). Kreisel introduced the connective $*$ by a second-order propositional condition: $*(\varphi := \exists\psi(\varphi \leftrightarrow \neg\psi \vee \neg\neg\psi))$. Matters of definability, etc. of $*$ have been extensively investigated in [Troelstra, 1980].

Figure 1.

5.2 The Addition of Skolem Functions is not Conservative

It is a fact of classical logic that the extension of a theory by Skolem functions does not essentially strengthen T (Vol 1, p. 89), i.e. (a simple case) if $T \vdash \forall x \exists y \varphi(x, y)$ then we may form T^S by adding a function symbol f and the axiom $\forall x \varphi(x, f(x))$ and T^S is conservative over T : if $T^S \vdash \sigma$ where σ does not contain f , then $T \vdash \sigma$. In general this is not true in intuitionistic logic [Minc, 1966]. We will show this by means of a simple counter example of Smoryński [1978].

Consider the theory T of equality **EQ** plus the extra axiom $\forall x \exists y (x \neq y)$, and its Skolem extension $T^S = \mathbf{EQ} + \forall x (x \neq f(x)) \wedge \forall xy (x = y \rightarrow f(x) = f(y))$, then T^S is not conservative over T .

It suffices to find a statement σ in the language of **EQ** such that $T^S \vdash \sigma$ and $T \not\vdash \sigma$. We take $\sigma := \forall x_1 \exists y_1 \forall x_2 \exists y_2 [x_1 \neq y_1 \wedge x_2 \neq y_2 \wedge (x_1 = x_2 \rightarrow y_1 = y_2)]$.

Clearly $T^S \vdash \sigma$. The Kripke model of figure 1 establishes $T \not\vdash \sigma$.

Clearly $\alpha \Vdash \forall x \exists y (x \neq y)$.

Now suppose $\alpha \Vdash \sigma$. Take a, b for x_1, x_2 then we must take d, c for y_1, y_2 (in that order). However $\alpha \not\vdash a = b \rightarrow c = d$.

The equality fragment of T^S is axiomatised in [Smoryński, 1978].

5.3 Fragments of IPC

The situation in intuitionistic logic radically changes if one leaves out some connectives. We mention the following result: (Diego, McKay) there are only finitely many non-equivalent propositions built from finitely many atoms in the \vee -free fragment (cf. [Gabbay, 1981, p. 80]).

5.4 Some Remarks on Completeness and Intuitionistically Acceptable Semantics

This section uses notions of later sections, in particular Section 9. the reader is suggested to consult those sections.

As we have argued in Section 1, an interpretation of the logical constants based on intuitionistic principles must somehow exploit the notion of construction. This has been proposed by Heyting, and extended by Kreisel. It has not (so far), however, led to a flexible semantics that provided logic with completeness. The more successful semantics have provided completeness theorems, but at the price of importing classical metamathematics. This is a matter of considerable philosophical interest. As Intuitionism is a legitimate, well-motivated philosophy, it should at least have a semantics for its logic that stands up to the criteria of the underlying philosophy; unless one adopts Brouwer's radical view that 'mathematics is an essentially languageless activity'. The traditional semantics lend themselves perfectly well to an intuitionistic formulation. One has to select among the various classically equivalent formulations the intuitionistically correct one (e.g. in the topological interpretation $\llbracket \varphi \rightarrow \psi \rrbracket = \text{Int}\{x \mid x \in \llbracket \varphi \rrbracket \rightarrow x \in \llbracket \psi \rrbracket\}$ and *not* $\text{Int}((\llbracket \varphi \rrbracket^c \cup \llbracket \psi \rrbracket))$). Soundness does not present problems, so independence results can usually be obtained by Intuitionistic means. For the more sophisticated applications of semantics one usually needs completeness, and the original completeness proofs relied heavily on classical logic. For propositional logic the problem is relatively simple.

The first positive result was provided by Kreisel, who in [Kreisel, 1958] interpreted **IPC** by means of lawless sequences, and showed by intuitionistic means **IPC** to be complete for this particular interpretation.

The basic idea is to relate Beth models (which are special cases of topological models) to lawless sequences, considered as paths through the underlying trees; one assigns sets of lawless sequences to propositions, $\varphi \mapsto \llbracket \varphi \rrbracket$, cf. Theorem 17, such that the logical operations correspond to the Heyting algebra operations. Since one can restrict oneself to finitely branching trees in this context, one can show completeness for the topological space of lawless sequences using only the simple properties of lawless sequences (including the fan theorem). Kripke [1965] indicates a similar procedure on the basis of Kripke models.

A more serious matter is the completeness of predicate calculus. The plausible approach, i.e. to interpret 'validity' as 'validity in structure *à la* Tarski', called *internal validity* by Dummett [1977, p. 215], led to an unexpected obstacle. Kreisel [1962], following Gödel, established the following result: if **IQC** is complete for internal validity, then $\forall \xi \neg \neg \exists x \varphi(\xi, x) \rightarrow \forall \xi \exists x \varphi(\xi, x)$ holds for all primitive recursive predicates φ .

So validity of the above kind would give us Markov's 'Principle' (cf. Section 6.5.3), a patently non-intuitionistic principle. It does not do any good to consider Beth semantics, for one can obtain the same fact for validity in all Beth models [Dyson and Kreisel, 1961]. Even worse, under the assumption of Church's Thesis (i.e. all functions from $\mathbb{N} \rightarrow \mathbb{N}$ are recursive, cf. Chapter 4 of Vol. 1 of this *Handbook*) **IQC** is *incomplete* in the sense that the set

of valid formulae is not recursively enumerable, as established by [Kreisel, 1970] (cf. [van Dalen, 1973; Leivant, 1976]).

The strongest result so far is McCarty's theorem; constructive validity is nonarithmetic, [McCarty, 1988]. This bleak situation in semantics for **IQC** changed when Veldman in 1974 introduced a technical device that allowed for a modified Kripke (and similarly, Beth) semantics for which the completeness of **IQC** can be established in an intuitionistically acceptable manner. Although Veldman's proposal can be implemented in more than one way, its main feature is relaxation of the forcing conditions for atoms: $\alpha \Vdash \perp$ is in general allowed. For these more general models intuitionistic completeness proofs have been give for the Kripke version by [Veldman, 1976], and for the Beth version by [Swart, 1976].

Extensive discussions of the aspects of intuitionistic completeness of **IQC** are to be found in [Dummett, 1977] and [Troelstra, 1977]. H. Friedman [1977; 1977a] has sketched intuitionistically correct completeness proofs for **MQC** and the \perp (and \neg)-free part of **IQC**. The details of a slightly upgraded version can be found in [Troelstra and van Dalen, 1988, §13.2], there the result is cast in the form of a universal Beth model:

1. There is a Beth model \mathcal{M} such that $\mathcal{M} \Vdash \varphi \Leftrightarrow \mathbf{IQC} \vdash \varphi$ for all \perp -free formulas φ .
2. There is a Beth model \mathcal{M} for minimal logic such that $\mathcal{M} \Vdash \varphi \Leftrightarrow \mathbf{MQC} \vdash \varphi$ for all φ .
3. there is a *modified* Beth model \mathcal{M}^* such that $\mathcal{M}^* \Vdash \varphi \Leftrightarrow \mathbf{IQC} \vdash \varphi$ for all φ .

5.5 *The Intuitionistic View of Non-intuitionistic Model Theoretic Methods*

It should not come as a surprise that for intuitionists such semantical proofs as employed, e.g. in the case of DP (cf. Theorem 23) do not carry much weight. After all, one wants to extract a proof of either φ or ψ from a proof of $\varphi \vee \psi$, and the gluing proof doe not provide means for doing so. There is however a roundabout way of having one's cake and eating it. For example, in the case of the proof of DP one shows classically that ' φ has no proof in **IQC**' ' ψ has no proof in **IQC**' then ' $\varphi \vee \psi$ has no proof in **IQC**', and hence (classically) $\mathbf{IQC} \vdash \varphi \vee \psi \Rightarrow \mathbf{IQC} \vdash \varphi \vee \mathbf{IQC} \vdash \psi$.

One formalizes this statement in Peano's Arithmetic, so

$$\mathbf{PA} \vdash \exists x \text{Pr}_{\mathbf{IQC}}(x, \ulcorner \varphi \vee \psi \urcorner) \rightarrow \exists y \text{Pr}_{\mathbf{IQC}}(y, \ulcorner \varphi \urcorner) \vee \exists z \text{Pr}_{\mathbf{IQC}}(z, \ulcorner \psi \urcorner)$$

or

$$\mathbf{PA} \vdash \forall x \exists yz (\text{Pr}_{\mathbf{IQC}}(x, \ulcorner \varphi \vee \psi \urcorner) \rightarrow \text{Pr}_{\mathbf{IQC}}(y, \ulcorner \varphi \urcorner) \vee \text{Pr}_{\mathbf{IQC}}(z, \ulcorner \psi \urcorner)).$$

Now one uses the fact that **PA** is conservative over **HA** for Π_2^0 statements, so that $\mathbf{HA} \vdash \forall x \exists y z (\underline{\hspace{2cm}})$.

This shows that DP is intuitionistically correct. In [Smoryński, 1982] problems of this kind is considered in a more general setting. Of course, one might wonder why go through all this rigmarole when direct proofs (e.g. via natural deduction, or slash operations) are available. A matter of taste maybe.

6 INTERMEDIATE LOGICS

By adding the principle of the excluded middle to **IPC** we obtain full classical propositional logic. It is a natural question what logics one gets by adding other principles. We will consider extensions of **IPC** by schemas, e.g. $\mathbf{IPC} + (\varphi \rightarrow \psi) \vee (\psi \rightarrow \varphi)$. First we remark that all such extensions are subsystems of **CPC**, for let T be such an extension and suppose that $T \not\subseteq \mathbf{CPC}$, then there is a φ such that $T \vdash \varphi$ (and hence all substitution instances) and φ is not a tautology. but then we find by substituting, say $p_0 \wedge \neg p_0$ and $p_0 \rightarrow p_0$ for suitable atoms of φ an instance φ' which is false. therefore $\mathbf{CPC} \vdash \neg \varphi'$ and, by Glivenko's theorem (Corollary 51) $\mathbf{IPC} \vdash \neg \varphi'$. This contradicts $T \vdash \varphi'$.

So there are only logics between **IPC** and **CPC** to consider.

The study of intermediate logics is mainly a matter for pure technical logic, dealing with completeness, finite model property, etc. There are however certain intermediate logics that occur more or less naturally in real life (e.g. in the context of Gödel's Dialectica interpretation, or of realizability), so that their study is not merely *l'art pour l'art*. One such instance is Dummett's logic **LC**, which turns up in the provability logic of Heyting's arithmetic (cf. [Visser, 1982]).

One of the most popular topics in intermediate logic was the investigation of classes of semantics for which various logics are complete. Furthermore there is the problem to determine the structure of the family of all intermediate logics under inclusion.

The field has extensively been studied and an even moderately complete treatment is outside the scope of this chapter. the reader is referred to [Rautenberg, 1979] and [Gabbay, 1981].

6.1 Dummett's Logic **LC**

DEFINITION. $\mathbf{LC} = \mathbf{IPC} + (\varphi \rightarrow \psi) \vee (\psi \rightarrow \varphi)$.

Theorem. **LC** is complete for linearly ordered Kripke models.

One direction is simple, one just checks that $(\varphi \rightarrow \psi) \vee (\psi \rightarrow \varphi)$ holds in all linearly ordered Kripke models. For the converse, consider the model,

obtained in the Model Existence Lemma 14, consisting of prime theories, ordered by inclusion. The bottom node Γ_0 forces all instances of the schema $(\varphi \rightarrow \psi) \vee (\psi \rightarrow \varphi)$.

Consider Γ_1, Γ_2 with $\varphi \in \Gamma_1 - \Gamma_2$ for some φ . We will show that $\Gamma_2 \subseteq \Gamma_1$. Let $\psi \in \Gamma_2$. Since $\Gamma_0 \Vdash \varphi \rightarrow \psi$ or $\Gamma_0 \Vdash \psi \rightarrow \varphi$ and $\Gamma_0 \subseteq \Gamma_i (i = 1, 2)$ we have $\psi \in \Gamma_1$ or $\varphi \in \Gamma_2$. As the latter is ruled out we find $\psi \in \Gamma_1$. Hence for any two Γ_1, Γ_2 , we have $\Gamma_1 \subseteq \Gamma_2$ or $\Gamma_2 \subseteq \Gamma_1$.

This establishes the semantic characterisation of **LC**.

6.2 Filtration and Minimalisation

Some models are needlessly complicated because some of their nodes are in a sense redundant. A simple case is a model with two nodes $\alpha < \beta$, which force exactly the same formulas. The idea to collapse nodes that force the same formulas presents itself naturally. Scott and Lemmon introduced such a procedure in modal logic under the name of filtration [Lemmon and Scott, 1966], and Smoryński did something similar in intuitionistic logic under the name of minimalisation [Smoryński, 1973; Segerberg, 1968]. Let a Kripke model $\mathcal{K} = \langle K, \leq, \Vdash \rangle$ be given. We consider forcing on \mathcal{K} for a class of formulas Γ closed under subformulas. For $\alpha \in K$ define $[\alpha]_\Gamma := \{\varphi \in \Gamma \mid \alpha \Vdash \varphi\}$. Put $K_\Gamma = \{[\alpha]_\Gamma \mid \alpha \in K\}$, $[\alpha]_\Gamma \leq [\beta]_\Gamma$ if $[\alpha]_\Gamma \subseteq [\beta]_\Gamma$ and $[\alpha]_\Gamma \Vdash \varphi$ if $\varphi \in [\alpha]_\Gamma$ for atomic φ . Observe that the mapping $\alpha \rightarrow [\alpha]_\Gamma$ is a homomorphism of posets.

Obviously $\mathcal{K}_\Gamma = \langle K_\Gamma, \leq, \Vdash_\Gamma \rangle$ is a Kripke model.

THEOREM 31. $[\alpha]_\Gamma \Vdash_\Gamma \varphi \Leftrightarrow \alpha \Vdash \varphi$ for $\varphi \in \Gamma$.

Proof. Induction on φ . The only non-trivial case is the implication.

(i) $\alpha \not\Vdash \varphi \rightarrow \psi \Leftrightarrow \exists \beta \geq \alpha \beta \Vdash \varphi$ and $\beta \not\Vdash \psi \Leftrightarrow$ (induction hypothesis) $\Leftrightarrow \exists \beta \geq \alpha ([\beta]_\Gamma \Vdash_\Gamma \varphi$ and $[\beta]_\Gamma \not\Vdash_\Gamma \psi)$.

Since $\beta \geq \alpha$ implies $[\beta]_\Gamma \supseteq [\alpha]_\Gamma$, we have $\alpha \not\Vdash \varphi \rightarrow \psi$.

(ii) $\alpha \Vdash \varphi \rightarrow \psi$. Let $[\alpha]_\Gamma \subseteq [\beta]_\Gamma$ and $[\beta]_\Gamma \Vdash_\Gamma \varphi$. By induction hypothesis $\beta \Vdash \varphi$ and hence $\varphi \in [\beta]_\Gamma$. But $\varphi \rightarrow \psi \in [\alpha]_\Gamma \subseteq [\beta]_\Gamma$, so $\beta \Vdash \psi$ and again by induction hypothesis $[\beta]_\Gamma \Vdash_\Gamma \psi$. This shows $[\alpha]_\Gamma \Vdash_\Gamma \varphi \rightarrow \psi$. ■

Observe that this procedure does not preserve all desirable properties, e.g. being a tree.

EXAMPLE.

Gabbay has refined the notion of filtration in order to obtain models with special properties. For this *selective filtration* cf. [Gabbay, 1981, p. 87 ff.].

6.3 The Finite Model Property, FMP

An intermediate logic is said to have the Finite Model Property if it is complete for a class of finite models. We have already seen the importance of the FMP for logic: if T is effectively axiomatised (RE will do) and has the FMP, then T is decidable [Harrop, 1958].

The following facts may be helpful in establishing the FMP in some cases.

THEOREM 32 (Smoryński [1973]).

1. Let T be complete for a class of Kripke models with posets characterised by positive sentences in a language extended by individual constants, then T has the FMP.
2. as (1) but with universal sentences and finitely many constants.

Proof.

1. Let $\alpha_0 \not\models \varphi$ for α_0 bottom node of \mathcal{K} . Apply filtration to \mathcal{K} and call the result \mathcal{K}' . \mathcal{K}' is a homomorphic image of \mathcal{K} and since positive sentences are preserved under homomorphic images (a simple fact of model theory), \mathcal{K}' belongs to the given class. Since we only have to consider subformulas of φ , \mathcal{K}' evidently is finite.
2. Use the fact that universal sentences are preserved under substructures (cf. [van Dalen, 1997, p. 141, ex. 3]) and apply the construction given in the proof of Theorem 24. ■

COROLLARY 33. **LC** has the FMP and is decidable.

6.4 The ‘Bounded Height’ models

A Kripke frame (model) is said to have height n if the maximum length of its chains is n . If the length of the chains is unbounded, we say that the height is ω . Can we find an intermediate logic such that it is complete for all frames of height at most n ?

We define a sequence of propositions φ_i by:

$$\begin{aligned} \varphi_1 &:= p_1 \vee \neg p_1 \\ \varphi_{n+1} &:= p_{n+1} \vee (p_{n+1} \rightarrow \varphi_n), \end{aligned}$$

where p_n is the n th atom.

Let $\mathbf{BH}_n = \mathbf{IPC} + \varphi_n$, where we take φ_n to be a *schema* (i.e. we add all substitution instances of φ_n to \mathbf{IPC}).

THEOREM 34. \mathbf{BH}_n is complete for all Kripke frames of height $\leq n$.

Proof. Suppose that \mathcal{K} has height $\leq n$ and for some $\alpha_0 \in K, \alpha_0 \not\Vdash \varphi_n$. So $\alpha_0 \not\Vdash \tau_n \rightarrow \varphi_{n-1}, \alpha_0 \not\Vdash \tau_n$ for some τ_n . by definition of forcing we find an $\alpha_1 > \alpha_0$ such that $\alpha_1 \Vdash \tau_n$ and $\alpha_1 \not\Vdash \varphi_{n-1}$. By iterating this step we find an increasing sequence $\alpha_0 < \alpha_1 < \dots < \alpha_n$. This contradicts the condition on the heights, so $\mathcal{K} \Vdash \mathbf{BH}_n$.

Conversely, we have to show that if $\mathbf{BH}_n \not\Vdash \sigma$ then there exists a model of height $\leq n$ which falsifies σ . So let \mathcal{K} be a Kripke model of \mathbf{BH}_n and not of σ . We obtain \mathcal{K}' from it by filtration. It remains to show that \mathcal{K}' has height $\leq n$. Suppose \mathcal{K}' has a chain $\alpha_0 < \alpha_1 < \dots < \alpha_n$. Since \mathcal{K}' is filtrated we can find atoms $p_i (i = 1, \dots, n)$, such that $\alpha_{n-i+1} \Vdash p_i$ and $\alpha_{n-i} \not\Vdash p_i$. So $\alpha_j \Vdash p_i$ if and only if $j > n - i$.

Claim: $\alpha_{n-i} \not\Vdash \varphi_i$. We show this by induction on i . By definition $\alpha_{n-1} \not\Vdash \varphi_1$. $\alpha_{n-i-1} \Vdash \varphi_{i+1} \Leftrightarrow \alpha_{n-i-1} \Vdash p_{i+1} \vee (p_{i+1} \rightarrow \varphi_i)$. Now $\alpha_{n-i-1} \not\Vdash p_{i+1}$, and $\alpha_{n-1} \Vdash p_{i+1}$ but $\alpha_{n-1} \not\Vdash \varphi_i$, by induction hypothesis; so $\alpha_{n-i-1} \not\Vdash \varphi_{i+1}$. We now may apply the induction principle: $\alpha_0 \not\Vdash \varphi_n$. Contradiction.

So \mathcal{K}' has height $\leq n$. ■

COROLLARY 35. \mathbf{BH}_n has the FMP and is decidable.

Proof. The posets of height $\leq n$ are axiomatised by

$$\forall x_0 \dots x_n \left(\bigwedge_{i=0}^{n-1} x_i \leq x_{i+1} \rightarrow \bigvee_{i=0}^{n-1} x_i = x_{i+1} \right).$$

Apply Theorem 32. ■

It is obvious that \mathbf{BH}_ω coincides with \mathbf{IPC} , so only the finite \mathbf{BH}_n 's are relevant here for us.

Another approach to the bounded height logics is via a sequence of generalisations of *Peirce's law*:

$$\begin{aligned} \pi_1 &= ((p_1 \rightarrow p_0) \rightarrow p_1) \rightarrow p_1 \\ \pi_{n+1} &= ((p_{n+1} \rightarrow \pi_n) \rightarrow p_{n+1}) \rightarrow p_{n+1}. \end{aligned}$$

Put $\mathbf{LP}_n = \mathbf{IPC} + \pi_n, \mathbf{LP}_\omega = \mathbf{IPC}$.

Ono [1972] and Smoryński [1973] showed that $\mathbf{BH}_n = \mathbf{LP}_n$. The notion of *nth slice* was introduced by [Hosoi, 1967] to capture logic of exact height n : \mathfrak{S}_n is the class of logics that are complete for models of height n , but not for models of smaller height.

6.5 Cardinality Conditions

Consider the statement

$$C_n := \bigvee_{0 \leq i < j \leq n} p_i \leftrightarrow p_j;$$

if C_n holds in a model with bottom node then two atoms must be forced on exactly the same set of nodes. So if we have n nodes, then there are 2^n subsets and hence C_{2^n} holds in all models of $\leq n$ elements. This bound is in general too crude. Let us therefore specialise the class of models to linearly ordered frames.

Put $\mathbf{S}_n = \mathbf{LC} + C_{n+1}$ (as a schema).

THEOREM 36. *\mathbf{S}_n is complete for all linear models with n nodes.*

Proof. If the model has n nodes then by a simple inspection one sees that C_{n+1} holds. Conversely, if a model of \mathcal{K} of C_{n+1} , obtained by filtration, has at least $k + 1$ nodes $\alpha_0 < \alpha_1 < \dots < \alpha_n$, then by filtration we can find $\varphi_1, \dots, \varphi_n$ such that $\alpha_i \not\Vdash \varphi_{i+1}$ and $\alpha_{i+1} \Vdash \varphi_{i+1}$. Putting $\varphi_0 := p \rightarrow p$ and $\varphi_{n+1} := p \wedge \neg p$, we obtain an instance of C_{n+1} that is not forced by α_0 . This shows that \mathbf{S}_n is complete for models with linear poset of length $\leq n$. But, since we can always add some nodes for free, it is also complete for all linear models with exactly n nodes.

Converting the linear, finite Kripke frames into truth tables one obtains Gödel's many-valued logic, used to establish the fact that \mathbf{IPC} is not a (finite) many-valued logic [1932]. ■

6.6 Some More Intermediate Logics

A number of intermediate logics have found their way into the literature. We will mention some of them, with their main properties.

\mathbf{KC} is axiomatised by $\neg\varphi \vee \neg\neg\varphi$.

1. \mathbf{KC} is strongly complete for the class of directed Kripke frames. (A poset is direct if it satisfies $\forall\alpha\beta\exists\gamma(\alpha \leq \gamma \wedge \beta \leq \gamma)$.)
2. \mathbf{KC} is strongly complete for the class of Kripke frames with a maximum.

For proofs see [Gabbay, 1981, p. 66 ff.], [Smoryński, 1973]. \mathbf{KC} can alternatively be axiomatised by $(\neg\varphi \rightarrow \neg\psi) \vee (\neg\psi \rightarrow \neg\varphi)$. This shows that \mathbf{LC} is an extension of \mathbf{KC} .

The Kreisel–Putnam system \mathbf{KP} is axiomatised by $(\neg\sigma \rightarrow \varphi \vee \psi) \rightarrow [(\neg\sigma \rightarrow \varphi) \vee (\neg\sigma \rightarrow \psi)]$ [Kreisel and Putnam, 1957].

\mathbf{KP} has the DP and FMP, and Gabbay has shown it to be complete for the class of Kripke models satisfying the condition # below [Gabbay, 1970].

For a poset $\langle K, \leq \rangle$ with bottom element we define for a subset E of K :

$$E^+ = \{p \mid \exists q \in E (q \leq p)\}; E^- = \{p \mid \exists q \in E (p \leq q)\}.$$

For every $E \subseteq P$ the set $P - (E^+)^-$ is either empty or has a first element.

For a proof see [Gabbay, 1981, p. 96 ff.].

Notions of width

The width of a frame can be conceived in various ways. One can look for the length of maximal anti-chains, or the maximal number of successors of individual nodes (say in finite frames). We will consider some notions below.

(a) *Anti-chain width.* A Kripke frame \mathcal{K} has *a.c. width* n if it has an anti-chain length n , but no anti-chain of length $n + 1$. Define

$$\varphi_n = \bigvee_{i=0}^n \left(p_i \rightarrow \bigvee_{j \neq i} p_j \right) \text{ and } \mathbf{BA}_n = \mathbf{IPC} + \varphi_n \text{ (as a schema).}$$

THEOREM. [Smoryński, 1973] \mathbf{BA}_n is strongly complete for the class of frames of a.c. width at most n .

The proof is routine, use filtration.

COROLLARY. \mathbf{BA}_n has the FMP and is decidable.

(b) *Top-width.* In finite frames one can just count the number of top nodes, this gives a maximum width for trees, but not for posets in general.

Define the *top-width* of a frame as the number of maximal nodes and put

$$\begin{aligned} \delta_n &:= \bigvee_{i=0}^n \left(\neg p_i \rightarrow \bigvee_{j \neq i} \neg p_j \right), \\ \psi_n &:= \left(\bigwedge_{0 \leq i < j \leq n} \neg(\neg p_i \wedge \neg p_j) \right) \rightarrow \delta_n \end{aligned}$$

and $\mathbf{BTW}_n := \mathbf{IPC} + \psi_n$ (as a schema).

THEOREM. [Smoryński, 1973] \mathbf{BTW}_n is complete for the class of all frames of top-width at most n .

COROLLARY. \mathbf{BTW}_n has the FMP and is decidable.

(c) *Local width* [Gabbay and de Jongh, 1974]. We consider finite trees and define the *local width* of a tree frame as the maximum number of successors of its nodes. Define

$$\alpha_n := \left[\bigwedge_{i=0}^{n+1} \left(\left(p_i \rightarrow \bigvee_{i \neq j} p_j \right) \rightarrow \bigvee_{i \neq j} p_j \right) \right] \rightarrow \bigvee_{i=0}^{n+1} p_i$$

and $\mathbf{LW}_n = \mathbf{IPC} + \alpha_n$ (as a schema).

THEOREM. \mathbf{LW}_n is complete for tree frames of local width at most n .

COROLLARY. \mathbf{LW}_n has the FMP and is decidable.

Furthermore one can show that

1. \mathbf{LW}_n has the DP (use the gluing trick)
2. $\bigcap \mathbf{LW}_n = \mathbf{IPC}$
3. $\mathbf{LW}_n \neq \mathbf{LW}_{n+1}$.

For proofs see [Gabbay, 1981, p. 83 ff.].

6.7 The Lattice of Intermediate Logics

Intermediate logics constitute a poset under the natural order of inclusion. Let us agree to consider intermediate logics as being given by axiom schemata. Observe that any such consistent extension of \mathbf{IPC} is a subsystem of \mathbf{CPC} . Hence we can safely form the meet and join of intermediate logics as follows: let T_i be axiomatised by the schemas $\varphi_j^i (j \geq 0)$, then $T_1 \sqcap T_2 (T_1 \sqcup T_2)$ are axiomatised by $\varphi_1^j \vee \varphi_2^k (\varphi_1^j \wedge \varphi_2^k)$. It immediately follows that the intermediate logics constitute a distributive lattice.

This lattice has extensively been investigated. We have already met some properties: e.g. there is a descending sequence of logics with intersection \mathbf{IPC} (Section 5.6.3 (c)).

Further properties are:

There are 2^{\aleph_0} many intermediate logics [Jankov, 1968].

There are intermediate logics, that are not finitely axiomatisable.

There exists a sequence of formulas φ_i such that the logics T_A axiomatised by $\{\varphi_i \mid i \in A\}$ for $A \subseteq \omega$, satisfy $T_A = T_B \Leftrightarrow A = B$. Such a string is called strongly independent (cf. [Gabbay, 1981, p. 73 ff.]).

There are intermediate logics without the FMP (cf. [Gabbay, 1981, p. 103 ff]).

There exists a strictly increasing chain of intermediate logics [Jankov, 1968; Fine, 1970].

There are exactly eight intermediate logics with the interpolation theorem [Maximova, 1977]. For more information cf. [Rautenberg, 1979, p. 288 ff].

6.8 Extensions of **IQC**

The study of intermediate predicate logics has not yet made advances comparable to those in propositional logic. We refer the reader to, e.g. [Ono, 1973].

The best known extension of **IQC** is the *logic of constant domains* introduced by [Grzegorzcyk, 1964], and axiomatised and shown complete by [Görnemann, 1971].

Put $\mathbf{CD} = \mathbf{IQC} + \forall x(\varphi \vee \psi(x)) \rightarrow (\varphi \vee \forall x\psi(x))$.

THEOREM. [Görnemann] **CD** is complete for the class of Kripke models with constant domain.

Proof. See [Gabbay, 1981, p. 50 ff]. ■

CD has somewhat unpleasant features as it is not closed under relativisation, i.e. if $\tau(x)$ is some suitable formula then we may have $\mathbf{CD} \vdash \sigma$ but $\mathbf{CD} \not\vdash \sigma^{\tau(x)}$, where $\sigma^{\tau(x)}$ is the sentence obtained by relativizing all quantifiers. The reason being that although the domain is fixed, predicates need not be constant in Kripke models for **CD**.

The difference between **IQC** and **CD** disappears when we restrict ourselves to formula without \forall [Fitting, 1969] or without \forall and \exists [Gabbay, 1981].

Another noteworthy principle is the *double negation shift* DNS:

$$\forall x \neg \neg \varphi(x) \rightarrow \neg \neg \forall x \varphi(x).$$

Put $\mathbf{MH} := \mathbf{IQC} + \mathbf{DNS}$.

MH turns out to be complete for Kripke models with the property that each node is below some maximal node [Gabbay, 1981, p. 57 ff]. Keeping the proof of Glivenko's theorem in mind, it is not surprising that it holds for **MH**.

Actually **MH** is the smallest such extension of **IQC** [Gabbay, 1981, p. 14].

To finish this section, let us mention a rather different enterprise. Ono and Komori [1985] studied intuitionistic propositional calculus in the Gentzen sequent formalisation, without the contraction rule. They generalise Kripke models to monoid-Kripke models and establish the completeness theorem. Ono [1985] extends this study to predicate calculus.

The study of logics without structural rules is the subject of Girard's *linear logic*, cf. [Girard *et al.*, 1989].

7 FIRST-ORDER THEORIES

A number of basic notions of intuitionistic mathematics can faithfully be studied in the framework of intuitionistic first-order logic. Although the

situation is similar to that in classical logic, there is one disturbing aspect peculiar to intuitionistic logic (or rather its semantics): the absence of natural (or standard) models. Let us compare the state of affairs with classical logic. For theories in **CQC** we have not only the traditional notion of model, as presented by Tarski (cf. [van Dalen, 1997]), but also the notion of Boolean-valued model [Rasiowa and Sikorski, 1963]. The reader who is not familiar with the theory of Boolean valued models, may think of a topological model over a discrete space, i.e. with $\mathcal{O}(X) = \mathcal{P}(X)$. Or he may think of Heyting algebras with the extra condition $\neg\neg x = x$ for all x (or $\neg x \sqcup x = T$).

The truth values $\llbracket \varphi \rrbracket$ are simply elements of a Boolean algebra B . There is among the Boolean algebras a canonical one that is contained in all Boolean algebras, the two-element algebra $2 = \{0, 1\}$, with operations given by the traditional truth tables. Now there is for each Boolean-valued model a (truth preserving homomorphism onto a Boolean-valued model over 2, i.e. an ordinary model. Hence truth in all Boolean-valued models is equivalent to truth in all ordinary models. So the notion of truth according to ordinary model theory coincides with that of Boolean-valued model theory (cf. [Rasiowa and Sikorski, 1963, p. 295]). The ordinary models can thus be considered as the real (or standard) models among the Boolean-valued ones. This relation does not exist for intuitionistic semantics (say Heyting-valued, to take the most general one). For although 2 is contained in (and can be obtained as homomorphic image of) all Heyting-algebras, truth in all Heyting value model is certainly not the same as truth in all 2-valued (i.e. classical) models.

The fact that for intuitionistic first-order theories there does not exist a canonical model notion in the various semantics that we have exhibited is one that we have to accept, unpleasant as it may be.

Philosophically speaking there are two ways to open to use— (1) look for a codification of the Brouwer–Heyting–Kreisel notion of proof-interpretation, (2) give up the notion of ‘standard’ truth, or intended model.

We will discuss the problem of semantics later, but not without pointing out that the absence of a standard model for arithmetic in any of the semantics introduced earlier, is rather embarrassing (see below).

We will discuss a number of basic first-order theories below. The most fundamental is the theory of equality.

7.1 *The Theory of Equality* **EQ**

The axioms for **EQ** are the familiar ones:

the universal closures of

1. $x = x$
2. $x = y \rightarrow y = x$

$$3. x = y \wedge y = z \rightarrow x = z$$

(whenever we list axioms we will tacitly presuppose the clause ‘the universal closure of’).

As in classical logic one shows by induction on φ $x = y \rightarrow (\varphi(x) \rightarrow \varphi(y))$.

Let us consider a Kripke model for **EQ**. We will denote the binary relation that interprets $=$ in α by \approx_α . One easily sees that \approx_α is an equivalence relation in (the domain of) each node. In general, however, \approx_α is not the identity. For, suppose that \approx_α were the identity in each node, then if for $a, b \in \alpha$ $a \not\approx_\alpha b$, we see that for all $\beta \geq \alpha$, $a \not\approx_\beta b$ in β . Hence $\alpha \Vdash a = b \vee a \neq b$. Conversely, if $\mathcal{K} \Vdash \forall xy(x = y \vee x \neq y)$, then we can construct from \mathcal{K} a Kripke model \mathcal{K}' with \approx the identity in each node.

For, since \approx_α is an equivalence relation we can form equivalence classes $[a]_\alpha$ for each a in α .

Define $\alpha \Vdash' a = b := [a]_\alpha = [b]_\alpha (\Leftrightarrow a \approx_\alpha b)$.

Claim: $\alpha \Vdash \varphi \Leftrightarrow \alpha \Vdash' \varphi$ for all $\alpha \in K$.

Proof. Induction on φ . The definition of \Vdash' takes care of the atomic φ . \wedge and \vee are immediate, $\alpha \not\Vdash \varphi \rightarrow \psi \Leftrightarrow \exists \beta \geq \alpha, \beta \Vdash \varphi$ and $\beta \not\Vdash \psi \Leftrightarrow$ (induction hypothesis) $\exists \beta \geq \alpha, \beta \Vdash' \varphi$ and $\beta \not\Vdash' \psi \Leftrightarrow \alpha \not\Vdash' \varphi \rightarrow \psi$.

$\alpha \Vdash \forall x\varphi(x) \Leftrightarrow \forall a \in \alpha, \alpha \Vdash \varphi(\bar{a}) \Leftrightarrow \forall [a] \in \alpha, \alpha \Vdash' \varphi(\bar{a}) \Leftrightarrow \alpha \Vdash' \forall x\varphi(x)$ (where \bar{a} is the name of a in \mathcal{K} and of $[a]$ in \mathcal{K}'). A similar argument handles \exists . A slight boost of the argument yields the same result for arbitrary languages.

Summing up: **IQC** with decidable equality is complete for normal Kripke models (i.e. with $=$ interpreted by real equality).

The theory **EQ** is of interest since the basic theories of real life depend heavily on equality.

In general T^c will denote the classical theory $T + \varphi \vee \neg\varphi$, T^d will denote the theory $T +$ decidability for atoms. We will keep superscripts for ‘logical’ and prefixes for ‘mathematical’ variants of theories.

The following facts have been proved:

$$\mathbf{EQ}^d = \mathbf{EQ}^c$$

decidable

\mathbf{EQ}^d	+	[Lifschitz, 1969]
\mathbf{EQ}^s	-	[Lifschitz, 1969]
\mathbf{EQ}	-	[Lifschitz, 1969],

where \mathbf{EQ}^s is the theory of stable inequality: $\forall xy(\neg\neg x = y \rightarrow x = y)$. ■

7.2 The Theory of Apartness, **AP**

For practical purposes one needs in intuitionistic mathematics a strong inequality relation. For example, in the theory of the reals one needs a prop-

erty like ‘ x has a positive distance to 0 ($\exists k(|x| > 2^{-k})$), to make sure that x has an inverse. A mere inequality would not do.

The positive inequality relation was introduced by Brouwer in 1918 and axiomatized by Heyting.

Notation $x \# y$ read x is apart from y .

AP has the axioms of **EQ** plus the following ones:

$$\begin{aligned} \neg x \# y &\leftrightarrow x = y \\ x \# y &\rightarrow x \# z \vee y \# z. \end{aligned}$$

One easily derives the following:

FACT 37. The following are derivable in **AP**.

$$\begin{aligned} x \# y &\rightarrow y \# x \\ x \# y &\rightarrow x \neq y \\ \neg \neg x = y &\rightarrow x = y. \end{aligned}$$

In particular **AP** has a stable equality. Most theories that occur in basic mathematics have an apartness relation. Combinatory logic, however, does not allow an apartness relation since its equality is not stable.

A theory with decidable equality trivially has an apartness relation, namely the inequality. One and the same structure may, however, carry more apartness relations.

EXAMPLE

The above models carry the same, decidable, equality, but distinct apartness relation.

The apartness relation influences the equality relation, the question is does it stop at the stability axiom or does it carry stronger conditions? The answer is provided in [van Dalen and Statman, 1979] where the axiomatisation of the equality fragment of **AP** is studied.

Consider the following sequence of inequalities \neq_n

$$\begin{aligned} x \neq_0 y &:= \neg x = y \\ x \neq_{n+1} y &:= \forall z (x \neq_n z \vee y \neq_n z). \end{aligned}$$

For each n we formulate a stability axiom

$$S_n := \neg x \neq_n y \rightarrow x = y.$$

FACT.

$$\begin{array}{ll} \mathbf{EQ} \vdash S_n \rightarrow S_m & \text{for } n > m \\ \mathbf{AP} \vdash S_n & \text{for all } n \\ \mathbf{AP} \vdash x \# y \rightarrow x \neq_n y & \text{for all } n. \end{array}$$

Consider the ω -stable theory of equality $\mathbf{EQ}_\omega^s = \mathbf{EQ} + \{S_n \mid n \in \omega\}$

\mathbf{EQ}_ω^s turns out to be the equality fragment of \mathbf{AP} .

THEOREM.

1. \mathbf{AP} is conservative over \mathbf{EQ}_ω^s .
2. \mathbf{EQ}_ω^s is not finitely axiomatisable.

Van Dalen and Statman proved the theorem by means of a normal form theorem for \mathbf{AP} . There is however a short and elegant proof by Smoryński using model theory [Smoryński, 1977], that we will reproduce here.

Proof of 1. Suppose $\mathbf{EQ}_\omega^s \not\vdash \varphi$. Consider the Kripke model \mathcal{K} obtained in the model existence lemma.

Define $\Gamma \Vdash a \# b := \Gamma \Vdash a \neq_n b$ for all n .

Claim $\#$ is an apartness relation. We will only consider $\forall xy(\neg x \# y \rightarrow x = y)$ (everything else is trivial).

Suppose the bottom node, Γ_0 , does not force it, then $\Gamma_1 \Vdash \neg a \# b$ and $\Gamma_1 \not\vdash a = b$ for some Γ_1 . Since \mathcal{K} is a model of \mathbf{EQ}_ω^s we have $\Gamma_1 \not\vdash \neg a \neq_n b$ for all n .

Now $\Gamma_1 \cup \{a \neq_n b \mid n \in \omega\}$ is consistent, for else $\Gamma_1 \cup \{a \neq_n b \mid n \in \omega\} \vdash \perp$ and hence $\Gamma_1 \vdash \neg a \neq_m b$, i.e. $\Gamma_1 \Vdash \neg a \neq_m b$, for some m . Therefore there exists a prime theory $\Delta \supseteq \Gamma_1$ with $a \neq_n b \in \Delta$ for all n , so $\Delta \Vdash a \# b$. Contradiction.

Hence $\Gamma_0 \Vdash \forall xy(\neg x \# y \rightarrow x = y)$.

2. is shown by constructing suitable Kripke models ■

As a corollary we obtain the undefinability of $\#$ in terms of $=$. For, if $\mathbf{AP} \vdash x \# y \leftrightarrow \varphi(x, y)$ for a suitable equality formula φ , then we would have a finite axiomatisation of \mathbf{EQ}_ω^s (note that the above example also establishes the same fact).

Observe that we could accept the apartness relation as basic and define equality by $x = y := \neg x \# y$ if we replace $\neg x \# y \leftrightarrow x = y$ by $\neg x \# x$ and $x \# y \rightarrow y \# x$.

Further facts: **AP** is undecidable [Smoryński, 1973a], [Gabbay, 1981, p. 258]. There are Kripke models of \mathbf{EQ}_ω^s that do not carry any apartness relation at all [van Dalen and Statman, 1979]. For a treatment of apartness in a sequent calculus setting, see [Negri and von Plato, 2001].

7.3 The Theory of Order, **LO**

In classical logic linear order is singled out from the partial orders by requiring any two elements to be comparable, i.e. $x < y \vee x = y \vee y < x$. This axiom would be excessively strong in an intuitionistic context, since not even the reals would be ordered. Therefore Heyting proposed another axiom, that we shall adopt.

The language of **LO** contains the predicate symbols $<$ and $=$. The axioms of **LO** are those of **EQ**, plus

$$\begin{aligned} x < y \wedge y < z &\rightarrow x < z \\ x = y &\leftrightarrow \neg x < y \wedge \neg y < x \\ x < y &\rightarrow z < y \vee x < z. \end{aligned}$$

It is a simple exercise in logic to show the following:

Fact

1. $\neg x < x$
2. $x = y \wedge x < z \rightarrow y < z$
3. $x < y \vee y < x$ is an apartness relation.

Heyting called a relation satisfying the axioms of **LO** a *pseudo-order* relation and a relation satisfying, moreover, $x < y \vee x = y \vee y < x$ an order relation. Since, however, the first kind of relation turns out to be the more important and the more common of the two, we have adopted the present terminology.

Since

$$\mathbf{LO} + \forall xy(x < y \vee x = y \vee y < x) \vdash (x < y \vee \neg x < y) \wedge (x = y \vee \neg x = y)$$

we call this system *decidable linear order* **LO^d**.

Conversely, the decidability of $<$ and $=$ implies the comparability of x and y .

The theory of *dense linear ordering*, **DLO**, is obtained by adding

$$\exists z(x < y \rightarrow x < z < y), \exists y(x < y), \exists y(y < x).$$

Variants of **DLO** are considered by Smoryński [1977].

Not only can we define a canonical apartness relation in **LO**, but also show that the theory containing apartness and order (**AP** + **LO** + $x \# y \rightarrow x < y \vee y < x$) is conservative over **AP** (and hence over **EQ_w^s**) [Smoryński, 1977; Hartog, 1978].

The theories **LO** and **DLO** are undecidable [Smoryński, 1977] cf. [Gabbay, 1981], but **DLO^d** is decidable and coincides with its classical counterpart **DLO^c**, [Smoryński, 1973a].

In [Gabbay, 1981] a number of refinements of the above results are treated.

7.4 Logic with Operations

The set theoretical view of operations (functions) is that they are a special kind of relations, so we could do without the complications of introducing function symbols. However, the circumvention of function symbols is most unnatural, and, when we come to choice sequences, disastrous. The syntactic aspects of a first-order language with function symbols are strictly analogous to the classical ones.

We will therefore look into the semantic aspects. Consider a Kripke model \mathcal{K} with a functional relation $R(x, y)$, i.e. $\mathcal{K} \Vdash \forall x \exists ! y R(x, y)$. The properties of forcing tell us that for each α we have that for each $a \in D(\alpha)$ there is a unique $b \in D(\alpha)$ such that $\alpha \Vdash R(a, b)$. That is R is a function on $D(\alpha)$. hence we define for each function symbol f an n -ary function $f_\alpha : D(\alpha)^n \rightarrow D(\alpha)$, for each α .

The monotonicity condition is not quite obvious since elements of $|D(\alpha)|$ are determined up to the relation \approx_α .

The simplest solution is to put: $\alpha \leq \beta \Rightarrow f_\alpha \subseteq f_\beta$. There is another solution, however, that modifies the concept of Kripke model in the spirit of category theory, where one defines a Kripke model as a pre-sheaf over P , where P is a poset (cf. [Goldblatt, 1979, p. 256]).

Before formulating the modified notion of Kripke model, we recall the notion of *homomorphism* for (classical) structures.

$f : A \rightarrow B$ is a homomorphism from structure **A** to **B** if f is a function from the universe of **A** into the universe of **B** such that f preserves all relations and functions, i.e.,

$$R^{\mathbf{A}}(a_1, \dots, a_n) \Rightarrow R^{\mathbf{B}}(f(a_1), \dots, f(a_n)) \text{ for all relations } R,$$

and

$$f(F^{\mathbf{A}}(a_1, \dots, a_n)) = F^{\mathbf{B}}(f(a_1), \dots, f(a_n)) \text{ for all functions } F.$$

EXAMPLE

f is a homomorphism of the poset **A** into the poset **B**. We now come to our

DEFINITION 38. A Kripke model is a quintuple $\mathcal{K} = \langle K, \leq, d, f, \Vdash \rangle$ where (K, \leq) is a poset, D assigns to each $\alpha \in K$ a structure $D(\alpha)$, f assigns to each pair α, β with $\alpha \leq \beta$ a homomorphism $f_{\alpha\beta} : D(\alpha) \rightarrow D(\beta)$ such that $f_{\alpha\alpha} = id_{D(\alpha)}$, for all $\alpha, f_{\beta\gamma} \circ f_{\alpha\beta} = f_{\alpha\gamma}$ for all $\alpha \leq \beta \leq \gamma$. The forcing relation \Vdash is defined as in Definition 13. Furthermore, equality is always interpreted as real identity.

We can always associate a model in the new sense to a model in the old sense by lumping together elements in equivalence classes under \approx_α .

In dealing with concrete Kripke models we will act broad-mindedly and choose whichever notion is most convenient, or even use the old notion and think of a new one.

7.5 Heyting's Arithmetic, **HA**

The language of arithmetic contains, $=, +, \cdot, S, 0, 1$ (and, when convenient, as many primitive recursive functions as we wish).

The axioms of **HA** are those of Peano's arithmetic plus the axioms of **EQ**.

1. $x = y \leftrightarrow Sx = Sy$
2. $\neg Sx = 0$
3. $x + 0 = x$
 $x + Sy = S(x + y)$
4. $x \cdot 0 = 0$
 $x \cdot Sy = x \cdot y + x$
5. $\varphi(0) \wedge \forall x(\varphi(x) \rightarrow \varphi(Sx)) \rightarrow \forall x\varphi(x)$.

Number 5 is the schema of *mathematical* (or *complete*) *induction*. It can

also be presented in the form of a natural deduction rule

$$\frac{\begin{array}{c} [\varphi(x)] \\ \vdots \\ \varphi(0) \quad \varphi(Sx) \end{array}}{\varphi(x)}$$

It is a simple exercise to show the decidability of the equality relation.

THEOREM 39.

$$\begin{array}{l} \mathbf{HA} \vdash \forall xy(x = y \vee x \neq y) \\ \mathbf{HA} \vdash \forall x(x \neq 0 \Rightarrow \exists y(x = Sy)). \end{array}$$

For a number of formal proofs, see [Kleene, 1952].

Arithmetic has correctly received a considerable amount of attention. It is the theory of the hard core of intuitionistic mathematics, put forward by Brouwer in his *First Act of Intuitionism* (cf. [Brouwer, 1975, pp. 509], [Brouwer, 1981, p. 4], [Heyting, 1956, p. 13 ff]).

Apart from foundational motivations for studying **HA**, there is a pragmatic argument for investigating arithmetic. It is, so to speak, a showroom of metamathematical tools and results. We will only be able to discuss a minute part of the material that is available. The reader is referred to Troelstra [1973].

Since **HA** is a subsystem of **PA** (Peano's arithmetic) we cannot expect to find theorems contradicting the classical practice. We will have to look for metamathematical methods that capitalise on the constructive nature of intuitionistic logic.

HA has the properties EP and DP, that are popularly considered to be the hallmark of constructive theories. We will first show EP and return to the significance of EP and DP later.

THEOREM 40.

$$\begin{array}{ll} DP: & \mathbf{HA} \vdash \varphi \vee \psi \Rightarrow \mathbf{HA} \vdash \varphi \text{ or } \mathbf{HA} \vdash \psi \quad (\text{disjunction property}) \\ EP: & \mathbf{HA} \vdash \exists x\varphi(x) \Rightarrow \mathbf{HA} \vdash \varphi(n) \text{ for some } n. \quad (\text{existence property}) \end{array}$$

Proof. DP follows immediately from EP, since disjunction can be defined in terms of the existential quantifier: $\mathbf{HA} \vdash (\varphi \vee \psi) \leftrightarrow \exists x((x = 0 \rightarrow \varphi) \wedge (x \neq 0 \rightarrow \psi))$. therefore we will consider EP.

Let $\mathbf{HA} \vdash \exists x\varphi(x)$, but $\mathbf{HA} \not\vdash \varphi(n)$ for all n .

Then, by the completeness theory, there are Kripke models $\mathcal{K}_0, \mathcal{K}_1, \mathcal{K}_2, \dots$ such that $\mathcal{K}_n \not\vdash \varphi(n)$. We form a new Kripke model \mathcal{K} .

We take the disjoint union of the models \mathcal{K}_i and add an extra bottom node β .

The structure belonging to β is the standard model of (classical) arithmetic. Since \mathbb{N} is contained in all domains of the \mathcal{K}_i 's, the resulting model satisfies the conditions of the Kripke semantics. We will show that $\mathcal{K} \Vdash \mathbf{HA}$. The only non-trivial axiom is mathematical induction. So we must show $\gamma \Vdash \psi(0), \gamma \Vdash \forall x(\psi(x) \rightarrow \psi(Sx)) \Rightarrow \gamma \Vdash \forall x\psi(x)$, for all γ . For $\gamma \neq \beta$ this is so by hypothesis, so consider $\beta \Vdash \psi(0), \beta \Vdash \forall x(\psi(x) \rightarrow \psi(Sx))$. We must show $\forall \gamma \geq \beta \forall c \in D(\gamma), \gamma \Vdash \psi(c)$. Again the only case that must be taken care of is β itself. So we must show $\beta \Vdash \psi(n)$ for all n . but we know $\beta \Vdash \psi(0)$ and $\beta \Vdash \psi(n) \rightarrow \beta \Vdash \pi(Sn)$. Hence, by induction in the metalanguage we get $\beta \Vdash \psi(n)$ for all n .

Now $\beta \Vdash \mathbf{HA}$, so $\beta \Vdash \exists x\varphi(x)$, and hence $\beta \Vdash \varphi(n)$ for some n . Contradiction with $\mathcal{K}_n \not\Vdash \varphi(n)$.

Therefore $\mathbf{HA} \vdash \varphi(n)$ for some n . ■

Although EP seems to be stronger than DP, a result of Friedman shows this not to be the case for a large class of extensions of \mathbf{HA} .

THEOREM 41 ([Friedman, 1975]). *For all RE extensions of \mathbf{HA} EP follows from DP.*

It seems attractive to consider EP as the characteristic of constructivity; if we can show the existence of an object with a property φ , then we can effectively indicate such an object. This is the constructive counterpart of the classical notion of 'pure existence'.

Kreisel has shown, however, that the possession of EP is neither necessary nor sufficient for constructive theories. The following example (due to Kreisel, cf. [Troelstra, 1973, p. 91]) may illustrate the matter.

Let Prf be the proof predicate of \mathbf{HA} (cf. [Kleene, 1952, p. 254]). Define $\varphi(x) := \text{Prf}(x, \ulcorner 0 = 1 \urcorner) \vee \forall y \neg \text{Prf}(y, \ulcorner 0 = 1 \urcorner)$. As \mathbf{HA} is consistent on the intended interpretation, $\forall y \neg \text{Prf}(y, \ulcorner 0 = 1 \urcorner)$ is true, so evidently $\exists x\varphi(x)$ is true. Moreover, $\neg \text{Prf}(n, \ulcorner 0 = 1 \urcorner)$ is true for each n , and (Prf being primitive recursive) provable. Hence, for any n $\mathbf{HA} \vdash \varphi(n) \leftrightarrow \forall y \neg \text{Prf}(y, \ulcorner 0 =$

1^\top). By definition $\mathbf{HA} \vdash \exists x\varphi(x) \leftrightarrow [\exists y\text{Prf}(y, \ulcorner 0 = 1^\top \urcorner) \vee \forall y\neg\text{Prf}(y, \ulcorner 0 = 1^\top \urcorner)]$. Now $\mathbf{HA} \vdash \exists x\varphi(x) \rightarrow \varphi(n)$ yields $\mathbf{HA} \vdash [\exists y\text{Prf}(y, \ulcorner 0 = 1^\top \urcorner) \vee \forall y\neg\text{Prf}(y, \ulcorner 0 = 1^\top \urcorner)] \rightarrow \forall y\neg\text{Prf}(y, \ulcorner 0 = 1^\top \urcorner)$, hence $\mathbf{HA} \vdash \exists y\text{Prf}(y, \ulcorner 0 = 1^\top \urcorner) \rightarrow \forall y\neg\text{Prf}(y, \ulcorner 0 = 1^\top \urcorner)$, and so $\mathbf{HA} \vdash \forall y\neg\text{Prf}(y, \ulcorner 0 = 1^\top \urcorner)$, or \mathbf{HA} proves its own consistency, contradicting Gödel's second theorem.

Note that $T = \mathbf{HA} + \exists x\varphi(x)$ is an intuitionistically true theory and $T \vdash \exists\varphi(x)$, but by the above argument $\not\vdash \varphi(n)$ for all n . So T does not have EP.

The proof of EP above was itself not constructive, we have used a proof by contradiction. So we cannot actually exhibit the promised number n .

There are various proofs that do provide the required instances. For example, by means of the Kleene slash [Troelstra, 1973, p. 177], q -realisability [Troelstra, 1973, p. 189 ff], and normalisation in Gentzen systems [Minc, 1974]. An interesting feature is the stability of the instantiation member in various methods. That is, quite different techniques for converting a provable \exists -statement into its instantiation yield the same number (cf. [Stein, 1980]).

It is to be noted that all proofs of DP (or EP) for \mathbf{HA} go essentially beyond the means of \mathbf{HA} . Actually one can make this precise (Myhill) in the following form: let T be an r.e. extension of \mathbf{HA} then there are sentences φ and ψ such that if $T \vdash \text{Pr}(\varphi \vee \psi) \rightarrow \text{Pr}(\varphi) \vee \text{Pr}(\psi)$, then $T \vdash \text{Pr}(\ulcorner 0 = 1^\top \urcorner)$ where $\text{Pr}(x)$ is the provability predicate for T .

In words, the price for 'provable DP' is that T proves its own inconsistency (cf. [Leivant, 1985]).

Closure under rules

For a given derivation rule $\frac{\varphi_1, \dots, \varphi_n}{\psi} R$ we automatically get that provability of the premises yields provability of the conclusion. We say that a theory is closed under a rule R if $T \vdash \varphi_1, \dots, T \vdash \varphi_n \Rightarrow T \vdash \psi$. Intuitionistic systems tend to be closed under various rules that are themselves not correct. We will list a few cases below. Consider the following principle.

Markov's Principle, MP

$$\forall x(\varphi(x) \vee \neg\varphi(x)) \wedge \neg\neg\exists x\varphi(x) \rightarrow \exists x\varphi(x).$$

MP plays an important role in metamathematics. It naturally turns up in certain interpretations. Markov postulated it in the context of recursion theory in the form 'if it is impossible that a Turing machine does not halt, then it must halt', in the formalism of recursion theory: $\neg\neg\exists zT(e, n, z) \rightarrow \exists zT(e, n, z)$ (cf. [Troelstra, 1973]). Thus Markov's formulation can be taken to deal with a primitive recursive $\varphi(x)$.

THEOREM 42. *MP is not derivable in \mathbf{HA} .*

Proof.[Smoryński] Let $\varphi(x)$ be a primitive recursive formula such that $\exists x\varphi(x)$ is independent of **HA** (e.g. $\neg\text{Con}_{\mathbf{HA}}$, the inconsistency of **HA**). Let \mathcal{K} be a Kripke model of **HA** + $\exists x\varphi(x)$. We put an extra node a at the bottom of \mathcal{K} , with $D(\alpha)$ the standard model for **PA**.

Suppose **HA** $\vdash \neg\neg\exists x\varphi(x) \rightarrow \exists x\varphi(x)$. (*)

Since the new model is a model of **HA** (cf. the proof of Theorem 40), we have $\alpha \Vdash \neg\neg\exists x\varphi(x) \rightarrow \exists x\varphi(x)$. But evidently $\alpha \Vdash \neg\neg\exists x\varphi(x)$, therefore $\alpha \Vdash \exists x\varphi(x)$ and hence $\alpha \Vdash \varphi(n)$ for some n . $\varphi(x)$ being primitive recursive and $\varphi(n)$ being true, a theorem from arithmetic tells us that **HA** $\vdash \varphi(n)$, so **HA** $\vdash \exists x\varphi(x)$. This contradicts the independence of $\exists x\varphi(x)$. Therefore (*) is false. ■

Next we will show that **HA** is closed under Markov's rule.

THEOREM 43.

$$\begin{aligned} & \mathbf{HA} \vdash \forall x(\varphi(x) \vee \neg\varphi(x)), \mathbf{HA} \vdash \neg\neg\exists x\varphi(x) \Rightarrow \\ & \mathbf{HA} \vdash \exists x\varphi(x), \text{ for } FV(\varphi) = \{x\}. \end{aligned}$$

Proof. From **HA** $\vdash \neg\neg\exists x\varphi(x)$, we conclude **PA** $\vdash \exists x\varphi(x)$ and so $\exists x\varphi(x)$ is true in the standard model. Therefore, $\varphi(n)$ is true for some n . Now using **HA** $\vdash \varphi(n) \vee \neg\varphi(n)$ and DP we immediately get **HA** $\vdash \varphi(n)$, and thus **HA** $\vdash \exists x\varphi(x)$. ■

Our next principle is the

Independence of Premise Principle, IP

$$(\neg\varphi \rightarrow \exists x\psi(x)) \rightarrow \exists x(\neg\varphi \rightarrow \psi(x)).$$

The heuristic argument against IP is as follows: $\neg\varphi \rightarrow \exists x\psi(x)$ may be seen to hold by constructing an instance n that depends on the proof of $\neg\varphi$. In $\exists x(\neg\varphi \rightarrow \psi(x))$, however, we are required to construct the instance n beforehand. This evidently is a stronger requirement. Formal independence proofs are given in [Troelstra, 1973, pp. 179, 369].

THEOREM 44.

$$\begin{aligned} & \mathbf{HA} \vdash \neg\varphi \rightarrow \exists x\psi(x) \Rightarrow \mathbf{HA} \vdash \exists x(\neg\varphi \rightarrow \psi(x)) \\ & (FV(\psi) = \{x\}). \end{aligned}$$

Proof. See below. ■

The case of Church's Thesis will be considered in Section 8.

We return to the closure under Markov's Rule, to demonstrate an extremely elegant proof by H. Friedman [1977].

First we introduce the *Friedman translation* $\varphi \rightarrow \varphi^\rho$: replace in φ each atomic subformula ψ by $\psi \vee \rho$ (where ρ is a formula of **HA**). The translation has the following properties.

LEMMA 45.

1. $\Gamma \vdash \varphi \Rightarrow \Gamma^\rho \vdash \varphi^\rho$ and $\rho \vdash \varphi^\rho$.
2. **HA** $\vdash \varphi \rightarrow$ **HA** $\vdash \varphi^\rho$.
3. For any term t , **HA** $\vdash \neg \neg \exists x(t(x, y) = 0) \Rightarrow$ **HA** $\vdash \exists x(t(x, y) = 0)$.

Proof. (1) and (2) are easily shown by a suitable induction.

(3) **HA** $\vdash (\exists x t(x, y) = 0 \rightarrow \perp) \rightarrow \perp$.

We apply the Friedman Translation with respect to

$$\begin{aligned} \rho &:= \exists x(t(x, y) = 0), \text{ then } ((\exists x t(x, y) = 0 \rightarrow \perp) \rightarrow \perp)^\rho = \\ &[\exists x(t(x, y) = 0 \vee \exists x(t(x, y) = 0)) \rightarrow \perp \vee \exists x(t(x, y) = 0)] \\ &\rightarrow (\perp \vee \exists x(t(x, y) = 0)). \end{aligned}$$

The latter formula is equivalent to $\exists x(t(x, y) = 0)$. Now apply (2). ■

So for the special case of $t(x, y) = 0$, closure under Markov's Rule has been established (i.e. in particular for primitive recursive functions $f(x, y)$).

The general closure result is obtained by an application of closure under Church's Rule (cf. Section 8), i.e. if **HA** $\vdash \forall x \exists y \varphi(x, y)$, then **HA** $\vdash \forall x \varphi(x, \{e\}x)$ for some e (index of total recursive function).

One easily derives **HA** $\vdash \varphi(x, y) \vee \neg \varphi(x, y) \Rightarrow$ **HA** $\vdash \varphi(x, y) \leftrightarrow \{e\}(x, y) = 0$, for a suitable index e . We can replace $\{e\}(x, y) = 0$ by $\exists z(T(e, x, y, z) \wedge U(z) = 0)$ (cf. van Dalen's Algorithms chapter in Volume 1 of this *Handbook*).

The matrix of the latter expression is primitive recursive, so we may conservatively extend **HA** by adding a symbol f for its characteristic function. Hence we get **HA'** $\vdash \varphi(x, y) \leftrightarrow \exists z(f(x, y, z) = 0)$, where **HA'** is the extension by f and its defining equations. Now we may apply Lemma 45(3): **HA** $\vdash \neg \neg \exists x \varphi(x, y) \Rightarrow$ **HA'** $\vdash \neg \neg \exists x z(f(x, y, z) = 0) \rightarrow$ (Lemma 45 carries over to **HA'**) **HA'** $\vdash \exists x z(f(x, y, z) = 0) \Rightarrow$ **HA** $\vdash \exists x \varphi(x, y)$.

Observe that the above argument yields closure under Markov's Rule for formulas with parameters.

We now apply the Friedman translation to the rule of independence of premises (A. Visser). For convenience we write ' \vdash ' for '**HA** \vdash '.

Let $\vdash \neg\varphi \rightarrow \exists x\psi(x)$. We apply the Friedman translation with respect to $\neg\neg\varphi$. By Lemma 45(2) $\vdash (\neg\varphi)^{\neg\neg\varphi} \rightarrow (\exists x\psi(x))^{\neg\neg\varphi} \dots (1)$.

Observe that $\vdash \neg\rho \rightarrow (\sigma^\rho \leftrightarrow \sigma)$ for any σ and $\rho \dots (2)$, as one can easily show by induction on σ .

Therefore also $\vdash \sigma^\rho \rightarrow (\neg\rho \rightarrow \sigma) \dots (3)$.

From(1) we get $\vdash (\neg\varphi)^{\neg\neg\varphi} \rightarrow \exists x(\psi(x)^{\neg\neg\varphi})$, and an application of (3) yields $\vdash (\neg\varphi)^{\neg\neg\varphi} \rightarrow \exists x(\neg\varphi \rightarrow \psi(x))$. $(\neg\varphi)^{\neg\neg\varphi} = (\varphi \rightarrow \perp)^{\neg\neg\varphi} = \varphi^{\neg\neg\varphi} \rightarrow \neg\neg\varphi$. Now apply (3) with $\sigma = \varphi$ and $\rho = \neg\neg\varphi$, then $\varphi^{\neg\neg\varphi} \rightarrow (\neg\varphi \rightarrow \varphi)$, hence $\varphi^{\neg\neg\varphi} \rightarrow \neg\neg\varphi$. Hence $\vdash \exists x(\neg\varphi \rightarrow \psi(x))$. Friedman's translation is closely related to a straightforward translation of intuitionistic into minimal logic, cf. [Leivant, 1985] for details and also for syntactic criteria for closure under Markov's rule.

Closure under Markov's rule is exactly what one needs for identifying provably recursive functions in classical and intuitionistic arithmetic. Using the notion of Ch. 4 of Vol. 1 of this *Handbook*, we can say that the recursive function with index e is provably recursive in a theory S if $S \vdash \forall x\exists yT(e, x, y)$ (for each input x the computation provably halts). Closure under Markov's rule tells us that **PA** and **HA** have exactly the same provably recursive functions (Kreisel). In other words, by restricting our arguments to intuitionistic logic we do not lose any recursive functions. Friedman extended this result to classical and intuitionistic set theory ZF ([Friedman, 1977], cf. also [Leivant, 1985]).

8 RELATION WITH OTHER LOGICS

First we consider a sub-logic of intuitionistic logic. Minimal logic was proposed by Johansson in reaction to the role of negation, in particular the *Ex falso sequitur quodlibet* rule (our *falsum rule*). His critique resulted in a rejection of the rule ' \perp '. As a result, in his system of *minimal logic*, \perp cannot properly be distinguished from other atoms. This is reflected in the Kripke semantics for minimal logic.

DEFINITION 46. A Kripke model for **MQC** is obtained from Definitions 10 and 13 by deleting the condition on \perp (i.e. $\alpha \Vdash \perp$ is allowed).

By a proof that is completely similar to that of Lemma 14 we get

THEOREM 47 (Completeness for MQC).

$$\Gamma \Vdash_{\mathbf{MQC}} \varphi \Leftrightarrow \Gamma \Vdash \varphi$$

(where \Vdash is understood in the sense of Definition 46).

It now follows immediately that **MQC** is a proper subsystem of **IQC** (similarly for **MPC** and **IPC**), for **MQC** $\not\Vdash \perp \rightarrow \varphi$. Consider the one point model in which \perp is forced.

Although minimal logic is strictly weaker than intuitionistic logic, they are in a sense of the same strength. To be precise, each can faithfully be interpreted in the other.

DEFINITION 48. The translations $*$ and \dagger are defined by

$$\begin{aligned} \varphi^* &:= \varphi \vee \perp \text{ for atomic } \varphi \\ (\varphi \wedge \psi)^* &:= \varphi^* \wedge \psi^* \\ (\varphi \vee \psi)^* &:= \varphi^* \vee \psi^* \\ (\varphi \rightarrow \psi)^* &:= \varphi^* \rightarrow \psi^* \\ (\forall x\varphi)^* &:= \forall x\varphi^* \\ (\exists x\varphi)^* &:= \exists x\varphi^* \\ \\ \varphi^\dagger &:= \varphi[p/\perp]. \end{aligned}$$

where p is a propositional letter not occurring in φ .

Observe that the translation \dagger eliminates \perp , so for φ^\dagger we cannot use the falsum rule in **IQC**. That makes it plausible that φ^\dagger behaves in **IQC** as φ does in **MQC**.

THEOREM 49.

1. **IQC** $\vdash \varphi \Leftrightarrow$ **MQC** $\vdash \varphi^*$
2. **MQC** $\vdash \varphi \Leftrightarrow$ **IQC** $\vdash \varphi^\dagger$,

Proof. (1) \Leftarrow is trivial.

For \Rightarrow use induction on the derivation of $\Gamma \vdash \varphi$ and observe

$$\vdash \Gamma \rightarrow \varphi \Leftrightarrow \Gamma \vdash \varphi.$$

(2) \perp behaves in the semantics for minimal logic like any atom, so validity of φ in all ‘minimal’ Kripke models is equivalent to validity of φ^\dagger in all ‘intuitionistic’ Kripke models. Alternatively, a simple proof theoretic argument based on the normal form theorem will do. ■

Minimal logic enjoys most metalogical properties that can be expected, e.g. there is a normal form theorem for natural deduction derivations, normal derivations have the subformula property, etc. Its propositional calculus, **MPC**, is decidable (use Theorem 49). For more information the reader is referred to [Johansson, 1936; Prawitz, 1965; Prawitz and Malmnäs, 1968].

Our next goal is to investigate the relation between classical logic and intuitionistic logic. The first results antedate Heyting’s formalisation. Kolmogorov already in 1925 established a translation procedure [Kolmogorov, 1925], and in [Glivenko, 1929] a similar result is to be found. The next to investigate the relation between classical and intuitionistic logic (in the wider

context of arithmetic) were Gödel and Gentzen ([Gödel, 1933; Gentzen, 1933]). for more information on translations the reader is referred to [Leivant, 1985], [Troelstra and van Dalen, 1988].

We first present the result of Glivenko:

THEOREM 50.

$$\mathbf{CPC} \vdash \varphi \Leftrightarrow \mathbf{IPC} \vdash \neg\neg\varphi.$$

Proof. Recall that **IPC** is complete for finite Kripke models. Since in each maximal node all tautologies are forced, we see that $\neg\neg\varphi$ is valid in all finite Kripke models if φ is a classical tautology. This shows \Rightarrow . The converse is trivial. ■

COROLLARY 51.

$$\mathbf{CPC} \vdash \neg\varphi \Leftrightarrow \mathbf{IPC} \vdash \neg\varphi.$$

There are a number of translations from **IQC** into **CQC** that have roughly similar properties. The main feature is the elimination of \forall and \exists . Let us call a formula *negative* if it does not contain \forall and \exists and if all its atoms are negated. The translation below assigns to each formula a negative formula.

Negative formulas have the following convenient property

LEMMA 52. $\mathbf{IQC} \vdash \varphi \Leftrightarrow \neg\neg\varphi$ for negative φ .

Proof. An exercise in plain old logic. ■

DEFINITION 53. The translation $^\circ$ is given by

$$\begin{aligned} \varphi^\circ &:= \neg\neg\varphi \text{ for atomic } \varphi \\ (\varphi \wedge \psi)^\circ &:= \varphi^\circ \wedge \psi^\circ \\ (\varphi \rightarrow \psi)^\circ &:= \varphi^\circ \rightarrow \psi^\circ \\ (\varphi \vee \psi)^\circ &:= \neg(\neg\varphi^\circ \wedge \psi^\circ) \\ (\forall x\varphi)^\circ &:= \forall x\varphi^\circ \\ (\exists x\varphi)^\circ &:= \neg\forall x\neg\varphi^\circ \end{aligned}$$

THEOREM 54.

1. $\mathbf{CQC} \vdash \varphi \Leftrightarrow \mathbf{IQC} \vdash \varphi^\circ$
2. $\mathbf{CQC} \vdash \varphi \Leftrightarrow \varphi^\circ$.

Proof. (2) is routine. For (1) we consider instead $\Gamma \vdash^c \varphi$ and $\Gamma^\circ \vdash^i \varphi^\circ$ (where \vdash^c, \vdash^i stand for classical and intuitionistic derivability, and Γ° is the set of translated ψ 's from Γ). Proof by induction on the derivation of $\Gamma \vdash \varphi$, use Lemma 52. ■

Since negative formulas are invariant under the translation we get
COROLLARY 55.

1. $\mathbf{CQC} \vdash \varphi \Leftrightarrow \mathbf{IQC} \vdash \varphi$ for negative φ .
2. For theories with decidable atoms (i.e. $T \vdash \varphi \vee \neg\varphi$ for atomic φ) we have $T \vdash^c \varphi \Leftrightarrow T^\circ \vdash^i \varphi$ for negative φ .

The latter is the case for arithmetic, \mathbf{HA} .

The above result tells us that \mathbf{PA} and \mathbf{HA} are relatively consistent, so intuitionistic arithmetic is, from a foundational point of view, just as much in need of a consistency proof as \mathbf{PA} .

There are some special results in the area, we list some.

FACTS 56.

1. $\mathbf{CQC} \vdash \varphi \Leftrightarrow \mathbf{IQC} \vdash \varphi$ for φ a negation of a prenex formula (Kreisel).
2. $\mathbf{CQC} \vdash \varphi \Leftrightarrow \mathbf{IQC} \vdash \neg\neg\varphi$, and
 $\mathbf{CPC} \vdash \neg\varphi \Leftrightarrow \mathbf{IQC} \vdash \neg\varphi$, for φ without \forall . [Fitting, 1969, p. 52].
3. If \forall does not occur negatively in φ then $\mathbf{CQC} \vdash \neg\varphi \Leftrightarrow \mathbf{IQC} \vdash \neg\varphi$ [Smoryński, 1973].
4. If φ is a Π_2^0 -sentence (i.e. of $\forall\exists$ form), then $\mathbf{PA} \vdash \varphi \Leftrightarrow \mathbf{HA} \vdash \varphi$. (Kreisel, cf. [Troelstra, 1973, Ch. 3, S. 8], lemma 46.)

Intuitionistic logic seen from the modal viewpoint

As we have sketched earlier, intuitionistic logic has certain strong intensional aspects, in particular the meaning of the connectives—expressed in terms of proofs and construction, or of knowledge—has an intensional ring. This has been observed by Gödel, who proposed a translation of intuitionistic logic into modal logic [Gödel, 1932].

The ‘necessity’ operator could be read here as ‘I have a proof’ or ‘I know that’.

DEFINITION 57. The translation m is defined by

$$\begin{aligned} \varphi^m &:= \Box\varphi \text{ for atomic } \varphi \\ (\varphi \vee \psi)^m &:= \varphi^m \vee \psi^m \\ (\varphi \wedge \psi)^m &:= \varphi^m \wedge \psi^m \\ (\varphi \rightarrow \psi)^m &:= \Box(\varphi^m \rightarrow \psi^m) \end{aligned}$$

We will establish the relation between $\mathbf{S4}$ and \mathbf{IPC} . Observe that in $\mathbf{S4}$

$$\Box\perp \leftrightarrow \perp, \text{ so } (\neg\varphi)^m \leftrightarrow \Box\neg\varphi^m.$$

We borrow from modal logic the fact that **S4** is complete for Kripke models $\langle K, R, \Vdash \rangle$ with a reflexive, transitive R (cf. [Hughes and Cresswell, 1968; Schütte, 1968] and Chapter II.1 of the *Handbook*).

The forcing notion is defined by

$$\begin{aligned} \alpha &\not\Vdash \perp \\ \alpha &\Vdash \varphi \wedge \psi \Leftrightarrow \alpha \Vdash \varphi \text{ and } \alpha \Vdash \psi \\ \alpha &\Vdash \varphi \vee \psi \Leftrightarrow \alpha \Vdash \varphi \text{ or } \alpha \Vdash \psi \\ \alpha &\Vdash \varphi \rightarrow \psi \Leftrightarrow \alpha \not\Vdash \varphi \text{ or } \alpha \Vdash \psi \\ \alpha &\Vdash \Box\varphi \Leftrightarrow \text{for all } \beta \text{ with } \alpha R\beta, \beta \Vdash \varphi. \end{aligned}$$

Observe that the propositional fragment is classical. Further, an intuitionistic Kripke model may be viewed as a modal Kripke model (not always conversely).

LEMMA 58. *Let $\langle K, \leq, \Vdash \rangle$ be an intuitionistic Kripke model. Define a modal Kripke model with the same underlying poset and the same forcing for atoms denoted by \Vdash^m . Then for all $\varphi, \alpha \Vdash \varphi \Leftrightarrow \alpha \Vdash^m \varphi^m$,*

Proof. Induction on φ . ■

THEOREM 59. $\mathbf{IPC} \vdash \varphi \Leftrightarrow \mathbf{S4} \vdash \varphi^m$.

Proof. \Leftarrow . Let $\mathbf{IPC} \not\vdash \varphi$, then there is a Kripke model with $\alpha \not\Vdash \varphi$ for the bottom node α . Now apply Lemma 58, then $\mathbf{S4} \not\vdash \varphi^m$.

\Rightarrow . Let $\mathbf{S4} \not\vdash \varphi^m$, then there is a Kripke model such that $\alpha_0 \not\Vdash^m \varphi^m$ for the bottom node α : we turn this model into an intuitionistic Kripke model by first collapsing the model, i.e. we consider the equivalence relation $\alpha \sim \alpha' := \alpha \leq \alpha' \wedge \alpha' \leq \alpha$ and introduce a new underlying set of nodes α / \sim . For α / \sim we put $\alpha / \sim \Vdash \varphi := \alpha \Vdash^m \varphi^m$, for atomic φ . This relation is obviously well-defined, so is the forcing relation for all formulas. An argument similar to that of Lemma 58 establishes $\alpha / \sim \Vdash \varphi \Leftrightarrow \alpha \Vdash^m \varphi^m$. we now conclude $\alpha_0 / \sim \not\Vdash \varphi$, so $\mathbf{IPC} \not\vdash \varphi$. ■

Artemov has picked up Gödel's thread and designed logic which incorporates both 'proof' and 'modality', [Artemov, 2001].

8.1 Strong Negation

Intuitionistic negation does not conform to the classical laws of double negation, De Morgan, etc. This is mainly so because negation is a rather weak connective. Think of its interpretations in a Kripke model: it is not decided on the spot. Or one may think of inequality versus apartness, 'being unequal' carries so much less information than 'being apart'. Could we possibly strengthen negation, so that the classical rules would be obeyed? As a matter of fact, this is what Nelson [1949] and Markov [1950] have done.

The new connective can more or less be viewed as an attempt to save the classical laws by brute force. Let us write ‘ $\sim \varphi$ ’ for the strong negation of φ .

The axioms for the logic with strong negation are those of **IQC** plus the following

$$\begin{aligned}
& \sim (\varphi \rightarrow \psi) \leftrightarrow \varphi \wedge \sim \psi \\
& \sim (\varphi \wedge \psi) \leftrightarrow \sim \varphi \vee \sim \psi \\
& \sim (\varphi \vee \psi) \leftrightarrow \sim \varphi \wedge \sim \psi \\
& \sim \varphi \wedge \varphi \rightarrow \psi \\
& \sim \exists x \varphi(x) \leftrightarrow \forall x \sim \varphi(x) \\
& \sim \forall x \varphi(x) \leftrightarrow \exists x \sim \varphi(x) \\
& \sim \neg \varphi \leftrightarrow \varphi, \sim \sim \varphi \leftrightarrow \varphi, \sim \varphi \rightarrow \neg \varphi.
\end{aligned}$$

One obtains a Kripke model for a logic with strong negation by incorporating a strong falsity which is verified at the spot.

DEFINITION 60. A Kripke model is a quadruple $\langle K, \leq, D, i \rangle$ where K, \leq and D are as in Definition 10, i is the interpretation map which assigns $-1, 0, 1$ to atoms and nodes such that $\alpha \leq \beta, i(\varphi, \alpha) \neq 0 \Rightarrow i(\varphi, \alpha) = i(\varphi, \beta)$.

We define $[\varphi]_\alpha$ for formulas φ and nodes α :

$$[\varphi]_\alpha := i(\varphi, \alpha) \text{ for atomic } \varphi \text{ with parameters in } D(\alpha),$$

where $[\perp]_\alpha \neq 1$

$$[\varphi \wedge \psi]_\alpha := \min([\varphi]_\alpha, [\psi]_\alpha)$$

$$[\varphi \vee \psi]_\alpha := \max([\varphi]_\alpha, [\psi]_\alpha)$$

$$[\varphi \rightarrow \psi]_\alpha := \begin{cases} 1 & \text{if } \forall \beta \geq \alpha, [\varphi]_\beta = 1 \Rightarrow [\psi]_\beta = 1 \\ -1 & \text{if } [\varphi]_\alpha = 1 \text{ and } [\psi]_\alpha = -1 \\ 0 & \text{otherwise} \end{cases}$$

$$[\sim \varphi]_\alpha = \begin{cases} 1 & \text{if } [\varphi]_\alpha = -1 \\ -1 & \text{if } [\varphi]_\alpha = 1 \\ 0 & \text{otherwise} \end{cases}$$

$$[\neg \varphi]_\alpha = \begin{cases} 1 & \text{if } \forall \beta \geq \alpha, [\varphi]_\beta \neq 1 \\ -1 & \text{if } [\varphi]_\alpha = 1 \\ 0 & \text{otherwise} \end{cases}$$

$$[\forall x \varphi(x)]_\alpha = \begin{cases} 1 & \text{if } \forall \beta \geq \alpha, \forall b \in D(\beta) [\varphi(b)]_\beta = 1 \\ -1 & \text{if } \exists a \in D(\alpha) [\varphi(a)]_\alpha = -1 \\ 0 & \text{otherwise} \end{cases}$$

$$[\exists x \varphi(x)]_\alpha = \begin{cases} 1 & \text{if } \exists a \in D(\alpha), [\varphi(a)]_\alpha = 1 \\ -1 & \text{if } \forall \beta \geq \alpha, \forall b \in D(\beta) [\varphi(b)]_\beta = -1 \\ 0 & \text{otherwise.} \end{cases}$$

It is a matter of routine to show this semantics sound for logic with strong negation, \mathbf{IQC}^{sn} , in the sense that $\mathbf{IQC}^{sn} \vdash \varphi \Rightarrow [\varphi]_\alpha = 1$ in all Kripke models \mathcal{K} and nodes $\alpha \in K$.

There are alternative ways to present the same model. One can assign to each node two sets of atomic statements: $\alpha^+ = \{\varphi \mid i(\varphi, \alpha) = 1\}$ and $\alpha^- = \{\varphi \mid i(\varphi, \alpha) = -1\}$, and extend those sets as shown above to the strongly verified and strongly falsified sentences. Some authors write $\alpha \Vdash \varphi$ for $[\varphi]_\alpha = 1$ and $\alpha \dashv\vdash \varphi$ for $[\varphi]_\alpha = -1$. These notations are purely a matter of convenience.

The completeness of \mathbf{IQC}^{sn} can be shown by the usual Henkin- or tableaux-technique (cf. [Thomason, 1969]) but also by a reduction to \mathbf{IQC} . We will indicate the steps.

(1) Observe that all strong negations can be driven in, so each φ is provably equivalent to a φ^* with all strong negations in front of atoms.

(2) We want to consider strongly negated atoms as atoms in their own right, so we double the language by adding a predicate \hat{P} for each predicate P . Indicate the new atoms by $\hat{\varphi}$. At the very least the strongly negated atoms should imply the negated atoms. Put $\Gamma = \{\hat{\varphi} \rightarrow \neg\varphi \mid \varphi \text{ atomic sentence}\}$, and let $\bar{\sigma}$ be the formula one obtains by replacing $\sim\sigma$ (atomic φ) by $\hat{\varphi}$ in σ^* .

Claim: $\Gamma \vdash_{\mathbf{IQC}} (\sim\sigma) \rightarrow \neg\bar{\sigma}$ for all σ .

Prove this by induction on σ .

(3) Γ allows us to reduce \mathbf{IQC}^{sn} to \mathbf{IQC} in the following sense: $\mathbf{IQC}^{sn} \vdash \sigma \Leftrightarrow \mathbf{IQC} + \Gamma \vdash \bar{\sigma}$.

Proof: Induction on the proof length (or on the derivation in natural deduction).

(4) We can now apply the completeness theorem for \mathbf{IQC} . Let $\mathbf{IQC}^{sn} \not\vdash \sigma$ then $\mathbf{IQC} + \Gamma \not\vdash \bar{\sigma}$, so there is an ordinary Kripke model \mathcal{K} in which all axioms of Γ are valid, but not so $\bar{\sigma}$. Turn \mathcal{K} into a strong negation model \mathcal{K}' , putting $\alpha \dashv\vdash \varphi$ if $\alpha \Vdash \hat{\varphi}$ for atomic sentences φ . Now one shows that \mathcal{K}' is a model of \mathbf{IQC}^{sn} , but not of σ .

Since an ordinary model is trivially a strong negation model, it is immediately seen that \mathbf{IQC}^{sn} is conservative over \mathbf{IQC} .

\mathbf{IQC}^{sn} has some unusual properties, e.g. $\vdash \varphi \leftrightarrow \psi$ does not imply $\vdash \sim\varphi \leftrightarrow \sim\psi$ (consider $\neg\varphi \leftrightarrow \varphi \rightarrow \perp$). For more information, cf. [Gabbay, 1981, p. 124 ff], [Rasiowa, 1974, Ch. XII] and [Rautenberg, 1979, p. 305 ff].

8.2 The Connections with λ -Calculus and Combinatory Logic

Already in 1958 Curry pointed out that there is a remarkable correspondence between the implication fragment of \mathbf{IPC} and combinatory logic, \mathbf{CL} .

In particular the axioms correspond to the **CL** axioms as follows:

$$\begin{array}{lll}
\varphi \rightarrow \varphi & - Ix & = x \\
\varphi \rightarrow (\psi \rightarrow \varphi) & - Kxy & = x \\
(\sigma \rightarrow (\varphi \rightarrow \psi)) \rightarrow ((\sigma \rightarrow \varphi) \rightarrow (\sigma \rightarrow \psi)) & - Sxyz & = xz(yz).
\end{array}$$

Howard extended the correspondence in his ‘Formulas as types’ paper (1969, published in [Howard, 1980]). Once such a correspondence exists one is almost forced to look at the reduction processes in **CL** or λ -calculus and in natural deduction systems (cf. [Prawitz, 1971]). In Pottinger [1976] the isomorphism between natural deduction derivations and λ -terms has been exploited to obtain alternative proofs of the normalisation theorem for **IPC**.

In Martin-Löf’s type theory the parallelism between types and formulas is a key feature. For more information the reader is referred to Martin-Löf [1977; 1984] and Troelstra and van Dalen [1988].

9 THE ALGORITHMIC TRADITION

Intuitionistic logic was intended to codify constructive reasoning. The proof-interpretation expresses the meaning of the logical constants in terms of constructions. It seems plausible to try to delimit the class of constructions involved. Stephen Kleene conjectured in 1940 that in particular for a statement of the form $\forall x \exists y \varphi(x, y)$ provability in **HA** should entail the existence of a recursive function f that acts as a choice function: $\forall x \varphi(x, f(x))$ (cf. [Kleene, 1973]). This led Kleene to the notion of statements as ‘incomplete communications’, taking his cue from Hermann Weyl, see [van Dalen, 1995] e.g. $\exists x \varphi(x)$ is an incomplete communication of a fuller statement giving an object x such that $\varphi(x)$. Likewise the other composite statements can be considered as incomplete statements, to be supplemented by extra information.

The result was the so-called *1945-realizability* or *recursive realizability*, a notion that we will formulate in the framework of **HA**. The sentence φ is realized by the number n , $nr\varphi$, must, be thought of as n codes ‘the necessary information to establish φ ’.

DEFINITION 61. $x r \varphi$ is a formula of **HA** with at most one free variable x , associated to the sentence φ (we use notation from Ch. 4 of Vol. 1 of this *Handbook*).

$$\begin{array}{ll}
x r \varphi & := \varphi \text{ for atomic } \varphi \\
x r (\varphi \wedge \psi) & := (x)_0 r \varphi \wedge (x)_1 r \psi \\
x r (\varphi \vee \psi) & := ((x)_0 = 0 \rightarrow (x)_1 r \varphi) \wedge ((x)_0 \neq 0 \rightarrow (x)_1 r \psi) \\
x r (\varphi \rightarrow \psi) & := \forall y (y r \varphi \rightarrow \{x\}y \downarrow \wedge \{x\}y r \psi) \\
x r \exists y \varphi(y) & := (x)_1 r \varphi((x)_0) \\
x r \forall y \varphi(y) & := \forall y (\{x\}y \downarrow \wedge \{x\}y r \varphi(y))
\end{array}$$

Explanation: The first clause tells us that any number realizes a true atomic sentence. However, no number realizes a false atomic sentence. The second clause is self-evident. The clause for the disjunction exhibits the effective nature of the disjunction. We can effectively test if $(x)_0 = 0$ or $(x)_0 \neq 0$. Hence, the ‘realizer’ of a disjunction contains enough information to indicate the desired disjunct. The implication clause shows a resemblance to the proof interpretation of \rightarrow , x is the index of a partial recursive function that transforms any realizer of φ into a realizer of ψ . In the case of \forall a similar resemblance can be observed. The clause for \exists tells us that a realizer of $\exists y\varphi(y)$ contains the required instance and the information that realizes it.

Note that $xr\varphi$ is a formula of **HA**, so it makes sense to ask for the truth of an instance $nr\varphi$, or its derivability in **HA**.

EXAMPLES 62.

1. $x r (2 = 1 + 1) :\Leftrightarrow 2 = 1 + 1 (\leftrightarrow \top)$.
2. $x r \forall z \exists y (z = y) :\Leftrightarrow$
 $\forall z (\{x\}z \downarrow \wedge \{x\}z r \exists y (z = y)) :\Leftrightarrow$
 $\forall z (\{x\}z \downarrow \wedge (\{x\}z)_1 r (z = (\{x\}z)_0)) :\Leftrightarrow$
 $\forall x (\{x\}z \downarrow \wedge z = (\{x\}z)_0)$.

So if we take the index e of the identity function $z \mapsto z$, then $(\{x\}z)_0 = \{e\}z$ and we can put $\{x\}z = \langle \{e\}z, 0 \rangle$. This is a (total) recursive function, so it has an index, say e_0 . The number e_0 realizes $\forall z \exists y (z = y)$.

Kleene’s realizability can be considered as an interpretation of **HA** in **HA** bringing out the constructive character of **HA**. This interpretation is sound in the following sense:

THEOREM 63. $\mathbf{HA} \vdash \varphi \Rightarrow \mathbf{HA} \vdash n r \varphi$ for some n .

The proof is mainly a matter of perseverance (cf. [Kleene, 1952, p. 504], [Troelstra, 1973, p. 189]).

A consequence of this theorem is the fact that (assuming the consistency of **HA**) a realizable sentence φ is consistent with **HA**. For suppose that $nr\varphi$ and $\mathbf{HA} + \varphi$ is inconsistent, then $\mathbf{HA} \vdash \neg\varphi$, and hence $\mathbf{HA} \vdash mr(\neg\varphi)$ for some m . But $mr(\neg\varphi)$ is equivalent to $\forall y (yr\varphi \rightarrow \{m\}y \downarrow \wedge \{m\}yr \perp)$, and since \perp is not realisable, neither is φ . Contradiction.

The most striking application of this procedure for establishing consistency is:

THEOREM 64. *Church’s Thesis is consistent with HA.*

Proof. We have in mind a special form of Church’s Thesis, namely one that can be formulated in **HA**. We choose the following form:

$$\text{CT}_0 \quad \forall x \exists y \varphi(x, y) \rightarrow \exists z \forall x (\{z\}x \downarrow \wedge \varphi(x, \{z\}x)).$$

Observe that we can avoid the abbreviation $\{z\}x \downarrow: \forall x \exists y \varphi(x, y) \rightarrow \exists z \forall x \exists u (T(z, x, u) \wedge \varphi(x, Uu))$ where T is Kleene's T predicate (cf. van Dalen's Algorithms Chapter in Volume 1 of this *Handbook*), and U is the output-extraction function.

For convenience we suppose that φ has only the variables x and y free.

We will need the following notation: if t is a term for a partial recursive function, then $\Lambda x.t$ is the index of the partial recursive function given by t depending on x (if there are more variables we consider them as parameters; strictly speaking the notation is based on the S_n^m -theorem, Cf. Vol. 1 of this *Handbook*, p. 275, or [Kleene, 1952, p. 344]). For example, $\Lambda x.x + y$ is the index of the unary function that adds y .

We will sketch the proof in such a way that the reader, if he wishes to do so, can provide the full details himself.

Let $u r \forall x \exists y \varphi(x, y)$, then $\forall x (\{u\}x \downarrow \wedge \{u\}x r \exists y \varphi(x, y))$, i.e.

$$\forall x (\{u\}x \downarrow \wedge (\{u\}x)_1 r \varphi(x, (\{u\}x)_0)) \dots (0).$$

Put $t := \{u\}x$, and $a = \Lambda x.(t)_0, b = \mu w T(a, x, w), \delta(u) = \langle a, \Lambda x.\langle b, \langle 0, (t)_1 \rangle \rangle \rangle$.

Claim: $\delta(u) r \exists z \forall x \exists v (T(z, x, v) \wedge \varphi(x, Uv)) \dots (1)$.

We carry out the steps as given in the definition.

$$\Lambda x.\langle b, \langle 0, (t)_1 \rangle \rangle r \forall x \exists v (T(a, x, v) \wedge \varphi(x, Uv)) \dots (2).$$

$$\langle b, \langle 0, (t)_1 \rangle \rangle r \exists v (T(a, x, v) \wedge \varphi(x, Uv)) \dots (3).$$

$$\langle 0, (t)_1 \rangle r T(a, x, b) \wedge \varphi(x, Ub) \dots (4).$$

or

$$T(a, x, b) \wedge (t)_1 r \varphi(x, Ub) \dots (5).$$

Now observe that by the definition of a and $b, T(a, x, b)$ is true for all x . So 0 realizes it (where for convenience $T(a, x, b)$ has been taken to be atomic; this is achieved by a simple conservative extension of **HA**). Furthermore, Ub is the output of $\{a\}$ on input x , which is $(t)_0$, so $(t)_1 r \varphi(x, Ub)$ can be read as $(\{u\}x)_1 r \varphi(x, (\{u\}x)_0)$. This holds by (0). The passage from (0) to (1) tells us that $\Lambda u.\delta(u) r \text{CT}_0$. \blacksquare

Almost the same argument establishes ECT_0 (see below) [Troelstra, 1973, p. 195].

Troelstra has investigated the theory of the realizable sentences of arithmetic. It turns out that this fragment has a simple axiomatization (cf. [Troelstra, 1998, p. 416]).

$$\begin{aligned} \mathbf{HA} + \text{ECT}_0 &\vdash \varphi \leftrightarrow \exists x (x r \varphi) \\ \mathbf{HA} + \text{ECT}_0 &\vdash \varphi \leftrightarrow \mathbf{HA} \vdash \exists x (x r \varphi), \end{aligned}$$

where ECT_0 is the Extended Thesis of Church:

$$\forall x(\varphi \rightarrow \exists y\psi xy) \rightarrow \exists u\forall x(\varphi \rightarrow (\{u\}x \downarrow \wedge \psi(x, \{u\}x)))$$

for *almost negative* φ (i.e. φ does not contain \forall , and \exists only in front of atoms).

$\mathbf{HA} + \text{CT}_0$ has been studied in detail by David McCarty, for his results see [McCarty, 1988]. Perhaps the most striking fact established by him is the categoricity of the theory: $\mathbf{HA} + \text{CT}_0$ has no non-standard models.

Since Kleene's pioneering papers there has been a proliferation of notions. The reader is referred to [Troelstra, 1973] and [Troelstra, 1998] for the major notions in the context of arithmetic. There are also extensions to higher theories (e.g. set theory- like ones) (cf. [Feferman, 1979], [Beeson, 1985]).

In the fifties Gödel proposed a new interpretation of \mathbf{HA} (and extensions) based on functionals of all finite types (cf. [Gödel, 1958; Kreisel, 1959; Troelstra, 1973; Avigad and Feferman, 1998]). The basic idea is to reduce the logical complexity of sentences at the cost of increasing the types of the objects. Kreisel proposed the notion of 'modified realizability' (cf. Troelstra [1973; 1998]); Kleene transferred realizability to analysis by means of 'continuous function application'; in the context of first-order logic we mention Läuchli's 'abstract realizability'. A systematic and unifying treatment of various realizabilities has been given (cf. [Stein, 1980]).

The above-mentioned interpretations have led to a wealth of proof theoretic results, such as conservative extensions, and closure under rules. the reader is referred to [Troelstra, 1973; Troelstra, 1998] for detailed information.

The Russian school of A. A. Markov has made the algorithmic tradition the guideline for its actual mathematical practice. Its members consider mathematics as dealing with concrete, constructive objects. In particular they adhere to Church's thesis, so that, e.g. real numbers in their approach are given by recursive Cauchy sequences (hence the name 'recursive analysis'). Following Markov, they accept the principle $\neg\neg\exists x\varphi(x) \rightarrow \exists x\varphi(x)$ for primitive recursive $\varphi(x)$ —*Markov's Principle*. For a survey, cf. [Demuth and Kučera, 1979].

For a long time the 'algorithmic' interpretations have withstood attempts of unifying treatment together with the semantic interpretations. Recently, however, the framework of topos theory has provided a more semantic treatment of, e.g. realisability interpretations. In particular work of Hyland, Johnstone and Pitts [1980] on tripos theory and Hyland [1982] on the effective topos has provided a semantical home for the above kind of interpretations.

10 SECOND-ORDER LOGIC

Whereas first-order intuitionistic logic and its prominent theories, such as arithmetic, are just subtheories of the corresponding classical ones, the notions of second-order logic seem to dictate their own laws in the light of intuitionistic conceptions.

Traditionally, second-order logic is concerned with individuals, sets (and relations) and the only non-logical principle that is considered is the so-called comprehension axiom. Most studies are centered around second-order arithmetic, and extensions of it.

We will first discuss second-order logic.

The language of intuitionistic second-order logic \mathbf{IQC}^2 contains variables and constants for

$$\begin{array}{ll} \text{individuals} & - \quad x_0, x_1, x_2, \dots, \quad c_0, c_1, c_2, c_3, \dots \\ n\text{-ary relations} & - \quad X_0^n, X_1^n, X_2^n, \dots, \quad C_0^n, C_1^n, C_2^n, \dots, \end{array}$$

where $n \geq 0$.

0-ary variables (constants) are called *propositional variables* (constants), 1-ary variables (constants) are called *set (species) variables* (constants). The atoms of \mathbf{IQC}^2 are of the form X^0, C^0 for 0-ary second-order terms, or $X^n(t_1, \dots, t_n), C^n(t_1, \dots, t_n)$ for n -ary second-order terms X^n, C^n and first-order terms t_1, \dots, t_n (i.e. individual variables or constants).

In classical logic one thinks of 0-ary terms as denoting the truth values ‘true’, ‘false’. In our case we may think of truth values in a Heyting-algebra.

Formulas are defined as usual by means of the connectives $\wedge, \vee, \rightarrow, \perp, \forall x, \forall X^n, \exists x, \exists X^n$.

The rules of derivation (in Natural Deduction) are extended by the following quantifier rules:

$$\begin{array}{ccc} \forall^2 I \frac{\varphi}{\forall X^n \varphi} & & \forall^2 E \frac{\forall X^n \varphi}{\varphi^*} \\ & & \exists X^n \varphi \quad [\varphi] \\ \exists^2 I \frac{\varphi^*}{\exists X^n \varphi} & & \exists^2 E \frac{\begin{array}{c} \vdots \\ \psi \end{array}}{\psi} \end{array}$$

where φ^* is obtained from φ by replacing each occurrence of $X^n(t_1, \dots, t_n)$ by $\sigma(t_1, \dots, t_n)$, for a certain σ , such that no free variable among the t_i becomes bound after substitutions.

Observe that $\exists^2 I$ takes the place of the traditional *Comprehension Principle* (cf. [van Dalen, 1997, Chapter 4])

$$\exists X^n \forall x_1, \dots, x_n [\varphi(x_1, \dots, x_n) \leftrightarrow X^n(x_1, \dots, x_n)].$$

The surprise of second-order logic is the fact that the usual connectives are definable in terms of \forall and \rightarrow , this in sharp contrast to **IQC** (Prawitz). Given the rules for \forall and \rightarrow we can define the connectives as follows.

DEFINITION 65.

1. $\perp := \forall X^0.X^0$
2. $\varphi \wedge \psi := \forall X^0[(\varphi \rightarrow (\psi \rightarrow X^0)) \rightarrow X^0]$
3. $\varphi \vee \psi := \forall X^0[(\varphi \rightarrow X^0) \rightarrow ((\psi \rightarrow X^0) \rightarrow X^0)]$
4. $\exists x\varphi := \forall X^0[\forall x(\varphi \rightarrow X^0) \rightarrow X^0]$
5. $\exists X^n\varphi := \forall X^0[\forall X^n(\varphi \rightarrow X^0) \rightarrow X^0]$.

To be precise: given the rules for \forall and \rightarrow we can prove the rules for the defined connectives (cf. [Prawitz, 1965, p. 67], [van Dalen, 1997, p. 152]). For proof theoretical purposes the reduction of the number of connectives turns out to be an asset (cf. [Tait, 1975; Prawitz, 1971]),

The semantics for second-order logic are relatively straightforward generalizations of the existing semantics for first-order logics (cf. [Prawitz, 1970; Takahashi, 1970; Fourman and Scott, 1979]).

10.1 Second-order Arithmetic, **HAS**

The simplest formalisations of **HAS** (Heyting's second-order arithmetic with set variables), is obtained by adding the axioms for **HA** to second-order logic (in an extended language containing the obligatory operations and relations for arithmetic). Observe that, as a schema, the induction axiom is defined for the full language. The traditional issue in second-order arithmetic concerns the Comprehension Principle, CA. Should it have the full strength or should it be restricted to the predicative case? This topic has never been really central in intuitionistic considerations on higher-order objects. There certainly is not much to go on in Brouwer's writings. If we embrace the viewpoint that a set X is given when we know what it means to prove $n \in X$, then it is still not obvious to decide between the predicative and the impredicative viewpoint. Since the matter of predicativity is an issue in its own right, we bypass the topic.

Even at a quite low level sets of natural numbers turn out to be rather elusive. If we consider

$$\{n \mid \text{the } n^{\text{th}} \text{ decimal of } \pi \text{ is preceded by 20 nines}\}$$

then we do not know whether it is empty or not. So, even sets that have simple definitions may be rather wild (although not surprisingly so, as recursion theory has already shown us).

The universe of sets differs in an essential way from the universe of natural numbers. Whereas the latter are discretely given and completely determined with respect to each other, the first are pretty undetermined in the extensional sense, i.e. considered as being determined by their elements. This undeterminedness is brought out in the following *uniformity principle*, formulated by Troelstra

$$UP \quad \forall X \exists x \varphi(X, x) \rightarrow \exists x \forall X \varphi(X, x).$$

In words: if for each set X one can find a natural number x such that $\varphi(X, x)$ then there is already one number x_0 that satisfies $\varphi(X, x_0)$ for *all* X . Surprising as this may seem, the almost immediate counter-examples from classical logic are seen not to work. For example, consider $\forall X (X = \emptyset \vee X \neq \emptyset)$, which can be written as $\forall X \exists x ((x = 0 \rightarrow X = \emptyset) \wedge (x \neq 0 \rightarrow X \neq \emptyset))$. Classically, this statement is true, but intuitionistically is in general not decidable whether a set is empty, cf. the set defined above. The uniformity principle is consistent with **HAS** + AC-NS, where the axiom or choice from number to species reads

$$AC-NS \quad \forall x \exists X \varphi(X, x) \rightarrow \exists Y \forall x \varphi((Y)_x, x)$$

(where $y \in (Y)_x \Leftrightarrow \langle x, y \rangle \in Y$) [Troelstra, 1973a; van Dalen, 1974].

HAS has been studied via Kripke semantics in [Jongh and Smoryński, 1976]. They interpreted the first-order part as usual and took for sets of natural numbers growing families of sets (just like unary predicates in an ordinary Kripke model).

EXAMPLE 66.

Take in α and β the standard model of (classical) arithmetic and let $S_\alpha = \emptyset, S_\beta = N$. Then $\alpha \Vdash \neg \forall x (x \in S)$, i.e. $\neg \neg S = N$, but $\alpha \not\Vdash \forall x (x \in S)$ and even $\alpha \not\Vdash \exists x (x \in S)$.

A number of proof theoretic results are obtained by semantic means, e.g. **HAS** has the disjunction and the existence property, but also the existence property for $\exists X$:

$$\mathbf{HAS} \vdash \exists X \varphi(X) \Rightarrow \mathbf{HAS} \vdash \varphi(\{x \mid \sigma(x)\}), \text{ for a suitable } \sigma(x),$$

i.e. if ‘there (provably) exists a set’ X , then ‘there already exists a definable set’. We list a few closure properties.

1. **HAS** is closed under the Uniformity Rule, UR^c
 $\mathbf{HAS} \vdash \forall X \exists \varphi(X, x) \Rightarrow \mathbf{HAS} \vdash \exists x \forall X \varphi(X, x)$
 (where $FV(\varphi) = \{X, x\}$).
2. **HAS** is closed under Markov's Rule, MR
 $\mathbf{HAS} \vdash \forall x(\varphi(x) \vee \neg\varphi(x)) \wedge \neg\neg\exists x\varphi(x) \Rightarrow \mathbf{HAS} \vdash \exists x\varphi(x)$.
3. **HAS** is closed under Church's Rule, CR
 $\mathbf{HAS} \vdash \forall x \exists y \varphi(x, y) \Rightarrow \mathbf{HAS} \vdash \exists e \forall x \varphi(x, \{e\}x)$.
4. **HAS** is closed under the Rule of Choice, RC-NS
 $\mathbf{HAS} \vdash \forall x \exists X \varphi(X, x) \Rightarrow \mathbf{HAS} \vdash \exists X \forall x \varphi((X)_x, x)$.

Intuitionistic second-order arithmetic has been extensively studied by proof-theoretical means, e.g. [Martin-Löf, 1971; Prawitz, 1971; Girard, 1971] and Troelstra [1973; 1973a].

10.2 Choice Sequences

Whereas in classical mathematics one can define functions in terms of sets and vice versa, we here treat functions and sets more or less independently. Philosophically speaking this is rather obvious; the two notions are radically different. A set (say of natural numbers) is given to us as a *property* of natural numbers (cf. Brouwer [1918; 1981a]), whereas a function (say from natural numbers to natural numbers) is given as a process of assigning values to arguments. Interdefinability of these notions would be an unexpected coincidence. One can, of course, consider a function as a set of pairs, conversely one cannot, in general, give a set by a characteristic function. For let $f : \mathbb{N} \rightarrow \{0, 1\}$ and $n \in A \Leftrightarrow f(n) = 1$, then it follows from $\forall m(m = 1 \vee m \neq 1)$ that $\forall n(n \in A \vee n \notin A)$, i.e. A is *decidable* (mind you, not recursive, but decidable in the sense that ‘ n belongs to A or does not belong to A ’). Since there is in intuitionistic mathematics an abundance of undecidable sets, we must conclude that the characteristic function approach to sets does not work.

For the sake of perspicuity we will in the following restrict ourselves to functions from \mathbb{N} to \mathbb{N} .

The nineteenth century had already brought us the immense progress of widening the function concept, in the form of ‘a function is a law that assigns a natural number to each natural number’, thus doing away with conditions of analyticity, etc. However, the discussions at the beginning of this century made it clear that on a reasonable reading of ‘law’, one would end up with a countable universe of functions, with all its mathematical drawbacks. Or, even worse, with the definability paradoxes (Richard and Berry).

In order to overcome these difficulties Brouwer introduced in 1918 a more liberal notion of function, which identified functions with choice processes. To quote from Brouwer [1981a]: “*Admitting two ways of creating new mathematical entities: firstly in the shape of more or less freely proceeding infinite sequences of mathematical entities previously acquired; . . .*”

These sequences were introduced in 1918 as *choice sequences* (Wahlfolgen). In a later stage Brouwer spoke of *arrows*. One has to think an idealised mathematician who at consecutive stages chooses natural numbers. This (mental) choice process may be highly involved, e.g. the subject may be in the course of the process put all kinds of restrictions on future choices. He may, for example, at a certain stage give up all freedom and follow a given law, or he may decide at the beginning that he will never completely give up his freedom of choice.

The matter of higher-order restrictions on future choices (i.e. restrictions on restrictions, etc.) has sparked some debate. Indeed, Brouwer himself has questioned their usefulness (cf. Brouwer [1981a, p.13]; [1975, p. 511]).

Once choice sequences were introduced, Brouwer was faced with the non-trivial problem of how to exploit them in mathematics. Put otherwise, what properties can one extract from the basic conception of a choice process? In the very first paper on the subject Brouwer laid down the following continuity principles: *A law that assigns to each choice sequence ξ a natural number n must completely determine n after a finite initial segment of ξ has been determined* (cf. Brouwer [1918, p. 13]; [1975, p. 160]).

The matter of establishing the basic properties of choice sequences calls for ‘informal rigour’ (a term introduced by Kreisel [1967], referring to a precise non-formal analysis of certain conceptually given concepts, leading to more or less basic axioms (principles)). A general analysis of this kind is not within the scope of the present chapter. The reader is referred to [Troelstra, 1977; Dummett, 1977] and [van Atten and van Dalen, forthcoming]. Without going into all details we will indicate a language for a theory of choice sequences (also called *intuitionistic analysis*).

Add to the language of arithmetic, function variables $\xi_1, \xi_2, \xi_3, \dots$ and suitable function constants (e.g. the primitive recursive functions). The result is a two sorted language. We add all axioms of **IQC** for both sorts. In general one adds the (rather weak) comprehension principle

$$\forall x \exists! y \varphi(x, y) \rightarrow \exists \xi \forall x \varphi(x, \xi(x)).$$

What more is to be added depends on the notion under consideration. The comprehension principle is, e.g., correct for general choice sequences, but not in general for lawlike or lawless sequences. We will use roman symbols f, g, h, \dots for lawlike sequences (i.e. choice sequences given by a law). One may use various sorts of choice sequences in one and the same context (cf. [Kreisel and Troelstra, 1970; Troelstra, 1977]). We will, however, consider

a particularly perspicuous kind of choice sequence, introduced by Kreisel. The choice sequences we have in mind constitute, so to speak, a limiting case where no restrictions whatsoever will be placed on future choices. The resulting notion is that of ‘*lawless sequence*’. In what way does the lawlessness of a sequence manifest itself? Let us do a thought experiment: we make successive choices $\xi(0), \xi(2), \xi(2), \dots$, such that at each stage there is a complete freedom for the next choice (think of the throws of a die, where there is however an overall restriction to numbers ≤ 6), we add the successive values and we find that the sum of a certain initial segment is a prime number. For example, $\xi(0) = 4, \xi(1) = 2, \xi(2) = 2, \xi(3) = 0, \xi(4) = 1, \xi(5) = 8, \xi(6) = 2, \dots$, and $4 + 2 + 2 + 0 + 1 + 8 = 17$, which is a prime. So for this ξ we have established ‘There is an initial segment of ξ such that its sum is a prime number’—abbreviated by $\varphi(\xi)$.

It is, however, immediately clear that any lawless sequence η that starts with the same initial segment $\langle 4, 2, 2, 0, 1, 8 \rangle$ also satisfies φ . This is an instance of the general principle of *open data*:

$$\varphi(\xi) \rightarrow \exists x \forall \eta (\bar{\xi}x = \bar{\eta}x \rightarrow \varphi(\eta)),$$

where $\bar{\xi}x = \langle \xi(0), \xi(1), \dots, \xi(x-1) \rangle$, i.e. the coded (cf. Algorithms Chapter, volume 1 of this *Handbook*) initial segment of length x of ξ . *In words*: if φ holds for the lawless sequence ξ then there is an initial segment of ξ such that all lawless continuations of it also satisfy φ . Or less precise, ξ having the property φ is determined by a suitable initial fragment.

The principle can be justified as follows: the idealized mathematician establishes $\varphi(\xi)$ after a finite number of values of ξ has been chosen, because at any time that is all the available information on ξ he has. but, therefore, the continuation of this particular initial segment is irrelevant, i.e. all continuations η also have the property φ .

It is quite often helpful to think of a choice sequence (function) as a path in the full tree of all finite sequences of natural numbers. So suppose $\varphi(\xi)$ holds on the basis of the information of segment $\langle 0, 2, 3, 0, 1 \rangle$, then φ holds for all lawless sequences (paths) that pass through the node $\langle 0, 2, 3, 0, 1 \rangle$ in the tree. but in the tree topology this is a (basic) open. Hence if φ holds for ξ , it holds for an open neighbourhood of ξ (this explains the name ‘open data’).

There are two more basic principles:

$$\text{LS1} \quad \forall x \exists \xi (\xi \in x),$$

where x is a coded initial segment and $\xi \in x$ stands for $\xi(0) = (x)_0, \dots, \xi(k-1) = (x)_{k-1}$, where k is the length of x . In words each initial segment can be extended into a lawless sequence.

This principle is harder to justify, if no restrictions at all are allowed, how does one make certain that the first k choices can be made to conform to

a given segment? It is best to view this principle as slightly modifying the original notion: we allow at the beginning the specification of an arbitrary finite initial segment. In this way all finite sequences actually occur as initial segments.

If we make no assumptions about initial segments then the sequences offer a less satisfactory mathematical theory. Troelstra [1983] introduced this weaker notion (without LS1) under the name of *proto-lawless* sequences.

Finally, if the idealized mathematician considers two (mental) lawless choice processes, then he knows if the processes are identical or not, so we have

$$\text{LS2 } \forall \xi \eta (\xi \equiv \eta \vee \neg \xi \equiv \eta),$$

where \equiv is the intensional identity between sequences, considered as mental choice processes.

The principle of open data is formulated as

$$\text{LS3 } \varphi(\xi) \rightarrow \exists x (\xi \in x \wedge \forall \eta \in x \varphi(\eta)).$$

Actually, Kreisel's notion of 'lawlessness' requires also a certain independence of sequences, so that the sequences are also lawless with respect to each other. An example: say we generate a lawless sequence $\xi(0), \xi(1), \xi(3), \dots$ and we drop the first value, is the remaining sequence $\xi(1), \xi(2), \xi(3), \dots$ lawless? Individually viewed, yes, but in conjunction with the original sequence, no.

This leads us to extend LS3 as follows:

$$\begin{aligned} \text{LS3}_n \quad & \varphi(\xi, \xi_1, \dots, \xi_n) \wedge \not\equiv (\xi, \xi_1, \dots, \xi_n) \\ & \exists x (\xi \in x \wedge \forall \eta \in x (\not\equiv (\eta, \xi_1, \dots, \xi_n) \rightarrow \varphi(\eta, \xi_1, \dots, \xi_n))), \end{aligned}$$

where $\rightarrow \equiv (\xi, \xi_1, \dots, \xi_n)$ stands for $\bigwedge_{i=1}^n \xi \not\equiv \xi_i$.

Without the extra clause $\not\equiv (\xi, \xi_1, \dots, \xi_n)$ the principle is false. For example, consider $\varphi(\xi, \xi) := \xi \equiv \xi$. Suppose we could apply LS3₁, then

$$\xi \equiv \xi \rightarrow \exists x (\xi \in x \wedge \forall \eta \in x (\xi \equiv \eta)),$$

i.e. there is an initial segment of ξ such that every extension of it coincides with ξ . This plainly contradicts LS1.

From these principles we can already derive a number of unusual results.

THEOREM 67.

1. $\xi \equiv \eta \leftrightarrow \forall x (\xi x = \eta x)$
2. $\forall \xi \neg \neg \exists x (\xi x = 0)$
3. $\forall \xi \neg \exists \eta \forall x (\xi(x+1) = \eta(x))$

4. $\neg\exists\xi(\xi = f)$, for a lawlike function f .

Proof. (a) \rightarrow is trivial. For \leftarrow we can use a proof by contradiction by LS2. So let $\xi \neq \eta$, we may apply LS3₁ to $\varphi(\xi, \eta) := \forall y(\xi(y) = \eta(y))$:

$$\exists x(\xi \in x \wedge \forall \zeta \in x(\zeta \neq \eta \rightarrow \forall y(\zeta(y) = \eta(y))).$$

Let, therefore, the initial segment $\langle \xi(0), \dots, \xi(k) \rangle$ be such that for $\zeta \neq \eta$ and $\zeta(0) = \xi(0), \dots, \zeta(k) = \xi(k)$ it follows that $\forall y(\zeta(y) = \eta(y))$. Since $\zeta(k+1)$ can be chosen freely, we choose $\zeta(k+1) = \eta(k+1) + 1$ (i.e. we apply LS2 to $\langle \xi(0), \dots, \xi(k), \eta(k+1) + 1 \rangle$ to obtain a ζ). But this contradicts $\forall y(\zeta(y) = \eta(y))$. Hence $\xi \equiv \eta$.

(b) Suppose $\neg\exists x(\xi x = 0)$, or by logic, $\forall x(\xi x \neq 0)$. Apply LS3 and add a zero to the initial segment of ξ that exists according to LS3.

(c) Apply LS3₁ to $\forall x(\xi(x+1) = \eta(x))$.

(d) $\xi = f$ is an abbreviation for $\forall x(\xi(x) = f(x))$ (*extensional equality*). Apply LS3 to the latter formula. ■

Could we do better than (b) and even show $\forall \xi \exists x(\xi(x) = 0)$? The answer is no, but we need a strengthening of the system to show this.

We have already defined what a bar is (cf. p. 25). Now we can formalise it in analysis: B is a bar (in the tree of all finite sequences) if $\forall \xi \exists x(\xi \bar{x} \in B)$. Such a bar is a denumerable set of sequences. Can we present such a bar by a convenient function? The technique is not difficult, we consider a function $e : \mathbb{N} \rightarrow \mathbb{N}$, such that $e(x) = 0$ if x is a (coded) sequence above the bar, and $e(x) > 0$ for x on or below the bar.

More formally:

$$e \in K_0 := \forall \xi \exists x(e(\bar{\xi}x) > 0) \wedge \forall xy(e(x) > 0 \\ \wedge y \geq x \rightarrow e(x) = e(y))$$

(where $y \geq x$ stands for ‘the sequence y extends x ’). K_0 is the class of neighbourhood functions (or moduli of continuity, also called *Brouwer operations*). Note that the part of the tree above B is a well-founded tree. Kreisel and Troelstra have considered K_0 as an inductively defined class of lawlike functions (cf. [Troelstra and van Dalen, 1988, p. 223 ff.]).

The neighbourhood functions have been introduced with respect to lawless sequences, i.e. if e gives a bar B then each lawless sequence ξ hits the

bar. It is however plausible to widen the scope of such e , such that *each* sequence (not necessarily lawless) hits the bar. This *extension principle* which states that for each $e \in K_0$ we have $\forall \alpha \exists x (e(\bar{\alpha}x) \neq 0)$ (where α ranges over *all* sequences), is required for certain applications of the theory. A justification of the extension principle by means of an abstraction operator is put forward by Troelstra [1977, p. 20].

Here we will for simplicity use K_0 as given above. We will now formulate a strong continuity principle: if $\forall \xi \exists x \varphi(\xi, x)$, then x can be found for a given ξ by a neighbourhood function e from K_0 as follows: look for the first initial segment ξy such that $e(\xi y) = k + 1 > 0$ and put $x = k$. Let us agree to write $e(\xi) = k$ when we follow the above procedure, then we get the following principle:

$$\text{LS4} \quad \forall \xi \exists x \varphi(\xi, x) \rightarrow \exists e \in K_0 \forall \xi \varphi(\xi, e(\xi)).$$

By the extension principle e operates on all possible sequences. We will use this to show $\neg \forall \xi \exists x (\xi(x) = 0)$. Suppose $\forall \xi \exists x (\xi(x) = 0)$, then by LS4 $\forall \xi (\xi(e(\xi)) = 0)$, i.e. e picks a zero of ξ . Now consider f such that $\forall x (f(x) = 1)$. Determine $e(f)$, say k . f ‘hits’ the bar determined by e in a node m , which hence is an initial segment of f . Now extend this segment m with enough 1’s such that the total length of the resulting n exceeds k . By LS1 there is a lawless sequence ξ with initial segment n . By definition, however, $e(\xi) = e(f)$ and $0 = \xi(e(\xi)) = f(e(f)) = 1$. Contradiction. Hence $\neg \forall \xi \exists x (\xi(x) = 0)$.

The above lines may serve to illustrate the highly unusual character of lawless sequences and the extraordinary richness of the intuitionistic universe of functions. Kreisel and Troelstra have established for a certain system elimination theorems, i.e. translations that eliminate the choice sequences (cf. [Kreisel and Troelstra, 1970]; [Troelstra and van Dalen, 1988, 12.3.1]). This may, with due caution, be viewed as evidence for the viewpoint that choice sequences are only a *façon de parler*.

Note however that the evidence is rather incomplete in the sense that the theorems range over a few formal theories. Moreover such a viewpoint would violently conflict with the ontological status of the mentally generated objects of intuitionism.

Choice sequence have the didactic disadvantage that one cannot show an isolated copy, unless it happens to be given by a law. This situation changed when Joan Moschovakis adapted a topological model of Scott for the reals to choice sequences. A similar interpretation was presented by the author in the framework of Beth models. Since the latter approach allows one a nice visualisation we will sketch it here (cf. [van Dalen, 1978]).

In order to facilitate the presentation, we consider models with the universal tree (the tree of all finite sequences of natural numbers) as underlying poset. We will also denote the finite sequences (n_0, \dots, n_{k-1}) by \vec{n} .

Whereas in a Kripke model the condition $\forall x \exists! y \xi(x)y$ forces us to interpret a sequence (function) in each node as a total function, in a Beth model $\vec{n} \Vdash \forall x \exists! y \xi(x) = y$ only tells us that eventually on a bar B , the outputs y for an input x will be determined, so the natural interpretation of a sequence ξ is a growing family $\xi^{\vec{n}}$ of partial functions with the property that along a path the union of all these $\xi^{\vec{n}}$'s yield a total function. A concept that confirms rather well to the heuristic notion of 'choices being made in time'. In the nodes the choice function is only partially determined, but the whole model allows us to view the choice sequences, as it were from a higher viewpoint, as completed.

So we take a Beth model of arithmetic (containing only standard numbers) and consider as the universe of choice sequences *all* such growing families of partial functions.

EXAMPLES

(1) Define $\xi^{\vec{n}} := \vec{n}$ for each \vec{n} , i.e. in each finite sequence the partial function is just this sequence. Evidently the conditions are satisfied.

(2) Define $\xi^{\langle \rangle} = \langle \rangle$ and $\xi^{\langle i \rangle} = \lambda x. i$, i.e. at the bottom node we take the empty function, and at its immediate successors $\langle i \rangle$ we take the constant functions with value i . Observe that $\langle \rangle \Vdash \exists x \forall y (\xi(y) = x)$ (a simple exercise in Beth semantics), so the model tells us that the sequence is constant, although externally it is *not*.

The particular model with underlying tree of all finite sequences of natural numbers validates a list of principles:

$$\text{AC - NF} \quad \forall x \exists \xi \varphi(x, \xi) \rightarrow \exists \eta \forall x \varphi(x, (\eta)_x),$$

where $(\eta)_x(y) = \eta(\langle x, y \rangle)$, *the axiom of choice from numbers to functions*.

$$\text{SC!} \quad \forall \xi \exists! x \varphi(x, \xi) \rightarrow \exists \tau \in K_0 \forall \xi \varphi(\tau(\xi), \xi),$$

the strong continuity principle with uniqueness restriction.

BI_M *monotone bar induction*, a principle that can be considered as an intuitionistic version of induction over well-founded relations, or of transfinite induction (cf. [Troelstra and van Dalen, 1988; Kleene and Vesley, 1965]).

$$\text{KS} \quad \exists \xi (\varphi \leftrightarrow \exists x \xi(x) \neq 0),$$

Kripke's Schema, a principle which will be discussed in the next section.

The validity of Kripke's Schema is fairly simple to establish. For the remaining principles we refer to [van Dalen, 1978]. The idea is to go up in the tree and in each node to check if φ has been forced. So we define $\xi^{\vec{n}}$ to be a finite sequence of the same length as \vec{n} . Let \vec{n} have length k , then we put $\xi^{\vec{n}}(k) = 0$ if $\vec{n} \not\Vdash \varphi$ and $\xi^{\vec{n}}(k) = 1$ if $\vec{n} \Vdash \varphi$. this defines a proper choice sequence. Clearly, for any \vec{n} , if $\vec{n} \Vdash \varphi$ then $\vec{n} \Vdash \exists x \xi(x) \neq 0$.

Conversely, suppose that $\vec{n} \Vdash \exists x \xi(x) \neq 0$, then there is a bar B for \vec{n} such for each $\vec{m} \in B, \vec{m} \Vdash \xi(n) \neq 0$ for some n . This implies $\xi^{\vec{m}}(n) = 1$, which by definition means that $\vec{m} \Vdash \varphi$. So φ is forced on a bar for \vec{n} . Hence $\vec{n} \Vdash \varphi$ (cf. Lemma 11). Therefore $\langle \cdot \rangle \Vdash \exists \xi(\varphi \leftrightarrow \exists x \xi(x) \neq 0)$.

Although Kripke semantics has shown itself superior to Beth semantics in many respects, the latter is the more convenient one to treat functions. For, in the Kripke model, a function must in each world be interpreted by a total function (just evaluate $\alpha \Vdash \forall x \exists y (f(x) = y)$); in a Beth model however one can ‘postpone’ the assignment of outputs to inputs, and this allows for a particularly simple model for analysis. In order to use Kripke models for dealing with analysis one has to exploit the expanding of the domains, and this calls, in the case of arithmetic, immediately for non-standard numbers. Hardly natural!

The above model for analysis has the drawback that its first-order theory is classical, i.e. each classically true sentence of first-order arithmetic holds in the model. Therefore the model cannot play the role of ‘standard model’ of analysis. The model shows, however, that it is consistent to put an intuitionistic second-order theory on top of a classical first-order theory. The problem of the ‘standard model’ occurs already for first order arithmetic. In **HA** one can show not only $\forall xy(x = y \vee x \neq y)$, but also $m = n \Leftrightarrow \mathbf{HA} \vdash \vec{m} = \vec{n}$. So in a topological model for arithmetic, with only standard numbers we have $\llbracket t = s \rrbracket = X$ or \emptyset , i.e. atoms take only the values \top or \perp . Now a simple induction shows that $\llbracket \varphi \rrbracket$ takes the values \top or \perp for all sentences φ . So we get full true, classical arithmetic. Therefore, in order to obtain intuitionistic features, say the failure of the principle of the excluded middle, we have to assume the presence of non-standard numbers. This all points towards serious limitations of the present semantic treatment of intuitionistic theories.

10.3 The Disjunction Property for Analysis

We have seen that Kripke models may be ‘put together’ as a means for proving metalogical results, e.g. the disjunction property (cf. p. 44). In view of the usefulness of Beth models for interpreting analysis, it would be convenient to have a similar operation in Beth semantics.

Roughly speaking, one takes the disjoint union of two Kripke models and adds one bottom node (left-hand figure). The domain of the bottom node is contained in all domains of the Kripke models **A** and **B**. In the case of Beth models one would place the models **A** and **B** alternately on top of the linearly ordered set of natural numbers (right-hand figure). Here we run into difficulties; what should the domain be in the nodes $0, 1, 2, \dots$? The semantics does not allow for non-constant domains, so we reach a dead-end. Now our generalised semantics comes in handy, if we allow expanding domains then we can use this ‘gluing’ technique. Let us outline how to

obtain DP.

Suppose $T \vdash \varphi \vee \psi$ and $T \not\vdash \varphi, T \not\vdash \psi$, and $\mathbf{B} \not\vdash \psi$. Find a domain that is contained in the bottom nodes of \mathbf{A} and \mathbf{B} (this is not always possible, it depends on the class of models of $T!$), and place this in the nodes $0, 1, 2, \dots$ of the co-called *spine*.

Now $0 \Vdash \varphi \vee \psi$, so there is a bar B such that for each $\beta \in B, \beta \Vdash \varphi$ or $\beta \Vdash \psi$. The bar intersects the spine, say in n . If $n \Vdash \varphi$ then there is a copy of \mathbf{A} above n in which φ is forced. Contradiction. Similarly for $n \Vdash \psi$. Hence $T \vdash \varphi$ or $T \vdash \psi$.

The above gluing construction is particularly fruitful for analysis, (cf. Dalen [1984; 1986]). It yields simple proofs of the disjunction and existence property for various systems of analysis. The main problem is the definition of the universe of sequences in the resulting model. One assigns to the nodes n on the spine, the set of finite sequences of length n . The sequences (in the sense of the model) in node n are then all possible extensions of these sequences to partial functions in higher nodes.

J. Moschovakis had already established DP and EP for some systems by proof theoretical means in [Moschovakis, 1967].

The reason for dwelling on arithmetic and its extensions, in particular analysis, is that this hard core of mathematical logic is the ultimate testing ground for logical methods. Analysis is extremely important because it illustrates the typical consequences of intuitionism. In analysis one can most clearly see the conflict between the classical and the intuitionistic approaches. Brouwer used the following theorem to illustrate the typical

properties of intuitionism:

Each function from the closed interval $[0,1]$ to \mathbb{R} is uniformly continuous [1923].

From the intuitionistic principles we can derive similar results. The continuity principle SC! tells us that each function from sequences to numbers is continuous. however, classically one can define the function F such that

$$F(\xi) = \begin{cases} 0 & \text{if } \xi \text{ contains a } 0 \\ 1 & \text{otherwise.} \end{cases}$$

This F cannot be continuous, because continuity would mean that the occurrence of a 0 in a sequence ξ can be predicted on the basis of an initial segment of ξ . *Quod non.*

The conflict with classical mathematics is here particularly striking. In general, analysis and higher-order systems are the perfect grounds for demonstrating the proper character of intuitionism; it distinguishes itself from narrow constructivism and finitism by its embracing abstract notions.

A topic that has been omitted altogether is *second-order propositional logic*. Whereas in classical logic this is a subject of great dullness (think of quantifications over a set of two truth-values), it is not so in the intuitionistic version. In contrast to the classical system, the intuitionistic one is undecidable (cf. [Gabbay, 1981] for a systematic treatment of this topic).

10.4 Remarks on the Axiom of Choice

In classical mathematics the axiom of choice used to be considered as something that, if it should hold at all, should hold globally (this is not to say that no refinements of AC have been considered, but that the foundational evidence seems to point that way (cf. [Shoenfield, 1967, p. 253]). In intuitionism there is fairly solid evidence for the validity of the principle of countable choice; let $\forall x \exists y \varphi(x, y)$ be given for, say x and y ranging over natural numbers, then we have a proof of $\forall x \exists y \varphi(x, y)$, i.e. a construction that provides for each $x \in \mathbb{N}$ a proof of $\exists y \varphi(x, y)$. this, in turn, means that we have a construction that yields a y and a proof of $\varphi(x, y)$. So we have a construction that for each x yields a y such that $\varphi(x, y)$ holds (i.e. has a proof). This construction provides a choice function f , such that $\forall x \varphi(x, f(x))$ holds. So AC-NN is valid on an intuitionistic interpretation of the logic. (In Martin-Löf's type theory is is actually provable.)

Let us now consider AC-RN. The following is true: for each real number x there is a natural number y such that $x < y$ (recall that x is given by a Cauchy sequence). If there were a choice function f such that $x < f(x)$, then—by Brouwer's theorem (cf. [Heyting, 1956, p. 46], [Brouwer, 1981a, p. 80])— f has to be continuous. But a continuous function from \mathbb{R} to \mathbb{N} is constant. Contradiction.

An inspection of the proof, as given for AC-NN, will show what has gone wrong.

Our assumption reads in full: $\forall x \in \mathbb{R}, \exists y \in \mathbb{N}(x < y)$, so the proof interpretation tells us that for each choice sequence x of rational numbers $\pi(x)$ is a proof of ‘ x is a Cauchy sequence $\rightarrow \exists y \in \mathbb{N}(x < y)$ ’, i.e. $\pi(x)$ applied to a proof of ‘ x is a Cauchy sequence’ yields a proof of

$$\exists y \in \mathbb{N}(x < y).$$

Now, finishing the argument, we find a choice function that depends on x and on a proof that x is a Cauchy sequence. But now we see that f is not extensional, i.e. $x_1 = x_2 \rightarrow f(x_1, \pi_1) = f(x_2, \pi_2)$ fails, where π_i is a proof that x_i is a Cauchy sequence. Therefore the continuity theorem was not applicable. The moral of this digression is that one has to spell out the assumption of AC in full. In case of AC-NN we are on safe ground because a natural number by virtue of its mode of generation carries its own proof that it is a natural number.

The general axiom of choice is intuitionistically out of the question, as Diaconescu (cf. [Goldblatt, 1979]) has shown that it implies the excluded third. The following simple argument, due to Goodman and Myhill, proves Diaconescu’s result.

Let φ be any statement. Form the sets

$$\begin{aligned} A &:= \{n \in \mathbb{N} \mid n = 0 \vee (n = 1 \wedge \varphi)\}, \\ B &:= \{n \in \mathbb{N} \mid n = 1 \vee (n = 0 \wedge \varphi)\}. \end{aligned}$$

We have $\forall X \in \{A, B\} \exists y \in \mathbb{N}(y, X)$.

AC would supply us with a function f such that $\forall X \in \{A, B\} (f(X) \in X)$. Since $f(X)$ is a natural number, we get $f(A) = f(B) \vee f(A) \neq f(B)$. If $f(A) = f(B)$, then φ holds, and if $f(A) \neq f(B)$, then $\neg\varphi$ holds. For suppose φ , then $A = B$ (extensionally) so $f(A) = f(B)$. Contradiction. So the validity of AC for this particularly simple case implies $\varphi \vee \neg\varphi$.

11 THE CREATING SUBJECT

In Brouwer’s writings some explicit references to the agent of mathematical activity occur (1948) (cf. [Brouwer, 1975, p. 478]). The basic ideas were already present in his lectures in the late 1920s, cf. [Brouwer, 1992]; the publication was, however, postponed until after the second world war. In due time this practice has become known under the name ‘theory of the creating subject’. Brouwer introduced the creating subject for the purpose of establishing some stronger results in the area of so-called negative predicates. In particular he showed that inequality on the reals is strictly weaker than apartness: $\neg\forall xy(x \neq y \rightarrow x \# y)$.

Kreisel, Kripke and others have analyzed the principles involved in those proofs (cf. [Kreisel, 1967]).

The creating subject is assumed to operate in linear time of order-type ω . It ‘experiences the truth’ of statements φ at stages $0, 1, 2, \dots$. The exact nature of ‘experiencing the truth’ is, of course, left open. One may think of ‘proving’, ‘observing’ or ‘knowing’, etc. By suitably idealising the creating subject we may assume that:

1. it retains truths that have been experienced;
2. at each stage it knows φ or it does not know φ . that is, ‘knowing φ at stage n ’ is *decidable*;
3. φ holds if it has been ‘experienced’, by the creating subject.

This is in perfect accordance with the intuitionistic dogma that mathematics has its seat in the human mind, and that the only way to establish something is to have a mental ‘proof’ or ‘experience’ for it.

The converse can be defended under the purely solipsistic view that what is the case solely depends on mental experience of the (unique) creating subject. Then, if φ holds it follows that the creating subject has come to know it at some stage. If one allows for an intersubjective viewpoint, then the matter is less clear. The statement φ may hold without the creating subject (one of many) having established it. In this case it seems plausible that it is impossible that the creating subject will never experience φ .

The theory of the creating subject has been formalized by Kreisel [1967], in a theory containing at least (a fragment of) arithmetic, and a tensed modal operator \Box_x , to be read as ‘the creating subject knows (has evidence, a proof for, . . . etc.) at time x ’.

The principles under (1), (2) and (3) can now be formulated as

1. $\Box_x \varphi \rightarrow \Box_{x+y} \varphi$
2. $\Box_x \varphi \vee \neg \Box_x \varphi$
3. $\varphi \leftrightarrow \exists x \Box_x \varphi$.

In the intersubjective case (3) splits into the following parts

$$\Box_x \varphi \rightarrow \varphi \text{ and } \varphi \rightarrow \neg \neg \exists x \Box_x \varphi.$$

For the applications that Brouwer had in mind the weaker reading suffices. The justification for the solipsistic version, however, is more convincing. In principle there is no objection to iterate the operator \Box , and in Brouwer’s consistent view that reflection on one’s own mental activity is possible, or even necessary it seems quite correct to do so. However, all problems that arise in and around predicativity, reappear here as well.

In the following pages we will look at the full theory as given by (1), (2) and (3).

11.1 Kripke's Schema

If we have function variables available, then we can eliminate the modal operator and retain all its benefits by keeping track of the knowledge of the creating subject by means of a function that registrates if the creating subject knows φ at stage x .

Define

$$\xi(x) = \begin{cases} 0 & \text{if } \neg \Box_x \varphi \\ 1 & \text{if } \Box_x \varphi, \end{cases}$$

then by (3) $\varphi \rightarrow \exists x \Box_x \varphi$, so $\varphi \rightarrow \exists x \xi(x) \neq 0$. conversely $\exists x \xi(x) \neq 0 \rightarrow \exists x \Box_x \varphi$ and hence $\exists x \xi(x) \neq 0 \rightarrow \varphi$. This proves *Kripke's Schema*.

KS

$$\exists \xi (\varphi \leftrightarrow \exists x \xi(x) \neq 0).$$

By a similar argument one obtains the weak Kripke's Schema in the inter-subjective case

KS⁻

$$\exists \xi ((\exists x \xi(x) \neq 0 \rightarrow \varphi) \wedge (\neg \varphi \rightarrow \forall x \xi(x) = 0)).$$

Kripke's Schema is used, for instance, for the construction of certain strong counterexamples (cf. [Hull, 1969]). We list some of them:

The statements refer to the intuitionistic reals.

1. $\neg \forall xy ((\neg x < y \wedge x \neq y) \rightarrow y < x)$
2. $\neg \forall xy (x \neq y \rightarrow x \# y)$
3. $\neg \forall xy (x \neq y \rightarrow \neg x < y \vee \neg y < x)$
4. not every bounded set without points of accumulation is bounded in number (refutation of the Bolzano–Weierstrauss theorem).

Note that these results are *strong* in comparison to the older results which only yielded 'we cannot prove that ...'. The first of these strong counterexamples was presented by Brouwer in 1949.

Myhill has shown that KS is inconsistent with the continuity principle for functions, which is a generalisation of SC:

$$\forall \xi \exists \eta \varphi(\xi, \eta) \rightarrow \exists F \forall \xi \varphi(\xi, F(\xi)),$$

where F is a continuous function (cf. [Troelstra, 1969]). KS is however consistent with SC (Kroll (cf. [Grayson, 1981; Scowcroft, 1999])).

11.2 Kripke's Schema and the Continuum

Brouwer's strong refutations already show that the creating subject refines our insight into the structure of the continuum. Further results in this area have been obtained in [van Dalen 1999A]. Brouwer had already shown that the continuum is *indecomposable*, in the sense that if $\mathbb{R} = A \cup B$ and $A \cap B = \emptyset$, then $A = \mathbb{R}$ or $A = \emptyset$. On the basis of KS it can be shown that all negative, dense subsets of \mathbb{R} are likewise indecomposable (where $X \subseteq \mathbb{R}$ is negative if $\neg\neg x \in X \rightarrow x \in X$). Hence, e.g., the irrationals and the not-not-rationals are indecomposable. These subsets are therefore connected in the topological sense, and they have dimension 1. This is in sharp contrast to the classical theory, where the irrationals are zero-dimensional.

Kripke's schema also allows us to show a kind of converse to Brouwer's indecomposability theorem: $\text{KS} + \mathbb{R}$ is indecomposable \Rightarrow there are no discontinuous functions on \mathbb{R} . We will, by way of illustration, sketch the proof: let $f : \mathbb{R} \rightarrow \mathbb{R}$ be discontinuous. It is no restriction to assume that $f(0) = 0$ and that f is discontinuous in 0. So there is a k and there are x_n such that $|x_n| < 2^{-n}$ and $|f(x_k)| > 2^{-k}$. Now consider the statement $r \in \mathbb{Q}$ for an $r \in \mathbb{R}$. We apply KS to $r \in \mathbb{Q} \vee r \notin \mathbb{Q}$:

$\exists \xi (\exists x \xi(x) \neq 0 \leftrightarrow r \in \mathbb{Q} \vee r \notin \mathbb{Q})$. For convenience we assume that ξ is positive at most once, with value 1.

Define $a_n = \begin{cases} x_n & \text{if } \forall k \leq n (\xi(k) = 0) \\ x_p & \text{if } p \leq n \text{ and } \xi(p) = 1 \end{cases}$

Clearly (a_n) converges, say $\lim a_n = a$. Now $|f(a_n)| < 2^{-k}$ or $|f(a_n)| > 0$, hence $a \neq x_n$ for all n , or $a \neq 0$. The first is impossible, since it would imply $\neg(r \in \mathbb{Q} \vee r \notin \mathbb{Q})$. The latter implies $\exists n \xi(n) = 1$, and hence $r \in \mathbb{Q} \vee r \notin \mathbb{Q}$. Since this holds for arbitrary r , we have got a decomposition of \mathbb{R} . Contradiction. Therefore there are no discontinuous functions on \mathbb{R} .

Although the theory of the creating subject has a richer language it is actually conservative over the theory with Kripke's Schema ([van Dalen, 1978]).

11.3 The Interpretation of the Creating Subject

We have already seen how to validate KS in the Beth model for analysis. A slight adaptation will provide an interpretation of the tensed modal 'knowledge' operator. We define $\vec{n} \Vdash \Box_k \varphi$ if for all \vec{m} on the bar for \vec{n} of nodes of length k , $\vec{m} \Vdash \varphi$ (note that this bar may be below \vec{n}). We'll check the axioms (2) and (3).

(2) For a given φ we have for each \vec{m} of length k , $\vec{m} \Vdash \varphi$ or $\vec{m} \not\Vdash \varphi$. For such a \vec{m} we can conclude $\forall \vec{p} \geq \vec{m}, \vec{p} \not\Vdash \Box_n \varphi$ from $\vec{m} \not\Vdash \varphi$, i.e. $\vec{m} \not\Vdash \varphi \Rightarrow \vec{m} \Vdash \neg \Box_k \varphi$. So for each \vec{m} on the bar of nodes of length k we have $\vec{m} \Vdash \Box_k \varphi$ or $\vec{m} \Vdash \neg \Box_k \varphi$. Hence $\langle \rangle \Vdash \Box_k \varphi \vee \neg \Box_k \varphi$.

(3) If $\vec{n} \Vdash \varphi$ and with $\text{lth}(\vec{n}) = k$, then $\vec{n} \Vdash \Box_k \varphi$ and hence $\vec{n} \Vdash \exists x \Box_x \varphi$. Conversely, if $\vec{n} \Vdash \exists x \Box_x \varphi$ then there is bar B for \vec{n} such that for each $\vec{m} \in B$ there is an $k(\vec{m})$ with $\vec{m} \Vdash \Box_k \varphi$. Applying the above definition and Lemma 11 we conclude $\vec{m} \Vdash \varphi$ for each $\vec{m} \in B$.

Applying Lemma 11 once more we get $\vec{n} \Vdash \varphi$.

11.4 Kripke's Schema and a Representation of Sets of Natural Numbers

Although we cannot use characteristic functions to represent sets, we can use Kripke's Schema to obtain a substitute.

Let X be a set of natural numbers, then by KS

$$\forall x \exists \xi [x \in X \leftrightarrow \exists y (\xi y = 0)].$$

(switching = and \neq is a harmless act). Applying the axiom of choice from numbers to functions, AC-NF, we get

$$\exists \eta \forall x [x \in X \leftrightarrow \exists y (\eta \langle x, y \rangle = 0)].$$

So each set X can be represented by a sequence. This allows for a translation of second-order arithmetic into analysis with KS.

Using this representation, there is a simple argument that deduces the Uniformity Principle,

$$\forall X \exists x \varphi(X, x) \rightarrow \exists x \forall X \varphi(X, x),$$

from the Weak Continuity Principle,

$$\forall \xi \exists x \varphi(\xi, x) \rightarrow \forall \xi \exists xy \forall \eta (\xi y = \bar{\eta} y \rightarrow \varphi(\eta, x)),$$

in the presence of KS, cf. [van Dalen, 1977].

The theory of the creating subject has remained controversial until this day. The introduction of an element of subjectivity runs counter to the tradition of the exact sciences. It is, however, an unavoidable step in representing some of Brouwer's arguments.

Evidently the theory, as it stands, is far from complete. Questions concerning the number of conclusions per step, or regarding disjunction (e.g. is $\Box_n(\varphi \vee \psi) \rightarrow \Box_n\varphi \vee \Box_n\psi$ a valid principle?), remain unsettled, and evidence seems to be scarce. Dummett has investigated the subject [Dummett, 1977] and Posy has applied the theory in a case study of Brouwer's paper on virtual order [Posy, 1980], cf. also [Posy, 1976].

12 THE LOGIC OF EXISTENCE

For the practice of classical logic and mathematics it suffices to consider only total operations. For example, consider the inverse-operation, a^{-1} . For real numbers a^{-1} exists if $a \neq 0$, so we cannot apply the classical trick of defining $a^{-1} := 0$ for the remaining a 's. This should leave us with a partial function, since \neq is not a decidable relation on \mathbb{R} .

$$a^{-1} = \begin{cases} 1/a & \text{if } a \neq 0 \\ 0 & \text{if } a = 0 \end{cases}$$

(note that it could not possibly be total, (for then it had to be uniformly continuous on $[0,1]$). One could avoid the problem by only discussing multiplication, but that would be a sin against the time-honoured practice of mathematics. So we would prefer to have a^{-1} , even if it means allowing partially defined terms and problems of existence.

Traditionally the matter is dealt with in free logic (cf. Bencivenga's chapter on Free Logics in this *Handbook*); we will, however briefly discuss existence here since it comes up naturally in intuitionistic logic, and since it has surprising semantic aspects.

The semantic aspects of partial elements can conveniently be demonstrated in any of the models introduced earlier. We will first consider Kripke models. Elements occur in certain domains and not in others, so they have a natural mode of existence in Kripke models. We define $\alpha \Vdash Ea$ iff $a \in D(\alpha)$. E behaves as an ordinary predicate and we can handle it as usual. We may explicitly introduce the *extent* of a as follows. $\llbracket Ea \rrbracket = \{\alpha \mid a \in D(\alpha)\}$, clearly $\llbracket Ea \rrbracket$ is an open set in the canonical topology. $\llbracket Ea \rrbracket$ is that part of the underlying topological space where a exists; this explains the name *partial element*: $\llbracket Ea \rrbracket$ need not be all of the space. Since in Beth models elements exist always (likewise in topological models), one has to consider the general models of Section 3 in order to introduce partial elements.

There is a kind of paradigm for the semantics of partial elements: sheaves over topological spaces. Without going into technical details we will sketch

the approach so that the reader can form an impression. Consider two topological spaces X and Y and continuous maps into Y defined on open subsets of X . The reader may take \mathbb{R} for X and Y . We define for such a map (*section*) $a : \llbracket Ea \rrbracket = \text{domain } a$.

In order to get a reasonable realistic theory we also want to interpret equality of partial elements. A natural choice is $\llbracket a = b \rrbracket = \text{Int}\{t \in X \mid a(t) = b(t)\}$.

Note that $\llbracket a = a \rrbracket = \llbracket Ea \rrbracket$ and also $\llbracket a = b \rrbracket \subseteq \llbracket Ea \rrbracket \cap \llbracket Eb \rrbracket$. Using our knowledge of the topological interpretation (i.e. the interpretation of the connectives), we see that $a = b \rightarrow Ea \wedge Eb$ is true. Equality satisfies the laws $a = b \leftrightarrow b = a$ and $a = b \wedge b = c \rightarrow a = c$, since $\llbracket a = b \rrbracket = \llbracket b = a \rrbracket$ and $\llbracket a = b \rrbracket \cap \llbracket b = c \rrbracket \subseteq \llbracket a = c \rrbracket$, but not $a = a$. For $\llbracket a = a \rrbracket \neq X$, in general, we see that the presence of partial elements affects the theory of identity (cf. [Scott, 1979]).

Of course propositional logic is not affected by the introduction of partial elements. It is predicate logic that requires attention. Turning Quine's dictum 'existence = being quantified over' around, we stipulate that one can only quantify over existing elements.

For existential quantification this makes sense, $\exists x\varphi(x)$ means that there *exists* an element that satisfies φ . Adding 'but it need not exist' would be plain cheating. For universal quantification we read $\forall x\varphi(x)$ as 'for any a picked from the domain $\varphi(a)$ holds', which commits us to existing elements (note that in classical logic \exists decides the matter for \forall).

The above is reflected in the axioms and rules of quantification.

$$\begin{array}{c}
[Ex] \\
\vdots \\
\forall I \frac{\varphi(x)}{\forall x\varphi(x)} \\
\exists I \frac{\varphi(t) \quad Et}{\exists x\varphi(x)}
\end{array}
\qquad
\begin{array}{c}
\forall E \frac{\forall x\varphi(x) \quad Et}{\varphi(t)} \\
\qquad \qquad \qquad [\varphi(x), Ex] \\
\exists E \frac{\exists x\varphi(x) \quad \begin{array}{c} \vdots \\ \sigma \end{array}}{\sigma}
\end{array}$$

(with the obvious restrictions).

In a Hilbert-type system we retain the rules $\forall I$ and $\exists E$ in the form

$$\frac{\psi \wedge Ex \rightarrow \varphi(x)}{\psi \rightarrow \forall x\varphi(x)} \qquad \frac{\varphi(x) \wedge Ex \rightarrow \sigma}{\exists x\varphi(x) \rightarrow \sigma}$$

and add the axioms

$$\forall x\varphi(x) \wedge Et \rightarrow \varphi(t) \quad \varphi(t) \wedge E(t) \rightarrow \exists x\varphi(x).$$

As sketched above one also has to revise the identity rules. There are two possible notions of identity, a strong one, where one requires both elements to exist, and a weaker one, where one automatically equates elements there where they do not exist.

The above equality, $=$, is the strong one. The weaker one can be defined by $a \equiv b := Ea \vee Eb \rightarrow a = b$.

The notions are interdefinable as is shown by the following fact

$$a = b \leftrightarrow a \equiv b \wedge Ea \wedge Eb.$$

this provides us with the following axioms

$$\begin{array}{l}
x = x \leftrightarrow Ex \\
x = y \rightarrow y = x \\
x = y \wedge y = z \rightarrow x = z.
\end{array}$$

One has to select carefully the right formulation in cases involving equivalence or existence. For example, $x \equiv x \rightarrow Ex$ is false, but $\forall x(x \equiv x \rightarrow Ex)$ is correct, for it is equivalent on logical grounds to $\forall x(Ex \rightarrow (x \equiv x \rightarrow Ex))$.

The theory of partial elements is the ideal setting for the introduction of a description operator. For $Ix.\varphi(x)$ is just a term, it has no existential import; it has to satisfy a certain formula when and where it uniquely exists. For instance, it is axiomatized by

$$\forall y[y = Ix.\varphi(x) \leftrightarrow \forall x(\varphi(x) \leftrightarrow x = y)].$$

In our model we just look for those nodes where a unique element is forced to satisfy $\varphi(x)$ and we put them together to one partial element. Let $\alpha \Vdash \varphi(0) \wedge \exists! x \varphi(x)$, $\beta \Vdash \varphi(1) \wedge \exists! \varphi(x)$, $\gamma \Vdash \varphi(0) \wedge \varphi(1)$, then $Ix.\varphi(x)$ is interpreted in the model as being 0 in α and 1 in β and undefined (non-existent) in γ . So $Ix.\varphi(x)$ is locally equal to given elements. This being ‘locally’ equal to something, or ‘locally’ true, etc. is a characteristic consequence of the forcing conditions of Beth semantics (cf. Section 3 above).

In a theory with identity we want to be able to replace equals by equals. Should one restrict this to the strong equality? For general (extensional) formulas this seems too restrictive, even weak equality would preserve properties, so we formulate the axiom as

$$x \equiv y \wedge \varphi(x) \rightarrow \varphi(y).$$

Following Scott [1979] we call ‘=’ identity and ‘ \equiv ’ equivalence. The reader is referred to this basic paper, and to [Troelstra and van Dalen, 1988, p. 50], for more information on existence and partial elements. We add one more remark: if the theory has function symbols, then the following can be said: if one gets an output, then there must have been an input, or more formally $Ef(x) \rightarrow Ex$. Reversing the arrow we get the condition for a total function: $Ex \rightarrow Ef(x)$.

One should observe that quantifiers affect existence; they are not neutral as one would maybe expect. the interpretation of ‘ $\forall x$ _____’ is ‘for all x that exist _____’. One can actually prove $\forall x \varphi(x) \leftrightarrow \forall x (Ex \rightarrow \varphi(x))$.

We now return to the model of continuous maps from \mathbb{R} to \mathbb{R} .

We can operate on these functions in a pointwise manner, e.g. add multiply etc. By definition we have

$$[f \equiv g] := \text{Int}\{x \in \mathbb{R} \mid f(x) = g(x) \vee f(x) \text{ and } g(x) \text{ are undefined}\}.$$

For quantification we put:

$$\begin{aligned} \llbracket \forall x \varphi(x) \rrbracket &= \text{Int} \cap_f \llbracket Ef \rightarrow \varphi(f) \rrbracket \\ \llbracket \exists x \varphi(x) \rrbracket &= \cup_f \llbracket Ef \wedge \varphi(f) \rrbracket. \end{aligned}$$

Now it is a matter of simple verification to check the axioms listed above.

Let us look at the description operator in this model.

The elements of the model have the convenient property, peculiar to sheaves, that they can be glued together if they coincide on overlapping domains (elementary analysis). Moreover, one can always restrict a function to a smaller open domain. We use these properties to interpret $Ix.\varphi(x)$ as the union of all continuous functions restricted to the part where they uniquely satisfy $\varphi(x)$, more formal $\cup_f f \upharpoonright \llbracket \forall x(\varphi(x) \leftrightarrow f = x) \rrbracket$, where $f \upharpoonright U$ stands for the subfunction of f obtained by restriction of f to U .

Applying this to the inverse, we put $h^{-1} = Ix.(xh = 1)$. Putting together all small functions, that locally act as in inverses, we obtain a function defined on the subdomain of h obtained by leaving out the zero's of h .

Note that the model once more demonstrates the necessity of strengthening the equality relation for the existence of inverses. Note that $\llbracket f \neq 0 \rrbracket = \text{Int}\llbracket f = 0 \rrbracket^c = \text{Int}(\text{Int}\{x \mid f(x) = 0\})^c = \mathbb{R}$ but $\llbracket \exists x(xf = 1) \rrbracket = \mathbb{R} \setminus \{0\}$. So $\llbracket f \neq 0 \rightarrow \exists x(xf = 1) \rrbracket \neq \mathbb{R}$.

Therefore we use the apartness relation, $\#$,

$$\llbracket f \# g \rrbracket := \{x \mid f(x) \neq g(x) \text{ and } f(x) \text{ and } g(x) \text{ are defined}\}.$$

Now we get $\llbracket f \# 0 \rightarrow \exists x(xf = 1) \rrbracket = \mathbb{R}$ (observe that this amounts to $\llbracket f \# 0 \rrbracket \subseteq \llbracket \exists x(xf = 1) \rrbracket$).

After Fourman had developed the *sheaf interpretation* for the case of topological spaces, Fourman and Scott generalised the approach to sheaves over complete Heyting algebra's (so-called Ω -sets), this approach is to be found in their paper of 1979. At that time there had already been done

a great deal in categorical logic, after the pioneering work of W. Lawvere. This topic has reached a size and technical refinement that places it utterly beyond the present book. For an introduction the reader is referred to Goldblatt's book [1979], Fourman and Scott [1979], Grayson [1984], [MacLane and Moerdijk, 1992; McLarty, 1992].

The generalisations of sheaves over topological spaces (in particular over *sites*) have provided models for various kinds of choice sequences (cf. [Hoeven and Moerdijk, 1984]).

WALTER FELSCHER

DIALOGUES AS A FOUNDATION FOR INTUITIONISTIC LOGIC

SUMMARY OF CONTENTS

The principal content of this article is a (new) foundation for intuitionistic logic, based on an analysis of argumentative processes as codified in the concepts of a *dialogue* and a *strategy* for dialogues. This work is presented in Section 3. A general historical introduction is given in Section 2. Since already there the reader will need to know exactly what a dialogue and a strategy shall be, these basic concepts are defined in the (purely technical) Section 1.

1 BASIC CONCEPTS: DIALOGUES AND STRATEGIES

I consider a first-order language, built with variables x, y, \dots and terms t ; formulas shall be constructed from atomic formulas with the propositional connectives $\wedge, \vee, \rightarrow, \neg$ and the quantifiers \forall, \exists ; I shall also consider $\vee, \wedge_1, \wedge_2, \exists$ as *special symbols* in their own right. By an *expression* I understand either a term or a formula or a special symbol. I introduce two further symbols P and Q ; taking two new (and disjoint) copies of the set of expressions, I form for every expression e two new expressions Pe and Qe , the *P-signed* and the *Q-signed version* of the expression e .

The symbols P, Q shall symbolise two persons engaged in an argument or in a dialogue; I shall use X, Y as variables for P, Q and shall assume $X \neq Y$. An *argumentation form* is a schematic presentation of an argument, concerning a logically composite assertion; it describes how a composite assertion made by C may be *attacked* by Y and how, if possible, this attack may be *answered* by X . As the logical form of the composite assertion shall completely determine the argument, each of the four propositional connectives and each of the two quantifiers determines an argumentation form:

\wedge :	assertion:	$X w_1 \wedge w_2$	
	attack:	$Y \wedge_i$	(i.e., Y chooses $i = 1$ or $i = 2$)
	answer:	$X w_i$	
\vee :	assertion:	$X w_1 \vee w_2$	
	attack:	$Y \vee$	
	answer:	$X w_i$	(i.e., X chooses $i = 1$ or $i = 2$)
\rightarrow :	assertion:	$X w_1 \rightarrow w_2$	
	attack:	$Y w_1$	
	answer:	$X w_2$	
\neg :	assertion:	$x \neg w$	
	attack:	$Y w$	
	answer:	<i>no answer possible</i>	
\forall :	assertion:	$X \forall x w$	
	attack:	$Y t$	(i.e., Y chooses the term t)
	answer:	$X w(t)$	
\exists :	assertion:	$X \exists x w$	
	attack:	$Y \exists$	
	answer:	$X w(t)$	(i.e., X chooses the term t).

In the last two answers I have written $w(t)$ for the substitution instance obtained from w if the term t is substituted for the variable x .

A dialogue shall be a (finite or infinite) sequence δ of statements, i.e., signed expressions, stated alternately by P and Q and progressing in accordance with the argumentation forms; I shall consider only such dialogues which are begun by P . Since it is necessary to distinguish carefully between attacks, answers and the assertions they refer to, I shall introduce besides δ an accompanying sequence η of references, and there I shall use the symbols A for *attack* and D for *answer (defense)*. For notational convenience, I shall assume that a natural number *is* the set of all smaller natural numbers (whence 0 is the first natural number), and a *sequence* shall always be a function, defined on either a natural number or on the set ω of all natural numbers. The precise definition then reads as follows:

A *dialogue* δ, η consists of two sequences such that

δ is a sequence of signed expressions,

η is a function defined on the *positive* members of $\text{def}(\delta)$, and if n in $\text{def}(\eta)$ is an ordered pair $[m, Z]$ such that m is a natural number less than n and Z is either A or D ,

satisfying the properties (D00)–(D02):

- (D00) $\delta(n)$ is P -signed if n is even and Q -signed if n is odd; $\delta(0)$ is a composite formula.
- (D01) If $\eta(n) = [m, A]$ then $\delta(m)$ is a composite formula and $\delta(n)$ is attack upon $\delta(m)$ according to the appropriate argumentation form.
- (D02) If $\eta(p) = [n, D]$ then $\eta(n) = [m, A]$ and $\delta(p)$ is the answer to the attack $\delta(n)$ according to the appropriate argumentation form.

The signed formulas occurring as values of δ are called the *assertions* of the dialogue while the remaining values of δ are *symbolic statements* or, more correctly, *symbolic attacks*. The numbers in $\text{def}(\delta)$ are called the *positions* or *places* of the dialogue. If Pv is the assertion $\delta(0)$, the dialogue is said to be a dialogue *for* the formula v (or, sometimes, for Pv).

Assume now that a particular class H of dialogues is given, defined maybe by additional conditions, which has the property that, for every position n of an H -dialogue δ, η , the *restrictions* of δ, η to positions i such that $i \leq n$ form an H -dialogue again. Assume further that a subclass of H has been defined, consisting of certain *finite* H -dialogues which then are said to be the H -dialogues *won* by P . Let v be a composite formula; to say that P has an H -strategy shall mean that P is in possession of a system of information, consisting of possible choices of P -statements in dialogues, such that every H -dialogue for v is won by P if only P chooses, after every statement made by Q , its own statement from this system of information. In order to formulate a more precise definition, recall that a *tree* S is a partially ordered set of elements called *nodes* with the following properties: there exists a *largest* element e_S (the top node), and for every node e the number $\|e\|$ of nodes f such that $e \leq f < e_S$ is *finite*; every node except e_S has exactly one *upper neighbour* but may have arbitrarily many *lower neighbours* (i.e., the tree is branching downwards). A *path* in S is a linearly ordered subset of nodes which, together with each of its elements e , contains all the preceding nodes f with $e \leq f$; a *branch* is a path which is maximal. If A is a branch of S , let α_A be the unique order-preserving bijection which maps either a natural number or all of ω onto A , i.e. $\|\alpha_A(i)\| = i$ holds for every node $\alpha_A(i)$ in A . Consider now a tree S and functions δ, η where δ is defined on all nodes of S and η on the nodes different from e_S ; for every branch A define $\delta_A = \delta \cdot \alpha_A, \eta_A = \eta \cdot \alpha_A$. The triplet S, δ, η then is an H -strategy for v if

- (S0) For every branch A of S the pair δ_A, η_A is an H -dialogue for v which is won by P .
- (S1) For every node e of S the following is the case. If $\|e\|$ is odd then S does not branch at e . If $\|e\|$ is even then e has as many lower neighbours as Q has possibilities to extend, by adding a new position, to an H -dialogue the (restricted) dialogue leading to e ,

and δ, η assign these lower neighbours the values which realise these possibilities.

The general definitions having been established, particular classes of dialogues can be introduced. To do so, I shall need the following terminology. Let δ, η be a dialogue, and let $\delta(n)$ be one of its attacks. The attack $\delta(n)$ will be said to be *open at a position k* with $n < k$ if there is no position n' with $n < n' \leq k$ which carries an answer $\delta(n')$ to that attack. In particular, an attack upon a formula $X \neg v$ remains open at all later places. A *D-dialogue* shall be a dialogue δ, η satisfying the following properties (D10)–(D13) :

- (D10) P may assert an atomic formula only after it has been asserted by Q before: if $\delta(n) = Pa$ and a is atomic then there exists m such that $m < n$ and $\delta(m) = Qa$.
- (D11) If, at a position $p-1$, there are several open attacks suitable to be answered at p , then only the *latest* of them may be answered at p : if $\eta(p) = [n, D]$ and if $n < n' < p, n'-n \equiv 0 \pmod{2}$, $\eta(n') = [m', A]$ then there exists p' such that $n' < p' < p, \eta(p') = [n', D]$.
- (D12) An attack may be answered at most once: for every n there exists at most one p such that $\eta(p) = [n, D]$.
- (D13) A P -formula may be attacked at most once: if m is even then there exists at most one n such that $\eta(n) = [m, A]$.

A D -dialogue is said to be *won by P* if it is finite, ends with an even position and if the rules do not permit Q to continue with another attack or answer. In that case the last position carries an atomic formula asserted by P .

The importance of D -dialogues rests in the fact that the formulas for which there exist D -strategies are precisely those provable in intuitionistic logic. This follows from the following, stronger

EQUIVALENCE THEOREM. *There exist recursive algorithms which, for every formula v , transform a proof of the sequent $\Rightarrow v$ in Gentzen's calculus LJ (for intuitionistic logic) into a D -strategy — and vice versa.*

Contrary to first appearances, a proof of this theorem is by no mean obvious; it cannot be pursued here and may be found in Felscher [1981; 1985].

An *E-dialogue* shall be a D -dialogue satisfying the additional condition that Q can react only upon the immediately preceding utterance of P :

- (E) For every n in $\text{def}(\delta)$: if n is odd then $\delta(n)$ is either attack upon $\delta(n-1)$ or answer to $\delta(n-1)$.

An E -dialogue is said to be *won by P* if, again, it is finite, ends with an even position and if now the rules for E -dialogues do not permit Q to continue

with either an attack or an answer. There will be occasion to refer to the following result which is auxiliary to the proof of the Equivalence Theorem.

EXTENSION LEMMA. *There is a recursive algorithm by which every E -strategy can be embedded into a D -strategy.*

It follows from this lemma that the Equivalence theorem holds also for E -strategies in place of D -strategies.

Readers not familiar with the use of dialogues may appreciate the following *examples* in which a, b, \dots are assumed to be atomic formulas.

- (1a)
- | | | |
|----|--|----------|
| 0. | $P(a \wedge b) \rightarrow (a \wedge b)$ | |
| 1. | $Q(a \wedge b)$ | $[0, A]$ |
| 2. | $P \wedge_1$ | $[1, A]$ |
| 3. | Qa | $[2, D]$ |
| 4. | $P \wedge_2$ | $[1, A]$ |
| 5. | Qb | $[4, D]$ |
| 6. | $P(a \wedge b)$ | $[1, D]$ |
| 7. | $Q \wedge_1$ | $[6, Q]$ |
| 8. | Pa | $[7, D]$ |
| | | |
| 7. | $Q \wedge_2$ | $[6, Q]$ |
| 8. | Pb | $[7, D]$ |

- (1b)
- | | | |
|----|--|----------|
| 0. | $P(a \wedge b) \rightarrow (a \wedge b)$ | |
| 1. | $Q(a \wedge b)$ | $[0, A]$ |
| 2. | $P(a \wedge b)$ | $[1, D]$ |
| 3. | $Q \wedge_1$ | $[2, A]$ |
| 4. | $P \wedge_1$ | $[1, A]$ |
| 5. | Qa | $[4, D]$ |
| 6. | Pa | $[3, D]$ |
| | | |
| 3. | $Q \wedge_2$ | $[2, A]$ |
| 4. | $P \wedge_2$ | $[1, A]$ |
| 5. | Qb | $[4, D]$ |
| 6. | Pb | $[3, D]$ |

Here we have two different D -strategies for the same formula.

- (2a)
- | | | |
|----|-------------------------------|----------|
| 0. | $P(a \rightarrow \neg\neg a)$ | |
| 1. | Qa | $[0, A]$ |
| 2. | $P\neg\neg a$ | $[1, D]$ |
| 3. | $Q\neg a$ | $[2, A]$ |
| 4. | Pa | $[3, A]$ |

- (2b)
- | | | |
|----|-------------------------------|----------|
| 0. | $P(\neg\neg a \rightarrow a)$ | |
| 1. | $Q\neg\neg a$ | $[0, A]$ |
| 2. | $P\neg a$ | $[1, A]$ |
| 3. | Qa | $[3, A]$ |

The first example is a D -strategy. In the second example, P cannot win if $(D11)$ shall not be violated.

- (3)
- | | | |
|----|--------------------------------------|----------|
| 0. | $P((a \wedge \neg a) \rightarrow b)$ | |
| 1. | $Q(a \wedge \neg a)$ | $[0, A]$ |
| 2. | $P \wedge_1$ | $[1, A]$ |
| 3. | Qa | $[2, D]$ |
| 4. | $P \wedge_2$ | $[1, A]$ |
| 5. | $Q \neg a$ | $[4, D]$ |
| 6. | Pa | $[5, A]$ |

This is a D -strategy. The same reasoning holds for $P \neg(a \wedge \neg a)$.

- (4)
- | | | |
|----|--|----------|
| 0. | $P((a \rightarrow a) \rightarrow b) \rightarrow b$ | |
| 1. | $Q(a \rightarrow a) \rightarrow b$ | $[0, A]$ |
| 2. | $P(a \rightarrow a)$ | $[1, A]$ |
| 3. | Qb | $[2, D]$ |
| 4. | Pb | $[1, D]$ |
| 5. | Qa | $[2, A]$ |
| 6. | Pa | $[5, D]$ |
| 3. | Qa | $[2, A]$ |
| 4. | Pa | $[3, D]$ |
| 5. | Qb | $[2, D]$ |
| 6. | Pb | $[1, D]$ |

This is a D -strategy. If we omit positions 5 and 6, we still obtain an E -strategy.

- (5a)
- | | | |
|----|--|----------|
| 0. | $P((a \rightarrow b) \rightarrow a) \rightarrow a$ | |
| 1. | $Q(a \rightarrow b) \rightarrow a$ | $[0, A]$ |
| 2. | $P(a \rightarrow b)$ | $[1, A]$ |
| 3. | Qa | $[2, D]$ |
| 4. | Pa | $[1, D]$ |
| 3. | Qa | $[2, A]$ |

The left E -dialogue is won by P but not the right one. There is no strategy as long as $(D11)$ shall not be violated.

- (5b)
- | | | |
|----|--|----------|
| 0. | $P \neg \neg(((a \rightarrow b) \rightarrow a) \rightarrow a)$ | |
| 1. | $Q \neg(((a \rightarrow b) \rightarrow a)$ | $[0, A]$ |
| 2. | $P((a \rightarrow b) \rightarrow a) \rightarrow a)$ | $[1, A]$ |
| 3. | $Q(a \rightarrow b) \rightarrow a$ | $[2, A]$ |
| 4. | $P(a \rightarrow b)$ | $[3, A]$ |
| 5. | Qa | $[4, D]$ |
| 6. | Pa | $[3, D]$ |
| 5. | Qa | $[4, A]$ |
| 6. | $P((a \rightarrow b) \rightarrow a) \rightarrow a$ | $[1, A]$ |
| 7. | $Q(a \rightarrow b) \rightarrow a$ | $[6, A]$ |
| 8. | Pa | $[7, D]$ |

This an E -strategy and is easily extended to a D -strategy.

- (6)
- | | | | | |
|-----|----------------------|--|-------|------------------------------|
| | 0. | $P((a \rightarrow b) \rightarrow (a \rightarrow c)) \rightarrow (a \rightarrow (b \rightarrow c))$ | | 0 |
| | 1. | $Q(a \rightarrow b) \rightarrow (a \rightarrow c)$ | [0,A] | 1 |
| | 2. | $P(a \rightarrow (b \rightarrow c))$ | [1,D] | 0 |
| | 3. | Qa | [2,A] | 1 |
| | 4. | $P(b \rightarrow c)$ | [3,D] | 0 |
| | 5. | Qb | [4,A] | 1 |
| | 6. | $P(a \rightarrow b)$ | [1,A] | 2 |
| 7. | Qa | [6,A] | | |
| 8. | Pb | [7,D] | 7. | $Q(a \rightarrow c)$ [6,D] 1 |
| 9. | $Q(a \rightarrow c)$ | [6,D] | 8. | Pa [7,A] 2 |
| 10. | Pa | [9,A] | 9. | Qc [8,D] 1 |
| 11. | Qc | [10,D] | 10. | Pc [5,D] 0 |
| 12. | Pc | [5,D] | 11. | Qa [6,A] 3 |
| | | | 12. | Pb [11,D] 2 |

This is again a D -strategy. If we omit positions 9–12 on the left branch and positions 11–12 on the right branch then we obtain an E -strategy. The numbers appearing to the right of the values of η are the *orders* of the respective assertions as they will be defined in Section 3.3.

- (7) Let d_0 be the formula $f \wedge \neg f$ for some (atomic) f .

- | | | | | |
|----|--------|---|-------|----------------|
| | 0. | $P(a \wedge ((b \rightarrow a) \rightarrow d_0)) \rightarrow c$ | | 0 |
| | 1. | $Q(a \wedge ((b \rightarrow a) \rightarrow d_0))$ | [0,A] | 1 |
| | 2. | $P \wedge_1$ | [1,A] | |
| | 3. | Qa | [2,D] | 1 |
| | 4. | $P \wedge_2$ | [1,A] | |
| | 5. | $Q(b \rightarrow a) \rightarrow d_0$ | [4,D] | 1 |
| | 6. | $P(b \rightarrow a)$ | [5,A] | 2 |
| 7. | Qd_0 | [6,D] | 7. | Qb [6,A] 3 |
| | | | 8. | Pa [7,D] 2 |
| | | | 9. | Qd_0 [6,D] 1 |

This can be completed so as to become a D -strategy; Qd_0 can be handled as in example (3), and on the left branch we then will have to add the steps occurring in the right branch as positions 7 and 8.

- (8) Let d_0 be as in (7) and define recursively for $i = 0, 1, \dots$

$$e_i = a \wedge ((b \rightarrow a) \rightarrow d_i) \rightarrow c,$$

$$d_{i+1} = e_i \rightarrow d_0.$$

Example (7) then gives a d -strategy for e_0 and, moreover, shows that there is a D -strategy for each e_{i+1} with Qd_i appearing in the positions 7 and 9 respectively. The D -strategy for e_i then contains assertions of orders up to $i+3$.

- (9)
- | | | |
|-----|--|-------|
| 0. | $P((a \rightarrow b) \rightarrow v) \rightarrow (c \rightarrow (b \rightarrow a))$ | |
| 1. | $Q(a \rightarrow b) \rightarrow v$ | [0,A] |
| 2. | $P(c \rightarrow (b \rightarrow a))$ | [1,D] |
| 3. | Qc | [2,A] |
| 4. | $P(a \rightarrow b)$ | [1,A] |
| 5. | Qa | [4,A] |
| 6. | $P(b \rightarrow a)$ | [3,D] |
| 7. | Qb | [6,A] |
| 8. | Pa | [7,D] |
| 9. | Qv | [4,D] |
| 10. | Pb | [5,D] |

The left-dialogue satisfies (D10), (D12), (D13), and observing these rules Q has no possibility to continue it. The rule (D11) is violated at place 6. If the formula v is chosen suitably then the dialogues can be extended so as to obtain a strategy, e.g., if v is $a \wedge b$ or $c \rightarrow a$ or $(a \rightarrow d) \rightarrow d$. However, for these choices of v already a D -strategy for the initial contention can be found.

- (10)
- | | | |
|----|---|-------|
| 0. | $P(\neg(a \rightarrow b)) \rightarrow (a \vee d)$ | |
| 1. | $Q\neg(a \rightarrow b)$ | [0,A] |
| 2. | $P(a \vee d)$ | [1,D] |
| 3. | $Q\vee$ | [2,A] |
| 4. | $P(a \rightarrow b)$ | [1,A] |
| 5. | Qa | [4,A] |
| 6. | Pa | [3,D] |
| 7. | Qc | [4,D] |

Also this dialogue satisfies (D10), (D12), (D13) and violates (D11).

- (11)
- | | | |
|----|--|-------|
| 0. | $P(a \wedge ((\neg a \rightarrow b) \rightarrow c)) \rightarrow c$ | |
| 1. | $Q(a \wedge ((\neg a \rightarrow b) \rightarrow c))$ | [0,A] |
| 2. | $P\wedge_1$ | [1,A] |
| 3. | Qa | [2,D] |
| 4. | $P\wedge_2$ | [1,A] |
| 5. | $Q(\neg a \rightarrow b) \rightarrow c$ | [4,D] |
| 6. | $P(\neg a \rightarrow b)$ | [5,A] |

7. $Q\neg a$ [6,A] 8. Pa [7,A] 9. Qc [6,D] 10. Pc [1,D]	7. Qc [6,D] 8. Pc [1,D] 9. $Q\neg a$ [6,A] 10. Pa [9,A]
--	--

In the left dialogue, Q violates (D11) at place 9. If this place and the following place 10 are omitted, a D -strategy remains.

(12)

0. $P(\neg(b \rightarrow (c \vee d))) \rightarrow (a \rightarrow b)$	
1. $Q\neg(b \rightarrow (c \vee d))$	[0,A]
2. $Pa \rightarrow b$	[1,D]
3. Qa	[2,A]
4. $P(b \rightarrow (c \vee d))$	[1,A]
5. Qb	[4,A]
6. $Pc \vee d$	[5,D]
7. $Q\vee$	[6,A]
8. Pb	[3,D]

P violates (D11) at place 8.

2 THE LITERATURE ON DIALOGUES

2.0

It was P. Lorenzen who, in addresses in 1958 and 1959, published as Lorenzen [1960; 1961], proposed the idea that an autonomous foundation of intuitionistic logic should be based on the concepts of a dialogue and of a strategy for dialogues. Emphasizing the autonomy of such a foundational approach, Lorenzen preferred to speak of a *constructive* or *effective* logic and avoided the more familiar name of *intuitionistic* logic. While the first descriptions of dialogues seemed to use only the properties named here (D00)–(D02), it soon became clear that additional rules would be required if *only* intuitionistically provable formulas should be those which could be secured by strategies for dialogues. Such additional rules were formulated by Lorenz [1961] who defined (among other types) the kind of dialogues called D -dialogues here; they appear in Lorenzen [1962; 1967] and in Kamalah and Lorenzen [1967]. While these presentations attempted to arrive at an appropriate definition for a dialogue by specializing the general notion, a different approach was taken in [Lorenz, 1973] and [Lorenzen and Schwemmer, 1973] where there is considered at first a very narrow type of dialogue (permitting both P and Q to react only upon the immediately preceding step) which then is liberalised to types of dialogues which are, essentially, the E -dialogues of Section 1.

Lorenzen's basic idea is indeed a very attractive one. However, although described in a variety of articles and books, its presentations have been marred by a recurrence of ambiguous definitions and incomplete, if not erroneous proofs. And all these elaborations so far have suffered from two major defects.

2.1

The first defect is of a technical-mathematical character. If a new development of intuitionistic logic, based on the concepts of dialogues and strategies, shall be given, then one expects an equivalence theorem to be established which states that provability by strategies coincides with provability by one of the known calculi for intuitionistic logic. The proof of such a theorem remained missing for many years.

A first attempt to prove an equivalence theorem was made in Lorenz's dissertation [Lorenz, 1961]; it was repeated in [Lorenz, 1968]. A certain part of Lorenz's dissertation was corrected in [Stegmüller, 1964]; some claims made in other parts were proved while other ones were refuted in the Diplomarbeit of W. Kindt [1970]. Kindt's refutations were acknowledged in footnote 12 of [Lorenz, 1968] where it is said that a correction of the erroneous statements in [Lorenz, 1961] would require "ein paar detaillierte technische Vorbereitungen" (cf. also a similar remark in footnote No. 16); unfortunately, these few, detailed technical preparations have never been presented to the public, and the gaps in Lorenz's attempt still appear to be unfilled. (It is somewhat distressing that in the presumably authoritative collection of [Lorenzen and Lorenz, 1978] the article [Lorenz, 1968] is simply reprinted together with its footnotes; the part of [Lorenz, 1961] to which footnote No.12 refers has been omitted altogether.)

A first correct proof of an equivalence theorem was given by Kindt [1972]; however, the dialogues studied by Kindt are *not* D -dialogues but employ instead of $(D11)$ a different rule. In [Lorenzen and Schwemmer, 1973, pp. 59 and 71] it is observed that the E -strategies (in the sense of Section 1) considered there give rise to a calculus of 'Dialogstellungen' which (at least in the propositional case) may be transformed into a calculus of Beth-tableaux such that provability by E -strategies implies intuitionistic provability. A new, and simpler approach to an equivalence theorem for D -dialogues was developed by Haas [1980] and it seems that the technical gaps contained in this work are only minor and can actually be filled. An attempt to prove an equivalence theorem for E -dialogues is contained in [Mayer, 1981] and Dr E. C. W. Krabbe informs me that an equivalence theorem for E -dialogues is contained in [Krabbe, 1982] and in [Barth and Krabbe, 1982].

The equivalence theorem stated in Section 1 was presented in [Felscher, 1981] and in a revised form in [Felscher, 1985].

2.2

The second defect from which the elaborations of Lorenzen's idea have suffered concerns the matter of foundations. The rules (D00)–(D01) are just precise descriptions of the intention that dialogues should proceed through applications of the argumentation forms. But when additional rules (the 'Dialog-Rahmenregeln' in the terminology of the Lorenzen school) had to be imposed, the question arose whether such rules could be explained as natural codifications of principles of argumentation. Such principles, if foundationally sound, would have to be based on an analysis of the use of dialogues as a means to establish a systematical, indisputable and convincing conduction of formal arguments.

When Lorenzen [1960; 1961] wrote about 'Sprachspiele', i.e., language games, he used this word in the sense of the ancients' $\alpha\gamma\omega\nu$, referring to a regulated (linguistic) process, the rules of which were to be governed by an insight which, although not further explained, was clearly assumed to be present. This attitude changed with [Lorenz, 1961] who, attempting a mathematical formalisation, began to make use of the concepts of a mathematical discipline known as the Theory of Games. Games there are mathematical objects, describing procedures as varied as whist and rummy at the one end and the games invented by warriors and economists at the other end. The rules then may be arbitrary: what matters is that they are adhered to; and the convention that a game is won because the other player can't draw any more may be brought about by rather odd rules of the game (such as, e.g., the categorical application of an equaliser). Matters were not improved when Lorenz [1961] observed that a change of dialogue rules would give rise to a type of dialogue the strategies for which would prove precisely the *classically* provable formulas. For this situation made it perfectly clear that the mathematical arbitrariness of the Theory of Games, being a tool to describe formally such different ways of reasoning as are classical logic and intuitionistic logic, could not possibly produce a philosophical foundation for either one of them. The mathematical apparatus for the Theory of Games was used heavily in the mathematical work of Kindt [1970; 1972]. On the other hand, phrases referring to 'dialogue games' have spread through a certain kind of literature where a mathematical terminology is borrowed in order to give at least the appearance of conceptual precision.

It appears that Lorenzen himself did not follow the fashion of a game-theoretical reduction. However the foundational discussions presented, e.g. in [Lorenzen and Schwemmer, 1973] are not based on an argumentative analysis; in particular, atomic statements and their negations are discussed with respect to a semantical distinction of true and false, and the difference between classical and intuitionistic logic is made to depend on the decidability ('Wahrheits-Definitheit': definiteness with respect to truth) of atomic statements. As crown's evidence for the generally unsatisfactory state of

a foundational discussion I may quote Kambartel [1979] who, in the very conclusion of this article, writes in respect to the problem of justification:

... Rechtfertigungsproblem. Dieses besteht darin, die *schematischen* Dialogspiele selbst von einem *argumentativen* Gebrauch der logischen Partikeln her zu begründen. Die dialogische Logik hat dieses Problem bisher dadurch überspielt, dass sie die Dialogspiele methodisch als 'erste' Festlegung des Gebrauchs der logischen Partikeln behandelt. Das dabei vernachlässigte, über die schematische Ebene hinausführende Rechtfertigungsproblem schlägt dann spätestens in der Rahmenregeldiskussion wieder durch. In der Tat werden dort 'Rechtfertigungen' für die Wahl solcher Regeln, z.B. neuerdings immament schematisch oder, wie zunächst geschehen, im eher intuitiven Rückgriff auf halb-schematisch analysierte Beispiele, beigebracht. Weder 'technische' Kriterien noch die Verallgemeinerung von Beispielen stellen aber bereits einen im engeren Sinne *normativen* Zugang zur Logik dar ...

2.3

Lorenzen's argumentation forms have also been put to use by K. J. J. Hintikka, but this with quite different intentions. Hintikka, beginning with [Hintikka, 1968], developed what he calls a *game-theoretical semantics*, and a more recent series of articles on this topic have been collected in [Saarienen, 1979]. A *semantical game* in Hintikka's terminology may indeed be viewed as a dialogue in the sense of Section 1 although Hintikka restricts his attention to the single argumentation forms and nowhere cares to formulate game rules proper (such that the implied reference to mathematical games remains but an incantation). The point, however, is that Hintikka is concerned with a linguistical analysis of natural languages and *not* with a foundation of (classical or intuitionistic) logic. For this purpose, argumentation forms and dialogues are used as tools for the semantical evaluation of logically composite expressions (which may be more complex than first-order logic would permit to express) in domains governed by classical logic. There is, therefore, no connection of Hintikka's work with that discussed in the present article.

3 FOUNDATIONS OF DIALOGUES

In this Section I shall develop an argumentative foundation for the use of particular types of dialogues, the *D*-dialogues, as a basis for intuitionistic logic. That such a foundation is wanted was outlined in subsection 2.2.

3.1 *The Argumentative Interpretation of Logical Operators*

There exists a well known provability interpretation of the logical operations (connectives and quantifiers) which then may be considered as being represented by Gentzen's calculi of proofs, i.e., natural deduction and the sequent calculus LJ; for details, cf. van Dalen's article in this volume. In the same manner, the argumentation forms may be viewed as expressing an *argumentative interpretation* of the logical operations, and as far as the positive connectives and the quantifiers are concerned this interpretation is obvious enough. Concerning implication, Y attacks $Xw_1 \rightarrow w_2$ by offering Yw_1 as an *admission* (or *local hypothesis*) and X may react by either answering with Xw_2 or attacking Yw_1 (provided w_1 is composite). Concerning negation, the situation is the same as in the case of the provability interpretation: if external, semantical references to truth and falsity shall be avoided, we must enrich the basic concept of provability by adding either refutability or absurdity as a primitive notion. Since we are aiming for intuitionistic logic, we introduce a constant Δ symbolising *absurdity* and then understand $\neg w$ as an abbreviation of $w \rightarrow \Delta$. The principle of *ex absurdo quodlibet* takes as its first form that he, X , who is forced to assert Δ then must concede, without further argument, any assertion made by Y . A speaker professing Δ thus brings himself into a position precluding any further debate, and so we may just as well omit this fatal step and state, as the second form of *ex absurdo quodlibet*, that Δ must not be asserted. This then explains why an attack Yw upon $Xw \rightarrow \Delta$, i.e., $X\neg w$, cannot be answered.

3.2 *Basic Principles for Dialogues*

Gentzen's calculi of proofs are easily explained in that they represent the weakest consequence relation for which the provability interpretation is valid. The connection between dialogues and the argumentative interpretation of logical operations is (not only more complicated but also) located on a different level: it is not the dialogues but the *strategies* for dialogues which will correspond to proofs. I thus formulate the *basic purpose* for the use of dialogues:

- (A₀) Logically provable assertions shall be those which, for *purely formal* reasons, can be upheld by a strategy covering every dialogue chosen by Q .

The dialogue rules (D00)–(D02), describing the use of argumentation forms, simply produce the (linguistic) material of the dialogue which then will have to be organised by the dialogue rules proper. Extending the intentions expressed in the formulation of the argumentation forms, I formulate the *argumentative intent* in the pursuit of a single dialogue:

- (A₁) A dialogue is, on the part of Q an attempt to put into doubt (to refute) the initial assertion made by P ; it is, on the part of P , an attempt to uphold this assertion, and if P succeeds in doing so this will mean that P wins the dialogue.

In the light of these intentions we now will have to clarify

- (b₀) how to determine the dialogue rules proper,
 (b₁) the notion that P wins a dialogue.

It must be emphasised that the concepts occurring here *cannot* be studied separately but must be analysed *simultaneously* and in constant regard of the purpose (A₀).

3.3 Dependence, Positive Dependence and Order

The notions to be discussed in this subsection are auxiliary. Let δ, η be a dialogue. I shall say that a statement *depends directly* on an earlier statement if it is either an attack upon or an answer to that statement; I define *dependence* to be the transitive and reflexive relation generated by direct dependence. Dependence, therefore, is an order relation, contained in the linear order given by δ ; since every statement, different from the initial one, depends directly on *exactly one* earlier statement, it follows that dependence defines the ordering of a *tree* on the set of all statements, i.e., on $\text{im}(\delta)$ with $\delta(0)$ as its top node. I define a *chain* to be a sequence of statements in $\text{im}(\delta)$ such that each of its members, except the first one, depends directly on its predecessor in that sequence; every chain κ thus arises from a path in the dependence tree by removing the nodes above $\kappa(0)$ from the path. Every chain is a subsequence of δ and δ itself is pieced together from various chains, some of which may only have one member.

While dependence is a relation defined between arbitrary statements, a second relation will be defined only between assertions of a dialogue δ, η . An assertion Xv is an *immediate positive dependent* of an earlier assertion Xw if it is an answer to an attack upon Xw ; I define *positive dependence* to be the transitive and reflexive relation generated by immediate positive dependence.

The relation of positive dependence leads to the following classification of assertions. The initial assertion and its positive dependence shall be *of order 0* ; if $Xv \rightarrow w$ or $X\neg v$ is *of order n* then an attack Yv shall be *of order $n+1$* , and so shall be the positive dependence of this attack. It follows that the P -assertions are exactly those of even order and the Q -assertions are exactly those of odd order.

3.4 Contentions and Hypotheses

When asserting the initial statement of a dialogue, P contends it to be defensible. In this sense, the initial assertion is *contended*, and in the same manner assertions of order 0 are contended. Assertions of order 1, if they do not arise as positive dependents of earlier ones, are attacks Qw_1 upon assertions $Pw_1 \rightarrow w_2$ or $P\neg w_1$; hence they are (global) *hypotheses* offered by Q , and then also their positive dependents are (particularisations of) hypotheses. Assertions of order 2, if they do not arise as positive dependents of earlier ones, are attacks Pw_2 upon hypotheses $Qw_1 \rightarrow w_2$ or $Q\neg w_1$; here P takes up the hypotheses by admitting Pw_1 as a (higher order) contention. Consequently, also these assertions are contended by P , and so are their positive dependents. Repeating this argument, it follows that *all* P -assertions are contended and that *all* Q -assertions are hypothetical. It will be advisable to observe the distinction made between global hypotheses in a dialogue as discussed here, and local hypotheses occurring as admissions in instances of argumentation forms.

Applying the argumentation forms, assertions of logically composite formulas are dissolved into assertions of lesser complexity: contentions are *upheld* and hypotheses are *developed*. Obviously, contentions $Pw_1 \wedge w_2$, $Pw_1 \vee w_2$, $P\forall xw$, $P\exists xw$ are upheld by holding up the immediate positive dependents (as chosen by P or prescribed by Q), and the same holds for the development of the analogous hypotheses. Consider now contentions $Pw_1 \rightarrow w_2$ where we include the case $P\neg w_1$ by writing it as $Pw_1 \rightarrow \Delta$; when attacked by Qw_1 then P may either uphold the answer Pw_2 or attack Qw_1 in order to force Q into a further development of this hypothesis. Similarly, if a hypothesis $Qw_2 \rightarrow w_2$ is attacked by Pw_1 then Q may develop it into the answer Qw_2 or Q may attack the contention Pw_1 .

The process of dissolving logically composite assertions comes to an end once atomic assertions have been reached. Atomic formulas asserted by Q are hypotheses, intended by Q as describing particular situations which serve to refute P 's contention to have a defensible initial assertion; they do *not* need further justification. Atomic formulas asserted by P , however, remain contentions *in need* of justification. Securing them by material insight, such as, e.g., illumination or revelation, is unacceptable (anyway and in particular) if *purely formal* defensibility has been claimed by P . There remains, therefore, only one possibility for P to assert an atomic formula Pa for purely formal reasons:

- (c₀) P may assert Pa only if Q admits Qa as a hypothesis *relevant* to the position of Pa .

For in that case P confronts Q with its own hypothesis to which Q cannot possibly object (in [Krabbe, 1982] this principle is mentioned with the ap-

appropriate name of *ipse dixisti*). This principle (c_0) is purely descriptive in that it refers to a given, completed dialogue; it does not provide the means in order to enforce that, already during the performance of the dialogue, assertions Pa are made *only* in observance of (c_0). Making reference to the linear structure of a dialogue, we therefore strengthen (c_0) to

(c_1) P may assert Pa only *after* Q has admitted Qa at an earlier, relevant position.

It appears that we now would have to clarify the notion of *relevance*, and a first attempt to do so would consist in producing a definition which describes, for every position of a dialogue, the set of hypotheses relevant for this position. I shall not proceed in this manner; rather, I shall introduce additional restrictive rules for dialogues with the effect that the family of *all* hypotheses occurring in a dialogue becomes *coherent* in the sense that its members, being admitted simultaneously, *do not* create distinctions of relevance: each of them is relevant for all atomic contentions asserted afterwards. The additional rules will, obviously, restrict the amount of information analysed in a dialogue. But the principal objects for us are strategies, not methods for winning a single dialogue, and no information will be lost if it only remains available within the system of dialogues belonging to a strategy.

3.5 How to Win a Dialogue

P wins a dialogue if it succeeds in holding up its contentions. During the course of a dialogue, the initial contention is dissolved into more and more specialised subcontentions, and this specialisation comes to an end with the contention of atomic formulas as regulated by (c_1). It is implicit in this conception that no composite contention is accepted as being upheld without further dissolution, for Q may always challenge it with an attack. Consider now a dialogue containing an atomic contention Pa which, for the moment, we assume as being of order 0. We then find a unique sequence of contentions, beginning with the initial contention Pv and ending with Pa , each of which (except the first one) is an immediate positive dependent of its predecessor. Consequently, Pa is the final step of a process by which Pv is narrowed down to more special contentions — and in view of (c_1) this final step may be asserted for purely formal reasons. Of course, other sequences of specialisations of Pv , ending with other atomic formulas, may be possible, but since we are considering provability by strategies, these other possibilities are covered by other dialogues which a strategy will have to take into account. We thus arrive at

(WA) The initial contention is considered as having been upheld successfully if P has asserted an atomic contention of order 0.

Obviously, the same reasoning can be used to say that a contention of order n can be considered as having been upheld successfully if P has narrowed it down to an atomic contention of order n — but this observation remains without consequences.

There is, however, another way to consider the initial contention as having been upheld successfully; it rests on the principle of *ex absurdo quodlibet* applied to dialogues (and not only to argumentation forms). As a simplest situation, consider a hypothesis Qw_1 of order 1, arising as an attack upon $Pw_1 \rightarrow w_2$ of order 0, and assume that, after a sequence of positive dependents of Qw_1 , the only possibility left to Q would be the assertion of an absurdity $Q\Delta$. In that case, the hypothesis Qw_1 has been developed (and we may assume: by P 's prodding) into an absurdity and, therefore, has itself been shown as untenable. But as this hypothesis had been granted in the attack Qw_1 , we conclude by *ex absurdo quodlibet* that $Pw_1 \rightarrow w_2$ can be upheld *without* any further argument. More generally, a hypothesis Qr_1 of order $n+1$, $n > 0$, arising as an attack upon $r_1 \rightarrow r_2$ of order n , is itself a development of the earlier hypothesis $Qs_1 \rightarrow s_2$ of order $n-1$ which gave rise to an attack Ps_1 of which $Pr_1 \rightarrow r_2$ is a positive dependent. Consequently, if Qr_1 can be shown as leading to an absurdity, then also $Qs_1 \rightarrow s_2$ must be considered as leading to an absurdity. Descending from $n-1$ to 1, we conclude that already the first hypothesis Qw_1 of order 1, giving rise to the higher order hypotheses resulting in $Qs_1 \rightarrow s_2$, leads to an absurdity, and thus again $Pw_1 \rightarrow w_2$ can be upheld without further argument. We thus arrive at

(*WB*) The initial contention is considered as having been upheld successfully if (P has not asserted an atomic contention of order 0 but) Q has been brought into a position where its only possibility to continue would be the assertion of an absurdity.

Of course, at the present stage of our discussion no reason is visible why Q may become so restricted in its possibilities as is supposed in (*WB*); this will become clear after the following sections. What *can* be said already here is that if a dialogue is won by P then its last position is even (i.e., the last move is P 's), and if the initial contention does not contain a negation then the dialogue can be won only according to (*WA*).

3.6 Ramifications

I shall now discuss how to avoid the distinctions of relevance as they appear in condition (c_0). Let us begin by considering more closely the situation described there: let δ, η be a dialogue with positions j, k such that $j < k, \delta(j) = Qa, \delta(k) = Pa$ where a is atomic. Since both these assertions depend on $\delta(0)$, there exist chains κ_0, κ_1 from $\delta(0)$ to $\delta(j)$ and to $\delta(k)$, and it follows from $j < k$ that κ_1 cannot be an initial part of κ_0 . Consequently,

either κ_0 is an initial part of κ_1 or κ_0, κ_1 ramify at a position preceding $\delta(j)$. The first case is unproblematical. For let n be the last argument of κ_0 such that $\kappa_0(n) = \delta(j)$; being an atomic hypothesis, $\kappa_0(n)$ must be an attack upon $\kappa_0(n-1) = Pa \rightarrow w$ which then is answered by $\kappa_1(n+1) = Pw$, for this is the only way in which the atomic hypothesis Qa can have dependents in κ_1 . Thus Pa is Pw or a dependent of Pw , and Qa must certainly be considered as relevant for Pa . In the second case, however, the ramification may cause distinctions of relevance.

I shall say that there is a *ramification at n* for two chains κ_0, κ_1 of a dialogue if both chains coincide for all i such that $i \leq n$, if further both chains are defined (at least) for $n+1$ and if $\kappa_0(n+1)$ is different from $\kappa_1(n+1)$, i.e., if $\kappa_0(n+1), \kappa_1(n+1)$ are stated at different positions of the dialogue. A ramification then arises in one of the three following ways:

- (1) $\kappa_0(n+1), \kappa_1(n+1)$ are different attacks upon $\kappa_0(n)$;
- (2) $\kappa_0(n+1), \kappa_1(n+1)$ are different answers to the attack $\kappa_0(n)$ upon $\kappa_0(n-1)$;
- (3) $\kappa_0(n)$ is an attack Yw_1 upon $\kappa_0(n-1) = Xw_1 \rightarrow w_2$, $\kappa_i(n+1)$ is an attack upon $\kappa_0(n)$ and $\kappa_{1-i}(n+1)$ is the answer Xw_2 to $\kappa_0(n)$, $i = 0, 1$.

The attacks in (1) shall be called *distinct* if not only their positions but also the statements made by them are different; otherwise they are only *repeated attacks*. In the same way, I shall speak of *distinct* and of *repeated* answers. In this subsection I shall be concerned with ramifications of the first two types.

Distinct *attacks* are possible upon assertions $Xw_1 \wedge w_2, X\forall xw$. If P contends, say, $Pw_1 \wedge w_2$ then P certainly should be able to contend both Pw_1 and Pw_2 . But a hypothesis arising during the analysis of Pw_1 (e.g., if w_1 is $a \rightarrow a$) will *not* be relevant during the analysis of Pw_2 (e.g., if w_2 is $b \rightarrow a$) and vice versa: such hypotheses are admitted for *one* but not for the *other* subcontention. Distinct attacks upon contentions, therefore, do cause distinctions of relevance. In a strategy, however, the possibility of distinct attacks by Q is already taken into consideration in that it leads to different dialogues which all have to be won by P . Consequently, there will be no loss of information if such distinct attacks are excluded from every single dialogue. On the other hand, a hypothesis $Qw_1 \wedge w_2$ is present already *before* any ramification caused by different attacks and it should remain *before* in effect with its *complete content* also after the ramification. If, for instance, during the development of Qw_1 the moves of P lead Q to admit Qa then this hypothesis should be considered as coherent with Qw_1 as well as with $Qw_1 \wedge w_2$ and also with Qw_2 : Qa should be relevant also for any development of Qw_2 .

Distinct *answers* can be given to attacks upon assertions $Xw_1 \vee w_2, X\exists xw$. If P contends, say, $Pw_1 \vee w_2$ then it will have to contend only *one* of

Pw_1, Pw_2 . Again now, hypotheses arising during the analysis of one of these answers (e.g., if w_1 is $\neg a$) will not be relevant during the analysis of the other (e.g., if w_2 is a). Distinct answers to attacks upon contentions, therefore, do cause distinctions of relevance. However, if P has answered an attack with, say, Pw_1 then a second, later answer with Pw_2 would be useful only if Pw_1 could not be upheld successfully and if P now would try a second attempt. But in a strategy we can demand that P knows what it is doing and does not proceed by trial and error, and there will be no loss of information if we exclude distinct answers to attacks upon contentions. On the other hand, if Q were to answer an attack upon, say $Qw_1 \vee w_2$ with both Qw_1 and Qw_2 then it would grant not only the content of $Qw_1 \vee w_2$ but actually that of $Qw_1 \wedge w_2$. In a strategy, however, P has to provide dialogues for all possible answers, and there will be no loss of information if we also exclude distinct answers to attacks upon hypotheses.

In order to discuss repeated attacks and repeated answers, we may now assume that the two chains κ_0, κ_1 ramifying at n , are chosen as being maximal, i.e., as branches of the dependence tree. I now define inductively the notion of *corresponding couples*: $\kappa_0(0), \kappa_1(0)$ form a corresponding couple; if $\kappa_0(i), \kappa_1(i)$ form a corresponding couple then $\kappa_0(i+1), \kappa_1(i+1)$ shall form a corresponding couple if they either appear at the same position of the dialogue or if they are (at least) identical as signed expressions *and also* are identical in their *mode* within the dialogue, i.e., as attacks or answers referring to $\kappa_0(i), \kappa_1(i)$. Let us assume now that the ramification at n arises under repetitions. Then $\kappa_0(n+1), \kappa_1(n+1)$ still form a corresponding couple, and we may look for all corresponding couples $\kappa_0(n+i), \kappa_1(n+i)$. If these couples exhaust already one of the two chains, say κ_0 , then that part of κ_0 which starts at $n+1$ does not contain any information which is not available in the corresponding part of κ_1 . No information will be lost if that part of κ_0 (or the corresponding part of κ_1) is omitted from the dialogue, and so we may exclude the repetition at $n+1$ which gave rise to the twofold presence of that part.

It remains to consider the case that there exists a common argument m of κ_0, κ_1 , $n+1 < m$, such that $\kappa_0(m), \kappa_1(m)$ is not a corresponding couple. Let m be minimal for this property and observe that either P or Q acts at m in both of κ_0, κ_1 . If P attacks at m , say $Qw_1 \wedge w_2$ with Pw_1 in the one and with Pw_2 in the other chain, then these distinct attacks could have been carried out *without* the repetitive ramification at n (and with an acceptable ramification at the position of $Qw_1 \wedge w_2$ instead). If P answers at m , say Qv with Pw_1 and Pw_2 , then the repetitive ramification at n just hides the fact that there is actually a ramification caused by distinct answers. The same types of ramifications occur if Q in both κ_0, κ_1 attacks m or answers at m . Finally, if either P or Q attacks m in the one and answers m in the other chain then the repetitive ramification at n delays an actual ramification of type (3). Again now, *either* this ramification of type (3) could have been

carried out already at n or there are restrictions on the execution of such ramifications (as they actually will be discussed in the next section) and the repetitive ramification at n is employed in order to circumvent these restrictions.

Consequently, in *all* cases repetitive ramifications either can be avoided immediately or lead to distinctions of relevance of the sort discussed already for distinct ramifications. In any case, therefore, they may be excluded without loss of information.

The conditions effecting the exclusion of different answers and of different attacks upon contentions are precisely (D12) and (D13).

3.7 Nested Attacks and Nested Answers

There are good reasons why, in a dialogue, a certain answer upon an attack by Q is not stated immediately but only after some delay. The necessity to observe (c_1) will cause such situations if

a contention $Pw_1 \rightarrow w_2$ has been attacked and the admitted hypothesis Qw_1 needs further elaboration in order to permit P either to assert Pw_2 or to force Q into an absurdity,

or a contention, itself stated already under a hypothesis, has been attacked and now the earlier hypothesis needs further elaboration.

Delayed answers, therefore, cannot be excluded. It is such delays which cause a nesting of attacks and, thereby, a nesting of answers.

Let δ, η be a dialogue and let $\delta(m), \delta(n)$ be assertions such that $m-n \equiv 0 \pmod{2}$, let $\delta(i)$ be an attack upon $\delta(m)$ and let $\delta(j)$ be an attack upon $\delta(n)$ (whence also $i-j \equiv 0 \pmod{2}$). I shall call $\delta(j), \delta(i)$ a pair of *nested attacks* if $j < i$ and if the attack $\delta(j)$ is still open at i ; in that case $\delta(i)$ is the *inner* attack and $\delta(j)$ is the *outer* attack. I shall speak of *H-nested attacks* if the inner attack is a hypothesis; in that case, both m, n are even, $\delta(m)$ is of the form $Pw_1 \rightarrow w_2$ or $P\neg w_1$ and $\delta(i)$ is Qw_1 .

Consider a pair of *H-nested attacks* as above and let Ps be the contention which P would have to state in order to answer the outer attack. The question then arises whether the hypothesis Qw_1 can be considered as relevant for Ps and its dependents, since P contended the assertion $\delta(n)$ *before* Qw_1 has been admitted. For instance, if $\delta(n)$ is $Pr \rightarrow s$ then, by contending it, P states that it is prepared to hold up Ps under the hypothesis Qr — an additional hypothesis such as Qw_1 is, at this stage, not available. Obviously, hypotheses available at the position n may be used as well, and we also can assume that distinctions of relevance have already been excluded at least as far as the positions n, m . The complete content now of $\delta(m)$, i.e., of $Pw_1 \rightarrow w_2$ or $P\neg w_1$ is, again, that P is prepared to hold up Pw_2

(or, for that matter, even $P\Delta$) under the hypothesis Qw_1 . Therefore, the hypothesis Qw_1 should be counted as being relevant if P actually fulfils the obligation to assert PW_2 (or $P\Delta \dots$): Qw_1 together with Pw_2 preserves the complete content of $\delta(m)$. We thus arrive at the principle

- (d_0) For every pair of H -nested attacks: the hypothesis granted by the inner attack may be used as relevant in order to contend the answer to the outer attack *provided* P also contends the answer to the inner attack.

The dialogue won by P in example (9) satisfies (d_0) for the H -nested attacks with $n = 1$, $m = 4$, $j = 3$, $i = 5$; the hypothesis $Qw_1 = Qa$ is used in order to contend the answer $\delta(6)$ to $\delta(j)$ at 8, and conversely also this answer itself is employed in order to develop the hypothesis Qb which is needed when contending the answer $\delta(10)$ to $\delta(i)$.

The principle (d_0) is purely descriptive; it does not provide the means in order to enforce that only the situation described as desirable occurs. If the inner attack is upon $P\neg w_1$ then P will never be able to fulfil the obligation expressed in (d_0), and if we wish to avoid an additional label declaring Qw_1 to be irrelevant for Ps then another formulation is wanted. But also if $\delta(m)$ is $Pw_1 \rightarrow w_2$ with $w_2 \neq \Delta$, a different formulation would be useful: the example (10) shows a pair of H -nested attacks violating (d_0), but P has won the dialogue in accordance with (WA) and Q , if it is left to respect ($D12$), ($D13$), cannot continue: there just is no position left for P to state the answer to the inner attack. We thus formulate a *rule* which forces P to contend this answer *before* it makes use of the hypothesis:

- (d_1) For every pair of H -nested attacks: the inner attack must have been answered before the outer attack may be answered.

In this manner, we now have also a well-defined nesting of answers.

Consider now a pair of nested attacks upon contentions which is not H -nested; this means that the inner attack is symbolic. The statement of such an attack does not create any hypotheses possibly needed for the contention of the answer Ps to the outer attack. Still, there may be various reasons for P *not* to answer the outer attack $\delta(j)$ immediately at $j+1$, but to delay this answer to a position following that of the inner attack: actually the observance of (d_1), together with that of (c_1) may be one such reason. The example (12) communicated to me by Dr. E. C. W. Krabbe, shows a dialogue satisfying ($D10$), ($D12$), ($D13$) and (d_1), but the outer attack at 3 is answered at 8 while the inner attack at 7 remains open. Given the outer attack 3, also the hypothesis $\delta(5)$ arises as an inner attack, and observance of (d_1) forces P to state the contention $\delta(6)$ before $\delta(5)$ can be used in order to state the answer Pb to the outer attack. In avoiding the answer to the inner attack at 7, P now *fails* to uphold the contention $\delta(6)$. Thus (d_1) has

been observed, but the promise to uphold $\delta(6)$ is given lip service only. It follows from this example that, in order to observe the full meaning of (d_0) we have to strengthen the rule (d_1) to

(d_2) For every pair of nested attacks upon contentions: the inner attack must have been answered before the outer attack may be answered.

As for nested attacks upon hypotheses, it follows from the definition of a strategy that, if P has a strategy at all, then P *a fortiori* has a strategy respecting

(d'_2) For every pair of nested attacks upon hypotheses: the inner attack must have been answered before the outer attack may be answered.

There is reason to conjecture that also the converse implication holds, and a proof should be related to that of the Extension Lemma mentioned in Section 1. The idea of such a proof is illustrated by example (11): violating $(D11)$, Q may try to withhold a certain hypothesis (e.g., absurdity), but P knows from the strategy how the answer to the outer attack had to be treated if it was stated immediately after this attack.

3.8 *D-Dialogues*

It was the purpose of the last two subsections to look for restrictions on dialogues which would permit us to avoid distinctions of relevance. We thus arrived at the rules $(D12)$, $(D13)$ in subsection 3.6 and at rule $(D11)$ which is the conjunction of (d_1) and (d'_2) in subsection 3.7. Having imposed these rules, let us look once more at the family of hypotheses occurring in a dialogue. Clearly, every positive dependent of a hypothesis Qw is nothing but a specification or an instantiation of Qw ; and dependents of higher order, coming from intermediary contents, keep this character as well. Passing through a chain of dependents, we see that the hypotheses occurring there form a coherent set, i.e., a set of simultaneously admitted assumptions without distinctions of relevance. Different chains of dependents are joined together with the help of delayed attacks and answers, and the three types of ramifications which thus may arise were described at the beginning of subsection 3.6. The presence of our rules now insures that all those ramifications are excluded which would cause distinctions of relevance. What remains permitted are ramifications of type (3) with properly nested answers and ramifications of type (1) caused by different attacks upon a hypothesis. If P attacks a hypothesis Qw a first time, it forces from Q a certain system of specifications of the hypothesis Qw asserted by Q in the beginning; if P attacks Qw a second time then it may obtain a different system of specifications which, nevertheless, still is a system of specifications of this *same* hypothesis Qw : once Q has admitted Qw then it must

bear the consequences of being forced into specifications, and the specified hypotheses brought forward under the different answers given by Q to the *same* attack of P upon Qw express, when considered simultaneously, *more* than is contained in Qw alone, and thus they *do* create distinctions of relevance. It must be emphasised that this difference in the effects of attacks and answers is fundamental.

We thus find that, in the presence of $(D11)$, $(D12)$, $(D13)$, the set of *all* hypotheses occurring in a dialogue is coherent in the sense that no distinctions of relevance appear. Consequently, the condition (c_1) becomes $(D10)$, and our dialogues are D -dialogues.

At this point, a methodological observation appears to be appropriate. In the preceding two subsections I have presented arguments resulting in the introduction of additional rules with the purpose to avoid distinctions of relevance ($(D12)$, $(D13)$, (d_0)). In subsection 3.6 the exclusion of certain moves in a dialogue was supported with the observation that no information will be lost if the possibilities, excluded from single dialogues, remain present in strategies; in subsection 3.7 the introduction of (d_0) was explained with the necessity to preserve the complete content. It should be noticed very clearly that these argumentations are based on an *informal understanding of purposes*; they are *not* justifications based on mathematical theorems. As a matter of fact, as long as we abstain from a formal definition of relevance, we cannot even formulate a theorem saying that strategies for dialogues *with* precautions on relevance (?) prove the same formulas as do strategies for dialogues with $(D12)$, $(D13)$, (d_0) .

3.9 How to Win a D -dialogue

I have defined in subsection 3.5 what it means that P wins a dialogue. On the other hand, there is the purely formalist definition, taken from the literature and mentioned in Section 1, that a D -dialogue is won by P if Q has no way to continue. It remains to be shown that both notions are equivalent with respect to strategies.

If a D -dialogue has been won according to (WB) then it also has been won in the formal sense. If a D -dialogue has been won according to (WA) then it contains an atomic contention Pa of order 0 which, therefore, must be an answer. Consequently, Q cannot continue the dialogue at this position by referring to Pa . We now can show:

If for some formula v , P has a strategy to win with (WA) , (WB) all D -dialogues for v then P also has a strategy to win in the formal sense all D -dialogues for v . For consider a strategy the branches of which are won with (WA) , (WB) . These branches could not be continued by Q if Q would have to respect the rules for E -dialogues. We thus obtain an E -strategy if, where necessary, we cut off ends of branches when Q begins to violate the

rule (*E*). It then follows from the Extension Lemma that this *E*-strategy may be extended again to a *D*-strategy.

For the converse implication, it can even be shown that a *D*-dialogue δ, η which is won in the formal sense is won also according to (*WA*), (*WB*). As this is clear if, during the dialogue, *P* has stated an atomic contention of order 0, we may assume now that *P* has *not* stated an atomic contention of order 0; (*WB*) then will hold if we can prove that *Q* could continue if it were to state an absurdity: there still should exist a (last) open attack of the form $P\neg w$. Before continuing the proof, it will be useful to prepare some auxiliary notions.

Let δ, η be a dialogue; let n be an odd position and assume that *Q* has already stated $\delta(n)$. Then $\xi_0(n)$ shall be the number of contentions which, after this statement, still may be attacked by *Q* at later positions, and $\xi_1(n)$ shall be the number of contentions which, being attacks, still may be answered by *Q* at later positions — and here I expressly *include* the unspeakable answers $Q\Delta$ to attacks Pw upon some $Q\neg w$. The number $\xi(n) = \xi_0(n) + \xi_1(n)$ is called the *degree* (of freedom) of n . The following characterisation will be useful:

$\xi(n)$ is the difference $a(n) - d(n)$ where $a(n)$ is the number of attacks upon hypotheses $Qw_1 \rightarrow w_2$, w_1 not atomic, which are contended before n , and $d(n)$ is the number of atomic *P*-answers contended before n . This follows from the following observations in which $2i+1$ is a position of δ, η . If $\delta(2i)$ is an attack then $\xi(2i-1) \leq \xi(2i+1) \leq \xi(wi-1) + 1$, and the right inequality becomes equality if, and only if, $\delta(2i)$ is an attack upon a hypothesis $Qw_1 \rightarrow w_2$ such that w_1 is not atomic (whereas w_2 may be Δ). If $\delta(2i)$ is an answer which is not atomic then $\xi(2i-1) = \xi(2i+1)$. If $\delta(2i)$ is an answer which is atomic then $\xi(2i-1)$ must be positive (for otherwise *Q* could not act at $2(i+1)$), and $\xi(2i+1) = \xi(2i-1) - 1$.

Consider now a *D*-dialogue. It follows from (*D12*) (*D13*) that every assertion has *at most one* atomic immediate positive dependent; consequently, every assertion has *at most one* atomic positive dependent. Let now Pa be an atomic contention of *positive* order; there then exists a first (highest) contention Pw_a of which Pa is a positive dependent, and Pa, Pw_a have the same order. By the preceding remark, Pw_a is unique, and as it has no positive predecessor, it must be an attack upon a hypothesis $Qw_a \rightarrow u_a$ (where u_a may be Δ).

I now resume the proof where it was interrupted. Let $2i$ be the last position of the dialogue. Then $\delta(2i)$ cannot be a composite formula (since that could be attacked by *Q*) nor can it be a symbolic attack (since that could be answered); thus it must be an atomic contention Pa , necessarily of positive order. Let Pw_a be the unique, highest contention determined by Pa as above. If Pw_a is Pa then u_a must be Δ (for otherwise *Q* could answer), and thus (*WB*) holds. Assume now that Pw_a is different from Pa ; then w_a is not atomic. It now will be sufficient to show that $\xi(wi-1)$ is positive

— because the possibilities numbered by $\xi(i-1)$ cannot comprise attacks or answers which actually could be stated (for in that case Q could still continue), and thus there must be at least one open attack to be answered only by absurdity. I thus have to prove that the difference $a(2i-1)-d(2i-1)$ is positive. Let Pb be an atomic answer which contributes to $d-(2i-1)$; it is of positive order and thus determines the unique attack Pw_b . Since Pb is an answer and Pw_b is an attack, Pb must be a proper dependent of Pw_b . Thus w_b is not atomic and, therefore, the attack Pw_b contributes to $a(2i-1)$. It follows that the map φ sending b into w_b is an injection of the set of contentions contributing to $d(2i-1)$ into the set of contentions contributing to $a(2i-1)$. Since w_a is not atomic, the latter set contains Pw_a ; the former set, however, does not contain Pa . Consequently, $a(w_i-1)$ is strictly larger than $d(2i-1)$.

3.10 Intuitionistic versus Classical Logic

As was mentioned in Section 2, Lorenz [1961] has observed that a change in the rules for D -dialogues produces a class of dialogues which I shall call C -dialogues, such that the formulas provable by C -strategies are precisely the classical provable formulas. The change leading from D -dialogues to C -dialogues consists in

cancelling (D11) and (D12) for P , but leaving them in effect for Q .

(If I understand Lorenz's and Lorenzen's writings correctly then they seem to demand the cancellation for P of (D12) only; the examples (2b) and (5a) show that this would not suffice.) It is not hard to see that C -strategies prove *only* classically provable formulas. For the case of *propositional* logic, the converse implication (i.e., every classically provable formula can be proved by a C -strategy) can be seen as follows. Observe first that an intuitionistically provable formula, being provable by a D -strategy, is trivially provable by a C -strategy. It is well known that if w is a classically provable formula then $\neg\neg w$ is intuitionistically provable; assume now that w is not intuitionistically provable. Every D -dialogue δ, η for $\neg\neg w$, won by P , begins with attacks $\delta(1) = Q\neg w, \delta(2) = Pw$, and since we assume that the part beginning at position 2 is *not* a D -dialogue for w won by P , there must be positions below 2 at which P attacks $\delta(1)$ again. If we compare the branches in the dependence tree and look for the first positions at which they differ, we will find, refining the discussion in subsection 3.6, that this happens at contentions which could be obtained *without* the repetitive first part of the branch if repeated answers or answers in disregard of (D11) were permitted to P . Permitting such answers in C -dialogues, it can be shown that a D -strategy for $\neg\neg w$ can be rebuilt into a C -strategy for w .

The mathematical fact that C -strategies can be used for classical logic is, in principle, not surprising; other proof-theoretical systems, e.g., those of Hilbert-type, can also be used for many varieties of logics. Rather than leading to amazement over the universal applicability of a mathematical tool (trees and strategies), this situation should teach us to emphasise the fundamental differences between intuitionistic and classical logic.

For the provability interpretation, as represented by Gentzen's calculi, Curry [1963, p. 260] has attempted a provability *explanation* of classical negation with help of his concept of *complete absurdity*, but this hardly will be considered to be a conceptual *foundation*. For the argumentative approach presented here, classical logic *cannot* be given a foundation by simply changing formal details of a foundation for intuitionistic logic. If we want to explain the rules governing classical negation then there appears to be no way to avoid the semantical notions of *true* and *false*: without these notions we cannot explain why distinctions of relevance may be discarded as it is done when P is permitted to repeat answers and to disregard ($D11$). Thus, for classical logic, the entire conceptual frame employed for the foundation of intuitionistic strategies, has to be abandoned: there is no use for contentions and hypotheses, for defendability by purely formal reasons and for considerations of relevance. What *is* required, is a completely different conceptual framework, based on the notions of true and false and on the distribution of truth-values under logical operations. The foundation of classical logic within such a framework is well known, and the elegant formulation of classical tableaux due to Smullyan [1968] may easily be read as to depict a dialogue-strategy leading to a failure of the attempt to falsify a formula. Again, the argumentative explanation of winning a dialogue according to (A) , (WB) is only formally related to the closure of branches in Smullyan's tableaux which *always* means the advent of absurdity.

4 APPENDIX: CONCEPTS CONNECTED WITH THE EQUIVALENCE THEOREM

The equivalence theorem, formulated in Section 1, states the existence of certain transformations between strategies and proofs in the calculus LJ; the proof of this theorem cannot be presented here. It may, however, be instructive for the reader to become familiar with some concepts which originally were developed for this proof. For details which have to be suppressed here I refer to Felscher [1981; 1985].

The reader will have noticed that among the examples, listed at the end of Section 1, there is none which treats a formula with quantifiers. But this is no serious omission since the argumentation forms for quantifiers are, so to speak, the direct generalisations of the forms for conjunction and disjunction to the infinite case. For strategies, however, this treatment of quantifiers has

the effect that there may occur infinite ramifications: if S, δ, η is a strategy and if a node e carries as $\delta(e)$ either a formula $P\forall xw$ or an attack $P\exists$ upon a formula $Q\exists xw$ then the tree S has an infinite ramification at e — every term t determines a lower neighbour of e , carrying either an attack Qt or an answer $Qw(t)$. Although the branches of S must be finite (as follows from (S0)), the strategy itself is an infinite object. It is obvious that this is a clear disadvantage of strategies as compared to the more usual notions of proof. I now shall abstract a *finite* object from a strategy, its skeleton.

Let H be a class of dialogues as in Section 1. An H -skeleton for a formula v is a triplet S, δ, η with the same properties as an H -strategy for v *except* that in (S1) certain nodes e are excepted and, instead, are covered by

- (S1_e) If $\delta(e)$ is $P\forall xw$ then only one lower neighbour of e carries an attack upon $\delta(e)$, and this attack is Qy where y is a variable not occurring free in any *expression* $\delta(h)$ with $h \geq e$. If $\delta(e)$ is an attack $P\exists$ upon $Q\exists xw$ then only one lower neighbour of e carries an answer, and this answer is $Qw(y)$ where y is a variable not occurring free in any *expression* $\delta(h)$ with $h \geq e$.

As is usual, the variable y will be called the *eigenvariable* in these situations. It is clear that every H -strategy contains various H -skeletons, and it is not hard to see that, conversely, every H -skeleton can be extended to an H -strategy. This observation has the important consequence that it suffices to consider H -skeletons which, having finite trees, are more easily handled in induction proofs. For instance, the Extension Lemma of Section 1 is proved in the form that every E -skeleton can be extended to a D -skeleton.

Unfortunately, E -skeletons still have certain undesirable properties. Consider the example of a formula $\exists xa \rightarrow \exists xa$ where a is atomic; there are two E -strategies, viz.

0. $P\exists xa \rightarrow \exists xa$		0. $P\exists xa \rightarrow \exists xa$	
1. $Q\exists xa$	[0, Q]	1. $Q\exists xa$	[0, A]
2. $P\exists$	[1, A]	2. $P\exists xa$	[1, D]
3. $Qa(y)$	[2, D]	3. $Q\exists$	[2, A]
4. $P\exists xa$	[1, D]	4. $P\exists$	[1, A]
5. $Q\exists$	[4, A]	5. $Qa(y)$	[4, D]
6. $Pa(y)$	[5, D]	6. $Pa(y)$	[3, D]

In the right skeleton, the attack at 3 is answered with the substitution term y at 6; this answer must be delayed because the choice of the substitution term depends on the eigenvariable y appearing at 5. There are no phenomena of an analogous type in, say, the sequent calculus; in Lorenzen and Schwemmer [1973] and in Haas [1980], where an informal use of E -skeletons is made, the possibility that this situation might occur has been overlooked.

In order to circumvene this difficulty, I introduce the concepts of a *formal dialogue* and of a *formal strategy*, making use of the *formal argumentation forms* for \forall and \exists :

$Q\forall$:	assertion: $Q\forall xw$	$P\forall$:	assertion: $P\forall xw$
	attack: Pt		attack: Qy (<i>eigenvariable</i>)
	answer: $Qw(t)$		answer: $Pw(y)$
$Q\exists$:	assertion: $Q\exists xw$	$P\exists$:	assertion: $P\exists xw$
	attack: $P\exists$		attack: Qt
	answer: $Qw(y)$ (<i>eigenvariable</i>)		answer: $Pw(t)$.

I define a *formal E-dialogue* in exactly the same way in which I defined an *E-dialogue*, only now in (D01), (D02) the formal argumentation forms are used for quantifiers *and* the eigenvariable condition is imposed at the position indicated. The adjective *formal* then refers to the fact that, contrary to the intuitive understanding, in the attack Qt the term t is stated already by Q ; eigenvariables chosen at a later position then *must* respect these expressions Qt . I define a *formal E-strategy* in the same way in which I defined an *E-strategy*, but now with formal dialogues instead *and* with the following changes: there is *only one* possibility for Q taken into account for

answering an attack $P\exists$ (case $Q\exists$),
 making an attack Qy (case $P\forall$),
 making an attack Qt (case $P\exists$).

It then is obvious that every formal *E-strategy* can be transformed into an *E-skeleton*; it can be shown that, conversely, every *E-skeleton* can be transformed into a formal *E-strategy*.

It is the formal *E-strategies* which can be set into correspondence with LJ-proofs.

It follows from these observations that the disadvantage of dialogues consisting in

1. the treatment of quantifiers as infinite conjunctions and disjunctions disregarding Frege's discovery of finitary quantifier rules made possible by the use of free variables, and
2. the ensuing appearance of infinite strategies

is only apparent. It arose because we wanted to use the *same* argumentation forms (concerning quantifiers) for *both* P and Q ; it could have been avoided if, from the outset, we would have studied strategies instead of dialogues. This illustrates once more the difficulty, mentioned at the beginning of Section 3.2, that it is not the dialogues but the strategies which correspond to proofs: working with dialogues, we have to describe *in advance* the branches

of strategies which themselves are to be defined only with the help of these dialogues.

It also should be observed that, in contrast to Gentzen's calculi for provability, strategies and dialogues do *not* appear as natural representations of the relation of *provability from hypotheses* but only as those of the relation of *absolute provability*. Of course, if M is a finite set of sentences and m is a conjunction of these sentences then, for every sentence w , the sequents

$$M \Rightarrow w \quad \text{and} \quad \Rightarrow m \rightarrow w$$

are simultaneously derivable in LJ, and this permits us to reduce the provability of w from the hypotheses M to the absolute provability of $m \rightarrow w$. It also is obvious that a dialogue, discussing the derivability of $M \Rightarrow w$, should begin with an initial list of the Q -formulas determined by M , followed (or preceded) by the P -formula Pw . But no general rule on how to proceed from this initial list can be stated as long as we want to keep the alternation between P and Q during the progress of our dialogue. If a is atomic, a sequent such as $a \Rightarrow a \vee w$ produces the initial list $Qa, Pa \vee w$ which *must* be followed by an attack of Q ; on the other hand, a sequent such as $a \wedge w \Rightarrow a$ produces the initial list $Qa \wedge w, Pa$ which *must* be followed by an attack of P . Certainly, regulations circumventing these difficulties may be formulated, but apparently only at the cost of a loss in intuitive appeal.

EDITOR'S NOTE

The dialogue system of this chapter has recently been implemented as a theorem prover **DIALOG** [1] and **COLOSSEUM** [2]. **DIALOG**, written in Lisp, offers a rule language for redefining the rules of the game. It also supports automatic and interactive proving and has a user-friendly interface. Efficiency, however, has not been the major concern, and therefore, **DIALOG** may serve more as a tool for teaching or for experimenting with the dialogue rules.

COLOSSEUM is a no-frills re-implementation of Dialogue Games in Prolog. Its dialogue rules are hardwired for intuitionistic first order predicate logic (as specified by Felscher above). **COLOSSEUM** allows automatic proving only, but it is much faster than **DIALOG** and is web accessible.¹

FREE LOGICS

I: Introduction

1 WHAT ARE FREE LOGICS?

Some theorems of **CQC=**, such as those of the form

$$(1) \quad \exists x(x = \tau)$$

and

$$(2) \quad \varphi[\tau/x] \rightarrow \exists x\varphi,$$

are often accused of introducing into that theory—and thus into the very core of ‘our logic’—undesired ‘existential commitments’. However, the mere derivability of these sequences of symbols can hardly accomplish such a major feat by itself, and even when the theory is supplied with the usual ‘referential’ semantics, metaphysics is still far from being determined one way or another. 1 and 2 certainly require—by way of this semantics—that every singular term of the language receive an interpretation in the domain of quantification, but so what? The formal instrument does not specify the metaphysical counterpart of the relation between a symbol and its interpretation, nor does it tell you which things can or cannot belong to a domain of quantification. The formal instrument is neutral with respect to all these questions, and thus *by itself* cannot introduce any metaphysical commitments, existential or otherwise.

Things get more complicated when one takes into account the ideology most commonly associated with **CQC=** and its referential semantics. Then it becomes very ‘natural’ to think of a singular term as *denoting* its interpretation, hence to read the semantical requirement evoked by 1 and 2 as the requirement that every singular term denote. Even more importantly, if one agrees with Quine that ‘to be is to be a value of a bound variable’¹—that is, if one assigns ‘existential import’ to quantifiers—the domain of quantification becomes the set of all and only those objects which exist in a given (possible) situation, and the above requirement is drastically strengthened, to the demand that every singular term denote *an existing object*. Now the ontological commitments are certainly apparent, and someone is bound to react to them in the name of logic’s ‘purity’.

¹See for example [Quine, 1939]. In what follows, we will sometimes refer to this statement as *Quine’s dictum*.

Free logics² result from this reaction. However, since what they are a reaction to is a very delicate combination of many factors—a certain philosophical understanding of a certain formal interpretation of a certain formal system—it is difficult to say exactly what they are and how far they extend. To say—as is often said—that they are ‘logics free of existence assumptions with respect to their singular terms’ is too vague to be of much help, and also somewhat inaccurate from a historical point of view. For *every* formal system and *every* formal semantics can be free in this sense, given a suitable ideology, but this much tolerance was certainly not in the minds of the people who created free logics.³ They wanted to *reform* classical logic, and *substitute* for it a *better* instrument, they thought that both the usual formal systems and the usual formal semantics were faulty in important ways, and it is only fair to define free logics so as to make sense of the precise task that they set for themselves.

On the other hand, it would not do to identify free logics with a certain class of theorems. For one thing, there is no *one* such class (as the expression ‘free logics’ should make clear),⁴ and there is even some debate as to whether free logics result from restricting or rather extending classical logic.⁵ But more importantly, we suggested above that all these modifications—whether restrictions or extensions—would make no sense (and in particular would not be legitimately referred to as free logics) if not in the context of certain interpretations of the formal systems, and of a certain understanding of these interpretations.

And finally, it would be totally unsatisfactory to define free logics in terms of a given semantics, or even a given *class* of semantics. For not only is a formal semantics (as well as a formal system) not enough to characterise the present enterprise in the absence of some ‘intuitive reading’ of it, but also the choice of a semantics is probably the most important question in this area, and we have to be careful not to prejudge such a fundamental issue by a biased *definition*.

Keeping all these reservations in mind will inevitably result in a less than straightforward characterisation of our subject, but the complications we will have to go through will prove instructive. For in this subject more than in others, logic, philosophy of logic and philosophy in general (especially metaphysics) are intertwined in a very delicate way, and it does not hurt if this delicate relation is emphasised right from the beginning.

In conclusion, I propose the following definition. A free logic is a formal system of quantification theory, with or without identity, which allows for some singular terms in some circumstances to be thought of as denoting no

²This expression was first used by Karel Lambert in 1960.

³See for example [Leonard, 1956] and [Lambert, 1967].

⁴Thus ‘free logics’ is the correct expression to refer to the whole subject, but ‘free logic’ is also very common.

⁵In this regard, see van Fraassen’s position sketched in Section 11.

existing object, and in which quantifiers are invariably thought of as having existential import.

A few comments and clarifications are in order. First of all, a terminological matter. The expression ‘thought of’, which occurs twice in the definition, must be regarded as inclusive of both the formal interpretation of the system and the intuitive (or philosophical) reading of this interpretation. When the formal semantics is missing (as was the case in free logics for several years), this ‘thinking of’ reduces entirely to its intuitive component.

Secondly, the definition requires that there be in the language of a free logic expressions construed as singular terms. A language containing no individual constants or descriptions and allowing individual variables to occur only bound in well-formed formulas (and there are languages of this sort for **CQC**, for example some of Quine’s) would hardly satisfy the present requirement.

Thirdly, the definition does not exclude the possibility that every singular term denotes in every circumstance, only that every singular term denotes *an existing object* in every circumstance. There are philosophers (Meinongians for example) who think that there are non-existing objects, and that singular terms may well denote them: the definition is neutral with respect to such views. However, to avoid awkwardness, usually I will refer to singular terms not denoting an existent simply as *non-denoting*.

Fourthly, the definition is concerned not with whether there *actually* are non-denoting singular terms, but only with whether there *may be*. A free logic is after all a *logic*; hence all that it can reasonably care for is logical possibility. When a logic acknowledges the possibility of non-denoting singular terms, we will say that it *allows for* non-denoting singular terms.

Fifthly, not every logic allowing for non-denoting singular terms is a free logic by our definition. In particular, all attempts at saving the formal system (and the formal semantics) of classical logic by some substitutional or Meinongian reading of the quantifiers are ruled out. On the other hand, it is perfectly possible to *add* to a free logic substitutional or Meinongian quantifiers, thus extending its expressive power.

Finally, even though referential semantics played a major role in the discussion above, the definition does not mention this semantics. The reason is that the existential import of quantifiers, and even the distinction between denoting and non-denoting singular terms, can be effectively mimicked in some non-referential semantics (for example, in Leblanc’s truth-value semantics),⁶ even if the best way to understand what is going on in these semantics is still to compare them with their referential analogues. Thus the three factors to whose combination a free logic is a reaction come to play different roles in its definition: a free logic is the result of a modification of

⁶On this and other alternatives to the standard referential approach, see the chapter by Leblanc in Volume 2 of the present 2nd edition of this *Handbook*.

the *formal system* of **CQC** (or **CQC=**), motivated by a certain *intuitive reading* of it, which is best understood (at least so far) in the context of the usual referential *interpretation* of that system.

2 WHY FREE LOGICS?

The most general answer to this question has already been suggested in the discussion preceding my definition of a free logic. Though vigorously attacked from some quarters, the neopositivistic suspicion towards metaphysics is still highly influential in contemporary logic. Whether they regard metaphysics as sheer ‘nonsense’ or as a set of ‘synthetic’ statements to be neatly distinguished from the ‘analytic’ ones constituting their discipline, many logicians like logic to be metaphysically ‘pure’, or not to carry any metaphysical ‘baggage’—as the many debates in the area of quantified modal logic show sometimes quite dramatically. To apply such a general motivation to the present case, it is enough to regard even the simplest existential statements as metaphysical in nature.

However, this motivation by itself does not go very far towards motivating anything close to free logics. As we will see in the next section, classical logic has its own ways of dealing with these matters, and certainly many classical logicians would not accept without a fight the claim—presupposed by the alleged ‘justification’ of free logics suggested above—that classical logic is in any sense existentially committed or metaphysically ‘impure’. To get closer to the justification we are looking for, we need to weaken that claim as follows. Classical logic (if filtered through the usual interpretation, and the usual reading of this interpretation) does not allow for non-denoting singular terms. To be sure, this logic can be *used* in such a way as to avoid any philosophical commitments or any problems resulting from the limitation in question, but this requires the adoption of convoluted and *ad hoc* procedures of translation from natural language into the formal language and back (in a word, of a number of epicycles). Free logics, on the other hand, represent a much more straightforward and direct approach to the same problems: they make the translations easier, they allow expressions of natural language to be taken more often at face value, and they require fewer *ad hoc* assumptions.

This justification is certainly better than the first one, but still, it does not entirely fulfil its purpose. For it does not take into account the fact that the classical logician can shape his philosophy of language so as to make it fit his logic perfectly (and make his logic the most ‘natural’ thing in the world): Russell’s position—to be mentioned briefly in the next section—is in this respect typical. And this makes it clear once and for all that the adoption of some specific view in the philosophy of language is an essential step towards the justification of free (and perhaps all) logics.

There is a whole spectrum of such views that would do the job nicely, ranging from an extremely ‘metaphysical’ one to an extremely ‘pragmatic’ one. For the sake of illustration, let me briefly discuss these two extremes.

The ‘metaphysical’ extreme states simply that in natural language *there are* non-denoting singular terms. A singular term is an expression that *purports to* denote a single object, and many a singular term fails to achieve this purpose. Nonetheless, they are still singular terms: ‘Pegasus’ is as much a singular term as ‘Caesar’ or ‘3’, and ‘the winged horse’ or ‘the round square’ are as much singular terms as ‘the President of the USA in 2000’. Hence no formal system can give a faithful representation of the structure of natural language (and so be reasonably applied to it) if it does not allow for non-denoting singular terms.

The ‘pragmatic’ extreme, on the other hand, regards the *real existence* of non-denoting singular terms in natural language as totally irrelevant. Whether there are or there aren’t any, there are contexts in which some people use expressions *as* singular terms without assuming that they denote anything, or maybe even in the process of wondering whether they denote or not. For example, an attempt by a person to prove that God exists—or that ‘God’ denotes—might be conceived as a case in point. Whether these people are right or not, a logic allowing for non-denoting singular terms would also allow for a more direct and faithful representation (and evaluation) of their reasoning in those contexts. So this logic would be an instrument of wider and simpler applicability than classical logic, and would not prejudge important issues which it is inappropriate for logic to decide.

Of course, the classical logician can be expected to have responses to these motivations. It is certainly not news that in philosophy, or anywhere else, you can’t get something valuable for nothing. In the present case, this suggests that you need a position in between the two above extremes to transform the fear of metaphysical commitment so well entrenched in most contemporary logicians into a defence of free logics.

3 CLASSICAL LOGIC AND NON-DENOTING SINGULAR TERMS

As suggested earlier, the classical logician is not *forced* to modify his formal instrument by the mere presence in natural language of expressions like ‘Pegasus’ or ‘the round square’. He has at his disposal several techniques for dealing with alleged non-denoting singular terms within his own framework. Since all these techniques are treated extensively in other parts of the *Handbook*,⁷ I will limit myself here to little more than listing them.

In the first section, I pointed out that the problem free logicians see in classical logic (and try to solve with their logics) is the following: classical

⁷In particular, in Hodges’ chapter in Volume 1 and Salmon’s chapter “Reference and Information Contents: Names and Descriptions” in a later volume.

logic makes it impossible to combine the presence of non-denoting singular terms with an ‘existential’ reading of quantifiers. A classical logician willing to avoid this problem, then, has two main options available: he can deny existential import to quantifiers, or exclude the possibility of non-denoting singular terms.

If he wants to go the first way, he will find two basic suggestions in the literature. One is to drop the referential scheme of interpretation altogether, and go back to the old substitutional scheme, quite popular in the days before Tarski’s systematisation of formal semantics. The other is to remain within the referential framework, but admitting non-existing objects (as well as existing ones) in the range of quantifiers.⁸

If he wants to go the second way, he will again have a choice between two alternatives: Russell’s theory of descriptions and Frege–Carnap’s chosen object theory. Within the first alternative, he will rule out non-denoting singular terms by simply denying the status of singular terms to all those expressions of natural language (that is, definite descriptions and ‘grammatically proper names’) that can ever be non-denoting, and retaining it only for those other expressions (that is, demonstratives) that look absolutely ‘secure’ from a denotational point of view. Within the second alternative, his strategy will be more subtle. For Frege never really denied (as Russell did—at least as far as logical form was concerned) that *there are* in natural language non-denoting singular terms, but claimed that their presence constitutes a *defect*, to be repaired in a ‘logically perfect’ language (see [Frege, 1892]). Thus, whereas Russell’s proposal extends very naturally to a complex philosophical position, which includes (at least) metaphysical and epistemological themes, Frege’s qualifies as an intrinsically pragmatic one, in whose favour nothing can be said better than Carnap’s words in [Carnap, 1947]: ‘there is no theoretical issue of right or wrong between the various conceptions, but only the practical question of the comparative convenience of different methods’ (p. 33).

4 INCLUSIVE LOGICS

Chronologically, some of the first instances of a revisionary attitude about the existential ‘commitments’ of classical logic can be found in what Quine called *inclusive* logics, that is, logics allowing the domain of quantification to be empty. To dispel what seems to be a quite common misunderstanding, it needs to be pointed out once and for all that inclusive logics and free logics *are two different subjects*. A logic can be free without being inclusive, and can be inclusive without being free. However, it is also convenient to treat

⁸The first suggestion is usually associated with Leśniewski, the second one with Meinong. For more recent formulations, see in the first case Lejewski [1954; 1958] and [Luschei, 1962], in the second Parsons [1980] and Routley [1980].

the two subjects together. For, on the one hand, the problems they face are strictly connected, and on the other, as for example [Belnap, 1960] has pointed out, it is quite natural to require inclusiveness of a free logic and *vice versa*.

The first inclusive logic was developed (twenty-five years before the first free logics) by [Jaskowski, 1934]. Jaskowski's is a natural deduction system, which, in contrast with most other such systems, allows for two different kinds of assumptions (or 'suppositions'). One can assume formulas (which one indicates by prefixing the formula with the metalinguistic symbol S), and one can assume singular terms (which one indicates by prefixing the term with the metalinguistic symbol T). The way the assumption of terms works is made clear by the quantificational rules of the system, which are given below.

1. *Supposition of a term*: at any point in a deduction it is possible to introduce an assumption of the form $T\tau$, where τ is a new term.
2. *Universal Instantiation*: $\varphi[\tau/x]$ follows from $\forall x\varphi$ and $T\tau$.
3. *Universal Generalisation*: if φ follows from $T\tau$ then it is possible to deduce $\forall\tau\varphi$, and this conclusion does not depend on the assumption $T\tau$ (which is thus 'discharged').⁹

To explain how these rules allow the domain to be empty (by disallowing proofs of formulas which would exclude this possibility), it is best to use an example. Consider then

$$(3) \quad \forall x\varphi \rightarrow \exists x\varphi,$$

a typical instance of an 'exclusive' formula and a theorem of classical logic, and try to prove it in Jaskowski's system. A reasonable way to go about this is to assume the antecedent of 3 and the negation of its consequent, that is, to start out with

$$(4) \quad S\forall x\varphi$$

$$(5) \quad S\forall x\neg\varphi.$$

However, given the particular form of (2) above, nothing follows from 4 or 5 without also supposing a singular term. Let us do so, and continue with

$$(6) \quad T\tau.$$

Now from 4 and 6 we get

⁹The fact that the Universal Generalisation can be given in this form depends on specific features of Jaskowski's system: in particular, on the fact that his only terms are variables.

$$(7) \quad \varphi[\tau/x]$$

and from 5 and 6 we get

$$(8) \quad \neg\varphi[\tau/x]$$

which of course contradict each other. So the assumptions are not consistent, but the key point here is that there are not two but *three* assumptions, and in particular 4 and 5 can still be perfectly consistent if nothing like 6 is accepted (which is exactly what one would find most natural in the case of the empty domain).¹⁰ Thus the attempted proof of 3 is blocked.

Jaskowski considers this quantificational system very briefly, almost as an appendix to a paper mostly devoted to propositional logic. Possibly for this reason, the system has a number of unnecessary limitations, and the consequences of removing them are not explored. If they had been explored, the system might have turned out to be the first *free* logic as well as the first inclusive logic. To understand what I mean, consider that in the system in question (i) open formulas are not provable, (ii) there are no individual constants, and (iii) the metalinguistic symbol T has no object-language counterpart. If (iii) and either (i) or (ii) were dropped (and, say, T^* were the object-language counterpart of T), rules (1)–(3) of p. 153 would immediately yield (in conjunction with the propositional rules) theorems like

$$(9) \quad (\forall x\varphi \wedge T^*\tau) \rightarrow \varphi[\tau/x]$$

$$(10) \quad \forall xT^*x,$$

while at the same time blocking the proof of formulas like

$$(11) \quad \forall x\varphi \rightarrow \varphi[\tau/x],$$

and as we will see these are the key features of most free logics.¹¹

When something like the above happens, and the solution of a problem can be found almost automatically by solving *another* problem, one naturally is led to suspect that there exists something more than a *coincidence*, that there is indeed a real *connection* between the two problems. In retrospect, it is not difficult to see what the connection is. Free logics are logics allowing for non-denoting singular terms, and of course if the domain is empty then *all* singular terms are non-denoting; hence if an inclusive logic

¹⁰For in this domain there are no objects, hence nothing to talk about by using singular terms.

¹¹This of course when T^* is read as a substitute of the more common $E!$. Furthermore, notice that removal of (iii) is not critical to generate a free logic: if (iii) is not dropped (but either (i) or (ii) is) what we obtain is a 'pure' free logic, that is, a free logic without existence or identity. Indeed, making the existence symbol metalinguistic is one way of constructing a natural deduction or Gentzen formulation of such a pure free logic.

allows for any singular terms at all, it must allow for non-denoting singular terms, and thus be free as well. In light of this consideration, it is easy to see that the only way Jaskowski's logic (or any inclusive logic for that matter) could avoid being free was by refusing to admit any singular terms (which is the philosophical meaning of limitations (i) and (ii) above). And one might expect that, simply by developing their instrument a little further, inclusive logicians would have finally 'reached' free logics in a very natural way. However, this is not what happened, and the reason is interesting.

As we will argue later at great length, the fundamental problem to be solved in the development of free logics is a semantical one: the problem of assigning reasonable truth-conditions to sentences containing non-denoting singular terms. Inclusive logicians went very close to hitting this problem when they considered dropping some of Jaskowski's limitations. Thus Mostowski [1951], when constructing an inclusive logic contravening (i) above, had to decide what to do with open formulas in the empty domain. In a language without individual constants (as his was), free variables are the only possible place-holders for singular terms, hence Mostowski's problem was at least in part a special case of the fundamental problem of free logics. But there was at the time no awareness of this, so he simply treated free variables in analogy with (universally) bound ones, and he made all open formulas true in the empty domain.

The system resulting from this choice had a surprising anomaly: *modus ponens* was not truth- or validity-preserving in it, as the following example illustrates.

$$(12) \quad \frac{\varphi(x) \quad \varphi(x) \rightarrow \exists y\varphi(y)}{\exists y\varphi(y)}$$

The presence of this anomaly could have worked as a stimulus towards more satisfactory solutions, if the general problem lingering in the background had been perceived. Since it was not, subsequent authors such as Hailperin [1953] and Quine [1954] regarded the anomaly as a mere nuisance, and preferred to avoid the question entirely by returning to Jaskowski's practice of excluding open theorems, thus contributing in a decisive way to sealing off what could otherwise have been a promising line of enquiry.

II: Proof-Theory

5 AXIOMATIC SYSTEMS

We saw in the last section how inclusive logicians avoided the crucial (semantical) problem of free logics. It might be surprising to find out that

even most free logicians basically side-stepped this problem for ten years (at least in their published works), by limiting themselves to a purely proof-theoretical development of their logics. As a result, the history of free logics can be neatly divided into two (partly overlapping) periods: the first one mostly devoted to proof-theory and the second one mostly devoted to semantics. It is natural, then, in accounting for the subject, to follow the same pattern, and here we will do just that. In the present part we will discuss the formal *systems* of free logic, as elaborated largely between 1956 and 1967,¹² and in the next one the *interpretations* of these systems, whose development took off only beginning in 1966. Within each part, however, we will make no attempt at preserving any chronological order, but will be guided entirely by considerations of systematicity.

Every axiomatic formulation of **CQC** contains as a primitive assumption either the so-called *Law of Specification*

$$(13) \quad \forall x\varphi \rightarrow \varphi[\tau/x]$$

or some other principle or rule deductively equivalent to it. (For definiteness, we will refer from now on to a system containing 13 as a primitive assumption.)¹³ Furthermore, all the theorems of **CQC** = that free logicians find questionable (including 1 and 2) are proved by making a substantial use of 13. It is natural to conclude, then, that the first step in the construction of an axiom system for free logic is going to be dropping 13.

When this is done, the remaining axioms permit the proof of the following weakened form of 13 (that we might call Restricted (Law of) Specification):

$$(14) \quad (\forall x\varphi \wedge \exists x(x = \tau)) \rightarrow \varphi[\tau/x]$$

Far from representing a problem for the free logician, however, this result is most welcome to him; for Restricted Specification (in contrast with Specification proper) is a law that makes perfectly good sense even in the presence of non-denoting singular terms (and existentially loaded quantifiers).

To understand why this is so, consider that the supplementary condition required in 14 to instantiate the universal quantification $\forall x\varphi$ with respect to the singular term τ can be legitimately read as stating that τ denotes a value of a bound variable, or more simply (*via* Quine's *dictum*) that τ is denoting. Thus on the one hand 14 says nothing (and in particular nothing

¹²For these systems, see Leonard [1956]; Leblanc and Hailperin [1959]; Hintikka [1959a] and Lambert [1963; 1967].

¹³Also, we will refer to a language without function symbols and with \forall as the only primitive quantifier. As a consequence of the latter, the counterpart of 13 in terms of \exists (that is, the *Law of Particularisation*

13* $\varphi[\tau/x] \rightarrow \exists x\varphi$)

will not occur among the primitive assumptions. And finally, let me notice once and for all that here we will try to give a *uniform* treatment of the various free logics, disregarding notational and stylistic differences among their authors.

questionable) about non-denoting singular terms, and on the other, though it cannot be used to justify the dubious inference from

(15) Nothing (existent) is a winged horse

to

(16) Pegasus is not a winged horse,

it *can* be used to justify the perfectly legitimate one from 15 *and*

(17) Secretariat exists

to

(18) Secretariat is not a winged horse.

Beginning with a seminal paper by Leonard [1956], that practically inaugurated the subject, free logicians have insisted that two of their most important tasks are (a) making explicit the existential assumptions that are tacit in classical logic (and that only can justify—in their opinion—the presence there of ‘laws’ like 13), and (b) discriminating between the cases in which these assumptions are relevant and the cases in which they are not. 14 is a good example of how these two tasks can be successfully performed: on the one hand, the assumption that (the singular term) τ be denoting—taken for granted by classical logic—is here expressed by

(19) $\exists x(x = \tau)$

and on the other the relevance of this assumption is signalled by its very presence, thus distinguishing the case of 14 from, say, that of

(20) $\varphi(\tau) \rightarrow \neg\neg\varphi(\tau)$,

which is also a theorem of both classical and free logic and in which no supplementary existential condition is given (or needed).

All of the above, however, is made possible by the fact that **CQC** = is a logic *with identity*, for the identity symbol plays a vital role in expressing existence in 19 and substitutivity of identicals a vital role in proving 14. What would happen if the starting point were an axiom system for **CQC**, that is, for classical logic *without* identity?

We can approach this problem in stages. First of all, notice that if indeed 19 expresses an existential commitment to the denotational character of τ , it seems legitimate to use it as *definiens* for a new *existence* symbol, say in the following way:

(21) $E!\tau =_{\text{df}} \exists x(x = \tau)$, where x is alphabetically the first variable distinct from τ .

By using this abbreviation, 14 could be rephrased as

$$(22) (\forall x\varphi \wedge E!\tau) \rightarrow \varphi[\tau/x],$$

thus making the meaning of the extra assumption even more explicit.

In the system resulting from **CQC** by dropping 13, neither 14 nor its definitional abbreviation 22 can be proved; yet, on the other hand, something like 14 or 22 is certainly *needed*. For, as already noted, the procedures of classical logic (and in particular, Universal Instantiation), though based on tacit existential assumptions, are of course unquestionable when these assumptions are *true*.

The simplest way of reintroducing the legitimate cases of instantiation after dropping 13 from **CQC** would be to add $E!$ to the set of primitive symbols, and 22 to the set of axiom-schemata. There is however a more ingenious way, which makes use of *neither* the existence *nor* the identity symbol, and is due to [Lambert, 1963].

To understand this alternative, it is enough to take a closer look at 14. What this ‘law’ says is that if something is a value of a bound variable then it has all the properties (expressible in the language and) shared by *all* such values. This conditional statement, however, could be reformulated in universal terms: *every* value of a bound variable has all the properties (expressible in the language and) shared by all such values. And this reformulation in turn suggests

$$(23) \forall y(\forall x\varphi \rightarrow \varphi[y/x])$$

as a possible replacement for 14 or 22.

I have now developed the core of a ‘pure’ free logic **FQC**, of a free logic with existence **FQCE!**, of a free logic with identity **FQC=**, and of course of a free logic with existence *and* identity **FQCE! =**. Before presenting their final formulations, however, two further problems must be mentioned.

First of all, consider the system obtained from **CQC=** by substituting 23 for 13. In this system

$$(24) \forall x\exists y(y = x)$$

is provable, which seems to be a perfectly reasonable result. For every value of a bound variable is certainly also a value of any other bound variable. However, as shown by Bencivenga [1978a; 1980a], this very natural result is *not* provable in the system obtained from **CQC=** by simply dropping 13, not is its counterpart in terms of the existence symbol

$$(25) \forall xE!x$$

¹⁴This existence symbol was first used by Russell, but only with descriptions. It was [Leonard, 1956] who generalised its application to all singular terms.

provable in the system obtained from **CQC=** by substituting 22 for 13 (which again is not good news, given the evident connection between 25 and that ‘existential import’ of quantifiers that we regarded as a defining feature of free logics).

Secondly, it long remained an open problem in pure free logic whether

$$(26) \quad \forall x \forall y \varphi \rightarrow \forall y \forall x \varphi$$

is provable in the system obtained from **CQC** by substituting 23 for 13. Fine [1983] solved this problem in the negative, showing the independence of 26 from the system in question.

In conclusion, then, let us agree on what follows. **FQC** is obtained from **CQC** by substituting 23 and 26 for 13. **FQC=** is obtained from **CQC=** by substituting 23 for 13. **FQCE!** and **FQCE! =** are obtained from **CQC** and **CQC=**, respectively, by substituting 22 and 25 for 13.

Two final remarks. First, all of the above are in a sense *minimal* systems of free logic: a few stronger systems will be considered in the part on semantics. Second, it will also become clearer in the part on semantics that all these systems are *inclusive* as well as free: once again, it is the strict connection between the two sets of problems that allows us to automatically solve the one while addressing the other.

6 NON-AXIOMATIC SYSTEMS

Something must be said about natural deduction and Gentzen formulations of free logics. Indeed, the first two formal systems for free logics—those by Leblanc and Hailperin [1959] and Hintikka [1959a]—were natural deduction systems, which however did not receive much currency in the literature. As to Gentzen systems for free logics, they can be found in [Routley, 1966; Trew, 1970; Bencivenga, 1980b]. Here in formulating both kinds of systems we will take for granted standard rules for connectives and identity (as well as, in the case of Gentzen systems, standard axioms), and we will make a substantial use of the existence symbol in the quantificational rules. Systems for pure free logic (or free logic with identity but not existence) may be obtained by using the same rules but making ‘**E!**’ into a metalinguistic symbol, and thus accepting as theorems only formulas not containing it.¹⁵

With all these qualifications, a natural deduction system for free logic can be characterised by the following four rules.

¹⁵This is the strategy suggested in note 11. In the case of a free logic with identity but without existence, it would also be possible to have $\exists x(x = \tau)$ do the job of $E!\tau$, but this would have the ‘unnatural’ consequence of making quantification theory dependent on identity theory.

(27) Introduction rule for \forall :

$$\frac{\begin{array}{c} \{E!a\} \\ \vdots \\ \varphi[a/x] \end{array}}{\forall x\varphi}$$

where a is a new individual constant not occurring in φ .

(28) Elimination rule for \forall :

$$\frac{\forall x\varphi \quad E!a}{\varphi[a/x]}$$

(29) Introduction rule for \exists :

$$\frac{\varphi[a/x] \quad E!a}{\exists x\varphi}$$

(30) Elimination rule for \exists :

$$\frac{\begin{array}{c} \{\varphi[a/x]\} \\ \{E!a\} \\ \vdots \\ \psi \end{array}}{\exists x\varphi \quad \psi}$$

where a is a new individual constant not occurring in φ or ψ .

On the other hand, a Gentzen system for free logic can be characterised by the following four rules.

(31) Introduction of \forall in the antecedent:

$$\frac{\Gamma, \varphi[a/x] \vdash \Delta \quad \Gamma' \vdash \Delta', E!a}{\Gamma, \Gamma', \forall x\varphi \vdash \Delta, \Delta'}$$

(32) Introduction of \forall in the succedent :

$$\frac{\Gamma, E!a \vdash \Delta, \varphi[a/x]}{\Gamma \vdash \Delta, \forall x\varphi}$$

where a does not occur in Γ, Δ or φ .

(33) Introduction of \exists in the antecedent :

$$\frac{\Gamma, E!a, \varphi[a/x] \vdash \Delta}{\Gamma, \exists x\varphi \vdash \Delta}$$

where a does not occur in Γ, Δ or φ .

(34) Introduction of \exists in the succedent :

$$\frac{\Gamma \vdash \Delta, \varphi[a/x] \quad \Gamma' \vdash \Delta', E!a}{\Gamma, \Gamma' \vdash \Delta, \Delta', \exists x\varphi}$$

III: Semantics

7 THE PROBLEM

Consider a simple subject-predicate sentence, say,

(35) Socrates is a man.

How is a truth-value to be assigned to 35 according to the usual referential semantics for classical logic (briefly, classical semantics)?

Very simply put, the answer is as follows. First of all, we establish a domain of quantification (which, given our adoption here of Quine's *dic-tum*, can be identified with the set of existing things). Then we look for the denotation of the singular term 'Socrates' and for the extension of the general term (or predicate) 'being a man' in that domain. And finally, we pronounce 35 true if that denotation is a member of that extension, and false otherwise.

There is more to this procedure than meets the eye. Indeed, it is impossible to set up (in a reasonable way) the conditions at which a given sentence is true without having some *theory of truth*, and the procedure in question is based on one such theory, that is, on what is usually called the *correspondence* theory of truth. 35 is (say) true—according to this theory—because it corresponds to *reality*, and it would be false if it did not. More generally, 35 is true in a given state of affairs (or 'possible world') if it corresponds to reality *there*, and false otherwise. If we were doing propositional logic, this correspondence between (atomic) sentences and reality would be the bottom line, but at the level of analysis of quantification theory, that is, when sentences are analysed into (singular and general) terms, the correspondence in question is to be reduced to some more *basic* correspondences: the ones between singular terms and the objects constituting extensions. If in general the correspondence theory wants to establish the truth of a sentence in terms of a fit between what the sentence says and the way the world is, then such basic correspondences represent at this level of analysis the points at which the fit must be sought. To go back to our example once more, 35 is true just in case the object corresponding to 'Socrates' is a member of the set corresponding to 'being a man'.

But then of course basic correspondences are the key to the whole matter. *Once* we have the basic correspondences relative to some sentence we can

determine whether the sentence corresponds to reality or not, but not before. In the world in which we live, we know that 35 is true and

(36) Plato is a table

is false, but this is because we know *who* Socrates and Plato are, and *which* things are men and tables. Probably we would not know if we did not know who Socrates is, and certainly we would be in big trouble if there were no Socrates.

This kind of trouble is exactly what awaits us when we introduce non-denoting singular terms into the picture. Non-denoting singular terms denote nothing existent. Of course, they could denote something else, and in what follows we will consider some such position, but this is *one* possibility among many, and we must also take into serious account the possibility that they denote nothing at all. And taking this possibility seriously means considering situations in which some of the basic correspondences required by classical semantics *are simply not there*.

This is more than an epistemological problem. Consider for example

(37) Secretariat is white

and

(38) Pegasus is white,

and suppose that Secretariat be taken to a remote planet, where its colour could not be ascertained. Also, to simplify things, suppose that none of the fictional writings about Pegasus said anything about its colour. Still, there would be a fundamental difference between 37 and 38. For the colour of Secretariat could not be ascertained *in fact*, due to the practical limitations of human beings, but could be ascertained *in principle*, by somebody able to overcome those practical limitations, whereas in the case of Pegasus the thing would be impossible in principle, too: since Pegasus is nowhere to be seen, no matter how our powers were to improve, they would not influence our ability (or rather, inability) to verify its colour.

So it is not a matter of what we know, but of what we think truth is. Under the circumstances imagined above, it looks like it's not the case that Pegasus is white. It is the case that it is *not* white? (Or—which is the same—it is *false* that it is white?) Maybe, but if it is so, it must be for (at least partly) different reasons than (say) in the case of 36, and we need our theory of truth to tell us exactly what the analogies and the differences are between the two cases. The correspondence theory by itself cannot tell us this, because its verdicts are based on data—the basic correspondences—that here are not always available. Perhaps all we need is a small clause taking explicit care of such 'exceptions', but still we need something, we need some way of deciding when sentences containing non-denoting singular

terms are true, and why. This is the main question to be faced in the course of constructing a semantics for free logics—and in my opinion in free logics in general. It is an important question because any answer to it is inevitably going to provide an alternative to, or at least a generalisation of, the correspondence theory of truth. It is a delicate question because the correspondence theory is an old and venerable one, and challenging it represents a true act of ‘revolutionary science’. In the rest of the present part, I will give an account of this revolution.

8 OUTER DOMAINS

Given the way in which we set up *the* problem of ‘free’ semantics (that is, accommodating for the presence of gaps in the basic correspondences), the easiest way to ‘solve’ this problem consists simply in *avoiding* any such gaps. This is substantially the way most classical logicians operate, either by assigning arbitrary denotations to (previously) non-denoting singular terms (*à la* Frege–Carnap) or by excluding (*à la* Russell) such (alleged) terms from the class of things in need of a direct semantical counterpart. However, there is a way of going in this direction without ending up in classical logic: all that we have to do is to acknowledge that ‘Pegasus’ or ‘the present King of France’ have a semantical counterpart (or a denotation) just as much as ‘Bill Clinton’ or ‘the present President of France’ do, only that such counterparts (or denotations) *are not members of the domain of quantification*, or, to put it more bluntly, *do not exist*.

Even if some suggestions of this kind are much older,¹⁶ the first such proposal that appeared in print was contained in the review by Church [1965] of Lambert [1963]. The purpose of the review was a critical one: Church indeed meant to show that the whole enterprise of free logic was of very little philosophical significance. Actually however (and a little ironically), the main result it achieved was that of sketching one of the very first semantical treatments of the subject, and one that was going to have a lot of success in the next few years.

Briefly, the substance of Church’s contribution was as follows. Let S be any set, and let a classical interpretation of individual and predicate constants be defined on S . Let P be any monadic predicate, and let two new quantifiers be defined, to be read ‘for every x , if x is P then . . .’ and ‘there is an x such that x is P and . . .’. Church suggested (without actually proving it, but the claim was indeed true, and was proved later)¹⁷ that the set of theorems of Lambert’s axiomatic system would coincide with the set

¹⁶For example [Leblanc and Thomason, 1968] mention a suggestion of outer domains made (to Leblanc) by Joseph Ullian in 1962, and apparently both Belnap and Lambert had outer domain semantics very early (but never published their results).

¹⁷A sketch of the proof is given in Section 11.

of (classically) logical truths containing only the new quantifiers. As Meyer and Lambert [1968] put it, free logic was then just a ‘simple exercise in a theory of restricted quantification’.

Shortly after Church’s ‘proposal’, at least three major attempts were under way at constructing free semantics along the lines implicitly (and unwillingly) suggested by it. None of them made explicit reference to Church, and quite possibly they were all totally independent of his review, but there is a factual, objective sense in which they were all developing the suggestions contained in it, and emphasising different aspects of them.

The system which went the closest to reproducing Church’s intuitions was the ‘logic of possible and actual objects’ proposed by Cocchiarella [1966]. Semantically, the basic unit of this logic (a *Cocchiarella structure*) can be conceived of as an ordered triple $\langle A, A', I \rangle$, where A is as usual a non-empty set and I is a (total) function interpreting individual and predicate constants on A . The new character in this story is A' , which is just any (possibly empty) subset of A . A is the range of quantifiers, but not of quantifiers having existential import: rather, its members are to be construed intuitively as ‘possible objects’. A' , on the other hand, is the range of *another* pair of quantifiers, which *do* have existential import. If we adopt the usual symbols for the ‘existentially committed’ quantifiers and for example \bigwedge and \bigvee for the more general ones, it is easy to see that $\forall x\varphi$ can be true in a Cocchiarella structure while $\varphi[\tau/x]$ is not (indeed, even while $\exists x\varphi$ is not, if A' is empty), hence that Specification fails for the restricted quantifiers. On the other hand, this principle does hold for the unrestricted quantifiers, which suggests that a formal system for the logic in question can be obtained simply by pairing a classical logic for \bigwedge and \bigvee with a free logic for \forall and \exists and adding the schema

$$(39) \quad \bigwedge x\varphi \rightarrow \forall x\varphi,$$

which supplies the connection between the two sets of quantifiers.

Due to the presence of two sets of quantifiers and of principles like 39, Cocchiarella’s logic of possible and actual objects is in fact more than a minimal free logic in the sense of Part II, but by dropping the unrestricted quantifiers from the language and all the theorems containing them from the formal system, we would obtain exactly a minimal free logic in that sense. On the other hand, if we were to do this then the larger set A would not be the range of any quantifiers but would only be providing denotations for the individual constants not interpreted in A' . It might be natural then to represent the situation in a slightly different way and, instead of insisting on the set of existents being a subset of a larger set of possibles, focus on the distinction between existents and *non*-existents (that is, in terms of a Cocchiarella structure, between A' and $A - A'$). And this in turn would bring us immediately to the variant of the present approach proposed by Leblanc and Thomason [1968]. Since this variant is probably the most

popular, we will give here a slightly more detailed account of it than we did of Cocchiarella's (or than we will do of Scott's). The reader can easily accommodate our remarks to the other variants.

A *Leblanc–Thomason* (or, more simply *LT*) structure is again an ordered triple $\langle A, A', I \rangle$, where however A and A' are two *disjoint* sets (called the *inner domain* and the *outer domain*, respectively) such that *their union* is non-empty (this union, of course corresponds to the set of possibles in a Cocchiarella structure, and it still plays an important role in the present context, though in a way it shifted to the background). I is a (total) function interpreting individual and predicate constants on $A \cup A'$. An LT structure is *null* if its inner domain is empty, and *non-null* otherwise. In a non-null LT structure, an *assignment* is a (total) function from the set of variables *to the inner domain*. Satisfaction is then defined as usual, but the fact that variables can only get values in the inner domain makes of this domain the range of quantifiers.

Leblanc and Thomason's semantics is inclusive as well as free, as is shown by the presence of null LT structures. Thus the problem arises once again of what to do in those structures with open formulas. However, this is not a problem that *we* need consider. Simplifying on Leblanc–Thomason's own treatment, we can agree to adopt the Jaskowski–Hailperin–Quine suggestion of accepting only closed theorems, and thus leave open formulas simply *uninterpreted* in null LT structures.¹⁸ In contrast with the above authors, this won't produce any limitation in our expressive powers, because we already have individual constants as place-holders for singular terms, and individual constants behave in null LT structures just as they behave (when they are non-denoting) in the non-null ones.¹⁹ Besides, we need not deal with open formulas as a preliminary step for evaluating quantified sentences in null LT structures, since we can agree once and for all that for all such structures \mathfrak{A} and all sentences $\forall x\varphi$

$$(40) \mathfrak{A} \models \forall x\varphi.$$

An analogous attitude will be adopted (without further mention) with respect to all the alternative semantics to be presented here.

We have thus considered two variants of what we will call in general the *outer domain* approach to free semantics. As suggested above, they emphasise different aspects of this approach (and of the original suggestions by Church). Cocchiarella makes the most of the notion of restricted quantification, whereas Leblanc and Thomason make the most of the presence of two kinds of *denotata*. A third aspect of this approach is its similarity to Frege–Carnap's classical device; in both cases indeed the problem of non-denoting singular terms is solved by making them *denoting* (in a sense). It

¹⁸As to Leblanc and Thomason themselves, they preferred to follow Mostowski in weakening *modus ponens*.

¹⁹That is, in both cases they denote members of the outer domain.

is not surprising then that there be a further variant of the approach in question which makes the most of this similarity. Such a variant is due to Scott [1967].

Scott's theory (as on the other hand both Frege's and Carnap's) is actually a theory of (definite) descriptions, but the general semantical strategy it embodies makes perfectly good sense at the level of unanalysed singular terms, too. Very simply put, this strategy is as follows. Associate with each domain of quantification an entity not belonging to it, say the entity $*$. Since $*$ is outside the range of quantifiers, by Quine's *dictum* it does not exist, but still it can be assigned as a semantical value to singular terms; hence $\{*\}$ works practically as an outer domain. At the same time however, since this outer domain is a singleton, $*$ works also like a Carnapian chosen object, in that all the (originally) non-denoting singular terms have it as their common semantical counterpart (or 'denotation').

Because of this last feature of Scott's semantics,

$$(41) (\neg E!\tau \wedge \neg E!\tau') \rightarrow \tau = \tau'$$

is logically true in it. Since of course 41 is not provable in the minimal free logics of Part II, they should be strengthened somewhat to generate a formal system adequate to the semantics in question. The simplest way to do this consists in adding 41 itself as a further axiom-schema. A more elaborate alternative would require the addition of a new symbol (for example, ' $*$ ') to the language, of a clause fixing its interpretation on the 'non-existent object' to the semantics, and of the schema

$$(42) \neg E!\tau \rightarrow \tau = *$$

to the deductive apparatus. Actually, if we were dealing with descriptions, this more elaborate alternative might turn out to be the simpler of the two, because in description theory ' $*$ ' could be introduced by definition, say by

$$(43) * =_{df} \iota x(x \neq x).$$

Our presentation of the outer domain approach to free semantics ends here, and we can conclude the present section with a brief appraisal of this approach. Such remarks will be of a general nature, and will leave aside the special developments recommended by Scott, which will be the subject of further discussion in the section on descriptions.

First of all, then, the positive side. Outer domain semantics is simple, and we know why: filling all the gaps left by non-denoting singular terms in the basic correspondences allows one to stick to the standard evaluation procedures, thus generating a feeling of familiarity for the whole enterprise. The problem of non-denoting singular terms is not so much solved as it is *dissolved*. The reason why 'Pegasus is white' is (say) true is not at all

different from the reason why ‘Secretariat is white’ would be: ‘Pegasus is white’ is true because the (non-existent) object Pegasus falls within the (non-existent part of the) extension of ‘white’.

Furthermore, outer domain semantics is formally very convenient. Semantical completeness is provable here in its stronger form: not only the set of logically true sentences but also the set of valid arguments is recursively enumerable, and thus the whole logic is under complete (proof-theoretical) control. Once again, the reason is not hard to find, even though probably it will be fully appreciated only later, when this semantics is contrasted with some of its alternatives.²⁰ The fact is that the semantics in question is *bivalent*: every sentence, whether or not it contains non-denoting singular terms, is either true or false (in any structure).

Whereas all the positive comments on this semantics have to do with practical or technical matters, all the negative ones have to do with philosophical matters. The first (and most common) of these comments is probably best put in the form of a question: what exactly is the status of the members of the outer domain? The most natural answer to this question is ‘non-existent objects’, but such an answer generates trouble.

It is not that non-existent objects are not philosophically ‘respectable’. On the contrary, they are quite popular in philosophy today, probably more than they ever were after Russell’s alleged ‘refutation’ of Meinong. Scholars of Meinongian inclination, for example Parsons [1980], have questioned the validity of that refutation, and constructed ingenious philosophical theories of non-existent objects. To be sure, such objects are difficult to deal with, mostly because—as noted by [Quine, 1948]—their identity conditions are far from clear, but to say that they are difficult is not to say—as Quine concluded a bit too hastily—that they are ‘well-nigh incorrigible’. After all, if we are not ready yet to give a satisfactory account of non-existent objects—and chances are that soon this will no longer be true, if indeed it is true now—the problem might be with us and our philosophy, rather than with the objects themselves.

All of this is very good, but unfortunately it does not even get close to removing the trouble we mentioned above. For the difficulty with using non-existent objects to construct a semantics for free logics is not that we are not ready to accept them or to account for them, but that accepting them and accounting for them should have little to do with one’s *logic*, and should depend instead on one’s *metaphysical* position—at least according to a quite common conception of logic and metaphysics.²¹ And if this conception is

²⁰See in this connection the end of Section 10.

²¹Given that metaphysics is often defined as the study of what *is* (insofar as it is), it may sound awkward to say that this discipline should also be concerned with what *is not*. The awkwardness however is reduced when we consider that most supporters of non-existent objects ascribe to them some sort of (watered-down) ‘being’ (often discriminating between ‘to be’ and the stronger ‘to exist’).

correct, then outer domain semantics is in conflict with what we regarded as the most basic motivation for having a free logic in the first place!

Another criticism of outer domain semantics has to do less with non-existent objects in themselves than with the particular use the semantics in question makes of them. For many supporters of such objects (including Meinong)²² have held that at least some of them are ‘incomplete’, that is, such that for some property P , they have neither P nor not- P , and indeed, there seems to be something to the claim that, if for example none of the stories about Pegasus says anything about its length, then (say) the sentence

(44) Pegasus is six feet long

is neither true nor false, but simply indeterminate. The present semantics, however, allows for no such ‘truth-value gaps’, and we must be careful not to introduce them too hastily into the picture. For if we decided to simply leave some members of the outer domain ‘undefined’ with respect to some predicate constant P , this would determine the immediate collapse of such logical laws as

(45) $\varphi \vee \neg\varphi$,

and with them of most of **CPC**.

Though certainly quite serious, this criticism of outer domain semantics is not as damaging as the first one was. Truth-value gaps cannot be introduced too hastily in this semantics, but can be introduced after all. In a later section, we will mention a compromise between the outer domain and the supervaluational approach which saves much of the spirit of both while allowing (as supervaluations do) for truth-value gaps and (in a sense) ‘incomplete’ objects.

A third negative comment on outer domain semantics is even more dependent than the previous one on the particular ways this semantics has been formulated so far, and furthermore is itself grounded on a debatable philosophical position. It is just that some people find it objectionable that there be ‘genuine’ relations between existent and non-existent objects, and the semantics in question (in its usual formulations) seems to allow for such relations.

What I mean by ‘genuine’ deserves some words of explanation. If we admit non-existent objects, there are inevitably going to be some relations between them and the existent ones, because it is simply true that, say,

(46) I am thinking of Pegasus.

Relations such as the one expressed by 46, however, are of a very special kind; without entering into any detail, we can qualify them as ‘intentional’ or in some sense ‘modal’, and contrast them with such ‘purely descriptive’ (or ‘genuine’) relations as the one expressed by

²²See [Findlay, 1963, p. 57].

(47) Peter is taller than Mary.

Now according to some philosophers of logic the predicate constants P, Q, R, \dots of quantification theory stand for genuine (nonintentional) relations, hence if you think that no such relations hold between existents and non-existents (and share this position in the philosophy of logic), you might be embarrassed by the fact that in the usual formulations of outer domain semantics an ordered pair $\langle o_1, o_2 \rangle$ can fall into the extension of (say) P even when o_1 is a member of the inner domain and o_2 a member of the outer domain (or vice versa).

It would be possible to reformulate outer domain semantics so as to avoid this (for some people) unwelcome feature of it. However, this has not been done yet, and the present context is certainly not the right place to do it. Let me just notice in closing that at some point the problems raised by these reformulations will become interwoven with the problems raised by our second criticism of outer domain semantics. For there are several ways to go after claiming that the existent object a cannot hold the genuine relation P to the non-existent object b , and one of them is to say that

(48) Pab

is an indeterminate sentence.

9 CONVENTIONS

The positions that we will consider in the present section are quite disparate. What holds them together (in my opinion at least) is the fact that they determine truth-values for sentences containing non-denoting singular terms pretty much by *fiat*, and that whatever discussions or justifications they offer of their choices are more or less of an ‘external’ nature, that is, have mostly to do with the practical consequences of these choices or with how much they ‘fit’ with other (already accepted) linguistic theories.²³ For this reason, I found it suggestive to group them around the word ‘convention’.

The most typical ‘conventional’ positions can be described very easily. Their basic semantical unit is a ‘partial’ structure $\langle A, I \rangle$, where A is the usual domain of quantification and I interprets (on A) all the predicate constants and *some* (possibly all, possibly even none) of the individual constants. Truth-values for atomic formulas not containing non-interpreted constants are determined as usual, whereas all the atomic formulas containing such constants have the same truth-value, true or false as the case

²³For example, [Burge, 1974] takes it as a crucial argument in favour of his approach that it allows him to save a Tarskian theory of truth. Of course, even authors going in different directions do sometimes offer ‘external’ justifications, but nowhere seem such justifications as crucial as in the semantics discussed in the present section.

may be. Borrowing (and adapting) some terminology by Lambert [1981], we can thus distinguish (on obvious grounds) between *positive* and *negative* conventional semantics.

The truth-values of complex formulas are also determined as usual. In particular, assignments are defined as (total) functions from the set of variables to the domain, and the satisfaction-condition for quantified formulas is the standard

$$(49) \mathfrak{A} \models \forall x\varphi[f] \text{ if and only if for every member } \alpha \text{ of the domain of } \mathfrak{A}, \mathfrak{A} \models \varphi[f, \alpha/x].$$

Completeness and the other usual metatheoretical results are not difficult to establish for conventional semantics: once more, bivalence makes things relatively easy. Indeed, there is in general not much to be said about the technicalities of these semantics; hence we might turn right away to some considerations for and against accepting them.

Given the present state of the literature, positive conventional semantics are little more than a theoretical possibility. Of course, it is a possibility of which most scholars in the field are aware, but nonetheless it has not become yet the core of a full-fledged semantical approach. In such a situation, we cannot expect to find a great deal of (published) discussion on the semantics in question; hence most of this discussion we will have to supply on our own.

An argument which could be given in favour of positive conventional semantics is that they make it very easy to validate the schema

$$(50) \tau = \tau,$$

which is usually regarded as expressing a logical law. However, this does not mean that such logics allow for a standard treatment of identity: they create problems with respect to the substitutivity of identicals. For consider a structure $\langle A, I \rangle$ such that $I(a)$ is not defined, $I(b)$ is defined and $I(b) \notin I(P)$. In this structure,

$$(51) a = b$$

and

$$(52) Pa$$

are both true, but

$$(53) Pb$$

is false. On the other hand, the situation is not so desperate as it might seem. As we will see, many free semantics are forced to treat identity in some special way, and in particular to require explicitly that a sentence of the form 51 be false when exactly one of a and b is denoting. A similar special provision is all that we would need here.

Another criticism of positive conventional semantics could be that they, too, allow for ‘genuine’ relations between existents and non-existents. Of course, this criticism should be slightly reformulated, since the semantics in question do not literally allow for any non-existents at all, but only for the truth of (atomic) *sentences* containing both denoting and non-denoting singular *terms*. And of course, once reformulated, the criticism might be easily answered in a number of different ways, by adopting some more ‘special provisions’.

Turning now to negative conventional semantics, we must notice first of all that they have had much more success than their positive counterparts. Indeed, the first semantical account of a free logic ever published, the one by Schock [1964; 1968], was a negative conventional semantics, and so was one of the latest ones, by [Burge, 1974]. If we add that Russell’s classical description theory has a lot in common—in the results if not in the methods or the motivations—with these semantics, and that even authors going in a different direction—such as Scott [1967]—tend to agree with them when it comes to determining the truth-values of sentences,²⁴ we will have an idea of the persistent attraction of the approach in question.

What are the reasons for this attraction? Schock [1968] expresses his motivation as follows: ‘The application of a predicate to various terms holds just when the denotations of the terms stand in the relation denoted by the predicate; if not all of the terms denote, then their denotations cannot stand in the relation and the application does not hold’ (p. 21). In other words, since there is no denotation of ‘Pegasus’, the denotation of ‘Pegasus’ cannot stand in any relation with (say) the denotation of ‘Bellerophon’; hence

(54) Pegasus is loved by Bellerophon

is false.

As it is, this is not much of an argument. For it basically reduces to the circular claim that 54 is false because

(55) The denotation of ‘Pegasus’ stands in the relation of being loved by with the denotation of ‘Bellerophon’

is—where the falsity of 55 is as much in need of a justification as that of 54. One might try to shore it up by pointing out that—in the usual set-theoretical terms of classical semantics—the set of ordered pairs corresponding to the relation of being loved by is not going to contain any member corresponding to Pegasus and Bellerophon. But one might answer that classical set theory—just as classical semantics—is not prepared to deal with non-denoting singular terms, and that things could be different

²⁴See the schema (I3) on p. 188 of [Scott, 1967], which Scott considers *very reasonable* when giving axioms for a theory (not however for pure logic).

in a ‘free set theory’ devised for this purpose.²⁵ The negative conventional semanticist might then reply that his approach does not require any such new technical instrument, that it allows one to preserve most of the classical framework, and that these ‘conservative’ features are very important from a pragmatic point of view.

With this appeal to conservatism we have struck a key note. For what exactly is so great about preserving the classical framework? And why should pragmatic arguments be so crucial in choosing a free semantics? Of course, one may think that pragmatic arguments are *always* crucial, or even that they are *the only* arguments one can give in favour of any theory, and that the traditional framework is *always* to be preserved whenever it is possible. This is a general position in the philosophy of logic (and of science), and I have nothing much to say about it—except that it does not seem to be shared by many free logicians. What I think deserves some comment is the opinion somebody might have that *in this particular case, because of the particular nature of the problem*, pragmatic arguments are more important than usual. More precisely, I refer to the opinion that, since non-denoting singular terms are basically ‘don’t cares’, the only criteria to use in assessing an attitude towards them are whether the attitude is simple, efficient, and does not require a vast revision of our conceptual framework. I think that this opinion may be very dangerous for free logic as a whole.²⁶ For after all, what is simpler and more conservative in this case than just sticking to *classical* logic, supplemented by some of the policies mentioned in Section 3? Thus, omitting any further comment on the specifics of negative conventional semantics,²⁷ I will conclude the present section with some remarks on why free logicians may think that non-denoting singular terms are *not* ‘don’t cares’, and why they might want something more than an efficient way to accommodate them in the classical framework.

It is not that free logicians are interested in non-denoting singular terms *in themselves*; it is not that they have some kind of perverse attraction for what does not exist. However, they are not bound to the realm of existents either; they do not share that ‘prejudice in favour of the actual’²⁸ which is so common (and possibly healthy) in other branches of knowledge. A scientific truth is true (at least in part) because of the way the world is, and given a sufficiently wide conception of the ‘world’ the same might be said of many philosophical truths, but a logical truth should be independent of any such factual matters, and in particular of what exists and what does not exist.

²⁵Such free set theories have been developed in [Scott, 1967] and [Bencivenga, 1976]. To my knowledge, however, they have never been used in formulating semantics.

²⁶Of course, so may be the more general position mentioned above. but that is also too general to be discussed here.

²⁷But let me stop a minute to notice that—as far as identity is concerned—these semantics are in a sense in a dual position with respect to their positive counterparts: they easily validate substitutivity of identicals but invalidate self-identity.

²⁸The expression is Meinong’s. See [Meinong, 1904].

A logical truth should depend only on (logical) form, and there seems to be no plausible (non *ad hoc*) ground for distinguishing between the form of ‘Pegasus is white’ and that of ‘Secretariat is white’. Of course, we know that somewhere there is a difference, because Secretariat exists and Pegasus does not, but invoking that piece of information, and discriminating on that score between the procedures involved in evaluating the two sentences, would be contaminating logic with mere contingencies.

In conclusion, non-denoting singular terms represent an important challenge for logic in general. For this reason, even though the free logician is not going to forget considerations of simplicity and theoretical conservatism, he may think that it is more crucial to rethink the whole subject, no matter how complicated and revisionary this process is going to be.

10 SUPERVALUATIONS AND BEYOND

The most organic attempt to date at rethinking the whole subject of truth theory in view of the presence of non-denoting singular terms was initiated in 1966 by two seminal papers by van Fraassen [1966a; 1966b], and pursued by van Fraassen himself and several other authors, including Skyrms [1968], Meyer and Lambert [1968], Woodruff [1971] and Bencivenga [1980b; 1981]. In the present section we will study this approach, which from its most characteristic technical instrument may be called the *supervaluational* approach.

The starting point of our analysis is once more conventions. According to van Fraassen [1966a], the truth-value of a sentence like

(56) Pegasus has a white hind leg,

or even the fact that this sentence has a truth-value, is ultimately to be established on the ground of some convention. This convention, however, belongs to the *philosophy of language*, and should receive *there* whatever justification it is going to receive. *Logic*, on the other hand, has nothing to do with any such conventions and justifications: the set of logical truths should be absolutely independent of the philosophy of language we decide to adopt. In particular, there will be conventions assigning True to 56 and conventions assigning False to it, but logic should not be committed to any of them. At the very most, we can think of logic as committed to the *logical product* of all possible conventions, to what all these conventions have in common, to what is going to be true (or false) *no matter what convention we adopt*.

This notion of the logical product of all possible conventions leads very naturally to the idea of a supervaluation, in the following way. Let a partial structure $\mathfrak{A} = \langle A, I \rangle$ be given, and suppose that $I(a)$ is not defined, $I(b)$ is defined and $I(b) \in I(P)$. Application of the standard evaluation procedures establishes the truth of sentences like

(57) Pb

(58) $Pb \vee \neg Pb$

(59) $\exists xPx$

as well as the falsity of

(60) $\neg Pb$

(61) $Pb \wedge \neg Pb$

(62) $\forall x\neg Px$,

but determines no truth-value at all for

(63) Pa

(64) $\neg Pa$

(65) $Pa \vee Pb$

(66) $Pa \wedge \neg Pb$

(67) $Pa \vee \neg Pa$

(68) $Pa \wedge \neg Pa$.

Of course, 63–68 might receive any combination of truth-values on the ground of some convention or other, but it seems reasonable to restrict our attention to those conventions that are *classical* in the following sense: they assign truth-values to atomic formulas containing non-denoting singular terms in some way that it is not our present concern to examine (indeed, that we could for our present purposes regard as totally *arbitrary*), but then they proceed to evaluate complex formulas *in the standard way*.

The combination of any such classical convention and the information supplied by the partial structure will determine a valuation of all the sentences of the language. Let us agree to call any such valuation a *classical valuation* (on \mathfrak{A}). Of course, all classical valuations will agree on all the sentences (like 57–62) that contain no non-denoting singular terms, but the interesting thing is that they will also agree on many sentences which *do* contain non-denoting singular terms. Thus for example 63 will receive the value True in some classical valuations and the value False in some others, but *every* classical valuation will verify 65 and 67 and falsify 66 and 68. In other words, there will be cases—and many of them—in which the logical product of all classical valuations will be non-empty, and as such informative, beyond what is determined by the partial structure. As the fate of

67 and 68 suggests, this supplementary information is enough to extend to non-denoting singular terms all of **CPC**.

The essence of van Fraassen's approach consists simply in *using* this supplementary information. More precisely, the *supervaluation* $W_{\mathfrak{A}}$ for a partial structure \mathfrak{A} is characterised by him as the (partial) valuation which assigns True to the sentences that are true in all classical valuations on \mathfrak{A} , False to the sentences that are false in all classical valuations on \mathfrak{A} , and no truth-value at all to the remaining sentences. Then, in at least one of the alternatives he contemplates,²⁹ supervaluations are to constitute the basic (or *admissible*) valuations of free semantics, and all the other semantical notions are defined in their terms.

The fact that supervaluations preserve all of **CPC** without espousing any specific convention or admitting non-existent objects is certainly remarkable, but it is also important to point out that when we move beyond propositional logic supervaluations create serious problems.

The most apparent of these problems concern identity. When a is non-denoting, nothing so far prevents a classical valuation from falsifying

$$(69) \quad a = a,$$

and when both a and b are non-denoting, nothing so far prevents a classical valuation from verifying 51 and 52 and falsifying 53 on p. 170, thus invalidating substitutivity of identicals.

Further (and more subtle) problems concern quantification. To understand them, we must first of all ask ourselves how the present approach can be extended to deal with variables and open formulas. A natural way would seem to be the following. Define a convention for a partial structure \mathfrak{A} as a binary function from the set of atomic formulas and the set of assignments for \mathfrak{A} to $\{T, F\}$ (that is, as a function assigning (arbitrary) truth-values to atomic formulas *relative to* assignments). Then let \mathfrak{A} , any convention and any assignment determine an *auxiliary classical valuation*, by using standard evaluation techniques for atomic formulas not containing non-denoting singular terms and for complex formulas, and relying on the convention for atomic formulas containing non-denoting singular terms. Point out that in the case of *sentences* assignments make no difference, and define on this ground the notion of a classical valuation on \mathfrak{A} , as determined only by \mathfrak{A} and a convention. Finally, define the supervaluation for \mathfrak{A} as the logical product of all classical valuations on \mathfrak{A} . All of this sounds very good, but unfortunately it does not work: for it may well be that in the case of sentences assignments *do* make a difference. Indeed, nothing so far prevents a convention from assigning True to some atomic sentence

²⁹He also considers an alternative in which classical valuations themselves are the admissible valuations, but such an alternative is far less interesting or philosophically defensible; hence we will totally disregard it here.

(containing a non-denoting singular term) relative to some assignment and False to the same sentence relative to a different assignment. Hence the ‘definition’ suggested above of a classical valuation is not legitimate.

Van Fraassen’s solution of these problems is disappointing. Very simply put, he adds to the definition of a convention a number of *ad hoc* clauses which rule out—by *fiat*—all the possibilities contemplated above. More precisely, a convention K is to be defined in such a way that

1. $K(\tau = \tau, f) = T$;
2. $K(\varphi[\tau/x], f) = K(\varphi[\tau'/x], f)$ if either $\tau[f] = \tau'[f]$ or $K(\tau = \tau', f) = T$;
3. $K(\varphi, f) = K(\varphi, f')$ if $f(x) = f'(x)$ for every variable x occurring (free) in φ .

For analogous reasons, it is also required that

4. $K(\tau = \tau', f) = F$ if exactly one of $\tau[f]$ and $\tau'[f]$ is defined.³⁰

These additional clauses simplify the technical developments, and make some of the desired metatheoretical results easily available, but certainly don’t go in the direction of providing a satisfactory philosophical motivation for the resulting semantics. Indeed, they rather weaken whatever motivation there was after our first introduction of the supervaluational approach. For remember, the crucial point there was the neat separation promised by supervaluations between logic and philosophy of language, and the fact that they were supposed to be independent of specific conventions, and committed only to the logical product of *all* conventions. Now it would be hard to hold this point of view—in presence of so many restrictions on what counts as a convention. Even the fact that we should limit ourselves to *classical* conventions (or valuations) might begin to look suspicious, and the whole enterprise appear dangerously close to a gigantic circle. To put it bluntly, it seems that van Fraassen can assign truth-values to sentences containing non-denoting singular terms only to the extent to which he is *not* independent of a conventional attitude.

In my opinion, these shortcomings of supervaluational semantics are due less to the general idea of a supervaluation than to a failure on van Fraassen’s part to get deeper into its analysis. Indeed, I think that supervaluations come very close to providing that generalisation of the correspondence theory of truth that we judged necessary for a reasonable treatment of non-denoting singular terms. To justify this claim, it will be convenient to have a fresh look at the whole thing.

³⁰Van Fraassen’s language does not contain $E!$. If it did, it would probably be necessary to add one more clause:

(e) $k(E!\tau, f) = T$ if and only if $\tau[f]$ is defined.

Let me begin by asking a direct question. Why is a sentence like 67 always true in supervaluational semantics, even when its only atomic component 63 is truth-valueless? One way to answer this question could be the following: even though 63 has no truth-value, if it *did* have a truth-value, *any* truth-value, 67 would be true. But what is required for 63 to have a truth-value? The semantics itself gives the answer: 63 has a truth-value if and only if *a* is denoting. Hence the answer to our original question may be rewritten as follows: 67 is true even when *a* is non-denoting (and 63 truth-valueless) because if *a were* denoting then it would be true.

This answer constitutes the core of a new theory of truth, which for the sake of a label we might call the *counterfactual* theory of truth. This theory substantially agrees with the correspondence theory on all sentences not containing non-denoting singular terms, but develops in an original way beyond that scope. Its most basic principle may be formulated as follows: a sentence containing non-denoting singular terms is true (false) if and only if it would be true (false) in case these terms *were* denoting, *no matter what their denotations were*. According to this principle, not only is 67 always (hence logically) true and 68 logically false, but also 69 is logically true and substitutivity of identicals is truth-preserving, and all of this as a consequence not of the adoption of *ad hoc* clauses but of the use of normal evaluation procedures. Also, it will be useful to point out right away that accepting the principle in question does not commit one in any way to outer domains or non-existent objects. For in outer domain semantics non-denoting singular terms simply ‘denote’ non-existents, whereas in the present approach these terms denote nothing, and we only take the liberty of considering *alternative* situations (or ‘possible worlds’) in which they denote, and of making their behaviour there relevant for the evaluation of sentences containing them in the situations (or worlds) in which they do not denote. We will see that compromises are possible between the counterfactual theory of truth and outer domain semantics, but such compromises are not inevitable.

Supervaluational semantics—as developed by van Fraassen—*suggests* the counterfactual theory, but does not explicitly *espouse* it. More precisely, this semantics does not get to the point of assigning a truth-value (or no truth-value) to a sentence containing non-denoting singular terms by considering situations in which these terms are denoting. Rather, it considers situations in which the atomic formulas containing these terms receive truth-values. In a way, it is as though supervaluational semantics were developing the suggestions leading to the counterfactual theory *only at a propositional level of logical analysis*. From this limitation springs in my opinion all the talk about conventions, for it seems that only on a conventional basis we can assign (what look like) arbitrary truth-values to unanalysed atomic formulas. And from the same source springs also the necessity of adding *ad hoc* clauses to the definition of a convention; for from a purely propositional

point of view there is simply no reason why a sentence like (69) should not be false, or more generally why the assignment of truth-values should fit the non-propositional logical structure of sentences.

The message sent by these considerations is quite clear: what we have to do to remove all that sounds *ad hoc* and circular in the semantics of supervaluations is carry the approach expressed by this semantics to a more specifically quantificational level. Several authors have received this message, and several semantics have been developed along these lines, but all of them had to face, and solve one way or another, a serious problem, whose realisation might well have been the main reason for van Fraassen's adoption of a 'propositional' treatment of non-denoting singular terms.

The problem is as follows. Suppose that supervaluational semantics be developed at a quantificational level in what looks like the most natural way. Given a partial structure \mathfrak{A} and a sentence φ containing singular terms that are non-denoting in \mathfrak{A} , one considers all *extensions* of \mathfrak{A} which make those terms denoting, and pronounces φ true (in \mathfrak{A}) if it is true in all such extensions, false if it is false in all such extensions, and truth-valueless otherwise. Now consider the sentence

$$(70) \quad \forall xPx \rightarrow Pa,$$

and suppose that a be non-denoting (in some structure \mathfrak{A}).

70 is an instance of Specification, and we know that rejecting Specification is the most distinctive feature of a free logic from a proof-theoretical point of view. In particular, 70 is not provable in any free logic unless a special clause is added to it which makes sure that a is denoting; hence we would expect that when a is *non*-denoting a free semantics had a way of invalidating 70. But this is simply not the case in the semantics sketched above. For 70 is certainly true in all extensions of \mathfrak{A} in which a is denoting, and so it is true in \mathfrak{A} itself. This argument can be easily generalised to any other instance of Specification, and the conclusion is startling: the most natural 'quantificational' development of supervaluational semantics leads not to free but to *classical* logic!

There are in the literature at least four different ways of addressing this problem.³¹ The simplest one is advocated by Woodruff [1971], and consists substantially in mixing the supervaluational approach with the outer domain approach. To get the compromise in question we need to qualify the counterfactual theory of truth in the following way: a sentence containing non-denoting singular terms is true (false) if and only if it would be true (false) in case these terms were denoting, no matter what their denotations were but provided that they were *non-existent objects*. Thus all

³¹Except for the last one, the semantics to be discussed below do not present themselves explicitly as 'ways of addressing this problem'. But this is a good way of perceiving the substance of their contribution.

extensions of a partial structure \mathfrak{A} are to be conceived as all possible ways of adding an outer domain to it, and 70 is easily invalidated. The resulting semantics has a few advantages over the straight outer domain approach, especially because it does not assign a truth-value to *every* sentence containing non-denoting singular terms, and thus in a sense can accommodate for ‘incomplete’ objects, but it shares the most substantial problem of that approach, that is, the metaphysical commitment to non-existents.

A more sophisticated variant of this strategy was proposed (earlier) by Meyer and Lambert [1968]. It still consists substantially in allowing for outer domains, but these domains are thought of as constituted by *words*, not by objects. More precisely, non-denoting singular terms are thought of as themselves contained in what Meyer and Lambert call the *semantical*—not outer—domain of a *nominal interpretation*, and then predicates are distributed in all possible ways over these new ‘entities’ to form the *logical points* over the nominal interpretation. A sentence is true (false) in a nominal interpretation if and only if it is true (false) in all logical points over it, and true (false) in the underlying *real interpretation* (which corresponds to a partial structure) if and only if it is true (false) in all the nominal interpretations which ‘complete’ it.

This approach is certainly suggestive, but insufficiently motivated, and it needs further elaboration before becoming really practicable. The main problem with non-denoting singular terms is that of explaining *why* a sentence like

(71) Pegasus is a horse

has whatever truth-value it has (if any), but just on this question the authors become elusive. 71 is true in a logical point—they say—not because the object Pegasus is a horse there, but because there the word ‘Pegasus’ is a *horse-word*. Again, this is suggestive, but what exactly is implied by being a horse-word? And how are horse-words to be identified if not in terms of the truth of sentences of the form

(72) τ is a horse?

Unless we answer these questions (and the authors don’t), the whole strategy might look circular, and haunted by the ghost of an ultimately ‘conventional’ attitude.

The third attempt at developing the suggestions contained in supervaluational semantics at a ‘deeper’ level of analysis is due to [Skyrms, 1968], and can be described as resulting from *two* distinct applications of those suggestions. Straight supervaluational technique (that is, assignment of arbitrary truth-values to atomic sentences containing non-denoting singular terms, and subsequent construction of the logical product of all the valuations so obtained) is used with truth-functional compounds, whereas with

atomic sentences (and in particular identities) containing non-denoting singular terms Skyrms substantially adopts the counterfactual theory of truth, by constructing the logical product of (the truth-values the sentences in question have in) all the *extensions* of the original structure that assign denotations to the (originally) non-denoting singular terms. Quantified sentences are treated in yet a third way, that is, *in the standard way*: $\forall x\varphi$ is true (or, in Skyrms' terminology, *holds*) in a structure \mathfrak{A} just in case φ holds in \mathfrak{A} for every assignment.

Skyrms' motivations are expressed very clearly. Frege seems to have thought—he says—that all sentences containing non-denoting singular terms should be truth-valueless, but supervaluations add 'an Aristotelian notion of Redemption to the Fregean notion of Sin', in that '*if the logical structure is such that every way of filling up the "holes" makes it true (false), then the sentence is true (false) regardless of the holes*' (his italics). 'Van Fraassen', he continues quite correctly, 'applies this idea only to the extent to which logical structure is determined by the sentential connectives', but 'identity is also a logical constant, and I suggest that we apply this idea to identity statements' (p. 479). Unfortunately, Skyrms stops short of noticing that quantifiers, too, are logical constants, and thus should also contribute to 'determining the logical structure'. As a result, the supervaluational idea is not applied to quantification, and very little of quantified logic is 'redeemed'. In particular, when a and b are non-denoting, not only 70 but also

$$(73) \quad \forall xRxa \rightarrow \forall yRya$$

$$(74) \quad \forall x(Qxa \rightarrow Rxa) \rightarrow (\forall xQxa \rightarrow \forall xRxa)$$

$$(75) \quad Pa \rightarrow \forall xPa$$

$$(76) \quad a = b \rightarrow (\forall xRxa \rightarrow \forall xRxb)$$

$$(77) \quad (\forall xPx \wedge \exists x(x = a)) \rightarrow Pa$$

are truth-valueless.

Skyrms does not propose a formal system adequate to his semantics, nor did anybody else, and in fact David Kaplan has apparently proved that the semantics in question is not recursively axiomatisable. On the other hand, the approach advocated by Bencivenga [1980b; 1981] falls well within the mainstream of the 'standard' free logics we presented in Part II.

To get immediately to the core of Bencivenga's semantics, let us concentrate on the solution he offers for the problem connected with 70. Once more, consider a structure \mathfrak{A} in which a is non-denoting. Suppose that the antecedent of 70 be true in \mathfrak{A} , and consider an extension \mathfrak{A}' of \mathfrak{A} which assigns a denotation to a . Of course, 70 is true in \mathfrak{A}' : if for example we

assume that its consequent be false there, its antecedent will be false, too. The situation can be depicted as follows:

	$\forall xPx$	Pa
\mathfrak{A}	T	$-$
\mathfrak{A}'	F	F

Now Bencivenga points out that, since we are trying to evaluate 70 in \mathfrak{A} , the truth-values this sentence has *in other structures* (such as \mathfrak{A}') are really of no independent interest. The only reason why we refer to \mathfrak{A}' and other extensions is that \mathfrak{A} gives no information about the consequent of 70, and we hope that this lack of information can be remedied by extending \mathfrak{A} . Thus in the case of 69, in which, too, \mathfrak{A} gives no direct information, we are able by extending it to determine the value True (and save the ‘logical law’ of self-identity). However, we must not forget the *purely instrumental* character of the extensions in question, and in particular must not let them prevail over the information \mathfrak{A} *already gives*. What this means—in terms of the above diagram—is that it is perfectly legitimate to take into account the truth-value assigned by \mathfrak{A}' to Pa , since \mathfrak{A} assigns no truth-value to it, but this truth-value should be combined—to the extent to which our evaluation procedure is relative to \mathfrak{A} —with the truth-value \mathfrak{A} —not \mathfrak{A}' —assigns to $\forall xPx$, since in this case \mathfrak{A} already gives a definite response, and one that \mathfrak{A}' does not ‘complete’, but simply contradicts. And of course if truth-values are combined in this way, 70 turns out to be false. In general, then, it is all right to extend \mathfrak{A} in all possible ways and to construct the logical product of all (the valuations relative to) such extensions, but in defining the valuations in question whatever information is provided by \mathfrak{A} must always weigh more than the information provided by the other (auxiliary) sources.

This discussion leads very naturally to the definition of a new technical instrument: the valuation $V_{\mathfrak{A}'(\mathfrak{A})}^{**}$ for an extension (or more precisely, a ‘completion’)³² \mathfrak{A}' of \mathfrak{A} *from the point of view of* \mathfrak{A} . Without entering into the details of this definition, we can say that $V_{\mathfrak{A}'(\mathfrak{A})}^{**}$ is determined by \mathfrak{A} wherever \mathfrak{A} assigns definite truth-values, and is determined by \mathfrak{A}' elsewhere. The supervaluational instrument is then applied to all these $V_{\mathfrak{A}'(\mathfrak{A})}^{**}$ (where \mathfrak{A}' is a completion of \mathfrak{A}), and gives the final truth-values (or lack of truth-values) relative to \mathfrak{A} .

Bencivenga’s semantics does not show any of the asymmetries or oddities of Skyrms’. There are not three different ways of evaluating sentences, and the formal systems introduced in Part II are provably adequate to (suitable versions of) it. Furthermore, this semantics is not committed in any way to outer domains, for exactly the same reasons for which the counterfactual theory of truth in general is not. In this semantics, the truth-value of a

³²A completion of \mathfrak{A} is an extension of \mathfrak{A} which assigns a denotation to *all* singular terms.

sentence in a given structure often depends on the truth-values some parts of the sentences have in other structures (in which the non-denoting singular terms occurring in the sentence are denoting), but this does not add to any structure any new category of objects, even less non-existent objects. There are different structures, and different sets of objects exist in them: this much seems pretty safe to say, and this is all that the semantics in question needs.

Of course, the price must be paid somewhere. Here the price of this metaphysical simplification is paid in terms of a number of *logical* complications, first and foremost the definition of $V_{\mathfrak{A}'(\mathfrak{A})}^{**}$. Some people (for example, [Posy, 1982]) have objected to this definition, mostly because the valuation in question does not correspond to *any* (single) structure: what is true (false) in it is not just what is true (false) in \mathfrak{A} , nor just what is true (false) in \mathfrak{A}' , but some combination of the two. To this objection one might answer that it seems to be a tendency of contemporary philosophical logic to regard structures as themselves constituting a *structure*, rather than just a set, that is, as bearing to one another *relations* that are semantically significant. Kripke's semantics for modal logic is a sign of this tendency, and Bencivenga's doubly determined valuations may be another (perhaps more radical) sign of it.

Before concluding the present section, something must be said about a few formal properties of supervaluations. Such properties have been proved within the context of van Fraassen's original semantics, but the proofs could be easily adapted to most of the variants we presented here.

Let us begin by considering the simple sentence

(78) Pa .

We have already mentioned (and used) the fact that in supervaluational semantics 78 is true in a structure \mathfrak{A} only if

(79) $E!a$

is also true there. And we also noticed that 78 cannot even be *false* in \mathfrak{A} unless 79 is true, or, to put it otherwise, that 79 is a semantical consequence not only of 78 but also of

(80) $\neg Pa$.

There are important historical connections here. Frege [1892] and Strawson [1950; 1952] emphasised the role that relations of *presupposition* play in natural language. According to their characterisation, a sentence φ presupposes a sentence ψ just in case the truth of ψ is a necessary condition for φ to have any truth-value at all. Thus for example

(81) John stopped beating his wife

presupposes both

(82) John has a wife

and

(83) John used to beat his wife.

For, if either 82 or 83 were not true, 81 would be neither true nor false: it would simply represent a ‘spurious’ use of language.

Particularly important are the relations of *existential* presupposition. According to Frege and Strawson, a sentence like

(84) The present King of France is wise

does not *imply*

(85) The present King of France exists

(as Russell claimed), but rather presupposes it, and in general any simple sentence containing singular terms presupposes the existence of denotations for those terms.

Classical semantics cannot express any *non-trivial* relation of presupposition

(and in particular existential presupposition). For in classical semantics every sentence (in every situation) has a truth-value, and thus the only sentences that can be presupposed are the logically true ones. Strawson used this fact as evidence that formal logic is in general inadequate to deal with natural language. On the other hand—as is illustrated by the relations between 78 and 79—supervaluational semantics does allow for non-trivial relations of existential presupposition (since 79 is not logically true in it); hence this semantics constitutes an implicit answer to Strawson’s challenge.³³

It is crucial to the above argument that supervaluational semantics is *non-bivalent*. There are less positive sides to this failure of bivalence. For example, van Fraassen proved that a suitable formal system of free logic is weakly complete with respect to his semantics, but proved also that this system is *not* strongly complete with respect to the same semantics.³⁴ The essence of the proof is as follows. Suppose the system *were* strongly complete. Then, since

(86) $Pa \vDash E!a$,

³³For some developments along these lines, see van Fraassen [1968; 1969]. Apparently, however, the discovery that supervaluations allow for non-trivial presuppositional relations is due to Lambert (see [van Fraassen, 1968, p. 151]).

³⁴For the first result, see [van Fraassen, 1966a], for the second one see [van Fraassen, 1966b].

we would have

$$(87) Pa \vdash E!a,$$

and since the Deduction Theorem is provable for the system in question, we could also conclude that

$$(88) Pa \rightarrow E!a$$

is a theorem in it. But this is impossible, because 88 is not logically true and the system is provably sound.

Once again, it is the failure of bivalence that allows for this result. For when 78 is true, we know from 86 that 79—hence also 88—is true, and when 78 is false 88 is true on purely propositional grounds. But 78 can also be neither true nor false, and in that case 88 has no truth-value either—which explains why it is not logically true.

The result in question leaves two interesting problems open. On the one hand, there is the obvious problem of whether or not a *different* formal system could be strongly complete for supervaluational semantics—that is, whether or not the set of supervaluationally valid arguments is recursively enumerable. On the other hand, we know that in bivalent semantics weak completeness (for a given formal system) plus compactness gives strong completeness (for the same system), but there is no reason to think that this implication should hold when bivalence fails. In particular, the above argument against strong completeness makes no reference to infinite sets of sentences; hence it still leaves the possibility open that the semantics be compact. Whether or not it is, is our second problem.

Woodruff [1984] answered both questions in the negative. The set of supervaluationally valid arguments is not recursively enumerable, and supervaluational semantics is not compact. On the other hand, [Bencivenga, 1983] has shown that the quantifier-free fragment of the semantics *is* compact. This result is interesting because our argument against strong completeness does not depend on quantifiers either; hence in quantifier-free supervaluational semantics it is indeed the case that weak completeness plus compactness does *not* give strong completeness.

IV: Extensions and Connections

11 FREE LOGIC AND CLASSICAL LOGIC

We already know that it is possible to deal with free logic as restricted quantification theory. We saw the semantical side of this when introducing the outer domain approach. A syntactical result along the same line was

proved by [Meyer and Lambert, 1968]. We will give now a brief sketch of their proof.

Let \mathbf{L} be a first-order language with the existence but without the identity symbol. Let \neg and \rightarrow be the only primitive connectives of \mathbf{L} , and \forall its only primitive quantifier. Let \mathbf{L}' be the result of adding a new monadic predicate constant Q to \mathbf{L} , and let a translation $*$ of \mathbf{L} into \mathbf{L}' be defined as follows:

1. $(P\tau_1 \dots \tau_n)^* = P\tau_1 \dots \tau_n$;
2. $(E!\tau)^* = Q\tau$;
3. $(\neg\varphi)^* = \neg(\varphi^*)$;
4. $(\varphi \rightarrow \psi)^* = \varphi^* \rightarrow \psi^*$;
5. $(\forall x\varphi)^* = \forall x(Qx \rightarrow \varphi^*)$.

What Meyer and Lambert showed (in effect) is that a sentence φ of \mathbf{L} is a theorem of **FQCE!** if and only if φ^* is a theorem of classical logic (briefly, a *classical theorem*).

The ‘only if’ part of this biconditional is straightforward. One need only show that the translation of every axiom of **FQCE!** is a classical theorem, and that if φ^* and $(\varphi \rightarrow \psi)^*$ are classical theorems, so is ψ^* .

The ‘if’ part is more complicated. The reason is obvious: classical logic is more powerful than free logic, hence it is not at all trivial that classical logic does not allow one to prove translations more than free logic allows to prove theorems. What we need here is a conservative extension result, showing that the more powerful deductive tools available in classical logic (in particular Specification) do not extend the class of provable sentences *of a certain form*.

First of all, then, we must give a clear *formulation* of the result we need. For this purpose, Meyer and Lambert construct, for every sentence φ^* of \mathbf{L}' , the sentence φ^{*1} , by substituting $E!$ for Q . Given that

$$(89) \quad \forall x(E!x \rightarrow \psi) \leftrightarrow \forall x\psi$$

is provable in **FQCE!**, φ^{*1} is provably equivalent to φ in **FQCE!**. Furthermore, it is obvious that φ^{*1} is a classical theorem just in case φ^* is. In conclusion, our problem reduces to showing that φ^{*1} is a classical theorem only if it is provable in **FQCE!**—and this is the conservative extension result we need.

Of course, if φ^{*1} is a classical theorem, its proof (in classical logic) may well contain instances of Specification. However, Meyer and Lambert want to show that, given the particular form of φ^{*1} , all the instances of Specification that might be needed to prove it are also instances of the weaker schema

$$(90) \quad \forall x(E!x \rightarrow \psi) \rightarrow (E!\tau \rightarrow \psi[\tau/x]),$$

which is provable in **FQCE!**. And this would follow if it were possible to show that, every time a universal quantification $\forall x\chi$ occurs in a proof of φ^{*1} (in classical logic), χ is of the form $E!x \rightarrow \psi$.

That φ^{*1} itself has the above property is trivial, but in an axiomatic system this shows nothing about the structure of the sentences that can be used to prove φ^{*1} . However, a solution is readily at hand. It is enough to reformulate the problem within a Gentzen system for classical logic.³⁵ Since this system has the subformula property, we may be sure that if $\vdash \varphi^{*1}$ is provable in it then universal quantifiers occur in the appropriate contexts *in the whole proof*, hence that the following Gentzen-variant of 90 is all that is ever applied in the proof:

$$\frac{\Gamma, E!\tau \rightarrow \psi[\tau/x] \vdash \Delta}{\Gamma, \forall x(E!x \rightarrow \psi) \vdash \Delta}.$$

This concludes Meyer and Lambert's argument.

An analogous (and simpler) result is available in the opposite direction. Let **L** be as before, except that it contains the identity but not the existence symbol. Consider the *exclusive* free logic **EFQC=** obtained by adding to **FQC=** the axiom-schema

$$(91) \quad \forall x\varphi \rightarrow \exists x\varphi,$$

and the translation $^+$ of **L** into **L** defined as follows:

1. $\varphi^+ = (\exists x(x = a_1) \wedge \dots \wedge \exists x(x = a_n)) \rightarrow \varphi$, where a_1, \dots, a_n are all the individual constants occurring in φ .

It is easy to show that a sentence φ is a classical theorem if and only if φ^+ is a theorem of **EFQC=**.

For more formal connections between free logics and classical logic, the reader may consult [Trew, 1970]. We prefer to close the present section by discussing an opinion that challenges the most common view of the relations between these two (kinds of) logics, a view that we have endorsed here.

It is quite natural to think of free logics as *alternatives* to classical logic.³⁶ After all, the people who created the subject were reacting against principles of classical logic (such as Specification) that they considered *wrong*. Van Fraassen [1969], however, would rather think of a free logic as an *extension* of a classical logic, obtained by adding to it a theory of singular terms that was simply not available in the classical framework.

³⁵To be precise, Meyer and Lambert do not refer to a Gentzen system but to a variant of such a system proposed by Anderson and Belnap. But the essence of their argument is the same as given here.

³⁶In the case of minimal free logics without $E!$, these alternatives qualify as *fragments* of classical logic.

The *rationale* of van Fraassen's position is as follows. We have already mentioned the fact that classical logic may be formalised so as to exclude both open theorems and individual constants. Quine [1940], for example, proceeds in this way. And Quine's system—which basically has no place for singular terms—is a *subsystem* of some free logics, for example of the pure exclusive free logic **EFQC**, which bears to **FQC** the same relation **EFQCE!** bears to **FQCE!**.³⁷

Of course, there are formalisations of classical logic that do account for singular terms, for example by admitting individual constants, and they are subsystems of *no* free logic whatsoever, but in van Fraassen's opinion these formalisations were adopted *faute de mieux*. In absence of an adequate theory of singular terms, classical logicians extended to these terms the principles of their logic of bound variables (or 'bound' logic). The extension was faulty, but this fault did not touch the substantial validity of classical logic as a bound logic. Free logics on the other hand set things right, restricting classical logic to its proper scope and supplying a specific treatment of singular terms (indeed, several such treatments).

In assessing this argument, it is of fundamental importance to notice that it operates at three different levels. At bottom, there is the simple fact that free logics handle quantifiers and bound variables in the standard (referential) way. As we said a number of times, free logics confer existential import to quantifiers, and accept Quine's *dictum* that to be is to be a value of a bound variable. Next, there is the fact that *it is possible* to construe classical logic as a bound logic, and thus make it a subsystem of some free logic. But finally, there is also the suggestion that *it is better* to construe classical logic in this way, that such a construal is more likely to 'capture the spirit' of both classical and free logics, and that any other position on the matter would be adopted *faute de mieux*.

This last is basically a value judgement, and as such more prescriptive than descriptive in nature. Its supporters might claim that its adoption would allow one to maintain a conservative attitude with respect to logic, and possibly remove some psychological obstacles to accepting free logics. I would rather insist that such a claim of conservatism does very little historical justice to both classical and free logicians. For classical logicians—*pace* van Fraassen—did have their own views about singular terms, views that *they* at least considered adequate and that free logicians did very little to preserve.

³⁷Of course, Quine's system is also a subsystem of **EFQCE!**, but its relation to **EFQC** is more interesting, because they have the same language.

12 DESCRIPTIONS

From the very beginning, free logicians were concerned with definite descriptions. There are at least two reasons for this interest. The first one is historical: Russell's description theory was one of the most important instruments in the hands of classical logicians to deal with (alleged) non-denoting singular terms, hence an important test for free logics was whether or not they were able to handle the same subject in a more satisfactory way. The second reason is theoretical: the necessity of a free logics is more apparent the more inevitable the presence of non-denoting singular terms seems to be, and certainly descriptions (if they are considered singular terms) make it very difficult to deny that there are non-denoting singular terms. You may think that 'Pegasus' does not denote, but no major problem would follow (apart of course from a conflict with your intuitions) if you were to decide instead that it does. On the other hand, if you decide that 'the winged horse' is denoting, this will appear to contradict the truth of

(92) No (existing) horse is winged,

and even worse consequences will follow if you decide that 'the round square' or 'the entity different from itself' are denoting.

The basic principles of Russell's description theory—as given for example in Whitehead and Russell [1910]—were the two definitions³⁸

(93) $E!ix\varphi =_{df} \exists y(\forall x(\varphi \leftrightarrow x = y))$

(94) $\psi[ix\varphi/y] =_{df} \exists y(\forall x(\varphi \leftrightarrow x = y) \wedge \psi)$.

However, free logicians usually regard definite descriptions as genuine singular terms; hence they are not interested in the elimination procedures connected with definitions like 93–94. Rather, they are interested in the acceptability of the corresponding biconditionals

(95) $E!ix\varphi \leftrightarrow \exists y(\forall x(\varphi \leftrightarrow x = y))$

(96) $\psi[ix\varphi/y] \leftrightarrow \exists y(\forall x(\varphi \leftrightarrow x = y) \wedge \psi)$.

Now free logicians never questioned 95; they usually regarded its right-hand member as giving both a necessary and a sufficient condition for the existence of a denotation of $ix\varphi$. Similarly, one half of 96, that is,

(97) $\exists y(\forall x(\varphi \leftrightarrow x = y) \wedge \psi) \rightarrow \psi[ix\varphi/y]$

³⁸For precision's sake, it must be noted that the two Russellian definitions contained scope operators. But these operators play practically no role in free description theories (the only exception I know of is [Scales, 1969]): hence to simplify things we will disregard them here. Also, in this paragraph we will always assume that y is free in ψ .

is universally accepted in free logic: *denoting* definite descriptions appear to everybody to conform to Russell's analysis. What is in question is the other half of 96, that is,

$$(98) \ \psi[\iota x\varphi/y] \rightarrow \exists y(\forall x(\varphi \leftrightarrow x = y) \wedge \psi),$$

and the main reason why it is in question is that it implies

$$(99) \ \psi[\iota x\varphi/y] \rightarrow E!\iota x\varphi.$$

For 99 forces one to consider false most sentences containing non-denoting descriptions,³⁹ including such sentences as

$$(100) \ \iota x\varphi = \iota x\varphi,$$

which most free logicians regard as logically true.

The first free description theory was proposed by [Leonard, 1956], but in a second-order modal language—which explains why it did not generate much response in the literature. A more accessible suggestion came from [Hintikka, 1959b].

Hintikka's theory is based on a single principle, the biconditional

$$(101) \ \tau = \iota x\varphi \leftrightarrow (\varphi[\tau/x] \wedge \forall x(\varphi \rightarrow x = \tau)).$$

101 implies both 95 and 97, but it also has a number of unwelcome consequences. In particular, [Lambert, 1962] showed that

$$(102) \ \varphi[\iota x\varphi/x]$$

follows from 101 and 100, and some instances of 102, such as

$$(103) \ P(\iota x(Px \wedge \neg Px)) \wedge \neg P(\iota x(Px \wedge \neg Px)),$$

are contradictory sentences!

Lambert's own solution of this problem consists in weakening Hintikka's theory, by substituting

$$(104) \ \forall y(y = \iota x\varphi \leftrightarrow (\varphi[y/x] \wedge \forall x(\varphi \rightarrow x = y)))$$

for 101. Now in a free logic assuming 104 as an axiom-schema is equivalent to assuming

$$(105) \ \underline{E!\iota x\varphi \rightarrow (\tau = \iota x\varphi \leftrightarrow (\varphi[\tau/x] \wedge \forall x(\varphi \rightarrow x = \tau)))},$$

³⁹Again, we must notice that unless we adopt scope operators or deny to descriptions the status of singular terms (and Russell did both) 99 leads to downright inconsistency. But the main point of the argument is independent of this, since it can be made in connection with such simple sentences as 100. So once more we need not enter into unnecessary complications.

which shows that Lambert's theory—to be called **FD**—has something specific to say about descriptions⁴⁰ only to the extent to which they are denoting. For this reason, several authors (including Lambert, van Fraassen and Scott)⁴¹ have considered **FD** a *minimal* free description theory, the common core as it were of all such theories.

The intuitive idea behind this characterisation is that, again, everybody agrees on how to treat denoting descriptions, and **FD** says nothing (specific) beyond that. Disagreements will arise among free description theorists only with respect to non-denoting descriptions and in this area a large number of alternatives are possible, which in general require the addition of further schemata to **FD**. Lambert [1962] mentions one of these alternatives, that is, the theory (to be called **FD**₁) which results from adding to **FD** the schema

$$(106) \quad \tau = \iota x(x = \tau),$$

and [Lambert, 1964] a different one, obtained by replacing 104 with

$$(107) \quad \iota x\varphi = \tau \leftrightarrow \forall y(\tau = y \leftrightarrow (\varphi[y/x] \wedge \forall x(\varphi \rightarrow x = y))),$$

from which however 104 is derivable.

This last theory—to be called **FD**'₂—is an interesting one. For it turns out that it is equivalent to the theory **FD**₂ which is obtained by adding to **FQCE**! = 104 and the principle 41 on p. 166—that is, by combining minimal description theory with Scott's free logic.

Van Fraassen and Lambert [1967] make some interesting remarks about the philosophical significance of the differences between all these description theories (which remarks—in view of the above equivalence result—apply *mutatis mutandis* to Scott's free logic). **FD**₂ (or **FD**'₂)—they say—may be the right theory for some specific (and limited) purposes. For example, in the course of reconstructing mathematics non-denoting descriptions may well be regarded as 'don't cares', and a compromise between free logic and the chosen object theory may be the most efficient way to handle them. On the other hand, if we are interested in natural language, **FD**₂ is going to be too strong. To give just one example, such a theory would allow us to derive

$$(108) \quad \text{John avoided the explosion of the White House in 1965,}$$

from

$$(109) \quad \text{John avoided the accident at the corner of High Street and Pleasant Street,}$$

⁴⁰That is, something that does not follow simply from treating descriptions as genuine singular terms, and thus extending to them the laws of (free) quantification and identity theory.

⁴¹See [van Fraassen and Lambert, 1967; Scott, 1970; Lambert, 1972].

and the fact that there was no accident at that corner or any explosion of the White House in 1965. For these other, more ‘philosophical’ purposes, a weaker theory like **FD** or **FD**₁ might be preferred.

The ‘liberality’ of this position is certainly attractive; however, there are problems with it. On the one hand, if **FD**₂ or **FD**₂’ are recommended on pragmatic grounds, to people who don’t care much about non-denoting descriptions, how can they be preferred to the original chosen object theory—which is certainly simpler and thus even more recommendable from a pragmatic point of view? On the other hand, if we reject **FD**₂ and move to weaker theories, how are we going to choose among them? The intuitive acceptability of ‘laws’ like 106 by itself won’t do, for we need a way of checking our intuitions on the matter, and even more importantly we need some kind of evidence that we have found *all* the relevant laws.

The problem with van Fraassen and Lambert’s approach is that they do not give a semantical analysis of their theories, except for the minimal **FD**. They do present semantics for all these theories, and completeness theorems for them, but such ‘semantics’ do little more than duplicating the theories, and the arbitrary selections that seem to be at their foundations. Thus for example the fundamental unit of the ‘semantics’ for **FD**₁—the **FD**₁-structure—is defined essentially as an **FD**-structure that verifies all instances of 106, and such an approach certainly says very little about *why* 106 is a logical law, and which other laws (if any) should be accepted. This leaves us with the semantics for **FD**, but **FD** is a very weak theory, too weak even for its author Lambert.⁴²

The above is substantially the same criticism already raised against van Fraassen’s semantics for (free) quantification and identity theory. Just as in that case (say) self-identity was validated by *fiat*, so it happens now for 106. Thus we may expect to find here the same kinds of developments of van Fraassen’s approach that we found there. And indeed, at least one such development is available, by Bencivenga [1978b; 1980c].

Once again, Bencivenga’s starting point is the counterfactual theory of truth: a sentence containing non-denoting singular terms is true (false) if and only if it would be true (false) in case these terms were denoting.

However, a major complication arises in applying this theory to descriptions, in that it is not always possible for a description to denote, or for a set of descriptions to denote simultaneously. Thus

$$(110) \quad \iota x(Px \wedge \neg Px)$$

will never have a denotation (if not in some variant of the chosen object theory, which Bencivenga is not willing to accept), and

$$(111) \quad \iota xPx$$

⁴²In this regard, see the conclusion of [Lambert, 1962].

$$(112) \quad \iota x \neg Px$$

$$(113) \quad \iota x(x = x),$$

though being all ‘consistent’ descriptions (and having denotations *somewhere*) will never have denotations *together*.

With respect to sentences containing either 110 or all of 111–113, Bencivenga faces a choice: he can either make them all vacuously true (or perhaps false) or modify his approach, for example by requiring as an additional condition for the truth (or falsity) of sentences containing non-denoting descriptions that there be at least one structure in which all such descriptions are denoting. He chooses the second route, and this choice gives rise to further complications. For now every sentence containing (say) 110, even such a sentence as

$$(114) \quad \iota x(Px \wedge \neg Px) = \iota x(Px \wedge \neg Px),$$

whose logical truth seems not to depend on a logical analysis of descriptions, becomes ‘essentially truth-valueless’—that is, does never receive a truth-value.

Bencivenga’s assessment of the situation is that free quantification and identity theories, though successful in removing the existential assumptions of classical logic, still carry with them some weaker assumptions, of possibility of existence. Such assumptions, however, are contradicted by (some) descriptions, hence our quantificational logic should be modified if we want to allow for a natural extension of it to descriptions. Whether we will actually make the modification in question or instead worry about assumptions of possibility where they really matter (that is, in languages with descriptions) will ultimately be decided—Bencivenga thinks—on practical grounds, and certainly relevant to these practical considerations is his proof that the set of logically true sentences of his (possibility-free) semantics for descriptions is not recursively enumerable.

So much for the extensions to descriptions of the supervaluational approach. Analogous extensions of the outer domain approach and of the ‘conventional’ approach were proposed by [Grandy, 1972] and by [Burge, 1974], respectively. Since Grandy’s development is less immediate than Burge’s, and contains at least one new theoretical notion, we will conclude the present section by briefly describing it.

The novelty of Grandy’s semantics is a function π , defined on all subsets of the union $A \cup A'$ of the inner and the outer domain of an LT-structure and with values in $A \cup A'$. By definition, $\pi(S) \in A$ if and only if $S \cap A = \pi(S)$, that is, the value of π for a given subset S of $A \cup A'$ ‘exists’ just in case it is the only existing member of S . In a *Grandy structure*, defined as an ordered 4-tuple $\langle A, A', I, \pi \rangle$, the denotation of a description $\iota x \varphi$ is the value π has for the subset of $A \cup A'$ constituted by all objects satisfying φ .

Grandy's semantics does not force one to identify all non-existents, as for example Scott's does. Thus, in intuitive terms, if π assigns different values to the set of winged horses and the set of golden mountains, the sentence

(115) The winged horse = the golden mountain

turns out false. On the other hand, however, if

(116) $\varphi[\tau/x] \leftrightarrow \psi[\tau/x]$

is *logically true*, then in every Grandy structure φ and ψ are satisfied by the same objects; hence

(117) $\imath x\varphi = \imath x\psi$

is logically true, too. This is certainly an asset of Grandy's approach: in it one can validate in a natural way such schemata as

(118) $\imath x\varphi = \imath x(\varphi \wedge \psi)$,

which are certainly as 'intuitive' as (say) 106 was and which in van Fraassen-Lambert's framework would require the addition of further *ad hoc* clauses. From a proof-theoretical point of view, the approach in question is characterised by the rule

(119)
$$\frac{\vdash \chi \rightarrow (\varphi[\tau/x] \leftrightarrow \psi[\tau/x])}{\vdash \chi \rightarrow \imath x\varphi = \imath x\psi}, \text{ if } \tau \text{ does not occur in } \chi,$$

which allows for a simple proof of 118 and the like.

ACKNOWLEDGEMENTS

Work for the completion of this paper was partly supported by a Faculty Fellowship of the School of Humanities, University of California at Irvine. Thanks are due to Nuel Belnap, Gerald Charlwood, Wilfrid Hodges, Karel Lambert and Brian Skyrms for comments on earlier drafts of the paper.

MORE FREE LOGIC

By a *free* logic is generally meant a variant of classical first-order logic in which constant terms may, under interpretation, fail to refer to individuals in the domain D over which the bound variables range, either because they do not refer at all or because they refer to individuals outside D . If D is identified with what is assumed by the given interpretation to exist, in accord with *Quine's dictum* that “to be is to be the value of a [bound] variable,”¹ then a free variation on classical semantics does not require that all constant terms refer to existents, and in this sense such terms lack existential import.

Classical semantics treats free variables like constants, at least in the quantifier clause of the valuation rules. When we stipulate that $\exists xA$ is true iff A is true for some assignment of a value $\alpha(x)$ in D to x , we are treating x at its free occurrences in A as a constant that refers to $\alpha(x)$. In free semantics, free variables are also generally treated like constants, which means that they need not be assigned values in D ; thus free variables and variable terms (such as $x + y$ or $1/x$) constructed from them also lack existential import. However, when reckoning the truth of $\exists xA$ in terms of the truth of A for assignments of values to x , we consider only assignments α for which $\alpha(x) \in D$. Thus, although neither constant nor variable terms need refer to individuals in D , free semantics honors Quine's dictum.²

In classical semantics, free variables have existential import because D is non-empty: there is always something in D for x to be assigned by α . Variants of classical semantics in which this requirement is relaxed so that D may be empty are said to be *inclusive*. A semantics that is free and inclusive is said to be *universally* free: the range of the bound variables may be empty, and even if it is not, neither constant nor variable terms have existential import.

This survey of free logic will begin by considering its motivation, then move to reviewing various kinds of free semantics and the syntactic proof systems designed to capture the forthcoming notions of logical truth or logical consequence, and conclude by describing some applications of free logics, notably free description theory. As this summary may suggest, my emphasis throughout will be on semantics. The account is self-contained

¹Quine [1948, p. 15]. That Quine means *bound* variables here is clear from his earlier statement [p. 13] that “a theory is committed to those and only those entities to which the bound variables of the theory must be capable of referring in order for the affirmations made in the theory to be true.”

²Compare Bencivenga's [1986, p. 375] characterization: “A free logic is a formal system of quantification theory, with or without identity, which allows for some singular terms in some circumstances to be thought of as denoting no existing object, and in which quantifiers are invariably thought of as having existential import.”

and does not presuppose familiarity with [Bencivenga, 1986], reproduced in this volume. There is new material on motivation, applications, and neutral free semantics, while areas of overlap differ in detail and emphasis. Semantic options are laid out in greater detail, as are free description theories built upon them, but I pay less attention to the history of ideas.

1 QUICK REVIEW OF CLASSICAL FIRST-ORDER LOGIC

Partly to settle notation and terminology, and partly because free logics are variants of it, let us first quickly review classical first-order logic with identity, which we may take to be framed in formal first-order languages L .

The logical vocabulary of L includes the identity operator $=$, plus an adequate set of quantifiers and truth-functional operators. Let us assume they are the universal quantifier \forall , negation \neg , and material conditional \rightarrow . The non-logical vocabulary of L includes (individual) variables, plus perhaps constants, (k -place) function-names, and (k -place) predicates. We need not specify these symbols, which will vary with L ; its sentences are to represent the logical forms of certain sentences of natural language, and its non-logical vocabulary will be chosen accordingly. Many formulations of free logic employ a 1-place existence predicate E or $E!$, but such a predicate can generally be defined in terms of identity,³ so we need not include it in the non-logical vocabulary. The proof method of L will require an unbounded list of variables or special constants.

After defining *terms* as (1) variables, (2) names, and (3) complex terms $ft_1 \dots t_k$, where the t_i are terms and f is a k -place function-name, the formation rules of L identify *formulae* as (4) subject-predicate formulae $Pt_1 \dots t_k$, where the t_i are terms and P is a k -place predicate, (5) identities $s = t$, where s and t are terms, (6) negations $\neg A$, where A is a formula, (7) conditionals $(A \rightarrow B)$, where A and B are formulae, and (8) universals $\forall xA$, where x is a variable and A is a formula.⁴ Identities and subject-predicate formulae are *atomic*; atomic formulae and their negations are *elementary*.

Subsequently, I shall use the following syntactical variables, with or without subscript: for variables: x , y , and z ; for constants: a , b , and c ; for function-names: f ; for predicates: P ; for terms: s and t ; for formulae: A , B , and C ; for sets of formulae: X . Conjunctions $(A \& B)$, disjunctions $(A \vee B)$, biconditionals $(A \leftrightarrow B)$, and existentials $\exists xA$ may be defined as usual in terms of \neg , \rightarrow , and \forall . $s \neq t$ abbreviates $\neg s = t$. The outermost parentheses in conditionals, conjunctions, disjunctions, and biconditionals standing alone will be omitted. $ft_1 \dots t_k$ and $Pt_1 \dots t_k$ will be used with

³For exceptions, see [Garson, 1991], discussed below in Section 5.3, and [Gumb, 1998].

⁴To avoid the notational clutter that attends the use of single- and quasi-quotation, I shall generally follow Church [1956] in using symbols of L as names for themselves and juxtaposition for juxtaposition.

the assumption that f and P are k -place; where necessary, commas and parentheses will disambiguate expressions, as in $Pf(x, y)$, and may also be inserted to enhance readability, as in $\exists x(x = fx)$.

An occurrence of a term t in a formula A is *bound* in A provided it is an occurrence in a part $\forall xB$ of A , where x occurs in t ; an occurrence of t in A is *free* if it is not bound. The *bound (free)* variables of A are those with a bound (free) occurrence in A . A *sentence* is a formula without free variables. $A(x_1, \dots, x_k/t_1, \dots, t_k)$ is the result of simultaneously replacing the x_i at each free occurrence in A by t_i , having (if necessary) first made such occurrences *free for* t_i in A : if a free occurrence of x_i in A is in a part $\forall yB$, where y occurs in t_i , replace each occurrence of y in $\forall yB$ by the first variable that occurs in neither A nor any of the t_j ; relabel the result ' A ' and repeat until there are no such occurrences. I shall write $A(x_1, \dots, x_k)$ for A and $A(t_1, \dots, t_k)$ for $A(x_1, \dots, x_k/t_1, \dots, t_k)$. $\exists!xA$ or $\exists!xA(x)$ abbreviates $\exists x\forall y(A(x/y) \leftrightarrow y = x)$, where y is not x . In writing $\exists x(x = t)$, I assume that x does not occur in t . The *universal closure* $\forall A$ of A is $\forall x_1 \dots \forall x_k A$, where the free variables of A are x_1, \dots, x_k .

An *interpretation* I of L is a pair $\langle D, d \rangle$, where D is a set and d is a denotation function defined on the constants, function-names, and predicates of L , such that:

- i1. D is non-empty;
- i2. $d(a) \in D$;
- i3. If f is k -place, $d(f)$ is a total k -ary function $D \rightarrow D$.
- i4. If P is k -place, $d(P)$ is a k -ary relation in D .

An *assignment* α is a function that assigns individuals $\alpha(x)$ in D to the variables. An x -variant of α is an assignment that differs from α at most at x .

Under I and α , terms refer to individuals of D according to the reference rules:

- r1. x refers to $\alpha(x)$.
- r2. a refers to $d(a)$
- r3. $ft_1 \dots t_k$ refers to $d(f)(\alpha_1, \dots, \alpha_k)$, if t_i refers to α_i .

Under I and α , formulae are true or false (and false if not true) according to the valuation rules:

- v1. $Pt_1 \dots t_k$ is true iff $\langle \alpha_1, \dots, \alpha_k \rangle \in I(P)$, if t_i refers to α_i .
- v2. If s refers to α and t to β , then $s = t$ is true iff α is β .

v3. $\neg A$ is true iff A is false.

v4. $A \rightarrow B$ is false iff A is true and B is false.

v5. $\forall xA$ is false iff A is false for some x -variant of α .⁵

Since the referents of terms without variables and the truth-values of sentences are independent of α , I shall speak of referents and truth-values under I in such cases.

Logical relations and properties are defined as usual in terms of the totality of interpretations: A is a *logical consequence* of X ($X \models A$) iff there is no interpretation and assignment under which all the X -formulae are true and A is false; X is *satisfiable* iff there is some interpretation and assignment under which all the X -formulae are true; A is *logically true (false)* iff A is true (false) under each interpretation and assignment; A and B are *logically equivalent* iff, under each interpretation and assignment, A is true iff B is true. $A_1, \dots, A_k \models B$ means: $\{A_1, \dots, A_k\} \models B$. $X, A \models B$ means: $X \cup \{A\} \models B$. $X \not\models A$ means: not $X \models A$.

These definitions embody what Kleene [1967, p. 103] terms the *conditional* reading of free variables: free variables are treated by r1 as names of D -individuals. By contrast, the *generality* reading treats free variables as if they were universally quantified. It may be captured by stipulating that A is true (false) under I iff A is true (false) under I and α for each α . We can then drop “and assignment” from the above definitions. However, we end up with weaker notions of logical consequence and logical equivalence (and a stronger notion of satisfiability). For the logical consequence relation \models_g , we have $X \models_g A$ iff $\forall X \models \forall A$, where $\forall X = \{\forall B : B \in X\}$, so that $X \models_g A$ if $X \models A$ but not conversely (e.g., $Px \models_g \forall xPx$, but $Px \not\models \forall xPx$). If X is a set of sentences, the two consequence relations coincide, since $X \models A$ iff $X \models \forall A$ and here we have $\forall X = X$.

From the semantic perspective assumed here, the aim of proof theory is to provide syntactic characterizations of logical properties and relations, which are defined in semantic terms. In particular, we want a syntactic notion of *proof from hypotheses* that captures the logical consequence relation: A is provable from hypotheses in X ($X \vdash A$) iff A is a logical consequence of X ($X \models A$), at least if X is a set of sentences. A proof system with this property is said to be *strongly complete*. A proof system in which A is

⁵Most presentations of free logic give a substitutional account of quantification, on which v5 would read instead: $\forall xA(x)$ is false iff $A(a)$ is false for some constant a . If $\forall x$ is to have the force of ‘for all individuals x ’, every individual in D must be named by some constant or other. If D is uncountable, the terms and formulae of L will then be undecidable. This awkward result may be avoided by proving, *via* the Löwenheim-Skolem theorem, that interpretations may be restricted to countable universes without altering logical consequence relations, so that no more than a countable infinity of constants need be assumed. By contrast, the objectual account of quantification given in v5 does not require an elaborate justification.

provable (from no hypotheses) iff A is logically true ($\vdash A$ iff $\models A$) is *weakly complete*. If detachment or *modus ponens*

MP $A, A \rightarrow B \vdash B$

holds, and the deduction theorem or conditional proof

CP $X \vdash A \rightarrow B$ provided $X, A \vdash B$

holds for sentences A , then weak completeness is equivalent to: $X \vdash A$ iff $X \models A$ for *finite* sets X of sentences.

Many strongly complete systems in a variety of styles are known for classical first-order semantics. It will be useful to give one that can be modified in simple ways to capture logical consequence for at least some free variations on classical semantics. The simplest proof systems to describe are Hilbert-style systems, which specify logical axioms and rules of inference, and define a proof of A from hypotheses X as a finite sequence $\langle A_1, \dots, A_k \rangle$ such that $A_k = A$ and each A_i is either a member of X , or a logical axiom, or is derived from previous formulae in the sequence by a rule of inference. Unlike natural deduction systems, in which some inference rules (such as CP) are conditional, those of a Hilbert-style system are (like MP) categorical.

Since the propositional part of the system does not matter here, we may adopt the simple inference rule

T $A_1, \dots, A_k \vdash B$

if B is a tautological consequence of $\{A_1, \dots, A_k\}$, that is, there is no assignment of truth-values to universals and atomic formulae for which each A_i is true and B is false in virtue of rules v3 and v4.

The quantifier rule and axioms are as in [Church, 1956, p. 172]; the rule is generalization:

UG $A \vdash \forall xA$

and the axiom schemas are distribution and specification:

A1 $\forall x(A \rightarrow B) \rightarrow (A \rightarrow \forall xB)$, if x is not free in A

A2 $\forall xA(x) \rightarrow A(t)$

Finally, we have the identity axiom schemas:

A3 $x = x$

A4 $x = y \rightarrow (A(x) \rightarrow A(y))$, where A is atomic.

Let us agree that $A(x)$ is $A(z/x)$ and $A(y)$ is $A(z/y)$, so that $A(y)$ results from $A(x)$ by replacing x at some occurrences by y .

Let us call this system CL. Like most Hilbert-style systems, CL is sound with respect to \models_g but not \models : if $X \vdash A$, then $X \models_g A$ but not necessarily $X \models A$ (consider UG). The limitation is immaterial if X consists of sentences, as it will if L is used to represent arguments in some natural language.

2 MOTIVATIONS FOR FREE LOGIC

The motivations for free logic may be grouped under four headings. (1) Classical first-order semantics embodies existence assumptions that can produce weird results and constrain what can be done to avoid them. Accordingly, (2) certain philosophical doctrines can be expressed in first-order languages, classically conceived, only with difficulty and in ways that will seem artificial. Then there are general considerations of logical form: (3) if logical form captures truth-conditions in the sense of determining correct truth-values in all possible situations, then logical semantics must be universally free. Finally, for those who remain unconvinced, there is a pragmatic argument: (4) the representation of logical moves in a classical system can often be considerably simplified if we *pretend* that certain expressions are terms that need not refer to any existent, either because they do not refer at all or because they refer to *pretend* objects.

2.1 Classical Existence Assumptions

The existence assumptions built into classical first-order semantics are implicit in i1–i3: D is non-empty, constants refer to individuals of D , and function-names refer to total functions $D \rightarrow D$. These assumptions constrain the meaning of logical forms. As implicit premises, they permit some surprising inferences. While such unwanted conclusions can be avoided, the ways of doing so, constrained as they are by these assumptions, may seem artificial and too complex.⁶ Let us consider the existence assumptions in turn.

⁶Various free logics can be represented as classical first-order theories. Let L_f be the first-order language of a free system FL in which free logical truth has been characterized in terms of Hilbert-style provability from logical axioms by logical rules of inference: $\models A$ iff $\vdash_{FL} A$; and let L_c result from L_f by adding a 1-place predicate E . Trew [1970] shows the dedicated reader how to (1) translate sentences A of L_f into sentences $tr(A)$ of L_c and, for each of a variety of systems FL, how to (2) write axioms $Ax(FL)$ that classically constrain the interpretation of E , so that $\vdash_{FL} A$ iff $Ax(FL) \vdash_{CL} tr(A)$, *i.e.*, iff $tr(A)$ is classically provable from $Ax(FL)$.

- (a) Existential conclusions may be validly drawn from premises that are not overtly existential, because the assumption of a non-empty universe operates as an implicit existential premise. For example, ‘A person is good iff she loves everyone, so some person loves all good persons’ is valid when assigned the simple form

$$\frac{\forall x(Gx \leftrightarrow \forall yLxy)}{\exists x\forall y(Gy \rightarrow Lxy)}$$

For if there is a good person x , then x loves everyone, hence all good persons. If there is no good person, let x be anybody: x loves all good persons (at least on the standard no-counterexample interpretation of ‘all’), so someone loves all good persons. The crucial step is the passage from ‘ $\forall y(Gy \rightarrow Lxy)$ is true of any x ’ to ‘ $\forall y(Gy \rightarrow Lxy)$ is true of some x ’, a move licensed (albeit *sotto voce*) by the assumption that the range of x is non-empty.⁷

These awkward results can be sidestepped by complicating logical form: take the variables to range, not over persons but over some wider class, and relativize the quantifiers to the subclass of persons by introducing an appropriate 1-place predicate. The resulting argument

$$\frac{\forall x(Px \rightarrow (Gx \leftrightarrow \forall y(Py \rightarrow Lxy)))}{\exists x(Px \& \forall y(Py \rightarrow (Gy \rightarrow Lxy)))}$$

is invalid, since the premise is true and the conclusion false when P is assigned the empty extension, which of course is permitted in classical semantics.

Constants and function-names complicate the transformation. To preserve the validity of ‘Pope John-Paul II is nobody’s spouse, so he isn’t his own spouse’, we will need to add a premise Pj to do the work of i2 and a premise $\forall x(Px \rightarrow PSx)$ to do the work of i3:

$$\frac{\begin{array}{c} \neg\exists x(Px \& j = Sx) \\ \forall x(Px \rightarrow PSx) \\ Pj \end{array}}{j \neq Sj}$$

⁷A more mathematical example is the generation of an empty set, apparently *ex nihilo*, in some ZF-formulations of pure set theory, *e.g.* [Shoenfield, 1967]: $\exists y\forall z(z \notin y)$ follows from the subset axiom in the form $\forall x\exists y\forall z(z \in y \leftrightarrow (z \in x \& A(z)))$. For let x be a set; by the subset axiom, there is a set y whose members are the sets z such that $z \in x$ and $z \neq z$; since no set z is such that $z \neq z$, there are no such sets and y has no members; so there is a set with no members. What is disturbing here is that the subset axiom has an essentially *conditional* form: if x exists, so does any describable subset of x . How can it yield a *categorical* existence claim? The answer is that classical semantics guarantees that the range of x is non-empty, so some set will exist.

If P is assigned the empty extension, then Pj will be false, but for a reason that will strike some people as incorrect: j refers to something not in the extension of P . If there were no people, ‘Pope John-Paul II is a person’ might be false, but not because ‘Pope John-Paul II’ refers to something (zero, say) which is not in the now empty extension of ‘person’; ‘Pope John-Paul II’ doesn’t refer at all in this situation. At best, we have a semantic proxy for failure of reference that delivers the right truth-values — at best because one might want to hold that ‘Pope John-Paul II is a person’ is neither true nor false when ‘Pope John Paul II’ does not refer.

None of these manoeuvres will alter the validity of such arguments as ‘Everything is self-identical, so something is’

$$\frac{\forall x(x = x)}{\exists x(x = x)}$$

since the range of x is non-empty. And it might be objected that the account of logical possibility given by classical semantics is defective, for surely the range of the variables *could* be empty.

- (b) i2 requires that constants refer to something in the range of the variables, which permits quick proofs of the existence of God (or Grendel, or anything you like), since $\exists x(x = g)$ is logically true if g refers to something in the range of x . If you feel bad about doing so little work for such large results, you can give a short CL-proof:

- | | |
|---|----------|
| 1. $x = x$ | A3 |
| 2. $\forall x(x = x)$ | UG(1) |
| 3. $\forall x(x = x) \rightarrow g = g$ | A2 |
| 4. $\forall x(x \neq g) \rightarrow g \neq g$ | A2 |
| 5. $\exists x(x = g)$ | T(2,3,4) |

The instances of A2 are logically true because g must refer to something in the range of x .

The standard Russellian fix for these problems is to replace constants g that may not refer by predicate constructions: find a *singular* predicate G true of at most one thing, which you’d be willing to label g if there were such a thing (in the present case, perhaps Anselm’s ‘nothing greater than x can be or be conceived’ will do) and replace atomic parts $A(g)$ by $\exists y(\forall z(Gz \leftrightarrow y = z) \& A(y))$, where y is not free in A . Then the existence claim $\exists x(x = g)$ becomes $\exists x\exists y(\forall z(Gz \leftrightarrow y = z) \& x = y)$, which is obviously not logically true.

Alternatively, add $\forall x\forall y((Gx \& Gy) \rightarrow x = y)$ as a premise (an axiom) to constrain interpretations of G , and replace atomic parts $A(g)$ by $\exists y(Gy \& A(y))$. This will transform the existence claim $\exists x(x = g)$ into $\exists x\exists y(Gy \& x = y)$, and the issue of its logical truth into that of the validity of

$$\frac{\forall x\forall y((Gx \& Gy) \rightarrow x = y)}{\exists x\exists y(Gy \& x = y)}$$

which is obviously invalid. This procedure will make atomic sentences $A(g)$ with non-referring terms g false, since the predicate G will be true of nothing. If you think that some subject-predicate sentences with non-referring subjects — such as ‘Grendel was slain’ — are true, you can use the replacement $\forall y(Gy \rightarrow A(y))$ for them, as Mendelson [1989, p. 613] observes. But something seems to be missing here. The reason for the truth of ‘Grendel was slain’ and the falsity of ‘Grendel was pink’ is really the same: whatever singular predicate we find for Grendel is true of nothing. Moreover, if you think that some subject-predicate sentences with non-referring subjects, such as van Fraassen’s [1966, p. 82] ‘Pegasus has a white hind leg’, are neither true nor false, you will not be happy with Russell’s way of dealing with them, since classical semantics is bivalent: any sentence is true or false.

- (c) i3 requires that functions be total, which validates such arguments as ‘Every spouse loves his or her spouse (and, of course, the spouse of one’s spouse is oneself), so nobody is unloved’, if it is given the simple form

$$\frac{\forall x\forall y(x = Sy \rightarrow (y = Sx \& LxSx))}{\neg\exists x\neg\exists yLyx}$$

For any person x is such that x ’s spouse loves the spouse of x ’s spouse, who of course is x , and everyone has a spouse, since S is total. In real life, not everyone has a spouse, but the straightforward way of saying this, $\neg\forall x\exists y(y = Sx)$, is logically false.

In mathematical applications of logic, it would be convenient to introduce notations for partial functions, *e.g.*, to define predecessor P in terms of successor S in the natural numbers by $\forall x\forall y(Px = y \leftrightarrow Sy = x)$ or division $/$ in terms of multiplication \times in the reals by $\forall x\forall y\forall z(x/y = z \leftrightarrow z \times y = x)$. However, such definitions will not do: given $\neg\exists x(Sx = 0)$, the first entails $\neg\exists x(P0 = x)$, which is logically false; given $\forall x(x \times 0 = 0)$, the second entails $S0 = 0$, which contradicts $\neg\exists x(Sx = 0)$. Nor can we simply exclude the troublesome arguments. $\forall x(x \neq 0 \rightarrow \forall y(Px = y \leftrightarrow Sy = x))$ leaves P undefined at 0, and

$\forall x\forall y(y \neq 0 \rightarrow \forall z(x/y = z \leftrightarrow z \times y = x))$ leaves x/y undefined when the value of y is 0, whereas classical semantics requires that functions be everywhere defined.

These difficulties may be avoided by replacing function names with relational predicates for their graphs.

$$\frac{\forall x\forall y(Syx \rightarrow (Sxy \& LxSx))}{\neg\exists x\neg\exists yLyx}$$

is invalid, and definitions like $\forall x\forall y(Pxy \leftrightarrow Sy = x)$ or $\forall x\forall y\forall z(Dxyz \leftrightarrow z \times y = x)$ are fine. For some applications, however, we will need to add a premise (an axiom) to the effect that the defined predicate is functional, *e.g.*, $\forall x\forall y\forall z((Sxy \& Sxz) \rightarrow y = z)$. And we lose the considerable advantages of functional notation.

Alternatively, we can represent a partial function f by a total function F that coincides with f where f is defined and is given some arbitrary value elsewhere. If the arbitrary value for the predecessor and division functions is 0, then their definitions may be given as $(\forall x(x \neq 0 \rightarrow \forall y(Px = y \leftrightarrow Sy = x)) \& P0 = 0)$ and $\forall x(\forall y(y \neq 0 \rightarrow \forall z(x/y = z \leftrightarrow z \times y = x)) \& x/0 = 0)$. In the case of the spouse function, we might pick an unmarried person (the Pope, say) and extend the spouse function to unmarried people x by stipulating that the spouse of x is the Pope. If S now represents this function and p names the Pope, then $Sx \neq p$ will tell us that x has a spouse (that the partial spouse function is defined at x), and we can recast the premise of the argument as $\forall x(Sx \neq p \rightarrow \forall y(x = Sy \rightarrow (y = Sx \& LxSx)))$. The price is a violation of ordinary usage: ‘The Pope’s spouse is the Pope’ is not true. Since the Pope is unmarried, ‘The Pope’s spouse’ doesn’t refer to the Pope or to anyone else; it doesn’t refer to anything. Where the partial function f is onto, as is the predecessor function, we cannot identify the arguments at which it is defined in this way. No matter what individual i is picked for the arbitrary value, $Fx \neq i$ will be false for some x at which f is defined.

2.2 Logical Habitats for Philosophical Doctrines

If free semantics permits us to avoid strange results, it also permits us to state strange doctrines. Free semantics provides a more neutral logical setting than classical semantics for certain philosophical views. It permits distinctions upon which they depend to be made in a straightforward way and does not prejudice the case against them by rendering important claims logically false. Let us consider an assortment.

- a. Meinong claimed, notoriously, that there are non-existent objects, that things like the golden mountain may have *being* while lacking *existence*. The straightforward form of ‘*a* does not exist’ is $\neg\exists x(a = x)$, but this is logically false in classical semantics, since *a* must refer to something in the range of *x*. A device like Russell’s will avoid this, but at the expense of a complex form $\neg\exists x\exists y(\forall z(Az \leftrightarrow z = y) \& y = x)$, where *Az* is uniquely true of *a*.

We could instead take the variables to range over beings and introduce a 1-place existence predicate *E*; quantification over existents would be represented by relativizing quantifiers to *E*, $\forall x(Ex \rightarrow A(x))$ indicating that *A(x)* is true of all existents, $\exists x(Ex \& A(x))$ that it is true of some existent. Then $\exists x\neg Ex$ will represent ‘there are non-existent objects.’ We can even let *Ex* abbreviate $\exists y(y = x)$, provided we follow Lejewski and give identity a non-standard meaning: an interpretation is $\langle D, d, o \rangle$, where $\langle D, d \rangle$ is classical and $o \in D$, and $s = t$ is true under *I* and α iff *s* and *t* refer under *I* and α to the same individual of *D* and this individual is not *o*. Relative to interpretations and valuations of this sort, $\exists x\neg\exists y(y = x)$ is *logically* true.

These classical or quasi-classical approaches do not really honor Quine’s dictum. Here to *be* is to be the value of a variable, all right, but to *exist* is not. By contrast, a free semantics that permits constants to refer to individuals *outside* the range of *x* allows us to say simply that *a* does not exist without immediately contradicting ourselves and without abandoning Quine’s useful connection between quantification and existence.

If we wish to make the more general Meinongian claim that there are non-existent objects — if we wish to quantify over them — then it may be argued that we are really committed to objects with being and should simply treat them classically, delimiting the subclass of existents with *E*. Alternatively, we could add a special quantifier $\exists_b y$, meaning ‘there is a being *y* such that’ and write $\exists_b y\neg\exists x(y = x)$: to be is to be the value of a variable bound by \exists_b , to exist is to be the value of a variable bound by \exists . For free semantics of this sort — and an argument that the semantics of *any* modal or tense logic can be built up from it — see [Cocchiarella, 1991]. More modestly, we could limit what does not exist to a single Lejewskian object, named by *o*, and then *define* $\exists_b xA(x)$ as $A(o) \vee \exists xA(x)$. For this approach — and a proof that it is deductively equivalent to Lejewski’s — see [Lambert and Scharle, 1967].

- b. The truth of ‘Fred exists, but might not have’ is typically explained by gesturing toward a world that is possible relative to ours at which ‘Fred does not exist’, *i.e.*, $\neg\exists x(x = f)$, is true. Accordingly, at such a

world, f cannot refer to something in the range of x : Fred is not among the existents of that world. Standard Kripke-style modal semantics is free.

- c. Intuitionists and constructivists influenced by them reject non-constructive proofs in mathematics. A proof of $\exists xA(x)$ is, for them, nothing more nor less than a proof of $A(t)$ for some t , and such a proof is not secured merely by showing that a contradiction can be obtained from the assumption that $\forall x\neg A(x)$. Now if we have not established that f is defined at s , we can hardly claim to have a proof of $fs = fs$ and therefore a proof of $\exists x(x = fs)$. Yet standard formulations of intuitionist logic follow classical logic in regarding $t = t$ as a logical axiom and licensing the inference to $\exists x(x = t)$. Accordingly, we must either banish partial functions from intuitionist logic, thereby limiting its reach in mathematics and ignoring the views of patriarchs like Brouwer, or further modify the logic, this time in the direction of free logic. For free variations on Kripke-style semantics for intuitionistic logic, see [Posy, 1982].
- d. Evans [1979] has noted that the standard examples of contingent *a priori* truths presuppose a free semantics. If we stipulate that ‘Julius’ refers to whoever (uniquely) invented the zipper, then ‘if someone (uniquely) invented the zipper, Julius did’ appears to be (1) true, (2) *a priori*, but (3) contingent. It is true because if someone (uniquely) invented the zipper, that person is Julius because ‘Julius’ refers to whoever (uniquely) invented the zipper. It is *a priori* because we need only understand the stipulation to see that it is true. It is contingent because there is a possible world in which it is false, given that someone actually did (uniquely) invent the zipper: in the actual world Julius (uniquely) invented the zipper, but he might not have: at a possible world in which someone else (uniquely) invented the zipper, ‘Julius did’ is false. A free semantics is presupposed because in classical semantics we cannot introduce a constant like j with a defining axiom $\forall x(x = j \leftrightarrow A(x))$ without first establishing that $\exists!x A(x)$. Otherwise, we could stipulate that $\forall x(x = j \leftrightarrow x \neq x)$ and end up with the logically false $j \neq j$. In this case, $A(x)$ is $\forall y(Zy \leftrightarrow y = x)$, representing ‘ x (uniquely) invented the zipper’. Thus, the candidate sentence $(\exists!xZx \rightarrow \forall y(Zy \leftrightarrow y = j))$ — if someone (uniquely) invented the zipper, Julius did — is not well-formed unless $\exists!xZx$ is true, so it cannot be known *a priori* to be true. If, however, we allow non-referring names with the understanding that atomic constructions involving them are false, $\forall x(x = j \leftrightarrow \forall y(Zy \leftrightarrow y = x))$ will be true whether or not $\exists!xZx$ is true; and if $\exists!xZx$ is true, j must refer and $\forall y(Zy \leftrightarrow y = j)$ will also be true.

- e. Aristotle held that true predication requires a subject: the truth of ‘Socrates is well’ presupposes the existence of Socrates: ‘Socrates’ must refer. However, the falsity of ‘Socrates is well’ does not: ‘Socrates is well’ is false if Socrates exists but illness is attributable to him; it is also false if Socrates does not exist. ‘Socrates is ill’ and ‘Socrates is not well’ do not give the same information: the former attributes illness to Socrates, the latter merely denies that wellness is attributable to him: he may be ill, or he may not exist at all.

While classical semantics can handle contrary predications like ‘John is rich’ and ‘John is poor’ simply by not identifying the extension of ‘rich’ with the complement of the extension of ‘poor’, it does not allow ‘Socrates is well’ and ‘Socrates is ill’ to be false if ‘Socrates’ does not refer: all names refer. A free semantics in which non-referring subject-terms render subject-predicate sentences false embodies Aristotle’s view in a natural way. Scales [1969] has extended it by allowing complex predicates $\lambda xA(x)$ to be formed from open sentences $A(x) : \lambda xA(x)t$ is true iff t refers and $A(t)$ is true. Since $A(t)$ may be true when t does not refer, $\lambda xA(x)t$ and $A(t)$ may differ in truth-value. For example, $\neg Wp$ representing ‘Pegasus is not winged’ is true, while $(\lambda x\neg Wx)p$, representing ‘Pegasus is wingless’ is false, if ‘Pegasus’ does not refer.

- f. Russell and Meinong go further than Aristotle, holding that ascribing to a sentence a subject-predicate *form* requires that the subject-term refer, whether the sentence is true or false, a doctrine now embodied in classical semantics. As Lambert [1986, p. 276] notes, Meinong held that ‘the golden mountain is golden’ is a predication, so there must *be* a golden mountain; Russell couldn’t swallow the conclusion, and so denied the sentence a subject-predicate form.

If the Russell–Meinong view of predication is accepted, ‘exists’ cannot be a predicate. One argument, extracted from Mendelson [1989, p. 609], is this: (1) If ‘exists’ is a predicate, then singular existentials of the form ‘ s exists’ are subject-predicate sentences with subject s . (2) In a subject-predicate sentence, “the subject stands for something and the predicate says something about that for which the subject stands.” So (3) if ‘exists’ is a predicate, ‘ s exists’ is trivially true. But (4) some singular existentials (such as ‘Neptune exists’) are not trivially true, and others (such as ‘Vulcan exists’) are simply false. So (5) ‘exists’ is not a predicate. Since (2) is enshrined in classical semantics, it will be difficult to treat ‘exists’ as a predicate E in the classical setting — unless we abandon (1) or Quine’s dictum.⁸ For the

⁸Mendelson, under the spell of (2), does abandon (1): he construes “atomic-looking”

extension of E will be the range of the bound variables and any term s must refer to something in this range, so Es will indeed be trivially true.

- g. An alternative to both Aristotle and Russell-Meinong holds that ‘The present king of France is bald’ is a *subject-predicate sentence* whose truth *or falsity* requires the existence of the present king of France, or the truth of ‘The present king of France exists.’ ‘The present king of France is bald’ then *presupposes* ‘The present king of France exists’ in Strawson’s [1952, p. 175] sense: a statement S presupposes a statement S' iff “the truth of S' is a precondition for the truth-or-falsity of S .” Presupposition is an interesting relation only if S can be neither true nor false, since otherwise S presupposes S' iff S' is necessarily true. So a formal treatment will require giving up bivalence. If classical semantics is assumed, then Bk does indeed presuppose $\exists x(x = k)$, for the latter is logically true. However, as just observed in Section 2.2f, $\exists x(x = k)$ cannot be an adequate representation of the contingent truth ‘The present king of France exists’.

The natural semantic setting for presupposition is a free semantics in which (1) subject-predicate sentences with non-referring subjects are neither true nor false, (2) existence claims of the form $\exists x(x = t)$ are false if t does not refer, (3) $\neg A$ is neither true nor false iff A is neither true nor false, and (4) $X \models A$ iff A is true whenever all the X -sentences are true. Presupposition may then be characterized as

$$A \text{ presupposes } B \text{ iff } A \models B \text{ and } \neg A \models B$$

and Bk presupposes $\exists x(x = k)$, because both $Bk \models \exists x(x = k)$ and $\neg Bk \models \exists x(x = k)$, although $\not\models \exists x(x = k)$. Free semantics of this “neutral” kind are discussed in Section 3.6. For a different supervaluational treatment of presupposition, see [van Fraassen, 1968].

- h. Mereology conceives of individuals as wholes with parts. For the mereologist, ‘The rivers of Canada are numerous’ does not claim that a particular set — the set of Canadian rivers — has many members, but that a particular whole — the mereological sum of the Canadian rivers — has many parts. Wholes whose parts are spatio-temporal individuals are also spatio-temporal, though perhaps spatio-temporally discontinuous; by contrast, sets of spatio-temporal individuals are abstract objects. Since every whole is a part of itself, there cannot be

sentences Ps as either $\exists x(Sx \& Px)$ or $\forall x(Sx \rightarrow Px)$, where S is a singular predicate. However, his non-standard semantics generates the truth-values that Ps would have if it were a subject-predicate sentence whose subject may refer to individuals outside the range of the bound variables.

a whole with no parts (though there may be wholes — true atoms — with no proper parts). While set theory can embrace the empty set, mereology does not recognize an empty whole.

In thinking rigorously and systematically about parts and wholes, it is very convenient to employ operators such as *binary sum* ($x + y$ is the whole whose parts z are such that z is part of x or z is part of y), *generalized sum* ($\sigma x A(x)$ is the whole whose parts z are such that there is a y such that $A(y)$ of which z is part), *binary product* ($x \times y$ is the whole whose parts z are such that z is part of x and z is part of y), etc. But such operators will not be everywhere defined, if there is no empty whole: both $\sigma x(x \neq x)$ and $x \times y$, where x and y have no common part, would be the empty whole, if there were such a thing, but there is not, so both $\sigma x(x \neq x)$ and $x \times y$, where x and y have no common part, are undefined. If mereological theories are to be framed as first-order theories, classical semantics is an unwelcome constraint: the mereologist must either do without these operators and conduct all logical business in terms of cumbersome predicates, or he must hold his nose and introduce a constant for something he denies exists, *viz.* the empty whole. A free semantics that permits partial operators is much more congenial. For a discussion of free mereological theories, see [Simons, 1991].

2.3 Logical Form

I take the present view of logical form to have these elements:

- a. Sentences-in-context have a semantic structure or logical form: their truth-values (truth, falsity, or lack thereof) reduce, *via* recursive semantic rules, to the semantic values of their unstructured parts or elements (*e.g.*, a subject-predicate sentence is true iff the referent of the subject term belongs to the extension of the predicate).
- b. An interpretation assigns appropriate semantic values to such elements (*e.g.*, extensions to predicates).
- c. Any logically possible situation is represented by some interpretation; in particular, the actual situation is represented by an interpretation, so that the actual truth or falsity of a sentence reduces to the actual semantic values of its elements.
- d. The logical properties and relations of sentences-in-context are determined by their semantic structures and the totality of interpretations *via* semantic definitions of these properties and relations (*e.g.*, logical truth is truth under every interpretation); such definitions provide the

basis for judging the soundness and adequacy of proof systems that give purely syntactic accounts of proof and proof from hypotheses.

Granting this, it is easy to argue for *inclusive* semantics: bound variables may range over the empty domain, for surely it is logically possible that there be nothing at all. To be sure, once we have investigated this case, we might want to heed Quine's advice [1953, p. 161] and put it aside for pragmatic reasons if, by including it, we would "cut ourselves off from laws applicable to all other cases". Or we might include it by using those laws but performing an extra check on results: existentials will be false and universals true in the empty domain, and the other sentences will be truth-functional compounds of these if we have followed Quine and purged the language of all singular terms but variables. Still, what justifies the truth-value assignments is a look at this case and thinking through the application of general semantic rules to it. Note that the no-counterexample interpretation is required if universals are to be true and that vacuous quantifiers are not idle in the empty domain ($\exists y\forall xPx$ is false while $\forall xPx$ is true).⁹

We may also argue for *free* semantics as follows: (1) In accord with Quine's dictum, the range of bound variables in a given interpretation is restricted to individuals that exist in the possible situation represented by the interpretation. (2) There are sentences in which expressions that look for all the world like names do not, in actual use, refer to actual individuals. So (3) if these expressions are treated as names, no interpretation that represents the actual situation can assign them referents in the range of the bound variables. (4) What is permitted in interpretations that represent the actual situation must also be permitted in interpretations that represent possible situations. So (5) if these expressions are treated as names, interpretations in general need not assign them referents in the range of the bound variables.

(1) is true of classical semantics, whether we identify an interpretation with (i) a meaning function that associates with each element an appropriate semantic value in the *actual* world, or (ii) a possible world, at which the meanings of elements in the actual world determine their semantic values, or (iii) a meaning function at a possible world.¹⁰ Sentences of type (2) include:

⁹For discussion of systems that treat vacuous quantifiers in the empty domain differently, see [Lin, 1983].

¹⁰The main defect of (i), aside from having to represent reasoning about hypothetical situations indirectly, is that the valid arguments depend upon how many individuals there are in the actual world. If the number is finite — k , say — any argument with a premise stating that there are more than k individuals will be valid, since the premises are not satisfiable. The main defect of (ii), aside from issues of epistemic access to possible worlds, is that arguments like 'Some even number has an irrational square root, 2 is an even number, so 2 has an irrational square root' will be valid, since the conclusion is presumably true at any possible world. Hence, (iii).

- s1. If *Vulcan* exists and its orbit lies within that of Mercury, it's going to be very hard to observe.
- s2. *Vulcan* doesn't exist.
- s3. *Zeus* is not Allah.
- s4. The ancient Greeks worshipped *Zeus*.
- s5. *Pegasus* is a winged horse.
- s6. Bosch painted a picture of *hell*.
- s7. Mary admires *Eustacia Vye*.

The simple thought behind (4) is that the actual is a special case of the possible. A name like 'Hillary Clinton' happens to refer to a particular individual of the actual world; but the name could have been attached to some other individual of this world or to an individual of some other possible world. If we are prepared to regard an expression like 'Eustacia Vye' as a name that does not in fact refer to an individual of this world (but to the heroine of Thomas Hardy's novel, *The Return of the Native*), then we should allow that in a possible situation, however conceived, it need not refer to an individual that exists in that situation.

(5), the conclusion of the argument, is conditional, and we may avoid adopting free semantics by refusing to admit that such expressions are, despite appearances, singular terms. The cost of such denial is dealing with them in some other way, and those we have seen above are awkward. What basis is there for holding that 'Mary admires Hillary Clinton' is a relational subject-predicate construction, while 'Mary admires Eustacia Vye' is not? The obvious difference is that 'Hillary Clinton' refers to a real person and 'Eustacia Vye' does not. But why should logical form depend upon *that*?

Lambert [1998, p. 157] and Kroon [1991, p. 21] suggest that logical form is independent of empirical fact, and hence independent of whether terms actually refer. The premise, however, seems too strong. We may agree that the logical form of a sentence cannot depend upon its truth or falsity, since its truth or falsity is determined by its logical form and the actual semantic values its elements, including the referents of its terms. But it does not follow that form cannot depend on whether expressions that we are tempted to classify as terms refer, particularly if we cannot figure out how to get semantic rules to deliver truth-values smoothly in such cases.

Indeed, it may be argued that logical form does depend to an extent on empirical fact, since it is sentences-in-use that have such forms. When Alice says, 'I'm hungry', and Bill adds, 'But I'm not', there is no contradiction: the form of what Alice says is represented by *Ha* and the form of what Bill says by $\neg Hb$. If logical forms reflect the different uses of indexicals

like ‘I’, as they must in one way or another, then why may they not reflect such empirical facts as whether “terms” refer? We might want to say that the logical form of ‘I’m hungry’ is the same in both cases, namely, the simple subject-predicate form Ps , and that Ha represents, in this form, the *propositional content* of what Alice says. But then it is representations of propositional content that will do the work that (a)–(d) require of logical form.

I prefer a more pragmatic argument: logical form should be reasonably accessible, and the closer it is to surface form the better, other things equal. We do not want to misconstrue logical form and have to reformulate reasoning when we discover our error. If logical forms are contingent upon whether certain expressions refer — a matter that may be very difficult to settle — then logic may not be very useful. We don’t want to have to revise reasoning about the unknown solution to some equation if we find out, as a result of that very reasoning (how else?), that there is no solution (or no unique solution). Moreover, we’d like to be able to conduct such reasoning using a term t for the solution, rather than (say) in Russell’s indirect and clumsy fashion.¹¹

But perhaps we need not abandon the classical perspective, even if we admit that the italicized terms in s1-s7 are singular terms. Let me sketch two objections of this kind:

OBJECTION 1. Suppose we insist that sentences with terms that do not refer, or that seem to refer to things outside the range of the variables, are neither true nor false. Then applying classical laws will lead from truths to truths: we may apply existential generalization to ‘Mary admires Eustacia Vye’ to get ‘Mary admires someone’, but the premise is untrue, so the falsity of the conclusion (if it is false) does not invalidate the rule. The reason for including the actual situation (in which such terms as ‘Eustacia Vye’ do not refer to anyone) among the possible situations is to mesh logic with truth: the conclusion of a sound argument should be true. But if we insist that sentences with terms like ‘Eustacia Vye’ are truth-valueless, we need not worry that classical logic will lead us from true premises to untrue conclusions. Accordingly, such sentences can be set aside as ‘don’t cares’.¹²

There are three problems with this proposal. First, it is difficult to maintain that all such sentences are truth-valueless; indeed, anyone not bewitched by some theory will take most of s1–s7 to be *true*. Second, familiar rules of inference such as *addition*

¹¹Note, however, that a free semantics that does not support extensionality in the sense that $\forall x(A(x) \leftrightarrow B(x)) \models A(t) \leftrightarrow B(t)$ is probably not going to support this reasoning either, since it will typically involve moving from $A(t)$ and $\forall x(A(x) \leftrightarrow B(x))$ to $B(t)$. We shall probably have to conduct it under the additional assumption that t exists: $\exists x(x = t)$.

¹²This objection is suggested by van Fraassen [1966, Section 3].

ADD

 $A \vdash A \vee B$

will then not preserve truth, contrary to what is alleged: ‘Washington is the capitol of the USA so either Washington or Atlantis is the capitol of the USA’ has a true premise and a truth-valueless conclusion. Third, no justification has yet been given for the claim that terms which do not refer to things in the range of the bound variables render sentences truth-valueless; such a justification requires an extension of the ordinary semantic rules to this case.

OBJECTION 2. Let us concede that sentences with terms that do not refer to existents can be true or false; still, it does not follow that we must reject classical semantics for free semantics:

- a. Perhaps, as Stenlund [1973], Burge [1974], and Kroon [1991] suggest, some sentences of this kind can be handled classically, albeit by shifting from possible to imaginary or hypothetical worlds. In actual use, a sentence like ‘Pegasus is a winged horse’ invokes an implicit ‘in myth’ operator that, in effect, shifts attention from the actual situation to an imaginary one in which Pegasus exists (and indeed turns out to be a winged horse). That is, in actual use or context, the sentence is not about this world, but about another one, at which the normal reference conditions of classical semantics are fulfilled. Thus, classical semantics is all we need to understand why the reasoning of Sherlock Holmes in “Silver Blaze” about the missing horse is sound in the world of Doyle’s story: “. . . he must have gone to King’s Pyland or to Mapleton; he is not at King’s Pyland. Therefore he is at Mapleton.”¹³

However, this manoeuvre works only for sentences like s5. Consider s3: Zeus is not Allah, but *where?* Insofar as we can understand the truth of most of the sentences s1-s7 in terms of reference to imaginary individuals, it is reference *across*, not *within*, worlds, and that is not going to be accommodated by classical interpretations. All we need do to create problems for the recommended treatment of ‘Pegasus is a winged horse’ is to add ‘though such things do not exist’. If ‘Pegasus is a winged horse’ is true, so is ‘Pegasus is a winged horse, though such things do not exist’, but moving to a world of myth will render it self-contradictory. We can fix this by staying here in the actual world and understanding ‘Pegasus’ to refer to something in a world of myth, but that abandons classical semantics for some free variant of it.

- b. Perhaps what is problematic about sentences like s4, s6, and s7 is not failure of reference, but referential opacity, which we are not going to

¹³A. C. Doyle, “Silver Blaze”, in *The Complete Sherlock Holmes* (Garden City: Garden City Books, 1930), pp. 383–401 at p. 393.

be able to handle with extensional logical forms anyway. Contexts like ‘worshipped ...’, ‘picture of ...’ and ‘admires ...’, according to this view, are not referentially transparent: truth-value need not be preserved by replacing a referential term by a co-referring term. The suggestion is that if John worships God, it does not follow that John worships Satan, even if God and Satan turn out to be identical (or as identical as the members of the Trinity). And similarly for the others.

This objection does not help in the other cases. Nor does it seem very convincing. There is certainly a sense in which John does worship Satan if he worships God and God is Satan. And similar things may be said about the other contexts. A picture of Fred is a picture of the Grand Dragon of the Ku Klux Klan, if that’s who Fred is. ‘Admires’ is no more intensional than ‘loves’, the standard logic-text example of a relational predicate.

2.4 *Derived Rules and Axioms*

Reflection on the cases discussed in Section 2.1 will suggest that we can work around the constraints of classical semantics in various ways without giving up its familiar simplicity. We can relativize the quantifiers to a predicate E that we interpret as true of existents; irreferential terms are those that refer to individuals of D that are not in $d(E)$, function-names f such that $d(f)(\alpha) \notin d(E)$ for some $\alpha \in d(E)$ represent functions $d(E) \rightarrow d(E)$ that are not total. Or we can eliminate non-referring terms in Russell’s way. While such representations may not be perfect, they may be good enough for most purposes.

However, classical representations of irreferential names and partial functions can be cumbersome, and at some point those who work with them will want to develop some derived rules to facilitate reasoning and its formal or informal representation. Such rules will be those of a corresponding free logic. Development of various free logics can therefore provide a number of ‘off the shelf’ systems that can be applied in such cases. Let us consider two examples.

- a. Suppose that you believe Russell was correct in holding that descriptions like ‘the present King of France’ are not genuine singular terms and that what appear to be subject-predicate constructions like ‘the present King of France is bald’ are actually complex quantifier constructions. Still, working with these complex constructions is about as inviting as programming in machine language; you will want to develop some macros. So let’s *pretend* that ‘the present King of France’ is a term and ‘the present King of France is bald’ is a subject-predicate sentence whose truth-value is given by Russell’s quantifier construction, and attempt to develop a system of derived axioms and rules of

inference that enables you to treat descriptions *as if* they were terms. The obvious minimal constraint on such a system is that A should be provable iff the Russellian expansion of A is logically true. If we can pretend that descriptions are terms, we can also *pretend* that they can refer — or fail to refer, as the case may be — and ask what sort of logical semantics we may *pretend* underlies the system of derived axioms and rules. As Scales [1969] and Burge [1974] show, the result of this process is a free logic, whose underlying semantics may be sufficiently compelling to loosen your allegiance to Russell and to classical logic.

- b. Quine’s pure set theory NF [1969] is framed in a first-order language without identity, whose non-logical symbols are variables and the 2-place predicate \in . Identity (in the weak sense of indiscernibility) is introduced by definition: $x = y$ abbreviates $\forall z((z \in x \leftrightarrow z \in y) \& (x \in z \leftrightarrow y \in z))$.¹⁴ The only axioms are *extensionality*

$$\forall z(z \in x \leftrightarrow z \in y) \rightarrow x = y$$

and *restricted comprehension*

$$\exists x \forall y (y \in x \leftrightarrow A(y)),$$

where A is *stratified*: it is possible to replace the variables by numerals so that subject-predicate constructions $x \in y$ become $n \in n + 1$. The restriction is designed to secure the safety of type theory without the pain. Quine’s view [1969, p. 16] is that “much... of what is commonly said of classes with the help of ‘ \in ’ can be accounted for as a mere manner of speaking, involving no real reference to classes or any irreducible use of ‘ \in ’.” Singular terms $\{x : A(x)\}$ for classes — terms Quine calls *class abstracts* — are introduced by a pair of contextual definitions: $y \in \{x : A(x)\}$ abbreviates $A(y)$, and $\{x : A(x)\} \in \alpha$, where α is a class abstract, abbreviates $\exists y(y = \{x : A(x)\} \& y \in \alpha)$. If class abstracts are regarded as referring to *pretend* or *virtual* classes, then virtual classes which belong to virtual classes are real, though the virtual classes to which they belong need not be; sets are members of real classes. Identity may be extended to class abstracts by taking $\alpha = \beta$ to abbreviate $\forall x(x \in \alpha \leftrightarrow x \in \beta)$, so that $\alpha = \{x : A(x)\} \leftrightarrow \forall x(x \in \beta \leftrightarrow A(x))$ and $\alpha = \{x : x \in \alpha\}$.

Existential generalization fails for class abstracts: $A(\alpha) \not\equiv \exists x A(x)$ for some $A(\alpha)$. In particular, let $A(x)$ be $x = \alpha$, where α is $\{x : B(x)\}$. Then the premise $A(\alpha)$ is $\alpha = \alpha$, *i.e.*, $\{x : B(x)\} = \{x : B(x)\}$, *i.e.*,

¹⁴Of course, this will not force ‘ $=$ ’ to be interpreted as numerical identity; no set of axioms constraining the interpretation of ‘ $=$ ’ can do that, which is why identity is commonly regarded not as a predicate but as a logical operator.

$\forall y(y \in \{x : B(x)\} \leftrightarrow y \in \{x : B(x)\})$, *i.e.*, $\forall y(B(y) \leftrightarrow B(y))$, which is logically true. The conclusion $\exists xA(x)$ is $\exists x(x = \alpha)$, *i.e.*, $\exists x\forall y(y \in x \leftrightarrow y \in \{x : B(x)\})$, *i.e.*, $\exists x\forall y(y \in x \leftrightarrow B(y))$, which amounts to unrestricted comprehension, since $B(y)$ can be any formula and the premise will be true. If $B(y)$ is $y \notin y$, we obtain the logical falsehood $\exists x\forall y(y \in x \leftrightarrow y \notin y)$ of Russell's paradox. However, the inference will be valid if $\exists x(x = \alpha)$ is added as an extra premise: $A(\alpha)$, $\exists x(x = \alpha) \models \exists xA(x)$. For then we can move from $A(\alpha)$ to $A(x)$ (in virtue of $\models \alpha = \beta \rightarrow (A(\alpha) \leftrightarrow A(\beta))$ for variables or set abstracts α, β), from which of course $\exists xA(x)$ follows. This is not a problem here because the added premise is just the conclusion when $B(y)$ is $y \notin y$.

This is typical of free logics: $A(t)$, $\exists x(x = t) \models \exists xA(x)$, but not necessarily $A(t) \models \exists xA(x)$. A natural question now is whether we can capture the logical moves involving class abstracts α in a set of derived axioms and rules which treat them as genuine terms t and, if so, whether there is a natural free semantics that we might pretend underlies their use. A sufficiently natural semantics might blur the distinction between pretense and reality, especially in pure mathematics, where there does not seem to be much difference between pretending that mathematical objects exist and asserting that they do. For a restructuring of Quine's NF along these lines, see [Scott, 1967].

3 FREE SEMANTICS

Free departures from classical semantics are usually — though not always, as in [Farmer, 1995], [Feferman, 1995], and [Woodruff, 1984] — universally free. If we are going to permit terms that do not refer to individuals in the range of the bound variables, why not include the case where no term can refer to such an individual, simply because there are none? This is easy enough to do semantically, though the required adjustments to proof systems are a bit more trouble.

There are two ways in which terms may fail to refer to individuals in the range of the bound variables: either they refer to individuals outside this range, or they do not refer at all.

The first way leads to *outer domain* semantics, a straightforward bivalent modification of classical semantics in which a classical domain D is divided into a possibly empty inner domain D_i , over which the bound variables range, and an outer domain D_o . With the exception of the quantifier valuation clause $v5$, in which x -variants must now be understood to assign to x an individual of the inner domain, the interpretation and valuation clauses of classical semantics can be adopted without change.

The second way involves *partial* interpretations $I = \langle D, d \rangle$, where D may be empty and the denotation function d is partial on constants and assigns

partial functions $D \rightarrow D$ to function-names. Assignment functions α are also typically partial on variables. Here we face the problem of “assigning reasonable truth conditions to sentences containing non-denoting singular terms,” as Bencivenga [1986, p. 382] observes. This requires giving reasoned responses to the following questions:

- q1. If t does not refer, must ft also be non-referring? Does ‘Jack Aubrey’s sovereign’ refer to England’s George III, although ‘Jack Aubrey’ does not refer to a real person but to the fictitious captain of Patrick O’Brian’s sea novels?
- q2. Should d treat predicates as names of partial truth-valued functions on D ? Is ‘2 is green’ false (because ‘2’ refers to something that is not in the extension of ‘green’) or is it truth-valueless (because ‘2’ does not refer to something that is colored)?
- q3. If t does not refer, may Pt be true? If not, is it false or is it truth-valueless?
- q4. If t does not refer, is $t = t$ true, false, or truth-valueless? If s refers and t does not, is $s = t$ false or truth-valueless?
- q5. If formulae may lack truth-value, how are the classical truth-tables for the connectives to be extended? Shall we count $A \rightarrow B$ true or truth-valueless if A is false and B is truth-valueless, or B is true and A is truth-valueless?
- q6. If formulae may lack truth-value, how are the quantifier clauses to be modified? Should $\forall xA$ read ‘ $\forall xA$ is false if A is false for some x -variant of α , and $\forall xA$ is true otherwise’ or ‘ $\forall xA$ is false if A is false for some x -variant of α , and $\forall xA$ is true if A is true for each x -variant of α ’ or ‘ $\forall xA$ is true if A is true for each x -variant of α , and false otherwise’?
- q7. If formulae may lack truth-value, how are the definitions of logical properties and relations to be modified? Should logical consequence preserve truth? non-falsehood? both?

Applications may decide some of these questions. For example:

1. If we wish to allow for the non-strict functions and relations of computer science, then we will answer ‘No’ to q1 and ‘Yes’ to the first part of q3. Following Gumb and Lambert [1997], we might then implement such permissions by adding a virtual entity u (for ‘undefined’) to D : d will assign to a k -place function-name f a total k -ary function $d(f) : D \cup \{u\} \rightarrow D \cup \{u\}$ and to a k -place predicate P a k -ary relation $d(P)$ in $D \cup \{u\}$ as its extension. If we want ft to be undefined, though t refers to α , we will set $d(f)(\alpha) = u$; if we want ft

to be defined, though t does not refer, we will require $d(f)(u) \in D$; if we want Pt to be true when t does not refer, we will put u in the extension $d(P)$ of P . u is not to be regarded as a strange entity, but as a notational device for simplifying the statement of semantic rules, as in [Kroon, 1991].

2. If we think that ‘2 is green’ presupposes ‘2 is colored’ in the sense of Section 2.2g, we will answer ‘Yes’ to q2. We can then follow Smiley [1960] and Ebbinghaus [1969] and have I assign P both a domain of application $D(P)$ in D and, within that domain, an extension $d(P)$. If we want Px to be truth-valueless when x is assigned α , then we put α outside $D(P)$; if we want Px to be false when x is assigned α , then we put α in $D(P) - d(P)$.

The large decision is whether to answer q3 and q4 in a way that permits truth-valueless atomic formulae — and forces us to answer q5-q7. We can prune the choice tree considerably by opting for bivalence at the atomic level. However, such a decision needs to be rationalized. It will not do simply to argue that atomic formulae with non-referring terms should be false because (a) any atomic formula $A(t)$ is a predication which is true just in case the $A(x)$ is true of the referent of t , so that (b) where t fails to refer, $A(t)$ is not true, so (c) where t fails to refer, $A(t)$ must be false. For what underwrites the move from (b) to (c) is bivalence. However, there may be applications which call for such a ruling. For example, Farmer [1995, p. 281] claims that in the “traditional approach to partial functions” in mathematics, variables and constants *always* refer, functions may be partial and ft does not refer if t does not refer or $d(f)$ is not defined at $d(t)$, while Pt is *false* if t does not refer.

The usual route to *true* atomic formulae with non-referring terms is *story semantics*, a non-referential variant of outer domain semantics: treat non-referring terms *as if* they referred to individuals in an outer domain, taking the formulae that are true under such a pretense to constitute a *story S* which supplements a partial referential interpretation I and assignment α . Story semantics is equivalent to outer domain semantics in which the individuals of the outer domain D_o are treated as virtual or pretend objects. Story (or virtual outer domain) semantics seems to provide a natural way of dealing with sentences that are about fictional or mythical entities, at least if we do not want to follow Meinong in reifying them. Note, however, that we don’t yet have a justification for the bivalence that is built into this type of semantics, because *actual* stories or myths, unlike the stories of story semantics, are not complete. Nothing Doyle wrote decides the fictional truth-value of ‘Sherlock Holmes died before 1920,’ yet if Bh represents this sentence and h does not refer, any story S will include either Bh or $\neg Bh$.

If atomic formulae with non-referring terms are all to be false, then an excursion into stories is unnecessary: we can simply modify the valuation

rules $v1$ and $v2$ for atomic formulae to require as much. Note, however, that $t = t$ will then be false, if t does not refer. Even stranger results await those who follow Frege [1892] and deny truth-values to atomic formulae with non-referring terms. For if Pt lacks truth-value, then $\neg Pt$ and $Pt \vee \neg Pt$ also appear to lack truth-value. Accordingly, some instances of $A \vee \neg A$ are not logically true, if logical truth is truth under each partial interpretation and assignment. This is sufficiently disturbing to motivate a search for an respectable alternative that permits Pt to be truth-valueless while insuring that $t = t$ and $A \vee \neg A$ are logically true. The usual proposal is a *supervaluational* semantics, in which truth under a partial interpretation is understood as truth under all completions of it.

A free semantics in which *some* atomic formulae with terms that do not refer to individuals in the range of the bound variables are *true* is said to be *positive*.¹⁵ If *all* such atomic formulae are *false* (*truth-valueless*), the semantics is said to be *negative* (*neutral*). Both outer domain and story semantics are positive in this sense, as is supervaluational semantics. However, the more significant divide is between bivalent and non-bivalent accounts. I shall first discuss bivalent free semantics, both positive and negative, then non-bivalent free semantics, including supervaluations.

3.1 Positive Bivalent Semantics: Outer Domains

Outer domain free semantics involves minimal change in classical semantics. An outer domain interpretation $I = \langle D, d \rangle$ is classical, except that D is partitioned into an inner domain D_i and an outer domain D_o . Thus, it is altered to:

$i_o1.$ D is non-empty, and $D = D_i + D_o$

No change is needed in the classical notion of an assignment. However, bound variables are to range over D_i , so the classical notion of an x -variant must be modified to require that x is assigned a value in D_i : an x -variant of α is an assignment that differs from α at most at x and assigns x a value in D_i . Note that α now need not be an x -variant of α . If D_i is empty, α has no x -variants, so in this case universals are true and existentials are false. Evidently:

$$\begin{aligned} & \not\models \exists x(x = x) \\ Pt \not\models \exists xPx; & \text{ but } A(t), \exists x(x = t) \models \exists xA(x) \\ \forall xPx \not\models Pt; & \text{ but } \forall xA(x), \exists x(x = t) \models A(t) \\ Pt \not\models \exists x(x = t) \\ & \models t = t \end{aligned}$$

¹⁵Here I follow the recent usage of Lambert [1997, p. 62]. Other meanings of ‘positive’ can be found in the free logic literature. Bencivenga [1986, p. 397] terms (conventional) semantics *positive* if *each* atomic formula containing a non-referring term is true, while Lambert [1991b, p. 344] uses ‘positive’ merely as a synonym for ‘non-negative’.

If desired, an existence predicate $E!$ may be introduced by taking $E!t$ to abbreviate $\exists x(x = t)$. The extension $d(E!)$ of $E!$ under I will be D_i .

A Hilbert-style system PFL (for ‘positive free logic’) of axioms and rules¹⁶ that is strongly complete relative to outer domain free semantics may be obtained from CL by replacing A1 with

$$\begin{aligned} & \forall x(A \rightarrow B) \rightarrow (\forall xA \rightarrow \forall xB) \\ & A \rightarrow \forall xA, \text{ if } x \text{ is not free in } A \end{aligned}$$

modifying A2 to

$$(\forall xA(x) \& \exists x(x = t)) \rightarrow A(t)$$

modifying A3 to

$$t = t$$

modifying A4 to

$$s = t \rightarrow (A(s) \rightarrow A(t)), \text{ if } A \text{ is atomic}$$

and adding

$$\forall x \exists y (y = x).$$

Lambert [1991a, p. 9] characterizes outer domain semantics as embodying a “Meinongian world picture”: the inner domain consists of existents, while beings that lack existence are relegated to the outer domain. This identification is a bit misleading, since Meinong held that non-existent beings are indeterminate with respect to certain properties — the golden mountain has no specific height — whereas the objects of an outer domain are determinate in virtue of $i4$ and $v1$. A true Meinongian outer domain semantics would not be bivalent. Moreover, outer domains are sometimes taken to consist of pretend or virtual objects: that is, objects that we pretend exist so as to provide a referential semantics for terms that do not refer to existents. But Meinong did not regard having being as a matter of pretense.

3.2 Positive Bivalent Semantics: Stories

Story semantics can be regarded as a non-referential version of outer domain semantics. A story interpretation $\langle I, S \rangle$ consists of a *partial* interpretation I that permits non-referring terms and a *story* (or *convention*) S that assigns truth-values to atomic formulae containing such terms.

¹⁶This formulation is based on [Meyer and Lambert, 1968]; see also [Lambert, 1997, p. 39]. Leblanc [1968] has shown how to derive $(\forall xA \& E!t) \rightarrow A(t)$ from the other axioms by the rules of inference. For discussion of related systems, see [Bencivenga, 1986, Sections 5 and 6].

A partial interpretation $I = \langle D, d \rangle$ is classical except that D may be empty, d is partial on constants, and d assigns function-names partial functions $D \rightarrow D$. In particular:

- $i_p1.$ D is a possibly empty set.
 - $i_p2.$ If d is defined at a , $d(a) \in D$.
 - $i_p3.$ If f is k -place, $d(f)$ is a partial k -ary function $D \rightarrow D$.
- $i4$ remains unchanged. Assignments α may be partial, but as in i_p2 if α is defined at x , $\alpha(x) \in D$. The rules for reference under I and α must be reformulated to take account of non-referring terms:
- $r_p1.$ If α is defined at x , then x refers to $\alpha(x)$; otherwise, x does not refer.
 - $r_p2.$ If d is defined at a , then a refers to $d(a)$; otherwise, a does not refer.
 - $r_p3.$ If each t_i refers and $d(f)$ is defined at $\langle \alpha_1, \dots, \alpha_k \rangle$, where t_i refers to α_i , then $ft_1 \dots t_k$ refers to $d(f)(\alpha_1, \dots, \alpha_k)$; otherwise, $ft_1 \dots t_k$ does not refer.

However, irreferential terms do not lead to truth-valueless formulae, since the story S supplies the missing truth-values for atomic formulae. A substitutional account of quantification would permit us simply to identify S with a set of atomic sentences satisfying certain conditions.¹⁷ Objectual quantification requires a somewhat more complicated account, derived from Woodruff [1984]. Here a story is a *function* S from assignments α to sets $S(\alpha)$ of atomic formulae with non-referring terms satisfying the following conditions:

- s1. If t does not refer, then $t = t \in S(\alpha)$.
- s2. If just one of s and t refers, then $s = t \notin S(\alpha)$.
- s3. If neither s nor t refers and $s = t \in S(\alpha)$, then $A(s) \in S(\alpha)$ iff $A(t) \in S(\alpha)$.
- s4. If both s and t refer to the same individual of D , then $A(s) \in S(\alpha)$ iff $A(t) \in S(\alpha)$.
- s5. If α and β agree on the free variables of A , then $A \in S(\alpha)$ iff $A \in S(\beta)$.

Truth-values for atomic formulae under $\langle I, S \rangle$ and α are fixed by I and α if all terms refer, and by S and α otherwise:

- $v_s1.$ If each t_i refers, then $Pt_1 \dots t_k$ is true iff $\langle \alpha_1, \dots, \alpha_k \rangle \in d(P)$, where t_i refers to α_i ; otherwise, $Pt_1 \dots t_k$ is true iff $Pt_1 \dots t_k \in S(\alpha)$.

¹⁷The conditions are s1–s4 with ‘ $S(\alpha)$ ’ replaced by ‘ S ’.

- v_s2. If both s and t refer, then $s = t$ is true iff α is β , where s refers to α and t refers to β ; otherwise, $s = t$ is true iff $s = t \in S(\alpha)$.

The classical valuation rules v3–v5 are unchanged, except that truth and falsity are now relative to $\langle I, S \rangle$ and α . Note that if t does not refer under I and α , then $\exists x(x = t)$ is false under $\langle I, S \rangle$ and α . If t does not refer because D is empty, there are no x -variants of α , hence no x -variants β of α for which $x = t$ is true under $\langle I, S \rangle$ and β ; so $\exists x(x = t)$ is false under $\langle I, S \rangle$ and α . If D is not empty, let β be any x -variant of α . Since x refers under I and β and t does not, $x = t \notin S(\beta)$ and $x = t$ is false under $\langle I, S \rangle$ and β ; therefore, $\exists x(x = t)$ is false under $\langle I, S \rangle$ and α .

It can be shown that to any outer domain interpretation $\langle D_i + D_o, d \rangle$ and assignment α there corresponds a story interpretation $\langle D_i, d', S' \rangle$ and assignment α' that preserves truth-values, and conversely. Thus, adopting story semantics does not require any change in PFL.

Story semantics is now somewhat unfashionable. Lambert [2001] regards his creation as an unsuccessful attempt to develop “a philosophically palatable semantics for positive free logic whose domain consists of a single set of (intuitively) existing objects, whose denotation function is partial, and whose truth definition makes no appeal to other worlds or ‘extensions’ of the domain.” It is unsuccessful, in his view, because a story is “simply a list of sentences governed by some logical laws, hence a story in a very Pickwickian sense indeed.” However, it seems no more Pickwickian than identifying *properties* of D -individuals with the subsets of D , as is standard in classical semantics.

Another objection is Bencivenga’s: without a semantic rationale, conditions s1–s5 are *ad hoc*, and the “logical laws” that they build into a story S are without foundation.¹⁸ For example, if we are going to require that $a = a \in S(\alpha)$ when a does not refer under I , why shouldn’t we also require that $Pa \in S(\alpha)$ when $\forall xPx$ is true, but a does not refer, under I ? Why can’t $\forall xA(x) \rightarrow A(t)$ also claim the status of a logical law, contrary to the desires of free logicians? Perhaps this objection can be partially met by arguing that conditions s1–s5 capture the rules of language games about fictional or pretend entities.¹⁹ However, as noted above, this justification will be incomplete unless we can argue that such language games commit

¹⁸Bencivenga [1986, p. 403], and [this volume, p. 176]. Woodruff [1984, p. 944] characterizes conditions like s1–s5 as “constraints designed to ensure that we get the right results (for instance, that the laws of identity continue to hold).”

¹⁹I confess that I do not find Walton’s use of this idea very illuminating. According to Walton [1990, p. 400], when Sally claims that Tom Sawyer attended his own funeral, she is claiming that *The Adventures of Tom Sawyer* is such that “to behave in a certain way, to engage in an act of pretense of a certain kind while participating in a game authorized for it, is fictionally to speak the truth.” Unless Sally is a very unusual person, this is false. As an account of when Sally’s assertions of ‘Tom Sawyer attended his own funeral’ are true, it is more promising, but obscure.

participants to bivalence, *i.e.*, to accepting A or $\neg A$, for any atomic sentence A with a non-referring term.

3.3 Negative Bivalent Semantics

Negative free semantics is story semantics without the story: an interpretation I is precisely as it is in story semantics, that is, it is a partial interpretation defined by i_p1 – i_p3 and $i4$. The rules of reference r_p1 – r_p3 are unchanged, but v_s1 and v_s2 are altered to declare that atomic formulae with non-referring terms are false:

- v_r1 . If each t_i refers, then $Pt_1 \dots t_k$ is true if $\langle \alpha_1, \dots, \alpha_k \rangle \in d(P)$, where t_i refers to α_i ; otherwise, $Pt_1 \dots t_k$ is false.
- v_r2 . If s and t refer, then $s = t$ is true if α is β , where s refers to α and t refers to β ; otherwise, $s = t$ is false.

The subscript ‘ r ’ is for ‘Russell’. In contrast to outer domain semantics, we have:

$$\begin{aligned} Pt & \models \exists x(x = t) \\ & \not\models t = t \\ \neg \exists x(x = t) & \models t \neq t. \end{aligned}$$

A Hilbert-style system NFL (for ‘negative free logic’) of logical axioms and rules²⁰ that is strongly complete with respect to this semantics may be obtained from PFL by altering the identity axiom schema $t = t$ to

$$\forall x(x = x)$$

and adding

$$A(t) \rightarrow \exists x(x = t), \text{ if } A \text{ is atomic.}$$

A somewhat less free version of negative free semantics is employed by Farmer [1995] and Feferman [1995] to formalize reasoning about partial functions in mathematics. Since mathematical domains — natural numbers, sets, etc. — are assumed to be non-empty, i_p1 is replaced by the classical $i1$. Since in mathematical practice variables and constants are assumed to refer, assignments are total and i_p2 is replaced by the classical $i2$; the classical reference rules $r1$ and $r2$ (resp.) replace r_p1 and r_p2 (resp.). For a Hilbert-style axiomatization LPT of this semantics, with extensions to a partial combinatory logic CL_p and a partial λ -calculus λ_p , see [Feferman, 1995]. For a type-theoretical extension LUTINS of this semantics that has been axiomatized to provide a basis for automated theorem proving, see

²⁰See [Burge, 1974, p. 191] and [Lambert, 1997, p. 83].

[Farmer, 1995]. Following Beeson [1985, p. 98], Farmer and Feferman replace the existence predicate $E!$ with \downarrow (read ‘is defined’); $t \downarrow$ is equivalent to $\exists x(x = t)$.

Lambert [1991a, p. 9] characterizes negative free semantics as *Russellian*: there are no entities, Meinongian or virtual, beyond the existents, and non-referring terms render atomic formulae false just as they do for Russell. However, Russell’s truth-values result from treating non-referring terms as descriptive and atomic formulae containing them as abbreviations for more complex formulae that turn out to be false if the descriptions are empty. So his truth-values are rationalized by some analysis of constructions containing non-referring terms. That is not yet the case here. If we hold, with Burge [1974, p. 193] following Aristotle, that “true predications at the most basic level express comments on topics, or attributions of properties or relations to objects,” then we will agree that “lacking a topic or object, basic predications cannot be true.” But this will not get us all the way to negative free semantics unless we buy bivalence, for which Burge does not argue. The rest of the justification will probably have to be provided by particular applications, as when Farmer [1995, p. 282] notes that the “traditional approach to partial functions” in mathematics holds that “formulae are always true or false” and that “application of a predicate is false if any argument is undefined.”

3.4 *Intermission: Axiomatizing Equivalence and Implication*

Before turning to non-bivalent free semantics, let us take note of Lin’s [1983] study of equivalence and implication for various bivalent free semantics.

Some elementary logic texts, such as [Tidman and Kahane, 1999], present natural deduction systems that include replacement rules $A[B] \vdash A[C]$, where $A[C]$ results from $A[B]$ by replacing a part B by C . For each such rule, there is a decidable syntactic relation R such that (i) $B R C$ or $C R B$ and (ii) R -related formulae are logically equivalent. Examples are double negation, where $\neg\neg B R B$, and DeMorgan’s laws, where $\neg(B \vee C) R \neg B \wedge \neg C$ and $\neg(B \wedge C) R \neg B \vee \neg C$. Any rule of this kind is *closed under ordinary replacement*: if $B \vdash C$ is an instance, so is $A[B] \vdash A[C]$. Let us call such rules *replacement closed*.

Classical semantics supports ordinary replacement in the sense that if B is logically equivalent to C , then $A[B]$ is logically equivalent to $A[C]$. So if B is provable from A by replacement closed rules, B is logically equivalent to A . For classical semantics and free variants that support ordinary replacement, it is natural to ask if the converse holds: is there a system S of replacement closed rules such that B is S -provable from A if B is logically equivalent to A ? Positive results are summarized in Chart *B* of [Lin, 1983, p. 86].

Textbook authors warn students not to apply implicational rules like ADD to parts of formulae, since $\neg B \vdash \neg(B \vee C)$ is unsound. However,

applications of such rules to certain parts of formulae are sound. If a positive (negative) part B of a formula $A[B^+](A[B^-])$ is characterized as in [Schütte, 1960, p. 11], then $A[B^+] \vdash A[B \vee C^+]$ is sound because the truth (falsity) of a positive (negative) part renders a formula true. Moreover, $A[B \vee C^-] \vdash A[B^-]$ is sound as well. So we may generalize addition to a pair of rules: $A[B^+] \vdash A[B \vee C^+]$ and $A[B \vee C^-] \vdash A[B^-]$.

A natural question is whether implication can be characterized by a system of such paired rules R1 and R2, where R1 is $A[B^+] \vdash A[C^+]$, R2 is $A[C^-] \vdash A[B^-]$, and B bears some decidable syntactic relation R to C . Given Schütte's account of positive and negative parts, classical semantics supports polar replacement: if $B \models C$, then $A[B^+] \models A[C^+]$ and $A'[C^-] \models A'[B^-]$. This suggests that the paired rules R1 and R2 should be *closed under polar replacement*: if $B \vdash C$ is an instance of R1 (R2), then $A[B^+] \vdash A[C^+]$ is an instance of R1 (R2) and $A'[C^-] \vdash A'[B^-]$ is an instance of R2 (R1). For then, from a proof $\langle B = B_1, \dots, B_k = C \rangle$ of C from B , we could obtain (1) a proof of $A[C^+]$ from $A[B^+]$ by $B_i \rightarrow A[B_i^+]$, and (2) a proof of $A'[B^-]$ from $A'[C^-]$ by $B_i \rightarrow A'[B_i^-]$ and reversing the resulting sequence of formulae.

Schütte's notion of positive and negative part does not license closure under polar replacement, since a positive (negative) part of a negative part of A need not be a negative (positive) part of A . In the case of addition, for example, $B \vee A \vdash (B \vee C) \vee A$ is an instance of R1, but $\neg((B \vee C) \vee A) \vdash \neg(B \vee A)$ is not an instance of R2. However, there is another notion of positive and negative part that does support polar replacement and for which implicational replacement holds for classical semantics: B is a positive (negative) part of A iff B occurs within the scope of an even (odd) number of negations in A , where the quantifier is \forall and the connectives are \neg , $\&$, and \vee , and \exists and \rightarrow are defined as usual in terms of them. It is this notion that Lin uses in defining closure under polar replacement. He then characterizes implication in classical semantics and various free (bivalent) variations by systems of implicational rules closed under polar replacement; results are summarized in Chart A of [Lin, 1983, p. 47].

3.5 Non-bivalent Semantics: Supervaluations

Frege [1892, p. 70] claims that “anyone who seriously took [‘Odysseus was set ashore at Ithaca while sound asleep’] to be true or false would ascribe to the name ‘Odysseus’ a reference.” His view is that subject-predicate sentences with non-referring terms are truth-valueless. If interpretations and assignments are partial, then Frege's view dictates that $v_r 1$ be replaced by

$v_f 1$. If each t_i refers, then $Pt_1 \dots t_k$ is true if $\langle \alpha_1, \dots, \alpha_k \rangle \in d(P)$ and $Pt_1 \dots t_k$ is false if $\langle \alpha_1, \dots, \alpha_k \rangle \notin d(P)$, where t_i refers to α_i ; otherwise,

$Pt_1 \dots t_k$ lacks truth-value.

If ‘=’ is regarded as a predicate — or as a binary truth-valued operator that has no output without a pair of inputs — then v_r2 must be replaced by

v_f2 . If s and t refer, then $s = t$ is true if α is β and $s = t$ is false if α is not β , where s refers to α and t refers to β ; otherwise, $s = t$ lacks truth-value.

Once bivalence is lost at the atomic level, we must face questions q5–q7. There are two plausible answers to q5: either the *weak* or the *strong* truth-tables, as Kleene [1950, p. 334] calls them. The weak tables assign precisely the same truth-values as do the classical tables, leaving the compound truth-valueless in all other cases. Thus $\neg A$ is truth-valueless when A is truth-valueless, and $A \rightarrow B$ is truth-valueless when A or B (or both) is truth-valueless. The strong tables treat negation in the same way, but preserve certain features of the classical tables for other compounds: $A \rightarrow B$ is true when A is false or B is true, regardless of whether the other constituent has a truth-value. Thus, treating $A \vee B$ as $\neg A \rightarrow B$ and $A \& B$ as $\neg(A \rightarrow \neg B)$, disjunctions are true if at least one disjunct is true, and conjunctions are false if at least one conjunct is false. Neither of these answers to q5 will prevent such classical logical truths as $Pt \vee \neg Pt$ and $s = t \rightarrow (Ps \rightarrow Pt)$ from ending up with no truth-value when t and s do not refer. Note also that $t = t$ will have no truth-value if t does not refer.

Supervaluational semantics is an attempt to avoid such alien results, while permitting some atomic formulae to lack truth-values. The basic idea is to consider *completions* of a partial interpretation I and to revise the valuation rules so that A is *supertrue* (*superfalse*) under I and α if, for each completion I' of I and α' of α , A is true (false) under I' and α' , and A is *supervalueless* under I and α otherwise. In van Fraassen’s [1966] original development of the idea, completions of I are achieved by adding stories S , which he terms *classical valuations over I* : if $I = \langle D, d \rangle$, then $I' = \langle I, S \rangle$, where S is defined as in story semantics.

Since $Pt \vee \neg Pt$, $s = t \rightarrow (Ps \rightarrow Pt)$, and $t = t$ are true under any story interpretation $\langle I, S \rangle$, they are supertrue under any partial interpretation I , and hence logically true with respect to supervaluational semantics. More generally, A is logically true with respect to supervaluational semantics (in the sense of being supertrue under every partial interpretation I) iff A is logically true with respect to story semantics. Accordingly, the Hilbert-style axiomatization PFL of story semantics is weakly complete with respect to supervaluational semantics.

However, it is not strongly complete: $Pa \models_s \exists x(x = a)$ but $Pa \not\models \exists x(x = a)$, where $X \models_s A$ iff A is supertrue under each partial interpretation I and assignment α for which each $B \in X$ is supertrue. Note first that if a does not refer under I , Pa has no supervalue, since there are stories S and S'

for which $Pa \in S$ but $Pa \notin S'$.²¹ Thus, if Pa is supertrue under I , then a must refer under I . So $\exists x(x = a)$ is true under any I' , where I' is a completion of I , and therefore $\exists x(x = a)$ is supertrue under I . Accordingly, $Pa \models_s \exists x(x = a)$. However, $\not\models_s Pa \rightarrow \exists x(x = a)$, since if a does not refer under I , then, as noted in Section 3.2, $\exists x(x = a)$ is false under any $\langle I, S \rangle$. However, for some completions $\langle I, S \rangle$ of I , Pa is true under $\langle I, S \rangle$ and for others, it is false; thus, $Pa \rightarrow \exists x(x = a)$ is not supertrue under every interpretation I . Accordingly, by weak completeness, $\not\vdash Pa \rightarrow \exists x(x = a)$. But the deduction theorem holds for PFL, so $Pa \not\vdash \exists x(x = a)$.

Since PFL is strongly complete with respect to story semantics, we have $Pa \models_s \exists x(x = a)$ but $Pa \not\models \exists x(x = a)$. This is analogous to the situation in classical semantics, where $Px \models_g Pa$ but $Px \not\models Pa$. This suggests that, just as the generality interpretations of classical logic treat free variables as if they were universally quantified, supervaluations may also involve implicit quantification. Woodruff [1984] has shown that they do indeed, and that it is second-order.²² Consider a subject-predicate formula Pxa , a partial interpretation I , where $d(a)$ is undefined, and an assignment α , for which $\alpha(x) \in D$. The story S in a completion $I' = \langle I, S \rangle$ of I may be regarded as assigning an extension $d(P_a)$ to a predicate P_a defined by $P_a x \leftrightarrow Pax$: $\beta(x) \in d(P_a)$ iff $Pax \in S(\beta)$, where β is an x -variant of α . Thus, Pxa is supertrue under I and α iff for each S , Pxa is true under $\langle I, S \rangle$ and α iff for each extension $d(P_a)$, $P_a x$ is true under I and α iff $\forall P_a P_a x$ is true under I and α . This sketch of the argument assumes that a does not refer. Woodruff shows how to conditionalize such assumptions to obtain, for any A , a second-order normal form $tr(A)$, such that A is supertrue under I and α iff $tr(A)$ is supertrue under I and α . Moreover, $tr(A)$ is such that if A is supertrue under I and α , a part of $tr(A)$ of the form $\forall P_1 \dots \forall P_k B$, where B contains no constant that does not refer under I and α , is true under I and α .²³

Woodruff goes on to establish that supervaluational semantics inherits the pathologies of classical second-order semantics. Compactness (X is satisfiable if every finite subset of X is satisfiable), the upward Löwenheim–Skolem theorem (X is satisfiable in ω if there is some k such that X is satisfiable in $\{0, \dots, k + j\}$ for each j), and the downward Löwenheim–Skolem theorem (X is satisfiable in ω if X is satisfiable in some larger set) all fail; and finite logical consequence is not recursively axiomatizable (there is no recursive set of axioms such that $A_1, \dots, A_k \models_s B$ iff $A_1, \dots, A_k \vdash B$).

²¹Since we are dealing with sentences here, I suppress mention of assignments.

²²Note that supervaluations are also like generality interpretations in not treating connectives as (strict) truth-functions. $Px \vee \neg Px$ can be true (supertrue) without either Px or $\neg Px$ being true (supertrue).

²³Woodruff's construction is carried out for languages without function-names. In addition, partial interpretations are partial only with respect to constants: domains are non-empty and assignment functions are total.

The question naturally arises whether there are constraints on stories that restore a first-order regime. That is, are there constraints \mathcal{C} such that if supertruth under I is understood as truth under each completion $\langle I, S \rangle$ of I such that S satisfies \mathcal{C} , then the desirable properties of classical first-order semantics (compactness, the Löwenheim–Skolem theorems, and the recursive axiomatizability of logical consequence) are assured? Woodruff [1991] shows that what he terms ‘actualist’ constraints will do the trick. Constraints \mathcal{C} of this type, which require too much development to describe here, have the effect of making each formula A superequivalent to an *actualist* formula A' , in which every occurrence of a constant a is in a part of the form $\exists x(x = a)$, $\exists x(x = a) \& B$, or $\exists x(x = a) \rightarrow B$. Superequivalence here means that A is supertrue under I iff A' is supertrue under I , where supertruth under I is now truth under $\langle I, S \rangle$ for each S that satisfies \mathcal{C} . What Woodruff [1991, p. 227] terms “the first-order character of actualist semantics” then follows from the fact that actualist formulae are *stable*: A is true under $\langle I, S \rangle$ iff A is true under $\langle I, S' \rangle$, for any stories S and S' .²⁴ Woodruff [1991, p. 225] suggests that “the text of some story, theory or myth” could function as an actualist constraint. Details, however, are left to the reader’s imagination; as he notes at the outset, his treatment is quite abstract.

The equivalence of story semantics and outer domain semantics will suggest another way to complete a partial interpretation $I = \langle D, d \rangle$: embed it in an outer domain interpretation $I' = \langle D + D_o, d' \rangle$, where:

- i_e2. $d'(a) = d(a)$ if d is defined at a , and $d'(a) \in D_o$ otherwise.
- i_e3. $d'(f)(\alpha_1, \dots, \alpha_k) = d(f)(\alpha_1, \dots, \alpha_k)$ if $d(f)$ is defined at $\langle \alpha_1, \dots, \alpha_k \rangle$, and $d'(f)(\alpha_1, \dots, \alpha_k) \in D_o$ otherwise.
- i_e4. $d(P)$ is the restriction of $d'(P)$ to D^k , if P is k -place.

Partial assignments α are similarly completed by requiring that $\alpha'(x) = \alpha(x)$ if α is defined at x and $\alpha'(x) \in D_o$ otherwise. We can then stipulate that A is supertrue (superfalse) under I and α iff, for each completion I' of I and completion α' of α , A is true (false) under I' and α' .

Bencivenga [1980] develops an equivalent semantics that embeds partial interpretations in *classical* interpretations with non-standard valuation

²⁴Instead of stories S over I , Woodruff speaks of *conventions* C over I , which he characterizes as consisting of (1) an equivalence relation \sim on the constants that do not refer under I and (2) an extension in D for each atomic formula whose terms are non-referring constants and, for some $k \geq 0$, the first k variables. (2) treats atomic formulae as predicates (sentences as 0-place predicates) and is subject to the constraints that (a) $a = x$ and $x = a$ are true of nothing in D , (b) $a = b$ is true if $a \sim b$, and (c) if A is obtained from B by replacing constants by equivalent constants, then A and B are true of the same tuples of individuals of D . Evidently, to each story S corresponds a convention C that gives us the same information about the truth values of atomic formulae with non-referring terms, assuming that D is non-empty and $\alpha(x) \in D$, and conversely.

rules. A classical interpretation $I' = \langle D', d' \rangle$ over a partial interpretation $I = \langle D, d \rangle$ satisfies the following conditions:

- i_c1. D' is non-empty and $D \subset D'$.
- i_c2. If d is defined at a , then $d'(a) = d(a)$.
- i_c3. If $d(f)$ is defined at $\langle \alpha_1, \dots, \alpha_k \rangle$,
then $d'(f)(\alpha_1, \dots, \alpha_k) = d(f)(\alpha_1, \dots, \alpha_k)$.²⁵
- i_c4. $d(P) \subset d'(P)$.

Partial assignments α are completed by stipulating that $\alpha'(x) = \alpha(x)$ if α is defined at x . Note that, save for i_c1, these conditions are weaker than those on outer domain completions.

If supertruth is reckoned in terms of classical completions, then $Pt \vee \neg Pt$, $s = t \rightarrow (Ps \rightarrow Pt)$, and $t = t$ will be logically supertrue, but so will $\exists x(x = a)$ and $Pt \rightarrow \exists xPx$ — an unwelcome result in free logic. Bencivenga’s technical solution to this problem is essentially to modify the valuation rules v₁, v₂, and v₅ for classical interpretations over partial interpretations.²⁶ The notion of an x -variant in v₅ must be understood as in outer domain semantics: x must be assigned something in D . v₁ and v₂ become:

- v_b1. If each t_i refers under I and α , then $Pt_1 \dots t_k$ is true under I' and α' if $\langle \alpha_1, \dots, \alpha_k \rangle \in d(P)$ and $Pt_1 \dots t_k$ is false under I' and α' if $\langle \alpha_1, \dots, \alpha_k \rangle \notin d(P)$, where the referent of t_i under I and α is α_i ; otherwise, $Pt_1 \dots t_k$ is true under I' and α' if $\langle \beta_1, \dots, \beta_k \rangle \in d'(P)$ and $Pt_1 \dots t_k$ is false under I' and α' if $\langle \beta_1, \dots, \beta_k \rangle \notin d'(P)$, where β_i is the referent of t_i under I' and α' .
- v_b2. If just one of s and t refers under I and α , then $s = t$ is false under I' and α' ; otherwise, $s = t$ is true under I' and α' if s and t refer under I' and α' to the same individual, and $s = t$ is false under I' and α' if s and t refer under I' and α' to different individuals.²⁷

²⁵Bencivenga’s formal language does not contain function-names, but presumably they would be handled in this way.

²⁶The non-standard valuation rules capture valuation under I' “from the point of view of” I , as Bencivenga [1986, p. 409] and [this volume, p. 181], puts it. For his own somewhat different presentation of the rules, see [Bencivenga, 1980, pp. 101–103].

²⁷The long-winded form of these rules permits their use in Bencivenga’s [1980b] free description theory, where such atomic sentences as $P(\iota x(x \neq x))$ lack truth-value under I' . See Section 4.4 below.

v_b2, like s₂ or i_e2, implies that $s = t$ is superfalse if s refers and t does not. On Frege’s view, reflected in v_f2, $s = t$ should lack truth-value in this case. For a variant of supervaluational semantics that aims to honor Frege’s position, see [Skyrms, 1968]. Skyrms account is not quite correct — subscripts on ‘ G ’ must be reversed in (ii), lest $s = t$ be supervalueless when s and t refer to different individuals (or, where s is not t , to the same individual) — and it has the strange consequence that $\exists x(x = a)$ is supervalueless, not superfalse, when a does not refer.

These adjustments preserve the logical supertruth of $Pt \vee \neg Pt$, $t = t$, and $s = t \rightarrow (Ps \rightarrow Pt)$. However, if a does not refer under I , $\exists x(x = a)$ is superfalse under I and α . (Let I' and α' classically complete I and α . If D is empty, there are no x -variants of α' , so $\exists x(x = a)$ is false under I' and α' . If D is non-empty and β' is any x -variant of α' , then $x = a$ is false under I' and β' by v_b2 , so $\exists x(x = a)$ is false under I' and α' .) Moreover, $Pt \rightarrow \exists xPx$ is not logically supertrue. (If t does not refer under $I = \langle D, d \rangle$ and α , but $d(P)$ is empty, then $Pt \rightarrow \exists xPx$ is supervalueless under I and α . For $\exists xPx$ is false under each classical completion $I' = \langle D', d' \rangle$ of I , whereas $d'(P)$ may be defined so as to include or to exclude the referent of t under I' and α' .)

Supervaluations do turn out desired results, subject to the limitations revealed by Woodruff [1984]. Though certain sentences (such as Pa and $t = s$) may be supervalueless, the classical laws that free logicians like (such as $t = t$, $Pt \vee \neg Pt$, and $(Pt \ \& \ \exists x(x = t)) \rightarrow \exists xPx$) are logically supertrue, while those they dislike (such as $Pt \rightarrow \exists xPx$) are not. However, anyone who regards logical properties and relations as fundamentally semantic will regard such a justification of laws as circular. Bencivenga's appeal to classical completions with non-standard valuation rules is designed to provide a semantic rationale for supervaluations, which otherwise appear to be merely a "technical instrument".²⁸

Bencivenga's case is as follows: (1) Where terms refer (as in 'Caesar wore a white tunic when he crossed the Rubicon'), truth or falsity may be identified with the outcome of an ideal *practical* experiment that compares what the sentence says with the way the world is. (2) In most cases where terms do not refer (as in 'Pegasus has a white hind leg'), such practical experiments are out of the question; but we may nonetheless identify truth or falsity with the outcome of *mental* experiments (represented by classical completions of partial interpretations) that assign such terms non-existent referents. (3) However, no mental experiment can override the facts, in the sense of altering the outcome of an ideal practical experiment (*e.g.*, that 'Pegasus exists' is false); hence, the non-standard valuation rules v_b1 and v_b2 . (4) Where all mental experiments (so constrained by the facts) agree on a truth-value for a sentence (as with 'Pegasus is Pegasus'), it is reasonable to assign it that value; where they disagree (as with 'Pegasus has a white hind leg'), it is reasonable to regard it as truth-valueless.²⁹ Together, these conditions give us what Bencivenga [1986, p. 406], and [this volume, p. 179], calls the *counterfactual* theory of truth: "a sentence containing non-denoting singular terms is true (false) if and only if it would be true (false) in case these terms were denoting, no matter what their denotations were but provided that they were *non-existent objects*".

²⁸The phrase is Bencivenga's [1986, p. 405], and [this volume, p. 178].

²⁹Bencivenga [1980a, p. 225].

Unfortunately, the counterfactual theory of truth seems merely to restate the difficulty. Why should truth, which is ordinarily regarded as *correspondence to fact*, be reckoned in terms of what is *contrary to fact*? Why should we reckon that ‘Pegasus is Pegasus’ *is* true because it *would be* true if, *contrary to fact*, ‘Pegasus’ did refer? We do sometimes decide what is the case by considering what would be the case if things were different, as when we apply the semantic definition of a valid argument. But usually this is not a good idea. The fact that Milosevic would agree to autonomy for Kosovo if he were reasonable does not, unfortunately, tell us that he will do so. Why is truth more like validity than Balkan politics? If partial interpretations merely reflected incomplete information about referents, lack of truth-value would represent ignorance of truth-value and supervaluations would make sense. I don’t know whether ‘The first person born in China in 1999 was a boy’ is true, but clearly ‘The first person born in China in 1999 is the first person born in China in 1999’ is true no matter who this person turns out to be. But lack of information about the referent of ‘Odysseus’ is not what leads Frege to deny a truth-value to ‘Odysseus was set ashore at Ithaca while sound asleep’. I think we know everything there is to know about the referent of ‘Odysseus’: there is no such thing. If supervaluations make sense in free logic, I believe we do not yet know why.

Before leaving supervaluational semantics, let us note a connection with Kripke-style modal semantics established by Barba [1989]. The introduction to Barba’s paper suggests that we will be shown how to translate sentences A of an ordinary first-order language L with identity into sentences $tr(A)$ of the corresponding modal language L_{\square} and how to associate with a partial interpretation I of L a modal interpretation I' of L_{\square} so that A is supertrue (superfalse) under I iff $tr(A)$ is true (false) under I' . But no such scheme is possible, since standard modal semantics is bivalent and supervaluational semantics is not. Instead, Barba shows how to associate with a partial interpretation I of L a class K_I of modal interpretations so that A is supertrue under I iff $\square \diamond A$ is true under each interpretation in K_I . Modal interpretations here are non-standard in some respects. For example, they are partial: a need not refer at world w — but if it refers at w to α , α exists in w and in every world w' accessible from w , and a refers at w' to α . However, Barba’s [1989, p. 134] valuation rules V_L are bivalent: if a does not refer at w , Pa is true (!) at w .

3.6 Non-bivalent Semantics: Neutral Free Semantics

Supervaluations are the last stop before neutral free semantics, where even $t = t$ will lack truth-value if t does not refer, and lack of truth-value at the atomic level is inherited by at least some compounds, among them such classical logical truths as $Pt \vee \neg Pt$ and $s = t \rightarrow (Ps \rightarrow Pt)$, when neither s nor t refers. This may not appear to be a very promising destination for the

logician: if logical truths are conceived as those sentences which are always true, there are not going to be many — or perhaps any — logical truths.

However, the situation may not be as bad as it appears to be, for two reasons. First, quantification may restore truth-values: if $\exists x(x = y)$ is to express ‘ y exists’, then $\exists x(x = a)$ should be false when a does not refer under I and α , although $x = a$ will lack truth-value under I and any x -variant of α . This can be achieved by understanding $\exists xA$ to be true under I and α if A is true under I and some x -variant of α and to be false otherwise. Second, a weaker notion of logical truth — A is logically true iff A is never false — may serve as well in many applications. $t = t$, $Pt \vee \neg Pt$, and $s = t \rightarrow (Ps \rightarrow Pt)$ are logically true in this weaker sense, as are such laws of free logic as $(A(t) \& \exists x(x = t)) \rightarrow \exists xA(x)$, where x does not occur in t .

The underlying semantic rationale for neutral free semantics is Frege’s functional view of reference: predicates and ‘=’ name functions from individuals to truth-values. If functions are operations, as Frege seems to have thought, then the semantic rules governing subject-predicate and identity constructions are v_f1 and v_f2 , for where there is no input to an operation, there is no output either. The truth-functional connectives name truth-functions, so the same line of thought dictates the weak tables for them.³⁰ v_3 and v_4 become:

v_f3 . $\neg A$ is true if A is false; $\neg A$ is false if A is true; $\neg A$ lacks truth-value if A lacks truth-value.

v_f4 . $A \rightarrow B$ is false if A is true and B is false; $A \rightarrow B$ is true if A is true and B is true, or A is false and B is true, or A is false and B is false; $A \rightarrow B$ lacks truth-value if either A or B lacks truth-value.

In classical semantics, \exists and \forall may be regarded as naming functions from ‘propositional functions’ to truth-values. Under I and α , $A(x)$ names the 1-ary propositional function $\mathcal{A}: D \rightarrow \{T, F\}$ whose value at $\alpha'(x)$, where α' is an x -variant of α , is the truth-value of $A(x)$ under I and α' . Then $\exists(\mathcal{A}) = T$ if $\mathcal{A}(\alpha) = T$ for some $\alpha \in D$ and $\exists(\mathcal{A}) = F$ otherwise, while $\forall(\mathcal{A}) = T$ if $\mathcal{A}(\alpha) = T$ for each $\alpha \in D$ and $\forall(\mathcal{A}) = F$ otherwise. If these clauses are carried over to the present case, where \mathcal{A} may be a *partial* function $D \rightarrow \{T, F\}$, we have:

v_f5 . $\exists xA$ is true if A is true for some x -variant of α ; otherwise, $\exists xA$ is false; $\forall xA$ is true if A is true for each x -variant of α ; otherwise, $\forall xA$ is false.

Note that $\exists xA$ and $\neg\forall x\neg A$ are no longer equivalent in the sense of being true, false, or truth-valueless together. If a does not refer, $\exists xPxa$ is false

³⁰Woodruff [1970, p. 128] argues that the strong tables — which dictate replacing the second clause of v_f4 by ‘ $A \rightarrow B$ is true if A is false or B is true’ and the third by ‘ $A \rightarrow B$ lacks truth-value otherwise’ — are required by Frege’s view that reference is a function of sense. For skepticism, see [Lehmann, 1994, p. 326].

(because Pxa lacks truth-value for any assignment to x) but $\neg\forall x\neg Pxa$ is true ($\forall x\neg Pxa$ is false, since $\neg Pxa$ is always truth-valueless).

The valuation rules v_f1 – v_f5 are those of Lehmann [1994], except that he defines $\forall xA$ as $\neg\exists x\neg A$, so that the universal clause of v_f5 becomes ‘ $\forall xA$ is false if A is false for some x -variant of α ; otherwise $\forall xA$ is true’ and hence $\forall xPxa$ is true (!) when a does not refer. Smiley’s [1960, p. 126] rules differ only in taking $\exists xA(\forall xA)$ to lack truth-value if A lacks truth-value for some assignments to x but is otherwise false (true). Thus, $\exists x(a = fx)$ will lack truth-value under $\langle D, d \rangle$ if a refers, $d(f)$ is partial, but $d(a) \neq d(f)(\alpha)$ for any $\alpha \in D$ at which $d(f)$ is defined.

I have noted that logical truth may be understood in a strong or a weak sense. Similarly, logical consequence may be defined in a number of ways, depending upon whether we want valid inference (1) to lack counterexamples, (2a) to preserve truth, or (2b) to preserve non-falsehood:

$X \models_1 A$ iff there are no I and α such that: each X -formula is true while A is false.
 $X \models_{2a} A$ iff there are no I and α such that: each X -formula is true while A is not true.
 $X \models_{2b} A$ iff there are no I and α such that: A is false while no X -formula is false.

\models_1 supports contraposition ($\neg B \models \neg A$ provided $A \models B$) but not transitivity ($X \models A$ provided $X' \models A$ and $X \models B$ for each $B \in X'$): $\neg\exists x(x = a) \models_1 a = a$ and $a = a \models_1 \exists x(x = a)$, but $\neg\exists x(x = a) \not\models_1 \exists x(x = a)$. Both \models_{2a} and \models_{2b} support transitivity, but neither supports contraposition: $Pa \models_{2a} \exists x(x = a)$ but $\neg\exists x(x = a) \not\models_{2a} \neg Pa$, while $\neg\exists x(x = a) \models_{2b} \neg Pa$ but $Pa \not\models_{2b} \exists x(x = a)$. Both transitivity and contraposition can be had by combining (2a) and (2b), as in Blamey [1986, pp. 5 and 58], to require that valid inference preserve (3) both truth and non-falsity. That is, $X \models_3 A$ iff $X \models_{2a} A$ and $X \models_{2b} A$. \models_3 is obviously stronger than \models_{2a} or \models_{2b} , each of which is stronger than \models_1 . Note that A is strongly logically true iff $\models_{2a} A$ and weakly logically true iff $\models_1 A$ (or $\models_{2b} A$).

Each of these consequence relations can be expressed in terms of a notion of satisfiability, which in turn can be represented syntactically by a variant of Jeffrey’s [1991] tree method. Add a marker $*$ to L , and call A^* a **-formula*. Let Y range over sets of formulae and **-formulae*. Y is **-satisfiable* iff there is some I and α for which each **-formula* of Y is true and no formula of Y is false. The basic free consequence relations defined above may be expressed in terms of **-satisfiability* as:

$X \models_1 A$ iff $X^* \cup \{\neg A^*\}$ is not **-satisfiable*
 $X \models_{2a} A$ iff $X^* \cup \{\neg A\}$ is not **-satisfiable*
 $X \models_{2b} A$ iff $X \cup \{\neg A^*\}$ is not **-satisfiable*

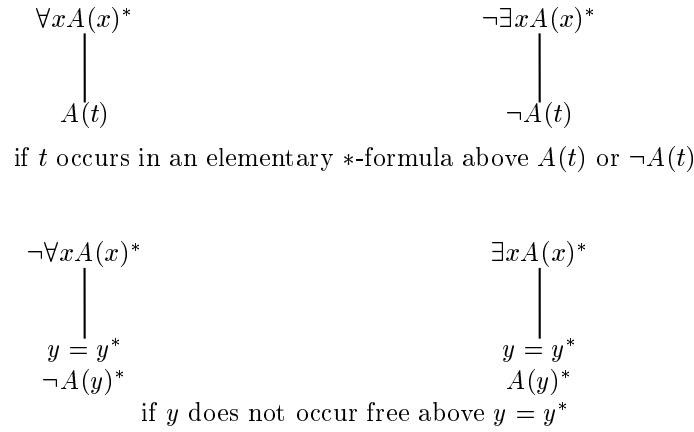

As in the classical case, a tree for finite Y is obtained by first listing the members of Y vertically and then extending this list downward in a branching array by application of reductive rules.³¹ Here, each classical

³¹The tree method may be modified to accommodate infinite sets of formulae. For a sketch of the argument applied to the free case, see [Lehmann, 1994, Section 4].

rule for a connective is replaced by two rules: one governing formulae, the other governing *-formulae.

Quantifier rules apply only to *-formulae:

In addition, we need a rule for converting formulae into *-formulae:

if A is (i) a quantified formula or the negation thereof; or (ii) an elementary formula, each term of which occurs in an elementary *-formula³² above A^* .

As the rule for $\neg(A \rightarrow B)$ will suggest, branches are not closed when they contain A and $\neg A$, as they are in the classical case, because both may lack truth-value. Instead, at least one of A and $\neg A$ must be a *-formula. Similarly, $t \neq t^*$, not the classical $t \neq t$, closes a branch. A tree is *closed* if each of its branches is closed. Let $Y \vdash$ iff some tree for some finite subset of Y is closed. It can be proved that $Y \vdash$ iff Y is not *-satisfiable; for details, albeit for a slightly different system of rules, see [Lehmann, 1994].

A Hilbert-style axiomatization of \models_{2a} or \models_{2b} would probably require introducing a non-Fregean connective t , as in [Smiley, 1960], [Woodruff, 1970], or [Robinson, 1974]: tA is true if A is true and is false otherwise.³³ Many classical tautologies are only weakly logically true, rules like ADD do not preserve truth, while rules like MP do not preserve non-falsehood. A Hilbert-style axiomatization of \models_1 seems beyond reach, since \models_1 is not transitive.

4 FREE DESCRIPTION THEORIES

The requirement that singular terms denote something in the range of the variables constrains classical description theory, just as it constrains classical logic. In natural languages there are many singular terms that may be regarded as *descriptions* having the form ‘the (one and only) x such that $\dots x \dots$ ’, where ‘ $\dots x \dots$ ’ is some condition on x : if ‘ $\dots x \dots$ ’ is true only of α , then ‘the (one and only) x such that $\dots x \dots$ ’ refers to α . For example, ‘the least prime’ refers to 2 because ‘ x is prime and no prime is less than x ’ is true only of 2. Indeed, one might want to maintain, as does Quine [1997, p. 103], that the “universal form of singular terms” is ‘the (one and only) x such that $\dots x \dots$ ’ in the sense that *any* constant or variable singular term may be regarded as having this form. Names, such as ‘Socrates’, can be handled by introducing singular predicates, such as ‘ x Socratizes’. Variable terms,

³²Assuming $\forall_f 1$. If subject-predicate formulae with referring terms can lack truth-value, replace ‘elementary *-formula’ here with ‘identity *-formula or negated identity *-formula’.

³³If A^* is identified with tA , then X is *-satisfiable iff some I and α fails to falsify any member of X . Smiley [1960] does not give any proof method, and Woodruff’s [1970] natural deduction system is unsound.

such as ‘the least prime greater than y ’, may be construed as descriptions whose referents will generally depend upon the values of their variables.

We may represent descriptions by adding to a first-order language L the description operator ι with formation rule: if A is a formula, ιxA is a term. Let L_ι be the resulting language. The corresponding semantic rule will specify that under I and α ,

r4. ιxA refers to whatever uniquely satisfies A

where α uniquely satisfies A iff (i) A is true under I and α' , where α' is the x -variant of α for which $\alpha'(x) = \alpha$, and (ii) A is false under I and any other x -variant of α . This understanding we might hope to capture proof-theoretically by adding to CL a schema sometimes termed ‘Lambert’s Law’:

LL $\quad \forall y(y = \iota xA \leftrightarrow \forall x(A \leftrightarrow y = x))$

where y is not free in A (and a free occurrence of y in A is now any occurrence not in a part of A of the form $\forall yB$ or ιyB).³⁴

If A has no free variables other than x , then whatever ιxA designates under I and α will be an individual of D that is independent of α , so we may treat ιxA as a constant. If in addition y is free, then whatever ιxA designates will be an individual of D that depends upon the value $\alpha(y)$ of y , and we may regard ιxA as giving the value of some function at y . Thus, having descriptions ιxA available would permit defining constants c by $c = \iota xA$ and function-names f by $\forall y(fy = \iota xA)$.

However, if ιxA is to be a singular term, classical semantics demands that it refer to something in the range of the variables. There is no problem if $\exists!x A$ is true. For then some individual α of D will uniquely satisfy A , and ιxA will refer to it by r4; such descriptions are said to be *proper*. But r4 tells us nothing about the referent of an *improper* description ιxA . If $\exists!x A$ is false, so that nothing uniquely satisfies A , we must nonetheless specify a referent in D for ιxA . Moreover, LL is *false* if $\exists!x A$ is false, since $\forall y(y = \iota xA \leftrightarrow \forall x(A \leftrightarrow y = x)) \models \exists!x A$: both $\forall x(A \rightarrow x = \iota xA)$ and $A(\iota xA)$ follow classically from LL, so $\exists!x A$ follows as well.

Indeed, some instances of LL, as when A is $x \neq x$ or $Px \& \neg Px$, are *logically false*. The corresponding instances of $A(\iota xA)$ — $\iota x(x \neq x) \neq \iota x(x \neq x)$ or $P(\iota x(Px \& \neg Px)) \& \neg P(\iota x(Px \& \neg Px))$ — are sometimes called *Meinong’s paradox*, after Russell’s derivation of them from Meinong’s principle that ‘... x ...’ is true of the x such that ... x ..., a principle expressed by $A(\iota xA(x))$. Lambert [1991b; 1995] shows that Russell’s paradox may also be derived from LL and that ways of evading it in set theory parallel ways of evading Meinong’s paradox in description theory.

³⁴Lambert [1991b; 1995] labels this system ‘NTDD’ (for ‘naive theory of definite descriptions’).

4.1 Classical Fixes

Accordingly, if we wish to take descriptive terms seriously within the classical framework, we must either modify the formation rule to exclude improper descriptions, or we must specify a referent in D for improper descriptions and modify LL.

The first approach is associated with Hilbert and Bernays. Recall that we may extend a first-order theory T to T' by adding a new constant c with the defining axiom $\forall x(x = c \leftrightarrow A_c(x))$, provided x is the only free variable of $A_c(x)$ and $\exists!xA_c(x)$ is a theorem of T . Similarly, we may introduce a new function name f with the defining axiom $\forall x\forall y(y = fx \leftrightarrow A_f(x, y))$, provided x and y are the only free variables of A_f and $\forall x\exists!yA_f(x, y)$ is a theorem of T . Each addition is really only a notational change. We may eliminate c from a formula B' by replacing atomic parts Pc by $\exists x(A_c(x) \& Px)$ and the resulting formula B will be a theorem of T iff B' is a theorem of T' . Similarly, we may eliminate f from a formula B' by replacing atomic parts Pft by $\exists y(A_f(t, y) \& Py)$, where y does not occur in t — and the resulting formula B will be a theorem of T iff B' is a theorem of T' .

Since we may think of c as $\iota xA_c(x)$ and fx as $\iota yA_f(x, y)$, the conditions on defining c and f give the Hilbert-Bernays conditions for considering descriptive terms well-formed: $\exists!xA_c(x)$ and $\forall x\exists!yA_f(x, y)$. Essentially, this amounts to saying that a descriptive term ιxA is well-formed only under (consistent) assumptions X — the axioms of T — that entail $\exists!xA$, assumptions which accordingly function as additional premises in any argument involving ιxA .

The Hilbert-Bernays approach has the awkward consequence of making the question of whether ιxA is a term undecidable, since logical consequence is not decidable. Normally, of course, the syntactical categories of term, formula, and sentence are decidable, provided the basic categories of constant, variable, (k -place) function-name, and (k -place) predicate are decidable. But that is not the case here.

Instead of limiting attention to proper descriptions, we can instead follow Frege and stipulate a referent in D for the improper descriptions, modifying LL accordingly. To L we add a constant e for the designated ('empty') element. An interpretation of L , is just an interpretation $\langle D, d \rangle$ of L , which accordingly will assign e a referent $d(e)$ in D . The reference rule for ιxA will now read:

- r_f4. If some individual α of D uniquely satisfies A , then ιxA refers to α ;
 otherwise, ιxA refers to $d(e)$.

Thus, all instances of the schema

$$F \ B(\iota xA) \leftrightarrow (\exists y(\forall x(A \leftrightarrow y = x) \& B(y)) \vee (\neg \exists y \forall x(A \leftrightarrow y = x) \& B(e)))$$

are logically true. To axiomatize logical truth, we may add

$$\text{LL}_f \quad \forall y(y = \iota xA \leftrightarrow ((\exists! xA \& A(y)) \vee (\neg \exists! xA \& y = e)))$$

in place of LL to CL.

Assigning improper descriptions an arbitrary referent is like arbitrarily completing a partial function, and here as there we must be prepared for some weird results: if some other constant c refers to $d(e)$, then $c = \iota x(x \neq x)$, will be true, though it will represent sentences like ‘Zero is the non-self-identical number’. Moreover, $\exists y(y = \iota x(x \neq x))$ and $\iota x(x = x) = \iota x(x \neq x)$ are logically true.

An alternative to treating descriptions ιxA as genuine terms is to follow Russell and to regard formulae $B(\iota xA)$ in which they appear as giving only the surface form of corresponding sentences of natural language, their logical form being obtained by a transformation of $B(\iota xA)$ that eliminates descriptions. A sentence like ‘The present King of France is bald’ looks like a subject-predicate sentence with form $B(\iota xKx)$, where Kx represents ‘ x is King of France at present’, but ιxKx is not a genuine singular term, according to Russell. Why? Because (1) genuine singular terms are meaningful, (2) the meaning of a meaningful singular term is its denotation, and (3) ‘the present King of France’ has no denotation. In Russell’s view, the logical form of ‘The present King of France is bald’ is not subject-predicate, but existential: $\exists y(\forall x(Kx \leftrightarrow y = x) \& Bx)$, which says that one and only one thing is King of France at present, and that thing is bald. For Russell, we have

$$\text{R} \quad P(\iota xA) \leftrightarrow \exists y(\forall x(A \leftrightarrow y = x) \& Py)$$

for predicates P , but not in general.

‘The present King of France is not bald’ looks like a negated subject-predicate sentence with form $\neg B(\iota xKx)$; what is its logical form? If we think of ιxKx as occurring in $B(\iota xKx)$, the form of $\neg B(\iota xKx)$ will be $\neg \exists y(\forall x(Kx \leftrightarrow y = x) \& Bx)$; if we think of ιxKx as occurring in $\neg B(\iota xKx)$, the form of $\neg B(\iota xKx)$ will be $\exists y(\forall x(Kx \leftrightarrow y = x) \& \neg Bx)$. In the former *narrow-scope* reading, the sentence is true: it is being read as ‘it’s not the case that: the present King of France is bald’. In the latter *wide-scope* reading, the sentence is false: it is being read as ‘the present King of France is non-bald’. If A is description-free, LL is logically true if ιxA is taken to have narrowest *scope*:

$$\forall y(\exists z(\forall x(A \leftrightarrow z = x) \& y = z) \leftrightarrow \forall x(A \leftrightarrow y = x))$$

But LL is false if ιxA is improper and is taken to have wider scope:

$$\begin{aligned} & \forall y \exists z (\forall x (A \leftrightarrow z = x) \& (y = z \leftrightarrow \forall x (A \leftrightarrow y = x))) \\ & \exists z (\forall x (A \leftrightarrow z = x) \& \forall y (y = z \leftrightarrow \forall x (A \leftrightarrow y = x))) \end{aligned}$$

Accordingly, the transformation of a formula B containing descriptions into a ι -free formula $tr(B)$ requires an indication of the scope of the descriptions in B . This may be done by using the notation $[\iota xA]B$ to indicate that the scope of ιxA in B is B . The wide scope reading of ιxKx in $\neg B(\iota xKx)$ would then be indicated by $[\iota xKx]\neg B(\iota xKx)$ and the narrow scope reading by $\neg[\iota xKx]B(\iota xKx)$. More formally, we may add to the formation rules of L two clauses:

1. If B is a formula in which ιxA appears, $[\iota xA]B$ is a formula
2. If B is a formula in which (a) each description ιxA that occurs in B occurs in a subformula $[\iota xA]C$ of B and (b) any subformula $[\iota xA]C$ of B is such that some occurrence of ιxA in C is not in a subformula $[\iota xA]C'$ of C , then B is a $[\iota]$ -formula.

For the purposes of (2), subformulae of B include formulae that appear in descriptions in B . Scope indicators $[\iota xA]$ are like quantifiers, and (2) is analogous to a clause defining sentences as formulae lacking free occurrences of variables. (a) rules out unscoped occurrences of descriptions, and (b) rules out vacuous scope indicators. Let this language be $L_{[\iota]}$. tr then maps $[\iota]$ -formulae of $L_{[\iota]}$ into ι -free formulae of L :

- t1. $tr(A) = A$ if A is not a $[\iota]$ -formula.
- t2. tr commutes with connectives and quantifiers.
- t3. $tr([\iota xA]B(\iota xA)) = \exists y(\forall x(tr(A) \leftrightarrow y = x) \& tr(B(y)))$.

Despite its enormous influence, Russell's treatment of descriptive terms is ill-motivated and cumbersome. The denotative theory of meaning which led Russell to banish improper descriptions from the realm of terms has little plausibility, especially in view of the many failed attempts to capture intension in extension (*e.g.*, the meaning of a sentence is the proposition it expresses, and that is a *set of possible worlds*). Although scope indicators may be useful to disambiguate constructions like 'The present King of France isn't bald', they introduce a complication that in many cases is of no use. For example, 'Winston Churchill or the present King of France is bald' appears to be unambiguous in English, though Russell's formalism provides two readings: $Bc \vee [\iota xKx]B(\iota xKx)$, which is true, and $[\iota xKx](Bc \vee B(\iota xKx))$, which is false. There are no scope indicators in English, and assigning Russellian forms is an *ad hoc* business. The validity of 'The janitor is guilty, so the janitor or the accused is guilty' requires a narrow-scope construal of 'the accused'; the validity of 'The accused is not guilty, those who are not guilty are innocent, so the accused is innocent' requires a wide-scope construal of 'the accused' in the premise.

A treatment of descriptions that enables us to handle them as we would other terms, while avoiding the problems of the other two approaches is obviously worth pursuing. Insofar as these problems arise from the straightjacket of classical semantics, we may hope to avoid them either by permitting improper descriptions to refer to individuals of an outer domain or not to refer at all.

4.2 Outer Domain Free Description Theory

An outer domain interpretation for descriptions may be obtained from an outer domain interpretation $\langle D_i + D_o, d \rangle$ by adding a denotation function d' for descriptions:

i_o5. $d'(\iota xA) \in D_o$.

$d'(\iota xA)$ will be the referent of ιxA , if ιxA turns out to be improper. Thus, r4 is rewritten:

r_o4. If some individual α of D_i uniquely satisfies A , then ιxA refers to α ; otherwise, ιxA refers to $d'(\iota xA)$.

Relative to this semantics, LL is logically true. If LL is added to PFL, we obtain a complete axiomatization of this semantics. This free description theory is rather weak; let us call it mFD ('m' for 'minimal').³⁵

mFD permits many individuals in D_o and places no restrictions on their assignment as referents to improper descriptions. The limiting case appears to be the one in which D_o consists of a single individual, which accordingly must be the referent of any improper description. If interpretations of L_i require as much, then

$$\text{FD2} \quad (\neg\exists x(x = s) \& \neg\exists x(x = t)) \rightarrow s = t$$

is logically true. If s and t do not refer to existents, *i.e.*, to individuals in the inner domain, then they must refer to individuals of the outer domain, but there is just one of these. This semantics may be axiomatized by adding FD2 to mFD. Alternatively, we could add $\neg\exists y(y = \iota xA) \rightarrow \iota xA = \iota x(x \neq x)$, where y is not free in ιxA , as in [Scott, 1967, p. 35]. Let us term this theory MFD ('M' for 'maximal').

MFD has obvious affinities with the Fregean treatment of improper descriptions in classical semantics. The classical principle F holds with $\iota x(x \neq x)$ in place of e , and we must identify the present King of France with the unicorn in the closet. However, $\exists y(y = \iota x(x \neq x))$ and $\iota x(x = x) = \iota x(x \neq x)$ are no longer logically true.

³⁵This theory is called FD by Lambert and van Fraassen [1972, p. 160] and MFD by Lambert [1997, p. 118].

Lambert [1997, p. 118] notes that between mFD and MFD lie various free description theories, partially ordered by inclusion. One linear progression is:

$$T_1 \quad \text{mFD} + \iota x(x = t) = t$$

$$T_2 \quad \text{mFD} + (A(t) \ \& \ \forall x(A \rightarrow x = t)) \rightarrow A(\iota xA)$$

$$T_3 \quad \text{mFD} + (\neg \exists x(x = t) \ \& \ A(t)) \rightarrow A(\iota xA)$$

These theories tell us when $A(\iota xA)$ is true. LL $\models \exists y(y = \iota xA) \rightarrow A(\iota xA)$, if y is not free in ιxA , so $\exists y(y = \iota xA) \rightarrow A(\iota xA)$ is a theorem of mFD and thus of T_1 , T_2 , T_3 , and MFD: $A(\iota xA)$ holds when ιxA refers to an existent. If A is false of every individual, as when A is $x \neq x$ or $Px \ \& \ \neg Px$, then of course A is not true of ιxA . Otherwise, mFD is non-committal about whether $A(\iota xA)$ is true, and theories T_1 , T_2 , and T_3 give us more information.

- T_1 . If $A(x)$ is $x = t$ and ιxA refers to a non-existent, so does t . $\iota x(x = t) = t$ identifies these nonexistents and thus makes $A(\iota xA)$ true when A is $t = x$. Hence, the one and only thing that is Vulcan is Vulcan.
- T_2 . If t refers to a non-existent and A is true of it, then $\forall x(A \rightarrow x = t)$ will hold only if A is not true of any existent. Thus $(A(t) \ \& \ \forall x(A \rightarrow x = t)) \rightarrow A(\iota xA)$ tells us that $A(\iota xA)$ provided A is true of some non-existent but not true of any existent. This will be the case if A is $t = x$ and t does not refer, so T_2 contains T_1 . But it also makes *the* unicorn in the closet *a* unicorn in the closet, since Ux will not be true of any existent.
- T_3 . $(\neg \exists x(x = t) \ \& \ A(t)) \rightarrow A(\iota xA)$ says that A is true of ιxA provided (i) A is true of some non-existent. LL assures that A is true of ιxA provided A is uniquely true of some existent, so the extra content of T_3 over mFD is that A is true of ιxA provided (i) and either (ii) A is not true of any existent or (iii) A is true of more than one existent. So the extra content over T_2 is that A is true of ιxA provided (i) and (iii). Hence, *the* lost treasure is *a* lost treasure, since there are mythical lost treasures and more than one real one. Models of MFD have just one non-existent, so if ιxA refers to a non-existent, $A(\iota xA)$ will be true provided A is true of some non-existent. However, MFD is stronger than T_3 , since the latter permits more than one non-existent.

Another linear progression is:

$$T'_1 \quad \text{mFD} + \forall_c x(A(x) \leftrightarrow B(x)) \rightarrow \iota xA = \iota xB$$

$$T'_2 \quad \text{mFD} + \forall x(A(x) \leftrightarrow B(x)) \rightarrow \iota xA = \iota xB$$

\forall_c is the *comprehensive* universal quantifier with the classical valuation rule v5, where D is $D_i + D_o$ and x -variants may assign values in D_0 . $\forall_c x(A(x) \leftrightarrow B(x)) \rightarrow \iota xA = \iota xB$ says that ιxA and ιxB are co-referential provided A and B are co-extensive in the strong sense of being true of the same existents and non-existents. Thus, the present King of France needn't be the unicorn in the closet. $\forall x(A(x) \leftrightarrow B(x)) \rightarrow \iota xA = \iota xB$ says that ιxA and ιxB are co-referential provided A and B are co-extensive in the weaker sense of being true of the same existents. Thus, the present King of France is the unicorn in the closet, though the lost treasure needn't be identified with either: T'_2 , like T_2 , is weaker than MFD. Note that $\forall x(A(x) \leftrightarrow B(x)) \rightarrow \forall y(y = \iota xA \leftrightarrow y = \iota xB)$, and hence $\forall_c x(A(x) \leftrightarrow B(x)) \rightarrow \forall y(y = \iota xA \leftrightarrow y = \iota xB)$, is a theorem of mFD.

Outer domain semantics for descriptions permits a formal representation of Anselm's ontological argument. Here individuals that exist *in re* belong to the inner domain, while individuals that exist *in intellectu* populate the outer domain. If Gx represents 'nothing greater than x can be conceived', then a simple version of the argument is:

$$\frac{\neg \exists y(y = \iota xGx) \rightarrow \neg G(\iota xGx) \quad G(\iota xGx)}{\exists y(y = \iota xGx)}$$

This argument is valid by *modus tollens*. In mFD, the premises are falsifiable, and both are required for validity. By contrast, as Mann [1967] has observed, a Russellian treatment of the descriptions collapses the argument into something trivial and question-begging. The antecedent of the first premise is equivalent to $\exists x(x \neq x)$ if its form is taken to be $[\iota xGx] \neg \exists y(y = \iota xGx)$ and to $\neg \exists! xGx$ if its form is taken to be $\neg [\iota xGx] \exists y(y = \iota xGx)$ or $\neg \exists y[\iota xGx](y = \iota xGx)$; the consequent is equivalent to $\exists x(Gx \& \neg Gx)$ if its form is taken to be $[\iota xGx] \neg G(\iota xGx)$ and to $\neg \exists! xGx$ if its form is taken to be $\neg [\iota xGx] G(\iota xGx)$. Hence the first premise is either logically true or logically false. The second premise is equivalent to $\exists! xGx$, as is the conclusion, read either as $[\iota xGx] \exists y(y = \iota xGx)$ or as $\exists y[\iota xGx](y = \iota xGx)$. So the argument becomes: $A, \exists! xGx / \exists! xGx$, where A is logically true or logically false.

4.3 Russellian Free Description Theory

To obtain a ‘Russellian’ free description theory for L_i , we need only supplement negative free semantics with

- r_p4. If some individual α of D uniquely satisfies A , then ιxA refers to α ; otherwise, ιxA does not refer.

While this treatment of descriptions differs from Russell’s in taking ιxA to be a genuine term, it does make $P(\iota xA)$ false if ιxA is improper, just as Russell insisted: the Russellian biconditionals R are logically true. Every instance of LL is also logically true, and indeed logical truth relative to this semantics may be axiomatized by adding LL to NFL, as in [Burge, 1974]. Let us call this theory rFD.

Principles defining extensions of mFD generally do not carry over to rFD. Both $(A(t) \& \forall x(A \rightarrow x = t)) \rightarrow A(\iota xA)$ and $(\neg \exists x(x = t) \& A(t)) \rightarrow A(\iota xA)$ are OK: if ιxA refers, then $A(\iota xA)$; if ιxA does not refer, then $A(t)$ and $A(\iota xA)$ will have the same truth-value if t does not refer, and t cannot refer if $\neg \exists x(x = t)$ is true or $(A(t) \& \forall x(A \rightarrow x = t))$ is true while ιxA does not refer. The other principles are not OK. The “cancellation” principle $\iota x(x = t) = t$ is false when t does not refer. FD2 is not always true; indeed, some instances, such as $\neg \exists y(y = \iota x(x \neq x)) \rightarrow \iota x(x \neq x) = \iota x(x \neq x)$, are logically false, since its antecedent is logically true and its consequent is logically false. $\forall x(A(x) \leftrightarrow B(x)) \rightarrow \forall y(y = \iota xA \leftrightarrow y = \iota xB)$, which says that if A and B are co-extensive, ιxA and ιxB do not differ in denotation, is always true. But $\forall x(A(x) \leftrightarrow B(x)) \rightarrow \iota xA = \iota xB$ is not always true; indeed, $\forall x(x \neq x \leftrightarrow x \neq x) \rightarrow \iota x(x \neq x) = \iota x(x \neq x)$ is logically false.

rFD does not capture Russell’s scope distinctions. We have schema R

$$[\iota xA]P(\iota xA) \leftrightarrow \exists y(\forall x(A \leftrightarrow y = x) \& Py)$$

but not, for example,

$$[\iota xA]\neg P(\iota xA) \leftrightarrow \exists y(\forall x(A \leftrightarrow y = x) \& \neg Py)$$

In a sense, only descriptions with narrowest scope are treated as genuine singular terms.

By introducing machinery for forming *complex predicates* λxB from formulae B , Scales [1969] is able to represent scoped descriptions as genuine singular terms satisfying the more general schema

$$S \quad \lambda yB(y)(\iota xA) \leftrightarrow \exists y(\forall x(A \leftrightarrow y = x) \& B(y))$$

Obtain L_λ from L_i by adding the predicate-forming operator λ with formation rule: $\lambda x_1 \dots x_k A$ is a k -place (complex) predicate if the free variables of A are x_1, \dots, x_k . “Russellian” interpretations of L_λ are obtained from those of L_i by stipulating that the extension $d(\lambda x_1 \dots x_k A)$ of the complex

predicate $\lambda x_1 \dots x_k A$ is the set of k -tuples $\langle \alpha_1, \dots, \alpha_k \rangle$ of elements of D of which A is true, where A is true of $\langle \alpha_1, \dots, \alpha_k \rangle$ iff A is true when x_i is assigned α_i . Note that if t does not refer, $\lambda x \neg Px(t)$ is false while $\neg Pt$ is true. L_λ thus embodies Aristotle's view that truly attributing a property requires an existing subject, though truly denying an attribution does not; 'Pegasus is wingless' is false, while 'Pegasus does not have wings' is true.

Schema S holds because (1) if $\iota x A$ refers to α , A is true only of α , and α is in the extension of $\lambda y B(y)$ iff $B(y)$ is true of α , and (2) if $\iota x A$ does not refer, $\lambda y B(y)(\iota x A)$ is false and, because $\exists! x A$ is false, so is the right side of S. Logical truth in L_λ may be axiomatized by adding LL and

$$\lambda x_1 \dots x_k A(t_1, \dots, t_k) \leftrightarrow (\exists x_1 (x_1 = t_1) \& \dots \& \exists x_k (x_k = t_k) \& A(t_1, \dots, t_k))$$

to NFL; see Scales [1969, p. 11] and Lambert [1997, p. 112].

Recall that for Russell, $[\iota]$ -formulae A of $L_{[\iota]}$ are abbreviations for ι -free formulae $tr(A)$ of L : $tr(A)$ gives the Russellian meaning of A . We may also translate $[\iota]$ -formulae A into formulae of L_λ by tr' , where tr' is defined by t1, t2 and

$$t3'. \quad tr'([\iota x A]B(\iota x A)) = \lambda y tr'(B(y))(\iota x tr'(A)).$$

Under any interpretation I of L_λ and assignment α , $tr'(A)$ gets the same value as $tr(A)$: in the basis case where both A and B are ι -free, $tr(A)$ is the left side of schema S , while $tr'(A)$ is the right side. Accordingly, scoped descriptions can be regarded as genuine singular terms without altering Russellian truth-values, provided their contexts are treated as complex predicates.

Kroon [1991, p. 24] has observed that "the Russellianizing of definite descriptions is a clumsy and unnatural business — far more clumsy and unnatural than its defenders seem to realize". The problematic constructions Kroon has in mind are those in which we refer to something by *describing* a description, as in 'The man denoted by the description John just used is bald.' To represent constructions of the general form 'what's denoted by the description that ϕ s has P ' *à la* Russell, we would need a description predicate DES true of descriptions ' $\iota x \phi(x)$ ', a corresponding open-sentence predicate COS true of pairs $\langle \iota x \phi(x), \phi(x) \rangle$, and a satisfaction predicate SAT true of pairs $\langle \alpha, \phi(x) \rangle$ iff α satisfies ' $\phi(x)$ '. Then the ugly Russellian analysis would be: $\exists x (\exists y (\forall z ((DES(z) \& \phi(x)) \leftrightarrow z = y) \& COS(y, x)) \& \exists w (\forall z (SAT(z, x) \leftrightarrow z = w) \& P(w)))$. How much simpler it would be if we could write $P(den(\iota x (DES(x) \& \phi(x))))$, where den represents the denotation function.

Kroon develops a modified free Russellian semantics for such constructions. Imagine that L_ι has been supplemented with vocabulary that permits naming its terms and formulae (so that DES may be defined) and let $L_{\iota'}$

result from L_t by adding semantic predicates $TRUE$ and DEN (so that den may be defined by $den(x) = y \leftrightarrow DEN(x, y)$). Interpretations I of L_t are as in negative free semantics, except that Kroon assumes that every individual of D is named by some constant of L_t so that reference and valuation rules need be given only for constant terms and sentences. $d(TRUE)$ and $d(DEN)$ are defined by a fixed point construction over I . The extensions of I used in this construction assign semantic predicates P both a set $d_t(P)$ of which they are true and a set $d_f(P)$ of which they are false; the initial extension I_0 of I makes $TRUE$ false of every non-sentence and true of nothing and DEN false of every pair $\langle \alpha, \beta \rangle$ where α is not a constant term and true of nothing. If t refers to α and α is neither in $d_t(TRUE)$ nor in $d_f(TRUE)$, then $TRUE(t)$ lacks truth-value; if s refers to α and t refers to β and $\langle \alpha, \beta \rangle$ is neither in $d_t(DEN)$ nor in $d_f(DEN)$, then $DEN(s, t)$ lacks truth-value. r_p4 is modified so that ιxA is *undefined* if $\exists!xA$ lacks truth-value. As usual in negative free semantics, subject-predicate and identity sentences containing non-referring terms are false; however, if no constituent term fails to refer and at least one is undefined, they lack truth-value. Strong tables are used for the connectives; $\forall xA$ lacks truth-value if $A(c)$ is not false for any c but lacks truth-value for some c .

4.4 Non-bivalent Free Description Theories

Finally, it is possible to give L_t a supervaluational or a neutral free semantics, so that non-referring descriptions ιxA generate truth-value gaps.

A slight obstacle to extending Bencivena's [1980] supervaluational semantics to L_t is that some terms, such as $\iota x(x \neq x)$, are now not going to refer under any classical extension I' and α' of a partial interpretation I and assignment α . Thus, valuation rules v3-v5 need to be rewritten to allow for formulae that are neither true nor false under I' and α' . Bencivena [1980b, p. 396] specifies Kleene's strong tables for the connectives and stipulates that $\forall xA$ is truth-valueless if A is never false but lacks truth-value for some assignment to x :

$\forall xA$ is true (false) under I' and α' if A is true (false) under I' and α'_x for each (some) x -variant α'_x of α ; otherwise, $\forall xA$ lacks truth-value under I' and α' .

The reference rule for descriptions will be

If some individual uniquely satisfies A under I and α , then ιxA refers to it under I' and α' ; if no individual uniquely satisfies A under I and α but some individual uniquely satisfies A under I' and α' , then ιxA refers to it under I' and α' ; otherwise ιxA does not refer under I' and α' .

Supervaluational semantics for L renders $t = t$ and $Pt \vee \neg Pt$ logically true, but that is not the case for L_ι . Since $\iota x(x \neq x)$ does not refer under any classical extension I' of I , neither $\iota x(x \neq x) = \iota x(x \neq x)$ nor $P\iota x(x \neq x) \vee \neg P\iota x(x \neq x)$ is true or false under I' , so both are supervalueless under (any) I . $\iota xPx = \iota xPx$ will also be supervalueless under $I = \langle D, d \rangle$ if $d(P)$ is empty (as when Px represents ‘ x is a unicorn in the closet’), since ιxPx will fail to refer under some extension I' of I . If you want ‘the unicorn in the closet is the unicorn in the closet’ to be true, then you can follow Bencivena [1980b, p. 398] and modify the notions of supertruth and superfalsity so that A is *supertrue* (*superfalse*) under I and α iff A has a truth-value under some some classical extension I' and α' of I and α , and A is true (false) under each such extension. The semantic rationale for this manoeuvre, however, is unclear.

All instances of LL are logically supertrue for this semantics. Under I' and α' , ιxA refers, if at all, to something in D that uniquely satisfies A , whereas if ιxA does not refer, both $y = \iota xA$ and $\forall x(A \leftrightarrow y = x)$ are false of each individual of D in virtue of v_b2 . The principles generating positive free description theories stronger than mFD are, in general, not logically supertrue. Counterexamples to $\iota x(x = t) = t$, $(A(t) \& \forall x(A \rightarrow x = t)) \rightarrow A(\iota xA)$, $(\neg \exists x(x = t) \& A(t)) \rightarrow A(\iota xA)$, $(\neg \exists x(x = t) \& \neg \exists x(x = s)) \rightarrow s = t$, and $\forall x(A \leftrightarrow B) \rightarrow (\iota xA = \iota xB)$ are provided by $t = s = \iota x(x \neq x)$ and $A = B = x \neq x$. No axiomatization of logical supertruth is given, since Bencivena establishes that no axiomatization is possible.

Description theories that incorporate neutral free semantics have been developed by Stenlund [1973] and Robinson [1974]. Indeed, their systems probably deserve to be regarded as the first complete neutral free logics. Both theories essentially identify referenceless terms with improper descriptions: interpretations of L_ι are classical for Robinson and Stenlund.³⁶ Thus, constants — and variables under assignment³⁷ — refer *via* i1–i2 and r1–r2 to individuals of D , and function-names designate total functions on D by i3.

Robinson’s treatment of free semantics leaves a good deal to the imagination — it must be inferred from his proof system.³⁸ Except as noted below, however, he appears to be committed to the same rules of reference

³⁶Stenlund [1973, p. 63] permits D to be empty. However, this does not appear to be consistent with his Theorem 6.2.1 [p.66], which states that $t \downarrow$ is provable iff t refers under each interpretation, and the fact that $c \downarrow$ is an axiom [p.17].

³⁷Both Stenlund and Robinson treat quantification substitutionally.

³⁸For example, Robinson’s [1974, p. 498] rule viii allows us to derive $\forall xA \rightarrow A(t)$ provided we have derived formulae, written below as $\forall xA \downarrow$ and $t \downarrow$, to the effect that $\forall xA$ has a truth-value and t refers. This seems to require the understanding of the quantifiers given below, since if $\forall xA$ is false and t refers, we cannot be sure that $A(t)$ — and therefore $\forall xA \rightarrow A(t)$ — is not truth-valueless unless $A(x)$ has a truth-value for any assignment to x .

and valuation that Stenlund [1973, p. 64] gives explicitly. The classical r3 is modified to:

If t_i refers to α_i , then $ft_1 \dots t_k$ refers to $d(f)(\alpha_1, \dots \alpha_k)$; otherwise, $ft_1 \dots t_k$ does not refer.

Descriptions are governed by r_p4, and subject-predicate formulae, identities, and negations by the Fregean valuation rules v_f1–v_f3. Robinson appears to endorse the weak reading of \rightarrow embodied in v_f4. Stenlund, however, amends it so that $A \rightarrow B$ is *true* if A is false and B is truth-valueless; the weak table would render his system unsound, since $\exists!x(x \neq x) \rightarrow (\iota x(x \neq x) = \iota x(x \neq x))$ is provable in it. Stenlund regards $\forall xA$ as truth-valueless if A is truth-valueless for some assignment to x , as when A is $P\iota y(f(y) = x)$ and $d(f)$ is not 1-1. Thus, the Fregean valuation rule v_f5 needs to be modified to:

$\forall xA$ is true if A is true for each x -variant of α , and $\forall xA$ is false if A is false for some x -variant of α and not truth-valueless for any x -variant of α ; otherwise, $\forall xA$ is truth-valueless.

A peculiar consequence of this understanding of the quantifiers is that sentences like $\neg\exists x(x = \iota y(y \neq y))$ are not true, but truth-valueless.

As one might expect of a neutral semantics, not all instances of LL are logically true in the sense of being true under every interpretation — $\forall y(y = \iota x(x \neq x) \leftrightarrow \forall x(A \leftrightarrow y = x))$ is truth-valueless under any interpretation — though none are false under any interpretation. The same substitutions that generate supervalueless instances of the principles that extend mFD will generate truth-valueless instances of them here.

Stenlund supplies a natural deduction system of rules for this semantics, Robinson a Hilbert-style system. Both employ notation for indicating that terms refer and formulae have truth-value.³⁹ Let us use Beeson's [1985, p. 98] operator \downarrow for this purpose. Define a \downarrow -formula as $e \downarrow$, where e is a term or formula, and extend the valuation rules to \downarrow -formulae by:

$t \downarrow$ is true if t refers; otherwise, $t \downarrow$ is false.
 $A \downarrow$ is true if A is true or false; otherwise, $A \downarrow$ is false.

Both systems have axioms and rules of three kinds. Those of the first kind, such as

$$\begin{array}{l} \vdash c \downarrow \\ t \downarrow \vdash ft \downarrow \\ \exists!xA \vdash \iota xA \downarrow \\ t \downarrow \vdash Pt \downarrow \\ s \downarrow t \downarrow \vdash s = t \downarrow \\ A \downarrow \vdash \neg A \downarrow \end{array}$$

³⁹Stenlund uses $t \in I$ for $t \downarrow$ and $A \in F$ for $A \downarrow$; Robinson uses $\triangleleft e$ for $e \downarrow$.

permit us to prove \downarrow -formulae. Rules of the second kind license moving from \downarrow -formulae to formulae, as by

$$t \downarrow \vdash t = t$$

More interesting examples are Robinson's

$$A_1 \downarrow, \dots, A_k \downarrow \vdash B(A_1, \dots, A_k),$$

provided $B(A_1, \dots, A_k)$ is a classical tautology,⁴⁰ and Stenlund's rule of conditional proof:

$$X \vdash A \rightarrow B \text{ provided } X \vdash A \downarrow \text{ and } X, A \vdash B.$$

More familiar rules of the third kind permit deriving formulae from formulae; they include MP and

$$\exists! x A \vdash A(\iota x A).$$

Both Stenlund and Robinson provide completeness proofs. Robinson sketches a proof that $K \vdash A$ iff $K \models_{2a} A$, where A is a formula or \downarrow -formula, K is a set of ι -free sentences, and each non-logical symbol of A occurs somewhere in K . Stenlund claims only weak completeness ($\vdash A$ iff $\models_{2a} A$), though his proof may be generalizable to a result like Robinson's.

5 OTHER APPLICATIONS

5.1 Predication Again

Recall the Russell-Meinong view that predication presupposes a subject in the strong sense that a subject-predicate form cannot be ascribed to a sentence unless the subject exists. Quine [1960, p. 96] is more liberal: "Predication joins a general term and a singular term to form a sentence that is true or false according as the general term is true or false of the object, if any, to which the singular term refers."⁴¹ This is really just a special case, since Quine counts any open sentence with purely referential occurrences of variables as a predicate: such open sentences are true or false *of* (tuples of) objects.

The generalization to open sentences obliterates Aristotle's distinction between 'Socrates is ill' and 'Socrates is not well', but Quine's account of predication is like Aristotle's in allowing for irreferential terms. Strangely enough, as Lambert [1986, p. 277] observes, Quine's preferred logical idiom has no singular terms at all, except for variables, which do not challenge

⁴⁰This is presumably what Robinson [1974, p. 498] intends by rule vii; the paper is marred by an unusually large number of printing errors and omissions.

⁴¹See also [Quine, 1953, p. 163], where Quine argues that "the notion that ' Fa ' and ' $\sim Fa$ ' implies 'a exists'" is rooted in the "familiar confusion" of meaning with denotation.

the Russell-Meinong view if their range is non-empty. The others, “a major source of theoretical confusion” in Quine’s view [1953, p. 167], are to be eliminated in favor of predicate constructions *à la* Russell. Lambert argues that Quine ought instead to have embraced a free semantics, and to a limited extent Quine [1997] has recently done so. In any case, his expressed view of predication needs a free setting, where its development is not entirely obvious.

In classical semantics, Quinean predications are extensional in two senses: (1) $s = t \models A(s) \leftrightarrow A(t)$ and (2) $\forall x(A(x) \leftrightarrow B(x)) \models A(t) \leftrightarrow B(t)$. (1) says that if s and t are co-referring, then $A(s)$ is true iff $A(t)$ is true; it realizes Quine’s condition that the terms in predications occur purely referentially. (2) says that if $A(x)$ and $B(x)$ are co-extensive predicates, then $A(t)$ is true iff $B(t)$ is true. Free semantics will generally support (1), but not necessarily (2). ‘ x rotates’, ‘ x exists and x rotates’, and ‘if x exists, then x rotates’ are co-extensive predicates, but ‘Vulcan rotates’, ‘Vulcan exists and rotates’, and ‘if Vulcan exists, it rotates’ will not end up with the same truth-values in bivalent free semantics. If v does not refer in outer domain semantics, we can make Rv true or false, but $\exists y(y = v) \& Rv$ is false and $\exists y(y = v) \rightarrow Rv$ is true regardless. If v does not refer in negative free semantics, Rv is false, but $\exists y(y = v) \& Rv$ is false and $\exists y(y = v) \rightarrow Rv$ is true.

Extensionality of type (2) may be restored by following Scales [1969] and regarding predications $A(t)$ as the result of applying a complex predicate λxA to t . Recall that the extension $d(\lambda xA)$ of λxA in L_λ consists of those individuals of D (or of D_i , if we employ outer domain semantics) of which $A(x)$ is true. Thus, we have $\forall x(\lambda xA(x) \leftrightarrow \lambda xB(x)) \models \lambda xA(t) \leftrightarrow \lambda xB(t)$. For discussion, see Lambert [1986; 1997a; 1998]. For a supervaluational treatment of L_λ that supports “general-term extensionality” of this kind, see Lambert and Bencivenga [1986].

On any of these free semantic treatments, L_λ embodies two kinds of predication: ordinary predication, which does not have existential import ($Pt \not\models \exists x(x = t)$), and complex predication, which does ($\lambda xPx(t) \models \exists x(x = t)$). Of course, we needn’t introduce complex predicates to achieve this; we could simply define two types of subject-predicate constructions in L , say, $P(t)$ for ordinary predication and $P[t]$ for predication with existential import. Lambert and Simons [1994] suggest that ordinary predication $P(t)$ corresponds to *characterization*, while $P[t]$ corresponds to *classification*. The latter (‘Catso is a tuxedo cat’) presupposes an individual to classify, the former (‘Catso is hungry’) traditionally does not.

5.2 Definitions

The fact that neither outer domain nor Russellian free semantics supports $\forall x(A(x) \leftrightarrow B(x)) \models A(t) \leftrightarrow B(t)$ creates problems for introducing definitions in theories based on them. To take the simplest case, we may wish to

add a new predicate P to the language of T with a defining axiom

$$\text{Df} \quad \forall x(Px \leftrightarrow A(x))$$

and then regard Pt as an abbreviation of $A(t)$. But when t does not refer to an existent, this may not be possible. If t refers to something in the outer domain, Df does not tell us whether $Pt \leftrightarrow A(t)$, because the bound variables range only over the inner domain. If t does not refer in Russellian free semantics, Pt will be false but $A(t)$ may be true, as when A is $x \neq x$.

If outer domains consist of some fixed finite number of individuals $\alpha_1, \dots, \alpha_k$, we can name them e_1, \dots, e_k and use Lambert and Scharle's [1967] trick, noted above in Section 2.2a, to extend quantification to the outer domain: let $\forall_c x A$ abbreviate $\forall x A \& A(e_1) \& \dots \& A(e_k)$. If we then give what Gumb and Lambert [1997] call a "full explicit definition" of P by

$$\text{Df}_c \quad \forall_c x(Px \leftrightarrow A(x)),$$

we may regard Pt as an abbreviation of $A(t)$, since $\forall_c x(Px \leftrightarrow A(x)) \models Pt \leftrightarrow A(t)$. Gumb and Lambert develop this approach to definitions for outer domains with just one individual *err*, which could represent the 'error object' of certain programming languages. A proof of Beth's definability theorem is sketched.

Dwyer's [1988] approach is somewhat more general. In outer domain semantics, partial functions $D_i \rightarrow D_i$ are represented by total functions $D_i \rightarrow D_i + D_o$: if $\alpha \in D_i$ but $d(f)(\alpha) \in D_o$, then f represents a function that is undefined at α . More precisely, from an outer domain interpretation $\langle D_i + D_o, d \rangle$ we may extract a partial interpretation $\langle D_i, d_p \rangle$:

Let $d_p(c) = d(c)$ if $d(c) \in D_i$; otherwise, d_p is not defined at c .

If $\alpha_i \in D_i$, then let $d_p(f)(\alpha_1, \dots, \alpha_k) = d(f)(\alpha_1, \dots, \alpha_k)$

if $d(f)(\alpha_1, \dots, \alpha_k) \in D_i$; otherwise, $d_p(f)$ is not defined at $\langle \alpha_1, \dots, \alpha_k \rangle$.

If $\alpha_i \in D_i$, let $\langle \alpha_1, \dots, \alpha_k \rangle \in d_p(P)$ iff $\langle \alpha_1, \dots, \alpha_k \rangle \in d(P)$.

Outer domain interpretations that coincide when restricted to the inner domain generate the same partial interpretation I . The class $C(I)$ of such "internally invariant" outer domain interpretations can be regarded as representing I . Dwyer exploits this connection to characterize definability for partial functions from an outer domain perspective.

The problem here again is that the classical conditions on definitions do not carry over. We cannot allow just any formula $A(x)$ in definition Df of P , because not every open sentence is *stable* in the sense of being true of the same individuals of D_i as we move from one interpretation of $C(I)$ to another. For example, let I be a partial interpretation in which D is the set of real numbers, so that under assignment neither $x/0$ nor $x + 1/0$ refers.

Under any assignment relative to $I' \in C(I)$, however, $x/0$ and $x + 1/0$ will designate “unreal” numbers α and β in D_o , where α and β may or may not coincide. Accordingly, as we move from one $C(I)$ -interpretation to another, $x/0 = x + 1/0$ will be true of different sets of reals; it is not stable. If $A(x)$ is $x/0 = x + 1/0$, then Df does not characterize any property of reals.

Dwyer [1988, p. 31] develops a sufficient syntactic condition on stability (*viz.*, atomic constituents of A contain no more than one non-logical symbol), which is used in reformulating the classical conditions on admissible definitions. Free versions of Robinson’s joint consistency theorem, Craig’s interpolation lemma, and Beth’s definability theorem are proved to establish the adequacy of this account.

5.3 Modality

As noted at the end of Section 3.5, Barba [1989] has shown how to understand the supertruth of A in terms of something like the logical truth of $\Box \Diamond A$. Two additional connections between free and modal logic are described in this section.

- a. Garson [1991] develops a general system of quantified intensional logic based on free logic. By a general system, he means one (1) from which particular systems can be obtained by specifying (a) constraints on interpretations and (b) additional axioms or rules and (2) for which completeness can be established by a general proof — one easily modified to establish the completeness of these particular systems.

Let us assume a first order language L' without function-names, but with operators \Box (if A is a formula, so is $\Box A$) and $E!$ (if t is a term, $E!t$ is a formula). QS-interpretations $I = \langle W, w_0, R, D, E, d \rangle$ of L' are generalizations of Kripke interpretations. As usual, W is a set of possible worlds, $w_0 \in W$ represents the actual world, R is a binary accessibility relation on W , D is a (non-empty) set of possible individuals, and d assigns *intensions* $d(P) : W \rightarrow \mathcal{P}(D^k)$ to k -place predicates P , $d(P)(w)$ being the extension of P at w . In Kripke semantics, $E(w) \subset D$ is the set of individuals that exist in w ; in Garson’s generalization, $E(w)$ is a set of *individual intensions* $W \rightarrow D$, and α exists in w if $\alpha = f(w)$ for some $f \in E(w)$. In Kripke semantics, d also assigns possible individuals $d(a)$ to constants a ; in Garson’s version, d assigns individual intensions $d(a)$ to constants a . Like constants, variables x are assigned individual intensions $\alpha(x)$; an x -variant of α at w is an assignment β that differs from α at most at x , where $\beta(x) \in E(w)$. Kripkean interpretations and assignments, in which designation is rigid, are the special case where individual intensions are constant functions.

Under interpretation I and assignment α :

- r_i1. x refers at w to $\alpha(x)(w)$.
- r_i2. a refers at w to $d(a)(w)$.

- v_i1. If t_i refers at w to α_i , $Pt_1 \dots t_k$ is true at w iff $\langle \alpha_1, \dots, \alpha_k \rangle \in d(P)(w)$.
- v_i2. If t_i refers at w to α_i , then $t_1 = t_2$ is true at w iff $\alpha_1 = \alpha_2$.
- v_i3. $\neg A$ is true at w iff A is false at w .
- v_i4. $A \rightarrow B$ is false at w iff A is true at w and B is false at w .
- v_i5. $\forall xA$ is true at w iff A is true at w for each x -variant of α at w .
- v_i6. $\Box A$ is true at w iff A is true at each w' such that wRw' .
- v_i7. $E!t$ is true at w iff the intension of $t \in E(w)$.
- v_i8. A is true iff A is true at w_0 .

As noted in Section 2.2b, Kripke-semantics is basically outer domain free semantics, with the individuals that exist in w constituting w 's inner domain, while the rest of D functions as w 's outer domain. In Kripke semantics, $E!t$ can be defined by $\exists x(x = t)$, but not here: v_i7 treats $E!$ as a predicate of intensions. If R is universal, $E!t$ is equivalent to $\exists x\Box(x = t)$; but in general existence is not definable from identity.

For this semantics, Garson sketches a complete Hilbert-style system GS, consisting of (a) propositional modal axioms and rules appropriate to the accessibility relation R , (b) identity axioms and rules that we may (with the stipulation that $E!t$ is *not* atomic) identify with the identity axioms of PFL, and (c) quantifier rules which are generalizations of those of free logic:⁴²

$$\text{GUI} \quad G[\forall xA] \vdash G[E!t \rightarrow A(t)]$$

GUG

If $\vdash G[E!t \rightarrow A(t)]$ and t does not occur in $G[\forall xA]$, then $\vdash G[\forall xA]$

Here $G[B]$ is any formula of one of the following forms

$$\frac{B}{A \rightarrow B} \quad \frac{\Box(A_1 \rightarrow \dots \Box(A_k \rightarrow B) \dots)}{A \rightarrow \Box(A_1 \rightarrow \dots \Box(A_k \rightarrow B) \dots)}$$

⁴²This is apparently what Garson [1991, p. 134] intends by rules GUI and GUG, which are not clear as stated.

After sketching a Henkin-style completeness argument for GS, Garson illustrates the generality of QS+GS by showing how to obtain several familiar systems (including Kripke's) as special cases.

- b. Schweizer [1990] develops Skryms' [1978] defense of the metalinguistic reading of necessity claims against Montague's [1963] argument that such readings are incoherent. The metalinguistic reading treats necessity not as an operator \Box (for 'necessarily') applying to sentences, but as a predicate N (for 'is necessary') applying to names of sentences. M -interpretations I of such languages are pairs $\langle I_0, C \rangle$, where C is a set of interpretations and $I_0 \in C$. A is true under I iff A is true under I_0 , and $d(N)$ is such that if $\ulcorner A \urcorner$ names A , $N\ulcorner A \urcorner$ is true under $I' \in C$ iff A is true under each C -interpretation.

Gödel-numbering allows us to develop the metalinguistic interpretation of necessity in an extension T of formal arithmetic, whose language includes the predicate N . If $\ulcorner A \urcorner$ is the numeral for $g(A)$, we want to read $N\ulcorner A \urcorner$ as ' $\ulcorner A \urcorner$ is necessary'. To support this reading, Montague argues, T should be such that for any sentence A ,

- (1) $\vdash_T A$, then $\vdash_T N\ulcorner A \urcorner$
- (2) $\vdash_T N\ulcorner A \urcorner \rightarrow A$

Assuming T 's proof method is complete, (1) says that if $\ulcorner A \urcorner$ is necessary in the sense of being true in every model of T , then it is provable that $\ulcorner A \urcorner$ is necessary. (2) says that the standard modal principle 'if $\ulcorner A \urcorner$ is necessary, then A is true' is provable. Now diagonalization gives us a sentence B such that

- (3) $\vdash_T \neg N\ulcorner B \urcorner \leftrightarrow B$

(2) and (3) imply $\vdash_T \neg N\ulcorner B \urcorner$. But $\vdash_T \neg N\ulcorner B \urcorner$ and (3) imply $\vdash_T B$, which with (1) implies $\vdash_T N\ulcorner B \urcorner$. So T is inconsistent.

Let L be a first-order language that includes the language of formal arithmetic, let L_\Box be the standard modal extension of L , and let L_N result from L by adding the necessity predicate N . Assuming a Gödel-numbering of L_N , we may translate L_\Box -formulae A into L_N -formulae $tr(A)$ by: $tr(\Box A) = N\ulcorner A \urcorner$; tr commutes with \neg , \rightarrow , and $\forall x$; and $tr(A) = A$ for L -formulae A . If $I = \langle W, w_0, R, D, E, d \rangle$ is a Kripke interpretation of L_\Box with universal accessibility relation R ,⁴³ Schweizer shows how to obtain an M -interpretation $tr(I)$ of L_N so that for sentences A , A is true under I iff $tr(A)$ is true under $tr(I)$. The

⁴³Schweizer [1990, p. 165] stipulates only that I is an S5 interpretation (R is an equivalence relation), but his construction assumes that R is universal. This is a stronger assumption: $\Box(Pa \ \& \ \neg\forall xPx)$ can be true if R is an equivalence relation but not if R is universal, assuming as usual that $D = \cup_{w \in W} E(w)$.

construction evades Montague's problem because the Gödel-sentence B that issues from diagonalization is not $tr(A)$ for any sentence A , whereas the modal axiom holds only in the form $N^\top tr(A)^\top \rightarrow tr(A)$.

Since $tr(I)$ is an M -interpretation $\langle I_0, C \rangle$, C is a set of interpretations such that $N^\top A^\top$ is true under $tr(I)$ iff A is true under each interpretation in C . The connection with free logic is that these C -interpretations are outer domain interpretations. At each $w \in W$, I induces an outer domain interpretation $I(w) = \langle D_i + D_o, d_w \rangle$ of L , where $D_i = E(w)$, $D_o = D - E(w)$, and d_w is the restriction of d to w : $d_w(a) = d(a)$ and $d_w(P) = d(P)(w)$. When d_w is appropriately extended to N , we can identify I_0 with $I(w_0)$ and C with $\{I(w) | w \in W\}$.⁴⁴ The extension of d_w is in stages corresponding to the number of nested occurrences of \Box in A : we put $g(tr(A))$ in $d_w(N)$ at stage $k + 1$ provided $tr(A)$ is true under $I(w)$ at stage k . At stage 0, A is \Box -free, so $tr(A) = A$, which gets a truth-value under each outer domain interpretation $I(w)$.

Schweizer [1990, p. 170] states that "analogous equivalence results can be obtained for the other normal systems of quantified modal logic, by simply utilizing the relevant accessibility relation $R \dots$ within the eligible set of models." Presumably, his suggestion is that M -interpretations I now be conceived as triples $\langle I_0, C, R \rangle$, where C is a set of interpretations, R is a binary relation on C , and $I_0 \in C$. Then A is true under I iff A is true under I_0 and $N^\top A^\top$ is true under $I' \in C$ iff A is true under each I'' such that $I'R I''$. The ordinary notion of a metalinguistic interpretation is then the special case where R is universal.

ACKNOWLEDGEMENTS

I thank Karel Lambert for directing my attention to many of the works cited in this survey.

STEPHEN BLAMEY

PARTIAL LOGIC

INTRODUCTION

When I was originally asked to write about ‘partial logic’ for the first edition of the *Handbook*, I was a little puzzled: I was taken to be an expert in an apparently well defined subject area that I didn’t know existed. But it turned out to be the sort of thing I had written about in my D.Phil. thesis, so I had somewhere to start. Nowadays the label ‘partial logic’ is much more familiar, and a lot of work is being done in the area it covers. The bulk of my own work, though—most of it dating right back to thesis days—has not yet been published: I have been bewilderingly bad about this. In particular, the various promises made in the first edition about forthcoming work have still not been fulfilled. In spite of this, I have resisted the temptation just to shove in more material of my own for the second edition—except in small ways here and there. Additions are largely in response to what has newly appeared in print.

A wide range of work will be surveyed (much more now than in the first edition), but the backbone of this chapter is the development of what I call ‘simple partial logic’. It is against this backbone that other more sophisticated projects are discussed. Simple partial logic results from the simple-minded following through of the idea that classical logic may be loosened up to cater for non-denoting singular terms and neither-true-nor-false sentences—to cater for them in a uniform way as semantically ‘undefined’ items—and at the same time to cater for ‘partially defined’ functors: term-forming functors, predicates, and sentence connectives. These functors have to accommodate undefined arguments, but they may also produce undefined compounds even when all their arguments are fully defined. In particular, we shouldn’t ignore sentence connectives of this kind: once loosened up, classical propositional logic needs to be filled out with connectives such as *interjunction* and *transplication*. The uniformity behind all this comes from the idea of representing partial functions by monotonic functions—as explained in Section 1—and using monotonically representable partial functions to interpret functors of whatever logical category.

All sections have undergone some stylistic revision for the second edition, and most of them have been expanded. Note that Section 2 now has more subsections: there is a new introductory subsection, which means that subsections 2.1 to 2.5 have become subsections 2.2 to 2.6; and the old subsection 2.6 has split into three—2.7 to 2.9—so that the old 2.7 is now 2.10. Section 4 has been disrupted in a similar way: the old subsection 4.1 has split into 4.1 and 4.2; subsection 4.3 is new; and the old subsection 4.2 has

split into 4.4 and 4.5. There has been a more straightforward reorganization to Sections 6 and 7: a new subsection has been introduced as 6.3, which means that the old subsections 6.3 and 6.4 become 6.4 and 6.5; and the old subsection 7.2 has split into two: 7.2 and 7.3. The other Sections retain their original structure.

× × ×

Notation for *interjunction*:— In the first edition an interjunction sign was formed by juxtaposing two ‘×’s: ××. This was a pity, because it made the symbol a bit too flat. Interjunction is a squadging of conjunction and disjunction, and so the symbol for it should be a simultaneous occurrence of ‘∧’ and ‘∨’: ⋈. Sadly, the notation ‘××’ has found its way into the literature, and—much worse—this has sometimes become just two ‘x’s: xx. I urge anyone who wants to write an interjunction sign in the future to avoid ‘xx’ at all costs: ‘××’ is tolerable, but I recommend ‘⋈’.

1 A SKETCH OF SIMPLE PARTIAL LOGIC

1.1 *Classical Semantics as Partial Semantics*

In classical logic sentences are either true (\top) or false (\perp) and the interpretation of the standard sentence connectives can be given in the following way:

$$\begin{aligned} \neg\phi \text{ is } & \begin{cases} \top & \text{iff } \phi \text{ is } \perp \\ \perp & \text{iff } \phi \text{ is } \top, \end{cases} \\ \phi \wedge \psi \text{ is } & \begin{cases} \top & \text{iff } \phi \text{ is } \top \text{ and } \psi \text{ is } \top \\ \perp & \text{iff } \phi \text{ is } \perp \text{ or } \psi \text{ is } \perp, \end{cases} \\ \phi \vee \psi \text{ is } & \begin{cases} \top & \text{iff } \phi \text{ is } \top \text{ or } \psi \text{ is } \top \\ \perp & \text{iff } \phi \text{ is } \perp \text{ and } \psi \text{ is } \perp, \end{cases} \\ \phi \rightarrow \psi \text{ is } & \begin{cases} \top & \text{iff } \phi \text{ is } \perp \text{ or } \psi \text{ is } \top \\ \perp & \text{iff } \phi \text{ is } \top \text{ and } \psi \text{ is } \perp, \end{cases} \\ \phi \leftrightarrow \psi \text{ is } & \begin{cases} \top & \text{iff } (\phi \text{ is } \top \text{ and } \psi \text{ is } \top) \text{ or } (\phi \text{ is } \perp \text{ and } \psi \text{ is } \perp) \\ \perp & \text{iff } (\phi \text{ is } \top \text{ and } \psi \text{ is } \perp) \text{ or } (\phi \text{ is } \perp \text{ and } \psi \text{ is } \top). \end{cases} \end{aligned}$$

For simple partial logic we shall adopt precisely these classical \top/\perp conditions; only we give up the assumption that all sentences have to be classified either as \top or as \perp . This leaves room for the classification *neither- \top -nor- \perp* . At present we are concerned merely to highlight a parallel with classical semantics, and under the parallel we can think of the third classification as a ‘truth-value gap’. This thought is taken a little further in Sections 1.2

and 3. But the point, if any, of seeing the third classification as different in philosophical kind from \top and \perp will of course depend on what particular motivation we consider for adopting the forms of partial logic. (See, especially, Sections 2 and 5.)

To interpret universal and existential quantifiers over a given domain D , we shall again exploit the fact that the classical interpretation leaves room for a gap between \top and \perp when we write out \top -conditions and \perp -conditions separately. Assuming that a language has—or can be extended so as to have—a name \bar{a} for each object a in D ,

$$\begin{aligned} \forall x\phi(x) \text{ is } & \begin{cases} \top & \text{iff } \phi(\bar{a}) \text{ is } \top \text{ for every } a \text{ in } D \\ \perp & \text{iff } \phi(\bar{a}) \text{ is } \perp \text{ for some } a \text{ in } D, \end{cases} \\ \exists x\phi(x) \text{ is } & \begin{cases} \top & \text{iff } \phi(\bar{a}) \text{ is } \top \text{ for some } a \text{ in } D \\ \perp & \text{iff } \phi(\bar{a}) \text{ is } \perp \text{ for every } a \text{ in } D. \end{cases} \end{aligned}$$

Most treatments of classical logic stipulate that the domain be non-empty. We shall not be so restrictive: D may be empty.

These \top/\perp -conditions for $\forall x$ and $\exists x$ of course presuppose a semantic account of predicate/singular-term composition. And this mode of composition deserves some attention, since it is the most familiar place to locate the cause of a sentence's being neither 'true' nor 'false'. It has been considered to give rise to a truth-value gap in two different ways: either (i) because a term t may lack a denotation and may, for this reason, make a sentence $\phi(t)$ neither true nor false; or (ii) because a predicate $\phi(x)$ may be only 'partially defined'—not either true or false of some object or objects—so that, if t denoted such an object, $\phi(t)$ would be neither true nor false. We shall want to accommodate both these ideas in one uniform account of predicate/singular-term composition. Our approach will be sketched in Section 1.2, along with an approach to functors which form singular terms from singular terms.

But there is one particular atomic predicate to consider immediately: the identity predicate. Once again we can adopt classical \top -conditions and \perp -conditions *verbatim* for a sentence $t_1 = t_2$:

$$t_1 = t_2 \text{ is } \begin{cases} \top & \text{iff } t_1 \text{ and } t_2 \text{ denote the same thing} \\ \perp & \text{iff } t_1 \text{ and } t_2 \text{ denote different things.} \end{cases}$$

This means that if either t_1 or t_2 is non-denoting, then $t_1 = t_2$ is neither \top nor \perp . Identity is an untypically straightforward case. At least, so it is if we restrict attention to a determinate relation over a discrete domain of objects—as we shall.

× × ×

Whatever general framework we set up for predicate/singular-term composition, our logic has so far been revealed as 'partial' only in the weak sense

that it accommodates value-gaps that might arise from the interpretation of non-logical terms or predicates. This is because the interpretation of classical logical vocabulary is classical. But there is a stronger sense of ‘partial logic’: a logic will be partial in the stronger sense if it provides the resources for explaining why a sentence may be neither \top nor \perp in terms of logical vocabulary—vocabulary, that is, with a fixed meaning in the logic. We should look for modes of logical composition whose interpretation can give rise to truth-value gaps, even when any classical sentence constructed out of the same non-logical vocabulary (with the same interpretation) would have to be either \top or \perp .

Assuming that we have worked out the general account of how non-denoting terms can give rise to truth-value gaps, a term-forming descriptions operator would be an example of gap-introducing logical vocabulary. This is because a term $\iota x\phi(x)$ may turn out not to denote, even when $\phi(x)$ is totally defined. Assuming that $\phi(x)$ is in fact totally defined, then the denotation conditions for $\iota x\phi(x)$ must be that if a is an object in the domain, then:

$$\iota x\phi(x) \text{ denotes } a \quad \text{iff} \quad \forall x[x = \bar{a} \leftrightarrow \phi(x)] \text{ is } \top,$$

where, as before, \bar{a} is a name—pre-existing or specially introduced—for a . In other words, $\iota x\phi(x)$ denotes an object if and only if that object uniquely satisfies $\phi(x)$ and is non-denoting if there is no such object. Of course, we also have to consider the case where $\phi(x)$ is not totally defined, but the denotation conditions stated will continue to make sense. Furthermore, given the general constraint to emerge in Section 1.2, they will turn out to be the only possible ones for a determinate relation of identity over a discrete domain of objects (see Section 6.4).

These ι -terms involve a rather complicated route to neither- \top -nor- \perp sentences. There is a much more straightforward, and no less interesting, kind of gap-introducing vocabulary: sentence connectives. Consider the following \top/\perp -conditions for the connectives $\&$ and $/$, the first of which we shall call *interjunction* and the second *transplication*:

$$\begin{aligned} \phi \& \psi \text{ is } & \begin{cases} \top & \text{iff } \phi \text{ is } \top \text{ and } \psi \text{ is } \top \\ \perp & \text{iff } \phi \text{ is } \perp \text{ and } \psi \text{ is } \perp, \end{cases} \\ \phi / \psi \text{ is } & \begin{cases} \top & \text{iff } \phi \text{ is } \top \text{ and } \psi \text{ is } \top \\ \perp & \text{iff } \phi \text{ is } \top \text{ and } \psi \text{ is } \perp. \end{cases} \end{aligned}$$

Notice that $\&$ has the \top -conditions of \wedge and the \perp -conditions of \vee , while $/$ has the \top -conditions of \wedge but the \perp -conditions of \rightarrow . And so these connectives clearly meet our desideratum of introducing value gaps: we do not necessarily have to look to predicate/singular-term composition to find a logical explanation why a sentence may be neither \top nor \perp . The particular usefulness of $\&$ and $/$ will be touched upon in Section 2.2 and several later sections.

Among our logical vocabulary we shall also include a constantly true sentence \top , and a constantly false one \perp . Thus we are using ‘ \top ’ and ‘ \perp ’ both as truth-value labels and to stand for logical constants; and, in a similar way, we shall use ‘ $*$ ’ both to label the classification ‘neither- \top -nor- \perp ’ and to stand for a sentence which is logically neither \top nor \perp . There will also be a logically non-denoting singular-term, denoted by ‘ \otimes ’—which will be used also to denote the classification ‘non-denoting’. In the presence of the term \otimes , we shall then be able to abandon \neg -terms without any loss in expressive power: this is explained in Section 6.4.

x x x

Finally, we must consider the relation of (logical) consequence. Our semantic definition of ‘ ψ is a consequence of ϕ ’ is, loosely stated, that

- (i) whenever ϕ is \top , ψ is \top , and (ii) whenever ψ is \perp , ϕ is \perp .

And so, yet again, we are using a definition which conjoins two formulations of the classical definition, one involving \top and the other \perp —formulations which are equivalent in total logic, but not in partial logic. To illustrate the idea, consider for the moment just a propositional calculus with formulae built up from atomic sentences using the connectives we have introduced. Then ‘interpretations’ will simply be partial assignments of \top and \perp to atomic sentences, and formulae may be evaluated according to our \top/\perp -clauses for the connectives. We shall use ‘ \vDash ’ for the relation of logical consequence, and so $\phi \vDash \psi$ if only if (i) and (ii) above both hold when ‘whenever’ is understood to mean ‘under any partial assignment under which’. (By ‘partial assignment’ I do not mean to exclude total assignments: here, as elsewhere, ‘partial’ means ‘not necessarily total’.)

The tendency among authors on partial logics of one sort or another is to take condition (i) on its own to define logical consequence; and sometimes (i) and (ii) are used to frame two separate notions—for example, in [Dunn 1975], [Hayes 1975] and, in disguised form, in [Woodruff 1970]. In [Cleave 1974], on the other hand, there is a (rather algebraic) version of our double-barrelled definition. And across the literature of the last twenty years the picture has not greatly changed. But perhaps making a choice between these alternatives is not such a fundamental matter. After all, we can define the two halves of our single notion:

$$\begin{aligned} \phi \vDash^{\top} \psi & \text{ iff } \phi \vDash * \vee \psi, \\ \phi \vDash^{\perp} \psi & \text{ iff } \phi \wedge * \vDash \psi. \end{aligned}$$

And, putting them back together again,

$$\phi \vDash \psi \text{ iff } \phi \vDash^{\top} \psi \text{ and } \phi \vDash^{\perp} \psi.$$

Or, if we invoke negation, either one of the halves on its own would do:

$$\phi \vDash \psi \text{ iff } \phi \vDash^{\top} \psi \text{ and } \neg \psi \vDash^{\top} \neg \phi \text{ iff } \phi \vDash^{\perp} \psi \text{ and } \neg \psi \vDash^{\perp} \neg \phi.$$

The issue might be set in a more interesting context if thought were given to the connection between these definitions and inferential practice; but this question goes far beyond our semantics-orientated essay.

To motivate working with the double-barrelled definition we can adduce some arguments from theoretical neatness. First, the law of contraposition holds:

$$\phi \vDash \psi \quad \text{iff} \quad \neg\psi \vDash \neg\phi.$$

Secondly, logical equivalence—a relation which must be taken to obtain between two formulae if and only if they take the same resultant classification under any interpretation—turns out as mutual consequence. Using ‘ \simeq ’ for equivalence,

$$\phi \simeq \psi \quad \text{iff} \quad \phi \vDash \psi \text{ and } \psi \vDash \phi.$$

Thirdly, equivalence and consequence fit together with conjunction and disjunction in the natural (at least the classical) way:

$$\phi \simeq \psi \wedge \phi \quad \text{iff} \quad \psi \simeq \phi \vee \psi \quad \text{iff} \quad \phi \vDash \psi.$$

These properties of \vDash break down for \vDash^\top and for \vDash^\perp .

Neatness aside, some interesting differences between working with \vDash and working just with \vDash^\top (equally just with \vDash^\perp) can be extracted from [Langholm 1988]. In particular, it emerges that in a first-order logic without non-denoting terms some interpolation results for \vDash^\top are much cheaper than corresponding results for \vDash . (On interpolation for \vDash in a full first-order language, see Sections 6.5, 7.2, and 7.3.)

In Section 6.5 we shall present a rigorous definition of (double-barrelled) consequence for first order languages, and there will be two generalisations. First, we shall be interested not *merely* in logical consequence, but in relations of consequence determined by a given range of interpretations—to match a proof theoretical notion of consequence in a given theory (presented in Section 7.1). Secondly, consequence will be defined between sets of formulae, rather than individual formulae: not only will several premises be allowed, but also several ‘conclusions’—to be understood disjunctively. This will match our sequent-style proof theory; and another advantage of the double-barrelled definition will then emerge: we shall be able to frame fewer and simpler rules, since sequent principles will be able to constrain the \top -conditions and \perp -conditions of logical vocabulary at one go.

There is, finally, a different kind of generalization to consider: more-than-two-place ‘consequence’ relations. For example, \vDash^\top and \vDash^\perp are combined into a four-place relation in [Langholm 1989, Fenstad 1997, Bochman 1998]. If, for simplicity’s sake, we restrict attention to single formulae rather than sets of formulae, then the relation—call it C —can be defined as follows: $C(\phi_1, \psi_1, \phi_2, \psi_2)$ if and only if whenever ϕ_1 is \top and ψ_2 is \perp , then either

ψ_1 is \top or ϕ_2 is \perp . Notice that we could define C , using negation, in terms of either \vDash^\top or \vDash^\perp :

$$C(\phi_1, \psi_1, \phi_2, \psi_2) \text{ iff } \phi_1 \wedge \neg\psi_2 \vDash^\top \psi_1 \vee \neg\phi_2 \text{ iff } \neg\psi_1 \wedge \phi_2 \vDash^\perp \neg\phi_1 \vee \psi_2.$$

Alternatively—and I have myself found this more useful to work with—we could adopt a four-place relation C' that just conditionalizes the two place \vDash : $C'(\phi_1, \psi_1, \phi_2, \psi_2)$ if and only if whenever ϕ_1 is \top and ψ_1 is \perp , then $\phi_2 \vDash \psi_2$. In terms of \vDash this relation could be defined as follows:

$$C'(\phi_1, \psi_1, \phi_2, \psi_2) \text{ iff } \phi_1 \wedge \neg\psi_1 \wedge \phi_2 \vDash \psi_2 \vee \neg\phi_1 \vee \psi_1.$$

In Section 7.1 we shall use the the proof-theoretical correlate of \vDash to define a three-place consequence relation along these lines—one that ignores the ψ_1 argument place. Some of the quantifier and identity rules are most perspicuously presented in terms of this relation. (Compare the three- and four-place relations used for systems of modal logic in [Blamey and Humberstone 1991].)

1.2 Partial Semantics as Monotonic Semantics

To interpret sentence connectives we have specified \top -conditions and \perp -conditions for formulae constructed by means of them: $*$ -conditions then take care of themselves. Even so, $*$ is a semantic classification, and the apparatus of 3-valued logic is at our disposal: our \top/\perp -conditions are summed up in the following matrices. (The constant sentences \top , $*$ and \perp can be thought of as 0-place connectives, but their matrices are trivial).

ϕ	$\neg\phi$	ϕ	ψ	$\phi \wedge \psi$	$\phi \vee \psi$	$\phi \times \psi$	$\phi \leftrightarrow \psi$	$\phi \rightarrow \psi$	ϕ / ψ
\top	\perp	\top	\top	\top	\top	\top	\top	\top	\top
$*$	$*$	\top	$*$	$*$	\top	$*$	$*$	$*$	$*$
\perp	\top	\top	\perp	\perp	\top	$*$	\perp	\perp	\perp
		$*$	\top	$*$	\top	$*$	$*$	\top	$*$
		$*$	$*$	$*$	$*$	$*$	$*$	$*$	$*$
		$*$	\perp	\perp	$*$	$*$	$*$	$*$	$*$
		\perp	\top	\perp	\top	$*$	\perp	\top	$*$
		\perp	$*$	\perp	$*$	$*$	$*$	\top	$*$
		\perp	\perp	\perp	\perp	\perp	\top	\top	$*$

Partial assignments of \top or \perp to atomic constituents can now be replaced by total assignments of \top , $*$ or \perp . And, if we take it that each assignment assigns a classification to all of a denumerable stock of atomic formulae, then everything will fit neatly into place when we just assign $*$ to any vocabulary we are not interested in.

Let us now impose a simple ordering \sqsubseteq on $\{\top, *, \perp\}$:

$$x \sqsubseteq y \quad \text{iff} \quad \text{either } x = * \text{ or } x = y.$$

Equivalently: $x \sqsubseteq y$ iff both, if $x = \top$, then $y = \top$, and, if $x = \perp$, then $y = \perp$. Then we can extend the use of ' \sqsubseteq ' to define a 'degree-of-definedness' relation between assignments v and w :

$$v \sqsubseteq w \quad \text{iff} \quad v(p) \sqsubseteq w(p) \text{ for every atomic formula } p.$$

In other words, $v \sqsubseteq w$ if and only if wherever v assigns the value \top or \perp , w assigns that value also. If $v(\phi)$ is the result of evaluating a formula ϕ under v , it is then easy to deduce the following *monotonicity of evaluation*:

$$\text{if } v \sqsubseteq w, \text{ then } v(\phi) \sqsubseteq w(\phi), \text{ for every formula } \phi.$$

An intuitive way to think about this is that if a formula has taken on a value (\top or \perp), then this value persists when any atomic gaps ($*$) are filled in by a value (\top or \perp) (cf. Lemma 3 in section 6.2).

Here we have a global monotonicity condition, but we might direct attention to individual formulae. If all atomic formulae occurring in ϕ are among p_1, \dots, p_n , then we can specify a 3^n -row matrix for ϕ , which describes a function f from $\{\top, *, \perp\}^n$ into $\{\top, *, \perp\}$, where $f(x_1, \dots, x_n)$ is the classification of ϕ under the assignment of x_i to p_i , $1 \leq i \leq n$. And f will then be a monotonic function. That is to say

$$\text{if } x_i \sqsubseteq y_i \text{ for all } i, \text{ then } f(x_1, \dots, x_n) \sqsubseteq f(y_1, \dots, y_n).$$

Observe that this is equivalent to monotonicity in each coordinate separately.

What lies behind both forms of monotonicity is that the matrix for each sentence connective describes a monotonic function and that the class of monotonic functions is closed under composition. The question then arises: Is our logic expressively adequate for all monotonic functions? It is. In Section 4.1 we shall show that \neg , \wedge , \vee , \boxtimes , \top , and \perp form a neatly complete bunch of connectives.

Our 'partial' propositional logic could, then, simply be seen as the total logic of 3-valued monotonic modes of sentence composition—modes $\phi(p_1, \dots, p_n)$ that are interpreted by monotonic functions. The connection between the two ways of looking at it is made by the idea that monotonic functions from $\{\top, *, \perp\}^n$ into $\{\top, *, \perp\}$ can be taken to represent partial functions from $\{\top, \perp\}^n$ into $\{\top, \perp\}$. Modes of composition in the logic

can then be taken to be interpreted by partial functions. On this understanding of the mathematical semantics, \top and \perp are obviously the only ‘truth values’ that there are: $*$ plays a role merely in the representation of partial functions by monotonic total ones. Thus the idea that a sentence classified $*$ suffers from a ‘truth-value gap’ is given immediate, but in itself uninteresting, sense.

× × ×

The use of monotonic functions to represent partial ones has nothing specifically to do with truth functions. Given any domain D , we can pick on an extraneous object \otimes and consider functions from $(D \cup \{\otimes\})^n$ into $D \cup \{\otimes\}$ which are monotonic—in exactly the same sense as before—with respect to an order relation \sqsubseteq given by:

$$x \sqsubseteq y \quad \text{iff} \quad \text{either } x = \otimes \text{ or } x = y.$$

Equivalently: $x \sqsubseteq y$ if and only if, for any $a \in D$, if $x = a$ then $y = a$. These functions can be taken to represent partial functions from D^n into D . And we can just as easily consider a range of different domains D_1, \dots, D_{n+1} , each fixed up with their own extraneous objects $\otimes_1, \dots, \otimes_{n+1}$, and represent a system of partial functions from $D_1 \times \dots \times D_n$ into D_{n+1} by functions from $(D_1 \cup \{\otimes_1\}) \times \dots \times (D_n \cup \{\otimes_n\})$ into $D_{n+1} \cup \{\otimes_{n+1}\}$ which are monotonic with respect to the respective orderings. A simple example would be the system of partial n -place relations on a domain D , represented by monotonic functions from $(D \cup \{\otimes\})^n$ into $\{\top, *, \perp\}$. If $n = 1$, these would be ‘partial subsets’ of D .

The functions represented are partial not only in that they may be undefined for some n -tuple of arguments, but also in that they allow for ‘empty argument places’: $*$ and \otimes stand equally for the gap of an empty argument place and for the gap of no output value. This suggests that these partial functions might aptly be deployed to provide the uniform account of linguistic composition that we demanded in Section 1.1—to handle partially defined functors that may embrace non-denoting terms.

But what kind of sense does it make to say that monotonic functions represent partial ones? The notion of representation is itself unproblematic: it is just the same as when we say that ordinary total functions can be represented in set theory by sets of a certain kind. Still, when it is observed that an ‘empty argument place’ does not necessarily mean no output value

(consider for example the matrices for \wedge and \vee), it may be objected that it is nonsense to talk of a *function* which can yield an output value from an incomplete, possibly total vacuous, array of input values. This thought, only thinly veiled in talk about functors, seems to have figured in some discussions of Frege, and we shall tackle it in this context in Section 3.2. A different—and opposite—reaction would be to question all the fuss about monotonicity: granted the idea of $*$ and \otimes representing gaps in both input and output, why restrict the range of representing functions at all? In Section 2 we shall see how some specific applications for partial functions in semantics call for the monotonicity constraint, and a more general view will emerge when we discuss the first reaction. For the moment we can put the point intuitively: the output value, if any, of a monotonically representable partial function can be seen to depend, and depend only, on the input values in occupied argument places (and not on the gaps of empty ones), precisely because of the monotonicity condition that if a gap is ‘filled in’, then the output value remains fixed.

The degree-of-definedness ordering \sqsubseteq becomes more interesting than merely a gap versus an object when we push the idea of representing partial functions up to higher-level categories—to functions with systems of partial functions as their domain (and possibly also as their range). Consider, the simple example of the system of partial subsets of a domain D , represented by monotonic functions from $D \cup \{\otimes\}$ into $\{\top, *, \perp\}$. Between two such functions f and g we can define $f \sqsubseteq g$ to mean that $f(x) \sqsubseteq g(x)$ for any x in $D \cup \{\otimes\}$. Then, to represent partial subsets of the system of partial subsets of D , we can use functions on the monotonic functions—functions F into $\{\top, *, \perp\}$ which are themselves monotonic:

$$\text{if } f \sqsubseteq g, \text{ then } F(f) \sqsubseteq F(g).$$

Intuitively, the point of this higher-level monotonicity is that if F yields a value when applied to f , then this depends, and depends only, on the range of output values of f , not on its gaps. This means that if g behaves like f except possibly that it is more defined, then F must send g to the same value it sends f to.

A full hierarchy will emerge for higher-level categories of monotonically-representable partial functions, and a non-trivial study of its characteristics can be found in [Lepage 1992]. In [Muskens 1989] and in [Lapierre 1992], on the other hand, there are special hierarchies designed to interpret intensional partial logic. Muskens has a cunning reduction of functional application and abstraction to operations on partial relations, which are what his hierarchy is actually a hierarchy of. But Lepage and Lapierre adopt a more familiar style of reduction: they take hierarchies of just one-place functions as primitive. Nothing is lost, because a domain of partial functions from $D_1 \times \dots \times D_n$ into D_{n+1} is isomorphic to, and can be modelled by, the domain of partial functions from D_1 into the domain of partial functions from

D_2 into ... into the domain of partial functions from D_n into D_{n+1} . And so, in particular, if $D_{n+1} = \{\top, \perp\}$, then we have a modelling of partial n -place relations. In [Tichý 1982] it had been argued that such a reduction to one-place functions was possible only with domains of total functions, but Lepage exposes the error in Tichý's argument.

* * *

To provide a semantics for first-order languages we need neither go very far up the hierarchy nor reduce all functions to one-place ones. Predicates will be interpreted by monotonically-representable partial sets and relations over a domain D . Similarly, n -place functors which form singular terms out of singular terms will be interpreted by monotonically representable partial functions from D^n into D . And in a model theory, conceived of as a theory developed in some standard set theory, we can expect to work with the representing monotonic functions. A model will directly assign such a function to unstructured predicate symbols and term-functor symbols, but we are no less interested in the complex predicates that arise as formulae $\phi(x_1, \dots, x_n)$, with free variables x_1, \dots, x_n signaling the argument places, and in the complex term-functors that arise as compound terms $t(x_1, \dots, x_n)$. If we take free variables to range over $D \cup \{\otimes\}$, are we guaranteed that these complex modes will be monotonic? We are, given that every unstructured functor—logical and non-logical alike—is interpreted *via* a monotonic function of the appropriate category, since combining monotonic functions invariably leads to a monotonic function. Straightforward functional composition lies behind all linguistic combinations except for the variable-binding quantifiers \forall and \exists (and also the variable-binding operator ι , if we include it: see Section 6.4).

In the simplest case quantifiers are just second-level predicates, taking a one-place predicate $\phi(x)$ to a sentence $\forall x\phi(x)$ or $\exists x\phi(x)$. Disentangling them from the apparatus of variable-binding, it is easy to see that the \top/\perp -conditions we gave for \forall and \exists match an interpretation *via* monotonic second-level functions F_\forall and F_\exists on the domain of partial subsets of D :

$$F_\forall(f) = \begin{cases} \top & \text{iff } f(a) = \top \text{ for every } a \text{ in } D \\ \perp & \text{iff } f(a) = \perp \text{ for some } a \text{ in } D, \end{cases}$$

$$F_\exists(f) = \begin{cases} \top & \text{iff } f(a) = \top \text{ for some } a \text{ in } D \\ \perp & \text{iff } f(a) = \perp \text{ for every } a \text{ in } D. \end{cases}$$

But quantifiers play a general role in converting any $(n+1)$ -place predicate $\phi(x_1, \dots, x_i, \dots, x_{n+1})$, into an n -place predicate $\forall x_i\phi(x_1, \dots, x_i, \dots, x_{n+1})$ or $\exists x_i\phi(x_1, \dots, x_i, \dots, x_{n+1})$, and we have to check that monotonicity will always be preserved in this move. This is easy enough. Notice that variables bound by a quantifier will 'range over' just the domain of objects D —not, as free variables do, over the whole of $D \cup \{\otimes\}$.

Finally, what about the interpretation of singular terms?—‘closed’ terms, which contain no free variables? To fit in with the model-theoretic apparatus for functors, we should expect to be able to assign an object in the domain of quantification to a term to mean that the term denotes that object, and to assign \otimes to a non-denoting term. If we stipulate the classification of all unstructured singular terms in this way, the apparatus of monotonic functions will then yield an appropriate classification for compound closed terms.

The reader who is eager for formal details could now skip on to Section 6. But a few further remarks are prompted, if we want seriously to understand a term’s denoting an element of D in a way that matches the informal idea of a term’s standing for an object. A sharp contrast must be drawn with the assignment of \otimes to a term. For \otimes is not the nonsense of an object which doesn’t exist; nor is it a special object picked on (Frege-style) to be the actual denotation for terms that should really be non-denoting: \otimes has been introduced simply as part of the apparatus for representing partial functions. It does then make sense to see \otimes playing a derived model theoretic role as the *semantic classification* ‘non-denoting’, but it would be courting confusion if we then went on to think of the monotonic functions of the model theory just as functions on semantic classifications. The classification of a denoting term would then turn out to be the very object denoted, but to keep semantic levels straight, we should distinguish the object a that a term denotes from the classification ‘denoting- a ’: such a classification is not an object in the domain and can be aligned with \otimes . Of course, objects and the corresponding classifications do correspond one-to-one, and so it is in fact open to us to adopt an alternative understanding of the semantics right from the start—as a semantics that operates throughout on classifications. And this could either be thought of as a total monotonic semantics on all classifications or as a partial semantics on the range of classifications ‘denoting-so-and-so’ (see Section 3).

Observe that a parallel finickiness over sentences and $*$ would be called for only if the assignment of \top or \perp to a sentence were intended to be more than a model-theoretic device for classifying sentences—as it would, for example, according to Frege’s unified theory of reference, where the truth-values \top and \perp are seriously thought of as objects denoted by sentences. Otherwise, it is harmless to take the monotonic functions that represent partial ones simply as (total) functions on semantic classifications.

1.3 Comparisons with Supervaluations

The preceding remarks bring our partial logic very much in line with traditional truth-table approaches. The most notable difference is simply in the choice of connectives. We have the novelty of gap-introducing modes, such as interjunction, but we have not introduced any of the familiar gap-closing

vocabulary, which tends to have a metalinguistic flavour. There is no ‘it is true that...’ connective, for example, which is often introduced to turn gappy sentences into false ones. Nor can we define such a mode: it would not be monotonic. In Section 4 we take up the theme of non-classical vocabulary, but now we contrast simple partial logic with an altogether more sophisticated approach, viz. supervaluations. See [Van Fraassen 1966].

To illustrate the basic—but by no means the theoretically most general—idea, consider the question of evaluating a classical propositional formula under a given partial assignment of the truth values \top and \perp to atomic constituents. First we are to evaluate the formula in the ordinary classical way, under all total assignments which extend the partial assignment. Then the formula is taken to be \top if all these total assignments make it \top ; \perp , if they all make it \perp ; and $*$ otherwise. In other words, using the definitions we have already introduced, the supervaluational evaluation $v^s(\phi)$ of a formula ϕ can be given by:

$$v^s(\phi) = \begin{cases} \top & \text{iff } w(\phi) = \top \text{ for all total } w \text{ such that } v \sqsubseteq w \\ \perp & \text{iff } w(\phi) = \perp \text{ for all total } w \text{ such that } v \sqsubseteq w. \end{cases}$$

It is easy to see that this scheme of evaluation yields global monotonicity of evaluation, just as well as simple partial logic (see Section 2.5):

$$\text{if } v \sqsubseteq w, \text{ then } v^s(\phi) \sqsubseteq w^s(\phi), \text{ for every (classical) formula } \phi.$$

However, since the basic evaluation of formulae is just classical, the idea of using monotonic functions to give the interpretation of sentence modes has no role to play. In simple partial logic the monotonicity of a mode $\phi(p_1, \dots, p_n)$ can be stated in terms of a substitutivity condition: given any particular assignment v , and any formulae $\psi_1, \dots, \psi_n, \chi_1, \dots, \chi_n$,

$$\text{if } v(\psi_i) \sqsubseteq v(\chi_i) \text{ for all } i, \text{ then } v(\phi(\psi_1, \dots, \psi_n)) \sqsubseteq v(\phi(\chi_1, \dots, \chi_n)).$$

But clearly there is nothing parallel for the supervaluational scheme. Say, for example, that $v^s(p) = v(p) = *$ and $v^s(q) = v(q) = \top$, then $v^s(p \vee \neg p) = \top$ but $v^s(p \vee \neg q) = *$.

This example points up in a particularly startling way the ‘intensional’ character of supervaluational semantics, which is a departure from the spirit of classical logic. It is, however, a price that supervaluation theorists are willing to pay in order to preserve what is considered to be a more important feature of classical logic, viz. the stock of classical tautologies. More exactly, it is considered important to be able to capture the ‘logical truths’ of classical logic—formulae true under any total assignment—as ‘logical truths’ of partial logic—formulae true under any partial assignment. The supervaluational scheme makes this work, because, if ϕ is a classical formula, then ϕ is a classical tautology if and only if $v^s(\phi) = \top$ for any partial assignment v .

This contrasts markedly with our naive scheme of evaluation: logical truths of *any* kind are very thin on the ground. Indeed, only formulae containing some occurrence of one of the constant sentences \top or \perp can ever be true under all partial assignments.

But why should we be interested in logical truth? In [Thomason 1972, p. 231], where the author is arguing in favour of supervaluational techniques in spite of their intensionality, the suggestion seems to be that the truths of a logic are supposed to capture distinctions between good and bad reasoning. But why so? Can we not leave it to the laws of logical consequence—or perhaps to a more encompassing theory of logical relationships between formulae—to capture cannons of correct reasoning? Then we might still be in a good position to show that classical tautologies are indeed ‘preserved’ in partial logic. Consider, for example, the relation \vDash which we defined in Section 1.1 (or \vDash^\top would serve equally well). It is easy to check that, assuming ϕ is a classical formula, ϕ is a classical tautology if and only if

$$[p_1 \vee \neg p_1] \wedge \dots \wedge [p_n \vee \neg p_n] \vDash \phi,$$

where p_1, \dots, p_n are the atomic constituents of ϕ . Does this not set classical tautologies in exactly their rightful place? The formula to the left of ‘ \vDash ’ could never be \perp , but it is not trivially \top , as it would be under the supervaluational scheme: it is \top precisely when all the p_i are either \top or \perp .

Observe that it would be vain to expect the logic of monotonic matrices to capture even its own relation of logical consequence in terms of truth: there can be no mode of composition $\phi(p, q)$ such that $\psi \vDash \chi$ if and only if $\phi(\psi, \chi)$ is logically true. For if there were, then $\phi(*, *)$ would be \top , but $\phi(\top, \perp)$ would not be, which violates monotonicity. And this has nothing specifically to do with our double-barrelled definition of \vDash : it is exactly the same with either \vDash^\top or \vDash^\perp . If we wanted to introduce some special conditional connective to play the role of $\phi(\cdot, \cdot)$, then either it would have to have a non-monotonic matrix (see Section 4.4), or else it would lead to an intensional semantics of the kind we discuss in Section 2.7. However, the exercise we have set ourselves is to use the framework of consequence to set up logic without any such connective.

It would be a mistake to suppose that the theory of supervaluations is not actually concerned with logical relations. On the contrary, there is much sophisticated work involved with comparing and contrasting relations of ‘implication’, ‘necessitation’, ‘presupposition’, etc., etc.—for example in [Van Fraassen 1967, Van Fraassen 1971]. But here the theory quickly becomes rather abstract and we lose sight of any particular formal language. In contrast, simple partial logic puts emphasis on a particular logical vocabulary, and this includes gap-introducing connectives such as interjunction and transplication. These connectives actually prove something of a nuisance to the supervaluational idea: the definition we gave

for $v^s(\psi)$ continues to make sense when $\&$ and $/$ are allowed to occur in ψ , but the point of the exercise is rather spoilt, since there will be formulae of the overall form of classical tautologies which do not come out true. For example, if ϕ is $p \& \neg p$, then there can be no v —not even a v which is already total—such that $v^s(\phi \vee \neg\phi) = \top$. In the face of this problem various supervaluational manoeuvres might be prompted: consider, for example, [Van Fraassen 1975], where Belnap’s connective of ‘conditional assertion’ (see Sections 2.3 and 4.5) is supervaluationalized.

The supervaluational evaluation of a formula ϕ under an assignment v is a boosting-up of its simple evaluation, in that $v(\phi) \sqsubseteq v^s(\phi)$. The question then arises what other kinds of boost-up evaluation may be defined—in particular, what kinds k such that $v(\phi) \sqsubseteq v^k(\phi) \sqsubseteq v^s(\phi)$ —and [Langholm 1988] experiments with various definitions. So long as we remain with propositional logic, these in fact turn out to yield the same result as supervaluational semantics, but corresponding definitions of the evaluation of first-order formulae in partial relational structures give rise to non-trivial differences. Aside from any intrinsic interest in varying the definition of evaluation, this proves to be a useful model-theoretic technique for investigating extensions of a classical language. However, Langholm’s partial relational structures do not capture the full semantics of monotonically-representable partial functions. And, as far as I know, it remains uninvestigated how his work fits in with the model theory we introduce in Section 6 and use in Section 7.

2 SOME MOTIVATIONS AND APPLICATIONS

2.1 *Varieties of Partiality*

In classical logic a sentence, or the assertion of a sentence in a particular context, is classified as either TRUE or FALSE: the classification is an assessment of propositional content against how things are—or maybe against a possible way for things to be. And the propositional content is fixed as what it is precisely by conditions for its assessment. Specifying such conditions is then a way of specifying meaning for a sentence, due account being taken, in one way or another, of contextual parameters. This, roughly, is the picture that standardly goes along with classical logic. What about partial logic?

Different concerns prompt different partial-logic pictures: these are not necessarily intended to supplant the classical picture, but may offer a modification of a part of it, or may simply offer something to complement it or to flesh it out in some way. Among the variety of motivations for adopting partial logic, some will wear on their sleeves a picture they fit, but others leave it a contentious matter what picture to fit them into. As an introduction to this variety, I want to draw two rough and ready distinctions to

be discerned between different accounts of the point of classifying sentences as \top ('true'), or \perp ('false'), or neither- \top -nor- \perp , rather than just TRUE or FALSE.

First, let us distinguish between a one-tier and a two-tier framework for assessment. The one-tier framework is something like this:

- (1) The classification 'neither- \top -nor- \perp ' is, like \top and \perp , *a way of assessing content expressed* in (the assertion of) a sentence (in a context)—a way of assessing it against how things actually are, or against a possible way for things to be.

This framework lends itself to a straightforward scheme of meaning-specification: a specification of content-fixing conditions for assessment as either \top , or \perp , or neither- \top -nor- \perp , will be a specification of meaning. But it leaves open how, as an assessment of content, to understand what 'neither- \top -nor- \perp ' means. In what sense, if any, is this a 'gap' rather than just a third truth value? How do the three classifications \top , \perp , and neither- \top -nor- \perp mesh with the two classical truth values, if they mesh at all?—in other words, how, if at all, does content fixed by classification in partial logic mesh with classical propositional content?

The two-tier framework, on the other hand, does not leave these questions open:

- (2) The classification 'neither- \top -nor- \perp ' is a way of assessing (the assertion of) a sentence (in a context) *to signify that no content is expressed*—nothing to be either \top or \perp . Then \top and \perp may themselves just be taken to be the classical truth values TRUE and FALSE.

But in this framework for assessment the account of meaning-specification will be complicated. We seem to need both a specification of conditions for assessing when there is content, and a specification of content-fixing conditions (which will be classical TRUTH/FALSITY conditions). But how exactly these two tiers fit together, or whether they can somehow be wrapped up into one, is left open. The two-tier framework will suggest itself most obviously—though not exclusively—when things have to do with the contribution of a context in determining propositional content. For example, it might be said of an assertion of the sentence 'This is blue' that it is a precondition for there being any content to be either \top or \perp that there is something which, in the context of the assertion, can be understood to be what 'this' stands for.

The second distinction is between two different choices for what a sentence is to be assessed against. The contrast between a one-tier and a two-tier framework was formulated with the following 'global' kind of set-up in mind:

- (A) The assessment of (the assertion of) a sentence (in a context) as either \top , or \perp , or neither- \top -nor- \perp , is against (a formal representation of) the *whole* way things are, or a possible *whole* way for things to be.

But there may be reasons to invoke a ‘local’ kind of set-up:

- (B) The assessment of (the assertion of) a sentence (in a context) as either \top , or \perp , or neither- \top -nor- \perp , is against (a formal representation of) some *part of* the way things are, or some possible *part of* a way for things to be.

The wholeness of a global set-up is not meant to rule out relativity to a particular domain of discourse, or to the vocabulary of a particular language. For example, there would be nothing non-whole about the standard model for a first-order language of arithmetic. But in a local set-up we might be working with a mere ‘part’ of this model which, say, consisted just of the information that 10 to 31 are natural numbers and that $10 < 30$ and $11 < 29$, but nothing more.

In a global set-up the classification neither- \top -nor- \perp will arise—whether in the one-tier or the two-tier framework—in virtue of some specific feature of a sentence, perhaps in conjunction with a feature of a particular context of assertion. But in a local set-up a different sort of explanation arises for the classification neither- \top -nor- \perp . The classifications \top and \perp may be thought of as ‘positive’ truth values that an assessment can determine, leaving ‘neither- \top -nor- \perp ’ to mean that no positive truth value is determined: a sentence may be neither \top nor \perp because the mere part against which it is assessed does not have enough in it to determine anything positive. Local set-ups, will not appear standing on their own: they will be constitutive of some wider semantic system which invokes assessment against partial states or stages of information in one way or another. And it will only be within the wider system that questions about propositional content and sentence meaning can be raised and answered.

Three different ways have emerged to understand ‘neither \top nor \perp ’, and there would be nothing but confusion if we tried to assimilate them. But in an overall semantic enterprise more than one of these ways may be in play at the same time—perhaps independently of one another, or perhaps interdependently: there will then be issues about criss-crossing or meshing. (And to complicate things further, our characterization of a one-tier framework describes a general kind of understanding of ‘neither \top nor \perp ’ of which there may be various instances.) Criss-crossing would arise, for example, if we were working with a notion of content determined by conditions for (global) assessment as either \top or \perp or neither \top nor \perp , but if we also wanted a classification for there being no content: then, presumably, sentences would have to be classified as either \top or \perp or neither \top nor \perp or neither \top nor \perp nor neither- \top -nor- \perp . An example of meshing, on the

other hand, will arise if the global assessment of sentences as either \top or \perp or neither \top nor \perp is to be explained as the outcome of a succession—or some more complicated structure—of set-ups for local assessment. We shall come across meshing of this sort in several places, and the question will arise whether the resulting global assessment is to be taken in a one-tier or a two-tier framework. Maybe, though, this distinction is not as cut and dried as my over-neat schematizing would suggest.

We shall be scratching only the surface of the possible complexity of things. The first few applications we consider are ones that assume global assessment, but a role for local set-ups will become increasingly more prominent as we move through the list. Some of the issues raised by the examples in this section will be discussed in subsequent sections; though the discussions still leave a lot of loose ends.

2.2 *Presupposition*

In the context of a logic which admits of sentences which are neither ‘true’ (\top) nor ‘false’ (\perp), the ‘presupposition’ of a sentence can simply be thought of as its ‘either- \top -or- \perp ’ conditions. Then, whether we are working with a one-tier or a two-tier framework in which to specify the overall \top/\perp -conditions of a sentence, its presupposition will be constitutive of these \top/\perp -conditions. Such a notion makes quite general sense, but the terminology is usually associated with a particular application: when triclassificatory logic is deployed in an account of a particular linguistic phenomenon called ‘presupposition’.

A paradigm example sentence would be one containing a definite description, such as

- (1) The present King of France is sane.

It might be said that if this sentence were used to make an assertion, then the existence of a (unique) present King of France is not thereby asserted as a straightforward ‘conjunctive constituent’—as it would be in an assertion of ‘There’s someone who (alone) is presently King of France and who is sane’—but figures in some other, subtler, way: it is presupposed. Theoretical approaches to the linguistic phenomenon vary widely: see Scott Soames’s chapter of the *Handbook*. But the kind of approach that partial logic has relevance to is that according to which the presupposition associated with (the assertion of) a sentence is to be captured semantically as a presupposition in the sense we began with. Of course, to explain what it is that is being captured in this way, we would still have to look to a wider theory of meaning—an issue we shall touch upon in some later sections.

Anyhow, if we wished to construe the description ‘The present King of France’ as a singular term, then we might be prompted to treat (1) along the lines introduced in Section 1.1. Such a treatment would make it a

case of a ‘truth-value gap’ caused by a denotationless term—an idea which authors on presupposition like to trace back to [Frege 1892] but associate more strongly with Strawson in his attack on Russell’s theory of descriptions: [Russell 1905, Russell 1959], [Strawson 1950, Strawson 1964].

This is an encounter we ought to consider. At a superficial level it may simply be seen as a debate between someone who is sensitive to presupposition, and therefore wants to say that a sentence such as (1) is neither true nor false (Strawson) and someone who takes a conservative line that classical logic is to apply and that the sentence is just plain false (Russell). However, there are deeper stands which confuse this simple contrast. According to Russell, definite descriptions are not properly construed as singular terms at all, but are to be defined away in terms of identity and the quantifiers \forall and \exists . Strawson, on the other hand, not only construes descriptions as singular terms but suggests a particular theory of reference for them according to which they function much like demonstratives: conditions to determine whether or not they have a denotation and, if so, what it is, cannot be schematized outside a theory about how they are used in particular contexts to refer to particular things. But then, with partial logic at hand, we might actually be prompted to side very much with Russell and against Strawson. Let us consider three progressive stages of becoming more Russellian and less Strawsonian.

First, we might agree to consider descriptions as singular terms, but abandon the Strawsonian account of reference. Partial logic provides a semantics for ‘logically pure’ terms $\iota x\phi(x)$ whose denoting-conditions depend solely on the way $\phi(x)$ determines its extension over a given domain of objects. Perhaps we could work with such a semantics? As a residue from the Strawsonian account, we should recognize that description terms call for a contextually determined restriction on the range of the bound variable; but contextual dependence of this sort is a quite general phenomenon, in no way specific to definite descriptions, and it might best be treated separately—in some suitably general account of such dependence.

The second stage away from Strawson towards Russell is the thought that perhaps we might not always want to construe definite descriptions as singular terms. They share many features with quantifier phrases of the form ‘every F ’, ‘most F ’, and so on. And it is perhaps a virtue of Russell’s analysis that it casts ‘the F ’ as a quantifier phrase along with these other forms: the Russellian formula $\exists x[\forall y[x = y \leftrightarrow Fy] \wedge Gx]$ —or anything equivalent will do equally well—can be seen as an analysis of a scheme of complex quantification $\iota x[Fx, Gx]$ for ‘the F is G ’, just as $\forall x[Fx \rightarrow Gx]$ is the familiar analysis of a scheme $\forall x[Fx, Gx]$ for ‘every F is G ’. This analysis imposes classical total \top/\perp -conditions on $\iota x[Fx, Gx]$, but why not impose presuppositional \top/\perp -conditions instead?

Universal quantification has now come into the picture, and so it is pertinent to observe that a sentence such as

(2) All Jack's children are bald.

provides another standard example of presupposition: (2) presupposes that Jack is not childless. Hence we should think of imposing presuppositional \top/\perp -conditions on $\forall x[Fx, Gx]$ as well as on $\iota x[Fx, Gx]$. What we need for these schemes is something along the following lines:

$$\begin{aligned} \iota x[Fx, Gx] \text{ is } \top & \text{ iff } \text{there is just one } F, \text{ which is } G; \\ \iota x[Fx, Gx] \text{ is } \perp & \text{ iff } \text{there is just one } F, \text{ which is not } G. \\ \\ \forall x[Fx, Gx] \text{ is } \top & \text{ iff } \text{something is an } F \text{ and any } F \text{ is } G; \\ \forall x[Fx, Gx] \text{ is } \perp & \text{ iff } \text{something is an } F \text{ and some } F \text{ is not } G. \end{aligned}$$

These interpretation clauses remain rather informal, but it is easy enough to see that $\iota x[Fx, Gx]$ will be neither \top nor \perp unless there is exactly one F , and $\forall x[Fx, Gx]$ will be neither \top nor \perp unless there is at least one F . In [Thomason 1979] the presupposition of universal sentences is handled in this way, though definite descriptions remain singular terms; in [Keenan 1973], on the other hand, descriptions are handled with a scheme of quantification. Note that if G is a straightforward unstructured predicate, then the \top/\perp -conditions of $\iota x[Fx, Gx]$ should turn out to match those of $G \iota x Fx$, but $\iota x[Fx, \dots x \dots]$ promises greater scope for scope distinctions than the singular term $\iota x Fx$ (see Section 6.4).

The third stage of Russellianization should now be obvious: why not provide an analysis for the scheme $\iota x[Fx, Gx]$ in terms of identity and the quantifiers \forall and \exists ? This, of course, should be an analysis in partial logic, which captures the presuppositional \top/\perp -conditions. And, while we are about it, why not give an analysis of $\forall x[Fx, Gx]$ as well? In Section 4.2 we shall show how interjunction and transpication may be used to do this.

If we work with connectives of this sort, perhaps we shall then have progressed some way towards the ideal expressed in [Thomason 1979] of a formal language 'rich enough that every genuine instance of presupposition is formalizable'? Various kinds of presuppositional idiom might be tackled, since with a simple semantics for languages enriched with $\&$ or $/$ we can produce formulae which actually *exhibit* non-trivial presuppositions in virtue of 'logical structure' of a very basic kind. This provides something to complement abstract theorising about *relations* of presupposition, such as what occurs in some of the literature on supervaluations, where there is a baroque formal semantics for no particular language at all. For we should, I think, object to the contrast made in [Van Fraassen 1971, p. 138]. According to van Fraassen some non-classical logics, such as modal logic, contain 'non-classical connectors', while others, such as the 'logic of presuppositions', are where 'one studies non-classical relations among (sets of) sentences'. No: the logic of presuppositions should be non-classical in the first sense.

Of course, it is easy enough in simple partial logic to define a formal relation of presupposing—if we want to. We can say that ϕ (logically) presupposes ψ if and only if ϕ is \top whenever ψ is either \top or \perp . And once we have interjunction and transpication in our language, then even this simple-minded definition becomes interesting—and even when we restrict attention to propositional logic: for example, ϕ/ψ presupposes ϕ , and $\phi \times \psi$ presupposes $\phi \leftrightarrow \psi$. On the other hand, observe that we could use transpication to define presupposing in terms of equivalence, in a way that matches the use of conjunction in a definition of entailment: ϕ logically presupposes ψ if and only if $\phi \simeq \psi/\phi$. But all this is of parenthetical interest only, since a formal relation of presupposing will have no essential role to play when a semantic theory is set up in our logic.

2.3 *Conditional Assertion*

Related to the idea of a truth-value gap for sentences whose presupposition fails to obtain is the thought that naturally occurring conditional sentences of the form ‘if ϕ , ψ ’ are neither true nor false when ϕ is false. And in [Belnap 1970] a possible world semantics is developed for a connective ‘/’ of ‘conditional assertion’ according to which, if ϕ is false, then ϕ/ψ is neither true nor false because it makes no assertion, in a degrammatized (*sic*) sense of assertion. Otherwise ϕ/ψ ‘asserts’ what ψ ‘asserts’ (unless ψ itself makes no assertion). In Section 4.5 we shall consider this semantics and contrast Belnap’s ‘/’ with transpication in simple partial logic. But observe straightaway that Belnap’s project is manifestly to provide a partial logic for what we called the two-tier framework for the assessment of sentences: ‘no assertion’ means no propositional content to be either true or false.

This prompts us to ask whether partial logic for presupposition should be understood in the same way. Well, any formal treatment of a Strawsonian context-involving account of presupposition would slip naturally enough into a two-tier framework (though Strawson himself might eschew a formal enterprise). But I want to suggest that such a framework would be less happy for the ‘logically pure’ treatment we outlined for the presuppositional schemes of quantification $\exists x[Fx, Gx]$ and $\forall x[Fx, Gx]$ —or indeed for description terms ιxFx . For example, the presupposition of the sentence ‘All Jack’s children are bald’ is taken simply to be the condition that Jack has children: whether or not this presupposition obtains is an objective fact of the matter, and in an assertion of the sentence it may be contextually quite remote, so that it would be something of a mystery how it might be supposed to effect the question whether or not there is assessable content in the assertion. To elaborate the point, say I know Jack, and say it is taken to be ‘mutual knowledge’ between us that Jack is a father; and say you announce ‘All Jack’s children are bald’. Let us assume, furthermore, that only

yesterday you had seen all Jack's children, and they were as bald as coots. Even so, if they had subsequently taken a wonder drug and had in the meantime sprouted hair, then we would say that you had made a false assertion, viz. an assertion with false content. If, on the other hand, they had all been run over by a bus, would this mean that your assertion was stripped of any content? What would the difference be between the two cases to the success of your linguistic performance as an expression of content? In particular, what difference to my understanding of your performance?

Any attempt to explain a two-tier framework for presuppositional semantics would need to counter these reflections. At least so far as sentences like our example sentence are concerned, it would seem to make more sense to espouse a one-tier framework and to seek an account of 'true', 'false' and 'neither-true-nor-false' simply as three different ways of assessing the content of assertions that sentences can be used to make, whatever status the classification 'neither-true-nor-false' might then turn out to have (see Sections 2.4 and 5.2).

2.4 *Sortal Incorrectness*

Some basic examples of 'category mismatch', or 'sortal incorrectness' motivate allowing predicate/singular-term composition to give rise to a truth-value gap in the second of the two ways mentioned in Section 1.1, viz. because the predicate is not considered to be either true or false of a given object. For example, we might want to say that

- (1) The moon is sane.

is neither true nor false, on the grounds that the moon is just not the kind of thing to be either sane or insane. A logically conservative response would be that this simply means the sentence is false—very obviously so. But there is a counter-response that appeals to the behaviour of negation. In the sentence

- (2) The moon is not sane.

the negation seems naturally to 'go with the predicate', just as much as it would have if we had had 'insane' in place of 'not sane'. If (1) is false, so should (2) be, and a certain tension then arises, since (1) seems to be the straightforward negation of (2).

Precisely this tension is familiar, of course, from logically conservative treatments of paradigm presuppositional sentences, according to which presupposition failure is a straightforward case of falsity. For example, both of the following sentences would be said to be false, yet one is the natural negation of the other:

- (3) The present King of France is sane.

(4) The present King of France is not sane.

There is room here for considerable discussion concerning negation and ambiguity, but the fact remains that on its most natural reading (4) both appears to play a role as the direct negation of (3) and yet fails to be true for precisely the same reasons as (3).

In partial logic there is no tension with negation, since failure-to-be-true is subdivided between the classifications \perp and $*$, and we have a mode of negation which switches \perp with truth (\top) but leaves $*$ fixed. And so, if (1) and (3) are cast as $*$, (2) and (4) fall into place. Indeed, a desire to do justice to the naturalness of natural negation might alone be sufficient to motivate the apparatus of ‘partial’ semantics. Then \top and \perp might be considered ‘proper truth values’, as opposed to the ‘gap’ $*$, just because they are the classifications that negation switches about. Saying this does not in itself preclude regarding $*$ as a case of falsity (see Section 5.2). In other words, we may have an application for partial logic in a one-tier framework, along with a clear answer to the question how the three sentence classifications mesh with the classical truth values TRUTH and FALSITY: \top coincides with TRUTH, while FALSITY spans both \perp and $*$.

However this may be, the idea of sortal incorrectness presents its own special issues, and in [Thomason 1972] the behaviour of negation is just one strand in a highly developed semantic theory. Thomason rejects three-entry matrices for giving the meaning of standard connectives and adopts a logical framework of a supervaluational kind. One reason for his doing is this is the thought that sentences of the form of classical tautologies ought to be true. In Section 1.3 we discussed—and found fault with—the general argument behind this thought; now we should consider the particular example sentence that is chosen to back up the argument. This is ‘What I am thinking of is shiny or not shiny’. Thomason points out that if we were using three-entry matrices, it would be necessary to find out what is being thought of before we can say whether or not the sentence is true. It would be true if I were thinking of an apple, say, but sortally incorrect, and hence neither true nor false, if I were thinking of the number 2: this is because on any matrix approach—at least, on any non-eccentric one— $\phi \vee \neg\phi$ would be $*$ if ϕ were $*$. However, it is not clear why this fact should constitute a special problem for matrices or provide any extra ammunition for the general argument, though it is presented as if it did. This is especially puzzling, given the way Thomason deploys the related sentence ‘What I am thinking of is shiny’ against a ‘syntactic’ account of sortal incorrectness, according to which sortally incorrect sentences are intrinsically ungrammatical. For he points out precisely that we cannot know just by looking at the sentence whether or not it is sortally incorrect: the answer depends on discovering what is being thought about. This is a neat argument, but it will be an

uncomfortable one if it is considered to be a problem when we cannot tell *a priori* the sortal correctness or incorrectness of a sentence.

2.5 *Semantic Paradox*

A partial-valued approach to the semantic paradoxes rivals the ‘orthodox’ Tarskian account of a hierarchy of languages, in which the semantical predicates of a given language can apply only to the language immediately preceding it in the hierarchy. On this account, a simple paradoxical sentence such as ‘This sentence is false’ would be ruled out as anomalous on the grounds that there can be no place for it in a hierarchy. But in [Kripke 1975] an argument is deployed against the Tarskian theory very similar to the one Thomason deploys against a syntactical account of sortal incorrectness. The point is that paradoxicality cannot be seen as an intrinsic anomaly of given sentences—or for that matter of given configurations of sentences—since even the most innocent of truth-assertions and falsity-assertions can, in unfavourable circumstances, turn out to be paradoxical: examples of this involve people talking about one another’s assertions.

A lot of work has recently been done on the paradoxes—and a lot of that involves partiality in one way or another: see Visser’s chapter in the *Handbook* (and see Section 2.10). Here I shall focus on Kripke. To replace a syntactical hierarchy of truth predicates in different languages, he proposed a single language containing its own partially defined truth predicate. This idea had previously occurred in various authors (see [Martin 1970]), but Kripke took up the formal challenge of addressing particular interpreted languages, such as arithmetic, which are sufficiently rich already to provide the kind of self-reference that leads to paradox. Briefly described, his procedure is to graft a predicate symbol T onto a language and then to expand its interpretation so as to make T a truth predicate. It is a truth predicate in the sense that for any sentence σ (of the expanded language), if $\bar{\sigma}$ is a name in the language for σ , then

$$\begin{aligned} T\bar{\sigma} \text{ is true } (\top) & \text{ iff } \sigma \text{ is true } (\top); \\ T\bar{\sigma} \text{ is false } (\perp) & \text{ iff } \sigma \text{ is false } (\perp). \end{aligned}$$

We shall be able to define a ‘Liar sentence’ σ , such that σ is true if and only if $\neg T\bar{\sigma}$ is true, and such that σ is false if and only if $\neg T\bar{\sigma}$ is false, but there is no contradiction: σ and $\neg T\bar{\sigma}$ will both be neither true nor false. The construction of a model to interpret T depends on the monotonicity of evaluation that partial logic can provide (see Sections 1.2 and 6.2). Kripke considers a supervaluational scheme of evaluation, but seems to prefer simply partial logic (see Section 5.1).

The actual method of model construction is a transfinite induction similar to ones used, for example, in [Gilmore 1974], [Feferman 1975] and, most cunningly, in [Scott 1975]. And compare Aczel’s induction in the appendix

to [Aczel and Feferman 1980]. These references all have to do with systems of type-free class abstraction, where paradoxes are diffused by going undefined: in particular, Scott defines truth/falsity conditions appropriate to turn a model for the λ -calculus into a partial-valued language of classes. From a *set*-theoretical point of view all these systems pay a rather high price, viz. the loss of extensionality, but some work has also been done using partial logic to set up extensional set theories: see [Hinnion 1994].

Truth theories and set theories are the obvious lairs for paradox, but it lurks too in quotational logic—logic set up in a language with explicit devices for talking about itself. For example, a sentence such as

$$M = \text{“}\exists p[“p” = M \wedge \neg p]\text{”}$$

may be thrown up, where M is a sentence name, and p is a sentence variable. If p is taken to range over *all* sentences, and if our background logic is classical, then we have a version of the Liar. One strategy for avoiding trouble is to impose a ranking on sentence variables, and a quotational logic with such a ranking is investigated in [Wray 1987a]. But Wray ends with a proposal for adopting partial logic as the background logic, so that variable-ranking can safely be dropped. And this proposal is carried through in [Wray 1987b].

In his article Kripke criticised other authors who had wanted to defuse the paradoxes by going partial, on the grounds that they did not provide ‘genuine theories’—no ‘precise semantical formulation of a language at least rich enough to speak of its own elementary syntax’, and no ‘mathematical definition of truth’. However, there is a sense of ‘theory’ in which Kripke himself did not provide a theory: that is to say a formal theory in the language for which we have a ‘precise semantical formulation’ and a ‘mathematical definition of truth’. Kripke’s definition of truth is a metalinguistic model-theoretic construction and he left it at that. He provided no system in which a truth-language can express its own semantical principles, let alone any stock of basic ‘axioms’ to generate such principles. I want to suggest that the way to fill in this gap is to use the definition we shall give in Section 7 of what a ‘theory’ is in partial logic. It is not clear, though, what Kripke himself would make of the suggestion, since he claimed that his *logic* is utterly classical. We shall pursue this thought a little way in Section 5.1.

2.6 *Stage-by-stage Evaluation*

The bare existence of models for a semantically closed language is only half of Kripke’s story about truth: the construction he employs to demonstrate the existence of such models is associated with an intuitive picture of how sentences can be evaluated as true or as false. In terms of this picture an

account is given—along lines originally explored in [Herzberger 1970]—of ‘paradoxicality’ and related notions. The monotonicity of evaluation now comes to life as a persistence condition governing a procedure of evaluation which runs through stages of increasing information. At a given stage the truth predicate has been defined to a given extent and sentences can be evaluated at that stage in the ordinary way—according to simple partial logic or a supervaluational scheme. But this evaluation then determines the truth predicate for the next stage of evaluation. The truth predicate becomes more defined, and as it becomes more defined so more sentences become true or false, and the truth predicate becomes still more defined . . . and so on. Monotonicity ensures that once a sentence has taken on the value ‘true’ or ‘false’, and the interpretation of the truth predicate has been strengthened accordingly, then it can neither become undefined nor switch truth value at any later stage of evaluation.

Recall the distinction we drew in section 2.1 between a ‘local’ and a ‘global’ set-up for assessing sentences. It would not seem inappropriate to think of the evaluation of sentences at each particular stage of information as a local set-up. But the succession of stages leads up to a global set-up, viz. a stable model to interpret semantically closed partial languages: this model can be seen as the result of pursuing a stage-by-stage evaluation process until it settles down and no new true or false sentences are produced. By general principles governing the inductive definition behind this process it must settle down sooner or later, though in the case of interesting languages this will not be without transfinite leaps to limit-ordinal stages, where all previous truths and falsehoods are gathered up to define the new interpretation of the truth predicate. Assuming, then, that the model we end up with constitutes a global set-up, the question arises whether it provides a one-tier or a two-tier framework of assessment. ‘One-tier’ would seem to be the obvious answer, but this seems to conflict with some of Kripke’s own remarks, and we shall return to the question in Section 5.1.

× × ×

However this may be, another, and in some ways rather simpler, illustration of monotonicity as a constraint in the context of a stage-by-stage process evaluation is provided by the discussion of partial recursive predicates in [Kleene 1952, Section 64]. ‘Kleene’s strong matrices’ are introduced here—the same matrices that we presented in Section 1.2. A partial recursive predicate $P(\vec{x})$ may be undefined for some n -tuple \vec{a} of numbers, and, accordingly, Kleene first offers the simple gloss ‘true’, ‘false’ and ‘undefined’ for the matrix entries \top , \perp and $*$ (for which he used ‘ t ’, ‘ f ’ and ‘ u ’). These classifications are intended to apply to sentences built up out of partial recursive predicates, and the point of monotonic (which Kleene calls ‘regular’) matrices can be described in terms of the derived role sentence modes play as modes which compound predicates. For, if $\phi(p_1, \dots, p_n)$ is

a monotonic mode of sentence composition and $P_1(\vec{x}), \dots, P_n(\vec{x})$ are partial recursive predicates, then $\phi(P_1(\vec{x}), \dots, P_n(\vec{x}))$ is partial recursive also; while, conversely, if $\phi(p_1, \dots, p_n)$ is *not* monotonic, then we can find predicates $P_1(\vec{x}), \dots, P_n(\vec{x})$ which are themselves partial recursive, but which are such that $\phi(P_1(\vec{x}), \dots, P_n(\vec{x}))$ is not. (See Kleene's Theorems XX and XXI.)

Kleene explains and illustrates monotonicity in terms of a particular kind of algorithm for the interpretation of partial recursive predicates. For a given input \vec{a} , one of these algorithms will either yield the output 'true', or yield the output 'false', or else go on for ever. A second, 'computational', construal then emerges for the matrix entries: 'true', 'false' and 'unknown (or value immaterial)'. These are classifications for a sentence $P(\vec{a})$ which can be applied at successive stages in pursuing the algorithm for $P(\vec{x})$ with input \vec{a} . The matrix for a given connective, \vee say, reflects the way algorithms for predicates $Q(\vec{x})$ and $R(\vec{x})$ are to be combined to yield an algorithm for $Q(\vec{x}) \vee R(\vec{x})$. The classification $*$ means 'unknown' because if the value \top or \perp has not been decided at a given stage, then we do not know what might or might not happen at a further stage. On the other hand, it can also be glossed 'value immaterial', since we may be able to determine the value \top or \perp for a compound sentence independently of some constituent sentence which remains $*$. For example, $Q(\vec{a}) \vee R(\vec{a})$ can be evaluated as \top if $R(\vec{a})$ has been decided as \top , even if $Q(\vec{a})$ remains $*$.

The original objective construal of the matrix-entries now falls into place in the following way: 'true' applies to sentences which are decided as \top at some stage, 'false' to those which are decided as \perp at some stage, and 'undecided' to sentences which are never decided as either \top or \perp at any stage—in other words, which remain $*$ for ever. Thus Kleene's algorithms can never actually *tell* us that a sentence $P(\vec{a})$ is undefined. (And since, if $P(\vec{x})$ is partial recursive, it is, in general, undecidable whether or not $P(\vec{a})$ is defined, it would, in general, be vain to demand a different kind of algorithm which did tell us.) This explains why none but monotonic connectives are admissible: a resultant value \top or \perp , decided by a compound algorithm, is allowed to depend only on out-put values \top or \perp from constituent algorithms—never on the classification $*$. (See Sections 1.2 and 3.2).

Here we appear to have a paradigm for the use of monotonically representable partial truth-functions. But in [Haack 1974, Haack 1978] it is claimed that Kleene ought rather to have used a supervaluational scheme of evaluation—indeed that his own arguments dictate this. There is no space to do full justice to Haack's remarkable claim, but it would appear to depend primarily on two things. The first is that Kleene mentions a secondary application for his matrices—to sentences built up from total predicates of a kind which are decidable (by one of his algorithms) on *part* of their domain and have their extension over the rest of the domain given by a separate stipulation. It seems that this enables Haack to misunderstand Kleene's gloss for $*$ as 'lack of information that a sentence is \top or is \perp ' to mean

lack of information which of either \top or \perp it is. Kleene does not mean this, however: $*$ (under its computational construal) signifies lack of information whether a sentence is \top or \perp or $*$ *for ever*. It is difficult to see what sense Haack can have made of Kleene's discussion of the 'law of the excluded fourth', which is required to advance from the computational to the objective construal.

Secondly, and connected in some not altogether clear way with the mistaken idea that all sentences under consideration are really either \top or \perp , there seems to be a confusion between the constraint of monotonicity (regularity) and a totally different point about the particular matrices chosen for classical connectives: that they are, in Kleene's words, 'uniquely determined as the strongest possible regular extensions of the classical 2-valued truth-tables'. For Haack never actually mentions the notion of regularity, but she interprets Kleene's explanatory discussion of the constraint as if it were some kind of direct argument for a *desideratum* that modes of composition be as strong as possible. In [Haack 1974] she reports on Kleene's illustrative discussion of \vee (which I sketched above), but she seems to get the point back-to-front. And, in conclusion, she is prepared to announce the 'underlying principle' to be that 'if $F(A, B, \dots)$ would be \top (\perp) whether A, B, \dots were true or false, then it is to be \top (\perp) if A, B, \dots are $*$ '. If Kleene's principle were something like this, then perhaps we *should* consider supervaluational semantics. But it isn't and we shouldn't.

2.7 Stages, States, and Exotic Connectives

Partial logic extends in various directions to more elaborate kinds of semantics than we shall be pursuing. In one direction the computational idea of a process of evaluation can actually be built into the interpretation of some of the logical connectives: consider for example the semantics in [Thomason 1969] for the theory of constructible falsity. This theory is a kind of two-sided intuitionism whose proper constructivist interpretation—handled in [Nelson 1949] and [Lopez-Escobar 1972]—would appeal to twin notions of 'provability' and 'refutability' in the way that intuitionists appeal just to provability. But for a model theory we can consider a two-sided version of Kripke's semantics for intuitionistic logic.

For simplicity of illustration let us consider just a propositional language. Models can then be taken to consist of a set \mathbf{V} , whose elements α , are each associated with a partial assignment v_α of \top and \perp to atomic sentences, and a reflexive transitive relation \leq on \mathbf{V} , which satisfies the condition that if $\alpha \leq \beta$ then $v_\alpha \sqsubseteq v_\beta$. The elements of \mathbf{V} are to be thought of as stages of information; and the condition on \leq is meant to embody the idea that when $\alpha \leq \beta$ then β has all the information at α but possibly more besides. Formulae are then evaluated at stages in \mathbf{V} . For atomic sentences the persistence of truth value (\top or \perp) through stages of increasing information

is constitutive of the model, and the guiding constraint on evaluation rules is that this persistence be extended to all formulae. In other words, our definition of $v_\alpha(\phi)$ must be such that, for any ϕ if $\alpha \leq \beta$ then $v_\alpha(\phi) \sqsubseteq v_\beta(\phi)$.

The evaluation of negations, conjunctions and disjunctions, at a given stage, involves only the classification at that stage of their immediate constituents—according to the \top/\perp -conditions of simple partial logic. But the evaluation of conditionals involves constituent classifications at stages of further information. Thus we have a system of local set-ups for assessment with a special kind of interdependence between the set-ups: it resides in the actual assessment conditions of a logical connective. Thomason and Lopez-Escobar give the following \top/\perp -conditions:

$$\begin{aligned} v_\alpha(\phi \rightarrow \psi) = \top & \text{ iff for every } \beta \geq \alpha, \text{ if } v_\beta(\phi) = \top \text{ then } v_\beta(\psi) = \top; \\ v_\alpha(\phi \rightarrow \psi) = \perp & \text{ iff } v_\alpha(\psi) = \top \text{ and } v_\alpha(\phi) = \perp. \end{aligned}$$

Notice that in fact it is only the \top -conditions that appeal to further stages. But, in virtue of them, \rightarrow matches a truth-preservation consequence relation: $\phi \rightarrow \psi$ is true at any α in any model if and only if, in any model, ψ is true at any α at which ϕ is true. We can take this to mean that $\phi \rightarrow \psi$ is logically true if and only if ψ is a (single-barrelled) logical consequence of ϕ .

This is how the theory has grown up, but the \top -conditions for \rightarrow could easily be modified to match a double-barrelled notion of consequence—one which also requires preservation of falsity from conclusion to premiss. And we might also adopt stronger \perp -conditions which, like the \top -conditions, appeal to further stages of information, and which match the failure of consequence:

$$\begin{aligned} v_\alpha(\phi \rightarrow \psi) = \top & \text{ iff for every } \beta \geq \alpha \left\{ \begin{array}{l} \text{if } v_\beta(\phi) = \top \text{ then } v_\beta(\psi) = \top \\ \text{and} \\ \text{if } v_\beta(\psi) = \perp \text{ then } v_\beta(\phi) = \perp; \end{array} \right. \\ v_\alpha(\phi \rightarrow \psi) = \perp & \text{ iff for every } \beta \geq \alpha \left\{ \begin{array}{l} v_\beta(\phi) = \top \text{ and } v_\beta(\psi) \neq \top \\ \text{or} \\ v_\beta(\psi) = \perp \text{ and } v_\beta(\phi) \neq \perp. \end{array} \right. \end{aligned}$$

The full point of adopting this strong interpretation of \rightarrow only emerges if we consider setting up non-logical theories in this sort of language: $\phi \rightarrow \psi$ will be true in all models of a theory if and only if ψ follows from ϕ in the theory; and $\phi \rightarrow \psi$ will be false in all models of a theory if and only if ψ 's following from ϕ is inconsistent with the theory. The details of this would take us too far afield, but see Sections 6.5 and 7.1 for non-logical theories in simple partial logic—and for an indication how to spell out theory-relative notions of ‘following-from’ and ‘(in)consistency’. Anyhow, in the framework of this kind of model there are various ways of ringing the changes on the

interpretation of particular connectives, and obviously a variety of different connectives could be introduced.

A similar framework is provided by the ‘data semantics’ of [Veltman 1981]: ‘data sets’ play the role of stages of information, and an increase-of-information ordering is given simply by the relation \sqsubseteq between these sets. In this framework Veltman interprets a pair of operators for ‘it may be that’ and ‘it must be that’. But analogous operators can be introduced into the two-sided Kripke models we have set up: let us write ‘ \diamond ’ and ‘ \square ’. For \diamond the \top/\perp -conditions will be that

$$\begin{aligned} v_\alpha(\diamond\phi) = \top & \text{ iff for some } \beta \geq \alpha, v_\beta(\phi) = \top; \\ v_\alpha(\diamond\phi) = \perp & \text{ iff for every } \beta \geq \alpha, v_\beta(\phi) = \perp; \end{aligned}$$

and \square is dual to \diamond : $\square\phi$ is equivalent to $\neg\diamond\neg\phi$. In [Turner 1984] and [Wansing 1995] the consistency operator M of [Gabbay 1982] is translated into a partial-logic setting by giving it precisely the interpretation we have given \diamond . But observe that we have now introduced a crucial departure from the original models: the general persistence condition—that if $\alpha \leq \beta$ then $v_\alpha(\phi) \sqsubseteq v_\beta(\phi)$ —has now broken down. It is scuppered by the \top -conditions for \diamond (and dually by the \perp -conditions for \square).

The search for exciting new operators can be continued by observing that \diamond and \square are a special case of something more general: ‘dynamic’ operators $\langle\phi\rangle$ and $[\phi]$, formed from a formula ϕ . For $\langle\phi\rangle$ the \top/\perp -conditions will be that

$$\begin{aligned} v_\alpha(\langle\phi\rangle\psi) = \top & \text{ iff for some } \beta \geq \alpha, v_\beta(\phi) = \top \text{ and } v_\beta(\psi) = \top; \\ v_\alpha(\langle\phi\rangle\psi) = \perp & \text{ iff for every } \beta \geq \alpha, \text{ if } v_\beta(\phi) = \top \text{ then } v_\beta(\psi) = \perp. \end{aligned}$$

And, again, $[\phi]$ is dual to $\langle\phi\rangle$: $[\phi]\psi$ is equivalent to $\neg\langle\phi\rangle\neg\psi$. The formulae $\langle\phi\rangle\psi$ and $[\phi]\psi$ could in fact be thought of as kinds of conditional—‘if ϕ , then it may be that ψ ’ and ‘if ϕ , then it must be that ψ ’. (Notice that the \top -conditions of $[\phi]\psi$, though not the \perp -conditions, are exactly the same as those we originally gave for $\phi \rightarrow \psi$.) Anyhow, \diamond and \square can now be captured as $\langle\top\rangle$ and $[\top]$.

In [Jaspars 1995] a logic is presented which not only contains these ‘upward-looking’ operators, but also a (mutually dual) pair of ‘downward-looking’ ones—let us write $\langle\phi\rangle'$ and $[\phi]'$ —whose \top -conditions and \perp -conditions at α involve quantifying over $\beta \leq \alpha$. The \top/\perp -conditions for $\langle\phi\rangle'$ are:

$$\begin{aligned} v_\alpha(\langle\phi\rangle'\psi) = \top & \text{ iff for some } \beta \leq \alpha, v_\beta(\phi) \neq \top \text{ and } v_\beta(\psi) = \top; \\ v_\alpha(\langle\phi\rangle'\psi) = \perp & \text{ iff for every } \beta \leq \alpha, \text{ if } v_\beta(\phi) \neq \top \text{ then } v_\beta(\psi) = \perp. \end{aligned}$$

Jaspars glosses $\langle\phi\rangle'\psi$ as meaning ‘it is possible to retract ϕ from the current state [of information] in such a way that ψ holds afterwards’. Now,

this takes us even further away from the original idea of a two-sided intuitionistic system than \diamond or $\langle\phi\rangle$ does. Originally we were to think of the elements of \mathbf{V} as representing progressive stages in a process of discovery, for which the quasi-ordering \leq represented possible advances in information—indefeasible advances, which once achieved remained firm. The idea of ‘losing’ information had no role to play in interpreting the language, and the possibility that we might not only lose information, but subsequently ‘advance’ in a different and incompatible way, would have been in clear conflict with the intended interpretation of the model. But this possibility is now envisaged: we have variable states, not progressive stages, of information. [Wansing 1993] is a comprehensive essay investigating the ups and downs of all this; and [Wang and Mott 1998] provides a discussion of how quantifiers fit in.

Jaspars emphasizes the dynamic character of his semantics by defining two relations over the elements of \mathbf{V} which a formula determines as its ‘dynamic meaning’:

$$\begin{aligned} \alpha \llbracket \phi \rrbracket_{\top}^{\leq} \beta & \text{ iff } \alpha \leq \beta \text{ and } v_{\beta}(\phi) = \top; \\ \alpha \llbracket \phi \rrbracket_{\top}^{\geq} \beta & \text{ iff } \alpha \geq \beta \text{ and } v_{\beta}(\phi) \neq \top. \end{aligned}$$

Thus $\alpha \llbracket \phi \rrbracket_{\top}^{\leq} \beta$ ($\alpha \llbracket \phi \rrbracket_{\top}^{\geq} \beta$) means that β is a possible way of extending (reducing) α to include (remove) the information that ϕ is true. The notation used here is mine; in particular, I have put in the subscript ‘ \top ’ to point up the one-sidedness of these definitions: there is a complementary pair of relations, defined by replacing ‘ \top ’ with ‘ \perp ’.

These relations between states of information have been defined in terms of \leq and the evaluation of a formula at a state of information (which is itself defined in terms of \leq). But an alternative strategy would be to take relations that determine dynamic meaning as semantically primitive—to define them directly, by recursion on the complexity of formulae. Definitions of this kind, giving an explicit ‘dynamic semantics’, are very popular nowadays: further examples appear at the end of Section 2.10 and in Section 4.3. In Section 4.3 there are also some general remarks on the very idea of a dynamic semantics.

2.8 Under-defined and Over-defined

Another way to extend simple partial logic is to consider more truth-value classifications than just \top , $*$ and \perp . In particular, if $*$ means ‘neither \top nor \perp ’, what about a classification for ‘both \top and \perp ’? This might even make some sense in an application where ‘neither \top nor \perp ’ signifies a kind of undefinedness that is *under*definedness: there might then be a correlative notion of *over*definedness.

There is in any case an irresistible temptation to add a top element—never mind what it could mean—to the degree-of-definedness ordering on truth-value classifications. This yields a four-element lattice:

The labels in brackets are the ones used in [Scott 1973a]. Let us call this lattice D_0 : the beauty of Scott's idea is that D_0 can be naturally embedded into the domain D_1 of monotonic functions from D_0 into D_0 —and this in a way which provides the basis for embedding D_1 into *its* monotonic function space D_2 , and so on. There is a sequence of nested domains, and a limit domain can be defined which constitutes a system of type-free functions closed under application and abstraction—a model for the λ -calculus.

But in fact a similar construction can be carried out if we start with our more modest *semi*-lattice of \top , $*$ and \perp —see [Barendregt 1984], for example—and so there is no special motivation here for adding ‘over-defined’ as a fourth truth-value classification. What a λ -calculus model of this sort provides is a kind of higher-order, but type-free, partial propositional logic: truth values and truth functions inhabit a single unified domain. Quantifiers, however, would seem to present something of a stumbling block in attempts to provide a full-blown type-free partial logic by means of this sort of construction. Application in a limit domain is, loosely speaking, defined in terms of approximations from preceding domains, and, even if we iterate the construction through transfinite stages, it is not clear how successive approximations could ever build up to any decent definition of quantification as a function both ranging over and contained in a limit domain. (The workable definitions I have discovered so far perhaps just about count as non-trivial, but they specify too weak a notion of quantification to be useful.) Furthermore, it does not seem that starting with the four-element lattice of truth-value classifications would offer any advantage. Intensional type-free logic, on the other hand, is much easier to obtain: consider [Scott 1975] and the other similar work mentioned in Section 2.5.

Anyhow, the idea that a sentence may be over-defined, in being both true and false, is one that paraconsistent logicians would like to make serious sense of: see Priest's chapter in the *Handbook*. But in this chapter we need only advert to places in work we have already mentioned where the

four-element lattice plays a role. First, then, it turns up in the type hierarchy of [Muskens 1989] (see Section 1.2). Secondly, the general framework set up in [Langholm 1988] allows both-truth-and-falsity as well as neither-truth-nor-falsity, though a definition of ‘coherence’ is immediately given to delineate those logics which run on just the three truth-value classifications \top , \perp and $*$ (see Section 1.3). And again in [Bochman 1998] partial logic turns out to be a special case in a more general four-valued framework (see Section 1.1). Compare, too, the work on the paradoxes in [Visser 1984].

2.9 *Non-deterministic Algorithms*

But four is still a small number: there are even more truth-value classifications in the ‘non-deterministic partial logic’ developed for the semantics of programming languages in [Päppinghaus and Wirsing 1981]. This logic is applicable to the evaluation of sentences under ‘non-deterministic algorithms’. The algorithms are ‘non-deterministic’ because at given stages in pursuing them a choice may be left of (finitely many) different ways to proceed. Assuming a particular choice is always made, then a sentence will either be evaluated as \top or as \perp , or else remain undefined ($*$) (either because the procedure grinds to a conclusionless halt or because it goes on forever). But different choices might result in different resultant classifications. And so, for a given non-deterministic algorithm, there is a spread of alternative classifications. The seven values of Pappinghaus and Wirsing’s logic are the different possible spreads: the non-empty subsets of $\{\top, *, \perp\}$. The authors explain various constraints on the interpretation of modes of sentence composition and provide a stock of connectives which is expressively complete for modes meeting these constraints.

I am too out of touch properly to survey the role partial logic and its relatives have played in computer science. But I do know that in an extended version of [Blamey 1991], a degree-of-definedness ordering derived from partial logic is called in to handle divergence—along with non-determinism—in models for CSP processes.

2.10 *Situation Semantics*

‘Situation Semantics’ was introduced in [Barwise and Perry 1981a, Barwise and Perry 1981b] as a rival to the Fregean tradition in semantics according to which truth and truth conditions are central notions. Rather, it was argued, situations and truth-in-a-situation conditions are central. Quite an industry has subsequently developed, and there is now a chapter in the *Handbook* which is dedicated to the theory of situations. Here I shall restrict attention largely to the early foundational papers. In this work objects and relations are taken as metaphysically basic, and—suppressing complications to do with time and place—situations are then configurations of objects and re-

lations. They could be modelled over a given domain D of objects as partial functions from the set of all $(n + 1)$ -tuples consisting of an n -place relation on D and n elements of D into the truth-values \top and \perp . (Empty argument places of the kind considered in Section 1.2 do not enter the picture here: we can take these functions, modelled set-theoretically, just as subsets of total functions.) Thus situations turn out to be a kind of partial model and provide a paradigm for the idea of a local set-up for the assessment of sentences. A simple sentence such as ‘John hits Mary’, for example, would be true (false) in a situation s if and only if $s(\text{hits}, \text{John}, \text{Mary}) = \top$ (\perp).

We might, then, think of the meaning of a sentence ϕ as a predicate of situations—one which determines, as its truth-sided interpretation, the set ‘ $\llbracket \phi \rrbracket_{\top}$ ’ of situations in which it is true. (Barwise and Perry use ‘ $\llbracket \phi \rrbracket$ ’ for this set.) However, we can only think in this way once a number of parameters have been filled in. For the linguistic meaning of a sentence, just like that of any subsentential item, is given as a many-place relation with an array of argument places designed to reveal its sensitivity to both linguistic and non-linguistic context: and a great many of these argument places are for situations. For example, a definite description is evaluated for a denotation relative to a situation—a situation which can cross-refer in various ways with situation slots elsewhere in the architecture of a sentence, possibly, but not necessarily, to be ultimately determined by the context of utterance. Furthermore, situations are taken to be the very objects of perception in certain ‘naked infinitive’ constructions such as ‘Hilary sees Mary hit John’: roughly, this would be true in a situation in which Hilary sees a situation in which Mary hits John. Along these lines Barwise and Perry offer an account of the ‘logical transparency’ of such ‘... sees ϕ ’ contexts, which contrasts with the opacity arising in sentences of the form ‘... sees *that* ϕ ’.

Anyhow, if we ignore the internal structure of situations, then they can be thought of just as ‘partial possible worlds’—points with respect to which sentences are to be evaluated as \top , \perp or neither \top nor \perp . This prompts comparison with other work: for example, in [Humberstone 1981] partial possible worlds are called ‘possibilities’ and are used to provide a semantics for traditional modal logic. (And see [Van Benthem and Van Eijck 1982, Fenstad *et al.* 1987, Van Benthem 1988] for more exploration of interconnections.)

× × ×

Classically propositions are often modelled as sets of possible worlds, but what happens if we are working with partial possible worlds or situations? In the early work we are considering Barwise and Perry suggest modelling propositions as sets of situations satisfying the coherence condition that if $s \in P$ and $s \subseteq s'$, then $s' \in P$. And the interpretation sets $\llbracket \phi \rrbracket_{\top}$ then turn out as propositions. This approach to propositions is later abandoned (see below), but it is worth pursuing a little way, if only as partial-

possible-world theory. In particular, the question arises how to define logical operations over propositions—operations to interpret modes of sentence composition. Conjunction and disjunction, obviously enough, turn out to be just intersection and union, so that $\llbracket \phi \wedge \psi \rrbracket_{\top} = \llbracket \phi \rrbracket_{\top} \cap \llbracket \psi \rrbracket_{\top}$ and $\llbracket \phi \vee \psi \rrbracket_{\top} = \llbracket \phi \rrbracket_{\top} \cup \llbracket \psi \rrbracket_{\top}$. But what about negation? Barwise and Perry do not actually treat negation as a mode of sentence composition: it turns up in more complicated categories. Even so, given a proposition P , another proposition $P^* = \{s^* \mid s \in P\}$ is determined, where s^* is the situation obtained from s by reversing the values \top and \perp . And for basic sentences ϕ , such as ‘John hits Mary’, $\llbracket \phi \rrbracket_{\top}^*$ turns out to be the set $\llbracket \phi \rrbracket_{\perp}$ of situations in which ϕ is false: this looks to be a likely candidate for $\llbracket \neg \phi \rrbracket_{\top}$.

But to cater for the negation of complex sentences, we had better modify our representation of propositions so that they have their negative side explicitly built in. If we take *pairs* $\langle P, P^* \rangle$ of Barwise-and-Perry propositions to interpret sententially atomic items, then to interpret compound sentences we can use the following clauses:

$$\begin{aligned} \langle \llbracket \neg \phi \rrbracket_{\top}, \llbracket \neg \phi \rrbracket_{\perp} \rangle &= \langle \llbracket \phi \rrbracket_{\perp}, \llbracket \phi \rrbracket_{\top} \rangle, \\ \langle \llbracket \phi \wedge \psi \rrbracket_{\top}, \llbracket \phi \wedge \psi \rrbracket_{\perp} \rangle &= \langle \llbracket \phi \rrbracket_{\top} \cap \llbracket \psi \rrbracket_{\top}, \llbracket \phi \rrbracket_{\perp} \cup \llbracket \psi \rrbracket_{\perp} \rangle, \\ \langle \llbracket \phi \vee \psi \rrbracket_{\top}, \llbracket \phi \vee \psi \rrbracket_{\perp} \rangle &= \langle \llbracket \phi \rrbracket_{\top} \cup \llbracket \psi \rrbracket_{\top}, \llbracket \phi \rrbracket_{\perp} \cap \llbracket \psi \rrbracket_{\perp} \rangle. \end{aligned}$$

And we can add clauses for interjunction and transplication too:

$$\begin{aligned} \langle \llbracket \phi \bowtie \psi \rrbracket_{\top}, \llbracket \phi \bowtie \psi \rrbracket_{\perp} \rangle &= \langle \llbracket \phi \rrbracket_{\top} \cap \llbracket \psi \rrbracket_{\top}, \llbracket \phi \rrbracket_{\perp} \cap \llbracket \psi \rrbracket_{\perp} \rangle, \\ \langle \llbracket \phi / \psi \rrbracket_{\top}, \llbracket \phi / \psi \rrbracket_{\perp} \rangle &= \langle \llbracket \phi \rrbracket_{\top} \cap \llbracket \psi \rrbracket_{\top}, \llbracket \phi \rrbracket_{\top} \cap \llbracket \psi \rrbracket_{\perp} \rangle. \end{aligned}$$

These equations of course just model the \top/\perp -conditions proposed in Section 1.1.

We should (in parenthesis) observe that the same equations will serve if we are interested in capturing not the local assessment of a formula in a system of situations, partial possible worlds, or whatever, but rather the global assessment of a formula against complete possible worlds—against whole possible ways for things to be. If $v_{\alpha}(p)$ is the (partial) evaluation of an atomic sentence p at a possible world α , the following pair gives the interpretation of p :

$$\langle \{\alpha \mid v_{\alpha}(p) = \top\}, \{\alpha \mid v_{\alpha}(p) = \perp\} \rangle.$$

Then, given an arbitrary formula ϕ , we may invoke the displayed equations to fix the sets of possible worlds $\llbracket \phi \rrbracket_{\top}$, in which ϕ is \top , and $\llbracket \phi \rrbracket_{\perp}$, in which ϕ is \perp . Assuming that this provides a one-tier framework of assessment—and it requires some ingenuity to see it providing anything else—the pair $\langle \llbracket \phi \rrbracket_{\top}, \llbracket \phi \rrbracket_{\perp} \rangle$ then models the ‘partial proposition’ that ϕ expresses.

Anyhow, in the framework of definitions of this kind, a natural version of our double-barrelled consequence relation would be that $\phi \vDash \psi$ if and only

if both $[\phi]_{\top} \subseteq [\psi]_{\top}$ and $[\psi]_{\perp} \subseteq [\phi]_{\perp}$. Barwise and Perry use just the first conjunct of this to define a notion of consequence (matching \models^{\top})—and hence to define equivalence as bi-consequence. Thus defined, consequence and equivalence are stronger, and so more discriminating, than relations which the authors grudgingly label ‘logical’ and define as follows: ψ is a ‘logical consequence’ of (is ‘logically equivalent’ to) ϕ if and only if, if s is any *total* situation, then $s \in [\phi]_{\top}$ only if (if and only if) $s \in [\psi]_{\top}$. (Total situations are just situations that are total functions.) It is then one strand in their argument against the Fregean tradition that trouble results if ‘logical’ equivalence is expected to play a role which should rather be played by the more discriminating relation. This involves ringing the changes on the problem, if substitutively of ‘logical’ equivalents is allowed, of non-truth-functional modes of composition which create extensional contexts. The general aim here is to point up oddities which result from thinking directly in terms of truth values (and truth conditions), rather than situations (and truth-in-a-situation conditions). But it’s far from clear that this aim is met. The more discriminating relation of equivalence has nothing specially to do with the local set-ups of situation theory: it is available in *any* partial semantics. Oddities may equally well be avoided by going partial with a global set-up for assessment—and thinking directly in terms of the truth values \top and \perp (and \top/\perp -conditions).

x x x

In [Barwise and Etchemendy 1987] the apparatus of situations is invoked to address semantic paradox. This involves subjecting the notion of a proposition to some scrutiny, and we are offered two conceptions—‘Russellian’ and ‘Austinian’. Under either conception, the formal modelling of propositions is very different from the one presented above. First we have to have ‘states of affairs’: these are the basic constituents of situations, which, working with the definition we set out at the start, can be taken just to be the members of the sets representing the partial functions that model situations, viz. $(n + 2)$ -tuples consisting of an n -place relation, n objects, and a truth value (\top or \perp). Russellian propositions are then defined as constructs built up from states of affairs, in much the way formulae of a formal language are built up from atomic sentences. At bottom we have basic propositions which just are—or directly correspond to—individual states of affairs, and these will be true in a situation if and only if they are contained in it: truth conditions for arbitrary propositions can then be given by recursive clauses that follow their construction, in just the way that clauses are given for evaluating formulae. Austinian propositions, on the other hand, have a particular situation built in as a kind of contextual parameter—what the proposition is ‘about’. A construction from states of affairs gives a ‘proposition *type*’, which needs to be paired with a situation to model an actual

proposition. So an Austinian proposition contains within itself a situation with respect to which it is true or not.

To give an adequate perspective on the Liar sentence, Barwise and Etchemendy espouse Austinian propositions. The Liar sentence is to be taken in a situation-supplying context and will express a proposition about that situation. If s is the situation supplied and p_s is the proposition expressed, then p_s will be a constituent of itself: its proposition type will consist just of the state of affairs $\langle T, p_s, \perp \rangle$, where T is (an item to represent) the property of being true. (Aczel's theory of non-well-founded sets is invoked as the framework in which to define such self-reflexive propositions.) Thus p_s will be true if and only if $\langle T, p_s, \perp \rangle \in s$. But assuming that no situation can be unfaithful to semantic facts, so that $\langle T, p_s, \perp \rangle \in s$ only if p_s is not true, it follows that p_s will not be true—in other words, $\langle T, p_s, \perp \rangle \notin s$. And, since s cannot be unfaithful to *this* fact, $\langle T, p_s, \top \rangle \notin s$.

But the modelling of propositions leaves no room for the conclusion that p_s is therefore neither true nor false: separate falsity conditions are not defined, and so, because p_s is not true, it's counted simply false. Rather than admitting a neither-true-nor-false proposition, we are invited to appreciate the inevitable partiality of the *situation*. This means we could always extend s to a situation $s' = s \cup \{\langle T, p_s, \perp \rangle\}$, which includes information about the proposition the Liar sentence expressed—though of course in a context supplying *this* situation the Liar sentence will express a different proposition $p_{s'}$, and $\langle T, p_{s'}, \perp \rangle$ will not be contained in s' .

In [Groeneveld 1994] the idea that the Liar sentence actually drives us on from situation s to situation s' is taken up and built into a semantics for languages in which the Liar sentence can be formulated. Partial logic now comes back into the picture—a dynamic partial logic, for which a pair of relations $[[\phi]]^+$ and $[[\phi]]^-$ are defined between situations ('+' for \top , and '-' for \perp). These may be glossed as follows: $s[[\phi]]^+ s'$ if and only if ' s' is the weakest extension of s that covers the information of ϕ '; $s[[\phi]]^- s'$ if and only if ' s' is the weakest extension of s that rejects the information of ϕ '.

3 FREGEAN THEMES

3.1 Reference Failure

In Section 1.1 we announced that we should, in partial logic, be able to do justice to the idea that a sentence $\phi(t)$ can be neither \top nor \perp because some constituent term t is non-denoting. This calls to mind Frege's theory of reference (*Bedeutung*), according to which the truth value 'true' or 'false' is the reference of a true or false sentence, just as the object denoted by a singular term is its reference, and according to which there is a general principle of reference failure that any compound expression lacks a reference

whenever any constituent expression lacks a reference. This principle would then explain particular claims that $\phi(t)$ is neither \top or \perp ‘because’ t is non-denoting. Of course, our partial logic does not obey this strict principle: if the range of interpretation for predicates $\phi(x)$ is the system of monotonically representable partial subsets of a domain (see Section 1.2), then, since an empty argument place does not necessarily mean no output value, $\phi(t)$ could be \top or \perp even if t is non-denoting. But can we argue that our semantics provides some other, subtler, general principle to give more than *ad hoc* content to particular claims that $\phi(t)$ is neither \top nor \perp because t is non-denoting?

This question leads to thoughts that are in any case prompted if we pursue a Fregean parallel and think of $\{\top, \perp\}$ as the range of reference for sentences and of a domain of objects, or indeed the corresponding classifications ‘denoting so-and-so’, as the range of reference for singular terms. And it is difficult to avoid the parallel. This is not because of any conception external to systematic semantics of what the ‘reference’ of a sentence or singular term is to consist in, but simply because it is a central strand in Frege’s theorising that compound reference be (functionally) dependent on constituent reference: the parallel points up precisely the dependence that must obtain according to the idea that modes of composition are interpreted by partial functions. But then there might seem to be a problem, since the dependence of reference on reference is supposed to be intimately connected with the strict Fregean principle of reference failure, which our logic does not obey. The connection is made (in rather different styles) in [Woodruff 1970, Dummett 1973, Haack 1974, Haack 1978], for example—and a host of more recent references could equally well be given. Haack even presents a deductive-looking argument to the effect that the principle actually follows from the idea of dependence. To defend our framework from the charge that its range of modes is too liberal for it to be understood as a semantics of partial functions, we have to argue that, on the contrary, the dependence of reference on reference does not in itself dictate the crude principle that a compound $\theta(\alpha)$ lacks a reference whenever any constituent α lacks a reference. Such an argument will be attempted in Section 3.2. It is not, of course, just a matter of predicate/singular-term composition: either $\theta(\alpha)$ or α could be either a singular term or a sentence. And at the end of Section 3.2 we shall generalize the question even further.

Frege himself regarded reference failure as a defect of ordinary language, and in his systematic logical language he went to great, and often artificial, lengths to avoid any kind of undefinedness arising. In [Frege 1891] the suggestion seems to be that logical laws could not be given otherwise. Perhaps this was because he tended to assimilate any kind of undefinedness into an intractable kind of ‘vagueness’, but it might anyway have seemed rather impractical to do with logic with so many gaps. In our semantics, however, there are not so many gaps. Moreover, what gaps there are will not ham-

per our formal development as they would have hampered Frege's, because we shall be presenting logic in terms of *consequence* rather than *truth* (see Sections 6.5 and 7.1.)

✕ ✕ ✕

However this might be, let us briefly consider some meta-semantical discussion of the Fregean idea that $\phi(t)$ seriously 'lacks' a reference (truth value) when t 'lacks' a reference (object denoted). [Dummett 1973, Chapters 10 and 12] approaches the matter by discerning different strands in Frege's notion of reference, and the possession of a 'semantic role' is taken to be the only strand in common between sentences and singular terms: the semantic role of an item turns out to be what we have been calling its 'semantic classification', though the *notion* of semantic role is anchored to more fundamental ideas (see Section 5.2). First, then, we should distinguish the realm of objects that can be denoted by terms from the realm of semantic roles, which includes the classification 'non-denoting'. Secondly, Dummett also insists on a distinction between the notion of 'truth-value' in the sense of semantic role, viz. classification or matrix entry in whatever semantics there is reason to adopt, and notions of truth and falsity applicable in the evaluation of what someone asserts using a sentence. Hence, no purchase is to be gained on the idea of sentences actually lacking a truth value by drawing a parallel with names lacking a bearer. Moreover, according to Dummett, whenever anyone ever asserts anything, one or other of the truth values in the second sense must apply (see Section 5.2). There is, though, room for the idea that a sentence may be neither 'true' nor 'false' if these labels apply to two, among more than two, semantic classifications. Dummett takes bearer-less names to be a paradigm source for the problems with negation that we discussed in Section 2.4, and, as we saw, these problems motivate a triclassificatory semantics.

According to Dummett we are concerned throughout with singular terms possessing a Fregean sense (*Sinn*), understood as a cognitive content which determines, but is independent of, the object, if any, denoted. In that case, there is no question of denotation failure in any way infecting what a sentence can express, and the right foundations for the use of partial logic to handle possibly-non-denoting singular terms will then be what in Section 2.1 we called a 'one-tier' framework for assessment. However, it would be contentious to assume that all singular terms can properly be treated in such a framework. It has been argued that the function of at least some singular terms is to introduce denoted objects so intimately into what their containing sentence is used to express that, should such a term in fact not denote, then nothing could have been expressed at all: there would be nothing to be either true or false. This is how we glossed 'neither \top nor \perp ' in the 'two-tier' framework, and it echoes the Strawsonian approach to the presupposition of definite descriptions, which we put on one side in Sec-

tions 2.2 and 2.3. But recent theorizing along these lines has become more concerned with demonstratives and proper names: some classic references are [Wiggins 1976], [McDowell 1977], and [Evans 1982], where it is argued that it is, in fact, an important strand in some of Frege's own thinking that bearerless proper names cannot be used to express anything—any Fregean thought. A rich debate has subsequently developed, encompassing both exegetical questions and the question what it is right to say: for example, [McDowell 1984, McDowell 1986, Bell 1990, Wiggins 1995, Sainsbury 1999, Wiggins 1999]. This is not the place to disentangle the debate, but we have to consider how it impinges on our theme about reference.

First, it would seem that at least pure description terms must fall within the scope of Dummett's account. (I eschew—though I cannot here provide a proper rebuttal of—the Russellian view that there should in principle be no such singular terms in a properly constituted logical language.) In that case, if we take descriptions as a paradigm for the singular terms that our logic is to accommodate, then it might be supposed that any problem about the dependence of reference on reference will have evaporated: surely we can simply extract from Dummett's account the picture of a total-valued semantics operating throughout on semantic classifications? But, even if we do this, the problem will reappear. Given our particular semantics, with monotonic functions interpreting modes of composition, we can ask what sense, if any, it makes to say of that semantics that it exhibits functional dependence just among the classifications \top and \perp and the classifications 'denoting-so-and-so'. This is precisely the question what sense it makes to say that monotonic functions represent partial ones. Itself the question remains internal to the mathematical semantics, but it becomes interesting in connection with at least some applications, if we want a general explanation behind the specific need for, or usefulness of, monotonic forms.

But what if we hanker after taking proper names as the paradigm for singular terms in partial logic? And what if we espouse the two-tier position that when a bearerless name makes a sentence neither true nor false, this is because there can be no Fregean thought expressed by the sentence? It might then be supposed that the kind of infection a bearerless name causes will be so radical that, however it occurs in a sentence, it must block the expression of a thought—so that the crudely Fregean principle will be inevitable. But I want tentatively to suggest that it is perhaps not so obviously inevitable. Central to arguments for the two-tier position is Frege's characterization of the sense of an expression as the 'mode of presentation' (*Art des Gegebenseins*) of a reference. It seems to follow from this that if there is no reference, then there can be no sense: there will be nothing for there to be any mode of presentation of. In particular, if a name has no bearer to be its reference, then it will have no mode of presentation of a bearer to be its sense. Now, suppose we espouse this characterization of sense, and accept the inference from it. Still, does it follow that a sentence containing

a bearerless name can express no thought? It might be supposed to follow, because a thought is the sense of a sentence and, as such, will be dependent on the sense of constituent expressions—in a way that somehow or other matches the dependence of the reference of the sentence (its truth value) on the reference of the constituents. But our thesis concerning reference is that such dependence does not entail the principle that a compound expression must lack a reference whenever any constituent does. If this is right, then a matching thesis concerning sense cannot be dismissed out of hand. There may be room for a sentence that can be used to express a thought even when a constituent name lacks a bearer. For there may be sense for the sentence even when there is no sense to the name.

This remains the mere mooting of a possibility: a thorough investigation is called for into the compositionality of sense, and this is no place for my inchoate thoughts on the matter.

3.2 *Functional Dependence*

The problem, recall, is to provide an account of functional dependence which makes sense of saying that the ‘reference’ if any, of a compound $\theta(\alpha)$ depends on the ‘reference’, if any, of a constituent α —an account which can explain why $\theta(\alpha)$ may *sometimes* lack a reference *because* α lacks a reference, but one which is not subject to the crude Fregean principle that it is *always* the case that

- (1) if α lacks a reference, then $\theta(\alpha)$ lacks a reference.

Here $\theta(\)$ is a functor, and for the moment we shall assume that both α and $\theta(\alpha)$ are either sentences or singular terms, though our remarks will be sufficiently general for it not to matter which. Frege himself wished actually to conflate these categories, but we will not be committed to that: indeed, we could envisage a many-sorted semantics with more than just two distinct domains of reference for basic, non-functor, categories. ([Wiggins 1984], for example, needs this.)

Now, when reference *failure* is *not* the issue, the principle that, with respect to given ranges of reference, ‘compound reference depends on constituent reference’ is familiar as an ‘extensionality’ condition—to pick out modes of composition as extensional predicates or truth-functional sentence functors, for example. Here the idea of dependence is actually being put to work, and what is important is not that each constituent reference has to pull its weight as something on which compound reference depends—a thought that would indeed suggest the crudely Fregean principle—but rather that compound reference depends *only* on constituent reference, not on anything else. This is often spelt out with the following substitutivity condition:

- (2) If α and β have the same reference,
then $\theta(\alpha)$ and $\theta(\beta)$ have the same reference.

As formulated, (2) presupposes that α , β , $\theta(\alpha)$ and $\theta(\beta)$ each have a reference; but we are considering the possibility that expressions lack a reference, and the question naturally arises how (2) might be modified so as to allow for this. In fact is an appropriate answer to this question not precisely what we are looking for?

Presumably, then, we must adopt at least the following constraint on modes of composition:

- (3) If α has a reference and $\theta(\alpha)$ has a reference,
then, if β has the reference of α , $\theta(\beta)$ has the reference of $\theta(\alpha)$.

But what if $\theta(\alpha)$ has a reference, though α lacks one? We do not want to rule out this possibility, but, to preserve the idea of dependence, it must be constrained. An obvious thought is that if $\theta(\alpha)$ has a reference even when α lacks one, then α must occur in $\theta(\alpha)$ in a slot that happens to be irrelevant to determining the reference of $\theta(\alpha)$ —given the reference of all other constituents. But in that case, *whatever* β we care to substitute for α , $\theta(\beta)$ must have the reference of $\theta(\alpha)$. Hence for any β (given any α):

- (4) If α lacks a reference but $\theta(\alpha)$ has a reference,
then $\theta(\beta)$ has the reference of $\theta(\alpha)$.

And now, to replace (2), the conjunction of (3) and (4) can be logically manipulated into the following substitutivity condition:

- (5) If β has the reference, if any, of α ,
then $\theta(\beta)$ has the reference, if any, of $\theta(\alpha)$.

Here, of course, we have to understand the antecedent in a way that makes it trivially true for any α that lacks a reference.

We are now in a position to explain why it is sometimes apt to say that $\theta(\alpha)$ lacks a reference ‘because’ α lacks one. For (4) yields a conditional form of Frege’s principle (1): (1) obtains when α ’s slot in $\theta(\alpha)$ *is* relevant to determining compound reference. It is a mark of relevance that there exist expressions β and γ such that $\theta(\beta)$ and $\theta(\gamma)$ take on a different reference, or such that one of them has a reference but not the other. And it follows from (4) that if such β and γ do exist, then condition (1) does obtain.

This discussion was originally prompted simply as a defence of our partial semantics against the strict Fregean principle (1). But the criterion of functional dependence embodied in condition (5) in fact does more: it dictates *precisely* a semantics of monotonically representable partial functions. Our semantics is not just not too liberal, but it is as liberal as it can be—given the criterion of dependence. To see this, consider a domain of reference D_1 for constituent expressions α and β , and a domain of reference D_2 for compounds $\theta(\alpha)$ and $\theta(\beta)$. Then (5) means precisely that

- (5') IF, for any a_1 in D_1 , if α refers to a_1 , β refers to a_1 ,
 THEN, for any a_2 in D_2 , if $\theta(\alpha)$ refers to a_2 , $\theta(\beta)$ refers to a_2 .

And so, if we assume that for any item in D_1 there is—or can be introduced—an expression whose reference it is, then we may deduce from (5') that the interpretation of $\theta(\)$ can be given as a partial function from D_1 into D_2 of the kind that is representable by a monotonic function from the fixed-up domain $D_1 \cup \{\otimes_1\}$ into the fixed-up domain $D_2 \cup \{\otimes_2\}$: recall Section 1.2. This deals with one-place modes of composition, but the idea generalizes easily enough to arbitrary n -place ones, since monotonicity coordinate by coordinate is equivalent to monotonicity across all coordinates.

It is interesting to contrast the discussion here with that in [Woodruff 1970, pp. 128-9], where the specific question is raised how to reconcile the use of Kleene's 'strong' matrices for \wedge and \vee (in other words the matrices we have adopted) with a generally Fregean way of thinking. Woodruff does not argue, as we have, that there is no trouble over the dependence of compound reference on constituent reference; rather, he argues that dependence may break down—for example when $\phi \vee \psi$ is \top because ϕ is \top , though ψ is $*$ —but that this does not matter. The idea seems to be that, provided the constituent items of a sentence all have a sense, including ones without a reference, then we at least have a compound sense for the whole sentence, and this sense can be considered as determining a reference. However, according to our criterion of dependence, this detour through sense is unnecessary. And, to avoid entanglement with the debate that figured at the end of Section 3.1, the detour is in any case best not taken.

x x x

So far we have been thinking of the function which interprets a functor simply as what exhibits dependence of compound reference on constituent reference, but, in Fregean theory, the interpreting functions are themselves the reference of functors, and compound reference 'depends' no less on this kind of reference than on the reference of a constituent singular term or sentence. What then of our monotonically representable partial functions? Can we see them as constituting a range of reference—or a range of 'partial reference'—which is subject to some suitable principle of dependence? It seems we can set them in this Fregean light by considering appropriate generalisations of principle (5) for higher-level functors $\theta(\)$ which take functors α for arguments. If $\theta(\)$ is a simple second-level predicate, for example, (such as a first-order quantifier) the principle would be one which linguistically embodied the intuitive idea of dependence that we sketched in Section 1.2 in connection with partial subsets of the system of partial subsets of a given domain. But in fact we can cater for a complete hierarchy of functor categories—one which includes not only functors which take functors as arguments, but also (though this unFregean) functors which *make* functors.

There is no space to pursue these thoughts, but we should point out that it would be inadequate to think of the ‘partial reference’ of partial functors as a ‘partially specified’ (total) reference. This is the idea that [Dummett 1973, p. 170] would like to offer Frege, but it could not explain the subtlety of monotonically representable partial functions. The reason is that first-level functors accommodate empty argument places for reference-less terms in a way which is subject only to the constraint of principle (5). Full account has to be taken of this in our generalization of (5) to higher-level functors.

4 NON-CLASSICAL CONNECTIVES

4.1 *Interjunction and Transplication: Expressive Adequacy*

Let us begin with the proof of expressive adequacy. We argued in Section 1.2 that, since the matrices for the connectives of simple partial logic all describe monotonic functions, any propositional formula, however complex, must also have a matrix which describes a monotonic function. We now show that, conversely, given any monotonic function f from $\{\top, *, \perp\}^n$ into $\{\top, *, \perp\}$, we can find a formula $\phi_f(p_1, \dots, p_n) \text{---} \phi_f$ for short—whose matrix describes f : in other words, ϕ_f will take the classification $f(x_1, \dots, x_n)$ under the assignment of x_i to p_i . We shall use just $\neg, \wedge, \vee, \wp, \top$ and \perp to define ϕ_f .

The case when $n = 0$ is easy: there are three 0-place functions, which are described by the trivial matrices for the logically constant sentences (or 0-place connectives) $\top, *$ and \perp . And $*$ can be defined away as $\top \wp \perp$. Otherwise, when $n > 0$, we can proceed as follows. First, for any n -tuple $\vec{x} \in \{\top, *, \perp\}^n$ and any number i from 1 to n . Let the formulae $\top(\vec{x}, i)$ and $\perp(\vec{x}, i)$ be defined by cases—by cases within cases—as follows:

$$\begin{aligned} \top(\vec{x}, i) &= \left. \begin{array}{l} p_i \text{ if } x_i = \top \\ \neg p_i \text{ if } x_i = \perp \\ \top \text{ otherwise} \end{array} \right\} \dots \text{ if } f(\vec{x}) = \top, \\ &= \perp \dots \dots \dots \text{ otherwise;} \\ \\ \perp(\vec{x}, i) &= \left. \begin{array}{l} p_i \text{ if } x_i = \perp \\ \neg p_i \text{ if } x_i = \top \\ \perp \text{ otherwise} \end{array} \right\} \dots \text{ if } f(\vec{x}) = \perp, \\ &= \top \dots \dots \dots \text{ otherwise.} \end{aligned}$$

Then we can define ϕ_f to be

$$\left[\bigvee_{\vec{x} \in \{\top, *, \perp\}^n} \bigwedge_{1 \leq i \leq n} \top(\vec{x}, i) \right] \wp \left[\bigwedge_{\vec{x} \in \{\top, *, \perp\}^n} \bigvee_{1 \leq i \leq n} \perp(\vec{x}, i) \right].$$

It is now not difficult to check that:

- (i) if the $\left\{ \begin{array}{l} \text{left-hand} \\ \text{right-hand} \end{array} \right\}$ interjunct of ϕ_f is $\left\{ \begin{array}{l} \top \\ \perp \end{array} \right\}$ under the assignment of x_i to p_i , then $f(x_n, \dots, x_n) = \left\{ \begin{array}{l} \top \\ \perp \end{array} \right\}$;
- (ii) if $f(x_n, \dots, x_n) = \left\{ \begin{array}{l} \top \\ \perp \end{array} \right\}$, then both interjuncts are $\left\{ \begin{array}{l} \top \\ \perp \end{array} \right\}$ under the assignment of x_i to p_i .

Given the \top/\perp -conditions of \mathbb{X} , it follows from (i) and (ii) that the matrix of ϕ_f does indeed describe the function f .

It also follows that the left-hand interjunct gives the \top -conditions of ϕ_f , while the right-hand interjunct gives the \perp -conditions. And so these formulae provide interesting ‘normal forms’ for monotonic modes of sentence composition. In Section 6.3 we shall show that interjunctive normal forms of this kind exist in quantifier logic too. As specified ϕ_f is likely to contain many otiose occurrences of \top and \perp , but there are obvious ways of obtaining a more economical formula.

We have shown that $\{\neg, \wedge, \vee, \mathbb{X}, \top, \perp\}$ is a set of connectives adequate to express any monotonic function from $\{\top, *, \perp\}^n$ into $\{\perp, *, \top\}$. The question now arises what other sets of connectives are expressively adequate. In particular, given the classical connectives (including \rightarrow and \leftrightarrow , which can be defined in terms of \neg, \wedge and \vee in the usual way), what are the variations on \mathbb{X} ? First, then, observe that transplication has equal expressive power. Not only is $/$ definable in terms of \mathbb{X} , but also conversely:

$$\begin{aligned} \phi / \psi &\simeq [\phi \wedge \psi] \mathbb{X} [\phi \rightarrow \psi], \\ \phi \mathbb{X} \psi &\simeq [\phi \leftrightarrow \psi] / \phi \simeq [\phi \leftrightarrow \psi] / \psi. \end{aligned}$$

Or we could take the logically undefined sentence $*$. We observed above that $*$ can be defined as $\top \mathbb{X} \perp$; now observe that \mathbb{X} can be defined in terms of $*$:

$$\phi \mathbb{X} \psi \simeq [\phi \wedge *] \vee [\phi \wedge \psi] \vee [* \wedge \psi] \simeq [\phi \vee *] \wedge [\phi \vee \psi] \wedge [* \vee \psi].$$

Hence each of \mathbb{X} , $/$ and $*$ has the same expressive power as either of the others.

But to give a more complete answer to our question, first consider the subclass of monotonic functions satisfying the following condition (a converse to the crude Fregean principle that we eschewed in Section 3):

$$\text{if } x_i \neq * \text{ for all } i, \text{ then } f(x_1, \dots, x_n) \neq *.$$

In [Van Benthem 1988] such functions are called ‘closed’. Thus the matrix of a formula ϕ will describe a closed function if and only if, for all total assignments v , either $v(\phi) = \top$ or $v(\phi) = \perp$; and in [Langholm 1988] such formulae are called ‘determinable’. Clearly the matrix for any formula which

contains no connectives beyond \neg, \wedge, \vee, \top and \perp will describe a closed function, since closed functions are closed under composition; furthermore—and less trivially—any such function is described by the matrix of some such formula: in other words, a formula is determinable if and only if it equivalent to a classical formula. There are proofs of this—all different—in [Blamey 1980] and in the two works referred to above.

We are now in a position to provide a general answer to the adequacy question for monotonic modes of composition: the set $\{\neg, \wedge, \vee, \top, \perp, \boxtimes\}$ is expressively adequate if and only if \boxtimes is a connective (of any arity) whose matrix describes a non-closed monotonic function. ‘Only if’ is immediate: compounding closed functions will never reach \boxtimes , for example. On the other hand, we can deduce ‘if’—the claim that *anything* monotonic and non-closed will do—from the fact that the constant sentence $*$ will do. First, $*$ itself is the one and only 0-place non-closed monotonic connective. Secondly, if $n > 0$ and \boxtimes is an n -place connective whose matrix describes a non-closed monotonic function f_{\boxtimes} , then $f_{\boxtimes}(x_1, \dots, x_n) = *$, for some x_1, \dots, x_n such that either $x_i = \top$ or $x_i = \perp$ for each i . And so, together with the constant sentences \top and \perp , \boxtimes will be sufficient to define $*$ —and hence any monotonic mode.

For some particular applications of partial logic, the determinability of all formulae in the language may be a *desideratum*, so that non-closed connectives would be out of place. But in [Jaspars 1995] there is a more general claim, which, in the light of the discussion in Sections 1.2 and 3, would seem to be incorrect. He claims that it follows from the idea that being neither \top nor \perp means being ‘genuinely undefined’, rather than having a third truth value, that ‘whenever all the parts of some proposition have obtained a truth value, then the proposition ought to get a truth value as well’. However, without some question-begging assumption about the possible structure of propositions—or the sentences that express them—I cannot see why it follows. You might just as well say that it follows from the idea of a singular term’s being genuinely undefined, rather than denoting some specially introduced object, that whenever the constituent terms of a compound term are all defined, then the compound term must be too. But in that case ‘0⁻¹’, for example, wouldn’t be undefined. No doubt Jaspars has particularly in mind the kind of undefinedness that arises from what in Section 2.1 I called a local set-up for assessment, so that being neither \top nor \perp means that so-and-so information is not sufficient to determine the value \top or \perp . But, even if so, this does not dictate any principle that information which *is* sufficient to determine a value for all constituents must *also* be sufficient to determine a value for the compound.

4.2 Interjunction and Transplication: Logical Analysis

The two formulae given to define \bowtie in terms of $*$ are each other's dual: and \bowtie is self-dual. This means that negation, when applied to an interjection, can be driven through to rest equally on both interjuncts. Applied to transplication, on the other hand, negation can be driven past the left-hand constituent—which we may call the *transplicator*—to rest on the right-hand constituent—which we may call the *transplicand*:

$$\neg[\phi \bowtie \psi] \simeq \neg\phi \bowtie \neg\psi, \quad \neg[\phi / \psi] \simeq \phi / \neg\psi.$$

If \top and \perp are thought of as the classifications which negation switches, then these equivalences reveal how it is that interjunction and transplication give rise to non-trivial either- \top -or- \perp conditions. Notice, then, that a transplicator can be taken to introduce a presupposition, in the sense that ϕ 's being \top is a necessary condition for ϕ / ψ 's being either \top or \perp . But interjunctions are more interesting: $\phi \bowtie \psi$ can be thought of as expressing ϕ and ψ 'as standing or falling together', or—as the definition of \bowtie in terms of $/$ makes explicit—under the presupposition that they are equivalent.

Recall that in Section 2.2 we gave informal \top / \perp -conditions for the schemes of presuppositional quantification $\exists x[Fx, Gx]$ and $\forall x[Fx, Gx]$. We can now show how to capture these \top / \perp -conditions by analysis under interjunction and transplication. This is a project that could be generalized—see [Van Eijck 1995] and [Sandu 1998] for general frameworks in which to handle modes of quantification in partial logic—but $\exists x[Fx, Gx]$ and $\forall x[Fx, Gx]$ will do to illustrate the use of interjunction and transplication. For the moment we shall adopt the simplifying assumption that F and G are unstructured predicates, totally defined over a given domain: we can then assume that classical principles govern all classical-looking formulae.

First, then, the scheme $\exists x[Fx, Gx]$, for 'the F is G ', admits the following interjunctive analysis (where $F!x$ abbreviates $\forall y[x = y \leftrightarrow Fy]$):

$$\exists x[F!x \wedge Gx] \bowtie \forall x[F!x \rightarrow Gx].$$

Clearly the left-hand interjunct had the desired \top -conditions, and whenever it is in fact \top , the right-hand interjunct must also be \top ; similarly, the right-hand interjunct has the desired \perp -conditions and, whenever it is in fact \perp , the left-hand interjunct must also be \perp ; while the conditions under which the two interjuncts take on opposing truth-values are precisely the required $*$ -conditions. Hence the interpretation of \bowtie guarantees that we have the right \top / \perp -conditions for $\exists x[Fx, Gx]$. Under presuppositional \top / \perp -conditions $\neg \exists x[Fx, Gx]$ must be equivalent to $\exists x[Fx, \neg Gx]$: the scheme is self-dual. This is revealed by our analysis, since the negation of the formula above is equivalent to

$$\exists x[F!x \wedge \neg Gx] \bowtie \forall x[F!x \rightarrow \neg Gx].$$

To see this, first drive negation through onto the interjuncts, and thence onto Gx , and finally switch the interjuncts around.

This analysis of $\downarrow x[Fx, Gx]$ is just the interjunction of formulae giving a classical Russellian analysis of $\downarrow x[Fx, Gx]$ and of $\neg \downarrow x[Fx, \neg Gx]$. But there are other versions of classical analysis which contain $\exists x F!x$ as a distinct conjunctive component. On a presuppositional interpretation this component is a presupposition, and the simple strategy of replacing conjunction by transplication yields the following formulae, either of which may serve to analyse $\downarrow x[Fx, Gx]$:

$$\begin{aligned} \exists x F!x / \forall x[Fx \rightarrow Gx], \\ \exists x F!x / \exists x[Fx \wedge Gx]. \end{aligned}$$

Notice that these formulae are equivalent because given that $\exists x F!x$ is \top the \top/\perp -conditions of the two transpicands must coincide. Notice too that when we apply negation it slips past the transpicator onto the transpicand, and thence through onto Gx , to give

$$\begin{aligned} \exists x F!x / \exists x[Fx \wedge \neg Gx], \\ \exists x F!x / \forall x[Fx \rightarrow \neg Gx]. \end{aligned}$$

So again our analysis reveals that $\neg \downarrow x[Fx, Gx]$ is equivalent to $\downarrow x[Fx, \neg Gx]$.

To provide a transpicative analysis for the scheme $\forall x[Fx, Gx]$ of universal quantification, we can follow a similar pattern:

$$\exists x Fx / \forall x[Fx \rightarrow Gx].$$

It is easy to check, given our simplifying assumption concerning F and G , that this formula captures the right presuppositional \top/\perp -conditions. And we should also consider a scheme $\exists x[Fx, Gx]$ —to be dual to $\forall x[Fx, Gx]$, in having the same \perp/\top -conditions as $\neg \forall x[Fx, \neg Gx]$. The obvious analysis is:

$$\exists x Fx / \exists x[Fx \wedge Gx].$$

We could use this to symbolize a sentence such as ‘Some of Jack’s children are bald’, which, no less than ‘All Jack’s children are bald’, carries the presupposition that Jack is not childless. I shall leave it as an exercise to provide an interjunctive analysis for $\forall x[Fx, Gx]$ and for $\exists x[Fx, Gx]$.

We cannot, of course, rest with the assumption that F and G are unstructured and totally defined: if our schemes of analysis are any good, then they should continue to make appropriate sense when applied to arbitrary formulae $\phi(x)$ and $\psi(x)$ in place of Fx and Gx . And so we should consider what happens when one scheme of presuppositional quantification occurs embedded in another. Horrendously complicated formulae can arise if a number of quantifiers are analysed out together: in particular, occurrences of $/$ or \times will be obscurely embedded not only within the scope of

sentence connectives (including other occurrences of themselves) but also within the scope of the quantifiers \forall and \exists . Yet it turns out that any formula, however complex, is in fact equivalent to one of the form ϕ/ψ where ϕ and ψ themselves contain no occurrence of either $/$ or $\&$. Furthermore, we can specify rules systematically to transform an arbitrary formula into an equivalent formula of this form; and these rules can be framed so that the transpicator ϕ will capture the ‘overall presupposition’ of the formula: ϕ ’s \top -conditions will be precisely the either \top -or- \perp conditions of ϕ/ψ —and hence too of the original formula. These transformation rules, which we shall present in Section 6.3, can be seen as a logician’s version of ‘projection rules’ for presupposition.

The examples presented here reveal only a small fraction of what interjunction and transpication have to offer in the analysis of presupposition: I hope there will very soon be a publication telling more of the story.

4.3 *Static versus Dynamic Semantics*

The idea of a ‘dynamic’ semantics that emerged rather abstractly at the end of Section 2.7, and turned up again in Section 2.10, has figured prominently in the linguistics literature: in particular, presupposition has been given a dynamic treatment. The questions therefore arise whether our use of transpication and interjunction in the analysis of presupposition can be captured in a dynamic semantics, and whether it has to be to provide an adequate foundation. The answers, I want to argue, are respectively ‘yes’ and ‘no’.

Approached dynamically, the meaning of a sentence is seen as captured by its potential to change contextual information states. These states might be taken to be cognitive states of an individual participant in linguistic exchange, or perhaps to be something more communal and complicated; and they might be represented in the form of a partial model of some kind, or as a set of total models or of possible worlds, or as structures that are formulae of some elaborate formal language, or whatever. The general idea can be traced back to work such as [Stalnaker 1972] and [Seuren 1976], and has been developed in [Kamp 1981, Kamp and Reyle 1993, Heim 1982, Seuren 1985, Veltman 1996], and so on. (See [Van Benthem 1991, Muskens *et al.* 1997], and so on, for illuminating surveys.) In such work the old-fashioned idea of giving meaning in terms of truth/falsity conditions is pushed aside—just as it is in situation semantics. Or, at least, it is pushed back, for we must come down to earth at some stage and actually *give* the meaning of the expressions of any particular language: this is the fundamental message of [Lewis 1972]. And presumably the way to come down to earth, *via* the dynamic apparatus, is to give conditions for the correctness of information states.

Anyhow, the presuppositional characteristics of a sentence seem always to be considered context-involving in some special way. But in [Blamey 1980] it was argued against [Karttunen 1973, Karttunen 1974] that a context-involving account of the meaning of presuppositional idioms was unnecessary and something of a distortion: contextual phenomena could best be accounted for on the basis of a semantical account—using the forms of partial logic—which was itself independent of a theory of context. A dynamic approach will not be set up in quite the same way as Karttunen’s, but can we make an analogous point? In [Beaver 1997] dynamic clauses are given to interpret a language with \neg , \wedge , and $/$ (though Beaver writes ‘ ψ_ϕ ’ for ‘ ϕ/ψ ’—notation which he adopts from the work in [Krahmer 1995]); and so let us consider his propositional semantics. We may describe the underlying models as consisting of a set \mathbf{V} of possible worlds α , each α determining a classical total assignment v_α of \top or \perp to atomic sentences. States of information are then represented by sets of possible worlds (all those possible worlds compatible with the state of information represented), and to interpret a formula ϕ there is a relation $\sigma[[\phi]]\tau$ between states σ and τ —glossed as meaning ‘it is possible to update σ with ϕ to produce τ ’. The definition of $\sigma[[\phi]]\tau$ has the following dynamic clauses:

$$\begin{aligned} \sigma[[p]]\tau &\text{ iff } \tau = \sigma \cap \{\alpha \mid v_\alpha(p) = \top\}, \\ \sigma[[\neg\phi]]\tau &\text{ iff for some } v, \sigma[[\phi]]v \text{ and } \tau = \sigma \setminus v, \\ \sigma[[\phi \wedge \psi]]\tau &\text{ iff for some } v, \sigma[[\phi]]v \text{ and } v[[\psi]]\tau, \\ \sigma[[\phi / \psi]]\tau &\text{ iff } \sigma[[\phi]]\sigma \text{ and } \sigma[[\psi]]\tau. \end{aligned}$$

The question we should now ask is whether this definition for $\sigma[[\phi]]\tau$ has to be taken as primitive, or whether the relation can be defined in terms of something which is static and arguably more basic.

Well, any formula ϕ can obviously be evaluated in simple partial logic under a (total) assignment v_α to yield a value $v_\alpha(\phi)$. And so if we define

$$[[\phi]]_\top = \{\alpha \mid v_\alpha(\phi) = \top\}, \quad [[\phi]]_\perp = \{\alpha \mid v_\alpha(\phi) = \perp\},$$

then ϕ ’s content (in \mathbf{V}) under partial semantics may be represented by the pair $\langle [[\phi]]_\top, [[\phi]]_\perp \rangle$. Alternatively, and equivalently, we could use the equations displayed in Section 2.10 directly to define content-evaluation for ϕ . It then turns out that this content is sufficient to define the relation $\sigma[[\phi]]\tau$: a straightforward inductive argument shows that

$$\sigma[[\phi]]\tau \text{ iff } \tau = \sigma \cap [[\phi]]_\top = \sigma \setminus [[\phi]]_\perp.$$

(Hence, observe, the relation is actually a function, though not a total one.) The right-hand side is equivalent to saying that (i) for all $\alpha \in \sigma$, either $v_\alpha(\phi) = \top$ or $v_\alpha(\phi) = \perp$, and (ii) τ is got from σ by taking away all those α such that $v_\alpha(\phi) \neq \top$ —equivalently, given (i), such that $v_\alpha(\phi) = \perp$. This argument is essentially the same as the one presented in [Muskens *et al.* 1997] concerning dynamic clauses formulated in a slightly different way.

This brief commentary on Beaver’s apparatus falls short of a full justification for my answers to the opening questions, but it does show that a natural possible world semantics for presuppositional analysis in partial logic is sufficient to determine natural dynamic clauses. These clauses do not have to be taken as the foundation. It would, though, be more natural still if the world-relative assignments v_α were not restricted to total ones: to function smoothly the atomic formulae of a logical syntax ought to be schematic for arbitrary sentences, and so not subject to any special semantic restriction.

4.4 Non-Monotonic Matrices

Non-monotonic matrices provide the most obvious examples of what our languages cannot express. In [Woodruff 1970], for instance, there are several of the ‘metalinguistic’ sort of connective that we mentioned in Section 1.3. These are obtained by semantic descent from metalinguistic predicates or relations:

ϕ	ψ	$\phi \cong \psi$	$\phi \Rightarrow \psi$	$\phi \mapsto \psi$
\top	\top	\top	\top	\top
\top	$*$	\perp	\perp	\perp
\top	\perp	\perp	\perp	\perp
$*$	\top	\perp	\top	\top
$*$	$*$	\top	\top	\top
$*$	\perp	\perp	\top	\top
\perp	\top	\perp	\top	\top
\perp	$*$	\perp	\perp	\top
\perp	\perp	\top	\perp	\top

ϕ	$T\phi$	$F\phi$	$*\phi$	$+\phi$
\top	\top	\perp	\top	\top
$*$	\perp	\perp	\top	\perp
\perp	\perp	\top	\perp	\top

Thus \cong , \Rightarrow , and \mapsto (for which Woodruff uses ‘ \rightarrow ’) are obtained from relations of equivalence, presupposition and single-barrelled consequence (the relation \models^\top of Section 1.1) respectively. Woodruff comments that the ‘distinctive feature’ of these connectives is that they yield compounds which are defined even when every constituent is undefined. However, a mode $t(p)$ which is just constantly \top , whatever the classification of p , would have this feature, and yet it is monotonic. From our point of view, ‘not monotonic’ is a more fundamental feature.

But is there any natural way of classifying more finely among additional connectives? It is a well-known result that the T connective, together with our \neg, \wedge, \vee and $*$, is expressively adequate for arbitrary matrices. And, given \neg, \wedge , and \vee , any of the other connectives listed above can define T . Hence together with monotonic modes they would each yield a full-blown 3-valued logic. This fact about Woodruff’s connectives is rather more interesting than

the simple fact that they are not monotonic, since it raises the question: are there non-monotonic connectives which would *not* provide a full-blown 3-valued logic if they were included with the monotonic modes? In other words: are there any logics whose expressive range is intermediate between the logic of monotonic matrices and the logic of arbitrary matrices? It turns out that there is precisely one.

To complement the relation \sqsubseteq on $\{\top, *, \perp\}$ we can define a relation \square , which might be thought of as a relation of ‘compatibility’, in the following way:

$$x \square y \quad \text{iff} \quad \text{neither } (x = \top \text{ and } y = \perp) \text{ nor } (x = \perp \text{ and } y = \top).$$

This relation will be of interest in Sections 6 and 7, but in the present context it provides a characterization of the intermediate logic: it is the logic of those matrices which describe functions f that are ‘ \square -preserving’ in the following sense:

$$\text{if } x_i \square y_i \text{ for all } i, \text{ then } f(x_1, \dots, x_n) \square f(y_1, \dots, y_n).$$

To see that \square -preserving logic fits in as we claim, notice first that monotonic functions are \square -preserving, though there are \square -preserving functions which are not monotonic: for example, f such that $f(\top) = \top$, $f(*) = \top$ and $f(\perp) = *$. And there are also functions which are not \square -preserving—including all the functions described by the matrices listed above. We now need two facts whose proofs are omitted, because they are tedious (though not difficult):

- (i) if we add to the monotonic sentence modes any non-monotonic \square -preserving mode, then we can express all \square -preserving functions.
- (ii) if we add to the monotonic sentence modes any non- \square -preserving mode, then we can express all three-valued functions.

It is easy to check that the class of \square -preserving functions is closed under composition, and so it follows from (i) that the \square -preserving modes do indeed provide an intermediate logic. And then it follows from (ii) that this is the only one.

As a corollary of this argument we also have a general answer to the adequacy question for \square -preserving modes of composition: $\{\neg, \wedge, \vee, \&, \top, \perp, \bowtie\}$ is expressively adequate if and only if \bowtie is a connective (of any arity) whose matrix describes a non-monotonic \square -preserving function.

4.5 Two-Tier Semantics

We now turn to something more exotic, viz. the semantics of [Belnap 1970], which is intended to model a two-tier framework for assessment in which the classification $*$ means ‘no assertion’: see Section 2.3 above. This is not to say it is intended to be a general modelling of any two-tier framework; nor is it plausibly taken as such: for example, it would not seem to be appropriate for developing any account of Fregean thoughts of the kind mooted at the end of Section 3.1. Anyhow, in Belnap’s semantics propositions are first modelled as sets of possible worlds in the usual classical way, so that a proposition is true at a world if and only if it contains that world, and then interpretation clauses are given which either assign a proposition to a formula at a world—for it to ‘assert’ at that world—or else leave a formula ‘unassertive’ at a world, with no proposition assigned to it. With this apparatus Belnap’s connective ‘/’ is interpreted by stipulating that at a world in which ϕ asserts a false proposition ϕ/ψ is unassertive, and at any other world ϕ/ψ asserts what ψ asserts, unless ψ itself is unassertive, in which case ϕ/ψ is again unassertive. Thus ‘/’ turns out very like transplication; though to match it up properly we should have to modify its interpretation so that ϕ/ψ is unassertive not only when ϕ is false, but also when ϕ is unassertive.

This is a minor modification and would not disrupt Belnap’s idea. But we should stress that our (monotonic) interpretation of transplication in simple partial logic is in no way committed to further explication with Belnap’s apparatus. If we want to consider a possible-world semantics, then we have the alternative, and simpler, one-tier option of modelling propositions as ‘partial propositions’ of the kind first introduced in Section 2.10 and later invoked in Section 4.3—that is, as pairs of sets of possible worlds which just model our talk of \top/\perp -conditions. Any formula would then express a proposition at any world: either- \top -or- \perp -conditions would be constitutive of this proposition rather than being conditions for the existence of a proposition expressed.

The simpler one-tier option would certainly be more appropriate for a logic of presuppositional analysis: recall Section 2.3. But there is a further special point about the use of transplication in analysis which shows that Belnap’s interpretation for ‘/’ makes it crucially different. It would not just be a mistake to think that the role of a transplicator ϕ in ϕ/ψ is to determine whether or not anything is ‘asserted’, but it would be an even worse mistake to take ψ on its own to represent *what* is asserted, if anything is. We can think of the transpicand in an assertion-specifying role only if we take it filtered through the transplicator, so to speak. Recall that we used $\forall x[Fx \rightarrow Gx]$ as a transpicand to analyse both $\top[Fx, Gx]$ and $\perp[Fx, Gx]$: thus we may filter the same transpicand through different transplicators to get something entirely different. Furthermore, different transpicands may be filtered through the same transplicator to yield the same thing—the same

\top/\perp -conditions. For if $\exists xF!x$ is taken as the transplicator, then we saw that either $\forall x[Fx \rightarrow Gx]$ or $\exists x[Fx \wedge Gx]$ does equally well as a transpicand in an analysis of $!x[Fx, Gx]$ —and there are plenty of other inequivalent formulae we could just as well have chosen: $\forall x[F!x \rightarrow Gx]$ or $\exists x[F!x \wedge Gx]$, for example.

In [Beaver 1997] there is some ambivalence over a formula ‘ ψ_ϕ ’, which in Section 4.3 we assimilated to a transplication ϕ/ψ . He glosses ψ_ϕ as ‘the assertion of ψ carrying the presupposition that ϕ ’, but this is ambiguous. Does it mean (i) the assertion of ψ , carrying the presupposition that ϕ ; or (ii) the assertion of ψ -carrying-the-presupposition-that- ϕ ? The wording is more likely to convey reading (i), though apparently Beaver actually wants to leave both readings open. But as a gloss on our use of transplication only reading (ii) is admissible, where ψ -carrying-the-presupposition-that- ϕ is understood to mean ψ -filtered-through- ϕ , in the way that our examples of analysis illustrate. This is the content of any assertion that ϕ/ψ represents: the presupposition that ϕ is *constitutive* of this content, not a separate item just stuck on alongside.

This point about the undetachability of a transplicator could in fact be made independent of our espousal of a one-tier rather than a two-tier framework for presuppositional semantics. For *even if* we wanted to gloss the ‘neither- \top -nor- \perp ’ of presupposition failure to mean no assertion, what *is* asserted when ϕ is true and ϕ/ψ represents an assertion could not be specified by ψ on its own. If, as in Belnap’s semantics, classical propositions are the only candidates for the content of assertions, then, to put it in Belnap’s language, what ϕ/ψ asserts when it asserts anything—that is, when ϕ is true and ψ asserts something—cannot be what ψ asserts, but can only be the *conjunction* (intersection) of what ϕ asserts and what ψ asserts. Indeed, it would be easy enough to revise Belnap’s clauses for ‘/’ along these lines. This is not a point against Belnap, of course; for recall that his ‘/’ is not intended for presuppositional analysis at all, but rather to construe conditionals.

Anyhow, as in an alternative to going to meet Belnap among the possible worlds, we could in fact unravel his semantics into simple \top/\perp -conditions. Clauses for evaluating a formula at a given world—clauses which make no appeal to any other world—are given in [Dunn 1975]. The following matrices for \wedge, \vee , and $/$ then emerge:

ϕ	ψ	$\phi \wedge \psi$	$\phi \vee \psi$	ϕ / ψ
\top	\top	\top	\top	\top
\top	*	\top	\top	*
\top	\perp	\perp	\top	\perp
*	\top	\top	\top	\top
*	*	*	*	*
*	\perp	\perp	\perp	\perp
\perp	\top	\perp	\top	*
\perp	*	\perp	\perp	*
\perp	\perp	\perp	\perp	*

Thus, quite apart from ‘/’, the matrices for \wedge and \vee show a difference from simple partial logic: conjunction and disjunction are not monotonic (nor even \Box -preserving). This prompts a question: If we started out with our monotonic matrices for \wedge and \vee , then could we sensibly convert them into a Belnap-style two-tier semantics? This becomes a pertinent question in Section 5.1, where we shall address it.

× × ×

But first we should observe that the above non-monotonic, and *prima facie* rather odd, matrix for \vee also arises in [Ebbinghaus 1969], where a first-order semantics is offered to handle the kind of undefinedness that arises from natural modes of mathematical expression. Ebbinghaus presents his semantics by first giving clauses for when a formula is defined—in a given model—and then building truth conditions on top of this. The rules for disjunction are:

$$\begin{aligned} \phi \vee \psi \text{ is defined} & \quad \text{iff} \quad \phi \text{ is defined} \quad \text{or} \quad \psi \text{ is defined,} \\ \phi \vee \psi \text{ is true} & \quad \text{iff} \quad \phi \text{ is true} \quad \text{or} \quad \psi \text{ is true.} \end{aligned}$$

Hence, if * means undefined, \top means true, and \perp means defined but not true, then Belnap’s matrix for \vee results. Negation is taken to work in the same way that it does in simple partial logic, and Ebbinghaus defines $\Delta(\phi)$ as $\phi \vee \neg\phi$, to yield a sentence-mode expressing ‘ ϕ is defined’. Hence $\Delta(\phi)$ yields *, if ϕ is * (just as it would if we had defined it in simple partial logic). Contrast Woodruff’s $+\phi$.

The interpretation of the existential quantifier is analogous to disjunction: $\exists x\phi(x)$ is taken to be defined just in case $\phi(x)$ is defined for at least one element in the domain of quantification, and to be true just in case $\phi(x)$ is true of at least one element. This interpretation is motivated by the desire to allow existential statements to come out false, even when the quantified predicate is undefined for some elements—and so not false of everything: for example, in the domain of rationals or reals, $\exists x[x^{-1} = 0]$ is to be false, though $0^{-1} = 0$ is undefined. Clearly this would not be possible

in monotonic logic. However, since (unlike Ebbinghaus) we envisage setting up all nonlogical theories directly in terms of consequence, we are not under the same pressure to assign such existential statements a truth value.

Disjunction and existential quantification thus turn out to be much ‘stronger’ than in simple partial logic. But conjunction and universal quantification are much ‘weaker’. For conjunction we have:

$$\begin{array}{ll} \phi \wedge \psi \text{ is defined} & \text{iff } \phi \text{ is defined and } \psi \text{ is defined,} \\ \phi \wedge \psi \text{ is true} & \text{iff } \phi \text{ is true and } \psi \text{ is true.} \end{array}$$

and so $\phi \wedge \psi$ is undefined whenever either ϕ or ψ is. Then \forall matches \wedge just as \exists matched \vee . These interpretations do not, therefore, yield the classical duality between \wedge and \vee and between \forall and \exists ; but they allow Ebbinghaus to frame neat rules for $\Delta(\)$ in a natural deduction system which is designed to axiomatize a truth-preservation notion of consequence.

This system falls squarely under the heading ‘partial logic’, but in much recent work there seems to be something of a division of interest. On the one hand, partial logicians tend to ignore undefined singular terms—perhaps because they are primarily concerned with partial states of information, or situations, or the like (see Sections 2.7 and 2.10); though this is certainly not a definitive reason for ignoring undefined terms. On the other hand, those setting up systems to accommodate undefined singular terms tend to prefer a logic which at the level of sentences is totally defined and two valued. See [Feferman 1995] for a magisterial exposition of doctrine—and for a survey of work; and for work specifically in the ‘free logic’ tradition, see Bencivenga’s chapter of the *Handbook*. But the system in [Lehmann 1994], for example, is an exception to the trend: it is a partial logic with undefined terms. This is work in the Fregean tradition, and I would want to take issue with it because it espouses the principle of functional dependence that in Section 3 I argued was unnecessarily crude.

5 PARTIAL LOGIC AS CLASSICAL LOGIC

5.1 *Partial Truth Languages*

A proper discussion of the idea of ‘alternative’ logics is far beyond the scope of this essay. But, *via* some themes we have touched upon already, we shall briefly puzzle over two particular accounts of how the triclassificatory semantics of partial logic can play a role which does *not*, in any interesting sense, give rise to an alternative to classical logic.

First consider [Kripke 1975] which we discussed in Sections 2.5 and 2.6. His remarks about logic are, in fact, rather sketchy and largely centred in footnotes, but nonetheless they are forcefully expressed. In footnote 18, for example, he claims that in adopting Kleene’s monotonic matrices for evaluating sentences he is doing no more than adopting ‘conventions for handling

sentences that do not express propositions’ and that these conventions ‘are not in any philosophically significant sense changes in logic’. For logic is supposed to apply primarily to propositions which are all either true or false. Kripke draws a parallel between handling possibly non-denoting (numerical) terms and handling sentences which are undefined (*), and this parallel calls to mind our account (in Sections 1.2 and 3) of the partial-functional interpretation of functors. However, the parallel there was the Fregean one between objects denoted and the truth-values \top and \perp , whereas Kripke’s parallel is between objects denoted by (numerical) terms and *propositions* expressed by sentences. And in the text he presents us with an explicitly two-tier picture of the meaning of a sentence: gapless truth conditions determine propositions, but sentences, which might turn out to be paradoxical and hence neither true nor false, are not directly interpreted by truth conditions, but by conditions for truth conditions.

Clearly these conditions must not only determine when a sentence expresses a proposition—has gapless truth conditions—but also *what* proposition a sentence expresses when it does express one. Kripke is vague at this point, but his picture of the interpretation of sentences looks to be of the same general kind that Belnap’s semantics is intended to model. And so we return to the question raised in Section 4.5: can Kleene’s monotonic matrices be made to fit with such a semantics? Kripke seems (in footnote 30) to suggest that they stand a better chance than a supervaluational scheme of evaluation. This is presumably because, according to this scheme, there would be the difficulty of sentences none of whose constituents expressed a proposition, but which are true, just because they are of the form of a tautology. The problem would be to say what proposition such a sentence expresses, in a way which does justice to ideas of compositionality whereby a compound proposition is in some sense determined by constituent propositions. However, even on the Kleene scheme we may have a sentence which is true even though one of its constituent sentences is neither true nor false, and so, according to Kripke, expresses no proposition: for example, something of the form $\phi \vee \psi$, where ϕ is a straightforward truth and ψ is paradoxical. What proposition does $\phi \vee \psi$ then express? And, in general, what are the rules which tell us what proposition a compound sentence expresses?

Let us assume we can make suitable sense of saying that propositions are closed under boolean operations (perhaps, but not necessarily, because we have modelled them as sets of possible worlds). And let us, by way of example, compare Belnap’s and Kleene’s matrices for disjunction:

\vee	\top	$*$	\perp
\top	\top	\top	\top
$*$	\top	$*$	\perp
\perp	\top	\perp	\perp

Belnap

\vee	\top	$*$	\perp
\top	\top	\top	\top
$*$	\top	$*$	$*$
\perp	\top	$*$	\perp

Kleene

The four corners of Belnap's matrix are accounted for by saying that if both disjuncts of a disjunction express (or 'assert') a proposition, then the disjunction expresses the corresponding disjunction of the propositions. If, on the other hand, neither disjunct expresses a proposition, then the disjunction expresses none: this explains the centre of the matrix. So far the two matrices coincide, but what happens when one disjunct expresses a proposition but not the other? The *prima facie* oddity of Belnap's matrix is explained by his stipulation that the disjunction expresses the same proposition as the proposition-expressing constituent. But what could Kripke say about Kleene's matrix? The only obvious course would be to make \vee the same kind of connective as Belnap's $'/'$ of conditional assertion and to say that the existence of a proposition expressed by the disjunction depends on the *truth value* of the disjunct which expresses a proposition (the truth value of that proposition): if it is true, then this is the true proposition expressed, and if it is false, then no proposition is expressed.

It might, then, be possible to make sense of things along these lines, treating conjunction in a parallel way and, of course, extending it all to handle quantifiers. And some such elaboration of partial semantics would have to be given, if Kripke ever wants to set up logic for his truth languages so that it can be seen to apply to classical propositions that sentences might or might not express. But then we might ask what role these propositions would play in his account of truth and paradoxicality. We are invited to see the monotonicity-dependent construction of models in some way reflecting an intuitive evaluation process of sentences, in a progression of successive stages: as the process is pursued more sentences receive truth values. But we can hardly think of this process as evaluating sentences for the propositions, if any, they express. For, though monotonicity guarantees persistence of truth value, there would not be persistence of propositions. If, for example, ϕ were true and ψ neither true nor false, but at some stage of evaluation ψ took on a truth value, then the proposition originally expressed by $\phi \vee \psi$ would disappear as a disjunctive constituent of the later proposition. Or are classical propositions meant to be there from the start, in some sense, so that they can determine the process of evaluation? This is a picture it seems difficult to make sense of. So what theoretical role would classical propositions play? The oddity is that they seem to have no role.

But why should we envisage a two-tier semantics at all? The alternative is to give a direct account of meaning in terms of (partial) \top/\perp -conditions, so that sentences have 'partial propositions' as their meaning: see Section 2.10 above, and compare the remarks in Section 4.5. This would mesh naturally with Kripke's account of the stage-by-stage evaluation of sentences: as the evaluation progresses, so propositions become progressively 'more defined'. The idea of partial propositions is crying out for further elucidation, but if it can be provided, then we have the most straightforward way to gloss the formal construction of models for semantically closed languages. As

we explained in Section 2.6, a succession of partial, but progressively less partial, models culminates in a model which is still partial but which is stable: it throws up no new true or false sentences in terms of which to define (the truth predicate of) any less partial model. There are \top/\perp -conditions for all sentences in each model in the succession, and in the final stable model they give the final stable meaning of sentences of the language.

The natural logical apparatus to adopt would then be, or be something similar to, what we shall outline in Sections 6 and 7. And there is surely nothing to stop us interpreting this apparatus as delivering a logic that is essentially classical—richer than usual simply because it embodies rules for handling varieties of undefinedness. The presentation of partial logic in Section 1 was meant to reveal this interpretation as a coherent option.

5.2 *Natural Negation*

If we turn to Dummett's views on presupposition and the role a logic such as ours might play in providing a semantics, then the debate becomes a very different one. The idea that a sentence classified as $*$ expresses no proposition, or that no assertion can be made using it, does not enter the picture at all. Thus Dummett's account is in what we have been calling a one-tier framework. But it does invoke two different aspects of meaning, and these give rise to two different levels of content. Sentences are semantically classified as \top or $*$ or \perp , and there is a notion of the 'semantic content' of a sentence as its \top -versus- $*$ -versus- \perp conditions; but assertions made using sentences are to be classified exhaustively into TRUE ones and FALSE ones, and the 'assertoric content' of a sentence matches TRUTH-versus-FALSITY conditions. Semantic classifications then divide into the 'designated', for sentences which can be used to make TRUE sentences, and the 'undesignated', for sentences which can be used to make FALSE ones. Presuppositional $*$ will side with \perp as a case of FALSITY.

With this framework at hand, Dummett is polemical—for example in the introduction to [Dummett 1978]—against theorists who would deploy notions of 'truth' and 'falsity' matching the semantic classifications \top and \perp in a way which he reserves exclusively for TRUTH and FALSITY. For according to Dummett, so long as we concern ourselves with the linguistic activity of making assertions and with the meaning a sentence manifests in this linguistic practice, then a basic notion of objective truth and falsity leaves no room for anything but an exhaustive dichotomy into the TRUE and the FALSE. There is an exclusion clause for 'vagueness' and 'ambiguity'—which Dummett thinks of as cases where an assertion would have no fully determinate content (and which he supposes have nothing to do with presupposition)—but, otherwise, the way things are is either incorrectly ruled out by an assertion, in which case it is FALSE, or else it is not, in which case it is TRUE.

This thesis emerges in various places in [Dummett 1973], but is crispest in [Dummett 1959]. (Note that ‘anti-realist’ worries are not at issue here.)

Why then bother with a semantics that operates on the classifications \top , $*$, and \perp ? The point, it is suggested, will simply be to obtain a smooth account of how sentences are composed from their constituents. To interpret modes of linguistic composition—not just sentence composition—a system of semantic classifications reveals how the meaning (semantic content) of a complex expression is determined by the meaning (semantic content) of its constituents; but the point of a systematic semantics of this sort is just to lead up in an appropriate way to a correct specification of TRUE-versus-FLASE conditions—assertoric content. It is here that the notion of ‘semantic role’, alluded to in Section 3.1, fits in: the classifications of a semantics capture one strand in the Fregean notion of reference because they play a role—a semantic role—in determining the TRUTH or FALSITY of (assertions made using) sentences. Thus the subtleties of a presuppositional semantics are taken to derive just from structural features we are prompted to discern in a language.

The most salient feature would seem to be negation. We saw in Section 2.4 that, to account for natural modes of negation as straight-forward sentence functors, we need to split non-truth (falsity) into \perp , which negation switches with \top (TRUTH), and $*$, which it leaves fixed. This is a standard example of Dummett’s to illustrate the role of triclassificatory semantics, and he uses it also to explain our naive inclination to apply the labels ‘true’, ‘false’ and ‘neither-true-nor-false’ directly to the evaluation of assertions themselves. For we are inclined, he suggests, to call the assertion of a sentence ‘false’ only if the assertion of the (natural) negation of that sentence would have been true (TRUE).

This seems to provide an explanation of the three-fold scheme of semantic classification—and hence of the phenomenon of presupposition—in terms of the TRUE/FALSE dichotomy and natural negation. But, as Dummett himself points out, natural negation is not a purely syntactical notion. Just consider the complex variety of forms: for example, ‘Some of Jack’s children are not bald’ is just as much a natural negation of ‘All Jack’s children are bald’ as ‘Not all Jack’s children are bald’ is. Hence natural negation is not identifiable as such in a meaning-independent way. Yet as natural speakers we do recognise it, and as theorists it is handy for us to do it justice. So, what *is* it? It is not unreasonable to call, in turn, for an explanation of this mode of sentence modification. Furthermore, why is natural negation *negation* at all? The classical truth values TRUE and FLASE are taken to be fundamental, but natural negation takes some FALSE sentences to ones that are again FALSE (when there is presupposition failure). At this point Dummett’s overall picture might leave us restless. For it does not seem to leave much room to answer these questions—or not without going round in a circle. For what can we say about natural negation other than that

it is a mode of sentence modification which is to be called in to spell out the way we talk about presupposition and its treatment in triclassificatory semantics?

To break out of the circle, we might be prompted to look to an account of presupposition in the theory of assertion—to mesh with the semantic notion cast in triclassificatory logic. And, whatever we think of the particular accounts on offer in the literature, there is surely *something* to be said along these lines. Dummett's response to this would probably be that we would just have decorated the circle with superficial aspects of meaning, unless it had been shown that presupposition can make a distinctive contribution to the cognitive adjustments that people undergo when they understand what is said to them; and that this could never be shown. Even so, in the work referred to at the end of Section 4.2 I'm foolhardy enough to attempt an account which is intended to provide more than superficial decoration.

6 FIRST-ORDER PARTIAL SEMANTICS

6.1 Languages and Models

In this section we outline a model-theoretic semantics to match the sketch of first-order partial logic given in Section 1. A few facts about the logic will emerge, and their proofs will be outlined in Section 7, after we have presented an axiomatization of logical laws. (I hope that a much fuller account of things will soon appear.) The languages we work with will contain no description terms, though Section 6.4 deals with how they would fit in.

Let us, then, take a language \mathcal{L} to consist of the following.

(a) Logical vocabulary:

- (1) sentence connectives \neg , \wedge , \vee , $\&$, \top , and \perp ,
- (2) quantifier symbols \forall and \exists ,
- (3) an identity predicate symbol $=$,
- (4) a constant symbol \otimes ,
- (5) a set Var of denumerably many variables.

(b) Non-logical vocabulary:

- (1) a set $Prd(\mathcal{L})$ of predicate symbols,
- (2) a set $Fnc(\mathcal{L})$ of function symbols,
- (3) a set $Cns(\mathcal{L})$ of constant symbols.

The elements P of $Prd(\mathcal{L})$ and f of $Fnc(\mathcal{L})$ are taken to come along with fixed numbers $\lambda(P)$ and $\mu(f)$ to give their number of argument places. Accordingly, a *model for* \mathcal{L} is to be a structure M consisting of

- (0) a set D_M (which does not have to be non-empty),
- (1) for each $P \in Prd(\mathcal{L})$,
a monotonic function $P_M : (D_M \cup \{\otimes\})^{\lambda(P)} \rightarrow \{\top, *, \perp\}$,
- (2) for each $f \in Fnc(\mathcal{L})$,
a monotonic function $f_M : (D_M \cup \{\otimes\})^{\mu(f)} \rightarrow D_M \cup \{\otimes\}$,
- (3) for each $c \in Cns(\mathcal{L})$,
an element $c_M \in D_M \cup \{\otimes\}$.

For assignments to variables we shall just use functions $s : Var \rightarrow D_M \cup \{\otimes\}$. Then, if we define the *terms* of a language \mathcal{L} in the usual inductive way, the classification $M_s(t)$ of a term t under an assignment s is given as follows:

$$\begin{aligned}
 M_s(x) &= s(x), \text{ for all } x \in Var, \\
 M_s(\otimes) &= \otimes, \\
 M_s(c) &= c_M, \\
 M_s(ft_1 \cdots t_{\mu(f)}) &= f_M(M_s(t_1), \dots, M_s(t_{\mu(f)})).
 \end{aligned}$$

We can now build on this to define the *formulae* of L and their interpretation in a model. Formulae—like terms—are taken to be defined by functor-first construction throughout. But we shall be writing ‘ $\phi \wedge \psi$ ’, ‘ $c = d$ ’, etc., rather than ‘ $\wedge \phi \psi$ ’, ‘ $= cd$ ’, etc., and so be helping ourselves to brackets when necessary. This is just so much notation. And we can regard the following ‘definitions’ in the same light:

$$\begin{aligned}
 * &=_{df} \top \text{ \& } \perp, \\
 \phi \rightarrow \psi &=_{df} \neg \phi \vee \psi, \\
 \phi \leftrightarrow \psi &=_{df} [\phi \rightarrow \psi] \wedge [\psi \rightarrow \phi], \\
 \phi / \psi &=_{df} [\phi \rightarrow \psi] \text{ \& } [\phi \wedge \psi].
 \end{aligned}$$

Given an assignment s , a variable x and an element a in the fixed-up domain $D_M \cup \{\otimes\}$ of a model M , let $s(x|a)$ be the assignment such that $s(x|a)(x) = a$ and $s(x|a)(y) = s(y)$ if y is a variable distinct from x . Then the classification $M_s(\phi)$ of a formula ϕ under an assignment s can be specified as follows:

$$\begin{aligned}
M_s(\top) &= \top, \\
M_s(\perp) &= \perp, \\
M_s(t_1 = t_2) &= \begin{cases} \top & \text{iff } M_s(t_1), M_s(t_2) \in D_M, \text{ and } M_s(t_1) = M_s(t_2) \\ \perp & \text{iff } M_s(t_1), M_s(t_2) \in D_M, \text{ and } M_s(t_1) \neq M_s(t_2), \end{cases} \\
M_s(Pt_1 \dots t_{\lambda(P)}) &= \begin{cases} \top & \text{iff } P_M(M_s(t_1), \dots, t_{\lambda(P)}) = \top \\ \perp & \text{iff } P_M(M_s(t_1), \dots, t_{\lambda(P)}) = \perp, \end{cases} \\
M_s(\neg\phi) &= \begin{cases} \top & \text{iff } M_s(\phi) = \perp \\ \perp & \text{iff } M_s(\phi) = \top, \end{cases} \\
M_s(\phi \wedge \psi) &= \begin{cases} \top & \text{iff } M_s(\phi) = \top \text{ and } M_s(\psi) = \top \\ \perp & \text{iff } M_s(\phi) = \perp \text{ or } M_s(\psi) = \perp, \end{cases} \\
M_s(\phi \vee \psi) &= \begin{cases} \top & \text{iff } M_s(\phi) = \top \text{ or } M_s(\psi) = \top \\ \perp & \text{iff } M_s(\phi) = \perp \text{ and } M_s(\psi) = \perp, \end{cases} \\
M_s(\phi \otimes \psi) &= \begin{cases} \top & \text{iff } M_s(\phi) = \top \text{ and } M_s(\psi) = \top \\ \perp & \text{iff } M_s(\phi) = \perp \text{ and } M_s(\psi) = \perp, \end{cases} \\
M_s(\forall x\phi) &= \begin{cases} \top & \text{iff } M_{s(x|a)}(\phi) = \top, \text{ for every } a \in D_M \\ \perp & \text{iff } M_{s(x|a)}(\phi) = \perp, \text{ for some } a \in D_M, \end{cases} \\
M_s(\exists x\phi) &= \begin{cases} \top & \text{iff } M_{s(x|a)}(\phi) = \top, \text{ for some } a \in D_M \\ \perp & \text{iff } M_{s(x|a)}(\phi) = \perp, \text{ for every } a \in D_M. \end{cases}
\end{aligned}$$

These are the conditions for \top and \perp : $M_s(\phi)$ is $*$ if it is neither \top nor \perp . Observe how it is that variables have nothing more to do with \otimes , once they are bound by a quantifier.

The classification of a formula has been defined relative to an assignment, but we can neatly advance to a non-relative definition: let $M(\phi)$ be $M_s(\phi)$, where s assigns \otimes to all variables. It will then follow (from Lemma 3) that $M(\phi) = \top(\perp)$ if and only if $M_s(\phi) = \top(\perp)$ for every assignment s . A *free* occurrence of a variable in a formula can be defined in the usual way, and sometimes we shall call free variables *parameters*. *Sentences* are parameter free formulae and, as we should expect, their classification is in any case quite independent of assignments. This is a corollary of the following standard semantical lemma:

LEMMA 1 (Relevant Variables).

- (1) If $s_1(x) = s_2(x)$ for every x in t , then $M_{s_1}(t) = M_{s_2}(t)$.
- (2) If $s_1(x) = s_2(x)$ for every x free in ϕ , then $M_{s_1}(\phi) = M_{s_2}(\phi)$.

Let us use the notation ‘ $u(t/x)$ ’ for the term obtained from a term u by substituting t for x throughout. Similarly, let us use ‘ $\phi(t/x)$ ’ for the formula obtained from ϕ by substituting t for all *free* occurrences of x in ϕ . And we shall say that t is *substitutable for x in ϕ* when no occurrence of a variable in t becomes a bound (i.e., not free) occurrence in $\phi(t/x)$. Then there is a second standard lemma:

LEMMA 2 (Substitution for Variables).

- (1) $M_s(u(t/x)) = M_{s(x|M_s(t))}(u)$.
- (2) $M_s(\phi(t/x)) = M_{s(x|M_s(t))}(\phi)$, *provided that t is substitutable for x in ϕ .*

6.2 Monotonicity and Compatibility

Now for something more interesting: the monotonicity of evaluation (cf. Section 1.2). First we need to define a ‘degree-of-definedness’ relation, \sqsubseteq , between models for a given language \mathcal{L} : this consists in the appropriate ‘ \sqsubseteq ’-relation holding between the respective interpretations of the vocabulary of \mathcal{L} . Writing it all out explicitly, in terms only of the basic relations on $\{\top, *, \perp\}$ and on a fixed-up domain $D \cup \{\otimes\}$, we have: $M \sqsubseteq N$ if and only if M and N have a common domain D and, for all $P \in \text{Prd}(\mathcal{L})$, $f \in \text{Fnc}(\mathcal{L})$ and $c \in \text{Cns}(\mathcal{L})$,

- (1) $P_M(\vec{a}) \sqsubseteq P_N(\vec{a})$, for all $\vec{a} \in (D \cup \{\otimes\})^{\lambda(P)}$,
- (2) $f_M(\vec{a}) \sqsubseteq f_N(\vec{a})$, for all $\vec{a} \in (D \cup \{\otimes\})^{\mu(f)}$,
- (3) $c_M \sqsubseteq c_N$.

We also need to extend \sqsubseteq , in the natural way, to assignments: $s_1 \sqsubseteq s_2$ iff $s_1(x) \sqsubseteq s_2(x)$, for all $x \in \text{Var}$. Then for terms as well as formulae:

LEMMA 3 (Monotonicity of Evaluation). *If $M_1 \sqsubseteq M_2$ and $s_1 \sqsubseteq s_2$, then*

- (1) $M_{1s_1}(t) \sqsubseteq M_{2s_2}(t)$,
- (2) $M_{1s_1}(\phi) \sqsubseteq M_{2s_2}(\phi)$.

The proof of this lemma is just a matter of checking—by induction on the complexity of terms and formulae.

To set alongside ‘degree-of-definedness’ there is also a ‘compatibility’ relation between models. In Section 4.4 we defined a relation \square on $\{\top, *, \perp\}$: neither $\top \square \perp$ nor $\perp \square \top$, but otherwise \square holds. And, analogously, we can define \square on a fixed-up domain $D \cup \{\otimes\}$ by:

$$a \square b \quad \text{iff} \quad a \text{ and } b \text{ are not distinct elements of } D.$$

Then to define compatibility between models: $M \square N$ if and only if M and N have a common domain D and for all $P \in \text{Prd}(L)$, $f \in \text{Fnc}(L)$ and $c \in \text{Cns}(L)$,

- (1) $P_M(\vec{a}) \sqsubseteq P_N(\vec{a})$, for all $\vec{a} \in (D \cup \{\otimes\})^{\lambda(P)}$,
- (2) $f_M(\vec{a}) \sqsubseteq f_N(\vec{a})$, for all $\vec{a} \in (D \cup \{\otimes\})^{\mu(f)}$,
- (3) $c_M \sqsubseteq c_N$.

And, as in the case of \sqsubseteq , a natural compatibility relation is induced between variable assignments: $s_1 \sqsubseteq s_2$ iff $s_1(x) \sqsubseteq s_2(x)$, for all $x \in Var$. We could now prove a lemma parallel to Lemma 3, got by replacing ‘ \sqsubseteq ’ by ‘ \sqsubset ’; but this result will shortly be generalized, at least so far as formulae are concerned (part (2)), to something usefully stronger: Lemma 6.

Observe now that if $M \sqsubseteq N$, then we can coherently stick M and N together to define a model $M \sqcup N$, which is the least upper bound of M and N with respect to the \sqsubseteq ordering: if D is the common domain of M and N , then, the interpretation of $P \in Prd(L)$, $f \in Fnc(L)$ and $c \in Cns(L)$, is given by stipulating that,

- (1) for any $\vec{a} \in (D \cup \{\otimes\})^{\lambda(P)}$:

$$P_{M \sqcup N}(\vec{a}) = \begin{cases} \top & \text{iff either } P_M(\vec{a}) = \top \text{ or } P_N(\vec{a}) = \top \\ \perp & \text{iff either } P_M(\vec{a}) = \perp \text{ or } P_N(\vec{a}) = \perp, \end{cases}$$
- (2) for any $\vec{a} \in (D \cup \{\otimes\})^{\mu(f)}$, and any $b \in D$:

$$f_{M \sqcup N}(\vec{a}) = b \text{ iff either } f_M(\vec{a}) = b \text{ or } f_N(\vec{a}) = b,$$
- (3) for any $b \in D$:

$$c_{M \sqcup N} = b \text{ iff either } c_M = b \text{ or } c_N = b.$$

Similarly, if s_1 and s_2 are assignments $D \cup \{\otimes\} \rightarrow Var$, and if $s_1 \sqsubseteq s_2$, then an assignment $s_1 \sqcup s_2$ is coherently defined by stipulating that for any $x \in Var$, and any $a \in D$, $s_1 \sqcup s_2(x) = a$ iff either $s_1(x) = a$ or $s_2(x) = a$.

We shall also be interested in purely ‘elementary’ relations \sqsubseteq_e and \square_e between models—and also a relation of elementary equivalence \sim_e —which can indifferently be characterised either in terms of the classification of arbitrary formulae ϕ , or sentences ϕ , as follows:

$$\begin{aligned} M \sqsubseteq_e N & \text{ iff } M(\phi) \sqsubseteq N(\phi), \text{ for any } \phi, \\ M \square_e N & \text{ iff } M(\phi) \square N(\phi), \text{ for any } \phi, \\ M \sim_e N & \text{ iff } M(\phi) = N(\phi), \text{ for any } \phi. \end{aligned}$$

Notice that $M \sim_e N$ if and only if $M \sqsubseteq_e N$ and $N \sqsubseteq_e M$, just as $M = N$ if and only if $M \sqsubseteq N$ and $N \sqsubseteq M$.

Notice, too, that the relations \sqsubseteq and \square —and indeed the identity relation—can be characterized in terms of the evaluation of formulae:

LEMMA 4.

$$\begin{aligned} M \sqsubseteq N & \text{ iff } D_M = D_N \text{ and } M_s(\phi) \sqsubseteq N_s(\phi), \text{ for any } \phi \text{ and any } s, \\ M \square N & \text{ iff } D_M = D_N \text{ and } M_s(\phi) \square N_s(\phi), \text{ for any } \phi \text{ and any } s, \\ M = N & \text{ iff } D_M = D_N \text{ and } M_s(\phi) = N_s(\phi), \text{ for any } \phi \text{ and any } s. \end{aligned}$$

‘Only if’ follows trivially from Lemma 3 and the parallel result for \sqsupseteq ; ‘if’ can easily be checked by considering atomic formulae.

Relations of ‘degree-of-definedness’ and ‘compatibility’ also arise in a natural way between *formulae*. Let us restrict attention to ‘purely logical’ relations, defined by generalising over all the models for a given language; then, including also a relation \simeq of equivalence:

$$\begin{aligned}\phi \sqsubseteq \psi & \text{ iff } M_s(\phi) \sqsubseteq M_s(\psi), \text{ for any } M \text{ and any } s, \\ \phi \sqsupset \psi & \text{ iff } M_s(\phi) \sqsupset M_s(\psi), \text{ for any } M \text{ and any } s, \\ \phi \simeq \psi & \text{ iff } M_s(\phi) = M_s(\psi), \text{ for any } M \text{ and any } s.\end{aligned}$$

Notice that $\phi \simeq \psi$ if and only if $\phi \sqsubseteq \psi$ and $\psi \sqsubseteq \phi$.

The relation of compatibility between formulae gives rise to an interesting question. If $\phi \sqsupset \psi$, then ϕ and ψ never take on conflicting truth values: can we then stick ϕ and ψ together to yield a more defined formula χ which takes the value \top or \perp whenever either one of ϕ and ψ does? In other words, is there for compatible formulae any thing analogous to $M \sqcup N$ for compatible models M and N ? Let us call χ a *joint* for ϕ and ψ if and only if, for any model M and assignment s ,

$$M_s(\chi) = \begin{cases} \top & \text{iff either } M_s(\phi) = \top \text{ or } M_s(\psi) = \top \\ \perp & \text{iff either } M_s(\phi) = \perp \text{ or } M_s(\psi) = \perp. \end{cases}$$

There is clearly no monotonic mode of sentence composition which we could use to compound ϕ and ψ and thereby produce such a χ , but in fact joints for compatible formulae always exist. In the restricted case of propositional logic this is an immediate corollary of ‘expressive adequacy’ (see Section 4.1 above), but it holds in quantifier logic too:

THEOREM 5 (Compatibility Theorem). *Any two logical compatible formulae have a joint.*

To prepare for our proof of this result in Section 7.3, we need two lemmas. The first is the promised generalization of the compatibility result parallel to Monotonicity of Evaluation (Lemma 3):

LEMMA 6. *If $\phi \sqsupset \psi$, $M_1 \sqsupset M_2$, and $s_1 \sqsupset s_2$, then $M_{1s_1}(\phi) \sqsupset M_{2s_2}(\psi)$.*

To see this, consider $M_1 \sqcup M_2$ and apply part (2) of Lemma 3. (Note that part (2) of Lemma 3 can itself be generalized along the lines of this lemma: replace ‘ \sqsupset ’ by ‘ \sqsubseteq ’.)

The second lemma could be thought of as saying that ϕ and ψ have a ‘least upper bound’, viz. a joint, when and only when they have an ‘upper bound’. (Indeed, this makes quite literal sense if we think of the relation induced by \sqsubseteq on the Lindenbaum algebra of a language.)

LEMMA 7. *ϕ and ψ have a joint if and only if there is a formula λ such that $\phi \sqsubseteq \lambda$ and $\psi \sqsubseteq \lambda$.*

‘Only if’ is trivial. Conversely, given λ , the following formula is obviously a joint: $[[\phi \vee \psi] \wedge \lambda] \bowtie [\lambda \vee [\psi \wedge \phi]]$.

6.3 Interjunctive and Transplivative Normal Forms

In section 4.1 we promised normal forms in quantifier logic to match the in propositional normal forms that derive from our proof of expressive adequacy. Let us, then, say that a formula is in *interjunctive normal form* when it is an interjunction $\psi \bowtie \chi$ such that neither ψ nor χ contains any occurrence of \bowtie and such that, for any model M and any assignment s , $M_s(\psi \bowtie \chi) = \top$ if and only if $M_s(\psi) = \top$, and $M_s(\psi \bowtie \chi) = \perp$ if and only if $M_s(\chi) = \perp$. Logical consequence has not yet been officially defined for our first-order languages, but from the outline in Section 1.1 it is easy to see that this condition will turn out equivalent to saying that $\psi \vDash \chi$. (The precise definition of \vDash is in section 6.5.) We can now show that an arbitrary formula ϕ is logically equivalent to a formula in interjunctive normal form: in fact we can describe a procedure to transform ϕ into normal form.

The procedure relies on the fact—easy to check—that our language admits ‘substitutivity of equivalents’: when a subformula is replaced by something equivalent, then the resulting formula is equivalent to the original one. This means we can first replace any atomic subformula ϕ' of a formula ϕ by $\phi' \bowtie \phi'$ —which itself is clearly in normal form—and, since $\phi' \simeq \phi' \bowtie \phi'$, the resulting formula will be equivalent to ϕ . Then we can progressively pull \bowtie out of the scope of the logical operators in ϕ —both connectives and quantifiers—working up from those with narrowest scope to the one with widest scope. What makes this possible is that if $\psi \bowtie \chi$ is in normal form, or if both $\psi_1 \bowtie \chi_1$ and $\psi_2 \bowtie \chi_2$ are in normal form, then the following equivalences hold, and the formula on the right of ‘ \simeq ’ will again be in normal form:

$$\begin{aligned} \neg(\psi \bowtie \chi) &\simeq \neg\chi \bowtie \neg\psi \\ (\psi_1 \bowtie \chi_1) \wedge (\psi_2 \bowtie \chi_2) &\simeq (\psi_1 \wedge \psi_2) \bowtie (\chi_1 \wedge \chi_2) \\ (\psi_1 \bowtie \chi_1) \vee (\psi_2 \bowtie \chi_2) &\simeq (\psi_1 \vee \psi_2) \bowtie (\chi_1 \vee \chi_2) \\ (\psi_1 \bowtie \chi_1) \bowtie (\psi_2 \bowtie \chi_2) &\simeq (\psi_1 \wedge \psi_2) \bowtie (\chi_1 \vee \chi_2) \\ \forall x(\psi \bowtie \chi) &\simeq \forall x\psi \bowtie \forall x\chi \\ \exists x(\psi \bowtie \chi) &\simeq \exists x\psi \bowtie \forall x\chi. \end{aligned}$$

Thus we can pull \bowtie out of the scope of an operator by replacing a subformula of one of the forms displayed on the left by the equivalent formula on the right. At each stage equivalence to ϕ is preserved; and at each stage the replacement subformula is in normal form: and so we end up with an equivalent formula in normal form.

The displayed equivalences do not of course hold unconditionally, except for the first. We could alternatively use ones that did, but the formulae

on the right would then be double the length. For example, to specify how to pull \bowtie out of the scope of a quantifier, when it governs an arbitrary interjunction, we need the following:

$$\begin{aligned}\forall x(\psi \bowtie \chi) &\simeq \forall x(\psi \wedge \chi) \bowtie \forall x(\psi \vee \chi) \\ \exists x(\psi \bowtie \chi) &\simeq \exists x(\psi \wedge \chi) \bowtie \exists x(\psi \vee \chi).\end{aligned}$$

Suitable equivalences for \wedge , \vee , and \bowtie I leave as an exercise.

Let us now pretend that $/$ is a primitive connective—and \rightarrow and \leftrightarrow as well. And let us say that a formula is in *transplicative normal form* when it is a transplicative ψ/χ such that neither ψ nor χ contains any occurrence of either $/$ or \bowtie (so that there are only classical logical operators in ψ and χ) and such that, for any M and any s , $M_s(\psi) = \top$ if and only if either $M_s(\psi/\chi) = \top$ or $M_s(\psi/\chi) = \perp$. Then if we have a procedure, along the lines of the one above, for transforming an arbitrary formula into an equivalent one in transplicative normal form, this will yield projection rules for presupposition of the kind we were interested in at the end of Section 4.2.

Such a procedure can be based on the following equivalences (which hold whether or not the constituents on the left are already in normal form):

$$\begin{aligned}\phi &\simeq (\phi \vee \neg\phi) / \phi \\ \neg(\psi / \chi) &\simeq \psi / \neg\chi \\ (\psi_1/\chi_1) \wedge (\psi_2/\chi_2) &\simeq ((\psi_1 \wedge \psi_2) \vee (\psi_1 \wedge \neg\chi_1) \vee (\psi_2 \wedge \neg\chi_2)) / (\chi_1 \wedge \chi_2) \\ (\psi_1/\chi_1) \vee (\psi_2/\chi_2) &\simeq ((\psi_1 \wedge \psi_2) \vee (\psi_1 \wedge \chi_1) \vee (\psi_2 \wedge \chi_2)) / (\chi_1 \vee \chi_2) \\ (\psi_1/\chi_1) \rightarrow (\psi_2/\chi_2) &\simeq ((\psi_1 \wedge \psi_2) \vee (\psi_1 \wedge \neg\chi_1) \vee (\psi_2 \wedge \chi_2)) / (\chi_1 \rightarrow \chi_2) \\ (\psi_1/\chi_1) \leftrightarrow (\psi_2/\chi_2) &\simeq (\psi_1 \wedge \psi_2) / (\chi_1 \leftrightarrow \chi_2) \\ (\psi_1/\chi_1) / (\psi_2/\chi_2) &\simeq (\psi_1 \wedge \psi_2 \wedge \chi_1) / \chi_2 \\ (\psi_1/\chi_1) \bowtie (\psi_2/\chi_2) &\simeq (\psi_1 \wedge \psi_2 \wedge (\chi_1 \leftrightarrow \chi_2)) / \chi_2 \\ \forall x(\psi / \chi) &\simeq (\forall x(\psi \wedge \chi) \vee \exists x(\psi \wedge \neg\chi)) / \forall x\chi \\ \exists x(\psi / \chi) &\simeq (\exists x(\psi \wedge \chi) \vee \forall x(\psi \wedge \neg\chi)) / \exists x\chi\end{aligned}$$

The first equivalence gives us a way to transform atomic subformulae, and the rest show to pull $/$ out of the scope of any logical operator—including other occurrences of $/$ itself.

If we have transformed a formula into transplicative normal form, then the resulting transplicator will be a summing up, in a $/$ -and- \bowtie -free formula, of any presupposition introduced into the original formula by $/$ or by \bowtie . (Some horrendously complicated transplicators can arise, but obvious simplifications will be possible particular cases.) Furthermore, since the transplicant is also $/$ -and- \bowtie -free, we can see that a single occurrence of $/$ is sufficient for representing the overall content—the \top/\perp -conditions—of the original formula.

But if projection rules are the only thing you want to get, then observe that the equivalences for $/$ and \bowtie may be brought in line with the others:

$$\begin{aligned} (\psi_1/\chi_1) / (\psi_2/\chi_2) &\simeq (\psi_1 \wedge \psi_2 \wedge \chi_1) / (\chi_1/\chi_2) \\ (\psi_1/\chi_1) \bowtie (\psi_2/\chi_2) &\simeq (\psi_1 \wedge \psi_2 \wedge (\chi_1 \leftrightarrow \chi_2)) / (\chi_1 \bowtie \chi_2). \end{aligned}$$

A procedure based on these equivalences will transform a formula ϕ into ψ/ϕ , where ψ sums up the overall presupposition, as before, but ϕ is left to stand.

On the other hand, we may want to pin down a $/$ -and- \bowtie -free transpicand more tightly. Observe that a formula $\psi \bowtie \chi$ in interjunctive normal form will be equivalent to $(\chi \rightarrow \psi) / \psi$ and to $(\chi \rightarrow \psi) / \chi$, which are in transpicative normal form. (We can make do with $\chi \rightarrow \psi$, rather than $\chi \leftrightarrow \psi$, because $\psi \vDash \chi$.) The transpicand ψ then fixes \top -conditions, while the transpicand χ fixes \perp -conditions. I shall leave it as an exercise to formulate equivalences on which to base a procedure for transforming a formula directly into a transpicative normal form of each of these special kinds: the equivalences given for \wedge , \vee , \forall , and \exists can be kept, but the others need to be revised.

6.4 A Parenthesis on Description Terms

If we expand our languages to contain a term-forming descriptions operator ι , and if we consider its interpretation in the kind of model we are working with, then the denotation conditions sketched in Section 1.1 turn out in the following way: for any model M , and any assignment s , if $a \in D_M$, then

$$M_s(\iota x\phi) = a \quad \text{iff} \quad M_{s(y|a)}(\forall x[x = y \leftrightarrow \phi]) = \top.$$

And $M_s(\iota x\phi) = \otimes$ if there is no such a . (We are here assuming that y is a variable distinct from x and extraneous to ϕ .) These denotation conditions can be spelt out to mean that if $a \in D_M$, then

$$M_s(\iota x\phi) = a \quad \text{iff} \quad \begin{cases} M_{s(x|a)}(\phi) = \top, \text{ and} \\ M_{s(x|b)}(\phi) = \perp, \text{ for every } b \in D_M \text{ not identical to } a. \end{cases}$$

Hence, to be the denotation of $\iota x\phi$, a has to be *determinately* ‘the unique x such that ϕ ’: ϕ must be false, not just not true, when any other object in D_M is assigned to x .

But do we have to work with such a stringent form of uniqueness? In the present context we do, on pain of violating monotonicity. Notice that, according to our definition, $M_s(\iota x\phi)$ is an element of D_M only if $M_{s(x|a)}(\phi)$ is either \top or \perp for any a in D_M . This guarantees monotonicity for ι -terms. If, for $M_s(\iota x\phi)$ to be an element a of D_M , we were to require only that $M_{s(x|a)}(\phi) = \top$ and that $M_{s(x|b)}(\phi) \neq \top$ for any b in D_M distinct from a , then there might be a model N such that $M \sqsubseteq N$ and $N_{s(x|b)}(\phi) = \top$ for

some such b , in which case $N_s(\iota x\phi)$ could not be a and monotonicity would have been violated. (For example, take M and N to be models interpreting a predicate symbol P over the domain $\{0, 1\}$, where $P_M(0) = P_N(0) = P_N(1) = \top$ and $P_M(1) = *$ —fill in other details as you like—and consider ιxPx .)

Notice, then, that according to our definitions $\iota x\phi$ may be non-denoting for two different kinds of reason: either (i) because ϕ is not sufficiently defined to determine a denotation, or (ii) because ϕ is sufficiently highly defined to rule out there being one. Case (i) arises when the formula $\exists y\forall x(x = y \leftrightarrow \phi)$ is $*$, and case (ii) when it is \perp . If we had a subtler theory of identity and of the interpretation of ‘singular terms’, then subtler interpretations for $\iota x\phi$ would be available. But this leads far beyond the simple kind of model we are working with.

The literature on description terms is vast and varied, but two approaches which it is interesting to compare and contrast with the present one occur in [Smiley 1960] and [Scott 1967]. Smiley entertains ‘neither-true-nor-false’ sentences, but he is unconstrained by monotonicity; while Scott treats non-denoting terms in a logic which, at sentence-level, is classical and total. In [Czermak 1974], on the other hand, there is a theory more like the one here. But it should be emphasized that our definitions do not involve any special ideas concerning the interpretation of description terms: they merely follow a path which was pre-determined once we embarked on partial logic as the logic of monotonic modes of composition.

The standard semantical definitions and lemmas of Sections 6.1 and 6.2 all extend in the obvious way to languages which contain ι —due account being taken of the fact that terms, as well as formulae, may now contain ‘bound’ variables. And so we have a framework in which to address the question whether, having introduced ι -terms, we can after all ‘eliminate’ them without decreasing the expressive power they provide. But what does this mean? There are various degrees of eliminability that we should distinguish. In a weak sense, ι would be eliminable provided that any formula were equivalent to an ι -free one. In a stronger sense of eliminability there would be some procedure which we could apply to transform a formula into an equivalent ι -free one. But we should really hope for something stronger still: to be in possession of a general scheme of *scope-free* elimination. And this is something we can indeed obtain.

To signal one or more occurrence in a formula of a term $\iota x\phi$ (possibly ignoring other occurrences of $\iota x\phi$) we can always pick on some extraneous variable y and describe the formula as $\psi(\iota x\phi/y)$. And so we can take our goal to be to define a scheme $I(x, \phi, y, \psi)$ which does not involve ι and which, for any ϕ and ψ , will yield a formula equivalent to $\psi(\iota x\phi/y)$, provided only that $\iota x\phi$ is ‘substitutable for y in ψ ’—i.e., that no free occurrence of a variable in $\iota x\phi$ becomes a bound occurrence in $\psi(\iota x\phi/y)$. Then we may read the scheme $I(x, \phi, y, \psi)$ as ‘the x such that ϕ is a y such that

ψ ', and it will provide for the 'scope-free' elimination of ι -terms simply because ι -languages admit 'substitutivity of equivalents': when a subformula is replaced by an equivalent one an equivalent formula results. The point is that to eliminate a term $\iota x\phi$ from a formula we can apply the scheme to any subformula $\psi(\iota x\phi/y)$ which binds no variables occurring free in $\iota x\phi$. Moreover, to transform a formula into an entirely ι -free one, we can apply the scheme to ι -terms in any order we like, and (variable-binding permitting) different occurrences of the same term can be eliminated all at once, or one at a time, or in any combination we choose. Such a scheme will then exhibit a semantical scope-freedom which exactly matches the scope-freedom possessed by an ι -term in virtue of its syntactic category.

In Section 4.2 we presented a 'Russellian' analysis for a definite-description quantifier $\iota x[\cdot, \cdot]$, but any thought that this could serve as the required elimination scheme is soon dispelled. The \top/\perp -conditions for $\iota x[\cdot, \cdot]$ certainly give definite descriptions a fair degree of semantical scope-freedom—in particular, freedom with respect to negation—but it is not thorough-going. For example, if χ is \top , then $\iota x[\phi, \psi] \vee \chi$ has to be \top , though $\iota x[\phi, \psi \vee \chi]$ might be $*$. This is not a defect of our analysis for $\iota x[\cdot, \cdot]$, since scope sensitivity can be important if we are considering natural language description idioms, but we have to look elsewhere for a scheme to go proxy for definite descriptions that are construed as terms. In fact, $\iota x[\cdot, \cdot]$ would not even serve to eliminate ι -terms from atomic formulae. This is because our monotonicity constraint is sufficiently liberal to allow sentences $Pt_1 \cdots \iota x\phi \cdots t_n$ which are \top or \perp even when $\iota x\phi$ is \otimes , though $\iota x\phi$ is \otimes only if $\exists y\forall x[x = y \leftrightarrow \phi]$ is not \top , in which case $\iota x[\phi, Pt_1 \cdots x \cdots t_n]$ must be $*$.

It is not surprising, given this last observation, that our scheme of elimination will involve the logically non-denoting term \otimes . Let us abbreviate the formula $\forall x[x = y \leftrightarrow \phi]$ as $\phi(x!y)$, then we could use either of the following as definitions of $I(x, \phi, y, \psi)$:

$$\begin{aligned} &\exists y[\phi(x!y) \wedge \psi] \vee [\forall y[\phi(x!y) \rightarrow \psi] \wedge \psi(\otimes/y)], \\ &\forall y[\phi(x!y) \rightarrow \psi] \wedge [\exists y[\phi(x!y) \wedge \psi] \vee \psi(\otimes/y)]. \end{aligned}$$

To see that these formulae work, it is just a matter of checking \top/\perp -conditions (with the aid of an extended version of Lemma 2) to show that they are equivalent to $\psi(\iota x\phi/y)$ —assuming, that is, that $\iota x\phi$ is substitutable for y in ψ .

We have emphasized that an elimination scheme of this kind allows us to dispense with the syntax of description terms as terms without disrupting any of the characteristics they manifest as such. But in fact this could be achieved much more cheaply: simply introduce a primitive mode of complex quantification $Dx[\cdot, \cdot]$ interpreted so that $\text{---}Dx[\phi, \cdots x \cdots]\text{---}$ will always mimic $\text{---}(\cdots \iota x\phi \cdots)\text{---}$. Stating explicit \top/\perp -conditions for $Dx[\cdot, \cdot]$ is routine. What we should now emphasize is that our definitions for a scheme

of elimination go a stage further than this: they show how a quantifier $Dx[\cdot, \cdot]$ may be analysed in terms of simple and basic logical vocabulary. In other words, we can do for $Dx[\cdot, \cdot]$ what in Section 4.2 we did for $!x[\cdot, \cdot]$.

In the basic languages presented in Section 6.1, the displayed elimination schemes can of course be viewed as definitions—explicit definitions for a complex quantifier or, ‘contextual definitions’ for an ι -term. And so we have a sense in which ι is definable in terms of \otimes . Conversely, if we have ι , then \otimes can be defined directly—for example, as $\iota x \perp$. Hence the presence of either \otimes or ι provides equivalent expressive resources in a first-order language subject to the kind of interpretation we are considering. However, we cannot dispense with \otimes in ι -free languages without a decrease in expressive power: the atomic sentence $P\otimes$, for example, is equivalent to no \otimes -free formula. (To see this consider models M and N with the singleton domain $\{0\}$ such that $P_M(0) = P_M(\otimes) = P_N(0)$ and $P_N(\otimes) = *$: if $s(x) = 0$, for all $x \in \text{Var}$, then for any \otimes -free formula ϕ , $M_s(\phi) = N_s(\phi)$, though $M_s(P\otimes) \neq N_s(P\otimes)$.) In the presence of \otimes , on the other hand, other vocabulary distinctive to partial logic could be dispensed with: given our interpretation of $=$, $*$ could be defined as $\otimes = \otimes$, and hence—as we showed in Section 4.1— \times (and $/$) could also be defined.

Although \otimes is not *logically* eliminable, it remains a possibility that it is in some sense eliminable in particular non-logical theories set up in partial logic: we shall mention a theorem about this in Section 7.3.

6.5 Semantic Consequence

To provide for a suitably powerful notion of semantic consequence, conceived along the lines suggested in Section 1.1, our basic definition is of what it is for a model M for a language \mathcal{L} , together with an assignment s , to *reject* a pair $\langle \Gamma, \Delta \rangle$ of sets of formulae of \mathcal{L} . We shall say that (M, s) rejects $\langle \Gamma, \Delta \rangle$ if and only if

- either: (i) $M_s(\phi) = \top$ for all $\phi \in \Gamma$ and $M_s(\psi) \neq \top$ for all $\psi \in \Delta$,
or: (ii) $M_s(\phi) \neq \perp$ for all $\phi \in \Gamma$ and $M_s(\psi) = \perp$ for all $\psi \in \Delta$.

And let us say that M (on its own) *rejects*, or *is a counter model to*, $\langle \Gamma, \Delta \rangle$ when there is an s such that (M, s) rejects $\langle \Gamma, \Delta \rangle$. Then, if \mathcal{M} is any class of models for \mathcal{L} , $\vDash_{\mathcal{M}}$ —consequence in \mathcal{M} —is defined by

$$\Gamma \vDash_{\mathcal{M}} \Delta \quad \text{iff} \quad \text{no model in } \mathcal{M} \text{ rejects } \langle \Gamma, \Delta \rangle.$$

When \mathcal{M} is the class of all models for a given language, we just write ‘ \vDash ’: this is *logical consequence*. Following the common notational practice with turnstiles, we shall ignore squiggly brackets and the empty set, and replace union signs by commas: for example, ‘ $\vDash \top, \phi, \Delta$ ’ means that $\emptyset \vDash \{\top, \phi\} \cup \Delta$.

In Section 1.1 we remarked on single-barrelled relations of consequence. Note the way in which $*$ may now be deployed to capture such relations:

$$\begin{aligned}\Gamma \vDash_{\mathcal{M}} *, \Delta & \text{ iff no model in } \mathcal{M} \text{ satisfies condition (i) above,} \\ \Gamma, * \vDash_{\mathcal{M}} \Delta & \text{ iff no model in } \mathcal{M} \text{ satisfies condition (ii) above.}\end{aligned}$$

And $\Gamma \vDash_{\mathcal{M}} \Delta$ if and only if both $\Gamma \vDash_{\mathcal{M}} *, \Delta$ and $\Gamma, * \vDash_{\mathcal{M}} \Delta$. In fact this biconditional is just an instance of a quite general principle: for *any* formula ϕ , $\Gamma \vDash_{\mathcal{M}} \Delta$ if and only if both $\Gamma \vDash_{\mathcal{M}} \phi, \Delta$ and $\Gamma, \phi \vDash_{\mathcal{M}} \Delta$.

In Section 7.1 we shall present logical laws using *sequents*: these will be understood to be pairs of *finite* sets, for which we use the special notation ' $\Gamma \succ \Delta$ ' instead of ' $\langle \Gamma, \Delta \rangle$ '. And we shall mention sequents in the same style that we state facts about consequence, writing ' $\succ, \top, \phi, \Delta$ ', for example, to stand for $\emptyset \succ \{\top, \phi\} \cup \Delta$. When M is not a counter model to $\Gamma \succ \Delta$ we shall say that M is a *model* of $\Gamma \succ \Delta$, or that $\Gamma \succ \Delta$ *holds in* M . More generally, if Σ is a set of sequents, M will be said to be a *model of* Σ if and only if M is a model of every sequent in Σ ; and ' $\mathcal{K}(\Sigma)$ ' will be the notation for the class of all such models. (Note: 'model for \mathcal{L} ', 'model of' Σ).

A sequent $\Gamma \succ \Delta$ embodies a principle of consequence— Δ 's following from Γ . It is a principle of *logical* consequence if $\Gamma \vDash \Delta$, in which case it holds in all models, but there are sequents which hold in some models but not in others; and there are also sequents, such as $\emptyset \succ \emptyset$, which hold in none. A set Σ of sequents then embodies a collection of such principles, and $\vDash_{\mathcal{K}(\Sigma)}$ is the relation of consequence semantically determined by them:

$$\Gamma \vDash_{\mathcal{K}(\Sigma)} \Delta \text{ iff no model of } \Sigma \text{ rejects } \langle \Gamma, \Delta \rangle.$$

Observe, then, that $\vDash_{\mathcal{K}(\emptyset)}$ is logical consequence; and that $\vDash_{\mathcal{K}(\{\emptyset \succ \emptyset\})}$ is the universal relation between sets of formulae.

Clearly, if $\Gamma \succ \Delta$ is contained in Σ , then $\Gamma \vDash_{\mathcal{K}(\Sigma)} \Delta$; but the converse does not generally hold: \emptyset is an obvious counterexample. When it does hold—when $\Sigma = \{\Gamma \succ \Delta \mid \Gamma \vDash_{\mathcal{K}(\Sigma)} \Delta\}$ —of sequents which is closed under the sequent principles it determines, and our proof theoretical apparatus will be designed to pick out precisely such sets of sequents as what 'theories' are in partial logic. Thus we shall be adopting an extensional notion of a theory, not involving any particular axiomatization. Pure logic, for a given language, will be one such theory, viz. $\{\Gamma \succ \Delta \mid \Gamma \vDash \Delta\}$.

But $\vDash_{\mathcal{K}(\Sigma)}$ is a full-blown consequence relation between arbitrary (not necessarily finite) sets of formulae, and we should demand of our proof system that it yield consequence relations \vdash_{Σ} to match $\vDash_{\mathcal{K}(\Sigma)}$. We shall produce a suitable definition which is 'sound and complete' in that, for any Γ and Δ ,

$$\Gamma \vDash_{\mathcal{K}(\Sigma)} \Delta \text{ iff } \Gamma \vdash_{\Sigma} \Delta.$$

But then we shall be able to show that the relation $\vDash_{\mathcal{K}(\Sigma)}$ does not actually go beyond the sequent principles—the finite principles of consequence—determined by Σ —in fact not beyond those determined by some finite subset of Σ . For the definition of \vdash_{Σ} will guarantee that $\Gamma \vdash_{\Sigma} \Delta$ if and only if $\Gamma_0 \vdash_{\Sigma_0} \Delta_0$ for some finite subsets Γ_0 of Γ , Δ_0 of Δ and Σ_0 of Σ ; so that $\vDash_{\mathcal{K}(\Sigma)}$ too turns out to be finitary in this way. Contraposing, we could state the fact as a two-pronged form of compactness:

THEOREM 8 (Compactness). *There is a model of Σ which rejects $\langle \Gamma, \Delta \rangle$ iff, for every finite subset Γ_0 of Γ , Δ_0 of Δ and Σ_0 of Σ , there is a model of Σ_0 which rejects $\langle \Gamma_0, \Delta_0 \rangle$.*

Two complementary parallels with standard treatments of classical logic are now emerging, which pervade the development of partial logic. First, *pairs* of sets of formulae and their rejectability (by a model and an assignment) play a role which *single* sets of formulae and their satisfiability (by a model and an assignment) usually play in classical logic. Secondly, sets of *sequents* and their models play the part which sets of *sentences* and their models play in classical logic. But why should things turn out like this?

It has already been explained—in Section 1.3—that principles of logical consequence cannot be summed up in terms of the truth of sentences, but the irreducibility of consequence to truth extends further than this. For, given a sequent $\Gamma \succ \Delta$, it is not in general possible to find a sentence σ such that M is a model of $\Gamma \succ \Delta$ if and only if $M(\sigma) = T$ —equivalently, if and only if M is a model of $\succ \sigma$. (Moreover, if there is no sentence, then there is no formula of any kind to play this role; since, if there were a formula ϕ then a suitable sentence could be obtained by substituting \otimes for all parameters in ϕ .) This contrasts with classical logic, in which a sequent $\Gamma \succ \Delta$ can always be summed up in the sentence $\forall \vec{x}[\mathbb{M}\Gamma \rightarrow \mathbb{W}\Delta]$, where $\mathbb{M}\Gamma$ is the conjunction of elements of Γ , $\mathbb{W}\Delta$ is the disjunction of elements of Δ , and $\forall \vec{x}$ binds all free variables.

We can extend and strengthen this point about partial logic: given a set Σ of sequents it is not in general possible to find a corresponding set Σ' of sequents of the truth-expressing form $\succ \sigma$ such that M is a model of Σ if and only if M is a model of Σ' . To see this observe that *if* we can find such a Σ' , then $\mathcal{K}(\Sigma)$ satisfies the following closure condition—because $\mathcal{K}(\Sigma')$ obviously does and $\mathcal{K}(\Sigma) = \mathcal{K}(\Sigma')$.

$$(\dagger) \quad \text{If } M \in \mathcal{K}(\Sigma) \text{ and } M \sqsubseteq_e N, \text{ then } N \in \mathcal{K}(\Sigma).$$

In fact we could use the Compactness Theorem to show that (\dagger) is a sufficient, as well as a necessary, condition for finding such a Σ' . But the present point depends on its being necessary: we just have to produce a Σ such that $\mathcal{K}(\Sigma)$ does not satisfy (\dagger) . A simple example would be $\{P \otimes \succ Q \otimes, *\}$: checking this is essentially an exercise in propositional logic.

Although the principles of consequence that arbitrary sequents express cannot be reduced to the *truth* of sentences, still, can we at least make do with parameter-free sequents, which contain only sentences, not arbitrary formulae? No, we cannot. Let us argue in the same pattern as before: the following is obviously a necessary condition (and in fact also a sufficient condition) for there being a set Σ' of parameter free sequents such that $\mathcal{K}(\Sigma) = \mathcal{K}(\Sigma')$.

$$(\ddagger) \quad \text{If } M \in \mathcal{K}(\Sigma) \text{ and } M \sim_e N, \text{ then } N \in \mathcal{K}(\Sigma).$$

However, $\{Px \succ Qx, *\}$, for example, does not satisfy (\ddagger) —though it is more involved to check out this example than the previous one. This is perhaps a little surprising: it means that the relation \sim_e of ‘elementary equivalence’ between models is a strictly weaker relation than the relation of being a model of the same sequents.

Anyhow, let us return to the relation \vDash of logical consequence. This has been defined relative to a particular language \mathcal{L} , but, as in classical logic, it is in fact an absolute notion, in the sense that $\Gamma \vDash \Delta$ in \mathcal{L}_1 if and only if $\Gamma \vDash \Delta$ in \mathcal{L}_2 , whenever the formulae in Γ and Δ are formulae of both \mathcal{L}_1 and \mathcal{L}_2 . In particular, $\Gamma \vDash \Delta$ in any given language if and only if $\Gamma \vDash \Delta$ in the language containing no non-logical vocabulary other than that occurring in Γ or Δ . Observe too that the relations of equivalence (\simeq), degree-of-definedness (\sqsubseteq) and compatibility (\square), which we defined in Section 6.2, are absolute in this sense. These facts are easy to check, using the notion of the *reduct* $M \upharpoonright \mathcal{L}'$ of a model M for \mathcal{L} to a smaller language \mathcal{L}' : $M \upharpoonright \mathcal{L}'$ is the model for \mathcal{L}' which has the same domain as M and interprets the vocabulary of \mathcal{L}' in the same way as M , just ignoring any vocabulary in \mathcal{L} but not in \mathcal{L}' . We shall use this definition later on, and we shall also talk of *expanding* a model M for \mathcal{L} to a model N for a bigger language \mathcal{L}^+ when $M = N \upharpoonright \mathcal{L}$.

The absoluteness of \vDash means that we can state the following theorem without reference to any particular language (though its proof—in Section 7.3—will depend on being very finicky about languages).

THEOREM 9 (Craig Interpolation). *If $\phi \vDash \psi$, then $\phi \vDash \lambda$ and $\lambda \vDash \psi$ for some formula λ which contains no non-logical vocabulary which does not occur both in ϕ and in ψ .*

It is noteworthy that there is an analogous result for degree-of-definedness: if $\phi \sqsubseteq \psi$, then $\phi \sqsubseteq \lambda$ and $\lambda \sqsubseteq \psi$ for an interpolant λ subject to the same constraint.

7 FIRST-ORDER PARTIAL THEORIES

7.1 Logical Laws

It will be neatest to take our logical laws as directly definitive of what a ‘theory’ is. The laws will be in the form of sequent axioms and sequent rules, and a *theory*, in a given language \mathcal{L} , is defined to be a set of sequents of \mathcal{L} which contains the sequent axioms and is closed under the sequent rules, in the sense that if the ‘premise(s)’ of a rule is (are) in the set then so is its ‘conclusion’. ‘Proofs’ then enter the picture in the following way. If, given a set Σ of sequents of \mathcal{L} , we define $\bar{\Sigma}$ to be the intersection of all theories in \mathcal{L} which contain Σ , then $\bar{\Sigma}$ will be a theory—the ‘smallest’ theory in \mathcal{L} containing Σ —and a sequent will be contained in $\bar{\Sigma}$ if and only if there is a sequent proof of it from a finite subset of Σ . That things fit together in this way is just part of the general theory of inductive definitions (see for example [Aczel 1977]). We shall call $\bar{\Sigma}$ the theory *axiomatised by* Σ ; and Σ will already be a theory if and only if $\Sigma = \bar{\Sigma}$. Pure logic, for a given language \mathcal{L} , then slots into place as the smallest theory in \mathcal{L} , viz. $\bar{\emptyset}$.

The first three laws are general principles of consequence, which we label after [Scott 1973b]: a basic axiom scheme (R), a (double) rule of thinning (M), and cut (T).

$$\begin{array}{l}
 \text{(R)} \qquad \qquad \phi \succ \phi \\
 \\
 \text{(M)} \qquad \frac{\Gamma \succ \Delta}{\Gamma \succ \phi, \Delta} \qquad \frac{\Gamma \succ \Delta}{\Gamma, \phi \succ \Delta} \\
 \\
 \text{(T)} \qquad \frac{\Gamma \succ \phi, \Delta \qquad \Gamma, \phi \succ \Delta}{\Gamma \succ \Delta}
 \end{array}$$

Clearly any instance of (R) will hold in any model, and if the ‘premise(s)’ of an instance of (M) or (T) hold in a model, then the ‘conclusion’ holds in that model. Hence individually these laws are ‘sound’. It will be left unsaid that all the remaining axioms and rules are individually sound in the same way: this can be checked using the definitions and lemmas of Section 6.1.

The next rule is a general rule of (S) of substitution. When Θ is a set of formulae, we use ‘ $\Theta(t/x)$ ’ to stand for $\{\theta(t/x) \mid \theta \in \Theta\}$.

$$\text{(S)} \qquad \frac{\Gamma \succ \Delta}{\Gamma(t/x) \succ \Delta(t/x)}$$

This holds provided that the term t is substitutable for x in all the formulae in Γ and Δ (see Section 6.1). In the presence of this rule we shall be able to specify the quantifier and identity laws with parameters, instead of using schematic letters for terms.

For propositional laws we can use the following. Double lines means the rule applies upwards as well as downwards, and ‘ $\neg\Theta$ ’ stands for $\{\neg\theta \mid \theta \in \Theta\}$.

$$\begin{array}{c}
\begin{array}{cc}
\triangleright \top & \perp \triangleright \\
\neg * \triangleright * & * \triangleright \neg * \\
\phi, \neg\phi \triangleright * & * \triangleright \neg\phi, \phi \\
\frac{\neg\Gamma \triangleright \Delta}{\neg\Delta \triangleright \Gamma} & \frac{\Gamma \triangleright \neg\Delta}{\Delta \triangleright \neg\Gamma} \\
\frac{\Gamma, \phi, \psi \triangleright \Delta}{\Gamma, \phi \wedge \psi \triangleright \Delta} & \frac{\Gamma \triangleright \phi, \psi, \Delta}{\Gamma \triangleright \phi \vee \psi, \Delta} \\
\frac{\Gamma, \phi, \psi \triangleright *, \Delta}{\Gamma, \phi \bowtie \psi \triangleright *, \Delta} & \frac{\Gamma, * \triangleright \phi, \psi, \Delta}{\Gamma, * \triangleright \phi \bowtie \psi, \Delta}
\end{array}
\end{array}$$

Observe how $*$ may be deployed to cancel one or the other half of our double-barrelled notion of consequence. Thus, in particular, the rules for interjunction match \bowtie with \wedge for \top -conditions and with \vee for \top -conditions.

From these laws we can immediately deduce some further fundamental principles (which could be swapped in various obvious ways to provide alternative sets of propositional laws):

$$\begin{array}{c}
\begin{array}{cc}
\phi \triangleright \neg\neg\phi & \neg\neg\phi \triangleright \phi \\
\phi, \neg\phi \triangleright \neg\psi, \psi \\
\frac{\Gamma \triangleright \Delta}{\neg\Delta \triangleright \neg\Gamma} \\
\begin{array}{cc}
\phi \wedge \psi \triangleright \phi & \phi \triangleright \phi \vee \psi \\
\phi \wedge \psi \triangleright \psi & \psi \triangleright \phi \vee \psi \\
\phi, \psi \triangleright \phi \wedge \psi & \phi \vee \psi \triangleright \phi, \psi \\
\phi \bowtie \psi \triangleright \phi, * & *, \phi \triangleright \phi \bowtie \psi \\
\phi \bowtie \psi \triangleright \psi, * & *, \psi \triangleright \phi \bowtie \psi \\
\phi, \psi \triangleright \phi \bowtie \psi & \phi \bowtie \psi \triangleright \phi, \psi
\end{array}
\end{array}
\end{array}$$

Let us now adopt the abbreviation ‘ $\Gamma \xrightarrow{\phi} \Delta$ ’ for ‘ $\Gamma, \phi \triangleright \neg\phi, \Delta$ ’. The

force of such sequents can be expressed informally as ‘when ϕ is true, then Δ follows from Γ ’: recall the discussion at the end of Section 1.1. Then for quantifiers we can use the following up-and-down rules, subject to the proviso that x does not occur free in Γ or in Δ :

$$\frac{\Gamma \succ^{x=x} \phi, \Delta}{\Gamma \succ \forall x \phi, \Delta} \qquad \frac{\Gamma, \phi \succ^{x=x} \Delta}{\Gamma, \exists x \phi \succ \Delta}$$

The proviso is only of importance for the downward rules, but given (S) its presence does not hamper the upward ones, which are equivalent to the following axioms:

$$\forall x \phi \succ^{x=x} \phi \qquad \phi \succ^{x=x} \exists x \phi.$$

Notice how $x = x$ is here playing the role of an ‘existence predicate’.

Of course, $x = x$ can never actually be false, and so we include the following axiom:

$$* \succ x = x.$$

And to capture the determinateness of identity:

$$x = x, y = y \succ x = y, \neg x = y.$$

For the substitutivity of identicals we adopt the following scheme, which means that whenever $x = y$ is true, then occurrences of x and y can be shuffled around in a formula in any way you like:

$$\phi(x/u, y/v) \succ^{x=y} \phi(y/u, x/v).$$

However a further substitutivity principle is required to govern non-denoting terms:

$$\phi(x/z) \succ x = x, \phi(y/z).$$

Since parameters are schematic for terms, the force of this is that a non-denoting term can be replaced by any term without affecting the truth value of a formula, if it already has one.

If we were envisaging subtler theories of identity these laws would need to be modified, but in the present context they capture our semantics of monotonic composition, once we include an axiom for the logically non-denoting term:

$$x = \otimes \succ *.$$

There is room for variation in the choice of primitive laws for identity; but let us adopt these. We can then go on to derive a characteristic principle for \otimes , whose effect is that if a formula is true (or false), then it remains so on making any substitution for an occurrence of \otimes :

$$\phi(\otimes/x) \succ \phi(y/x), *.$$

And other basic laws are easily obtained; for example, the symmetry of identity and distinctness:

$$x = y \succ y = x,$$

and the transitivity of identity:

$$x = y, y = z \succ x = z, *.$$

Observe that $*$ cannot be taken away here: if y assigned no object, then neither of the left-hand formulae can be false, even if $x = z$ is. However, we can easily derive a general principle to handle distinctness as well as identity:

$$x = y, y = z \succ \frac{y=y}{x = z} x = z.$$

The laws we have given provide the definition of a *theory* (in \mathcal{L}) and of the *theory* $\overline{\Sigma}$ (in *la*) *axiomatised by* Σ , in the way explained at the outset. Furthermore between arbitrary sets Γ and Δ of formulae of a language \mathcal{L} we can define the consequence relation \vdash_{Σ} , demanded in Section 6.5, by stipulating that $\Gamma \vdash_{\Sigma} \Delta$ if and only if, for some finite subsets Γ_0 of Γ and Δ_0 of Δ , $\Gamma_0 \succ \Delta_0 \in \overline{\Sigma}$. This will be if and only if there is a proof of $\Gamma_0 \succ \Delta_0$ from some finite subset Σ_0 of Σ —hence if and only if $\Gamma_0 \succ \Delta_0 \in \overline{\Sigma}_0$. Thus \vdash_{Σ} turns out to be finitary in the way announced in Section 6.5. Note that, although the definitions of $\overline{\Sigma}$ and \vdash_{Σ} are relative to a particular language \mathcal{L} , a given set Σ of sequents will always be a set of sequents of (infinitely) many different languages. This means that, on its own, our notation is radically ambiguous, and we need to be careful when more than one language is in play.

Since our laws are individually sound, it is easy to check that no model of Σ can be a counter model to any sequent in $\overline{\Sigma}$: in other words, not just is it the case that $\mathcal{K}(\overline{\Sigma}) \subseteq \mathcal{K}(\Sigma)$, but $\mathcal{K}(\overline{\Sigma}) = \mathcal{K}(\Sigma)$. And the following theorem, which makes reference to arbitrary sets Γ and Δ , is a trivial extension of this fact:

THEOREM 10 (Soundness). *If $\Gamma \vdash_{\Sigma} \Delta$ then $\Gamma \vDash_{\mathcal{K}(\Sigma)} \Delta$.*

The converse, guaranteeing that \vdash_{Σ} coincides with the semantically defined relation $\vDash_{\mathcal{K}(\Sigma)}$, is rather more difficult to establish:

THEOREM 11 (Completeness). *If $\Gamma \vDash_{\mathcal{K}(\Sigma)} \Delta$ then $\Gamma \vdash_{\Sigma} \Delta$.*

We shall turn our attention to the proof of completeness in Sections 7.2 and 7.3.

It is easy to see that $\overline{\overline{\Sigma}} = \overline{\Sigma}$, and so $\vdash_{\overline{\Sigma}}$ is the same relation as \vdash_{Σ} . Also, given soundness, $\vDash_{\mathcal{K}(\overline{\Sigma})}$ is the same relation as $\vDash_{\mathcal{K}(\Sigma)}$. Hence we would lose nothing by stating Theorem 11 with Σ restricted to theories. We *would* lose something if we restricted Γ and Δ to finite sets, viz. being able to deduce as a corollary the full version of compactness stated in Theorem 8. But note

that when we do consider just finite sets of formulae, then Theorems 10 and 11 may be wrapped up together into the following equation: $\bar{\Sigma} = \{\Gamma \succ \Delta \mid \Gamma \vDash_{\mathcal{K}(\Sigma)} \Delta\}$.

These remarks put us in a position to convert the discussion in Section 6.5 of the conditions labelled (†) and (‡) into facts about theories. We may deduce from that discussion that a theory Σ is axiomatizable by sequents of the form $\succ \sigma$ if and only if $\mathcal{K}(\Sigma)$ is closed under the relation \sqsubseteq_e , in the sense of condition (†), and that a theory Σ is axiomatizable by parameter-free sequents if and only if $\mathcal{K}(\Sigma)$ is closed under the relation \sim_e , in the sense of condition (‡). And there are various other results along these lines: necessary and sufficient conditions for a theory's being axiomatizable by sequents of a given kind are provided by specifying closure conditions on the class of its models.

In connection with soundness and completeness we should also think about 'consistency'. We have no use for a notion of the consistency of a set of formulae, but it makes sense to ask about the consistency of a set of sequents. Let us say that Σ is *consistent* if and only if $\emptyset \succ \emptyset \notin \bar{\Sigma}$. And '*inconsistent*' will just mean not consistent. Hence we may also define relational notions: Σ_1 is *(in)consistent with* Σ_2 if and only if $\Sigma_1 \cup \Sigma_2$ is (in)consistent (which in turn makes sense of the words ' ψ 's following from ϕ is inconsistent with ...', used in Section 2.7: this means that $\{\phi \succ \psi\}$ is inconsistent with ...). By rule (M), it follows that Σ is consistent if and only if $\bar{\Sigma}$ does not contain all sequents (of the language in question). It also follows, by Theorems 10 and 11, that Σ is consistent if and only if Σ has a model, since the statement that Σ is *inconsistent* if and only if Σ has *no* model is just the special case of soundness and completeness when Γ and Δ are both empty. On the other hand, the special case of Theorems 10 and 11 when Σ is empty gives the soundness and completeness of an axiomatization of the relation \vdash_{\emptyset} of logical consequence (for which we shall just write ' \vdash '). Happily the *theory* thus axiomatised, viz. $\bar{\emptyset}$, turns out to be consistent, according to our definition, since there will be models of \emptyset —and hence too of $\bar{\emptyset}$ —in great abundance.

It is noteworthy that to axiomatize pure logic we could abandon the system presented here and instead use a cut-free sequent calculus that has 'introduction rules' only. (See Sundholm's chapter in Volume 2 of the second edition of this *Handbook*.) One way to proceed would be to have 'negative' rules as well as 'positive' rules—the negative rules for vocabulary in the immediate scope of negation. In [Cleave 1974] there are rules of this kind that we could use for classical vocabulary, but to handle interjunction we need to include the following three-premise rules.

$$\begin{array}{c}
\frac{\Gamma, \phi, * \succ \Delta \quad \Gamma, \phi, \psi \succ \Delta \quad \Gamma, *, \psi \succ \Delta}{\Gamma, \phi \wp \psi \succ \Delta} \\
\\
\frac{\Gamma \succ \phi, *, \Delta \quad \Gamma \succ \phi, \psi, \Delta \quad \Gamma \succ *, \psi, \Delta}{\Gamma \succ \phi \wp \psi, \Delta} \\
\\
\frac{\Gamma, \neg\phi, * \succ \Delta \quad \Gamma, \neg\phi, \neg\psi \succ \Delta \quad \Gamma, *, \neg\psi \succ \Delta}{\Gamma, \neg[\phi \wp \psi] \succ \Delta} \\
\\
\frac{\Gamma \succ \neg\phi, *, \Delta \quad \Gamma \succ \neg\phi, \neg\psi, \Delta \quad \Gamma \succ *, \neg\psi, \Delta}{\Gamma \succ \neg[\phi \wp \psi], \Delta}
\end{array}$$

7.2 Model-Existence Theorems

Wrapping Soundness and Completeness up together, contraposing, and spelling out ‘ $\Gamma \not\vdash_{\mathcal{K}(\Sigma)} \Delta$ ’ we have that

$$\Gamma \not\vdash_{\Sigma} \Delta \quad \text{iff} \quad \text{there is a model of } \Sigma \text{ which rejects } \langle \Gamma, \Delta \rangle.$$

(The line through the turnstiles signifies negation.) We could then establish completeness (‘only if’) by adopting a Henkin-style strategy to boost up any pair $\langle \Gamma, \Delta \rangle$ such that $\Gamma \not\vdash_{\Sigma} \Delta$ to an exhaustive pair $\langle \Gamma^+, \Delta^+ \rangle$ of sets of sentences of an extended language, from which we could then read off a model rejecting $\langle \Gamma, \Delta \rangle$. But this strategy can be elaborated to yield much more powerful model-existence results: kinds of interpolation theorem. We can then go on to deduce the Completeness Theorem and a lot more besides—facts both about pure logic and about non-logical theories.

To introduce the idea, consider the following set up:— Σ_1 is a set of sequents of a language \mathcal{L}_1 , and Γ_1 and Δ_1 are sets of formulae of \mathcal{L}_1 ; Σ_2 is a set of sequents of a language \mathcal{L}_2 , and Γ_2 and Δ_2 are sets of formulae of \mathcal{L}_2 ; and Λ is a set of formulae common to both \mathcal{L}_1 and \mathcal{L}_2 . We can then ask:

$$\text{Is there a } \lambda \in \Lambda \text{ such that } \Gamma_1 \vdash_{\Sigma_1} \lambda, \Delta_1 \text{ and } \Gamma_2, \lambda \vdash_{\Sigma_2} \Delta_2?$$

(We may suppose that \vdash_{Σ_1} is defined relative to \mathcal{L}_1 and \vdash_{Σ_2} relative to \mathcal{L}_2 .) Notice that, provided Λ is non-empty, this is a generalization of the question ‘Is it the case that $\Gamma \vdash_{\Sigma} \Delta$?’. For if $\Sigma = \Sigma_1 = \Sigma_2$, $\Gamma = \Gamma_1 = \Gamma_2$, and $\Delta = \Delta_1 = \Delta_2$, then, by rules (M) and (T), the two questions must have the same answer.

And our interpolation theorems may be seen as generalizations of the Completeness Theorem, because they state that the answer ‘no’ to certain questions of the displayed form entails the existence of a pair of models M_1 of Σ_1 and M_2 of Σ_2 such that M_1 rejects $\langle \Gamma_1, \Delta_1 \rangle$, M_2 rejects $\langle \Gamma_2, \Delta_2 \rangle$ and

M_1 and M_2 are related in a particular specified way: different ways for M_1 and M_2 to be related correspond to different assumptions about Λ . We also have corresponding generalizations of the Soundness Theorem, since the non-existence of an interpolant will be necessary as well as sufficient for the existence of a suitably related pair of models. But necessity is not as interesting as sufficiency; it gives us nothing new: it will always be immediately deducible from soundness.

To give a taste for all this, I shall develop a little way the case where, in the set up described, Λ is the set of all formulae of some sublanguage \mathcal{L} of \mathcal{L}_1 and of \mathcal{L}_2 . This is a simple and straightforward case, but even so we shall be able to deduce quite a lot from it.

First, to specify appropriate relationships between models, we need a generalization of the relations \sqsubseteq and \square defined in Section 6.2: if M_1 is a model for \mathcal{L}_1 and M_2 is a model for \mathcal{L}_2 , then there are relations of degree-of-definedness ($\sqsubseteq_{\mathcal{L}}$) and of compatibility ($\square_{\mathcal{L}}$) *relative to the vocabulary of a common sublanguage \mathcal{L}* . With the notion of a reduct at hand (see Section 6.5), we can define the relations like this:

$$\begin{aligned} M_1 \sqsubseteq_{\mathcal{L}} M_2 & \text{ iff } M_1 \upharpoonright \mathcal{L} \sqsubseteq M_2 \upharpoonright \mathcal{L}, \\ M_1 \square_{\mathcal{L}} M_2 & \text{ iff } M_1 \upharpoonright \mathcal{L} \square M_2 \upharpoonright \mathcal{L}. \end{aligned}$$

Next observe that the claim that an interpolant exists can be analysed as the conjunction of three separate interpolant-existence claims:

LEMMA 12 (Combination Lemma).

There is a $\lambda \in \Lambda$ such that $\Gamma_1 \vdash_{\Sigma_1} \lambda, \Delta_1$ and $\Gamma_2, \lambda \vdash_{\Sigma_2} \Delta_2$

iff the following all hold:

- (1) *there is a $\lambda_1 \in \Lambda$ such that $\Gamma_1 \vdash_{\Sigma_1} *, \lambda_1, \Delta_1$ and $\Gamma_2, \lambda_1 \vdash_{\Sigma_2} *, \Delta_2$;*
- (2) *there is a $\lambda_2 \in \Lambda$ such that $\Gamma_1, * \vdash_{\Sigma_1} \lambda_2, \Delta_1$ and $\Gamma_2, \lambda_2, * \vdash_{\Sigma_2} \Delta_2$;*
- (3) *there is a $\lambda_3 \in \Lambda$ such that $\Gamma_1 \vdash_{\Sigma_1} *, \lambda_3, \Delta_1$ and $\Gamma_2, \lambda_3, * \vdash_{\Sigma_2} \Delta_2$.*

‘Only if’ is trivial: put $\lambda_1 = \lambda_2 = \lambda_3 = \lambda$. For ‘if’ it is straightforward to check that we may take $\lambda = [[\lambda_1 \wedge \lambda_3] \vee \lambda_2] \wp [\lambda_1 \wedge [\lambda_3 \vee \lambda_2]]$.

We shall sketch a proof of a model-existence result that is in fact split up into three parallel theorems, corresponding to the three cases above: Theorem 13. But the Combination Lemma will show how they can be combined into one: Theorem 14. So there are two theorems to state. The assumptions common to both are that \mathcal{L} is a sublanguage of \mathcal{L}_1 and of \mathcal{L}_2 , and Λ is the set of all formulae of \mathcal{L} ; that Γ_1 and Δ_1 are sets of formulae and Σ_1 a set of sequents of a language \mathcal{L}_1 ; and that Γ_2 and Δ_2 are sets of formulae and Σ_2 is a set of sequents of a language \mathcal{L}_2 .

THEOREM 13 (Interpolant-Excluding Model Pairs: split-up version).

In each of the three cases

$$(1) * \in \Delta_1 \cap \Delta_2, \quad (2) * \in \Gamma_1 \cap \Gamma_2, \quad (3) * \in \Delta_1 \cap \Gamma_2,$$

there is no $\lambda \in \Lambda$ such that $\Gamma_1 \vdash_{\Sigma_1} \lambda, \Delta_1$ and $\Gamma_2, \lambda \vdash_{\Sigma_2} \Delta_2$

iff

there are models M_1 of Σ_1 and M_2 of Σ_2 , with a common domain and assignments s_1 and s_2 such that (M_1, s_1) rejects $\langle \Gamma_1, \Delta_1 \rangle$, (M_2, s_2) rejects $\langle \Gamma_2, \Delta_2 \rangle$, and

in case (1), $M_1 \sqsubseteq_{\mathcal{L}} M_2$ and $s_1 \sqsubseteq s_2$;

in case (2), $M_2 \sqsubseteq_{\mathcal{L}} M_1$ and $s_2 \sqsubseteq s_1$;

in case (3), $M_1 \sqsubset_{\mathcal{L}} M_2$ and $s_1 \sqsubset s_2$.

THEOREM 14 (Interpolant-Excluding Model Pairs: combined version).

There is no $\lambda \in \Lambda$ such that $\Gamma_1 \vdash_{\Sigma_1} \lambda, \Delta_1$ and $\Gamma_2, \lambda \vdash_{\Sigma_2} \Delta_2$

iff

there are models M_1 of Σ_1 and M_2 of Σ_2 , with a common domain and assignments s_1 and s_2 such that at least one of the following holds:

$$(1) \quad M_1 \sqsubseteq_{\mathcal{L}} M_2, \quad s_1 \sqsubseteq s_2, \quad \text{and} \quad \begin{cases} (M_1, s_1) \text{ rejects } \langle \Gamma_1, \{*\} \cup \Delta_1 \rangle, \\ (M_2, s_2) \text{ rejects } \langle \Gamma_2, \{*\} \cup \Delta_2 \rangle; \end{cases}$$

$$(2) \quad M_2 \sqsubseteq_{\mathcal{L}} M_1, \quad s_2 \sqsubseteq s_1, \quad \text{and} \quad \begin{cases} (M_1, s_1) \text{ rejects } \langle \Gamma_1 \cup \{*\}, \Delta_1 \rangle, \\ (M_2, s_2) \text{ rejects } \langle \Gamma_2 \cup \{*\}, \Delta_2 \rangle; \end{cases}$$

$$(3) \quad M_1 \sqsubset_{\mathcal{L}} M_2, \quad s_1 \sqsubset s_2, \quad \text{and} \quad \begin{cases} (M_1, s_1) \text{ rejects } \langle \Gamma_1, \{*\} \cup \Delta_1 \rangle, \\ (M_2, s_2) \text{ rejects } \langle \Gamma_2 \cup \{*\}, \Delta_2 \rangle. \end{cases}$$

It is now easy to see that the split-up version together with the Combination Lemma entails the combined version; and it is easy to check directly—from basic definitions—that the combined version entails the split-up version. Some applications can appeal directly to just one of the three cases of the split-up version, but most will invoke the combined one.

Now we sketch a proof—in its barest outlines—of Theorem 13. ‘If’ follows easily from soundness in each of the three cases. ‘Only if’ is non-trivial, but the main construction is the same in each case: distinguishing between them comes only at the very end.

First, then, take two disjoint sets C and D of new constants, where C is denumerable, and the cardinality of D is the maximum of the cardinalities

of the the two languages \mathcal{L}_1 and \mathcal{L}_2 ; and take some one-one function π from Var onto C . Now let \mathcal{L}_1^+ and \mathcal{L}_2^+ be the extensions of \mathcal{L}_1 and \mathcal{L}_2 got by taking $C \cup D$ as additional constants; and let Λ^+ be the set of all sentences obtained from a formula in Λ by making any substitution of constants from $C \cup D$ for the parameters (so the sentences in Λ^+ will be common to both \mathcal{L}_1^+ and \mathcal{L}_2^+). And finally, (some notation: if θ is a formula, $\pi\theta$ is the formula obtained by substituting $\pi(x)$ for all free occurrences of x ; and if Θ is a set of formulae, $\pi\Theta = \{\pi\theta \mid \theta \in \Theta\}$).

Assuming that there is no $\lambda \in \Lambda$ such that $\Gamma_1 \vdash_{\Sigma_1} \lambda, \Delta_1$ and $\Gamma_2, \lambda \vdash_{\Sigma_2} \Delta_2$, it is now fairly easy to deduce that

there is no $\lambda \in \Lambda^+$ such that $\pi\Gamma_1 \vdash_{\Sigma_1} \lambda, \pi\Delta_1$ and $\pi\Gamma_2, \lambda \vdash_{\Sigma_2} \pi\Delta_2$,

where \vdash_{Σ_1} and \vdash_{Σ_2} are now defined relative to the extended languages \mathcal{L}_1^+ and \mathcal{L}_2^+ , rather than \mathcal{L}_1 and \mathcal{L}_2 . The hard work is then to provide a construction that achieves the following. First, $\pi\Gamma_1$, $\pi\Delta_1$, $\pi\Gamma_2$, and $\pi\Delta_2$ are extended to sets Γ_1^+ , Δ_1^+ , Γ_2^+ , and Δ_2^+ of sentences such that $\Gamma_1^+ \cup \Delta_1^+$ exhausts all the sentences of \mathcal{L}_1 , $\Gamma_2^+ \cup \Delta_2^+$ exhausts all the sentences of \mathcal{L}_2 , and

there is no $\lambda \in \Lambda^+$ such that $\Gamma_1^+ \vdash_{\Sigma_1} \lambda, \Delta_1^+$ and $\Gamma_2^+, \lambda \vdash_{\Sigma_2} \Delta_2^+$.

(Notice that, since $\perp \in \Lambda^+$, $\Gamma_1^+ \not\vdash_{\Sigma_1} \Delta_1^+$; and, since $\top \in \Lambda^+$, $\Gamma_2^+, \not\vdash_{\Sigma_2} \Delta_2^+$: thus $\Gamma_1^+ \cap \Delta_1^+ = \Gamma_2^+ \cap \Delta_2^+ = \emptyset$.) Secondly, the construction defines a subset D_0 of D such that

for all $d \in D_0$, $d = d \in \Gamma_1^+ \cap \Gamma_2^+$ and $\neg d = d \in \Delta_1^+ \cap \Delta_2^+$;
 if $\exists x\phi \in \Gamma_1^+$, then $\phi(d/x) \in \Gamma_1^+$, for some $d \in D_0$,
 if $\exists x\phi \in \Gamma_2^+$, then $\phi(d/x) \in \Gamma_2^+$, for some $d \in D_0$,
 if $\forall x\phi \in \Delta_1^+$, then $\phi(d/x) \in \Delta_1^+$, for some $d \in D_0$,
 if $\forall x\phi \in \Delta_2^+$, then $\phi(d/x) \in \Delta_2^+$, for some $d \in D_0$.

(Thus quantifiers will be ‘witnessed’ by elements of D_0 —which the first condition will guarantee are ‘defined’.)

Now we define relations \sim_1 and \sim_2 over D_0 as follows:

$$\begin{aligned} d \sim_1 e & \text{ iff } d = e \in \Gamma_1^+ \text{ and } \neg d = e \in \Delta_1^+, \\ d \sim_2 e & \text{ iff } d = e \in \Gamma_2^+ \text{ and } \neg d = e \in \Delta_2^+. \end{aligned}$$

These turn out to be equivalence relations, and we can use them to factor out D_0 to provide domains for models M_1^+ for \mathcal{L}_1^+ and M_2^+ for \mathcal{L}_2^+ , such that M_1^+ is a model of Σ_1 that rejects $\langle \Gamma_1^+, \Delta_1^+ \rangle$, and M_2 is a model of Σ_2 that rejects $\langle \Gamma_2^+, \Delta_2^+ \rangle$: the models can be defined in terms of $\langle \Gamma_1^+, \Delta_1^+ \rangle$ and $\langle \Gamma_2^+, \Delta_2^+ \rangle$ in much the same way that a classical model is defined from a consistent and complete set of sentences in a standard Henkin-style completeness proof.

But, by axiom (R), $\Gamma_1^+ \cap \Lambda^+ \cap \Delta_2^+ = \emptyset$, from which we can deduce that \sim_1 and \sim_2 are in fact the same relation, so that M_1^+ and M_2^+ have a common domain. Their reducts M_1 and M_2 to the original languages \mathcal{L}_1 and \mathcal{L}_2 then turn out to be models of Σ_1 and of Σ_2 such that (M_1, s_1) rejects $\langle \Gamma_1, \Delta_1 \rangle$ and (M_2, s_2) rejects $\langle \Gamma_2, \Delta_2 \rangle$, where s_1 and s_2 are defined by putting $s_1(x) = M_1^+(\pi(x))$ and $s_2(x) = M_2^+(\pi(x))$.

Finally, to deduce the relationship between M_1 and M_2 , and between s_1 and s_2 —which is peculiar to each of the three cases—we again make use of the fact that $\Gamma_1^+ \cap \Lambda^+ \cap \Delta_2^+ = \emptyset$. This guarantees the following facts:

- in case (1), $M_1^+(\lambda) \sqsubseteq M_2^+(\lambda)$ for any $\lambda \in \Lambda^+$;
- in case (2), $M_2^+(\lambda) \sqsubseteq M_1^+(\lambda)$ for any $\lambda \in \Lambda^+$;
- in case (3), $M_1^+(\lambda) \sqsupset M_2^+(\lambda)$ for any $\lambda \in \Lambda^+$.

Hence, first, we can deduce that

- in case (1), $M_{1s}(\lambda) \sqsubseteq M_{2s}(\lambda)$ for any $\lambda \in \Lambda$ and any s ;
- in case (2), $M_{2s}(\lambda) \sqsubseteq M_{1s}(\lambda)$ for any $\lambda \in \Lambda$ and any s ;
- in case (3), $M_{1s}(\lambda) \sqsupset M_{2s}(\lambda)$ for any $\lambda \in \Lambda$ and any s .

But Λ contains all formulae of \mathcal{L} . And, for any $\lambda \in \Lambda$, $M_{1s}(\lambda) = (M_1 \upharpoonright \mathcal{L})_s(\lambda)$ and $M_{2s}(\lambda) = (M_2 \upharpoonright \mathcal{L})_s(\lambda)$. It therefore follows from Lemma 4 that the displayed conditions are equivalent, respectively, to

- (1) $M_1 \sqsubseteq_{\mathcal{L}} M_2$,
- (2) $M_2 \sqsubseteq_{\mathcal{L}} M_1$,
- (3) $M_1 \sqsupset_{\mathcal{L}} M_2$.

Secondly, since, for any variable x and any $d \in D_0$, $\pi(x) = d$ and $\neg\pi(x) = d$ are both in Λ^+ , we can also deduce—from the facts about M_1^+ and M_2^+ —that

- (1) $s_1 \sqsubseteq s_2$,
- (2) $s_2 \sqsubseteq s_1$,
- (3) $s_1 \sqsupset s_2$.

7.3 Some Proofs

The Completeness Theorem (Theorem 11) can now immediately be established: we shall argue by contraposition. Assume, then, that $\Gamma \not\vdash_{\Sigma} \Delta$. By rule (T), it follows that there can be no formula λ such that $\Gamma \vdash_{\Sigma} \lambda, \Delta$ and $\Gamma, \lambda \vdash_{\Sigma} \Delta$. And so to show that some model of Σ rejects $\langle \Gamma, \Delta \rangle$ we may apply Theorem 14, taking each of \mathcal{L}_1 , \mathcal{L}_2 , and \mathcal{L} to be whatever language we're working with, and taking $\Sigma_1 = \Sigma_2 = \Sigma$, $\Gamma_1 = \Gamma_2 = \Gamma$, and $\Delta_1 = \Delta_2 = \Delta$. This guarantees models M_1 and M_2 , with assignments s_1 and s_2 , which satisfy at least one of the three conditions specified. But each of these conditions obviously entails that both M_1 and M_2 reject $\langle \Gamma, \Delta \rangle$ —which is over-kill: pick either one.

To establish the Compatibility Theorem (Theorem 5), we can appeal directly to case (3) of Theorem 13. Assume that $\phi \sqsupset \psi$, and—aiming for a

contradiction—assume that there is no joint for formulae ϕ and ψ . Then, by Lemma 7, there is no lambda such that both $\phi \sqsubseteq \lambda$ and $\psi \sqsubseteq \lambda$. But this is equivalent to the absence of any λ such that

$$\phi \vee \psi \vDash \lambda, * \quad \text{and} \quad *, \lambda \vDash \phi \wedge \psi.$$

By Soundness we can replace \vDash by \vdash , and then we have something in the right form to apply Theorem 13, case (3). Since we are working with pure logic in a single language, we take each of \mathcal{L}_1 , \mathcal{L}_2 , and \mathcal{L} to be this language—so that $\Box_{\mathcal{L}}$ will just be \Box —and we take $\Sigma_1 = \Sigma_2 = \emptyset$. Then we take $\Gamma_1 = \{\phi \vee \psi\}$, $\Gamma_2 = \{*\}$, $\Delta_1 = \{*\}$, $\Delta_2 = \{\phi \wedge \psi\}$. This guarantees models M_1 and M_2 , with assignments s_1 and s_2 , such that (M_1, s_1) rejects $\langle \Gamma_1, \Delta_1 \rangle$, (M_2, s_2) rejects $\langle \Gamma_2, \Delta_2 \rangle$, $M_1 \Box M_2$, and $s_1 \Box s_2$. But the rejections mean that

$$(M_{1s_1}(\phi) = \top \text{ or } M_{1s_1}(\psi) = \top) \quad \text{and} \quad (M_{2s_2}(\phi) = \perp \text{ or } M_{2s_2}(\psi) = \perp)$$

Distributing ‘and’ across ‘or’ there are then four possibilities, each of which, by Lemma 6, contradicts the assumption that $\phi \Box \psi$.

To establish Craig Interpolation (Theorem 9) we now make use of the fact that in Theorem 14 \mathcal{L}_1 and \mathcal{L}_2 might be different languages. Given formulae ϕ and ψ , let \mathcal{L}_1 be the language whose non-logical vocabulary is precisely that occurring in ϕ , let \mathcal{L}_2 be the language whose non-logical vocabulary is precisely that occurring in ψ , and let \mathcal{L} be the language whose non-logical vocabulary is precisely that common to both \mathcal{L}_1 and \mathcal{L}_2 . Assume now that there is no Craig interpolant for formulae ϕ and ψ : we have to show that $\phi \not\equiv \psi$. But, by Soundness, the absence of a Craig interpolant means that there is no formula λ of \mathcal{L} such that $\phi \vdash \lambda$ and $\lambda \vdash \psi$. And so we may apply Theorem 14 taking $\Sigma_1 = \Sigma_2 = \emptyset$, $\Gamma_1 = \{\phi\}$, $\Gamma_2 = \emptyset$, $\Delta_1 = \emptyset$, $\Delta_2 = \{\psi\}$. This guarantees models M_1 for \mathcal{L}_1 and M_2 for \mathcal{L}_2 , along with assignments s_1 and s_2 , such that at least one of three possible conditions obtains. We shall consider each in turn.

In case (1), $M_1 \sqsubseteq_{\mathcal{L}} M_2$, $s_1 \sqsubseteq s_2$, (M_1, s_1) rejects $\langle \{\phi\}, \{*\} \rangle$, and (M_2, s_2) rejects $\langle \emptyset, \{*, \psi\} \rangle$. But now let M be an expansion of M_2 which gives vocabulary in \mathcal{L}_1 but not in \mathcal{L}_2 the interpretation that M_1 gives it. Then $M_1 \sqsubseteq M \upharpoonright \mathcal{L}_1$. Thus, by Monotonicity of Evaluation (Lemma 3), and since $M \upharpoonright \mathcal{L}_1$ treats formulae of \mathcal{L}_1 in the same way as M , it follows that

$$M_{1s_1}(\phi) \sqsubseteq (M \upharpoonright \mathcal{L}_1)_{s_1}(\phi) = M_{s_1}(\phi) \sqsubseteq M_{s_2}(\phi).$$

But (M_1, s_1) ’s rejecting $\langle \{\phi\}, \{*\} \rangle$ means that $M_{1s_1}(\phi) = \top$, from which it follows that $M_{s_2}(\phi) = \top$. On the other hand, (M_2, s_2) ’s rejecting $\langle \emptyset, \{*, \psi\} \rangle$ means that $M_{2s_2}(\psi) \neq \top$, from which it follows that $M_{s_2}(\psi) \neq \top$. Hence (M, s_2) rejects $\langle \{\phi\}, \{\psi\} \rangle$ —showing that $\phi \not\equiv \psi$.

In case (2) we can argue in an exactly parallel way.

In case (3), $M_1 \sqsubset_{\mathcal{L}} M_2$, $s_1 \sqsubset s_2$, (M_1, s_1) rejects $\langle\{\phi\}, \{*\}\rangle$, and (M_2, s_2) rejects $\langle\{*\}, \{\psi\}\rangle$. But now let M_1^+ be an expansion of M_1 which gives vocabulary in \mathcal{L}_2 but not in \mathcal{L}_1 the interpretation that M_2 gives it; and let M_2^+ be an expansion of M_2 which gives vocabulary in \mathcal{L}_1 but not in \mathcal{L}_2 in the interpretation that M_1 gives it. Clearly $M_2^+ \sqsubset M_1^+$, and if $M = M_2^+ \sqcup M_1^+$ and $s = s_2 \sqcup s_1$, then, by Monotonicity of Evaluation,

$$M_{1s_1}(\phi) = M_{1^+s_1}(\phi) \sqsubseteq M_s(\phi) \quad \text{and} \quad M_{2s_2}(\psi) = M_{2^+s_2}(\psi) \sqsubseteq M_s(\psi).$$

But the rejections mean, respectively, that $M_{1s_1}(\phi) = \top$ and $M_{2s_2}(\psi) = \perp$. It follows that $M_s(\phi) = \top$ and $M_s(\psi) = \perp$. Hence (M, s) rejects $\langle\{\phi\}, \{\psi\}\rangle$ —again showing that $\phi \not\equiv \psi$.

Finally we shall use the Interpolant-Excluding Model Pairs Theorem to prove a result, which has not been mentioned before, about non-logical theories: a model-theoretic criterion for when a piece of non-logical vocabulary is definable in a theory Σ . First we need a relation \simeq_{Σ} of *equivalence in Σ* —or Σ -*equivalence*. Now that we have soundness and completeness in place, we can indifferently define this relation either in terms of \vdash_{Σ} or in terms of the models of Σ :

$$\begin{aligned} \phi \simeq_{\Sigma} \psi & \text{ iff } \phi \vdash_{\Sigma} \psi \text{ and } \psi \vdash_{\Sigma} \phi, \\ & \text{ iff } M_s(\phi) = M_s(\psi), \text{ for any } M \in \mathcal{K}(\Sigma) \text{ and any } s. \end{aligned}$$

Then let us say that (i) a predicate symbol P , (ii) a function symbol f , (iii) a constant symbol c , is (*explicitly*) *definable in Σ* if and only if there is a formula ϕ that does not contain (i) P , (ii) f , (iii) c , such that

$$(i) \ Px_1 \dots x_{\lambda(P)} \simeq_{\Sigma} \phi, \quad (ii) \ y = fx_1 \dots x_{\lambda(f)} \simeq_{\Sigma} \phi, \quad (iii) \ y = c \simeq_{\Sigma} \phi,$$

(where the displayed variables are assumed to be distinct from one another).

The definability theorem takes exactly the same form for each of these three cases, and so we can state it schematically for an item α of non-logical vocabulary. Say that \mathcal{L} is the language of the theory Σ , and let \mathcal{L}_{α} be the language got from \mathcal{L} by dropping α , then

THEOREM 15.

α is definable in Σ iff, for any models M and N of Σ ,

$$(a) \text{ if } M \sqsubseteq_{\mathcal{L}_{\alpha}} N, \text{ then } M \sqsubseteq N, \quad \text{and} \quad (b) \text{ if } M \sqsubset_{\mathcal{L}_{\alpha}} N, \text{ then } M \sqsubset N.$$

In other words, it is necessary and sufficient for the definability of α that given a pair of models of Σ , if (a) the relation \sqsubseteq , or (b) the relation \sqsubset , obtains between the interpretations of vocabulary other than α , then it also obtains between the interpretations of α . It is easy enough to check ‘only if’ directly. To establish ‘if’, we can argue by contraposition and invoke

Theorem 14. I shall sketch the case where α is a predicate letter P : the other cases are not too different.

Assume, then, that P is not definable in Σ . This means that there is no formula λ of \mathcal{L}_α such that $Px_1 \dots x_{\lambda(P)} \vdash_\Sigma \lambda$ and $\lambda \vdash_\Sigma Px_1 \dots x_{\lambda(P)}$. Hence we can apply Theorem 14, taking both the \mathcal{L}_1 and \mathcal{L}_2 of that theorem to be the language \mathcal{L} of this one, and taking the \mathcal{L} of that theorem to be \mathcal{L}_α . And we then take $\Sigma_1 = \Sigma_2 = \Sigma$, $\Gamma_1 = \{Px_1 \dots x_{\lambda(P)}\}$, $\Delta_1 = \emptyset$, $\Gamma_2 = \emptyset$, $\Delta_2 = \{Px_1 \dots x_{\lambda(P)}\}$. This guarantees models M_1 and M_2 of Σ , along with assignments s_1 and s_2 , such that at least one of three possible conditions obtains. We shall consider each in turn.

In case (1), $M_1 \sqsubseteq_{\mathcal{L}_\alpha} M_2$, but the rejection conditions, together with the fact that $s_1 \sqsubseteq s_2$, entail that $M_1 \not\sqsubseteq M_2$. For (M_1, s_1) rejects $\langle \{Px_1 \dots x_{\lambda(P)}\}, \{*\} \rangle$, so that $M_{1s_1}(Px_1 \dots x_{\lambda(P)}) = \top$, and therefore $M_{1s_2}(Px_1 \dots x_{\lambda(P)}) = \top$; but (M_2, s_2) rejects $\langle \emptyset, \{*, Px_1 \dots x_{\lambda(P)}\} \rangle$, so that $M_{2s_2}(Px_1 \dots x_{\lambda(P)}) \neq \top$.

In case (2) we can argue in an exactly parallel way.

In case (3), $M_1 \sqcap_{\mathcal{L}_\alpha} M_2$, but the rejection conditions, together with the fact that $s_1 \sqcap s_2$, entail that $M_1 \not\sqcap M_2$. For (M_1, s_1) rejects $\langle \{Px_1 \dots x_{\lambda(P)}\}, \{*\} \rangle$, so that $M_{1s_1}(Px_1 \dots x_{\lambda(P)}) = \top$; and (M_2, s_2) rejects $\langle \{*\}, \{Px_1 \dots x_{\lambda(P)}\} \rangle$, so that $M_{2s_2}(Px_1 \dots x_{\lambda(P)}) = \perp$: and therefore $M_{1s}(Px_1 \dots x_{\lambda(P)}) = \top$ and $M_{2s}(Px_1 \dots x_{\lambda(P)}) = \perp$, where $s = s_1 \sqcup s_2$.

There are two noteworthy comments on this definability result. First, the condition on models of Σ is strictly stronger than the condition that whenever models *agree exactly* on vocabulary other than α , then they also agree on α . Secondly, it follows from the definability of α in Σ that there will be a uniform procedure for transforming any formula into an α -free Σ -equivalent one. In the case of a predicate symbol this is just a matter of making the obvious substitution. In the case of a definable function symbol f , on the other hand, there will be a scheme of elimination for terms $ft_1 \dots t_{\mu(f)}$ that is scope-free in the same way that the description-scheme we specified in Section 6.4 is scope free. Given terms $t_1, \dots, t_{\mu(f)}$, we shall always be able to define f using a formula ϕ that contains no variables occurring in $t_1, \dots, t_{\mu(f)}$: $y = ft_1 \dots t_{\mu(f)} \simeq_\Sigma \phi$. (We can always rewrite variables as required.) Then, by rule (S),

$$y = ft_1 \dots t_{\mu(f)} \simeq_\Sigma \phi(t_1/x_1) \dots (t_{\mu(f)}/x_{\mu(f)}) \quad (\phi(t_i/x_i) \text{ for short}).$$

It follows that, provided $ft_1 \dots t_{\mu(f)}$ is substitutable for y in ψ , $\psi(ft_1 \dots t_{\mu(f)}/y)$ will be Σ -equivalent to each of the following:

$$\begin{aligned} & \exists y[\phi(t_i/x_i) \wedge \psi] \vee [\forall y[\phi(t_i/x_i) \rightarrow \psi] \wedge \psi(\otimes/y)]; \\ & \forall y[\phi(t_i/x_i) \rightarrow \psi] \wedge [\exists y[\phi(t_i/x_i) \wedge \psi] \vee \psi(\otimes/y)]. \end{aligned}$$

And a definable constant symbol can be handled in a parallel way—without any need to fuss about variables.

× × ×

Further model-theoretic results about non-logical theories can be derived from subtler versions of the Interpolant-Excluding Model Pairs Theorem(s). An example of this is the theorem we mentioned in Section 6.4 concerning the eliminability of \otimes in a theory Σ . By ‘eliminability’ let us agree to mean simply that any formula ϕ is equivalent in Σ to some \otimes -free formula ψ : $\phi \simeq_{\Sigma} \psi$. And let us define a new degree-of-definedness relation \sqsubseteq_{\otimes} between models M and N by taking over the definition of ‘ $M \sqsubseteq N$ ’ given in Section 6.2, but restricting \vec{a} , in clauses (1) and (2), to $D^{\lambda(P)}$ and to $D^{\mu(f)}$. D is the common domain of M and N , and so $M \sqsubseteq_{\otimes} N$ if and only if N is more defined than M over objects in the domain. In general \sqsubseteq_{\otimes} is a strictly weaker relation than \sqsubseteq , but

THEOREM 16. \otimes is eliminable in a theory Σ if and only if, whenever M and N are non-empty models of Σ and $M \sqsubseteq_{\otimes} N$, then $M \sqsubseteq N$.

Another result about non-logical theories arises from further consideration of the Compatibility Theorem (Theorem 5). This theorem was a result about pure logic, but the question arises concerning an arbitrary theory Σ whether formulae that are *compatible in* Σ —i.e. never take on conflicting truth values in models of Σ —have a *joint in the theory* Σ —i.e. a formula with the \top/\perp -conditions of a joint in all models of Σ . The answer is ‘no’, but we can derive a model-theoretic criterion for when a theory is guaranteed joints for all compatible formulae. This result, however, requires more apparatus than we have developed—even to state, let alone to prove.

PREFACE TO THE SECOND EDITION

It is with great pleasure that we are presenting to the community the second edition of this extraordinary handbook. It has been over 15 years since the publication of the first edition and there have been great changes in the landscape of philosophical logic since then.

The first edition has proved invaluable to generations of students and researchers in formal philosophy and language, as well as to consumers of logic in many applied areas. The main logic article in the *Encyclopaedia Britannica* 1999 has described the first edition as ‘the best starting point for exploring any of the topics in logic’. We are confident that the second edition will prove to be just as good!

The first edition was the second handbook published for the logic community. It followed the North Holland one volume *Handbook of Mathematical Logic*, published in 1977, edited by the late Jon Barwise. The four volume *Handbook of Philosophical Logic*, published 1983–1989 came at a fortunate temporal junction at the evolution of logic. This was the time when logic was gaining ground in computer science and artificial intelligence circles.

These areas were under increasing commercial pressure to provide devices which help and/or replace the human in his daily activity. This pressure required the use of logic in the modelling of human activity and organisation on the one hand and to provide the theoretical basis for the computer program constructs on the other. The result was that the *Handbook of Philosophical Logic*, which covered most of the areas needed from logic for these active communities, became their bible.

The increased demand for philosophical logic from computer science and artificial intelligence and computational linguistics accelerated the development of the subject directly and indirectly. It directly pushed research forward, stimulated by the needs of applications. New logic areas became established and old areas were enriched and expanded. At the same time, it socially provided employment for generations of logicians residing in computer science, linguistics and electrical engineering departments which of course helped keep the logic community thriving. In addition to that, it so happens (perhaps not by accident) that many of the Handbook contributors became active in these application areas and took their place as time passed on, among the most famous leading figures of applied philosophical logic of our times. Today we have a handbook with a most extraordinary collection of famous people as authors!

The table below will give our readers an idea of the landscape of logic and its relation to computer science and formal language and artificial intelligence. It shows that the first edition is very close to the mark of what was needed. Two topics were not included in the first edition, even though

they were extensively discussed by all authors in a 3-day Handbook meeting. These are:

- a chapter on non-monotonic logic
- a chapter on combinatory logic and λ -calculus

We felt at the time (1979) that non-monotonic logic was not ready for a chapter yet and that combinatory logic and λ -calculus was too far removed.¹ Non-monotonic logic is now a very major area of philosophical logic, alongside default logics, labelled deductive systems, fibring logics, multi-dimensional, multimodal and substructural logics. Intensive re-examinations of fragments of classical logic have produced fresh insights, including at time decision procedures and equivalence with non-classical systems.

Perhaps the most impressive achievement of philosophical logic as arising in the past decade has been the effective negotiation of research partnerships with fallacy theory, informal logic and argumentation theory, attested to by the Amsterdam Conference in Logic and Argumentation in 1995, and the two Bonn Conferences in Practical Reasoning in 1996 and 1997.

These subjects are becoming more and more useful in agent theory and intelligent and reactive databases.

Finally, fifteen years after the start of the Handbook project, I would like to take this opportunity to put forward my current views about logic in computer science, computational linguistics and artificial intelligence. In the early 1980s the perception of the role of logic in computer science was that of a specification and reasoning tool and that of a basis for possibly neat computer languages. The computer scientist was manipulating data structures and the use of logic was one of his options.

My own view at the time was that there was an opportunity for logic to play a key role in computer science and to exchange benefits with this rich and important application area and thus enhance its own evolution. The relationship between logic and computer science was perceived as very much like the relationship of applied mathematics to physics and engineering. Applied mathematics evolves through its use as an essential tool, and so we hoped for logic. Today my view has changed. As computer science and artificial intelligence deal more and more with distributed and interactive systems, processes, concurrency, agents, causes, transitions, communication and control (to name a few), the researcher in this area is having more and more in common with the traditional philosopher who has been analysing

¹I am really sorry, in hindsight, about the omission of the non-monotonic logic chapter. I wonder how the subject would have developed, if the AI research community had had a theoretical model, in the form of a chapter, to look at. Perhaps the area would have developed in a more streamlined way!

such questions for centuries (unrestricted by the capabilities of any hardware).

The principles governing the interaction of several processes, for example, are abstract and similar to principles governing the cooperation of two large organisations. A detailed rule based effective but rigid bureaucracy is very much similar to a complex computer program handling and manipulating data. My guess is that the principles underlying one are very much the same as those underlying the other.

I believe the day is not far away in the future when the computer scientist will wake up one morning with the realisation that he is actually a kind of formal philosopher!

The projected number of volumes for this Handbook is about 18. The subject has evolved and its areas have become interrelated to such an extent that it no longer makes sense to dedicate volumes to topics. However, the volumes do follow some natural groupings of chapters.

I would like to thank our authors and readers for their contributions and their commitment in making this Handbook a success. Thanks also to our publication administrator Mrs J. Spurr for her usual dedication and excellence and to Kluwer Academic Publishers for their continuing support for the Handbook.

Dov Gabbay
King's College London

Logic	IT			
	Natural language processing	Program control specification, verification, concurrency	Artificial intelligence	Logic programming
Temporal logic	Expressive power of tense operators. Temporal indices. Separation of past from future	Expressive power for recurrent events. Specification of temporal control. Decision problems. Model checking.	Planning. Time dependent data. Event calculus. Persistence through time—the Frame Problem. Temporal query language. temporal transactions.	Extension of Horn clause with time capability. Event calculus. Temporal logic programming.
Modal logic. Multi-modal logics	generalised quantifiers	Action logic	Belief revision. Inferential databases	Negation by failure and modality
Algorithmic proof	Discourse representation. Direct computation on linguistic input	New logics. Generic theorem provers	General theory of reasoning. Non-monotonic systems	Procedural approach to logic
Non-monotonic reasoning	Resolving ambiguities. Machine translation. Document classification. Relevance theory	Loop checking. Non-monotonic decisions about loops. Faults in systems.	Intrinsic logical discipline for AI. Evolving and communicating databases	Negation by failure. Deductive databases
Probabilistic and fuzzy logic	logical analysis of language	Real time systems	Expert systems. Machine learning	Semantics for logic programs
Intuitionistic logic	Quantifiers in logic	Constructive reasoning and proof theory about specification design	Intuitionistic logic is a better logical basis than classical logic	Horn clause logic is really intuitionistic. Extension of logic programming languages
Set theory, higher-order logic, λ-calculus, types	Montague semantics. Situation semantics	Non-well-founded sets	Hereditary finite predicates	λ -calculus extension to logic programs

Imperative vs. declarative languages	Database theory	Complexity theory	Agent theory	Special comments: A look to the future
Temporal logic as a declarative programming language. The changing past in databases. The imperative future	Temporal databases and temporal transactions	Complexity questions of decision procedures of the logics involved	An essential component	Temporal systems are becoming more and more sophisticated and extensively applied
Dynamic logic	Database updates and action logic	Ditto	Possible actions	Multimodal logics are on the rise. Quantification and context becoming very active
Types. Term rewrite systems. Abstract interpretation	Abduction, relevance	Ditto	Agent's implementation rely on proof theory.	
	Inferential databases. Non-monotonic coding of databases	Ditto	Agent's reasoning is non-monotonic	A major area now. Important for formalising practical reasoning
	Fuzzy and probabilistic data	Ditto	Connection with decision theory	Major area now
Semantics for programming languages. Martin-Löf theories	Database transactions. Inductive learning	Ditto	Agents constructive reasoning	Still a major central alternative to classical logic
Semantics for programming languages. Abstract interpretation. Domain recursion theory.		Ditto		More central than ever!

Classical logic. Classical frag- ments	Basic back- ground lan- guage	Program syn- thesis	A basic tool	
Labelled deductive systems	Extremely use- ful in modelling		A unifying framework. Context theory.	Annotated logic programs
Resource and substructural logics	Lambek calcu- lus		Truth maintenance systems	
Fibring and combining logics	Dynamic syn- tax	Modules. Combining languages	Logics of space and time	Combining fea- tures
Fallacy theory				
Logical Dynamics	Widely applied here			
Argumentation theory games		Game seman- tics gaining ground		
Object level/ metalevel			Extensively used in AI	
Mechanisms: Abduction, default relevance			ditto	
Connection with neural nets				
Time-action- revision mod- els			ditto	

	Relational databases	Logical complexity classes	The workhorse of logic	The study of fragments is very active and promising.
	Labelling allows for context and control.		Essential tool.	The new unifying framework for logics
Linear logic			Agents have limited resources	
	Linked databases. Reactive databases		Agents are built up of various fibred mechanisms	The notion of self-fibring allows for self-reference
				Fallacies are really valid modes of reasoning in the right context.
			Potentially applicable	A dynamic view of logic
				On the rise in all areas of applied logic. Promises a great future
			Important feature of agents	Always central in all areas
			Very important for agents	Becoming part of the notion of a logic
				Of great importance to the future. Just starting
			A new theory of logical agent	A new kind of model

RELEVANCE LOGIC

1 INTRODUCTION

1.1 *Delimiting the topic*

The title of this piece is not ‘A Survey of Relevance Logic’. Such a project was impossible in the mid 1980s when the first version of this article was published, due to the development of the field and even the space limitations of the *Handbook*. The situation is if anything, more difficult now. For example Anderson and Belnap and Dunn’s two volume [1975; 1992] work *Entailment: The Logic of Relevance and Necessity*, runs to over 1200 pages, and is their summary of just some of the work done by them and their co-workers up to about the late 1980s. Further, the comprehensive bibliography (prepared by R. G. Wolf) contains over 3000 entries in work on relevance logic and related fields.

So, we need some way of delimiting our topic. To be honest the fact that *we* are writing this is already a kind of delimitation. It is natural that you shall find emphasised here the work that we happen to know best. But still rationality demands a less subjective rationale, and so we will proceed as follows.

Anderson [1963] set forth some open problems for his and Belnap’s system **E** that have given shape to much of the subsequent research in relevance logic (even much of the earlier work can be seen as related to these open problems, e.g. by giving rise to them). Anderson picks three of these problems as major: (1) the admissibility of Ackermann’s rule γ (the reader should not worry that he is expected to already know what this means), (2) the decision problems, (3) the providing of a semantics. Anderson also lists additional problems which he calls ‘minor’ because they have no ‘philosophical bite’. We will organise our remarks on relevance logic around three major problems of Anderson. The reader should be told in advance that each of these problems are closed (but of course ‘closed’ does not mean ‘finished’—closing one problem invariably opens another related problem). This gives then three of our sections. It is obvious that to these we must add an introduction setting forth at least some of the motivations of relevance logic and some syntactical specifications. To the end we will add a section which situates work in relevance logic in the wider context of study of other logical systems, since in the recent years it has become clear that relevance logics fit well among a wider class of ‘resource-conscious’ or ‘substructural’ logics [Schroeder-Heister and Došen, 1993; Restall, 2000] [and cite the S–H article in this volume]. We thus have the following table of contents:

1. Introduction
2. The Admissibility of γ
3. Semantics
4. The Decision Problem
5. Looking About

We should add a word about the delimitation of our topic. There are by now a host of formal systems that can be said with some justification to be ‘relevance logics’. Some of these antedate the Anderson–Belnap approach, some are more recent. Some have been studied somewhat extensively, whereas others have been discussed for only a few pages in some journal. It would be impossible to describe all of these, let alone to assess in each and every case how they compare with the Anderson–Belnap approach. It is clear that the Anderson–Belnap-style logics have been the most intensively studied. So we will concentrate on the research program of Anderson, Belnap and their co-workers, and shall mention other approaches only insofar as they bear on this program. By way of minor recompense we mention that Anderson and Belnap [1975] have been good about discussing related approaches, especially the older ones.

Finally, we should say that our paradigm of a relevance logic throughout this essay will be the Anderson–Belnap system **R** or relevant implication (first devised by Belnap—see [Belnap, 1967a; Belnap, 1967b] for its history) and not so much the Anderson–Belnap favourite, their system **E** of entailment. There will be more about each of these systems below (they are explicitly formulated in Section 1.3), but let us simply say here that each of these is concerned to formalise a species of implication (or the conditional—see Section 1.2) in which the antecedent suffices *relevantly* for the consequent. The system **E** differs from the system **R** primarily by adding necessity to this relationship, and in this **E** is a modal logic as well as a relevance logic. This by itself gives good reason to consider **R** and not **E** as the paradigm of a relevance logic.¹

1.2 *Implication and the Conditional*

Before turning to matters of logical substance, let us first introduce a framework for grammar and nomenclature that is helpful in understanding the ways that writers on relevance logic often express themselves. We draw

¹It should be entered in the record that there are some workers in relevance logic who consider both **R** and **E** too strong for at least some purposes (see [Routley, 1977], [Routley *et al.*, 1982], and more recently, [Brady, 1996]).

heavily on the ‘Grammatical Propaedeutic’ appendix of [Anderson and Belnap, 1975] and to a lesser extent on [Meyer, 1966], both of which are very much recommended to the reader for their wise heresy from logical tradition.

Thus logical tradition (think of [Quine, 1953]) makes much of the grammatical distinction between ‘if, then’ (a connective), and ‘implies’ or its rough synonym ‘entails’ (transitive verbs). This tradition opposes

1. If today is Tuesday, then this is Belgium

to the pair of sentences

2. ‘Today is Tuesday’ implies ‘This is Belgium’,
3. That today is Tuesday implies that this is Belgium.

And the tradition insists that (1) be called a *conditional*, and that (2) and (3) be called *implications*.

Sometimes much philosophical weight is made to rest on this distinction. It is said that since ‘implies’ is a verb demanding nouns to flank it, that implication must then be a relation between the objects stood for by those nouns, whereas it is said that ‘if, then’ is instead a connective combining that implication (unlike ‘if, then’) is really a metalinguistic notion, either overtly as in (2) where the nouns are names of sentences, or else covertly as in (3) where the nouns are naming propositions (the ‘ghosts’ of linguistic entities). This last is then felt to be especially bad because it involves ontological commitment to propositions or some equally disreputable entities. The first is at least free of such questionable ontological commitments, but does raise real complications about ‘nested implications’, which would seem to take us into a meta-metalanguage, etc.

The response of relevance logicians to this distinction has been largely one of ‘What, me worry?’ Sometime sympathetic outsiders have tried to apologise for what might be quickly labelled a ‘use–mention confusion’ on the part of relevance logicians [Scott, 1971]. But ‘hard-core’ relevance logicians often seem to luxuriate in this ‘confusion’. As Anderson and Belnap [1975, p. 473] say of their ‘Grammatical Propaedeutic’: “the principle aim of this piece is to convince the reader that it is philosophically respectable to ‘confuse’ implication or entailment with the conditional, and indeed philosophically suspect to harp on the dangers of such a ‘confusion’. (The suspicion is that such harpists are plucking a metaphysical tune on merely grammatical strings.)”

The gist of the Anderson–Belnap position is that there is a generic conditional-implication notion, which can be carried into English by a variety of grammatical constructions. Implication itself can be viewed as a connective requiring prenominalisation: ‘that ___ implies that ___’, and as such it nests. It is an incidental feature of English that it favours sentences with main subjects and verbs, and ‘implies’ conforms to this reference by

the trick of disguising sentences as nouns by prenominalisation. But such grammatical prejudices need not be taken as enshrining ontological presuppositions.

Let us use the label ‘Correspondence Thesis’ for the claim that Anderson and Belnap come close to making (but do not actually make), namely, that *in general* there is nothing other than a purely grammatical distinction between sentences of the forms

4. If A , then B , and
5. That A implies that B .

Now undoubtedly the Correspondence Thesis overstates matters. Thus, to bring in just one consideration, [Castañeda, 1975, pp. 66 ff.] distinguishes ‘if A then B ’ from ‘ A only if B ’ by virtue of an essentially pragmatic distinction (frozen into grammar) of ‘thematic’ emphases, which cuts across the logical distinction of antecedent and consequent. Putting things quickly, ‘if’ introduces a sufficient condition for something happening, something being done, etc. whereas ‘only if’ introduces a necessary condition. Thus ‘if’ (by itself or prefixed with ‘only’) always introduces the state of affairs thought of as a condition for something else, then something else being thus the focus of attention. Since ‘that A implies that B ’ is devoid of such thematic indicators, it is not equivalent at *every* level of analysis to either ‘if A then B ’ or ‘ A only if B ’.

It is worth remarking that since the formal logician’s $A \rightarrow B$ is equally devoid of thematic indicators, ‘that A implies that B ’ would seem to make a better reading of it than either ‘if A then B ’ or ‘ A only if B ’. And yet it is almost universally rejected by writers of elementary logic texts as even an acceptable reading.

And, of course, another consideration against the Correspondence Thesis is produced by notorious examples like Austin’s

6. There are biscuits on the sideboard if you want some,

which sounds very odd indeed when phrased as an implication. Indeed, (6) poses perplexities of one kind or another for any theory of the conditional, and so should perhaps best be ignored as posing any special threat to the Anderson and Belnap account of conditionals. Perhaps it was Austin-type examples that led Anderson and Belnap [1975, pp. 491–492] to say “we think every use of ‘implies’ or ‘entails’ as a connective can be replaced by a suitable ‘if-then’; however, the converse may not be true”. They go on to say “But with reference to the uses in which we are primarily interested, we feel free to move back and forth between ‘if-then’ and ‘entails’ in a free-wheeling manner”.

Associated with the Correspondence Thesis is the idea that just as there can be contingent conditionals (e.g. (1)), so then the corresponding implications (e.g. (3)) must also be contingent. This goes against certain Quinean

tendencies to ‘regiment’ the English word ‘implies’ so that it stands only for *logical* implication. Although there is no objection to thus giving a technical usage to an ordinary English word (even requiring in this technical usage that ‘implication’ be a metalinguistic relation between sentences), the point is that relevance logicians by and large believe we are using ‘implies’ in the ordinary non-technical sense, in which a sentence like (3) might be true without there being any logical (or even necessary) implication from ‘Today is Tuesday’ to ‘This is Belgium’.

Relevance logicians are not themselves free of similar regimenting tendencies. Thus we tend to differentiate ‘entails’ from ‘implies’ on precisely the ground that ‘entails’, unlike ‘implies’, stands only for *necessary* implication [Meyer, 1966]. Some writings of Anderson and Belnap even suggest a more restricted usage for just *logical* implication, but we do not take this seriously. There does not seem to be any more linguistic evidence for thus restricting ‘entails’ than there would be for ‘implies’, though there may be at least more excuse given the apparently more technical history of ‘entails’ (in its logical sense—cf. The OED).

This has been an explanation of, if not an apology for, the ways in which relevance logicians often express themselves. but it should be stressed that the reader need not accept all, or any, of this background in order to make sense of the basic aims of the relevance logic enterprise. Thus, e.g. the reader may feel that, despite protestations to the contrary, Anderson, Belnap and Co. are hopelessly confused about the relationships among ‘entails’, ‘implies’, and ‘if-then’, but still think that their system **R** provides a good formalisation of the properties of ‘if-then’ (or at least ‘if-then relevantly’), and that they system **E** does the same for some strict variant produced by the modifier ‘necessarily’.

One of the reasons the recent logical tradition has been motivated to insist on the fierce distinction between implications and conditionals has to do with the awkwardness of reading the so-called ‘material conditional’ $A \rightarrow B$ as corresponding to any kind of implication (cf. [Quine, 1953]).

The material conditional $A \rightarrow B$ can of course be defined as $\neg A \vee B$, and it certainly does seem odd, modifying an example that comes by oral tradition from Anderson, to say that:

7. Picking a guinea pig up by its tail implies that its eyes will fall out.

just on the grounds that its antecedent is false (since guinea pigs have no tails). But then it seems equally false to say that:

8. If one picks up a guinea pig by its tail, then its eyes will fall out.

And also both of the following appear to be equally false:

9. Scaring a pregnant guinea pig implies that all of her babies will be born tailless.

10. If one scares a pregnant guinea pig, then all of her babies will be born tailless.

It should be noted that there are other ways to react to the oddity of sentences like the ones above other than calling them simply false. Thus there is the reaction stemming from the work of Grice [1975] that says that at least the conditional sentences (8) and (10) above are true though nonetheless pragmatically odd in that they violate some rule based on conversational co-operation to the effect that one should normally say the strongest thing relevant, i.e. in the cases above, that guinea pigs have no tails (cf. [Fogelin, 1978, p. 136 ff.] for a textbook presentation of this strategy).

Also it should be noted that the theory of the ‘counterfactual’ conditional due to Stalnaker–Thomason, D. K. Lewis and others (cf. Chapter [??] of this *Handbook*), while it agrees with relevance logic in finding sentences like (8) (not (10) *false*, disagrees with relevance logic in the formal account it gives of the conditional.

It would help matters if there were an extended discussion of these competing theories (Anderson–Belnap, Grice, Stalnaker–Thomason–Lewis), which seem to pass like ships in the night (can three ships do this without strain to the image?) but there is not the space here. Such a discussion might include an attempt to construct a theory of a relevant counterfactual conditional (if A were to be the case, then *as a result* B would be the case). The rough idea would be to use say The Routley–Meyer semantics for relevance logic (cf. Section 3.7) in place of the Kripke semantics for modal logic, which plays a key role in the Stalnaker–Thomason–Lewis semantical account of the conditional (put the 3-placed alternativeness relation in the role of the usual 2-placed one). Work in this area is just starting. See the works of [Mares and Fuhrmann, 1995] and [Akama, 1997] which both attempt to give semantics for relevant counterfactuals.

Also any discussion relating to Grice’s work would surely make much of the fact that the theory of Grice makes much use of a basically unanalysed notion of relevance. One of Grice’s chief conversational rules is ‘be relevant’, but he does not say much about just what this means. One could look at relevance logic as trying to say something about this, at least in the case of the conditional.

Incidentally, as Meyer has been at great pains to emphasise, relevance logic gives, on its face anyway, no separate account of relevance. It is not as if there is a unary relevance operator (‘relevantly’).

One last point, and then we shall turn to more substantive issues. Orthodox relevance logic differs from classical logic not just in having an additional logical connective (\rightarrow) for the conditional. If that was the only difference relevance logic would just be an ‘extension’ of classical logic, using the notion of Haack [1974], in much the same way as say modal logic is an extension of classical logic by the addition of a logical connective \square

for necessity. The fact is (cf. Section 1.6) that although relevance logic contains all the same theorems as classical logic in the classical vocabulary say, \wedge, \vee, \neg (and the quantifiers), it nonetheless does not validate the same inferences. Thus, most notoriously, the disjunctive syllogism (cf. Section 2) is counted as invalid. Thus, as Wolf [1978] discusses, relevance logic does not fit neatly into the classification system of [Haack, 1974], and might best be called ‘quasi-extension’ of classical logic, and hence ‘quasi-deviant’. Incidentally, all of this applies only to ‘orthodox’ relevance logic, and not to the ‘classical relevance logics’ of Meyer and Routley (cf. Section 3.11).

1.3 Hilbert-style Formulations

We shall discuss first the pure implicational fragments, since it is primarily in the choice of these axioms that the relevance logics differ one from the other. We shall follow the conventions of Anderson and Belnap [Anderson and Belnap, 1975], denoting by ‘ \mathbf{R}_{\rightarrow} ’ what might be called the ‘putative implicational fragment of \mathbf{R} ’. Thus \mathbf{R}_{\rightarrow} will have as axioms all the axioms of \mathbf{R} that only involve the implication connective. That \mathbf{R}_{\rightarrow} is in fact the implicational fragment of \mathbf{R} is much less than obvious since the possibility exists that the proof of a pure implicational formula could detour in an essential way through formulas involving connectives other than implication. In fact Meyer has shown that this does not happen (cf. his Section 28.3.2 of [Anderson and Belnap, 1975]), and indeed Meyer has settled in almost every interesting case that the putative fragments of the well-known relevance logics (at least \mathbf{R} and \mathbf{E}) are the same as the real fragments. (Meyer also showed that this does not happen in one interesting case, \mathbf{RM} , which we shall discuss below.)

For \mathbf{R}_{\rightarrow} we take the rule *modus ponens* ($A, A \rightarrow B \vdash B$) and the following axiom schemes.

$$A \rightarrow A \quad \text{Self-Implication} \quad (1)$$

$$(A \rightarrow B) \rightarrow [(C \rightarrow A) \rightarrow (C \rightarrow B)] \quad \text{Prefixing} \quad (2)$$

$$[A \rightarrow (A \rightarrow B)] \rightarrow (A \rightarrow B) \quad \text{Contraction} \quad (3)$$

$$[A \rightarrow (B \rightarrow C)] \rightarrow [B \rightarrow (A \rightarrow C)] \quad \text{Permutation.} \quad (4)$$

A few comments are in order. This formulation is due to Church [1951b] who called it ‘The weak implication calculus’. He remarks that the axioms are the same as those of Hilbert’s for the positive implicational calculus (the implicational fragment of the intuitionistic propositional calculus \mathbf{H}) except that (1) is replaced with

$$A \rightarrow (B \rightarrow A) \quad \text{Positive Paradox.} \quad (1')$$

(Recent historical investigation by Došen [1992] has shown that Orlov constructed an axiomatisation of the implication and negation fragment of \mathbf{R}

in the mid 1920s, predating other known work in the area. Church and Moh, however, provided a Deduction Theorem (see Section 1.4) which is absent from Orlov's treatment.)

The choice of the implicational axioms can be varied in a number of informative ways. Thus putting things quickly, (2) Prefixing may be replaced by

$$(A \rightarrow B) \rightarrow [(B \rightarrow C) \rightarrow (A \rightarrow C)] \quad \text{Suffixing.} \quad (2')$$

(3) Contraction may be replaced by

$$[A \rightarrow (B \rightarrow C)] \rightarrow [(A \rightarrow B) \rightarrow (A \rightarrow C)] \quad \text{Self-Distribution,} \quad (3')$$

and (4) Permutation may be replaced by

$$A \rightarrow [(A \rightarrow B) \rightarrow B] \quad \text{Assertion.} \quad (4')$$

These choices of implicational axioms are 'isolated' in the sense that one choice does not affect another. Thus

THEOREM 1. \mathbf{R}_{\rightarrow} may be axiomatised with modus ponens, (1) *Self-Implication* and any selection of one from each pair $\{(2), (2')\}$, $\{(3), (3')\}$, and $\{(4), (4')\}$.

Proof. By consulting [Anderson and Belnap, 1975, pp. 79–80], and fiddling. ■

There is at least one additional variant of \mathbf{R}_{\rightarrow} that merits discussion. It turns out that it suffices to have Suffixing, Contraction, and the pair of axiom schemes

$$[(A \rightarrow A) \rightarrow B] \rightarrow B \quad \text{Specialised Assertion,} \quad (4a)$$

$$A \rightarrow [(A \rightarrow A) \rightarrow A] \quad \text{Demodaliser.} \quad (4b)$$

Thus (4b) is just an instance of Assertion, and (4a) follows from Assertion by substitution $A \rightarrow A$ for A and using Self-Implication to detach. That (4a) and (4b) together with Suffixing and Contraction yield Assertion (and, less interestingly, Self-Implication) can be shown using the fact proven in [Anderson and Belnap, 1975, Section 8.3.3], that these yield (letting \vec{A} abbreviate $A_1 \rightarrow A_2$)

$$\vec{A} \rightarrow [(\vec{A} \rightarrow B) \rightarrow B] \quad \text{Restricted-Assertion.} \quad (4'')$$

The point is that (4a) and (4b) in conjunction say that A is equivalent to $(A \rightarrow A) \rightarrow A$, and so every formula A has an equivalent form \vec{A} and so 'Restricted Assertion' reduces to ordinary Assertion.²

²There are some subtleties here. Detailed analysis shows that both Suffixing and Prefixing are needed to replace \vec{A} with A (cf. Section 1.3). Prefixing can be derived from the above set of axioms (cf. [Anderson and Belnap, 1975, pp. 77–78 and p. 26]).

Incidentally, no claim is made that this last variant of \mathbf{R}_{\rightarrow} has the same isolation in its axioms as did the previous axiomatisations. Thus, e.g. that Suffixing (and not Prefixing) is an axiom is important (a matrix of J. R. Chidgey's (cf. [Anderson and Belnap, 1975, Section 8.6]) can be used to show this.

The system \mathbf{E} of entailment differs primarily from the system \mathbf{R} in that it is a system of relevant strict implication. Thus \mathbf{E} is both a relevance logic and a modal logic. Indeed, defining $\Box A =_{\text{df}} (A \rightarrow A) \rightarrow A$ one finds \mathbf{E} has something like the modality structure of $\mathbf{S4}$ (cf. [Anderson and Belnap, 1975, Sections 4.3 and 10]).

This suggests that \mathbf{E}_{\rightarrow} can be axiomatised by dropping Demodaliser from the axiomatisation of \mathbf{R}_{\rightarrow} , and indeed this is right (cf. [Anderson and Belnap, 1975, Section 8.3.3], for this and all other claims about axiomatisations of \mathbf{E}_{\rightarrow}).³

The axiomatisation above is a 'fixed menu' in that Prefixing cannot be replaced with Suffixing. There are other 'à la carte' axiomatisations in the style of Theorem 1.

THEOREM 2. \mathbf{E}_{\rightarrow} may be axiomatised with modus ponens, *Self-Implication* and any selection from each of the pairs $\{\text{Prefixing}, \text{Suffixing}\}$, $\{\text{Contraction}, \text{Self-Distribution}\}$ and $\{\text{Restricted-Permutation}, \text{Restricted-Assertion}\}$ (one from each pair).

Another implicational system of less central interest is that of 'ticket entailment' \mathbf{T}_{\rightarrow} . It is motivated by Anderson and Belnap [1975, Section 6] as deriving from some ideas of Ryle's about 'inference tickets'. It was motivated in [Anderson, 1960] as 'entailment shorn of modality'. The thought behind this last is that there are two ways to remove the modal sting from the characteristic axiom of alethic modal logic, $\Box A \rightarrow A$. One way is to add Demodaliser $A \rightarrow \Box A$ so as to destroy all modal distinctions. The other is to drop the axiom $\Box A \rightarrow A$. Thus the essential way one gets \mathbf{T}_{\rightarrow} from \mathbf{E}_{\rightarrow} is to drop Specialised Assertion (or alternatively to drop Restricted Assertion or Restricted Permutation, depending on which axiomatisation of \mathbf{E}_{\rightarrow} one has). But before doing so one must also add whichever one of Prefixing and Suffixing was lacking, since it will no longer be a theorem otherwise (this is easiest to visualise if one thinks of dropping Restricted permutation, since this is the key to getting Prefixing from Suffixing and *vice versa*). Also (and this is a strange technicality) one must replace Self-Distribution with its permuted form:

$$(A \rightarrow B) \rightarrow [[A \rightarrow (B \rightarrow C)] \rightarrow (A \rightarrow C)] \quad \text{Permuted Self-Distribution.} \quad (3'')$$

This is summarised in

³The actual history is backwards to this, in that the system \mathbf{R} was first axiomatised by [Belnap, 1967a] by adding Demodaliser to \mathbf{E} .

THEOREM 3 (Anderson and Belnap [Section 8.3.2, 1975]). \mathbf{T}_{\rightarrow} is axiomatised using *Self-Implication, Prefixing, Suffixing, and either of {Contraction, Permuted Self-Distribution}*, with modus ponens.

There is a subsystem of \mathbf{E}_{\rightarrow} called $\mathbf{TW}_{\rightarrow}$ (and $\mathbf{P-W}$, and $\mathbf{T-W}$ in earlier nomenclature) axiomatised by dropping Contraction (which corresponds to the combinator \mathbf{W}) from \mathbf{T}_{\rightarrow} . This has obtained some interest because of an early conjecture of Belnap's (cf. [Anderson and Belnap, 1975, Section 8.11]) that $A \rightarrow B$ and $B \rightarrow A$ are both theorems of $\mathbf{TW}_{\rightarrow}$ only when A is the same formula as B . That Belnap's Conjecture is now Belnap's Theorem is due to the highly ingenious (and complicated) work of E. P. Martin and R. K. Meyer [1982] (based on the earlier work of L. Powers and R. Dwyer). Martin and Meyer's work also highlights a system \mathbf{S}_{\rightarrow} (for Syllogism) in which Self-Implication is dropped from $\mathbf{TW}_{\rightarrow}$.

Moving on now to adding the positive extensional connectives \wedge and \vee , in order to obtain $\mathbf{R}_{\rightarrow, \wedge, \vee}$ (denoted more simply as \mathbf{R}^+) one adds to \mathbf{R}_{\rightarrow} the axiom schemes

$$A \wedge B \rightarrow A, \quad A \wedge B \rightarrow B \quad \text{Conjunction Elimination} \quad (5)$$

$$[(A \rightarrow B) \wedge (A \rightarrow C)] \rightarrow (A \rightarrow B \wedge C) \quad \text{Conjunction Introduction} \quad (6)$$

$$A \rightarrow A \vee B, \quad B \rightarrow A \vee B \quad \text{Disjunction Introduction} \quad (7)$$

$$[(A \rightarrow C) \wedge (B \rightarrow C)] \rightarrow (A \vee B \rightarrow C) \quad \text{Disjunction Elimination} \quad (8)$$

$$A \wedge (B \vee C) \rightarrow (A \wedge B) \vee C \quad \text{Distribution} \quad (9)$$

plus the rule of adjunction ($A, B \vdash A \wedge B$). One can similarly get the positive intuitionistic logic by adding these all to \mathbf{H}_{\rightarrow} .

Axioms (5)–(8) can readily be seen to be encoding the usual elimination and introduction rules for conjunction and disjunction into axioms, giving \wedge and \vee what might be called ‘the lattice properties’ (cf. Section 3.3). It might be thought that $A \rightarrow (B \rightarrow A \wedge B)$ might be a better encoding of conjunction introduction than (6), having the virtue that it allows for the dropping of adjunction. This is a familiar axiom for intuitionistic (and classical) logic, but as was seen by Church [1951b], it is only a hair's breadth away from Positive Paradox ($A \rightarrow (B \rightarrow A)$), and indeed yields it given (5) and Prefixing. For some mysterious reason, this observation seemed to prevent Church from adding extensional conjunction/disjunction to what we now call \mathbf{R}_{\rightarrow} (and yet the need for adjunction in the Lewis formulations of modal logic where the axioms are all strict implications was well-known).

Perhaps more surprising than the need for adjunction is the need for axiom (9). It would follow from the other axioms if only we had Positive Paradox among them. The place of Distribution in \mathbf{R} is continually problematic. It causes inelegancies in the natural deduction systems (cf. Section 1.5) and is an obstacle to finding decision procedures (cf. Section 4.8). Incidentally, all of the usual distributive laws follow from the somewhat ‘clipped’ version

(9).

The rough idea of axiomatising \mathbf{E}^+ and \mathbf{T}^+ is to add axiom schemes (5)–(9) to \mathbf{E}_{\rightarrow} and \mathbf{T}_{\rightarrow} . This is in fact precisely right for \mathbf{T}^+ , but for \mathbf{E}^+ one needs also the axiom scheme (remember $\Box A =_{\text{df}} (A \rightarrow A) \rightarrow A$):

$$\Box A \wedge \Box B \rightarrow \Box(A \wedge B) \quad (10)$$

This is frankly an inelegance (and one that strangely enough disappears in the natural deduction context of Section 1.5). It is needed for the inductive proof that necessitation ($\vdash C \Rightarrow \vdash \Box C$) holds, handling the case where C just came by adjunction (cf. [Anderson and Belnap, 1975, Sections 21.2.2 and 23.4]). There are several ways of trying to conceal this inelegance, but they are all a little *ad hoc*. Thus, e.g. one could just postulate the rule of necessitation as primitive, or one could strengthen the axiom of Restricted Permutation (or Restricted Assertion) to allow that \vec{A} be a conjunction $(A_1 \rightarrow A_1) \wedge (A_2 \rightarrow A_2)$.

As Anderson and Belnap [1975, Section 21.2.2] remark, if propositional quantification is available, $\Box A$ could be given the equivalent definition $\forall p(p \rightarrow p) \rightarrow A$, and then the offending (10) becomes just a special case of Conjunction Introduction and becomes redundant.

It is a good time to advertise that the usual zero-order and first-order relevance logics can be outfitted with a couple of optional convenience features that come with the higher-priced versions with propositional quantifiers. Thus, e.g. the propositional constant t can be added to \mathbf{E}^+ to play the role of $\forall p(p \rightarrow p)$, governed by the axioms.

$$(t \rightarrow A) \rightarrow A \quad (11)$$

$$t \rightarrow (A \rightarrow A), \quad (12)$$

and again (10) becomes redundant (since one can easily show $(t \rightarrow A) \leftrightarrow [(A \rightarrow A) \rightarrow A]$).

Further, this addition of t is conservative in the sense that it leads to no new t -free theorems (since in any given proof t can always be replaced by $(p_1 \rightarrow p_1) \wedge \dots \wedge (p_n \rightarrow p_n)$ where p_1, \dots, p_n are all the propositional variables appearing in the proof — cf. [Anderson and Belnap, 1975]).

Axiom scheme (11) is too strong for \mathbf{T}^+ and must be weakened to

$$t. \quad (11\mathbf{T})$$

In the context of \mathbf{R}^+ , (11) and (11 \mathbf{T}) are interchangeable, and in \mathbf{R}^+ , (12) may of course be permuted, letting us characterise t in a single axiom as ‘the conjunction of all truths’:

$$A \leftrightarrow (t \rightarrow A) \quad (13)$$

(in \mathbf{E} , t may be thought of as ‘the conjunction of all necessary truths’).

‘Little t ’ is distinguished from ‘big T ’, which can be conservatively added with the axiom scheme

$$A \rightarrow T \quad (14)$$

(in intuitionistic or classical logic t and T are equivalent).

Additionally useful is a binary connective \circ , labelled variously ‘intensional conjunction’, ‘fusion’, ‘consistency’ and ‘cotenability’. these last two labels are appropriate only in the context of \mathbf{R} , where one can define $A \circ B =_{\text{df}} \neg(A \rightarrow \neg B)$. One can add \circ to \mathbf{R}^+ with the axiom scheme:

$$[(A \circ B) \rightarrow C] \leftrightarrow [A \rightarrow (B \rightarrow C)] \quad \text{Residuation (axiom).} \quad (15)$$

This axiom scheme is too strong for other standard relevance logics, but Meyer and Routley [1972] discovered that one can always add conservatively the two way rule

$$(A \circ B) \rightarrow C \dashv \vdash A \rightarrow (B \rightarrow C) \quad \text{Residuation (rule)} \quad (16)$$

(in \mathbf{R}^+ (16) yields (15)). Before adding negation, we mention the positive fragment \mathbf{B}^+ of a kind of minimal (Basic) relevance logic due to Routley and Meyer (cf. Section 3.9). \mathbf{B}^+ is just like \mathbf{TW}^+ except for finding the axioms of Prefixing and Suffixing too strong and replacing them by rules:

$$A \rightarrow B \vdash (C \rightarrow A) \rightarrow (C \rightarrow B) \quad \text{Prefixing (rule)} \quad (17)$$

$$A \rightarrow B \vdash (B \rightarrow C) \rightarrow (A \rightarrow C) \quad \text{Suffixing (rule)} \quad (18)$$

As for negation, the full systems \mathbf{R} , \mathbf{E} , etc. may be formed adding to the axiom schemes for \mathbf{R}^+ , \mathbf{E}^+ , etc. the following ⁴

$$(A \rightarrow \neg A) \rightarrow \neg A \quad \text{Reductio} \quad (19)$$

$$(A \rightarrow \neg B) \rightarrow (B \rightarrow \neg A) \quad \text{Contraposition} \quad (20)$$

$$\neg \neg A \rightarrow A \quad \text{Double Negation.} \quad (21)$$

Axiom schemes (19) and (20) are intuitionistically acceptable negation principles, but using (21) one can derive forms of reductio and contraposition that are intuitionistically rejectable. Note that (19)–(21) if added to \mathbf{H}^+ would give the full intuitionistic propositional calculus \mathbf{H} .

In \mathbf{R} , negation can alternatively be defined in the style of Johansson, with $\neg A =_{\text{df}} (A \rightarrow f)$, where f is a false propositional constant, cf. [Meyer, 1966]. Informally, f is the disjunction of all false propositions (the ‘negation’ of t). Defining negation thus, axiom schemes (19) and (20) become theorems

⁴Reversing what is customary in the literature, we use \neg for the standard negation of relevance logic, reserving \sim for the ‘Boolean negation’ discussed in Section 3.11. We do this so as to follow the notational policies of the *Handbook*.

(being instances of Contraction and Permutation, respectively). But scheme (21) must still be taken as an axiom.

Before going on to discuss quantification, we briefly mention a couple of other systems of interest in the literature.

Given that **E** has a theory of necessity riding piggyback on it in the definition $\Box A =_{\text{df}} (A \rightarrow A) \rightarrow A$, the idea occurred to Meyer of adding to **R** a primitive symbol for necessity \Box governed by the **S4** axioms.

$$\Box A \rightarrow A \quad (\Box 1)$$

$$\Box(A \rightarrow B) \rightarrow (\Box A \rightarrow \Box B) \quad (\Box 2)$$

$$\Box A \wedge \Box B \rightarrow \Box(A \wedge B) \quad (\Box 3)$$

$$\Box A \rightarrow \Box \Box A, \quad (\Box 4)$$

and the rule of Necessitation ($\vdash A \Rightarrow \vdash \Box A$).

His thought was that **E** could be exactly translated into this system **R**[□] with entailment defined as strict implication. That this is subtly not the case was shown by Maksimova [1973] and Meyer [1979b] has shown how to modify **R**[□] so as to allow for an exact translation.

Yet one more system of interest is **RM** (cf. Section 3.10) obtained by adding to **R** the axiom scheme

$$A \rightarrow (A \rightarrow A) \quad \text{Mingle.} \quad (22)$$

Meyer has shown somewhat surprisingly that the pure implicational system obtained by adding Mingle to **R** is not the implicational fragment of **RM**, and he and Parks have shown how to axiomatise this fragment using a quite unintelligible formula (cf. [Anderson and Belnap, 1975, Section 8.18]). Mingle may be replaced equivalently with the converse of Contraction:

$$(A \rightarrow B) \rightarrow (A \rightarrow (A \rightarrow B)) \quad \text{Expansion.} \quad (23)$$

Of course one can consider ‘mingled’ versions of **E**, and indeed it was in this context that McCall first introduced mingle, albeit in the strict form (remember $\vec{A} = A_1 \rightarrow A_2$),

$$\vec{A} \rightarrow (\vec{A} \rightarrow \vec{A}) \quad \vec{\text{Mingle}} \quad (24)$$

(cf. [Dunn, 1976c]).

We finish our discussion of axiomatics with a brief discussion of first-order relevance logics, which we shall denote by **RQ**, **EQ**, etc. We shall presuppose a standard definition of first-order formula (with connectives $\neg, \wedge, \vee, \rightarrow$ and quantifiers \forall, \exists). For convenience we shall suppose that we have two denumerable stocks of variables: the bound variables x, y , etc.

and the free variables (sometimes called parameters) a, b , etc. The bound variables are never allowed to have unbound occurrences.

The quantifier laws were set down by Anderson and Belnap in accord with the analogy of the universal quantifier with a conjunction (or its instances), and the existential quantifier as a disjunction. In view of the validity of quantifier interchange principles, we shall for brevity take only the universal quantifier \forall as primitive, defining $\exists xA =_{df} \neg\forall x\neg A$. We thus need

$$\forall xA \rightarrow A(a/x) \quad \forall\text{-elimination} \quad (25)$$

$$\forall x(A \rightarrow B) \rightarrow (A \rightarrow \forall xB) \quad \forall\text{-introduction} \quad (26)$$

$$\forall x(A \vee B) \rightarrow A \vee \forall xB \quad \text{Confinement.} \quad (27)$$

If there are function letters or other term forming operators, then (25) should be generalised to $\forall xA \rightarrow A(t/x)$, where t is any term (subject to our conventions that the ‘bound variables’ x, y , etc. do not occur (‘free’) in it). Note well that because of our convention that ‘bound variables’ do not occur free, the usual proviso that x does not occur free in A in (26) and (27) is automatically satisfied. (27) is the obvious ‘infinite’ analogy of Distribution, and as such it causes as many technical problems for **RQ** as does Distribution for **R** (cf. Section 4.8). Finally, as an additional rule corresponding to adjunction, we need:

$$\frac{A(a/x)}{\forall xA} \quad \text{Generalisation.} \quad (28)$$

There are various more or less standard ways of varying this formulation. Thus, e.g. (cf. Meyer, Dunn and Leblanc [1974]) one can take all universal generalisations of axioms, thus avoiding the need for the rule of Generalisation. Also (26) can be ‘split’ into two parts:

$$\forall x(A \rightarrow B) \rightarrow (\forall xA \rightarrow \forall xB) \quad (26a)$$

$$A \rightarrow \forall xA \quad \text{Vacuous Quantification} \quad (26b)$$

(again note that if we allowed x to occur free we would have to require that x not be free in A).

The most economical formulation is due to Meyer [1970]. It uses only the axiom scheme of \forall -elimination and the rule.

$$\frac{A \rightarrow B \vee C(a/x)}{A \rightarrow B \vee \forall xC} \quad (a \text{ cannot occur in } A \text{ or } B) \quad (29)$$

which combines (26)–(28).

1.4 Deduction Theorems in Relevance Logic

Let **X** be a formal system, with certain formulas of **X** picked out as *axioms* and certain (finitary) relations among the formulas of **X** picked out as *rules*.

(For the sake of concreteness, \mathbf{X} can be thought of as any of the Hilbert-style systems of the previous section.) Where Γ is a list of formulas of \mathbf{X} (thought of as *hypotheses*) it is customary to define a *deduction from* Γ to be a sequence B_1, \dots, B_n , where for each B_i ($1 \leq i \leq n$), either (1) B_i is in Γ , or (2) B_i is an axiom of \mathbf{X} , or (3) B_i ‘follows from’ earlier members of the sequence, i.e. $R(B_{j_1}, \dots, B_{j_k}, B_i)$ holds for some $(k+1)$ —any rule R of \mathbf{X} and B_{j_1}, \dots, B_{j_k} all precede B_i in the sequence B_1, \dots, B_n . A formula A is then said to be *deducible* from Γ just in case there is some deduction from Γ terminating in A . We symbolise this as $\Gamma \vdash_{\mathbf{X}} A$ (often suppressing the subscript).

A *proof* is of course a deduction from the empty set, and a theorem is just the last item in a proof. There is the well-known

DEDUCTION THEOREM (Herbrand). *If $A_1, \dots, A_n, A \vdash_{\mathbf{H}_{\rightarrow}} B$, then we have also $A_1, \dots, A_n \vdash_{\mathbf{H}_{\rightarrow}} A \rightarrow B$.*

This theorem is proven in standard textbooks for classical logic, but the standard inductive proof shows that in fact the Deduction Theorem holds for any formal system \mathbf{X} having *modus ponens* as its sole rule and $\mathbf{H}_{\rightarrow} \subseteq \mathbf{X}$ (i.e. each instance of an axiom scheme of \mathbf{H}_{\rightarrow} is a theorem of \mathbf{X}). Indeed \mathbf{H}_{\rightarrow} can be motivated as the minimal pure implicational calculus having *modus ponens* as its sole rule and satisfying the Deduction Theorem. This is because the axioms of \mathbf{H}_{\rightarrow} can all be derived as theorems in any formal system \mathbf{X} using merely *modus ponens* and the supposition that \mathbf{X} satisfies the Deduction Theorem. Thus consider as an example:

- | | |
|--|-------------------------|
| (1) $A, B \vdash A$ | Definition of \vdash |
| (2) $A \vdash B \rightarrow A$ | (1), Deduction Theorem |
| (3) $\vdash A \rightarrow (B \rightarrow A)$ | (2), Deduction Theorem. |

Thus the most problematic axiom of \mathbf{H}_{\rightarrow} has a simple ‘*a priori* deduction’, indeed one using only the Deduction Theorem, not even *modus ponens* (which is though needed for more sane axioms like Self-Distribution).

It might be thought that the above considerations provide a very powerful argument for motivating intuitionistic logic (or at least some logic having the same implicational fragment) as The One True Logic. For what else should an implication do but satisfy *modus ponens* and the Deduction Theorem?

But it turns out that there is another sensible notion of deduction. This is what is sometimes called a *relevant deduction*. (Anderson and Belnap [1975, Section 22.2.1] claim that this is the *only* sensible notion of deduction, but we need not follow them in that). If there is anything that sticks out in the *a priori* deduction of Positive Paradox above it is that in (1), B was not *used* in the deduction of A .

A number of researchers have been independently bothered by this point and have been motivated to study a relevant implication that goes hand in

hand with a notion of relevant deduction. This, in this manner Moh [1950] and Church [1951b] came up with what is in effect \mathbf{R}_{\rightarrow} . And Anderson and Belnap [1975, p. 261] say “In fact, the search for a suitable deduction theorem for Ackermann’s systems ... provided the impetus leading us to the research reported in this book.” This research program begun in the late 1950s took its starting point in the system(s) of Ackermann [1956], and the bold stroke separating the Anderson–Belnap system \mathbf{E} from Ackermann’s system Π' was basically the dropping of Ackermann’s rule γ so as to have an appropriate deduction theorem (cf. Section 2.1).

Let us accordingly define a deduction of B from A_1, \dots, A_n to be *relevant with respect to a given hypothesis A_i* just in case A_i is actually *used* in the given deduction of B in the sense (paraphrasing [Church, 1951b]) that there is a chain of inferences connecting A_i with the final formula B . This last can be made formally precise in any number of ways, but perhaps the most convenient is to flag A_i with say a \sharp and to pass the flag along in the deduction each time *modus ponens* is applied to two items at least one of which is flagged. It is then simply required that the last step of the deduction (B) be flagged. Such devices are familiar from various textbook presentations of classical predicate calculus when one wants to keep track whether some hypothesis $A_i(x)$ was used in the deduction of some formula $B(x)$ to which one wants to apply Universal Generalisation.

We shall define a deduction of B from A_1, \dots, A_n to be *relevant simpliciter* just in case it is relevant with respect to each hypothesis A_i . A practical way to test for this is to flag each A_i with a different flag (say the subscript i) and then demand that all of the flags show up on the last step B .

We can now state a version of the

RELEVANT DEDUCTION THEOREM (Moh, Church). *If there is a deduction in \mathbf{R}_{\rightarrow} of B from A_1, \dots, A_n, A that is relevant with respect to A , then there is a deduction in \mathbf{R}_{\rightarrow} of $A \rightarrow B$ from A_1, \dots, A_n . Furthermore the new deduction will be ‘as relevant’ as the old one, i.e. any A_i that was used in the given deduction will be used in the new deduction.*

Proof. Let the given deduction be B_1, \dots, B_k , and let it be given with a particular analysis as to how each step is justified. By induction we show for each B_i that if A was used in obtaining B_i (B_i is flagged), then there is a deduction of $A \rightarrow B_i$ from A_1, \dots, A_n , and otherwise there is a deduction of B_i from those same hypotheses. The tedious business of checking that the new deduction is as relevant as the old one is left to the reader. We divide up cases depending on how the step B_i is justified.

Case 1. B_i was justified as a hypothesis. Then neither B_i is A or it is some A_j . But $A \rightarrow A$ is an axiom of \mathbf{R}_{\rightarrow} (and hence deducible from A_1, \dots, A_n), which takes care of the first alternative. And clearly on the second alternative B_i is deducible from A_1, \dots, A_n (being one of them).

Case 2. B_i was justified as an axiom. Then A was not used in obtaining B_i , and of course B_i is deducible (being an axiom).

Case 3. B_i was justified as coming from preceding steps $B_j \rightarrow B_i$ and B_j by *modus ponens*. There are four subcases depending on whether A was used in obtaining the premises.

Subcase 3.1. A was used in obtaining both $B_j \rightarrow B_i$ and B_j . Then by inductive hypothesis $A_1, \dots, A_n \vdash_{\mathbf{R}\rightarrow} A \rightarrow (B_j \rightarrow B_i)$ and $A_1, \dots, A_n \vdash_{\mathbf{R}\rightarrow} A \rightarrow B_j$. So $A \rightarrow B$ may be obtained using the axiom of Self-Distribution.

Subcase 3.2. A was used in obtaining $B_j \rightarrow B_i$ but not B_j . Use the axiom of Permutation to obtain $A \rightarrow B_i$ from $A \rightarrow (B_j \rightarrow B_i)$ and B_j .

Subcase 3.3. A was not used in obtaining $B_j \rightarrow B_i$ but was used for B_j . Use the axiom of Prefixing to obtain $A \rightarrow B_i$ from $B_j \rightarrow B_i$ and $A \rightarrow B_j$.

Subcase 3.4. A was not used in obtaining either $B_j \rightarrow B_i$ nor B_j . Then B_i follows from these using just *modus ponens*.

Incidentally, $\mathbf{R}\rightarrow$ can easily be verified to be the minimal pure implicational calculus having *modus ponens* as sole rule and satisfying the Relevant Deduction Theorem, since each of the axioms invoked in the proof of this theorem can be easily seen to be theorems in any such system (cf. the next section for an illustration of sorts).

There thus seem to be at least two natural competing pure implicational logics $\mathbf{R}\rightarrow$ and $\mathbf{H}\rightarrow$, differing only in whether one wants one's deductions to be relevant or not.⁵ ■

Where does the Anderson–Belnap's [1975] preferred system $\mathbf{E}\rightarrow$ fit into all of this? The key is that the implication of $\mathbf{E}\rightarrow$ is both a strict and a relevant implication (cf. Section 1.3 for some subtleties related to this claim). As such, and since Anderson and Belnap have seen fit to give it the modal structure of the Lewis system $\mathbf{S4}$, it is appropriate to recall the appropriate deduction theorem for $\mathbf{S4}$.

MODAL DEDUCTION THEOREM [Barcan Marcus, 1946] *If $A_1 \rightarrow B_1, \dots, A_n \rightarrow B_n, A \vdash_{\mathbf{S4}} B$ (\rightarrow here denotes strict implication), then $A_1 \rightarrow B_1, \dots, A_n \rightarrow B_n \vdash_{\mathbf{S4}} A \rightarrow B$.*

The idea here is that in general in order to derive the strict (*necessary*) implication $A \rightarrow B$ one must not only be able to deduce B from A and some other hypotheses but furthermore those other hypotheses must be supposed to be necessary. And in $\mathbf{S4}$ since $A_i \rightarrow B_j$ is equivalent to $\Box(A_i \rightarrow B_j)$, requiring those additional hypotheses to be strict implications at least suffices for this.

Thus we could only hope that $\mathbf{E}\rightarrow$ would satisfy the

⁵This seems to differ from the good-humoured polemical stand of Anderson and Belnap [1975, Section 22.2.1], which says that the first kind of 'deduction', which they call (pejoratively) 'Official deduction', is no kind of deduction at all.

MODAL RELEVANT DEDUCTION THEOREM [Anderson and Belnap, 1975]
If there is a deduction in \mathbf{E}_{\rightarrow} of B from $A_1 \rightarrow B_1, \dots, A_n \rightarrow B_n, A$ that is relevant with respect to A , then there is a deduction in \mathbf{E}_{\rightarrow} of $A \rightarrow B$ from $A_1 \rightarrow B_1, \dots, A_n \rightarrow B_n$ that is as relevant as the original.

The proof of this theorem is somewhat more complicated than its unmodalised counterpart which we just proved (cf. [Anderson and Belnap, 1975, Section 4.21] for a proof).

We now examine a subtle distinction (stressed by Meyer—see, for example, [Anderson and Belnap, 1975, pp. 394–395]), postponed until now for pedagogical reasons. We must ask, how many hypotheses can dance on the head of a formula? The question is: given the list of hypotheses A, A , do we have one hypothesis or two? When the notion of a *deduction* was first introduced in this section and a ‘list’ of hypotheses Γ was mentioned, the reader would naturally think that this was just informal language for a set. And of course the set $\{A, A\}$ is identical to the set $\{A\}$. Clearly A is relevantly deducible from A . The question is whether it is so deducible from A, A . We have then two different criteria of use, depending on whether we interpret hypotheses as grouped together into lists that distinguish multiplicity of occurrences (sequences)⁶ or sets. This issue has been taken up elsewhere of late, with other accounts of deduction appealing to ‘resource consciousness’ [Girard, 1987; Troelstra, 1992; Schroeder-Heister and Došen, 1993] as motivating some non-classical logics. Substructural logics in general appeal to the notion that the number of times a premise is used, or even more radically, the *order* in which premises are used, matter.

At issue in \mathbf{R} and its neighbours is whether $A \rightarrow (A \rightarrow A)$ is a correct relevant implication (coming by two applications of ‘The Deduction Theorem’ from $A, A \vdash A$). This is in fact not a theorem of \mathbf{R} , but it is the characteristic axiom of \mathbf{RM} (cf. Section 1.3). So it is important that in the Relevant Deduction Theorem proved for \mathbf{R}_{\rightarrow} that the hypotheses A_1, \dots, A_n be understood as a sequence in which the same formula may occur more than once. One can prove a version of the Relevant Deduction Theorem with hypotheses understood as collected into a set for the system $\mathbf{RMO}_{\rightarrow}$, obtained by adding $A \rightarrow (A \rightarrow A)$ to \mathbf{R}_{\rightarrow} (but the reader should be told that Meyer has shown that $\mathbf{RMO}_{\rightarrow}$, is *not* the implicational fragment of \mathbf{RM} , cf. [Anderson and Belnap, 1975, Section 8.15]).⁷

⁶Sequences are not quite the best mathematical structures to represent this grouping since it is clear that the order of hypotheses makes no difference (at least in the case of \mathbf{R}). Meyer and McRobbie [1979] have investigated ‘firesets’ (finitely repeatable sets) as the most appropriate abstraction.

⁷Arnon Avron has defended this system, $\mathbf{RMO}_{\rightarrow}$, as a natural way to characterise relevant implication [Avron, 1986; Avron, 1990a; Avron, 1990b; Avron, 1990c; Avron, 1992]. In Avron’s system, conjunction and disjunction are *intensional* connectives, defined in terms of the implication and negation of $\mathbf{RMO}_{\rightarrow}$. As a result, they do

Another consideration pointing to the *naturalness* of \mathbf{R}_{\rightarrow} is its connection to the λI -calculus. A formula is a theorem of \mathbf{R}_{\rightarrow} if and only if it is the type of a closed term of the λI -calculus as defined by Church. A λI term is a λ term in which every lambda abstraction binds at least one free variable. So, $\lambda x.\lambda y.xy$ has type $A \rightarrow ((A \rightarrow B) \rightarrow B)$, and so, is a theorem of \mathbf{R}_{\rightarrow} , while $\lambda x.\lambda y.x$, has type $A \rightarrow (B \rightarrow A)$, which is an intuitionistic theorem, but not an \mathbf{R}_{\rightarrow} theorem. This is reflected in the λ term, in which the λy does not bind a free variable.

We now briefly discuss what happens to deduction theorems when the pure implication systems \mathbf{R}_{\rightarrow} and \mathbf{E}_{\rightarrow} are extended to include other connectives, especially \wedge . \mathbf{R} will be the paradigm, its situation extending straight-forwardly to \mathbf{E} . The problem is that the full system \mathbf{R} seems not to be formulable with *modus ponens* as the sole rule; there is also need for adjunction ($A, B \vdash A \wedge B$) (cf. Section 1.3).

Thus when we think of proving a version of the Relevant Deduction Theorem for the full system \mathbf{R} , it would seem that we are forced to think through once more the issue of when a hypothesis is used, this time with relation to adjunction. It might be thought that the thing to do would be to pass the flag \ddagger along over an application of adjunction so that $A \wedge B$ ends up flagged if either of the premises A or B was flagged, in obvious analogy with the decision concerning *modus ponens*.

Unfortunately, that decision leads to disaster. For then the deduction $A, B \vdash A \wedge B$ would be a relevant one (both A and B would be ‘used’), and two applications of ‘The Deduction Theorem’ would lead to the thesis $A \rightarrow (B \rightarrow A \wedge B)$, the undesirability of which has already been remarked.

A more appropriate decision is to count hypotheses as used in obtaining $A \wedge B$ just when they were used to obtain both premises. This corresponds to the axiom of Conjunction Introduction $(C \rightarrow A) \wedge (C \rightarrow B) \rightarrow (C \rightarrow A \wedge B)$, which thus handles the case in the inductive proof of the deduction theorem when the adjunction is applied. This decision may seem *ad hoc* (perhaps ‘use’ simpliciter is not quite the right concept), but it is the only decision to be made unless one wants to say that the hypothesis A can (in the presence of the hypothesis B) be ‘used’ to obtain $A \wedge B$ and hence B (passing on the flag from A this way is something like laundering dirty money).

This is the decision that was made by Anderson and Belnap in the context of natural deduction systems (see next section), and it was applied by Kron [1973; 1976] in proving appropriate deduction theorems for \mathbf{R} , \mathbf{E} (and \mathbf{T}). It should be said that the appropriate Deduction Theorem requires simultaneous flagging of the hypothesis (distinct flags being applied to each formula occurrence, say using subscripts in the manner of the ‘practical suggestion’ after our definition of relevant deduction for \mathbf{R}_{\rightarrow}), with the requirement that all of the subscripts are passed on to the conclusion. So the

not have all of the distributive lattice properties of traditional relevance logics.

Deduction Theorem applies only to *fully* relevant deductions, where every premise is used (note that no such restriction was placed on the Relevant Deduction Theorem for \mathbf{R}_{\rightarrow}).

An alternative stated in Meyer and McRobbie [1979] would be to adjust the definition of deduction, modifying clause (2) so as to allow as a step in a deduction any theorem (not just axiom) of \mathbf{R} , and to restrict clause (3) so that the only rule allowed in moving to later steps is *modus ponens*.⁸ This is in effect to restrict adjunction to theorems, and reminds one of similar restrictions in the context of deduction theorems of similarly restricting the rules of necessitation and universal generalisation. It has the virtue that the Relevant Deduction Theorem and its proof are the same as for \mathbf{R}_{\rightarrow} . (Incidentally, Meyer's and Kron's sense of deduction coincide when all of A_1, \dots, A_n are used in deducing B ; this is obvious in one direction, and less than obvious in the other.)

There are yet two other versions of the deduction theorem that merit discussion in the context of relevance logic (relevance logic, as Meyer often points out, allows for many distinctions).

First in Belnap [1960b] and Anderson and Belnap [1975], there is a theorem (stated for \mathbf{E} , but we will state it for our paradigm \mathbf{R}) called The Entailment Theorem, which says that A_1, \dots, A_n 'entails' B iff $\vdash_{\mathbf{R}} (A_1 \wedge \dots \wedge A_n) \rightarrow B$. A formula B is defined in effect to be *entailed* by hypothesis A_1, \dots, A_n just in case there is a deduction of B using their conjunction $A_1 \wedge \dots \wedge A_n$. Adjunction is allowed, but subject to the restriction that the conjunctive hypothesis was used in obtaining both premises. The Entailment Theorem is clearly implied by Kron's version of the Deduction Theorem.

The last deduction theorem for \mathbf{R} we wish to discuss is the

ENTHYMEMATIC DEDUCTION THEOREM (Meyer, Dunn and Leblanc [1974]).
If $A_1, \dots, A_n, A \vdash_{\mathbf{R}} B$, then $A_1, \dots, A_n \vdash_{\mathbf{R}} A \wedge t \rightarrow B$.

Here ordinary deducibility is all that is at issue (no insistence on the hypotheses being used). It can either be proved by induction, or cranked out of one of the more relevant versions of the deduction theorem. Thus it falls out of the Entailment Theorem that

$$\vdash_{\mathbf{R}} X \wedge A \wedge T \rightarrow B,$$

where X is the conjunction of A_1, \dots, A_n , and T is the conjunction of all the axioms of \mathbf{R} used in the deduction of B . But since $\vdash_{\mathbf{R}} t \rightarrow T$, we have $\vdash_{\mathbf{R}} X \wedge A \wedge t \rightarrow B$.

⁸Of course this requires we give an independent characterisation of *proof* (and *theorem*), since we can no longer define a *proof* as a deduction from zero premisses. We thus define a proof as a sequence of formulas, each of which is either an axiom or follows from preceding items by either *modus ponens* or adjunction (!).

However, the following **R** theorem holds:

$$\vdash_{\mathbf{R}} (X \wedge A \wedge t \rightarrow B) \rightarrow (X \wedge t \rightarrow (A \wedge t \rightarrow B)).$$

So $\vdash_{\mathbf{R}} X \wedge t \rightarrow (A \wedge t \rightarrow B)$, which leads (using $\vdash_{\mathbf{R}} t$) to $X \vdash_{\mathbf{R}} A \wedge t \rightarrow B$, which dissolving the conjunction gives the desired

$$A_1, \dots, A_n \vdash_{\mathbf{R}} A \wedge t \rightarrow B.$$

In view of the importance of the notion, let us symbolise $A \wedge t \rightarrow B$ as $A \rightarrow_t B$. This functions as a kind of ‘enthymematic implication’ (A and some truth *really implies* B) and there will be more about Anderson, Belnap and Meyer’s investigations of this concept in Section 1.7. Let us simply note now that in the context of deduction theorems, it functions like intuitionistic implication, and allows us in \mathbf{R}_{\rightarrow} to have two different kinds of implication, each well motivated in its relation to the two different kinds of deducibility (ordinary and relevant).⁹ For a more extensive discussion of deduction theorems in relevance logics and related systems, more recent papers by Avron [1991] and Brady [1994] should be consulted.

1.5 Natural Deduction Formulations

We shall be very brief about these since natural deduction methods are amply discussed by Anderson and Belnap [1975], where such methods in fact are used as a major motivation for relevance logic. Here we shall concentrate on a natural deduction system \mathbf{NR} for **R**.

The main idea of natural deduction (cf. Chapters [[were I.1 and I.2]] of the *Handbook*) of course is to allow the making of temporary hypotheses, with some device usually being provided to facilitate the book-keeping concerning the use of hypotheses (and when their use is ‘discharged’). Several textbooks (for example, [Suppes, 1957] and [Lemmon, 1965])¹⁰ have used the device of in effect subscripting each hypothesis made with a distinct numeral, and then passing this numeral along with each application of a rule, thus keeping track of which hypothesis are used. When a hypothesis is discharged, the subscript is dropped. A line obtained with no subscripts is a ‘theorem’ since it depends on no hypotheses.

Let us then let α, β , etc. range over classes of numerals. The rules for \rightarrow are then naturally:

$$\frac{\frac{A \rightarrow B_{\alpha}}{A_{\beta}} \quad [\rightarrow E]}{B_{\alpha \cup \beta}} \quad \frac{\frac{A_{\{k\}}}{\vdots} \quad B_{\alpha}}{A \rightarrow B_{\alpha - \{k\}}} \quad [\rightarrow I]}{A \rightarrow B_{\alpha - \{k\}}} \quad (\text{provided } k \in \alpha)$$

⁹In **E** enthymematic implication is like **S4** strict implication. See [Meyer, 1970a].

¹⁰The idea actually originates with [Feys and Ladrière, 1955].

Two fussy, really incidental remarks must be made. First, in the rule $\rightarrow E$ it is to be understood that the premises need not occur in the order listed, nor need they be adjacent to each other or to the conclusion. Otherwise we would need a rule of ‘Repetition’, which allows the repeating of a formula with its subscripts as a later line. (Repetition is trivially derivable given our ‘non-adjacent’ understanding of $\rightarrow E$ —in order to repeat A_α , just prove $A \rightarrow A$ and apply $\rightarrow E$.) Second, it is understood that we have what one might call a rule of ‘Hypothesis Introduction’: anytime one likes one can write a formula as a line with a new subscript (perhaps most conveniently, the line number).

Now a non-fussy remark must be made, which is really the heart of the whole matter. In the rule for $\rightarrow I$, a *proviso* has been attached which has the effect of requiring that the hypothesis A was actually used in obtaining B . This is precisely what makes the implication relevant (one gets the intuitionistic implication system \mathbf{H}_\rightarrow if one drops this requirement). The reader should find it instructive to attempt a proof of Positive Paradox ($A \rightarrow (B \rightarrow A)$) and see how it breaks down for \mathbf{NR}_\rightarrow (but succeeds in \mathbf{NH}_\rightarrow). The reader should also construct proofs in \mathbf{NR}_\rightarrow of all the axioms in one of the Hilbert-style formulations of \mathbf{R}_\rightarrow from Section 1.3.

Then the equivalence of \mathbf{R}_\rightarrow in its Hilbert-style and natural deduction formulations is more or less self-evident given the Relevant Deduction Theorem (which shows that the rule $\rightarrow I$ can be ‘simulated’ in the Hilbert-style system, the only point at issue).

Indeed it is interesting to note that Lemmon [1965], who *seems* to have the same *proviso* on $\rightarrow I$ that we have for \mathbf{NR}_\rightarrow (his actual language is a bit informal), does not prove Positive Paradox until his *second* chapter adding conjunction (and disjunction) to the implication-negation system he developed in his first chapter. His proof of Positive Paradox depends finally upon an ‘irrelevant’ $\wedge I$ rule. The following is perhaps the most straightforward proof in his system (differing from the proof he actually gives):

(1)	A_1	Hyp
(2)	B_2	Hyp
(3)	$A \wedge B_{1,2}$	1, 2, $\wedge I$?
(4)	$A_{1,2}$	3, $\wedge E$
(5)	$B \rightarrow A_1$	2, 4, $\rightarrow I$
(6)	$A \rightarrow (B \rightarrow A)$	1, 5, $\rightarrow I$.

We think that the manoeuvre used in getting B ’s 2 to show up attached to A in line (4) should be compared to laundering dirty money by running it through an apparently legitimate business. The correct ‘relevant’ versions

of the conjunction rules are instead

$$\frac{A_\alpha}{B_\alpha} \quad [\wedge I] \quad \frac{A \wedge B_\alpha}{A_\alpha} \quad \frac{A \wedge B_\alpha}{B_\alpha} \quad [\wedge E]$$

What about disjunction? In **R** (also **E**, etc.) one has de Morgan's Laws and Double Negation, so one can simply define $A \vee B = \neg(\neg A \wedge \neg B)$. One might think that settling down in separate int-elim rules for \vee would then only be a matter of convenience. Indeed, one can find in [Anderson and Belnap, 1975] in effect the following rules:

$$\frac{A_\alpha}{A \vee B_\alpha} \quad \frac{B_\alpha}{A \vee B_\alpha} \quad [\vee I] \quad \begin{array}{c} A \vee B_\alpha \\ \vdots \\ A_k \\ \vdots \\ C_{\beta \cup \{k\}} \\ B_h \\ \vdots \\ C_{\beta \cup \{h\}} \\ \hline C_{\alpha \cup \beta} \end{array} \quad [\vee E]$$

But (as Anderson and Belnap point out) these rules are insufficient. From them one cannot derive the following

$$\frac{A \wedge (B \vee C)_\alpha}{(A \wedge B) \vee C_\alpha} \text{ Distribution.}$$

And so it must be taken as an additional rule (even if disjunction is defined from conjunction and negation).

This is clearly an unsatisfying, if not unsatisfactory, state of affairs. The customary motivation behind int-elim rules is that they show how a connective may be introduced into and eliminated from argumentative discourse (in which it has no essential occurrence), and thereby give the connective's role or meaning. In this context the Distribution rule looks very much to be regretted.

One remedy is to modify the natural deduction system by allowing hypotheses to be introduced in two different ways, 'relevantly' and 'irrelevantly'. The first way is already familiar to us and is what requires a subscript to keep track of the relevance of the hypothesis. It requires that the hypotheses introduced this way will *all* be used to get the conclusion. The second way involves only the weaker promise that at least *some* of the hypotheses so introduced will be used. This suggestion can be formalised by

allowing several hypotheses to be listed on a line, but with a single relevance numeral attached to them as a bunch. Thus, schematically, an argument of the form

$$\begin{array}{l} (1) \quad A, B_1 \\ (2) \quad C, D_2 \\ \quad \quad \vdots \\ (k) \quad E_{1,2} \end{array}$$

should be interpreted as establishing

$$A \wedge B \rightarrow (C \wedge D \rightarrow E).$$

Now the natural deduction rules must be stated in a more general form allowing for the fact that more than one formula can occur on a line. Key among these would be the new rule:

$$\frac{\begin{array}{l} \Gamma, A \vee B_\alpha \\ \quad \quad \vdots \\ \Gamma, A_k \\ \quad \quad \vdots \\ \Delta_{\beta \cup \{k\}} \quad [VE'] \\ \Gamma, B_l \\ \quad \quad \vdots \\ \Delta_{\beta \cup \{l\}} \end{array}}{\Delta_{\alpha \cup \beta}}$$

It is fairly obvious that this rule has Distribution built into it. Of course, other rules must be suitably modified. It is easiest to interpret the formulas on a line as grouped into a set so as not to have to worry about ‘structural rules’ corresponding to the commutation and idempotence of conjunction.

The rules $\rightarrow I$, $\rightarrow E$, $\vee I$, $\vee E$, $\wedge I$, and $\wedge E$ can all be left as they were (or except for $\rightarrow I$ and $\rightarrow E$, trivially generalised so as to allow for the fact that the premises might be occurring on a line with several other ‘irrelevant’ premises), but we do need one new structural rule:

$$\frac{\Gamma_\alpha \quad \Delta_\alpha}{\Gamma, \Delta_\alpha} \quad [\text{Comma } I]$$

Once we have this it is natural to take the conjunction rules in ‘Ketonen form’:

$$\frac{\Gamma, A, B_\alpha}{\Gamma, A \wedge B_\alpha} \quad [\wedge I']$$

$$\frac{\Gamma, A \wedge B_\alpha}{\Gamma, A, B_\alpha} [\wedge E']$$

with the rule

$$\frac{\Gamma, \Delta_\alpha}{\Gamma_\alpha} [\text{Comma } E]$$

It is merely a tedious exercise for the reader to show that this new system $N'\mathbf{R}$ is equivalent to $N\mathbf{R}$. Incidentally, $N'\mathbf{R}$ was suggested by reflection upon the Gentzen System LR^+ of Section 4.9.

Before leaving the question of natural deduction for \mathbf{R} , we would like to mention one or two technical aspects. First, the system of Prawitz [1965] differs from \mathbf{R} in that it lacks the rule of Distribution. This is perhaps compensated for by the fact that Prawitz can prove a normal form theorem for proofs in his system. A different system yet is that of [Pottinger, 1979], based on the idea that the correct $\wedge I$ rule is

$$\frac{\begin{array}{c} A_\alpha \\ B_\beta \end{array}}{A \wedge B_{\alpha \cup \beta}}$$

He too gets a normal form theorem. We conjecture that some appropriate normal form theorem is provable for the system $N'\mathbf{R}^+$ on the well-known analogy between cut-elimination and normalisation and the fact that cut-elimination has been proven for LR^+ (cf. Section 4.9). Negation though would seem to bring extra problems, as it does when one is trying to add it to LR^+ .

One last set of remarks, and we close the discussion of natural deduction. The system $N\mathbf{R}$ above differs from the natural deduction system for \mathbf{R} of Anderson and Belnap [1975]. Their system is a so-called ‘Fitch-style’ formalism, and so named $F\mathbf{R}$. The reader is presumed to know that in this formalism when a hypothesis is introduced it is thought of as starting a subproof, and a line is drawn along the left of the subproof (or a box is drawn around the subproof, or some such thing) to demarcate the scope of the hypothesis. If one is doing a natural deduction system for classical or intuitionistic logic, subproofs or dependency numerals can either one be used to do essentially the same job of keeping track the use of hypotheses (though dependency numerals keep more careful track, and that is why they are so useful for relevant implication).

Mathematically, a Fitch-style proof is a nested structure, representing the fact that subproofs can contain further subproofs, etc. But once one has dependency numerals, this extra structure, at least for \mathbf{R} , seems otiose, and so we have dispensed with it. The story for \mathbf{E} is more complex, since

on the Anderson and Belnap approach **E** differs from **R** only in what is allowed to be ‘reiterable’ into subproof. Since implication in **E** is necessary as well as relevant, the story is that in deducing B from A in order to show $A \rightarrow B$, one should only be allowed to use items that have been assumed to be necessarily true, and that these can be taken to be formulas of the form $C \rightarrow D$. So only formulas of this form can be reiterated for use in the subproof from A to B . Working out how best to articulate this idea using only dependency numerals (no lines, boxes, etc.) is a little messy. This concern to keep track of how premises are used in a proof by way of labels has been taken up in a general way by recent work on *Labelled Deductive Systems* [D’Agostino and Gabbay, 1994; Gabbay, 1997].

We would be remiss not to mention other formulations of natural deduction systems for relevance logics and their cousins. A different generalisation of Hunter’s natural deduction systems (which follows more closely the Gentzen systems for positive logics — see Section 4.9) is in [Read, 1988; Slaney, 1990].¹¹

1.6 Basic Formal Properties of Relevance Logic

This section contains a few relatively simple properties of relevance logics, proofs for which can be found in [Anderson and Belnap, 1975]. With one exception (the ‘Ackermann Properties’—see below), these properties all hold for both the system **R** and **E**, and indeed for most of the relevance logics defined in Section 1.3. For simplicity, we shall state these properties for sentential logics, but appropriate versions hold as well for their first-order counterparts.

First we examine the REPLACEMENT THEOREM *For both R and E*,

$$\vdash (A \leftrightarrow B) \wedge t \rightarrow (\chi(A) \leftrightarrow \chi(B)).$$

Here $\chi(A)$ is any formula with perhaps some occurrences of A and $\chi(B)$ is the result of perhaps replacing one or more of those occurrences by B . The proof is by a straightforward induction on the complexity of $\chi(A)$, and one clear role of the conjoined t is to imply $\chi \rightarrow \chi$ when $\chi(= \chi(A))$ contains no occurrences of A , or does but none of them is replaced by B . It might be thought that if these degenerate cases are ruled out by requiring that some actual occurrence of A be replaced by B , then the need for t would vanish. This is indeed true for the implication-negation (and of course the pure implication) fragments of **R** and **E**, but not for the whole systems in virtue of the non-theoremhood of what V. Routley has dubbed ‘Factor’:

¹¹The reader should be informed that still other natural deduction formalisms for **R** of various virtues can be found in [Meyer, 1979b] and [Meyer and McRobbie, 1979].

1. $(A \rightarrow B) \rightarrow (A \wedge \chi \rightarrow B \wedge \chi)$.

Here the closest one can come is to

2. $(A \rightarrow B) \wedge t \rightarrow (A \wedge \chi \rightarrow B \wedge \chi)$,

the conjoined g giving the force of having $\chi \rightarrow \chi$ in the antecedent, and the theorem $(A \rightarrow B) \wedge (\chi \rightarrow \chi) \rightarrow (A \wedge \chi \rightarrow B \wedge \chi)$ getting us home. (2) of course is just a special case of the Replacement Theorem. Of more ‘relevant’ interest is the

VARIABLE SHARING PROPERTY. If $A \rightarrow B$ is a theorem of **R** (or **E**), then there exists some sentential variable p that occurs in both A and B . This is understood by Anderson and Belnap as requiring some commonality of meaning between antecedent and consequent of logically true relevant implications. The proof uses an ingenious logical matrix, having eight values, for which see [Anderson and Belnap, 1975, Section 22.1.3]. There are discussed both the original proof of Belnap and an independent proof of Dončenko, and strengthening by Maksimova. Of modal interest is the

ACKERMANN PROPERTY. No formula of the form $A \rightarrow (B \rightarrow C)$ (A containing no \rightarrow) is a theorem of **E**. The proof again uses an ingenious matrix (due to Ackermann) and has been strengthened by Maksimova (see [Anderson and Belnap, 1975, Section 22.1.1 and Section 22.1.2]) (contributed by J. A. Coffa) on ‘fallacies of modality’.

1.7 First-degree Entailments

A *zero degree formula* contains only the connectives \wedge, \vee , and \neg , and can be regarded as either a formula of relevance logic or of classical logic, as one pleases. A *first degree implication* is a formula of the form $A \rightarrow B$, where both A and B are zero-degree formulas: Thus first degree implications can be regarded as either a restricted fragment of some relevance logic (say **R** or **E**) or else as expressing some metalinguistic logical relation between two classical formulas A and B . This last is worth mention, since then even a classical logician of Quinean tendencies (who remains unconverted by the considerations of Section 1.2 in favour of nested implications) can still take first degree logical relevant implications to be legitimate.

A natural question is what is the relationship between the provable first-degree implications of **R** and those of **E**. It is well-known that the corresponding relationship between classical logic and some normal modal logic, say **S4** (with the \rightarrow being the material conditional and strict implication, respectively), is that they are identical in their first degree fragments. The same holds of **R** and **E** (cf. [Anderson and Belnap, 1975, Section 2.42]).

This fragment, which we shall call **R_{fd_e}** (Anderson and Belnap [1975] call it **E_{fd_e}**) is stable (cf. [Anderson and Belnap, 1975, Section 7.1]) in the sense

that it can be described from a variety of perspectives. For some semantical perspectives see Sections 3.3 and 3.4. We now consider some syntactical perspectives of more than mere ‘orthographic’ significance.

The perhaps least interesting of these perspectives is a ‘Hilbert-style’ presentation of $\mathbf{R}_{\mathbf{fde}}$ (cf. [Anderson and Belnap, 1975, Section 15.2]). It has the following axioms:

3. $A \wedge B \rightarrow A, A \wedge B \rightarrow B$ Conjunction Elimination
4. $A \rightarrow A \vee B, B \rightarrow A \vee B$ Disjunction Introduction
5. $A \wedge (B \vee C) \rightarrow (A \wedge B) \vee C$ Distribution
6. $A \rightarrow \neg\neg A, \neg\neg A \rightarrow A$ Double Negation

It also has gobs of rules:

7. $A \rightarrow B, B \rightarrow C \vdash A \rightarrow C$ Transitivity
8. $A \rightarrow B, A \rightarrow C \vdash A \rightarrow B \wedge C$ Conjunction Introduction
9. $A \rightarrow C, B \rightarrow C \vdash A \vee B \rightarrow C$ Disjunction Introduction
10. $A \rightarrow B \vdash \neg B \rightarrow \neg A$ Contraposition.

More interesting is the characterisation of Anderson and Belnap [1962b; 1975] of $\mathbf{R}_{\mathbf{fde}}$ as ‘tautological entailments’. The root idea is to consider first the ‘primitive entailments’.

$$11. A_1 \wedge \dots \wedge A_m \rightarrow B_1 \vee \dots \vee B_n,$$

where each A_i and B_j is either a sentential variable or its negate (an ‘atom’) and make it a necessary and sufficient criterion for such a primitive entailment to hold that some A_i actually be identically the same formula as some B_j (that the entailment be ‘tautological’ in the sense that A_i is repeated). This rules out both

$$12. p \wedge \neg p \rightarrow q,$$

$$13. p \rightarrow q \vee \neg q,$$

where there is no variable sharing, but also such things as

$$14. p \wedge \neg p \wedge q \rightarrow \neg q,$$

where there is (of course all of (12)–(14) are valid classically, where a primitive entailment may hold because of atom sharing or because either the antecedent is contradictory or else the consequent is a logical truth).

Now the question remains as to which non-primitive entailments to count as valid. Both relevance logic and classical logic agree on the standard

count as valid. Both relevance logic and classical logic agree on the standard ‘normal form equivalences’: commutation, association, idempotence, distribution, double negation, and de Morgan’s laws. So the idea is, given a candidate entailment $A \rightarrow B$, by way of these equivalences, A can be put into disjunctive normal form and B may be put into conjunctive normal form, reducing the problem to the question of whether the following is a valid entailment:

$$15. A_1 \vee \cdots \vee A_k \rightarrow B_1 \wedge \cdots \wedge B_h.$$

But simple considerations (on which both classical and relevance logic agree) having to do with conjunction and disjunction introduction and elimination show that (15) holds if for each disjunct A_i and conjunct B_j , the primitive entailment $A_i \rightarrow B_j$ is valid. For relevance logic this means that there must be atom sharing between the conjunction A_i and the disjunction B_j .

This criterion obviously counts the Disjunctive Syllogism

$$16. \neg p \wedge (p \vee q) \rightarrow q,$$

as an invalid entailment, for using distribution to put its antecedent into disjunctive normal form, (16) is reduced to

$$16' (\neg p \wedge p) \vee (\neg p \wedge q) \rightarrow q.$$

But by the criterion of tautological entailments,

$$17. \neg p \wedge p \rightarrow q,$$

which is required for the validity of (16'), is rejected.

Another pleasant characterisation of $\mathbf{R}_{\mathbf{fde}}$ is contained in [Dunn, 1976a] using a simplification of Jeffrey’s ‘coupled trees’ method for testing classically valid entailments. The idea is that to test $A \rightarrow B$ one works out a truth-tree for A and a truth tree for B . One then requires that every branch in the tree for A ‘covers’ some branch in the tree for B in the sense that every atom in the covered branch occurs in the covering branch. This has the intuitive sense that every way in which A might be true is also a way in which B would be true, whether these ways are logically possible or not, since ‘closed’ branches (those containing contradictions) are not exempt as they are in Jeffrey’s method for classical logic. This coupled-trees approach is ultimately related to the Anderson–Belnap tautological entailment method, as is also the method of [Dunn, 1980b] which explicates an earlier attempt of Levy to characterise entailment (cf. also [Clark, 1980]).

1.8 Relations to Familiar Logics

There is a sense in which relevance logic contains classical logic.

ZDF THEOREM (Anderson and Belnap [1959a]). *The zero-degree formulas (those containing only the connectives \wedge, \vee, \neg) provable in **R** (or **E**) are precisely the theorems of classical logic.*

The proof went by considering a ‘cut-free’ formulation of classical logic whose axioms are essentially just excluded middles (which are theorems of **R** / **E**) and whose rules are all provable first-degree relevant entailments (cf. Section 2.7). This result extends to a first-order version [Anderson and Belnap Jr., 1959b]. (The admissibility of γ (cf. Section 2) provides another route to the proof to the ZDF Theorem.)

There is however another sense in which relevance logic does not contain classical logic:

FACT (Anderson and Belnap [1975, Section 25.1]). **R** (and **E**) lack as a derivable rule Disjunctive Syllogism:

$$\neg A, A \vee B \vdash B.$$

This is to say there is no deduction (in the standard sense of Section 1.4) of B from $\neg A$ and $A \vee B$ as premises. This is of course the most notorious feature of relevance logic, and the whole of Section 2 is devoted to its discussion.

Looking now in another direction, Anderson and Belnap [1961] began the investigation of how to translate intuitionistic and strict implication into **R** and **E**, respectively, as ‘enthymematic’ implication. Anderson and Belnap’s work presupposed the addition of propositional quantifiers to, let us say **R**, with the subsequent definition of ‘ A intuitionistically implies B ’ (in symbols $A \supset B$) as $\exists p(p \wedge (A \wedge p \rightarrow B))$. This has the sense that A together with some truth relevantly implies B , and does seem to be at least in the neighbourhood of capturing Heyting’s idea that $A \supset B$ should hold if there exists some ‘construction’ (the p) which adjoined to A ‘yields’ (relevant implication) B . Meyer in a series of papers [1970a; 1973] has extended and simplified these ideas, using the propositional constant t in place of propositional quantification, defining $A \supset B$ as $A \wedge t \rightarrow B$. If a propositional constant F for the intuitionistic absurdity is introduced, then intuitionistic negation can be defined in the style of Johansson as $\neg A =_{\text{df}} A \supset F$. As Meyer has discovered one must be careful what axiom one chooses to govern F . $F \rightarrow A$ or even $F \supset A$ is too strong. In intuitionistic logic, the absurd proposition *intuitionistically* implies only the *intuitionistic* formulas, so the correct axiom is $F \supset A^*$, where A^* is a translation into **R** of an intuitionistic formula. Similar translations carry **S4** into **E** and classical logic into **R**.

2 THE ADMISSIBILITY OF γ 2.1 Ackermann's Rule γ

The first mentioned problem for relevance logics in Anderson's [1963] seminal 'open problems' paper is the question of 'the admissibility of γ '. To demystify things a bit it should be said that γ is simply *modus ponens* for the material conditions ($\neg A \vee B$):

$$1. \frac{A \quad \neg A \vee B}{B}.$$

It was the third listed rule of Ackermann's [1956] system of *strenge Implikation* (α, β, γ ; 1st, 2nd, 3rd). This was the system Anderson and Belnap 'tinkered with' to produce **E** (Ackermann also had a rule δ which they replaced with an axiom).

The major part of Anderson and Belnap's 'tinkering' was the extremely bold step of simply deleting γ as a primitive rule, on the well-motivated ground that the corresponding object language formula

$$2. A \wedge (\neg A \vee B) \rightarrow B$$

is not a theorem of **E**.

It is easy to see that (2) could not be a theorem of either **E** or **R**, since it is easy to prove in those systems

$$3. A \wedge \neg A \rightarrow A \wedge (\neg A \vee B)$$

(largely because $\neg A \rightarrow \neg A \vee B$ is an instance of an axiom), and of course (3) and (2) yield by transitivity the 'irrelevancy'

$$4. A \wedge \neg A \rightarrow B.$$

The inference (1) is obviously related to the Stoic principle of the *disjunctive syllogism*:

$$5. \frac{\neg A \quad A \vee B}{B}.$$

Indeed, given the law of double negation (and replacement) they are equivalent, and double negation is never at issue in the orthodox logics. Thus **E** and **R** reject

$$6. \neg A \wedge (A \vee B) \rightarrow B$$

as well as (2).

This rejection is typically the hardest thing to swallow concerning relevance logics. One starts off with some pleasant motivations about relevant implication and using subscripts to keep track of whether a hypothesis has actually been used (as in Section 1.5), and then one comes to the point where one says ‘and of course we have to give up the disjunctive syllogism’ and one loses one’s audience. Please do not stop reading! We shall try to make this rejection of *disjunctive syllogism* as palatable as we can.

(See [Belnap and Dunn, 1981; Restall, 1999] for related discussions, and also discussion of [Anderson and Belnap, 1975, Section 16.1]); see Burgess [1981] for an opposing point of view.

2.2 The Lewis ‘Proof’

One reason that *disjunctive syllogism* has figured so prominently in the controversy surrounding relevance logic is because of the use it was put to by C. I. Lewis [Lewis and Langford, 1932] in his so-called ‘independent proof’: that a contradiction entails any sentence whatsoever (taken by Anderson and Belnap as a clear breakdown of relevance). Lewis’s proof (with our notations of justification) goes as follows:

- | | | |
|-----|-------------------|-----------------------------------|
| (1) | $p \wedge \neg p$ | |
| (2) | p | 2, \wedge -Elimination |
| (3) | $\neg p$ | 1, \wedge -Elimination |
| (4) | $p \vee q$ | 2, \vee -Introduction |
| (5) | q | 3, 4 <i>disjunctive syllogism</i> |

Indeed one can usefully classify alternative approaches to relevant implication according to how they reject the Lewis proof. Thus, e.g. Nelson rejects \wedge -Elimination and \vee -Introduction, as does McCall’s connexive logic. Parry, on the other hand, rejects only \vee -Introduction. Geach, and more recently, Tennant [1994], accept each step, but says that ‘entailment’ (relevant implication) is not transitive. It is the genius of the Anderson–Belnap approach to see disjunctive syllogism as the culprit and the sole culprit.¹²

Lewis concludes his proof by saying, “If by (3), p is false; and, by (4), at least one of the two, p and q is true, then q must be true”. As is told in [Dunn, 1976a], Dunn was saying such a thing to an elementary logic class one time (with no propaganda about relevance logic) when a student yelled out, “But p was the true one—look again at your assumption”.

¹²Although this point is complicated, especially in some of their earlier writings (see, e.g. [Anderson and Belnap Jr., 1962a]) by the claim that there is a kind of fallacy of ambiguity in the Lewis proof. The idea is that if \vee is read in the ‘intensional’ way (as $\neg A \rightarrow B$), then the move from (3) and (4) to (5) is OK (it’s just *modus ponens* for the relevant conditional), but the move from (2) to (4) is not (now being a paradox of implication rather than ordinary disjunction introduction).

That student had a point. Disjunctive syllogism is not obviously appropriate to a situation of inconsistent information—where p is assumed (given, believed, etc.) to be both true and false. This point has been argued strenuously in, e.g. [Routley and Routley, 1972; Dunn, 1976a] and Belnap [1977b; 1977a]. The first two of these develop a semantical analysis that lets both p and $\neg p$ receive the value ‘true’ (as is appropriate to model the situation where $p \wedge \neg p$ has been assumed true), and there will be more about these ideas in Section 3.4. The last is particularly interesting since it extends the ideas of Dunn [1976a] so as to provide a model of how a computer might be programmed as to make inferences from its (possibly inconsistent) database. One would not want trivially inconsistent information about the colour of your car that somehow got fed into the FBI’s computer (perhaps by pooled databases) to lead to the conclusion that you are Public Enemy Number One.

We would like to add yet one more criticism of *disjunctive syllogism*, which is sympathetic to many of the earlier criticisms.

We need as background to this criticism the natural deduction framework of [Gentzen, 1934] as interpreted by [Prawitz, 1965] and others. the idea (as in Section 1.5) is that each connective should come with rules that introduce it into discourse (as principal connective of a conclusion) and rules that eliminate it from discourse (as principal connective of a premise). further the ‘normalisation ideas of Prawitz, though of great technical interest and complication, boil down philosophically to the observation that an elimination rule should not be able to get out of a connective more than an introduction rule can put into the connective. This is just the old conservation Principle, ‘You can’t get something for nothing’, applied to logic.

The paradigm here is the introduction and elimination rules for conjunction. The introduction rule, from A, B to infer $A \wedge B$ packs into $A \wedge B$ precisely what the elimination rule, from $A \wedge B$ to infer either A or B (separately), then unpacks.

Now the standard introduction rule for disjunction is this: from either A or B separately, infer $A \vee B$. We have no quarrel with an introduction rule. an introduction rule gives meaning to a connective and the only thing to watch out for is that the elimination rule does not take more meaning from a connective than the introduction rule gives to it (of course, one can also worry about the usefulness and/or naturalness of the introduction rules for a given connective, but that (*pace* [Parry, 1933]) seems not an issue in the case of disjunction.

In the Lewis ‘proof’ above, it is then clear that the *disjunctive syllogism* is the only conceivably problematic rule of inference. Some logicians (as indicated above) have queried the inferences from (1) to (2) and (4), and from (2) to (3), but from the point of view that we are now urging, this is simply wrongheaded. Like Humpty Dumpty, we use words to mean what *we* say. So there is nothing wrong with introducing connectives \wedge and \vee

via the standard introduction rules. Other people may want connectives for which *they* provide different introduction (and matching elimination) rules, but that is *their* business. We want the standard (‘extensional’) senses of \wedge and \vee .

Now the d.s. is a very odd rule when viewed as an elimination rule for \vee parasitical upon the standard introduction rules (whereas the constructive dilemma, the usual \vee -Elimination rule is not at all odd). Remember that the introduction rules provide the actual inferences that are to be stored in the connective’s battery as potential inferences, perhaps later to be released again as actual inferences by elimination rules. The problem with the *disjunctive syllogism* is that it can release inferences from \vee that it just does not contain. (In another context, [Belnap, 1962] observed that Gentzen-style rules for a given connective should be ‘conservative’, i.e. they should not create new inferences not involving the given connective.)

Thus the problem with the *disjunctive syllogism* is just that $p \vee q$ might have been introduced into discourse (as it is in the Lewis ‘proof’) by \vee -Introduction from p . So then to go on to infer q from $p \vee q$ and $\neg p$ by the *disjunctive syllogism* would be legitimate only if the inference from $p, \neg p$ to q were legitimate. But this is precisely the point at issue. At the very least the Lewis argument is circular (and not independent).¹³

2.3 The Admissibility of γ

Certain rules of inference are sometimes ‘admissible’ in formal logics in the sense that whenever the premises are *theorems*, so is the conclusion a *theorem*, although these rules are nonetheless invalid in the sense that the premises may be true while the conclusion is not. Familiar examples are the rule of substitution in propositional logic, generalisation in predicate logic, and necessitation in modal logic. Using this last as paradigm, although the inference from A to $\Box A$ (necessarily A) is clearly invalid and would indeed vitiate the entire point of modal logic, still for the (‘normal’) modal logics, whenever A is a theorem so is $\Box A$ (and indeed their motivation would be somehow askew if this did not hold).

Anderson [1963] speculated that something similar was afoot with respect to the rule γ and relevance logic. Anderson hoped for a ‘sort of lucky accident’, but the admissibility of γ seems more crucial to the motivation of **E** and **R** than that. Kripke [1965] gives a list of four conditions that a propositional calculus must meet in order to have a normal characteristic matrix, one of which is the admissibility of γ .¹⁴ ‘Normal’ is meant in the

¹³This is a new argument on the side of Anderson and Belnap [1962b, pp. 19, 21].

¹⁴The other conditions are that it be consistent, that it contain all classical tautologies, and that it be ‘complete in the sense of Halldén’. **R** and **E** can be rather easily seen to have the first two properties (see Section 1.8 for the bit about classical tautologies), but the last is rather more difficult (see Section 3.11).

sense of Church, and boils down to being able to divide up its elements into the ‘true’ and the ‘false’ with the operations of conjunction, disjunction, and negation treating truth and falsity in the style of the truth tables (a conjunction is true if both components are true, etc.). If one thinks of **E** (as Anderson surely did) as the logic of propositions with the logical operations, and surely this should divide itself up into the true and the false propositions.¹⁵

2.4 Proof(s) of the Admissibility of γ

There are by now at least four variant proofs of the admissibility of γ for **E** and **R**. The first three proofs (in chronological order: [Meyer and Dunn, 1969], [Routley and Meyer, 1973] and [Meyer, 1976a]) are all basically due to Meyer (with some help from Dunn on the first, and some help from Routley on the second), and all depend on the same first lemma. The last proof was obtained by Kripke in 1978 and is unpublished (see [Dunn and Meyer, 1989]).

All of the Meyer proofs are what Smullyan [1968] would call ‘synthetic’ in style, and are inspired by Henkin-style methods. The Kripke proof is ‘analytic’ in style, and is inspired by Kanger–Beth–Hintikka tableau-style methods. In actual detail, Kripke’s argument is modelled on completeness proofs for tableau systems, wherein a partial valuation for some open branch is extended to a total valuation. As Kripke has stressed, this avoids the apparatus of inconsistent theories that has hitherto been distinctive of the various proofs of γ ’s admissibility.

We shall sketch the third of Meyer’s proofs, leaving a brief description of the first and second for Section 3.11. Since they depend on semantical notions introduced there.

The strategy of all the Meyer proofs can be divided into two segments: The Way Up and The Way Down. Of course we start with the hypotheses that $\vdash A$ and $\vdash \neg A \vee B$, yet assume not $\vdash B$ for the sake of *reduction*. We shall be more precise in a moment, but The Way Up involves constructing in a Henkin-like manner a maximal theory T (containing all the logical theorems) with $B \notin T$. The problem though is that T may be inconsistent in the sense of having both $C, \neg C \in T$ for some formula C . (Of course this could not happen in classical logic, for by virtue of the paradox of implication $C \wedge \neg C \rightarrow B, B$ would be a member of T contrary to construction.) The Way Down fixes this by finding in effect some subtheory $T' \subseteq T$ that is both complete and consistent, and indeed is a ‘truth set’ in the sense of [Smullyan, 1968] (Meyer has labelled it the Converse Lindenbaum Lemma). Thus for all formulas X and Y , $\neg X \in T'$ iff $X \notin T'$, and $X \vee Y \in T'$ iff at

¹⁵This would be less obvious to Routley and Meyer [1976], and Priest [1987; 1995] who raise the ‘consistency of the world’ as a real problem.

least one of X and Y is in T' . So since $\neg A \vee B \in T'$, at least one of $\neg A$ and B is in T' . But since $A \in T'$, then $\neg A$ is not in T' . So B must be in T' .¹⁶ But T' is a subset of T , which was constructed to keep B out. So B cannot be in T' , and so by *reductio* we obtain B as desired.

Enough of strategy! We now collect together a few notions needed for a more precise statement of The Way Up Lemma. Incidentally, we shall from this point on in our discussion of γ consider only the case of \mathbf{R} . Results for \mathbf{E} (and a variety of neighbours) hold analogously.

By an ‘ \mathbf{R} -theory’ we mean a set of formulas T of \mathbf{R} closed under adjunction and logical relevant implication, i.e. such that

1. if $A, B \in T$, then $A \wedge B \in T$;
2. if $\vdash_{\mathbf{R}} A \rightarrow B$ and $A \in T$, then $B \in T$.

Note that an arbitrary \mathbf{R} -theory may lack some or all of the theorems of \mathbf{R} (in classical logic and most familiar logics this would be impossible because of the paradox of strict implication which says that a logical theorem is implied by everything). We thus need a special name for those \mathbf{R} -theories that contain all of the \mathbf{R} -theorems—those are called *regular*.¹⁷ In this section, since we have no use of irregular theories and shall be talking only of \mathbf{R} , by a *theory* we shall always mean a regular \mathbf{R} theory (irregular \mathbf{R} -theories however play a great role in the completeness theorems of Section 3 below and there we shall have to be more careful about our distinctions).

A theory T is called *prime* if whenever $A \vee B \in T$, then $A \in T$ or $B \in T$. The converse of this holds for *any* theory T in virtue of the \mathbf{R} -axioms $A \rightarrow A \vee B$ and $B \rightarrow A \vee B$ and property (2). A theory T is called *complete* if for every formula A , $A \in T$ or $\neg A \in T$, and called *consistent* if for no formula A do we have both $A, \neg A \in T$. In virtue of the \mathbf{R} -theorem $A \vee \neg A$, we have that all prime theories are complete. A consistent prime theory is called *normal*, and it should by now be apparent that a normal theory is a truth set in the sense of Smullyan given above.

Where Γ is a set of formulas, we write $\Gamma \vdash_{\mathbf{R}} A$ to mean that A is deducible from Γ in the ‘official sense’ of there being a finite sequence B_1, \dots, B_n ,

¹⁶The proof as given here would appear to use *disjunctive syllogism* in the metalanguage at just this point, but it can be restructured (indeed we so restructured the original proofs [Meyer and Dunn, 1969]) so as to avoid at least such an explicit use of *disjunctive syllogism*. The idea is to obtain by distribution ($A \in T'$ and $A \notin T'$) or ($B \in T'$ and $B \notin T'$) from the hypothesis $B \notin T'$. The whole question of a ‘relevant’ version of the admissibility of γ is a complicated one, and admits of various interpretations. See [Belnap and Dunn, 1981; Meyer, 1978].

¹⁷It is interesting to note for regular theories, condition (2) may be replaced with the condition

(2') if $A \in T$ and $(A \rightarrow B) \in T$, then $B \in T$, in virtue of the \mathbf{R} -theorem $A \wedge (A \rightarrow B) \rightarrow B$.

with $B_n = A$ and each B_i being either a member of Γ , or an axiom of \mathbf{R} , or a consequence of earlier terms by *modus ponens* or adjunction (in context we shall often omit the subscript \mathbf{R}). We write $\Gamma \vdash_{\Delta} A$ to mean that $\Gamma \cup \Delta \vdash_{\mathbf{R}} A$, and quite standardly we write things like $\Gamma, A \vdash_{\mathbf{R}} B$ in place of the more formal $\Gamma \cup \{A\} \vdash_{\mathbf{R}} B$. Note that for any theory T , writing $\vdash_T A$ in place of $\phi \vdash_T A$ boils down to saying that A is a theorem of T ($A \in T$). Where Δ is a set of formulas not necessarily a theory, $\vdash_{\Delta} A$ can be thought of as saying that A is deducible from the ‘axioms’ Δ . The set $\{A : \vdash_{\Delta} A\}$ is pretty intuitively the smallest theory containing the axioms Δ , and we shall label it as $Th(\Delta)$.

We can now state and sketch a proof of the

WAY UP LEMMA. *Suppose not $\vdash_{\mathbf{R}} A$. Then there exists a prime theory T such that not $\vdash_T A$.*

Proof. Enumerate the formulas of \mathbf{R} : X_1, X_2, \dots . Define a sequence of sets of formulas by induction as follows.

$T_0 =$ set of theorems of \mathbf{R} .

$T_{i+1} = Th(T_i \cup \{X_{i+1}\})$ if it is not the case that $T_i, X_{i+1} \vdash A$;

T_i , otherwise.

Let T be the union of all these T_n ’s. It is easy to see as is standard that T is a theory not containing A . Also we can show that T is prime.

Thus suppose $\vdash_T X \vee Y$ and yet $X, Y \notin T$. Then it is easy to see that since neither X nor Y could be added to the construction when their turn came up without yielding A , we have both

1. $X \vdash_T A$,
2. $Y \vdash_T A$.

But by reasonably standard moves (\mathbf{R} has distribution), we get

3. $X \vee Y \vdash_T A$,

and so $\vdash_T A$ contrary to the construction. ■

THE WAY DOWN LEMMA. *Let T' be a prime theory. Then there exists a normal theory $T \subseteq T'$.*

The concept we need is that of a ‘metavaluation’ (more precisely as we use it here a ‘quasi-metavaluation’, but we shall not bother the reader with such detail). The concept and its use *re* γ may be found in [Meyer, 1976a]. (See also Meyer [1971; 1976b] for other applications.) For simplicity we assume for a while that the only primitive connectives are \neg, \vee and \rightarrow (\wedge can be defined *via* de Morgan). A metavaluation v is a function from the set of formulas into the truth values $\{0, 1\}$, such that

1. for a propositional variable p , $v(p) = 1$ iff $p \in T$;
2. $v(\neg A) = 1$ iff both (a) $v(A) = 0$ and (b) $\neg A \in T$;
3. $v(A \vee B) = 1$ iff either $v(A) = 1$ or $v(B) = 1$.
4. $v(A \rightarrow B) = 1$ iff both (a) $v(A) = 0$ or $v(B) = 1$, and (b) $A \rightarrow B \in T$.

One surprising aspect of these conditions is the double condition in (2) that must be met for $\neg A$ to be assigned the value 1. Not only must (a) A be assigned 0 (the usual ‘extensional condition’), but also (b) $\neg A$ must be a theorem of T (the ‘intensional condition’). and of course there are similar remarks about (4). The condition in (1) also relies upon G (actually to a lesser extent than it might seem—when both $p, \neg p \in T$, it would not hurt to let $v(p) = 0$).

We now set $T' = \{A : v(A) = 1\}$. The following lemma is useful, and has an easy proof by induction on complexity of formulas (the case when A is a negation evaluated as 0 uses the completeness of T).

COMPLETENESS LEMMA. *If $v(A) = 1$, then $A \in T$. If $v(A) = 0$, then $\neg A \in T$.*

It is reasonably easy to see that T' is in fact a truth set. That it behaves OK with respect to disjunction can be read right off of clause (3) in the definition of v , so we need only look at negation where the issue is whether T' is both consistent and complete. It is clear from clause (2) that T' is consistent, but T' is also complete. Thus, suppose $A \notin T'$, then by the Completeness Lemma $\neg A \in T$. This is the intensional condition for $v(\neg A) = 1$, but our supposition that $A \notin T'$ is just the extensional condition that $v(A) = 0$. Hence $v(\neg A) = 1$, i.e. $\neg A \in T'$ as desired.

It is also reasonably easy to check that T' is an **R**-theory. It is left to the reader to do the easy calculation that T' is closed under adjunction and **R**-implication, i.e. that these preserve assignments by v of the value 1. Here we will illustrate the more interesting verification that the **R**-axioms all get assigned the value 1. We shall not actually check all of them, but rather consider several typical ones.

First we check suffixing: $(A \rightarrow B) \rightarrow [(B \rightarrow C) \rightarrow (A \rightarrow C)]$. Suppose v assigns it 0. Since it is a theorem of **R** and *a fortiori* of T , then it satisfies the intensional condition and so must fail to satisfy the extensional condition. So $v(A \rightarrow B) = 1$ and $v((B \rightarrow C) \rightarrow (A \rightarrow C)) = 0$. By the Completeness Lemma, then $(A \rightarrow B) \in T$, and so by *modus ponens* from the very axiom in question (Suffixing) we have that $(B \rightarrow C) \rightarrow (A \rightarrow C) \in T$. So $v((B \rightarrow C) \rightarrow (A \rightarrow C))$ satisfies the intensional condition, and so must fail to satisfy the extensional condition since it is 0. So $v(B \rightarrow C) = 1$ and $v(A \rightarrow C) = 0$. By reasoning analogous to that above (one more *modus ponens*) we derive that $v(A \rightarrow C)$ must finally fail to satisfy the

extensional condition, i.e. $v(A) = 1$ and $v(C) = 0$. But clearly since all of $v(A \rightarrow B) = 1$, $v(B \rightarrow C) = 1$, $v(A) = 1$, then by the extensional condition, $v(C) = 1$, and we have a contradiction.

The reader might find it instructive in seeing how negation is handled to verify first the intuitionistically acceptable form of the Reductio axioms $(A \rightarrow \neg A) \rightarrow \neg A$, and then to verify its classical variant (used in some axiomatisations of **R**), $(\neg A \rightarrow A) \rightarrow A$. The first is easier. Also Classical Double Negation, $\neg\neg A \rightarrow A$ is fun.

This completes the sketch of Meyer's latest proof of the admissibility of γ for **R**.

2.5 γ for First-order Relevance Logics

The first proof of the admissibility of γ for first-order **R**, **E**, etc. (which we shall denote as **RQ**, etc.) was in Meyer, Dunn and Leblanc [1974], and uses algebraic methods analogous to those used for the propositional relevance logic in [Meyer and Dunn, 1969]. The proof we shall describe here though will again be Meyer's metavaluation-style proof.

The basic trick needed to handle first-order quantifiers is to produce this time a *first-order truth set*. Assuming that only the universal quantifier \forall is primitive (the existential can be defined: $\exists x =_{\text{df}} \neg\forall x\neg$), this means we need

$$(\forall) \quad \forall x A \in T \text{ iff } A(a/x) \in T \text{ for all parameters (free variables) } a.$$

This is easily accommodated by adding a clause to the definition of the metavaluation v so that

$$5. \quad v(\forall x A) = 1 \text{ iff } v(A(a/x)) = 1 \text{ for all parameters } a.$$

This does not entirely fix things, for in proving the Completeness Lemma we have now in the induction to consider the case when A is of the form $\forall x B$. If $v(\forall x B) = 1$, then (by (5)), $va(B(a/x)) = 1$ for all parameters a . By inductive hypothesis, for all a , $B(a/x) \in T$. But, and here's the rub, this does not guarantee that $\forall x B(a/x) \in T$. We need to have constructed on The Way Up a theory T that is ' ω -complete' in just the sense that this guarantee is provided. ([Meyer *et al.*, 1974] call such a theory 'rich'.) Of course it is understood by 'theory' we now mean a 'regular **RQ**-theory', i.e. one containing all of the axioms of **RQ** and closed under its rules (see Section 1.3). Actually things can be arranged as in [Meyer *et al.*, 1974] so that generalisation is in effect built into the axioms so that the only rules can continue to be adjunction and *modus ponens*.

Thus we need the following

WAY UP LEMMA FOR **RQ.** *Suppose A is not a theorem of first-order **RQ**. Then there exists a prime rich theory T so that $A \notin T$.*

This lemma is Theorem 3 of [Meyer *et al.*, 1974], and its proof is of basically a Henkin style with one novelty. In usual Henkin proofs one can assure ω -completeness by building into the construction of T that whenever $\neg\forall xB$ is put in, then so is $\neg B(a/x)$ for some *new* parameter a . This guarantees ω -completeness since if $B(a) \in T$ for all a , but $\forall xB \notin T$, then by completeness $\neg\forall xB \in T$ and so by the usual construction $\neg B(a) \in T$ for some a , and so *by consistency* (??) $B(a) \notin T$ for some a , contradicting the hypothesis for ω -completeness. But we of course have for relevance logics no guarantee that T is consistent, as has been remarked above.

The novelty then was to modify the construction so as to keep things out as well as put things in, though this last still was emphasised. Full symmetry with respect to ‘good guys’ and ‘bad guys’ was finally obtained by Belnap,¹⁸ in what is called the Belnap Extension Lemma, which shall be stated after a bit of necessary terminology.

We shall call an ordered pair (Δ, Θ) of sets of formulas of **RQ** and ‘**RQ**-pair’. We shall say that one **RQ** pair (Δ_1, Θ_1) *extends* another (Δ_0, Θ_0) if $\Delta_0 \subseteq \Delta_1$ and $\Theta_0 \subseteq \Theta_1$. An **RQ** pair is defined to be *exclusive* if for no $A_1, \dots, A_m \in \Delta, B_1, \dots, B_n \in \Theta$ do we have $\vdash A_1 \wedge \dots \wedge A_m \rightarrow B_1 \vee \dots \vee B_n$. It is called *exhaustive* if for every formula A , either $A \in \Delta$ or $A \in \Theta$.¹⁹ It is now easiest to assume that \wedge and \exists are back as primitive. We call a set of formulas Γ *\vee -prime* (*\wedge -prime*) if whenever $A \vee B \in \Gamma$ ($A \wedge B \in \Gamma$), at least one of A or $B \in \Gamma$ (clearly \vee -primeness is the same as primeness). Analogously, we call Γ *\exists -prime* (*\forall -prime*) if whenever $\exists xA \in \Gamma$ ($\forall xA \in \Gamma$), then $A(a/x) \in \Gamma$ for some a . Given an **RQ** pair (Δ, Θ) we shall call Δ (Θ) *completely prime* if Δ is both \vee - and \exists -prime (Θ is both \wedge - and \forall -prime). the pair (Δ, Θ) is called completely prime if both Δ and Θ are completely prime. We can now state the

BELNAP EXTENSION LEMMA. *Let (Δ, Θ) be an exclusive **RQ** pair. Then (Δ, Θ) can be extended to an exclusive, exhaustive, completely prime **RQ** pair (T, F) in a language just like the language of **RQ** except for having denumerably many new parameters.*

We shall not prove this lemma here, but simply remark that it is a surprisingly straightforward application of Henkin methods to construct a maximal **RQ**-pair and show it has the desired properties (indeed it simply symmetrises the usual Henkin construction of first-order classical logic).

¹⁸Belnap’s result is unpublished, although he communicated it to Dunn in 1973. Dunn circulated a write-up of it about 1975. It is cited in some detail in [Dunn, 1976d]. Gabbay [1976] contains an independent but precise analogue for the first-order intuitionistic logic with constant domain.

¹⁹We choose our terminology carefully, not calling (Δ, Θ) a ‘theory’, not using ‘consistency’ for exclusiveness, and not using ‘completeness’ for exhaustiveness. We do this so as to avoid conflict with our earlier (and more customary) usage of these terms and in this we differ on at least one term from usages on other occasions by Gabbay, Belnap, or Dunn.

In order to derive the **RQ** Way Up Lemma we simply set $\Delta = \mathbf{RQ}$ and $\Theta = \{A\}$ and extend it to the pair (T, F) using the Belnap Extension Lemma. It is easy to see that T is a (*regular*) **RQ**-theory, and clearly G is prime. but also T is ω -complete. Thus suppose $B(a/x) \in T$ for all a , but $\forall x B \notin T$. Then by exhaustiveness $\forall x B \in FR$. Then by \forall -primeness, $B(a/x) \in FR$ for some a . But since $\vdash_{\mathbf{RQ}} B(a/x) \rightarrow B(a/x)$, this contradicts the exclusiveness of the pair (T, F) .

2.6 γ for Higher-order Relevance Logics and Relevant Arithmetic

The whole point about γ being merely an *admissible* rule is that it might not hold for various extensions of **F** (cf. [Dunn, 1970] for actual counter examples). Thus, as we just saw, it was an achievement to show that γ continues to be admissible in **R** when it is extended to include first-order quantification. The question of the admissibility of γ naturally has great interest when **R** is further extended to include theories in the foundations of mathematics such as type theory (set theory) and arithmetic.

Meyer [1976a] contains investigations of the admissibility of γ for relevant type theory (**R $^\omega$**). We shall report nothing in the way of detail here except to observe that Meyer's result is invariant among various restrictions of the formulas A in the Comprehension Axiom scheme:

$$\exists X^{x+1} \forall y^n (X^{n+1}(y^n) \leftrightarrow A).$$

As for relevantly formulated arithmetic, most work has gone on in studying Meyer's systems **R $^\sharp$** , **R $^{\sharp\sharp}$** and their relatives, based on Peano arithmetic, though Dunn has also considered a relevantly formulated version of Robinson Arithmetic [Anderson *et al.*, 1992]. Here we will recount the results for **R $^\sharp$** and **R $^{\sharp\sharp}$** for they are rather surprising. In a nutshell, γ is admissible in relevant arithmetics with the infinitary ω -rule (from $A(0)$, $A(1)$, $A(2)$, \dots to infer $\forall x A(x)$), but not without it [Friedman and Meyer, 1992; Meyer, 1998].

The system **R $^\sharp$** is given by rewriting the traditional axioms of Peano arithmetic with relevant implication instead of material implication in the natural places. You get the following list of axioms

Identity	$y = z \rightarrow (x = y \rightarrow x = z)$
Successor	$x' = y' \rightarrow x = y$ $x = y \rightarrow x' = y'$ $0 \neq x'$
Addition	$x + 0 = x$ $x + y' = (x + y)'$
Multiplication	$x0 = 0$ $xy' = xy + x$
Induction	$A(0) \wedge \forall x (A(x) \rightarrow A(x')) \rightarrow \forall x A(x)$

which you add to those of \mathbf{RQ} in order to obtain an arithmetic theory. The question about the admissibility of γ was open for many years, until Friedman teamed up with Meyer to show that it is not [Friedman and Meyer, 1992]. The proof does not provide a direct counterexample to γ . Instead, it takes a more circuitous route. First, we need Meyer's classical containment result for \mathbf{R}^\sharp . When we map formulae in the extensional vocabulary of arithmetic to the language of \mathbf{R}^\sharp by setting $\tau(x = y)$ to $(x = y) \vee (0 \neq 0)$ and leaving the rest of the map to respect truth functions (so $\tau(A \wedge B) = \tau(A) \wedge \tau(B)$, $\tau(\neg A) = \neg\tau(A)$ and $\tau(\forall xA) = \forall x\tau(A)$) then we have the following theorem:

$\tau(A)$ is a theorem of \mathbf{R}^\sharp iff A is a theorem of classical Peano arithmetic.

This is a subtle result. The proof goes through by showing, by induction, that $\tau(A)$ is equivalent either to $(A \wedge (0 = 0)) \vee (0 \neq 0)$ or to $(A \vee (0 \neq 0)) \wedge (0 = 0)$, and then that γ and the classical form of induction (with material implication in place of relevant implication) is valid for formulae of this form in \mathbf{R}^\sharp . Then, if we had the admissibility of γ for \mathbf{R}^\sharp , we could infer A from $\tau(A)$. (If $\tau(A)$ is equivalent to $(A \wedge (0 = 0)) \vee (0 \neq 0)$, then we can use $0 = 0$ and γ to derive $A \wedge (0 = 0)$, and hence A . Similarly for the other case).

The next significant result is that not all theorems of classical Peano arithmetic are theorems of \mathbf{R}^\sharp . Friedman provided a counterexample, which is simple enough to explain here. First, we need some simple preparatory results.

- \mathbf{R}^\sharp is a conservative extension of the theory $\mathbf{R}^{\sharp+}$ axiomatised by the negation free axioms of \mathbf{R}^\sharp [Meyer and Urbas, 1986].
- If classical Peano theorem is to be provable in \mathbf{R}^\sharp and if it contains no negations, then it must be provable in $\mathbf{R}^{\sharp+}$.
- Any theorem provable in $\mathbf{R}^{\sharp+}$ must be provable in the classical positive system \mathbf{PA}^+ which is based on classical logic, instead of \mathbf{R} .

The proofs of these results are relatively straightforward. The next result is due to Friedman, and it is much more surprising.

- The ring of complex numbers is a model of \mathbf{PA}^+ .

The only difficult thing to show is that it satisfies the induction axiom. For any formula $A(x)$ in the vocabulary of arithmetic, the set of complex numbers α such that $A(\alpha)$ is true is either finite or cofinite. If $A(x)$ is atomic, then it is equivalent to a polynomial of the form $f(x) = 0$, and f must either have finitely many roots or be 0 everywhere. But the set of either finite or cofinite sets is closed under boolean operations, so no $A(x)$

we can construct will have an extension which is neither finite or cofinite.) As a result, the induction axiom must be satisfied. For if $A(0)$ holds and if $A(x) \supset A(x')$ holds then there are infinitely many complex numbers α such that $A(\alpha)$. So the extension of A is at least cofinite. But if there is a point α such that $A(\alpha)$ fails, then so would $A(\alpha - 1)$, $A(\alpha - 2)$ and so on by the induction step $A(x) \supset A(x')$, and this contradicts the cofinitude of the extension of A . As a result, $A(\alpha)$ holds for *every* α .

We can then use this surprising model of positive Peano arithmetic to construct a Peano theorem which is not a theorem of \mathbf{R}^\sharp . It is known that for any odd prime p , there is a positive integer y which is not a quadratic residue mod p . That is, $\exists y \forall z \neg(y \equiv z^2 \pmod{p})$ is provable in Peano arithmetic. This formula can be rewritten in the language of arithmetic with a little work. However, the corresponding formula is false in the complex numbers, so it is not a theorem of \mathbf{PA}^+ . Therefore it isn't a theorem of \mathbf{R}^\sharp , and by the conservative extension result, it is not a theorem of \mathbf{R}^\sharp . As a consequence, \mathbf{R}^\sharp is not closed under γ .

Where is the counterexample to γ ? Meyer's containment result provides a proof of $\tau(B)$, where B is the quadratic residue formula. The γ rule would allow us to derive B from $\tau(B)$, and it is here that γ must fail.

If we replace the induction axiom by the infinitary rule ω , we can prove the admissibility of γ using a modification of the Belnap Extension Lemma for the Way Up and using the standard metavaluation technique for the Way Down. The modification of the Belnap Extension Lemma is due to Meyer [1998].

BELNAP EXTENSION LEMMA, WITH WITNESS PROTECTION:

Let (Δ, Θ) be an exclusive \mathbf{R}^\sharp pair in the language of arithmetic (that is, with 0 as the only constant). Then (Δ, Θ) can be extended to an exclusive, exhaustive, completely prime \mathbf{R}^\sharp pair (T, F) in the same language.

This lemma requires the ω -rule for its proof. Consider the induction stage in which you wish to place $\forall x A(x)$ in Θ_i . The witness condition dictates that there be some term t such that $A(t)$ also appear in Θ_i . The ω -rule ensures that we can do this without the need for a new term, for if no term $0''\dots'$ could be consistently added to Θ_i , then each $A(0''\dots')$ is a consequence of Δ_i , and by the ω -rule, so is $\forall x A(x)$, contradicting the fact that we can add $\forall x A(x)$ to Θ_i . So, we know that some $0''\dots'$ will do, and as a result, we need add no new constants to form the complete theory T . The rest of the way up lemma and the whole of the way down lemma can then be proved with little modification. (for details, see [Meyer, 1998]). Consequently, γ is admissible in \mathbf{R}^\sharp .

These have been surprising results, and important ones, for relevant arithmetic is an important 'test case' for accounts of relevance. It is a theory in which we can have some fairly clear idea of what it is for one formulae to

properly *follow from* another. In $\mathbf{R}^\#$ and $\mathbf{R}^{\#\#}$, we have $0 = 2 \rightarrow 0 = 4$ because there is an ‘arithmetically appropriate’ way to derive $0 = 4$ from $0 = 2$ — by multiplying both sides by 2. However, we cannot derive $0 = 2 \rightarrow 0 = 3$, and, correspondingly, there is no way to derive $0 = 3$ from $0 = 2$ using the resources of arithmetic. The only way to do it within the vocabulary is to appeal to the falsity of $0 = 3$, and this is not a relevantly acceptable move. $0 \neq 3 \rightarrow (0 = 3 \rightarrow 0 = 2)$ does not have much to recommend as pattern of reasoning which respects the canons of relevance.

We are left with important questions. Are there axiomatisable extensions of $\mathbf{R}^\#$ which are closed under γ ? Can theories like $\mathbf{R}^\#$ and $\mathbf{R}^{\#\#}$ be extended to deal with more interesting mathematical structures, while keeping account of some useful notion of relevance? Early work on this area, from a slightly different motivation (paraconsistency, not relevance) indicates that there are some interesting results at hand, but the area is not without its difficulties [Mortensen, 1995].

The admissibility of γ would also seem to be of interest for relevant type theory (even relevant second-order logic) with an axiom of infinity (see [Dunn, 1979b]).

One of the chief points of philosophical interest in showing the admissibility of γ for some relevantly formulated version of a classical theory relates to the question of the consistency of the classical theory (this was first pointed out in Meyer, Dunn and Leblanc [1974]). As we know from Gödel’s work, interesting classical theories cannot be relied upon to prove their own consistency. To exaggerate perhaps only a little, the consistency of systems like Peano (even Robinson) arithmetic must be taken in faith.

But using relevance logic in place of classical logic in formulating such theories gives us a new strategy of faith. It is conceivable that since relevance logic is weaker than classical logic, the consistency of the resultant theory might be easier to demonstrate. This has proved true at least in the sense of absolute consistency (some sentence is unprovable) as shown by [Meyer, 1976c] for Peano arithmetic using elementary methods. Classically of course there is no difference between absolute consistency and ordinary (negation) consistency (for no sentence are both A and $\neg A$ provable), and if γ is admissible for the theory, then this holds for relevance logic, too. The interesting thing then would be to produce a proof of the admissibility of γ , which we know from Gödel would itself have to be non-elementary.

One could then imagine arguing with a classical mathematician in the following Pascal’s Wager sort of way [Dunn, 1980a].

Look. You have equally good reason to believe in the negation consistency of the classical system and the (relative) completeness of the relevant system. In both cases you have a non-elementary proof which secures your belief, but which might be mistaken. Consider the consequences in each case if it is mis-

taken. If you are using the classical system, disaster! Since even one contradiction classically implies everything, for each theorem you have proven, you might just as well have proven its negation. But if you are using the relevant system, things are not so bad. For at least large classes of sentences, it can be shown by elementary methods (Meyer's work) that not both the sentences and their negations are theorems.

2.7 Ackermann's γ and Gentzen's Cut: Gentzen Systems as Relevance Logic

In [Meyer *et al.*, 1974] an analogy was noted between the role that the admissibility of γ plays in relevance logic and the role that cut elimination plays in Gentzen calculi (even those for classical systems). For the reader unfamiliar with Gentzen calculi, this subsection will make more sense after she has read Sections 4.6 and 4.7. The Gentzen system for the classical propositional calculus **LK** with the material conditional and negation as primitive (as is well-known, all of the other truth-functional connectives can be defined from these) may be obtained by adding to the rules of **LR** \supset of Section 4.7. the rule of Thinning (see Section 4.6) on both the left and right. Gentzen also had as a primitive rule:

$$\frac{\alpha \vdash A, B \quad \gamma, A \vdash \delta}{\alpha, \gamma \vdash B, \delta}, \quad (\text{Cut})$$

which has as a special case

$$\frac{\vdash A \vdash B}{\vdash B}. \quad (1)$$

Since $A \vdash B$ is derivable just when $\vdash A \rightarrow B$ is derivable, and since in classical logic $A \rightarrow B$ is equivalent to $\neg A \vee B$, (1) above is in effect

$$\frac{\vdash A \quad \vdash \neg A \vee B}{\vdash B}, \quad (1')$$

which is just γ .

All of the Gentzen rules except Cut have the Subformula Property: Every formula that occurs in the premises also occurs in the conclusion, though perhaps there as a subformula. Gentzen showed *via* his *Hauptsatz* that Cut was redundant—it could be eliminated without loss (hence this is often called the Elimination Theorem). Later writers have tended to think of Gentzen systems as lacking the Cut Rule, and so the Elimination Theorem is stated as showing that Cut is admissible in the sense that whenever the premises are derivable so is the conclusion. There is thus even a parallel

historical development with Ackermann's rule γ in relevance logic, since writers on relevance logic have tended to follow Anderson and Belnap's decision to drop γ as a primitive rule.

Note that the Subformula Property can be thought of as a kind of relation of relevance between premises and conclusion. Thus Cut as primitive destroys a certain kind of relevance property of Gentzen systems, just as γ as primitive destroys the relevance of premises to conclusion in relevance logic. The analogies become even clearer if we reformulate Gentzen's system according to the following ideas of [Schütte, 1956].

The basic objects of Gentzen's calculus LK were the *sequents* $A_1, \dots, A_m \vdash B_1, \dots, B_n$, where the A_i 's and B_j 's are formulas (any or all of which might be missing). Such a sequent may be interpreted as a statement to the effect that either one of the A_i 's is false or one of the B_j 's is true. To every such sequent there corresponds what we might as well call its 'right-handed counterpart':

$$\vdash \neg A_1, \dots, \neg A_m, B_1, \dots, B_n$$

It is possible to develop a calculus parallel to Gentzen's using only 'right-handed' sequents, i.e. those with empty left side. This is in effect what Schütte did, but with one further trick. Instead of working with a right-handed sequent $\vdash A_1, \dots, A_m$, which can be thought of as a sequence of formulas, he in effect replaced it with the single formula $A_1 \vee \dots \vee A_m$.²⁰

With these explanations in mind, the reader should have no trouble in perceiving Schütte's calculus K_1 as 'merely' a notational variant of Gentzen's original calculus LK (albeit, a highly ingenious one). Also Schütte's system had the existential quantifier which we have omitted here purely for simplicity. Dunn and Meyer [1989] treats it as well.

The axioms of K_1 are all formulas of the form $A \vee \neg A$. The inference rules divide themselves into two types:

Structural rules:

$$\frac{\mathcal{M} \vee A \vee B \vee \mathcal{N}}{\mathcal{M} \vee B \vee A \vee \mathcal{N}} \text{ [Interchange]} \quad \frac{\mathcal{N} \vee A \vee A}{\mathcal{N} \vee A} \text{ [Contraction]}$$

Operational rules:

$$\frac{\mathcal{N}}{\mathcal{N} \vee B} \text{ [Thinning]} \quad \frac{\mathcal{N} \vee \neg A \quad \mathcal{N} \vee \neg B}{\mathcal{N} \vee \neg(A \vee B)} \text{ [de Morgan]} \quad \frac{\mathcal{N} \vee A}{\mathcal{N} \vee \neg \neg A} \text{ [Double Negation]}$$

It is understood in every case but that of Thinning that either both of \mathcal{M} and \mathcal{N} may be missing. Also there is an understanding in multiple disjunctions that parentheses are to be associated to the right.

²⁰It ought be noted that similar "single sided" Gentzen systems find extensive use in the proof theory for Linear Logic [Girard, 1987; Troelstra, 1992].

In [Meyer *et al.*, 1974] it was said that the rule Cut is just γ ‘in peculiar notation’. In the context of Schütte’s formalism the notation is not even so different. Thus:

$$\frac{\mathcal{M} \vee A \quad \neg A \vee \mathcal{N}}{\mathcal{M} \vee \mathcal{N}} [\text{Cut}] \quad \frac{A \quad \neg A \vee B}{B} [\gamma].$$

Since either \mathcal{M} or \mathcal{N} may be missing, obviously γ is just a special case of Cut.

It is pretty easy to check that each of the rules above corresponds to a provable first-degree relevant implication. Indeed [Anderson and Belnap Jr., 1959a] with their ‘Simple Treatment’ formulation of classical logic (extended to quantifiers in [Anderson and Belnap Jr., 1959b]) independently arrived at a Cut-free system for classical logic much like Schütte’s (but with some improvements, i.e. they have more general axioms and avoid the need for structural rules). They used this to show that **E** contains all the classical tautologies as theorems, the point being that the Simple Treatment rules are all provable entailments in **E** (unlike the usual rule for axiomatic formulations of classical logic, *modus ponens* for the material conditional, i.e. γ). Thus the later proven admissibility of γ was not needed for this purpose, although it surely can be so used. Schütte’s system can also clearly be adapted to the purpose of showing that classical logic is contained in relevance logic, and indeed [Belnap, 1960a] used **K**₁ (with its quantificational rules) to show that **EQ** contains all the theorems of classical first-order logic.

It turns out that one can give a proof of the admissibility of Cut for a classical Gentzen-style system, say Schütte’s **K**₁, along the lines of a Meyer-style proof of the admissibility of γ (see [Dunn and Meyer, 1989], first reported in 1974).²¹ We will not give many details here, but the key idea is to treat the rules of **K**₁ as rules of deducibility and not merely as theorem generating devices. Thus we define a *deduction* of A from a set of formulas Γ as a finite tree of formulas with A as its origin, members of Γ or axioms of **K**₁ at its tips, and such that each point that is not a tip follows from the points just above it by one of the rules of **K**₁ (this definition has to be slightly more complicated if quantifiers are present due to usual problems caused by generalisation). We can then inductively build a prime complete

²¹We hasten to acknowledge the nonconstructive character of this proof. In this our proof compares with that of Schütte [1956] (also proofs for related formalisms due to Anderson and Belnap, Beth, Hintikka, Kanger) in its uses of semantical (model-theoretic) notions, and differs from Gentzen’s. Like the proofs of Schütte *et al.* this proof really provides a completeness theorem. We may briefly label the difference between this proof and those of Schütte and the others by using (loosely) the jargon of Smullyan [1968]. Calling both Hilbert-style formalisms and their typical Henkin-style completeness proofs ‘synthetic’, and calling both Gentzen-style formalisms and their typical Schütte-style completeness proof ‘analytic’, it looks as if we can be said to have given an synthetic completeness proof for an analytic formalism.

theory (closed under deducibility) on The Way up, which will clearly be inconsistent since because of the ‘Subformula Property’ clearly, e.g. q is not deducible from $p, \neg p$. but this can be fixed on The Way Down by using metavaluation techniques so as to find a complete consistent subtheory.

In 1976 E. P. Martin, Meyer and Dunn extended and analogised the result of Meyer concerning the admissibility of γ for relevant type theory described in the last subsection, in much the same way as the γ argument for the first-order logic has been analogised here, so as to obtain a new proof of Takeuti’s Theorem (Cut-elimination for simple type theory). This unpublished proof dualises the proof of Takahashi and Prawitz (cf. [Prawitz, 1965]) in the same way that the proof here dualises the usual semantical proofs of Cut-elimination for classical first-order logic. This dualisation is vividly described by saying that in place of ‘Schütte’s Lemma’ that every semi- (partial-) valuation may be extended to a (total) valuation, there is instead the ‘Converse Schütte Lemma’ that every ‘ambi-valuation’ (sometimes assigns a sentence both the values 0, 1) may be restricted to a (consistent) valuation.

3 SEMANTICS

3.1 Introduction

In Anderson’s [1963] ‘open problems’ paper, the last major question listed, almost as if an afterthought, was the question of the semantics of **E** and **EQ**. Despite this appearance Anderson said (p. 16) ‘the writer does *not* regard this question as “minor”; it is rather the principle large question remaining open’. Anderson cited approvingly some earlier work of Belnap’s (and his) on providing an algebraic semantics for first-degree entailments, and said (p. 16), ‘But the general problem of finding a semantics for the whole of **E**, with an appropriate completeness theorem, remains unsolved’.

It is interesting to note that Anderson’s paper appeared in the same *Acta Philosophica Fennica* volume as the now classic paper of Kripke [1963] which provided what is now simply called ‘Kripke-style’ semantics for a variety of modal logics (Kripke [1959a] of course provided a semantics for **S5**, but it lacked the accessibility relation R which is so versatile in providing variations).

When Anderson was writing his ‘open problems’ paper, the paradigm of a semantical analysis of a non-classical logic was probably still something like the work of McKinsey and Tarski [1948], which provided interpretations for modal logic and intuitionistic logic by way of certain algebraic structures analogous to the Boolean algebras that are the appropriate structures for classical logic. But since then the Kripke-style semantics (sometimes referred to as ‘possible-worlds semantics’, or ‘set-theoretical semantics’) seems

to have become the paradigm. Fortunately, **E** and **R** now have both an algebraic semantics and a Kripke-style semantics. We shall first distinguish in a kind of general way the differences between these two main approaches to semantics, before going on to explain the particular details of the semantics for relevant logics (again **R** will be our paradigm).

3.2 Algebraic vs. Set-theoretical Semantics

It is convenient to think of a logical system as having two distinct aspects syntax (well-formed strings of symbols, e.g. sentences) and semantics (what, e.g. these sentences mean, i.e. propositions). These double aspects compete with one another as can be seen in the competing usages ‘sentential calculus’ and ‘propositional calculus’, but we should keep firmly in mind both aspects.

Since sentences can be combined by way of connectives, say the conjunction sign \wedge , to form further sentences, typically there is for each logical system at least one natural algebra arising at the level of syntax, the algebra of sentences (if one has a natural logical equivalence relation there is yet another that one obtains by identifying logically equivalent sentences together into equivalence classes—the so-called ‘Lindenbaum algebra’). And since propositions can be combined by the corresponding logical operations, say conjunction, to form propositions, here is an analogous algebra of propositions.

Now undoubtedly some readers, who were taught to ‘Quine’ propositions from an early age, will have troubles with the above story. The same reader would most likely not find compelling any particular metaphysical account we might give of numbers. We ask that reader then to at least suspend *disbelief* in propositions so that we can get on with the mathematics.

There is an alternative approach to semantics which can be described by saying that rather than taking propositions as primitive, it ‘constructs’ them out of certain other semantical primitives. Thus there is as a paradigm of this approach the so-called ‘UCLA proposition’ as a set of ‘possible worlds’.²² We here want to stress the general structural idea, not placing much emphasis upon the particular choice of ‘possible *worlds*’ as the semantical primitive. Various authors have chosen ‘reference points’, ‘cases’, ‘situations’, ‘set-ups’, etc.—as the name for the semantical primitive varying for sundry subtle reasons from author to author. We have both in relevance logic contexts have preferred ‘situations’, but in a show of solidarity we shall here join forces with the Routley’s [1972] in their use of ‘set-ups’.

Such ‘set-theoretical’ semantical accounts do not always explicitly verify such a construction of propositions. Indeed perhaps the more common approach is to provide an interpretation that says whether a formula A is

²²Actually the germ of this idea was already in Boole (cf. [Dipert, 1978]), although apparently he thought of it as an analogy rather than as a reduction.

true and false at a given set-up S writing $\phi(a, S) = T$ or $S \models A$ or some such thing. Think of Kripke's [1963] presentation of his semantics for modal logic. But (unless one has severe ontological scruples about sets) one might just as well interpret A by assigning it a class of set-ups, writing $\Phi(A)$ or $|A|$ or some such thing. One can go from one framework to the other by way of equivalence

$$S \in |A| \text{ iff } S \models A.$$

3.3 Algebra of First-degree Relevant Implications

Given two propositions a and b , it is natural to consider the implication relation among them, which we write as $a \leq b$ (' a implies b '). It might be thought to be natural to write this the other way around as $a \geq b$ on some intuition that a is the stronger or 'bigger' one if it implies b . Also it suggests $a \supseteq b$ (' b is contained in a '), which is a natural enough way to think of implication. There are good reasons though behind our by now almost universal choice (of course at one level it is just notation, and it doesn't matter what your convention is). Following the idea that a proposition might be identified with the set of cases in which it is true, a implies b corresponds to $a \subseteq b$, which has the same direction as $a \leq b$. Then conjunction \wedge corresponds to intersection \cap , and they have roughly the same symbol (and similarly for \vee and \cup).

It is also natural to assume, as the notation suggests, that implication is a partial order, i.e.

- (p.o.1) $a \leq a$ (Reflexivity),
- (p.o.2) $a \leq b$ and $b \leq a \Rightarrow a = b$ (Antisymmetry),
- (p.o.3) $a \leq b$ and $b \leq c \Rightarrow a \leq c$ (Transitivity).

It is natural also to assume that there are operations of conjunction \wedge and disjunction \vee that satisfy

- (\wedge lb) $a \wedge b \leq a, a \wedge b \leq b,$
- (\wedge glb) $x \leq a$ and $x \leq b \Rightarrow x \leq a \wedge b,$
- (\vee ub) $a \leq a \vee b, b \leq a \vee b,$
- (\vee lub) $a \leq x$ and $b \leq x \Rightarrow a \vee b \leq x.$

Note that (\wedge lb) says that $a \wedge b$ is a lower bound both of a and of b , and (\wedge glb) says it is the greatest such lower bound. Similarly $a \vee b$ is the least upper bound of a and b .

A structure (L, \leq, \wedge, \vee) satisfying all the properties above is a well-known structure called a lattice. Almost any logic would be compatible with the assumption that propositions form a lattice (but there are exceptions, witness Parry's [1933] Analytic Implication which would reject (\vee ub)).

Lattices can be defined entirely operationally as structures (L, \wedge, \vee) with the relation $a \leq b$ defined as $a \wedge b = a$. Postulates characterising the operations are:

$$\begin{aligned} \text{Idempotence:} & \quad a \wedge a = a, a \vee a = a \\ \text{Commutativity:} & \quad a \wedge b = b \wedge a, a \vee b = b \vee a \\ \text{Associativity:} & \quad a \wedge (b \wedge c) = (a \wedge b) \wedge c, a \vee (b \vee c) = (a \vee b) \vee c \\ \text{Absorption:} & \quad a \wedge (a \vee b) = a, a \vee (a \wedge b) = a. \end{aligned}$$

An (upper) *semi-lattice* is a structure (S, \vee) , with \vee satisfying Idempotence, Commutativity, and Associativity.

Given two lattices (L, \wedge, \vee) and (L', \wedge', \vee') , a function h from L into L' is called a (*lattice*) *homomorphism* if both $h(a \wedge b) = h(a) \wedge' h(b)$ and $h(a \vee b) = h(a) \vee' h(b)$. If h is one-one, h is called an *isomorphism*.

Many logics (certainly orthodox relevance logic) would insist as well that propositions form a *distributive* lattice, i.e. that

$$a \wedge (b \vee c) \leq (a \wedge b) \vee c.$$

This implies the usual distributive laws $a \wedge (b \vee c) = (a \wedge b) \wedge (a \wedge c)$ and $a \vee (b \wedge c) = (a \vee b) \wedge (a \vee c)$. (Again there are exceptions, important ones being quantum logic with its weaker orthomodular law, and linear logic with its rejection of even the orthomodular law.)

The paradigm example of a distributive lattice is a collection of sets closed under intersection and union (a so-called ‘ring’ of sets). Stone [1936] indeed showed that abstractly all distributive lattices can be represented in this way. Although we will not argue this here, it is natural to think that if propositions correspond to classes of cases, then conjunction should carry over to intersection and disjunction to union, and so productions should form a distributive lattice.

Certain subsets of lattices are especially important. A *filter* is a non-empty subset F such that

1. $a, b \in F \Rightarrow a \wedge b \in F$,
2. $a \in F$ and $a \leq b \Rightarrow b \in F$.

Filters are like theories. Note by easy moves that a filter satisfies

- 1'. $a, b \in F \Leftrightarrow a \wedge b \in F$,
- 2'. $a \in F$ or $b \in F \Rightarrow a \vee b \in F$.

When a filter also satisfies the converse of (2') it is called *prime*, and is like a prime theory. A filter that is not the whole lattice is called *proper*. Stone [1936] showed (using an equivalent of the Axiom of Choice) the

PRIME FILTER SEPARATION PROPERTY. In a distributive lattice, if $a \not\leq b$, then there exists a prime filter P with $a \in P$ and $b \notin P$.

This is related to the Belnap Extension Lemma of Section 2.5.

So far we have omitted discussion of negation. This is because there is less agreement among logics as to what properties it should have.²³ There is, however, widespread agreement that it should at least have these:

1. (Contraposition) $a \leq b \Rightarrow \neg b \leq \neg a$,
2. (Weak Double Negation) $a \leq \neg\neg a$.

These can both be neatly packaged in one law:

3. (Intuitionistic Contraposition) $a \leq \neg b \Rightarrow b \leq \neg a$.

We shall call any unary function \neg satisfying (3) (or equivalently (1) and (2)) a *minimal complement*. The intuitionists of course do not accept

4. (Classical Contraposition) $\neg a \leq \neg b \Rightarrow b \leq a$, or
5. (Classical Double Negation) $\neg\neg a \leq a$.

If one adds either of (4) or (5) to the requirements for a minimal complement one gets what is called a *de Morgan complement* (or quasi-complement), because, as can be easily verified, it satisfies all of de Morgan's laws

$$\begin{aligned} \text{(deM1)} \quad & \neg(a \wedge b) = \neg a \vee \neg b, \\ \text{(deM2)} \quad & \neg(a \vee b) = \neg a \wedge \neg b. \end{aligned}$$

Speaking in an algebraic tone of voice, de Morgan complement is just a (one-one) order-inverting mapping (a *dual automorphism*) of period two.

De Morgan complement captures many of the features of classical negation, but it misses

$$\begin{aligned} \text{(Irrelevance 1)} \quad & a \wedge \neg a \leq b, \\ \text{(Irrelevance 2)} \quad & a \leq b \vee \neg b. \end{aligned}$$

If (either of) these are added to a de Morgan complement it becomes a *Boolean complement*. If Irrelevance 1 is added to a minimal complement, it becomes a *Heyting complement* (or *pseudo-complement*).

A structure (L, \wedge, \vee, \neg) , where (L, \wedge, \vee) is a *distributive* lattice and \neg is a de Morgan (Boolean) complement is called a *de Morgan (Boolean) lattice*. Note that we did not try to extend this terminological framework to 'Heyting lattices', because in the literature a Heyting lattice requires an operation called 'relative pseudo-complementation' in addition to Heyting complementation (plain pseudo-complementation).

As an example of de Morgan lattices consider the following (here we use ordinary Hasse diagrams to display the order; $a \leq b$ is displayed by putting a in a connected path below b):

²³Cf. Dunn [1994; 1996] wherein the various properties below are related to various ways of treating incompatibility between states of information.

The backwards numeral labelling the third lattice over is not a misprint. It signifies that not only has the de Morgan complement been obtained by inverting the order of the diagram, as in the order three (of course $\neg I = \Theta$ and *vice versa*), but also by rotating it from right to left at the same time. 2 and 5 are Boolean lattices.

A *homomorphism (isomorphism)* h between de Morgan Lattice with de Morgan complements \neg and \neg' respectively is a lattice homomorphism (isomorphism) such that $h(\neg a) = \neg' h(a)$.

A valuation in a lattice outfitted with one or the other of these ‘complementations’ is a map v from the zero-degree formulas into its elements satisfying

$$\begin{aligned} v(\neg A) &= \neg v(A), \\ v(A \wedge B) &= v(A) \wedge v(B), \\ v(A \vee B) &= v(A) \vee v(B). \end{aligned}$$

Note that the occurrence of ‘ \neg ’ on the left-hand side of the equation denotes the negation connective, whereas the occurrence on the right-hand side denotes the complementation operation in the lattice (similarly for \wedge and \vee). Such ambiguities resolve themselves contextually.

A valuation v can be regarded as an interpretation of the formulas as propositions.

De Morgan lattices have become central to the study of relevance of logic, but they were antecedently studied, especially in the late 1950s by Moisil and Monteiro, by Białyński-Birula and Rasiowa (as ‘quasi-Boolean algebras’), and by Kalman (as ‘distributive i -lattices’) (see Anderson and Belnap [1975] or Rasiowa [1974] for references and information).

Belnap seems to have first recognised their significance for relevance logic, though his research favoured a special variety which he called an *intensionally complemented distributive lattice with truth filter* ('icdlw/TF'), shortened in Section 18 of [Anderson and Belnap, 1975] to just *intensional lattice*. An intensional lattice is a structure $(L, \wedge, \vee, \neg, T)$, where (L, \wedge, \vee, \neg) is a de Morgan lattice and T is a *truth-filter*, i.e. T is a filter which is complete in the sense T contains at least one of a and $\neg a$ for each $a \in L$, and *consistent* in the sense that T contains no more than one of a and $\neg a$.

Belnap and Spencer [1966] showed that a necessary and sufficient condition for a de Morgan lattice to have a truth filter is that negation have no fixed point, i.e. for no element a , $a = \neg a$ (such a lattice was called an *icdl*). For Boolean algebras this is a non-degeneracy condition, assuring that the algebra has more than one element, the one element Boolean algebra being best ignored for many purposes. But the experience in relevance logic has been that de Morgan lattices where some elements are fixed points are extremely important (not all elements can be fixed points or else we do have the one element lattice).

The viewpoint of [Dunn, 1966] was to take general de Morgan lattices as basic to the study of relevance logics (though still results were analogised wherever possible to the more special icdl's). Dunn [1966] showed that upon defining a first-degree implication $A \rightarrow B$ to be (*de Morgan*) *valid* iff for every valuation v in a de Morgan lattice, $v(A) \leq v(B)$, $A \rightarrow B$ is valid iff $A \rightarrow B$ is a theorem of \mathbf{R}_{fde} (or \mathbf{E}_{fde}). The analogous result for icdl's (in effect due to Belnap) holds as well.

Soundness ($\vdash_{\mathbf{R}_{\text{fde}}} A \rightarrow B \Rightarrow A \rightarrow B$ is valid) is a more or less trivial induction on the length of proofs in \mathbf{R}_{fde} fragment—cf. [Anderson and Belnap, 1975, Section 18].

Completeness ($A \rightarrow B$ valid $\Rightarrow \vdash_{\mathbf{R}_{\text{fde}}} A \rightarrow B$) is established by proving the contrapositive. We suppose not $\vdash_{\mathbf{R}_{\text{fde}}} A \rightarrow B$. We then form the 'Lindenbaum algebra', which has as an element for each zero degree formula (zdf) X , $[X] =_{\text{df}} \{Y : Y \text{ is a zdf and } \vdash_{\mathbf{R}_{\text{fde}}} X \leftrightarrow Y\}$. Operations are defined so that $\neg[X] = [\neg X]$, $[X] \wedge [Y] = [X \wedge Y]$, and $[X] \vee [Y] = [X \vee Y]$, and we set $[X] \leq [Y]$ whenever $\vdash_{\mathbf{R}_{\text{fde}}} X \rightarrow Y$. It is more or less transparent, given \mathbf{R}_{fde} formulated as it is, that the result is a de Morgan lattice. It is then easy to see that $A \rightarrow B$ is invalidated by the *canonical* valuation $v_c(X) = [X]$, since clearly $[A] \not\leq [B]$.

The above kind of soundness and completeness result is really quite trivial (though not unimportant), once at least the logic has had its axioms chopped so that they look like the algebraic postulates merely written in a different notation. The next result is not so trivial.

CHARACTERISATION THEOREM OF \mathbf{R}_{FDE} WITH RESPECT TO 4. $\vdash_{\mathbf{R}_{\text{fde}}} A \rightarrow B$ iff $A \rightarrow B$ is valid in \mathcal{L} , i.e. for every valuation v in \mathcal{L} , $v(A) \leq v(B)$.

Proof. Soundness follows from the trivial fact recorded above that \mathbf{R}_{fde} is

sound with respect to de Morgan lattices in general. For completeness we need the following:

4-Valued Homomorphism Separation Property. Let \mathcal{D} be a de Morgan lattice with $a \not\leq b$. Then there exists a homomorphism h of \mathcal{D} into 4 so that $h(a) \not\leq h(b)$.

Completeness will follow almost immediately from this result, for upon supposing that $\text{not } \vdash_{\mathbf{R}_{\text{rd}_e}} A \rightarrow B$, we have $v(A) = h[A] \not\leq h[B] = v(B)$ (the composition of a homomorphism with a valuation is transparently a valuation). So we go on to establish the Homomorphism Separation Property.

Assume that $a \not\leq b$. By the Prime Filter Separation Property, we know there is a prime filter P with $a \in P$ and $b \notin P$. for a given element x , we define $h(x)$ according to the following four possible ‘complementation patterns’ with respect to P .

1. $x \in P, \neg x \notin P$: set $h(x) = 1$;
2. $\neg x \in P, x \notin P$: set $h(x) = 0$;
3. $x \in P, \neg x \in P$: set $h(x) = p$;
4. $x \notin P, \neg x \notin P$: set $h(x) = q$.

It is worth remarking that if \mathcal{D} is a Boolean lattice, (3) (inconsistency) and (4) (incompleteness) can never arise, which explains the well-known significance of 2 for Boolean homomorphism theory. Clearly these specifications assure that $h(a) \in \{p, 1\}$ and $h(b) \in \{q, 0\}$, and so by inspection $h(a) \not\leq h(b)$. It is left to the reader to verify that h in fact is a homomorphism. (Hint to avoid more calculation: set $[p] = \{p, 1\}$ and $[q] = \{q, 0\}$ (the principal filters determined by p and q). Observe that the definition of h above is equivalent to requiring of h that $h(x) \in [p]$ iff $x \in P$, and $h(x) \in [q]$ iff $\neg a \notin P$. Observe that if whenever $i = p, q, y \in [i]$ iff $z \in [i]$, then $y = z$. Show for $i = p, q$, $h(a \wedge b) \in [i]$ iff $h(a) \wedge h(b) \in [i]$, $h(a \vee b) \in [i]$ iff $h(a) \vee h(b) \in [i]$, and $h(\neg a) \in [i]$ iff $\neg h(a) \in [i]$. ■

3.4 Set-theoretical Semantics for First-degree Relevant Implication

Dunn [1966] (cf. also [Dunn, 1967]) considered a variety of (effectively equivalent) representations of de Morgan lattices as structures of sets. We shall here discuss the two of these that have been the most influential in the development of set-theoretical semantics for relevance logic.

The earliest one of these is due to Białynicki-Birula and Rasiowa [1957] and goes as follows. Let U be a non-empty set and let $g : U \rightarrow U$ be such that it is of period two, i.e.

1. $g(g(x)) = x$, for all $x \in U$.

(We shall call the pair (U, g) and *involved set*— g is the *involution*, and is clearly 1–1). Let $Q(U)$ be a ‘ring’ of subsets of U (closed under \cap and \cup) closed as well under the operation of ‘quasi-complement’

$$2. \neg X = U - g[X] (X \subseteq U).$$

$(Q(U), \cup, \cap, \neg)$ is called a *quasi-field of sets* and is a de Morgan lattice.

QUASI-FIELDS OF SETS THEOREM [Białynicki-Birula and Rasiowa, 1957].
Every de Morgan lattice \mathcal{D} is isomorphic to a quasi-field of sets.

Proof. Let U be the set of all prime filters of \mathcal{D} , and let P range over U . Let $\neg P \rightarrow \{\neg a : a \in P\}$, and define $g(P) = \mathcal{D} - \neg P$. We leave to the reader to verify that U is closed under g . For each element $a \in \mathcal{D}$, set

$$f(a) = \{P : a \in P\}.$$

Clearly f is one–one because of the Prime Filter Separation Property, so we need only check that f preserves the operations.

ad \wedge : $P \in f(a \wedge b) \Leftrightarrow a \wedge b \in P \Leftrightarrow ((1')$ of Section 3.3) $a \in P$ and $b \in P \Leftrightarrow P \in f(a)$ and $P \in f(b) \Leftrightarrow P \in f(a) \cap f(b)$. So $f(a \wedge b) = f(a) \cap f(b)$ as desired.

ad \vee : The argument that $f(a \vee b) = f(a) \cup f(b)$ is exactly parallel using (2') (or alternately this can be skipped using the fact that $a \vee b = \neg(\neg a \wedge \neg b)$).

ad \neg : $P \in f(\neg a) \Leftrightarrow \neg a \in P \Leftrightarrow a \in \neg P \Leftrightarrow a \notin g(P) \Leftrightarrow g(P) \notin f(a) \Leftrightarrow P \notin g[f(a)] \Leftrightarrow P \in U - g[f(a)]$.

We shall now discuss a second representation. Let U be a non-empty set and let R be a ring of subsets of U (closed under intersection and union, but not necessarily under complement, quasi-complement, etc.). by a *polarity* in R we mean an ordered pair $X = (X_1, X_2)$ such that $X_1, X_2 \in R$. We define a relation and operations as follows, given polarities $X = (X_1, X_2)$ and $Y = (Y_1, Y_2)$:

$$X \leq Y \Leftrightarrow X_1 \subseteq Y_1 \text{ and } Y_2 \subseteq X_2$$

$$X \wedge Y = (X_1 \cap Y_1, X_2 \cup Y_2)$$

$$X \vee Y = (X_1 \cup Y_1, X_2 \cap Y_2)$$

$$\neg X = (X_2, X_1).$$

By a field of polarities we mean a structure $(P(R), \leq, \wedge, \vee, \neg)$ where $P(R)$ is the set of all polarities in some ring of sets R , and the other components are defined as above. We leave to the reader the easy verification that every field of polarities is a de Morgan lattice. ■

We shall prove the following

POLARITIES THEOREM [Dunn, 1966]. *Every de Morgan lattice is isomorphic to a field of polarities.*

Proof. Given the previous representation, it clearly suffices to show that every quasi-field of sets is isomorphic to a field of polarities.

The idea is to set $f(X) = (X, U - g[X])$. Clearly f is one-one. We check that it preserves operations.

$$\begin{aligned} ad\wedge: f(X \cap Y) &= (X \cap Y, U - g[X \cap Y]) = (X \cap Y, (U - g[X]) \cap (U - g[Y])) = \\ &= (X, U - g[X]) \wedge (Y, U - g[Y]) = f(X) \wedge f(Y). \end{aligned}$$

$ad\vee$: Similar.

$$\begin{aligned} ad\neg: f(\neg X) &= (\neg X, U - g(\neg X)) = (U - g[X], U - g(U - g[X])) = (U - \\ &= g[X], X) = \neg f(X). \end{aligned}$$

■

We now discuss informal interpretations of the representation theorems that relate to semantical treatments of relevant first-degree implications familiar in the literature.

Routley and Routley [1972] presented a semantics for \mathbf{R}_{fde} , the main ingredients of which were a set K of ‘atomic set-ups’ (to be explained) on which was defined an involution $*$. An ‘atomic set-up’ is just a set of propositional variables, and it is used to determine inductively when complex formulas are also ‘in’ a given set-up. A set-up is explained informally as being like a possible world except that it is not required to be either consistent or complete. The Routley’s [1972] paper seems to conceive of set-ups very syntactically as literally being sets of formulas, but the Routley and Meyer [1973] paper conceives of them more abstractly. We shall think of them this latter way here so as to simplify exposition. The Routleys’ models can then be considered a structure $(K, *, \vDash)$, where K is a non-empty set, $*$ is an involution on K , and \vDash is a relation from K to zero-degree formulas. We read ‘ $a \vDash A$ ’ as the formula A holds at the set-up a :

1. $(\wedge \vDash) \quad a \vDash A \wedge B \Leftrightarrow a \vDash A \text{ and } a \vDash B$
2. $(\vee \vDash) \quad a \vDash A \vee B \Leftrightarrow a \vDash A \text{ or } a \vDash B$
3. $(\neg \vDash) \quad a \vDash \neg A \Leftrightarrow \text{not } a^* \vDash A.$

The connection of the Routleys’ semantics with quasi-fields of sets will become clear if we let $(K, *)$ induce a quasi-field of sets Q with quasi-complement \neg , and let \vDash interpret sentences in Q subject to the following conditions:

$$1'. \quad |\wedge| \quad |A \wedge B| = |A| \cap |B|$$

$$2'. \quad |\vee| \quad |A \vee B| = |A| \cup |B|$$

$$3'. \quad |\neg| \quad |\neg A| = \neg|A|.$$

Clause $(\wedge \vDash)$ results from clause $|\wedge|$ by translating $a \in |X|$ as $a \vDash X$ (cf. Section 3.2). Thus clause $|\wedge|$ says

$$a \in |A \wedge B| \Leftrightarrow a \in |A| \text{ and } a \in |B|,$$

i.e. it translates as clause $(\wedge \vDash)$. The case of disjunction is obviously the same. The case of negation is clearly of special interest, so we write it out.

Thus clause $|\neg|$ says

$$\begin{aligned} a \in |\neg A| &\Leftrightarrow a \in \neg|A|, \\ &\Leftrightarrow a \in K - |A|^*, \\ &\Leftrightarrow a \notin |A|^*, \\ &\Leftrightarrow a^* \notin |A|. \end{aligned}$$

But the translation of this last is just clause $(\neg \vDash)$.

Of course the translation works both ways, so that the Routleys' semantics is just an interpretation in the quasi-fields of sets of Białynicki-Birula and Rasiowa written in different notation. Incidentally soundness and completeness of \mathbf{R}_{fde} relative to the Routleys' semantics follows immediately *via* the translation above from the corresponding theorem of the previous section *vis à vis* de Morgan lattices together with their representation as quasi-fields of sets. Of course the Routleys' conceived their results and derived them independently from the representation of Białynicki-Birula and Rasiowa.

We will not say very much here about what intuitive sense (if any) can be attached to the Routleys' use of the $*$ -operator in their valational clause for negation. Indeed this question has had little extended discussion in the literature (though see [Meyer, 1979a; Copeland, 1979]). The Routleys' [1972] paper more or less just springs it on the reader, which led Dunn in [Dunn, 1976a] to describe the switching of a with a^* as 'a feat of prestidigitation'. Routley and Meyer [1973] contains a memorable story about how a^* 'weakly asserts', i.e. fails to deny, precisely what a asserts, but one somehow feels that this makes the negation clause vaguely circular. Still, semantics often gives one this feeling and maybe it is just a question of degree. One way of thinking of a and a^* is to regard them as 'mirror images' of one another reversing 'in' and 'out'. Where one is inconsistent (containing both A and $\neg A$), the other is incomplete (lacking both A and $\neg A$), and *vice versa* (when $a = a^*$, a is both consistent and complete and we have a situation appropriate to classical logic). Viewed this way the Routleys' negation clause

makes sense, but it does require some anterior intuitions about inconsistent and incomplete set-ups. More about the interpretation of this clause will be discussed in Section 5.1.

Let us now discuss the philosophical interpretation(s) to be placed on the representation of de Morgan lattices as fields of polarities. In Dunn [1966; 1971] the favoured interpretation of a polarity (X_1, X_2) was as a ‘proposition surrogate’, X_1 consisting of the ‘topics’ the proposition gives definite positive information about and, X_2 of the topics the proposition gives definite negative information about. A valuation of a zero degree formula in a de Morgan lattice can be viewed after a representation of the elements of the lattice as polarities as an assignment of positive and negative content to the formula. The ‘mistake’ in the ‘classical’ Carnap/Bar-Hillel approach to content is to take the content of $\neg A$ to be the set-theoretical complement of the content of A (relative to a given universe of discourse). In general there is no easy relation between the content of A and that of $\neg A$. They may overlap, they may not be exhaustive. Hence the need for the double-entry bookkeeping done by proposition surrogates (polarities). If A is interpreted as (X_1, X_2) , $\neg A$ gets interpreted as the interchanged (X_2, X_1) .

Another semantical interpretation of the same mathematics is to be found in Dunn [1969; 1976a]. There given a polarity $X = (X_1, X_2)$, X_1 is thought of as the set of situations in which X is true and X_2 as the set of situations in which X is false. These situations are conceived of as maybe inconsistent and/or incomplete, and so again X_1 and X_2 need not be set-theoretic complements. This leads in the case when the set of situations being assessed is a singleton $\{a\}$ to a rather simple idea. The field of polarities looks like this

We have taken the liberty of labelling the points so as to make clear the informal meaning. (Thus the top is a polarity that is simply true in a and the bottom is one that is simply false, but the left-hand one is both true and false, and the right-hand one is neither.) Note that the de Morgan complement takes fixed points on both B and N . This is of course our old friend 4, which we know to be characteristic for $\mathbf{R}_{\mathbf{fde}}$.

This leads to the idea of an ‘ambi-valuation’ as an assignment to sentences of one of the four values \mathbf{T} , \mathbf{F} , \mathbf{B} , \mathbf{N} , conceived either as primitive or realised

as sets of the usual two truth values as suggested by the labelling. On this latter plan we have the valuation clauses (with double entry bookkeeping):

$$\begin{aligned}
 (\wedge) \quad & T \in v(A \wedge B) \Leftrightarrow T \in v(A) \text{ and } T \in v(B), \\
 & F \in v(A \wedge B) \Leftrightarrow F \in v(A) \text{ or } F \in v(B), \\
 (\vee) \quad & T \in v(A \vee B) \Leftrightarrow T \in v(A) \text{ or } T \in v(B), \\
 & F \in v(A \vee B) \Leftrightarrow F \in v(A) \text{ and } F \in v(B), \\
 (\neg) \quad & T \in v(\neg A) \Leftrightarrow F \in v(A), \\
 & F \in v(\neg A) \Leftrightarrow T \in v(A).
 \end{aligned}$$

We stress here (as in [Dunn, 1976a]) that all this talk of something's being both true and false or neither is to be understood epistemically and not ontologically. One can have inconsistent and or incomplete assumptions, information, beliefs, etc. and this is what we are trying to model to see what follows from them in an interesting (relevant!) way. Belnap [1977b; 1977a] calls the elements of the lattice 'told values' to make just this point, and goes on to develop (making connections with Scott's continuous lattices) a theory of 'a useful four-valued logic' for 'how a computer should think' without letting minor inconsistencies in its data lead to terrible consequences.

Before we leave the semantics of first-degree relevant implications, we should mention the interesting semantics of van Fraassen [1969] (see also Anderson and Belnap [1975, Section 20.3.1] and van Fraassen [1973]), which also has a double-entry bookkeeping device. We will not mention details here, but we do think it is an interesting problem to try to give a representation of de Morgan lattices using van Fraassen's facts so as to try to bring it under the same umbrella as the other semantics we have discussed here.

3.5 The Algebra of \mathbf{R}

This section is going to be brief. Dunn has already explicated on this topic in Section 28.2 of [Anderson and Belnap, 1975] and the interested reader should consult that and then Meyer and Routley [1972] for information about how to algebraise related weaker systems and how to give set-theoretical representations.

De Morgan monoids are a class of algebras that are appropriate to \mathbf{R} in the sense that (i) the Lindenbaum algebra of \mathbf{R} is one of them and (ii) all \mathbf{R} theorems are valid in them ((ii) gives soundness, and of course (i) delivers completeness by way of the canonical valuation). In thinking about de Morgan monoids it is essential that \mathbf{R} be equipped with the sentential constant \mathbf{t} . Also it is nice to think of fusion (\circ) as a primitive connective, with even perhaps \rightarrow defined ($A \rightarrow B =_{\text{df}} \neg(A \circ \neg B)$) but this is not essential since in \mathbf{R} (but not the weaker relevance logics) fusion can be defined as $A \circ B =_{\text{df}} \neg(A \rightarrow \neg B)$.

A de Morgan monoid is a structure $\mathcal{D} = (D, \wedge, \vee, \neg, \circ, e)$ where

- (I) (D, \wedge, \vee, \neg) is a de Morgan lattice,
- (II) (D, \circ, e) is an Abelian monoid, i.e. \circ is a commutative, associative binary operation on D with e its identity, i.e. $e \in D$ and $e \circ a = a$ for all $a \in D$,
- (III) the monoid is ordered by the lattice, i.e. $a \circ (b \vee c) = (a \circ b) \vee (a \circ c)$,
- (IV) \circ is upper semi-idempotent ('square increasing'), i.e. $a \leq a \circ a$,
- (V) $a \circ b \leq c$ iff $a \circ \neg c \leq \neg b$ (Antilogism).

De Morgan monoids were first studied in [Dunn, 1966] (although [Meyer, 1966] already had isolated some of the key structural features of fusion that they abstract). They also were described in [Meyer *et al.*, 1974] and used in showing γ admissible. Similar structures were investigated quite independently by Maksimova [1967; 1971].

The key trick in relating de Morgan monoids to \mathbf{R} is that they are residuated, i.e. there is a 'residual' operation \rightarrow so that

- (VI) $a \circ b \leq c$ iff $a \leq b \rightarrow c$.

Indeed this operation turns out to be $\neg(b \circ \neg c)$ (with the weaker systems or with positive \mathbf{R} it is important to postulate this law of the residual). Thus

- (1) $a \circ b \leq c \Leftrightarrow b \circ a \leq c$ Commutativity
- (2) $a \circ b \leq c \Leftrightarrow b \circ \neg a$ 1, (V)
- (3) $a \circ b \leq c \Leftrightarrow a \leq \neg(b \circ \neg c)$ 2, de Morgan lattice.

As an illustration of the power of (VI) we show how the algebraic analogue of the Prefixing axiom follows from Associativity. First note that one can get from (III) the law of

- (Monotony) $a \leq b \Rightarrow c \circ a \leq c \circ b$.

Now getting down to Prefixing:

1. $a \rightarrow b \leq a \rightarrow b$
2. $(a \rightarrow b) \circ a \leq b$ 1, (VI)
3. $(c \rightarrow a) \circ c \leq a$ 2, Substitution
4. $(a \rightarrow b) \circ ((c \rightarrow a) \circ c) \leq b$ 2,3, Monotony
5. $((a \rightarrow b) \circ (c \rightarrow a)) \circ c \leq b$ 4, Associativity
6. $(a \rightarrow b) \circ (c \rightarrow a) \leq c \rightarrow b$ 5, (VI)
7. $a \rightarrow b \leq ((c \rightarrow a) \rightarrow (c \rightarrow b))$ 6, (VI).

Incidentally, something better be said at this point about how validity in de Morgan monoids is defined. Unlike the case with \mathbf{R}_{fde} , there are theorems which are of the form $A \rightarrow B$, e.g. $A \vee \neg A$. We need some way of defining validity which is broader than insisting that always $v(A) \leq v(B)$. The identity e interprets the sentential constant t . By virtue of the \mathbf{R} axiom $A \leftrightarrow (t \rightarrow A)$ characterising t , it makes sense to count all de Morgan monoid elements a such that $e \leq a$ as ‘designated’, and to define A as valid iff $v(A) \geq e$ for all valuations in all de Morgan monoids. We have the following law

$$a \leq b \Leftrightarrow e \leq a \rightarrow b,$$

which follows immediately from (VI) and the fact that e is the identity element. This means that (7) just above can be transformed into

$$e \leq (a \rightarrow b) \rightarrow ((c \rightarrow a) \rightarrow (c \rightarrow b))$$

validating prefixing as promised.

Other axioms of \mathbf{R} can be validated by similar moves. Commutativity validates Assertion, that e is the identity validates self-implication, square-increasingness validates Contraction, antilogism validates Contraposition, and the other axioms fall out of de Morgan lattice properties with lattice ordering and the residual law pitching in.

We shall not here investigate the ‘converse’ questions about how the fusion connective in \mathbf{R} is associative, etc. (that the Lindenbaum algebra of \mathbf{R} is indeed a de Morgan monoid (cf. Dunn’s Section 28.2.2 of [Anderson and Belnap, 1975])), but the proof is by ‘fiddling’ with contraposition being the key move.

Not as much is known about the algebraic properties of de Morgan monoids as one would like. Getting technical for a moment and using unexplained but standard terminology from universal algebra, it is known that de Morgan monoids are equationally definable (replace (V) with $a \circ \neg(a \circ \neg b) \leq b$, which can be replaced by the equation $(a \circ \neg(a \circ \neg b)) \vee b = b$). So by a theorem of Birkhoff the class of de Morgan monoids is closed under sub-algebras, homomorphic images, and subdirect products. Further, given a de Morgan monoid \mathcal{D} with a prime filter P with $e \in P$, the relation $a \approx b \Leftrightarrow (a \rightarrow b) \wedge (b \rightarrow a) \in P$ is a congruence, and the quotient algebra \mathcal{D}/\approx is subdirectly irreducible, and every de Morgan monoid is a subdirect product of such. It would be nice to have some independent interesting characterisation of the subdirectly irreducibles.

One significant recent result about the algebra of \mathbf{R} has been provided by John Slaney. He has shown that there are exactly 3088 elements in the free De Morgan monoid generated by the identity e . Or equivalently, in the language of \mathbf{R} including the constant t , there are exactly 3088 non-equivalent formulae free of propositional variables. The proof technique is

quite subtle, as generating a large algebra of 3088 elements is not feasible, even with computer assistance. Instead, Slaney attacked the problem using a “divide and conquer” technique [Slaney, 1985]. Since \mathbf{R} contains all formulae of the form $A \vee \neg A$, for any A , whenever L is a logic extending \mathbf{R} , $L = (L + A) \cap (L + \neg A)$, where $L + A$ is the result of adding A as an axiom to L and closing under modus ponens and adjunction. Given this simple result, we can proceed as follows. \mathbf{R} is $(\mathbf{R} + f \rightarrow t) \cap (\mathbf{R} + \neg(f \rightarrow t))$. Now it is not difficult to show that the algebra of $\mathbf{R} + (f \rightarrow t)$ generated by t is the two element boolean algebra. Then you can restrict your attention to the algebra generated by t in the logic $\mathbf{R} + \neg(f \rightarrow t)$. If this has some characteristic algebra, then you can be sure that the elements freely generated by t in \mathbf{R} are bounded above by the number of elements in the direct product of the two algebras. To get the characteristic algebra of $\mathbf{R} + \neg(f \rightarrow t)$, Slaney goes on to divide and conquer again. He ends up considering six matrices, characterising six different extensions of \mathbf{R} . This would give him an upper bound on the number of constants (the matrices were size 2, 4, 6, 10, 10 and 14, so the bound was their product, 67200, well above 3088). Then you have to consider how many of these elements are generated by the identity in the direct product algebra. A reasonably direct argument shows that there are exactly 3088 elements generated in this way, so the result is proved.

3.6 The Operational Semantics (Urquhart)

This set-theoretical semantics is based upon an idea that occurred independently to Urquhart and Routley in the very late 1960s and early 70s. We shall discuss Routley’s contribution (as perfected by Meyer) in the next section and also just mention some related independent work of [Fine, 1974]. Here we concentrate upon the version of Urquhart [1972c] (cf. also Urquhart [1972b; 1972a; 1972d]).

Common to all the versions is the idea that one has some set K whose elements are ‘pieces of information’, and that there is a binary operation \circ on K that combines pieces of information. Also there is an ‘empty piece of information’ $0 \in K$. We shall write $x \vDash A$ to mean intuitively ‘ A holds according to the piece of information x ’. The whole point of the semantics is disclosed in the valuational clause

$$(\rightarrow) \quad x \vDash A \rightarrow B \text{ iff } \forall y \in K \text{ (if } y \vDash A, \text{ then } x \circ y \vDash B).$$

The idea of the clause from left-to-right is immediately clear: if $A \rightarrow B$ is given by the information x , then if A is given by y , then the combined piece of information $x \circ y$ ought to give B (by *modus ponens*). The idea of the clause from right-to-left is to say that if this happens for all pieces of information y , this can only be because x gives us the information that $A \rightarrow B$.

Perhaps saying the whole point of the semantics is given in the clause (\rightarrow) along is an exaggeration. There are at least two quick surprises. The first is that we do not require (or want) a certain condition analogised from a condition required by Kripke's (relational) semantics for intuitionistic logic:

(The Hereditary Condition) If $x \vDash A$, then $x \circ y \vDash A$.

This would yield that if $x \vDash A$, then $x \vDash B \rightarrow A$, i.e. if $y \vDash B$, then $x \circ y \vDash A$. This would quickly involve us in irrelevance.

The other surprise is related to the failure of the Hereditary Condition: Validity cannot be defined as a formula's holding at *all* pieces of information in all models, since even $A \rightarrow A$ would not then turn out to be valid. Thus $x \vDash A \rightarrow A$ requires that if $y \vDash A$ then $x \circ y \vDash A$. But this last is just a commuted form of the rejected Hereditary Condition, and there is no more reason to think it holds. We shall see in a moment that the appropriate definition of validity is to require that $0 \vDash A$ for the empty piece of information in all models.

Enough talk of what properties \circ does not have! What property does it have? We have just been flirting with one of them. Clearly $0 \vDash A \rightarrow A$ requires that if $x \vDash A$ then $0 \circ x \vDash A$, and how more naturally would that be obtained than requiring that 0 be a (left) identity?

$$0 \circ x = x. \quad (\text{Identity})$$

This then seems the minimal algebraic condition on a model. Urquhart in fact requires others, all naturally motivated by the idea that \circ is the 'union' of pieces of information.

$$\begin{aligned} x \circ y &= y \circ x && (\text{Commutativity}) \\ x \circ (y \circ z) &= (x \circ y) \circ z && (\text{Associativity}) \\ x \circ x &= x. && (\text{Idempotence}) \end{aligned}$$

These conditions combined may be expressed by saying that $(K, \circ, 0)$ is a '(join) semi-lattice with least element 0 ', and accordingly Urquhart's semantics is often referred to as the 'semi-lattice semantics'. It is well-known that every semi-lattice is isomorphic to a collection of sets with union as \circ and the empty set as 0 (map x to $\{y : x \circ y = y\}$ so that henceforward \circ will be denoted by \cup).

Each of the conditions above of course corresponds to an axiom of \mathbf{R}_{\rightarrow} when it is nicely axiomatised. Thus commutativity plays a natural role in verifying the validity of assertion. The following use of natural deduction

in the metalanguage makes this point nicely (we write ‘ A, x ’ rather than $x \vDash A$ for a notational analogy):

- | | | |
|----|---|-------------------------|
| 1. | A, x | Hypothesis |
| 2. | $A \rightarrow B, z$ | Hypothesis |
| 3. | $B, x \cup z$ | 1, 2, (\rightarrow) |
| 4. | $B, z \cup x$ | 3, Comm. |
| 5. | $(A \rightarrow B) \rightarrow B, x$ | 2, 4(\rightarrow) |
| 6. | $(A \rightarrow B) \rightarrow B, 0 \cup x$ | 5, Identity |
| 7. | $A \rightarrow ((A \rightarrow B) \rightarrow B), 0.$ | |

The reader may find it amusing to write out an analogous pair of proofs for Prefixing, seeing how Associativity of \cup enters in, and for Contraction watching the Idempotence.²⁴

The game has now been given away. There is some fiddling to be sure in proving a completeness theorem for \mathbf{R}_{\rightarrow} *re* the semi-lattice semantics, but basically the idea is that the semi-lattice semantics is just the system $F\mathbf{R}_{\rightarrow}$ ‘written in the metalanguage’.

There is not a problem in extending the semi-lattice semantics so as to accommodate conjunction. The clause

$$x \vDash A \wedge B \text{ iff } x \vDash A \text{ and } x \vDash B \tag{\wedge}$$

does nicely. Somewhat strangely, the ‘dual’ clause

$$x \vDash A \vee B \text{ iff } x \vDash A \text{ of } x \vDash B \tag{\vee}$$

causes trouble. It is analogous to having the rule of \vee -Elimination $N\mathbf{R}$ read:

$$\frac{\begin{array}{l} A \vee B, x \\ A, x \quad \text{Hyp.} \\ \vdots \\ c, x \cup y \\ B, x \quad \text{Hyp.} \\ \vdots \\ C, x \cup y \end{array}}{C, x \cup y.}$$

With this rule we can prove

$$\text{\#} \quad (A \rightarrow B \vee C) \wedge (B \rightarrow C) \rightarrow (A \rightarrow C),$$

²⁴Though unfortunately verification of this last does not depend purely on Idempotence, but rather on $(xy)y = xy$, which of course is equivalent to Idempotence given Associativity and Identity. The verification of the formula $A \wedge (A \rightarrow B) \rightarrow B$ ‘exactly’ uses Idempotence, but of course this is hardly a formula of the *implicational* fragment.

which is not a theorem of \mathbf{R} (see [Urquhart, 1972c]—the observation is Meyer’s and Dunn’s.)²⁵ And of course one can analogously verify that it is valid in the semi-lattice semantics.

Note that the condition (V) is not nearly as intuitive as the condition (\wedge). The condition (\wedge) is plausible for any piece of information x , at least if the relation $x \vDash c$ does not require that C be *explicitly* contained in x . On the other hand the condition (V) is much less than natural. Does not it happen all the time that a piece of information x determines $A \vee B$ to hold, without saying which? Is not this one of the whole points of disjunctions? Pieces of information x that satisfy (V) might be called ‘prime’ (in analogy with this epithet applied to theories of Section 2.4), and they have a kind of completeness or effeminateness that is rare in ordinary pieces of information. This by itself counts as no criticism of the semantics, since it is quite usual in semantical treatments to work with such idealised notions.

The condition (V) is not really as ‘dual’ to the condition (\wedge) as one might think. Thus the formula

$$(\#d) \quad (B \wedge C \rightarrow A) \wedge (C \rightarrow B) \rightarrow (C \rightarrow A),$$

which is the dual of ($\#$) is easily seen not to be valid in the semantics. This seems to be connected with another feature (problem?) of the semantics, to wit, no one has ever figured out how to add a natural semantical treatment of classical negation to the semantics (although it is straightforward to add a species of constructive negation—see [Urquhart, 1972c]).²⁶ The point of the connection is that ($\#d$) would follow from ($\#$) given classical contraposition principles, and yet the first is valid and the second one invalid in the positive semantics. So something about the positive semantics would have to be changed as well to accommodate negation.

The semi-lattice semantics has been extensively investigated in Charlewood [1978; 1981]. He fits it out with (two) natural deduction systems one with subscripts and one without. This last is in fact the (positive) system of Prawitz [1965], which Prawitz wrongly conjectured to be the same as Anderson and Belnap’s. Charlewood proves normalisation theorems (something that was anticipated by Prawitz for his system—incidentally the problem of normalisation for the Anderson–Belnap \mathbf{R} seems still open). Incidentally, one advantage of these natural deduction systems is that, unlike the Anderson–Belnap one for their system \mathbf{R} (cf. Section 1.5), they allow for a proof of distribution.

Charlewood also carries out in detail the engineering needed to implement K. Fine’s axiomatisation of the semi-lattice semantics. What is needed is

²⁵It would be with $C \rightarrow C$ as an additional conjunct in the antecedent.

²⁶Charlewood and Daniels have investigated a combination of the semi-lattice semantics for the positive connectives and a four-valued treatment of negation in the style of [Dunn, 1976a]. they avoid the problem just described by in effect building into their definition of a model that it must satisfy classical contraposition. This does not seem to be natural.

to add to the Anderson–Belnap’s \mathbf{R}^+ the following rule:

R1: From $B_0 \wedge ((A_1 \wedge q_1, \dots, q_n \wedge A_n) \rightarrow X) \rightarrow ((B_1 \wedge q_1, \dots, B_n \wedge q_n) \rightarrow E)$ for $X = B, C$, and $n \geq 0$ infer the same thing with $B \vee C$ put in place of the displayed X , provided that the q_i are distinct and occur only where shown.

We forbear taking cheap shots at such an ungainly rule, the true elegance of which is hidden in the details of the completeness proof that we shall not be looking into. Obviously Anderson and Belnap’s \mathbf{R} is to be preferred when the issue is simplicity of Hilbert-style axiomatisations.²⁷

3.7 The Relational Semantics (Routley and Meyer)

As was indicated in the last section, Routley too had the basic idea of the operational semantics at about the same time as Urquhart. Priority would be very hard to assess. At any rate Dunn first got details concerning both their work in early 1971, although J. Garson told him of Urquhart’s work in December of 1970 and he has seen references made to a typescript of Routley’s with a 1970 date on it (in [Charlewood, 1978]).

Meyer and Dunn were colleagues at the time, and Routley sent Meyer a somewhat incomplete draft of his ideas in early 1971. This was a courageous and open communication in response to our keen interest in the topic (instead he might have sat on it until it was perfected). The draft favoured the operational semantics, indeed the semi-lattice semantics, and was not clear that this was not the way to go to get Anderson and Belnap’s \mathbf{R} . But the draft started with a more general point of view suggesting the use of a 3-placed accessibility relation $Rxyz$ (of course a 2-placed operation like \cup is a 3-placed relation, but not always conversely), with the following valuation clause for \rightarrow :

$$(\rightarrow) \quad x \vDash A \rightarrow B \text{ iff } \forall y, z \in K \text{ (if } Rxyz \text{ and } y \vDash A, \text{ then } z \vDash B).$$

Forgetting negation for the moment, the clauses for \wedge and \vee are ‘truth functional’, just as for the operational semantics.

Meyer, having observed with Dunn the lack of fit between the semi-lattice semantics and \mathbf{R} , was all primed to make important contributions to Routley’s suggestion. In particular he saw that the more general 3-placed relation approach could be made to work for all of \mathbf{R} . In interpreting $Rxyz$ perhaps the best reading is to say that the combination of the pieces of information x and y (not necessarily the union) is a piece of information in z (in bastard symbols, $x \circ y \leq z$). Routley himself called the x, y , etc.

²⁷However, the semi-lattice semantics has been taken up and generalised in the field of substructural logics in the work of [Došen, 1988; Došen, 1989] and [Wansing, 1993].

‘set-ups’, and conceived of them as being something like possible worlds except that they were allowed to be inconsistent and incomplete (but always prime). On this reading $Rxyz$ can be regarded as saying that x and y are compatible according to z , or some such thing.

Before going on we want to advertise some work that we are not going to discuss in any detail at all because of space limitations. The work of Fine [1974] independently covers some of the same ground as the Routley–Meyer papers, with great virtuosity making clear how to vary the central ideas for various purposes. The book of Gabbay [1976, see chapter 15] is also deserving of mention.

We now set out in more formal detail a version of the Routley–Meyer semantics for \mathbf{R}^+ (negation will be reserved for the next section). The techniques are novel and the completeness proof quite complicated, so we shall be reasonably explicit about details. The presentation here is very much indebted to work (some unpublished) of Routley, Meyer and Belnap.

By an (\mathbf{R}^+) frame (or model structure) is meant a structure $(K, R, 0)$, where K is a non-empty set (the elements of which are called *set-ups*), R is a 3-placed relation on $K, 0 \in K$, all subject to some conditions we shall state after a few definitions. We define for $a, b \in K, a \leq b$ (Routley and Meyer used $>$) iff $R0ab$, and R^2abcd iff $\exists x (Rabx \text{ and } Rxcd)$. We also write this last as $R^2(ab)cd$ and distinguish it from $R^2a(bc)d =_{df} \exists x (Raxd \wedge Rbcx)$. The variables a, b , etc. will be understood as ranging over the elements of some K fixed by the content of discussion.

Transcribing the conditions on the semi-lattice semantics as closely as we can into this framework we get the requirements

1. (Identity) $R0aa$,
2. (Commutativity) $Rabc \Rightarrow Rbac$,
3. (Associativity) $R^2(ab)cd \Rightarrow R^2a(bc)d$,²⁸
4. (Idempotence) $Raaa$.

It should be remarked that these conditions fail to pick up the whole strength of the corresponding semi-lattice conditions. Thus, e.g. Identity here only picks up $0 \cdot a \leq a$ and not conversely, and similarly for Idempotence (also of course Commutativity and Associativity do not require any identity, but this is a slightly different point). We need for technical reasons one more condition:

5. (Monotony) $Rabc$ and $a' \leq a \Rightarrow Ra'bc$.

²⁸In the original equivalent conditions of Routley and Meyer [1973] this was instead ‘Pasch’s Law’: $R^2abcd \Rightarrow R^2acbd$. Also Monotony (condition (5) below) was misprinted there.

By a model we mean a structure $M = (K, R, 0, \vDash)$, where $(K, R, 0)$ is a frame and \vDash is a relation from K to sentences of \mathbf{R}^+ satisfying the following conditions:

- (1) (Atomic Hereditary Condition). For a propositional variable p , if $a \vDash p$ and $a \leq b$, then $b \vDash p$.
- (2) (Valuational Clauses). For formulas A, B
 - (\rightarrow) $a \vDash A \rightarrow B$ iff $\forall b, c \in K$ (if $Rabc$ and $b \vDash A$, then $c \vDash B$);
 - (\wedge) $a \vDash A \wedge B$ iff $a \vDash A$ and $a \vDash B$;
 - (\vee) $a \vDash A \vee B$ iff $a \vDash A$ or $a \vDash B$.

We shall say that A is *verified* on M if $0 \vDash A$, and that A *entails* B on M if $\forall a \in K$ (if $a \vDash A$, then $a \vDash B$). We say that A is *valid* if A is verified on all models.

It is easy to prove by an induction on A , the following (note how Monotony enters in):

HEREDITARY CONDITION. For an arbitrary formula A , if $a \vDash A$ and $a \leq b$, then $b \vDash A$.

VERIFICATION LEMMA. *If in a given model $(K, R, 0, \vDash)$ A entails B in the sense that for every $a \in K$, $a \vDash A$ only if $a \vDash B$, then $A \rightarrow B$ is verified in the model, i.e. $0 \vDash A \rightarrow B$.*

Proof. suppose that $R0ab$ and $a \vDash A$. By the hypothesis of the Lemma, $a \vDash B$, and by the Hereditary Condition, $b \vDash B$, as is required for $0 \vDash A \rightarrow B$. ■

We are now in a position to prove the

SOUNDNESS THEOREM. *If $\vdash_{\mathbf{R}} A$, then A is valid.*

Proof. Most of this will be left to the reader. We first show that the axioms of \mathbf{R}^+ are valid. Since they are all of the form $A \rightarrow B$ we can simplify matters a little by using the Verification Lemma. As an illustration we verify Assertion (the reader may wish to compare this to the corresponding verification *vis à vis* the semi-lattice semantics of the last section).

To show $A \rightarrow [(A \rightarrow B) \rightarrow B]$ is valid, it suffices by the Verification Lemma to assume $a \vDash A$ and show $a \vDash (A \rightarrow B) \rightarrow B$. For this last we assume $Rabc$ and $b \vDash (A \rightarrow B)$, and show $c \vDash B$. By Commutativity, $Rabc$. By (\rightarrow) since we have $b \vDash (A \rightarrow B)$ and $a \vDash A$, we get $c \vDash B$ as desired.

The verification of the implicational axioms of Self-Implication and Prefixing are equally routine, falling right out of the Verification Lemma and

Associativity for the relation R . Unfortunately the verification of Contraction is a bit contrived (cf. note 24 above), so we give it here.

To verify Contraction, we assume that (1) $a \vDash A \rightarrow .A \rightarrow B$ and show $a \vDash A \rightarrow B$. To show this last we assume that (2) $Rabc$ and (3) $b \vDash A$, and show $c \vDash B$. From (2) we get, by Commutativity, $Rbac$. But $Rbbb$ holds by Idempotence. so we have $R^2(bb)ac$. By Associativity we get $R^2b(ba)c$, i.e. for some x , both (4) $Rbxc$ and (5) $Rbax$. by Commutativity, from (5) we get $Rabx$. Using (\rightarrow) , we obtain from this, (1), and (3) that (6) $x \vDash A \rightarrow B$. by Commutativity from (4) we get $Rxbc$, and from this, (6), and (3) we at last get the desired $c \vDash B$.

Verification of the conjunction and disjunction axioms is routine and is safely left to the reader.

It only remains to be shown then that the rules *modus ponens* and adjunction preserve validity. Actually something stronger holds. It is easy to see that for any $a \in K$ (not just 0), if $a \vDash A \rightarrow B$ and $a \vDash A$, then $a \vDash B$ (by virtue of $Raaa$), and of course it follows immediately from (\wedge) that if $a \vDash A$ and $a \vDash B$, then $a \vDash A \wedge B$. ■

We next go about the business of establishing the

COMPLETENESS THEOREM. *If A is valid, then $\vDash_{\mathbf{R}^+} A$.*

The main idea of the proof is similar to that of the by now well-known Henkin-style completeness proofs for modal logic. We suppose that no $\vDash_{\mathbf{R}^+} A$ and construct a so-called ‘canonical model’, the set-up of which are certain prime theories (playing the role of the maximal theories of modal logic). The base set-up 0 is constructed as a regular theory (for the terminology ‘regular’, ‘prime’, etc. consult Section 2.4; of course everything is relativised to \mathbf{R}^+). From this point on for simplicity we shall assume that we are dealing with \mathbf{R}^+ outfitted with the optional extra fusion connective \circ and the propositional constant t (recall these can be conservatively added — cf. Section 1.3). We then define $Rabc$ to hold precisely when for all formulas A and B , whenever $A \in a$ and $B \in b$, then $A \circ B \in c$.²⁹

Let us look now at the details. Pick 0 as some prime regular theory T with $A \notin T$. We can derive that at least one such exists using the Belnap Extension Lemma (it was stated in Section 2.5 for \mathbf{RQ} , but it clearly holds for \mathbf{R}^+ as well). thus set $\Delta = \mathbf{R}^+$ and $\theta = \{A\}$.

Define $K =$ set of prime theories,³⁰ and define the accessibility relation R canonically as above.

²⁹The use of \circ and t is a luxury to make things prettier at least at the level of description. Thus, e.g. as we shall see, the associativity of \mathbf{R} follows from the associativity of \circ , and other mnemonically pleasant things happen. We could avoid its use by defining $Rabc$ to hold whenever if $A \in a$ and $A \rightarrow B \in b$, then $B \in c$. Incidentally, the valational clause for fusion is : $x \vDash A \circ B$ iff for some a, b such that $Rabx$, $a \vDash A$ and $b \vDash B$. The valational clause for t is $x \vDash t$ iff $0 \leq x$.

³⁰One actually has a choice here. We have required of theories that they be closed under implications provable in 0, i.e. require of T that whenever $A \in T$ and $A \rightarrow B \in 0$,

THEOREM 4. *The canonically defined structure $(K, 0, R)$ is an \mathbf{R}^+ frame.*

LEMMA 5. *The relation R defined canonically above satisfies Identity, Commutativity, Idempotence, and Associativity.*

PROOF.

ad Identity. We need to show that $R0aa$, i.e. if $X \in 0$ and $A \in a$, then $X \circ A \in a$. By virtue of the \mathbf{R} -theorem $A \rightarrow t \circ A$, we have $t \circ A \in a$. But using the \mathbf{R} -theorem $X \rightarrow .t \rightarrow x$, we have $t \rightarrow X \in 0$. By Monotony we have $X \circ A \in a$ as desired.

ad Commutativity. Suppose $Rabc$. We need show $Rbac$, i.e. if $B \in b$ and $A \in a$, then $B \circ A \in c$. From $Rabc$, it follows that $A \circ B \in c$. But by virtue of the \mathbf{R} -theorem $A \circ B \rightarrow B \circ A$ (commutativity of \circ) we have $B \circ A \in C$, as desired.

ad Idempotence. We need show $Raaa$, i.e. if $A \in a$ and $B \in a$, then $A \circ B \in a$. This follows from the \mathbf{R} -theorem $A \wedge B \rightarrow A \circ B$, which follows ultimately from the square increasingness of \circ , $(X \rightarrow X \circ X)$, as the proof sketch below makes clear.

1. $A \wedge B \rightarrow A$ Axiom
2. $A \wedge B \rightarrow B$ Axiom
3. $(A \wedge B) \circ (A \wedge B) \rightarrow A \circ B$ 1, 2, Monotony
4. $A \wedge B \rightarrow A \circ B$ 3, square increasingness

ad Associativity. This is by far the least trivial property. Let us then assume that $R^2(ab)cd$, i.e. $\exists x(Rabx$ and $Rxcd)$. We need then show that there is a prime theory y such that $Rayd$ and $Rbcy$, i.e. $R^2a(bc)d$.

Set $y_0 = \{Y : \exists B \in b, C \in c : \vdash_{\mathbf{R}} B \circ C \rightarrow Y\}$. (This is sometimes referred to as $b \circ c$). Clearly the definition of y_0 assures that $Rbcy_0$.

Observe that y_0 is a theory.³¹ Thus it is clear that y_0 is closed under provable \mathbf{R} -implication, since this is just transitivity. We show it is also closed under adjunction. Thus suppose for some $B, B' \in b, C, C' \in c, \vdash_{\mathbf{R}} B \circ C \rightarrow Y$ and $\vdash_{\mathbf{R}} B' \circ C' \rightarrow Y'$. Then $\vdash_{\mathbf{R}} (B \circ C) \wedge (B' \circ C') \rightarrow Y \wedge Y'$ using easy properties of conjunction. But we have the \mathbf{R} -theorem $(B \wedge B') \circ (C \wedge C') \rightarrow (B \circ C) \wedge (B' \circ C')$ (which follows basically from the one-way distribution of \circ over \wedge , $X \circ (Y \wedge Z) \rightarrow (X \circ Y) \wedge (X \circ Z)$, which

then $B \in T$. The latter is a stronger requirement and leads to the 'smaller' *reduced* models of [Routley *et al.*, 1982], which are useful for various purposes.

³¹The presentation of Routley–Meyer [1973] is more elegant than ours, developing as they do properties of what they call the calculus of 'intensional \mathbf{R} -theories', showing that it is a partially ordered (under inclusion) commutative monoid (\circ as defined above) with identity 0. Further \circ is monotonous with respect to \leq , i.e. if $a \leq b$ then $c \circ a \leq c \circ b$, and \circ is square increasing, i.e. $a \leq a \circ a$. Then defining $Rabc$ to mean $a \circ b \leq c$, the requisite properties of \mathbf{R} fall right out.

follows basically from Monotony, $Y_1 \rightarrow Y_2 \rightarrow X \circ Y_1 \rightarrow X \circ Y_2$, which is easy). So by transitivity we get $\vdash_{\mathbf{R}} (B \wedge B') \circ (C \wedge C') \rightarrow Y \wedge Y'$, from which it follows that $Y \wedge Y' \in y_0$ as promised ($B \wedge B' \in b, C \wedge C' \in c$ of course, since b, c are closed under adjunction).

We next verify that Ra_0d . Suppose that $A \in a$ and $Y \in y_0$. Then for some $B \in b, C \in c, \vdash_{\mathbf{R}} B \circ C \rightarrow Y$. Since $Rabx, A \circ B \in x$. And since $Rxcd(A \circ B) \circ C \in d$. By the associativity of \circ (since d is a theory), then $A \circ (B \circ C) \in d$. but by Monotony, since $\vdash_{\mathbf{R}} B \circ C \rightarrow Y$, we have $\vdash_{\mathbf{R}} A \circ (B \circ C) \rightarrow A \circ Y$. Hence $A \circ Y \in d$, as needed.

The reader is excused if he has lost the thread a bit and thinks that we are now finished verifying the associativity of R . We wanted some prime theory y which fills in the blanks

1. Ra_d and
2. $Rbc_$,

and we have just finished verifying that y_0 is a theory that does fill in the blanks. The kicker is that y_0 need not be prime. So we work next at pumping up y_0 to make it prime while continuing to fill in the blanks.

It clearly suffices to prove

THE SQUEEZE LEMMA. *Let a_0 and y_0 be theories that need not be prime, and let d be a prime theory. If Ra_0y_0d , then there exists a prime theory y such that (i) $y_0 \subseteq y$ and (ii) Ra_0yd .*

This can be accomplished by a Lindenbaum-style construction like that of Section 2.3 (or alternatively Zorn's Lemma may be used as in Routley and Meyer [1973]). The idea is to define y as the union of a sequence of sets of formulas y_n , where (relative to some fixed enumeration of the formulas) y_{n+1} is defined inductively as $y_n \cup \{A_{n+1}\}$ if $Ra(y_n \cup \{A_{n+1}\})d$, and otherwise y_{n+1} is just y_n .

But it is instructive to crank the existence of the given y out of the Belnap Extension Lemma for \mathbf{R} .

Thus set $\Delta = y_0$ and $\theta = \{A : \exists B(A \rightarrow B) \in a \text{ and } B \notin d\}$. We need check that (Δ, θ) is exclusive.

We observe first that θ is closed under disjunction. Thus suppose $A_1, A_2 \in \theta$. Then for some $B_1, B_2, A_1 \rightarrow B_1, A_2 \rightarrow B_2 \in a$, and yet $B_1, B_2 \notin d$. Then (since d is prime) $B_1 \vee B_2 \notin d$. but since a is a theory, then $A_1 \vee A_2 \rightarrow B_1 \vee B_2$ by an appropriate theorem of \mathbf{R} in the proximity of the disjunction axioms. So $A_1 \vee A_2 \in \theta$ as desired. Since Δ is closed dually under adjunction (that was the point of observing above that y_0 is a theory), this means that if the pair (Δ, θ) fails to be exclusive, then for some $X \in \Delta, A \in \theta, \vdash_{\mathbf{R}} X \rightarrow A$. So for some $B, A \rightarrow B \in a$ and $B \notin d$. But since a is a theory, by transitivity we derive that $X \rightarrow B \in a$. But since $Raxd$

and $X \in x$, we get $(X \rightarrow B) \circ X \in d$. But since $\vdash_{\mathbf{R}} X \circ (X \rightarrow B) \rightarrow B$, we have $B \in d$, contrary to the choice of B .

Now that we know (Δ, Θ) is an exclusive pair we apply the Belnap Extension Lemma to get a pair (y, y') with $y_0 = \Delta \subseteq y$ and y a prime theory, completing the proof of the Squeeze Lemma, which actually does complete the proof that the relation R is Associativity.

ad Monotony. (Yes, we still have something left to do.) Let us suppose that $R0a'a$ and $Rabc$, and show $Ra'bc$. Note that it follows from $R0a'a$ that $a' \leq a$,³² from which it follows at once from $Rabc$ and $Ra'bc$. Thus if $X \in a'$ then since $X \rightarrow X \in 0$, then $(X \rightarrow X) \circ X \in a$. But since $\vdash_{\mathbf{R}^+} (X \rightarrow X) \circ X \rightarrow X$, then $X \in a$.

Having now finally verified that the canonical $(K, 0, R)$ has all the properties of an \mathbf{R}^+ -frame, we need now to define an appropriate relation \vDash on it. The natural definition is $a \vDash A$ iff $A \in a$, but we need now to verify that this has the properties (1) and (2) required of \vDash above.

THEOREM 2. *The canonically defined $(K, 0, R, \vDash)$ is indeed an \mathbf{R} -model.*

Proof. *ad* (1) (the Hereditary Condition). Suppose $a \leq b$, i.e. $R0ab$. We show that $a \leq b$, from which the Hereditary Condition immediately follows. Suppose then that $A \in a$. Since $t \in 0, t \circ A \in b$. But *via* the \mathbf{R} -theorem $t \circ A \rightarrow A$, we have $A \in b$ as desired.

ad (2) (the valuation of clauses). The clauses (\wedge) and (\vee) are more or less immediate (primeness is of course needed for half of (\vee)). The clause of interest is (\rightarrow) . Applying the canonical definition of \vDash , this amounts to

$$(\rightarrow_c) \quad A \rightarrow B \in a \text{ iff } \forall b, c (\text{if } Rabc \text{ and } A \in b, \text{ then } B \in c).$$

Left-to-right is argued as follows. Suppose $A \rightarrow B \in a, Rabc, A \in b$, and show $B \in c$. $Rabc$ of course means canonically that whenever $X \in a$ and $Y \in b$, then $X \circ Y \in c$. Setting $X = A \rightarrow B$ and $Y = A$, we get $A \circ (A \rightarrow B) \rightarrow C$. Then using the \mathbf{R}^+ -theorem

$$A \circ (A \rightarrow B) \rightarrow B, \text{ we obtain } B \in c.$$

Right-to-left is harder, and in fact involves the third (and last) application of the Belnap Extension Lemma in the proof of Completeness. Thus suppose contrapositively that $A \rightarrow B \notin a$. We need to construct prime theories b and c , with $A \in b$ and $B \notin c$. We let $\Delta_b = \text{Th}(\{A\})$ and set $\Delta_c = a \circ \Delta_b$, i.e. $\{Z : \exists X \in a, \exists Y \in \Delta_b \vdash_{\mathbf{R}^+} X \circ Y \rightarrow Z\}$. This is the same as $\{Z : \exists X \in a \vdash_{\mathbf{R}^+} X \circ A \rightarrow Z\}$. We set $\theta_c = \{B\}$. Clearly (Δ_c, θ_c) is an exclusive pair, for otherwise $\vdash_{\mathbf{R}^+} X \circ A \rightarrow B$, i.e. $\vdash_{\mathbf{R}^+} X \rightarrow (A \rightarrow B)$ for some $X \in a$, and so $A \rightarrow B \in a$ contrary to our supposition. We apply Belnap's Extension Lemma to get an exclusive pair (c, c') with $\Delta_c \subseteq c$ and c prime theory. Note

³²In the 'reduced models (cf. note 46) one can show that $R0a'a$ iff $a' \leq a$.

that by definition of Δ_b and Δ_c , $Ra\Delta_b\Delta_c$, and so $Ra\Delta_b c$. We are now in a position to apply the Squeeze Lemma getting a prime theory $b \supseteq \Delta_b$ such that $Rabc$. Clearly $A \in b$, but also $B \notin c$ since $B \in \theta_c \subseteq c'$ (c and c' are exclusive).

This at last completes the proof of the Completeness Theorem for \mathbf{R}^+ . ■

REMARK. It is fashionable these days to always prove *strong* completeness. This could have been done. Thus define A to be a *logical consequence* of a set of formulas Γ iff for every \mathbf{R}^+ -model M , if $0 \models B$ for every $B \in \Gamma$, then $0 \models A$. This is a kind of classical notion and should not be confused with some kind of relevant consequence. Thus, e.g. where B is a theorem of \mathbf{R}^+ , since always $0 \models B$, B will be a logical consequence of any set Γ . Define B to be deducible from Γ (again in a neo-classical sense) to mean $B \in \text{Th}(\Gamma \cup \mathbf{R}^+)$. Appropriate modifications of the work above will show that logical consequence is equivalent to deducibility.

3.8 Adding Negation to \mathbf{R}^+

We now discuss the Routley–Meyer semantics for the whole system \mathbf{R} . The idea is simply to add the Routley’s treatment of negation using the $*$ -operator (discussed in Section 3.4). (This is not difficult and there is very little reason to segregate it off into this separate section, except that we thought that the treatment of \mathbf{R}^+ was complicated enough.)

Thus an \mathbf{R} -frame is a structure, $(K, R, 0, *)$ where $(K, R, 0)$ is an \mathbf{R}^+ -frame and K is closed under the unary operation $*$ satisfying:

$$\begin{array}{ll} \text{(Period two)} & A^{**} = a, \\ \text{(Inversion)} & Rabc \Rightarrow Rac^*b^* \end{array}$$

For an \mathbf{R} -model the valuations clauses for the positive connectives are as for an \mathbf{R} -model, and we of course add

$$(\neg) \quad a \models \neg A \text{ iff } a^* \not\models A.$$

The soundness and completeness results are relatively easy modifications of those for \mathbf{R}^+ . That $*$ is of period two naturally is used in the verification of Double Negation and Inversion is central to the verification of Contraposition. For completeness, a^* is defined canonically as $\{A : \neg A \notin a\}$ (cf. the definition of the analogue $g[P]$ in the proof of Białyński–Birula and Rasiowa’s representation of de Morgan lattices in Section 3.4), and one of course has to show that a^* is a prime theory when a is. One also has to show that canonical $*$ is of period two and satisfies (Inversion), and that canonical \models satisfies (\neg) above, i.e. $A \in a \Leftrightarrow \neg A \notin a^*$, i.e. $\neg A \notin \{B : \neg B \notin a\}$, i.e. $\neg\neg A \in a$, which of course just uses Double Negation.

It is worth remarking that since the canonical 0 is a prime regular theory, then since $\vdash_{\mathbf{R}} A \vee \neg A$, then 0 is complete (but not necessarily consistent—this is relevant to the development in Section 3.9). For your garden variety Routley–Meyer model (not necessarily canonical) notice also that $0 \vDash A$ or $0 \vDash \neg A$. This follows ultimately from $0^* \leq 0$, i.e. $R00^*0$, proven below.

1. $R0^*0^*0^*$
2. $R0^*00$ 1, (Inversion), (Period two)
3. $R00^*0$ 2, (Commutation).

Now $0^* \leq 0$ means by the Hereditary Condition that if $0 \vDash A$ then $0^* \vDash A$, i.e. $0 \vDash \neg A$ as desired.

It should be said that although either the four-valued treatment or the $*$ -operator treatment of negation work equally well for *first-degree* relevant implications (at least from a technical point of view), the $*$ -operator treatment seems to win hands down in the context of all of \mathbf{R} . Meyer [1979a] has succeeded in giving a four-valued treatment of all of \mathbf{R} , but at the price of great technical complexity (e.g. the accessibility relation has to be made four-valued as well, and that is just for starters). Further, as Meyer points out, one's models still have to be closed under $*$, so it still can be said to sneak in the back door.

3.9 Routley–Meyer Semantics for \mathbf{E} and other Neighbours of \mathbf{R}

Once one sets down a set of conditions on an accessibility relation, they can be played with in various ways so as to produce semantics for a wide variety of systems as the experience with modal logic has taught us. Also other features of the frames can be generalised.

We can here only give the flavour of a whole range of possible and actual results. In all the results below \vDash will satisfy the same conditions as for \mathbf{R}^+ (or \mathbf{R}) models (as appropriate). To begin with we follow Routley and Meyer [1973] with the description of a series of conditions on positive frames and corresponding axioms for propositional logic. They begin by requiring of a \mathbf{B}^+ -frame $(K, R, 0)$

- B1. $a \leq a$
- B2. $a \leq b$ and $b \leq x \Rightarrow a \leq x$
- B3. $a' \leq a$ and $Rabc \Rightarrow Ra'bc$.

B1–B2 of course say that \leq is a quasi-order, and B3 says something like that it is monotone.

‘**B**’ appears to be for ‘Basic’, for they regard the above postulates as a natural minimal set on their approach.³³ Gabbay [1976] investigates even weaker logics where no conditions at all are placed on the frame, but these have no theorems and are characterised only by rules of deducibility (unless Boolean negation and/or the Boolean material conditional is present, options which he does explore).

The sense in which the above postulates are minimal goes something like this. B3 is needed in proving the Hereditary Condition for implications, and the Hereditary Condition is needed in turn for verifying $0 \vDash A \rightarrow A$ (indeed anything) so we have at least some minimal theorems. The Hereditary Condition is used in showing the equivalence of the verification of an implication in a model and entailment in that mode, i.e. $0 \vDash A \rightarrow B$ iff $\forall x \in K(x \vDash A \Rightarrow x \vDash B)$ (cf. Section 3.7 to see how these conditions were used to establish these facts about \mathbf{R}^+ -models). What about B2? We think it is just a ‘freebie’. It seems to play no role in verifying axioms or rules, but the completeness proof can be made to yield canonical (‘reduced’) models (cf. note 3.7) that satisfy it, so why not have it? This seems to be what Routley *et. al.* [1982] say. It appears that B1 is even more a freebie.

It may be shown that A is a theorem of the system \mathbf{B}^+ (formulated in Section 1.3) iff A is valid in all \mathbf{B}^+ models.

Routley and Meyer establish the following correspondence between conditions on the accessibility relation R and axioms:

(1)	$Raaa$	$A \wedge (A \rightarrow B) \rightarrow B$
(2)	$Rabc \Rightarrow R^2a(ab)c$	$(A \rightarrow B) \wedge (B \rightarrow C) \rightarrow (A \rightarrow C)$
(3)	$R^2abcd \Rightarrow R^2a(bc)d$	$A \rightarrow B \rightarrow ([B \rightarrow C] \rightarrow [A \rightarrow C])$
(4)	$R^2abcd \Rightarrow R^2b(ac)d$	$A \rightarrow B \rightarrow ([C \rightarrow A] \rightarrow [C \rightarrow B])$
(5)	$Rabc \Rightarrow R^2abc$	$(A \rightarrow [A \rightarrow B]) \rightarrow (A \rightarrow B)$
(6)	$Ra0a$	$([A \rightarrow A] \rightarrow B) \rightarrow B$
(7)	$Rabc \Rightarrow Rbac$	$A \rightarrow ([A \rightarrow B] \rightarrow B)$
(8)	$0 \leq a$	$A \rightarrow (B \rightarrow B)$
(9)	$Rabc \Rightarrow b \leq c$	$A \rightarrow (B \rightarrow A)$.

Routley and Meyer connect these conditions on accessibility relations to axioms extending the basic logic \mathbf{B} . The correspondence is more perspicuous when you consider the *structural rules* corresponding to each axiom or condition. We can express these as conditions on fusion:

³³However, some notational confusion is possible, with Fine’s use of ‘**B**’ as another basic relevance logic differing slightly from Routley and Meyer’s usage [Fine, 1974]. For Fine, \mathbf{B} includes the law of the excluded middle, and for Routley and Meyer, it does not.

- | | | |
|-----|---------------------------------|--|
| (1) | $Raaa$ | $A \vdash A \circ A$ |
| (2) | $Rabc \Rightarrow R^2a(ab)c$ | $A \circ B \vdash A \circ (A \circ B)$ |
| (3) | $R^2abcd \Rightarrow R^2a(bc)d$ | $(A \circ B) \circ C \vdash A \circ (B \circ C)$ |
| (4) | $R^2abcd \Rightarrow R^2b(ac)d$ | $(A \circ B) \circ C \vdash B \circ (A \circ C)$ |
| (5) | $Rabc \Rightarrow R^2abbc$ | $A \circ B \vdash (A \circ B) \circ B$ |
| (6) | $Ra0a$ | $A \circ t \vdash A$ |
| (7) | $Rabc \Rightarrow Rbac$ | $A \circ B \vdash B \circ A$ |
| (8) | $0 \leq a$ | $B \circ A \vdash B$ (or $A \vdash t$) |
| (9) | $Rabc \Rightarrow b \leq c$ | $A \circ B \vdash B$. |

General recipes for translating between structural rules and conditions on accessibility relations are to be found in Restall [1998; 2000].

If one wants to add to \mathbf{B}^+ any of the axioms on the right to get a sentential logic \mathbf{X} , one merely adds the corresponding conditions to those for a \mathbf{B}^+ model to get the appropriate notion of an \mathbf{X} -model, with a resultant sound and complete semantics.

Some logics of particular interest arising in this way are (nomenclature as in [Anderson and Belnap, 1975]) (note well that \mathbf{T} has nothing to do with Feys' \mathbf{t} of modal logic fame):

- | | | |
|-----------------|---|-------------------------|
| \mathbf{TW}^+ | : | $\mathbf{B}^+ + (3, 4)$ |
| \mathbf{T}^+ | : | $\mathbf{TW}^+ + (5)$ |
| \mathbf{E}^+ | : | $\mathbf{T}^+ + (6)$ |
| \mathbf{R}^+ | : | $\mathbf{E}^+ + (7)$ |
| \mathbf{H}^+ | : | $\mathbf{R}^+ + (8)$ |
| $\mathbf{S4}^+$ | : | $\mathbf{E}^+ + (8)$. |

These are far from the most elegant formulations from a postulational point of view, being highly redundant (in particular the Prefixing and Suffixing *rules* of \mathbf{B}^+ are supplanted already in \mathbf{TW}^+ by the corresponding *axioms*. further the rule of Necessitation ($A \vdash (A \rightarrow A) \rightarrow A$) is also redundant already in \mathbf{TW}^+ (this is not so obvious—proof is by browsing through [Anderson and Belnap, 1975]).

What minimal conditions should be imposed on the $*$ -operator when it is added to a \mathbf{B}^+ -frame so as to give a \mathbf{B} -frame? Routley *et. al.* [1982] choose

B4. $a^{**} = a$, and

B5. $a \leq b \Rightarrow b^* \leq a^*$.

The minimality of B5 can be defended in terms of its being needed for showing that negations satisfy the Hereditary Condition. B4 would seem to have little place in a *minimal* system except for the fact that the dominant trend in relevance logic has been to keep classical double negation.³⁴

³⁴In fact, B5 is too strong for a purely *minimal* logic of negation. See Section 5.1 for more discussion on this.

One can get semantics for the full systems **TW**, **T**, etc. simply by adding the appropriate postulates to the conditions on a **B**-model.

We could go on, but will instead refer the reader to Routley *et al.* [1982], Fine [1974] and Gabbay [1976] for a variety of variations producing systems in the neighbourhood of **R**.

Some find the conditions on the “base point” 0 on frames rather puzzling or unintuitive. Why should the basic conditions on frames include conditions such as the fact that $a \leq b$ defined as $R0ab$ generate a partial order? Some recent work by Priest and Sylvan and extended by Restall has shown that these conditions can be done away with and the frames given an interpretation rather reminiscent of that of non-normal modal logics [Priest and Sylvan, 1992; Restall, 1993]. The idea is as follows. We have two sorts of set-ups in a frame — normal ones and non-normal ones. Then we split the treatment of implication along this division. Normal points are given an **S5**-like interpretation.

- $x \vDash A \rightarrow B$ iff for every y if $y \vDash A$ then $y \vDash B$

and non-normal points are given the condition which appeals to the ternary relation R

- $x \vDash A \rightarrow B$ iff for every y and z where $Rxyz$ if $y \vDash A$ then $z \vDash B$

The other connectives are treated in just the same way as in the original relational semantics. To prove soundness and completeness for this semantics, it is simplest to go through the original semantics — for it is not too difficult to show that this account is merely a notational variant, where we have set $Rxyz$ iff $y = z$ when x is a normal set-up. This satisfies all of the conditions in the original semantics, for we have set $a \leq b$ to be simply $a = b$.

We turn now to one such system **RM** deserving of special treatment.

3.10 Algebraic and Set-theoretical Semantics for **RM**

RM has been described by Meyer as ‘the laboratory of relevance logic’. It plays a role somewhat like **S5** among modal logics, being a place where conjectures can be tested relatively easily (e.g. the admissibility of γ was first shown for **RM**). This then could be a very long section because **RM** is by far the best understood of the Anderson–Belnap style systems. We shall try to keep it short by being dogmatic. The interested reader can verify the results claimed by consulting Meyer’s Section 29.3 and Section 29.4 of [Anderson and Belnap, 1975] (see also [Dunn, 1970; Tokarz, 1980]).

In the first place the appropriate algebras for **RM** are the *idempotent* de Morgan monoids (strengthening $a \leq a \circ a$ to $a = a \circ a$). The subdirectly irreducible ones are all chains with de Morgan complement where $a \circ b = a \wedge b$

if $a \leq \neg b$, and $a \circ b = a \vee b$ otherwise. The designated elements are all elements a such that $\neg a \leq a$, and of course these must have a greatest lower bound to serve as the identity e . (This is just another description with \circ as primitive instead of \rightarrow of the ‘Sugihara matrices’ described in the publications cited above.) Meyer showed that if $\vdash_{\mathbf{RM}} A$, then A is valid in all the finite Sugihara matrices, establishing the finite model property for **RM**.

Dunn showed that every extension of **RM** closed under substitution and the rules of **R** has some finite Sugihara matrix as a characteristic matrix (**RM** is ‘pretabular’). A similar result was shown by Scroggs to hold for the modal logic **S5**, and researchers (particularly Maksimova) have obtained results characterising all such pretabular extensions of **S4** and of the intuitionistic logic. Curiously enough there are only finitely many, and it is an interesting open problem to find some similar results for **R**. **RM** corresponds to the super-system of the intuitionistic propositional calculus **LC** (indeed **LC** can be translated into **RM**; see [Dunn and Meyer, 1971]). Much study has been done of the ‘superintuitionistic’ calculi (with an emphasis on the decision problem), and it would be good to see some of the ideas of this carried over to the ‘super-relevant’ calculi. A small start was begun in [Dunn, 1979a].

Routley and Meyer [1973] add the postulate

$$0 \leq a \text{ or } 0 \leq a^*$$

to the requirement on an **R**-frame to get an **RM**-frame. Dunn [1979a] instead adds the requirement

$$Rac \Rightarrow a \leq c \text{ or } b \leq c,$$

which neatly generalised to give a family of postulates yielding set-theoretical semantics for a denumerable family of weakenings of **RM** which are algebraised by adding various weakenings of idempotence ($a^{n+1} = a^n$). It is an open problem whether **R** itself is the intersection of this family and whether they all have the finite model property (if so, **R** is decidable). Since **R** is undecidable, one of these must be false. However, it is unknown at the time of writing which one fails.

Proof Sketch

1. $\neg X \rightarrow (\neg X \rightarrow \neg X)$ Mingle Axiom, Subst.
2. $X \rightarrow (\neg X \rightarrow X)$ 1, Permutation and Contraposition
3. $(A \vee \neg A) \wedge (B \vee \neg B) \rightarrow \neg((A \vee \neg A) \wedge (B \vee \neg B)) \rightarrow ((A \vee \neg A) \wedge (B \vee \neg B))$ 2, Subst.
4. $\neg(A \vee \neg A) \vee \neg(B \vee \neg B) \rightarrow (A \vee \neg A) \wedge (B \vee \neg B)$ 3, MP, de M
5. $A \wedge \neg A \rightarrow B \vee \neg B$ 4, $\vee I, \wedge E$, de M.

Kalman [1958] especially investigated de Morgan lattices with the property $a \wedge \neg a \leq b \vee \neg b$. We will call these *Kalman* lattices. He showed that every Kalman lattice is isomorphic to a subdirect product of the de Morgan lattice **3**. This implies a three-valued Homomorphism Separation Property for Kalman lattices (which also can be proven by modifying the proof of its four-valued analogue, noting that each ‘side’ of 4 is just a copy of 3). The representation in terms of polarities uses polarities $X = (X_1, X_2)$ where $X_1 \cup X_2 = U$, i.e. X_1 and X_2 are exhaustive.

This means informally that X always receives at least one of the values true and false. This leads to a semantics using ambivaluations into the left-hand side of 4:

This idea leads to a simpler Kripke-style semantics for **RM** using an ordinary binary accessibility relation instead of the Routley–Meyer ternary one (actually this semantics antedates the Routley–Meyer one, the results having been presented in [Dunn, 1969]—cf. [Dunn, 1976b] for a full presentation. No details will be supplied here. This semantics has been generalised to first-order **RM** with a constant domain semantics [Dunn, 1976c]). The analogous question with Routley–Meyer semantics is has now been closed in the negative in the work of [Fine, 1989], which we consider in Section 3.12.

Meyer [1980] has used this ‘binary semantics’ to give a proof of an appropriate Interpolation Lemma for **RM**. (Unfortunately, interpolation fails for **E** and **R** [Urquhart, 1993].)

3.11 Spin Offs from the Routley–Meyer Semantics

The Routley–Meyer semantical techniques can be used to prove a variety of results concerning the system **R** and related logics which were either more

complicated using other methods (usually algebraic or Gentzen methods), or even impossible. Thus (cf. [Routley and Meyer, 1973]), it is possible to give a variety of conservative extension results (being careful in constructing the canonical model to use only connectives and sentential constant available in the fragment being extended). Also it is possible to give a proof of the admissibility of γ (see [Routley and Meyer, 1973]) that is easier than the original algebraic proof (though not as easy as Meyer's latest proof using metavaluations—cf. Section 2.4). Admissibility of γ amounts to showing that if A is refutable in a given \mathbf{R} -model $(K, R, 0, \vDash)$ then A is refutable in a *normal* \mathbf{R} -model $(K', R', 0', \vDash')$ (one where $0'^* = 0'$) gotten by adding a new 'zero' and redefining R' and \vDash' in a certain way from R and \vDash .

Perhaps the most interesting new property to emerge this way is 'Halldén completeness', i.e. if $\vdash_{\mathbf{R}} A \vee B$ and A and B share no propositional variables in common, then $\vdash_{\mathbf{R}} A$ or $\vdash_{\mathbf{R}} B$ ([Routley and Meyer, 1973, Section 2.3]).

Another direction that the Routley–Meyer semantics has taken quickly ends up in heresy: classical (Boolean) negation \sim can be added to \mathbf{R} with horrible theorems resulting like $A \wedge \sim A \rightarrow B$, and yet \mathbf{R} does not collapse to classical logic. Indeed no new theorems emerge in the original vocabulary of \mathbf{R} . The idea is to take a normal \mathbf{R} -model $(K, R, 0, *, \vDash)$ and turn it in for a new \mathbf{R} -model $(K', R', 0', *', \vDash')$, whose $0'$ is a new element $K' = K \cup \{0'\}$, $*'$ is like $*$ but with $0'*' = 0'$, and R' is like R with the additional features:

1. $R'0'ab$ iff $R; a0'b$ iff $a = b$,
2. $R'ab0'$ iff $a = b^*$.

Also \vDash' is just like \vDash but with $0' \vDash A$ if $0 \vDash A$.

The whole point of this exercise is to provide refuting \mathbf{R} -models for all non- \mathbf{R} -theorems that have the property

$$a \leq b \text{ (i.e. } R0'ab) \Rightarrow a = b.$$

These are called 'classical \mathbf{R} -models' (first studied in Meyer and Routley [1973a; 1973b]) and upon them one can define

$$a \vDash \sim A \Leftrightarrow \text{not } a \vDash A.$$

One could not do this on ordinary \mathbf{R} -models without things coming apart at the seams, because in order to have the theorem $\sim p \rightarrow \sim p$ valid, one would need the Hereditary Condition to hold for $\sim p$, i.e. if $a \leq b$, then if $a \vDash \sim p$ then $b \vDash \sim p$, i.e. if $a \vDash p$ then $b \vDash p$. But one has no reason to think that this is the case, since all one has is the converse coming from the fact that the Hereditary condition holds for p . The inductive proof the Hereditary condition breaks down in the presence of Boolean negation, but of course with classical \mathbf{R} -models the Hereditary Condition becomes vacuous and there is no need for a proof.

This leads to certain technical simplicities, e.g. it is possible to give Gödel–Lemmon style axiomatisations of relevance logics like the familiar ones for modal logics, where one takes among one’s axioms all classical tautologies (using \sim)—cf. [Meyer, 1974].

But it also leads to certain philosophical perplexities. For example, what was all the fuss Anderson and Belnap made against contradictions implying everything and disjunctive syllogism? Boolean negation trivially satisfies them, so what is the interest in de Morgan negation failing to satisfy them. Will the real negation please stand up?

A certain schism developed in relevance logic over just how Boolean negation should be regarded. See [Belnap and Dunn, 1981; Restall, 1999] for the ‘con’ side and [Meyer, 1978] for the ‘pro’ side.

Belnap and Dunn [1981] point out that although Meyer’s axiomatisations of \mathbf{R} with Boolean negation do not lead to any new *theorems* in the standard vocabulary of \mathbf{R} , they do lead to new derivable rules, e.g. $A \wedge \neg A \vdash B$ and $\neg A \wedge (A \vee B) \vdash B$ (note well that the negation here is de Morgan negation). This can be seen quite readily if one recognises that the semantic correlate of $X \vdash Y$ is that $0 \vDash X \Rightarrow 0 \vDash Y$ in all classical \mathbf{R} -models, and that since all such are normal, \neg behaves at 0 in these just like classical negation. We both think this point counts against enriching \mathbf{R} with Boolean negation, but Meyer [1978, note 21] thinks otherwise.

3.12 Semantics for \mathbf{RQ}

The question of how to extend these techniques to handle quantified relevance logics was open for a long time. The first significant results were by Routley, who showed that the obvious constant domain semantics were sufficient to capture \mathbf{BQ} , the natural first-order extension of \mathbf{B} [Routley, 1980b]. However, extending the result to deal with systems involving transitivity postulates in the semantics (such as $Rabc \wedge Rcde \Rightarrow R^2abde$) proved difficult. To verify that the frame of prime theories on some constant domain actually satisfies this condition (given that the logic satisfies a corresponding condition, here the prefixing axiom) requires constructing a new prime theory x such that $Rabx$ and $Rxde$. And there seems to be no general way to show that such a theory can be constructed using the domain shared by the other theories. This is not a problem for logics like \mathbf{BQ} , in which the frame conditions do not have conditions which, to be verified in the completeness proof, require the construction of new theories.

Fine showed that this is not merely a problem with our proof techniques. Logics like \mathbf{RQ} , \mathbf{EQ} , \mathbf{TQ} and even \mathbf{TWQ} are incomplete with respect to the constant domain semantics on the frames for the propositional logics [Fine, 1989]. He has given a technical argument for this, constructing a formula in the language of \mathbf{RQ} which is true in all constant domain models, but which is not provable. The argument is too detailed to give here. It consists of a

simple part, which shows that the formula

$$\begin{aligned} & ((p \rightarrow \exists x E x) \wedge \forall x((p \rightarrow F x) \vee (G x \rightarrow H x))) \\ & \rightarrow (\forall x(E x \wedge F x \rightarrow q) \wedge \forall x((E x \rightarrow q) \vee G x) \rightarrow \exists x H x \vee (p \rightarrow q)) \end{aligned}$$

is valid in the constant domain semantics. This is merely a tedious verification that there is no counterexample. The subtle part of his argument is the construction of a countermodel. Clearly the countermodel cannot be a constant domain frame. Instead, he constructs a frame with variable domains, in which each of the axioms of **RQ** is valid (and in which the rules preserve validity) but the offending formula fails. This is quite a tricky argument, for variable domain semantics tend not to verify **RQ**'s analogue to the Barcan formula

$$\forall x(p \rightarrow F x) \rightarrow (p \rightarrow \forall x F x)$$

But Fine constructs his example in such a way that this formula is valid, despite the variable domains.

Despite this problem, Fine has found a semantics with respect to which the logic **RQ** is sound and complete. This semantics rests on a different view of the quantifiers. For Fine's account, a statement of the form $\forall x A(x)$ is true at a set-up not only when $A(c)$ is true for each individual c in the domain of the set-up, but instead, when $A(c)$ is true for an *arbitrary* individual c . In symbols,

$$a \models \forall x A(x) \text{ iff } (\exists a \uparrow)(\exists c \in D_{a \uparrow} - D_a)(a \uparrow \models A(c)).$$

That is, for every set-up a there are *expansions* of the form $a \uparrow$ where we add new elements to the domain, but these are totally arbitrary. The frames Fine defines are rather complex, needing not only the \uparrow operator but also a corresponding \downarrow operator which cuts down the domain of a set-up, and an across operator \leftarrow which identifies points in setups ($\rightarrow (a, \{c, d\})$ is the minimal extension of the set-up a in which the individuals c and d are identified. Instead of discussing the details of Fine's semantics, we refer the reader to his paper which introduced them [Fine, 1988]. Fine's work has received some attention, from Mares, who considers options for the semantics of identity [Mares, 1992]. However, it must be said that while the semantic structure pins down the behaviour of **RQ** and related systems exactly, it is not altogether clear whether the rich and complex structure of Fine's semantics is necessary to give a semantics for quantified relevance logics.

Whatever one's thoughts about the theoretical adequacy of Fine's semantics, they do raise some important issues for anyone who would give a semantic structure for quantified relevance logics. There are a number of issues to be faced and a number of options to be weighed up. One option is to give complete primacy to the frames for the propositional logics, and

to use the constant domain semantics on these frames. The task then is to axiomatise this extension. The task is also to give some interpretation of what the points in these semantic structures might be. For if they are theories (or prime theories) then the evaluation clauses for the quantifiers do not make a great deal of sense without further explanation. No-one thinks that a claim of the form $\exists xA(x)$ can be a member of a theory only if there is an object in the language of the theory which satisfies A according to that theory. Nor are we so readily inclined to think that all theories need share the same domain of quantification.

If, on the other hand, we take the set-ups in frames to be quite like (some class of) theories, then we must face the issue of the relationships between these theories. No doubt, if $\forall xA(x)$ is in some theory, then $A(c)$ will be in that theory for any constant c in the language of the theory. However, the converse need not be the case.

Anyway, it is clear that there is a lot of work to be done in the semantics of relevance logics with quantifiers. One area which hasn't been explored at any depth, but which looks like it could bring some light is the semantics of positive quantified relevance logics. Without the distribution of the universal quantifier over disjunction, these systems are subsystems of intuitionistic logic.

4 THE DECISION PROBLEM

4.1 Background

When the original of this Handbook article was published back in 1985, without a doubt the outstanding open problem in relevance logics was the question as to whether there exists a decision procedure for determining whether formulas are theorems of the system **E** or **R**. Anderson [1963] listed it second among his now historic open problems (the first was the admissibility of Ackermann's rule γ discussed in Section 2). Through the work of Urquhart [1984], we now know that there is no such decision procedure.

Harrop [1965] lends interest to the decision problem with his remark that 'all "philosophically interesting" propositional calculi for which the decision problem has been solved have been found to be decidable ...'.³⁵ We now have a very good counterexample to Harrop's claim.

In this section we shall examine Urquhart's proof, but before we get there we shall also consider various fragments and subsystems of **R** for which there are decision procedures. **R** will be our paradigm throughout this discussion, though we will make clear how things apply to related systems.

³⁵He continues somewhat more technically '... and none is known for which it has been proved that it does not possess the finite model property with recursive bound.'

4.2 Zero-degree Formulas

These are formulas containing only \wedge , \vee , and \neg . As was explained in Section 1.7, the zero-degree theorems of \mathbf{R} (or \mathbf{E}) are precisely the same as those of the classical propositional calculus, so of course the usual two valued truth tables yield a decision procedure.

4.3 First-degree Entailments

Two different (though related) ‘syntactical’ decision procedures were described for these in Section 1.7 (the method of ‘tautological entailments’ and the method of ‘coupled trees’). A ‘semantical’ decision procedure using a certain four element matrix $\mathbf{4}$ is described in Section 3.3. The story thus told leaves out the historically (and otherwise) very important role of a certain eight element matrix M_0 (cf. [Anderson and Belnap, 1975, Section 22.1.3]). This matrix is essential for the study of first-degree formulas and higher (see Section 4.4 below), in so much as it is impossible to define an implication operation on $\mathbf{4}$ and pick out a proper subset of designated elements so as to satisfy the axioms of \mathbf{E} (*a fortiori* \mathbf{R}). Indeed M_0 was used in [Anderson and Belnap Jr., 1962b] and [Belnap, 1960b] to isolate the first-degree entailments of \mathbf{R} , and the formulation of Section 1.7 presupposes this use.

4.4 First-degree Formulas

These are ‘truth functions’ of first-degree entailments and/or formulas containing no \rightarrow at all (the ‘zero-degree formulas’). Belnap [1967a] gave a decision procedure using certain finite ‘products’ of M_0 . No one such product is characteristic for \mathbf{D}_{fdf} , but every non-theorem of \mathbf{E}_{fdf} is refutable in some such products M_0^n (where n may in fact be computed as the largest number of first-degree entailments occurring in a disjunction once the candidate theorem has been put in conjunctive normal form). Hence \mathbf{E}_{fdf} has the finite model property which suffices of course for decidability (cf. [Harrop, 1965]). This is frankly one of the most difficult proofs to follow in the whole literature of relevance logics. A sketch may be found in [Anderson and Belnap, 1975, Section 19].

4.5 ‘Career Induction’

This is what Belnap has labelled the approach, exemplified in Sections 4.1–4.3 above of extending the positive solution to the decision problem ‘a degree at a time’. The last published word on the Belnap approach is to be found in his [1967b] where he examines entailments between conjunctions of first-degree entailments and first degree entailments.

Meyer [1979c], by an amazingly general and simple proof, shows that a positive answer to the decision problem for ‘second-degree formulas’ (no \rightarrow within the scope of an arrow within the scope of an \rightarrow) is equivalent to finding a decision procedure for all of **R**.

4.6 Implication Fragment

We now start another tack. Rather than looking at fragments of the whole system **R** delimited by complexity of formulas, we instead consider fragments delimited by the connectives which they contain. The earliest result of this kind is due to [Kripke, 1959b], who gave a Gentzen system for the implicational fragments of **E** and **R**, and showed them decidable. We shall here examine the implicational fragment of **R** (**R** $_{\rightarrow}$) in some detail as a kind of paradigm for this style of argument.³⁶

The appropriate Gentzen calculus³⁷ LR_{\rightarrow} is the same as that given by Gentzen [1934] except for two trivial differences and one profound difference. The first trivial difference is the obvious one that we take only the operational rules for implication, and the second trivial difference consequent on this (with negation it would have to be otherwise) is that we can restrict our sequents to those with a single formula in the consequent. The profound difference is that we drop the structural rule variously called ‘thinning’ or ‘weakening’. This leaves:

Axioms.

$$A \vdash A.$$

Structural Rules.

$$\text{Permutation } \frac{\alpha, A, B, \beta, \vdash C}{\alpha, B, A, \beta, \vdash C} \quad \text{Contraction } \frac{\alpha, a, A \vdash B}{\alpha, A \vdash B}$$

Operational Rules.

$$(\vdash \rightarrow) \frac{\alpha, A \vdash B}{\alpha \vdash A \rightarrow B} \quad (\rightarrow \vdash) \frac{\alpha \vdash A \quad \beta, B \vdash C}{\alpha, \beta, A \rightarrow B \vdash C}.$$

It is easy to see why thinning would be a disaster for relevant implication.

³⁶Actually this and various other results discussed below using Gentzen calculi presupposes ‘separation theorems’ due to Meyer, showing, e.g. as is relevant to this case, that all of the theorems containing only \rightarrow are provable from the axioms containing only \rightarrow .

³⁷We do not follow Anderson and Belnap [1975] in calling Gentzen systems ‘consecution calculi’, much as their usage has to recommend it.

Thus:

$$\frac{\frac{\frac{A \vdash A}{A, B \vdash A} \text{Thinning}}{A \vdash B \rightarrow A} (\vdash \rightarrow)}{\vdash A \rightarrow (B \rightarrow A)} (\vdash \rightarrow)$$

It is desirable to prove ‘The Elimination Theorem’, which says that the following rule would be redundant (could be eliminated).

$$\text{(Cut)} \quad \frac{\alpha \vdash A \quad \beta, A \vdash B}{\alpha, \beta \vdash B}.$$

This is needed to show the equivalence of LR_{\rightarrow} to its usual Hilbert-style (axiomatic system ‘ HR_{\rightarrow} ’, R_{\rightarrow} one of the formulations of Section 1.3). We will not pause on details here, but the principal question regarding the equivalence is whether *modus ponens* (The sole rule for HR_{\rightarrow}) is admissible in the sense that whenever $\vdash A$ and $\vdash A \rightarrow B$ are both derivable in LR_{\rightarrow} , so is $\vdash B$ (let α and β be empty).

The strategy of the proof of the Elimination Theorem can essentially be that of Gentzen with one important but essentially minor modification. Thus, Gentzen actually proved something stronger than Cut elimination, namely,

$$\text{(Mix)} \quad \frac{\alpha \vdash A \quad \beta \vdash B}{\alpha, [\beta - A] \vdash B},$$

where $[\beta - A]$ is the result of deleting *all* occurrences of A from β . This is useful in the induction, but sometimes it takes out too many occurrences of A . In Gentzen’s framework these could always be thinned back in, but of course this is not available with LR_{\rightarrow} . We thus instead generalise Cut to the rule

$$\text{(Fusion)} \quad \frac{\alpha \vdash A \quad \beta \vdash B}{\alpha, (\beta - A) \vdash B},$$

where β contains some occurrences of A and $(\beta - A)$ is the result of deleting as many of those occurrences as one wishes (but at least one).

The main strategy of the decision procedure for LR_{\rightarrow} is to limit applications of the contraction rule so as to prevent a proof search from running on forever in the following manner: ‘Is $p \vdash q$ derivable? Well it is if $p, p \vdash q$ is derivable. Is $p, p \vdash q$ derivable? Well it is if $p, p, p \vdash q$ is, etc.’.

We need one simple notion before strategy can be achieved. We shall say that the sequent of $\alpha' \vdash A$ is a *contraction* of sequent $\alpha \vdash A$ just in

case $\alpha' \vdash A$ can be derived from $\alpha \vdash A$ by (repeated) applications of the rules Contraction and Permutation (with respect to this last it is helpful not even to distinguish two sequents that are mere permutations of one another). The idea that we now want to put in effect is to drop the rule Contraction, replacing it by building into the operational rules a limited amount of contraction (in the generalised sense just explained).

More precisely, the idea is to allow a contraction of the conclusion of an operational rule only in so far as the same result could not be obtained by first contracting the premises. A little thought shows that this means no change for the rule $(\vdash \rightarrow)$, and that the following will suffice for

$$(\rightarrow \vdash') \frac{\alpha \vdash A \quad \beta, B \vdash C}{[\alpha, \beta, A \rightarrow B] \vdash C}$$

where $[\alpha, \beta, A \rightarrow B]$ is any contraction of $\alpha, \beta, A \rightarrow B$ such that :

1. $A \rightarrow B$ occurs only 0, 1, or 2 times fewer than in $\alpha, \beta, A \rightarrow B$;
2. Any formula other than $A \rightarrow B$ occurs only 0 or 1 time fewer.

It is clear that after modifying LR_{\rightarrow} by building some limited contraction into $(\rightarrow \vdash)$ in the manner just discussed, the following is provable by an induction on length of derivations:

CURRY'S LEMMA.³⁸ *If a sequent Γ' is a contraction of a sequent Γ and Γ has a derivation of length n , then Γ' has a derivation of length $\leq n$.*

Clearly this lemma shows that the modification of LR_{\rightarrow} leaves the same sequents derivable (since the lemma says the effect of contraction is retained). So henceforth we shall by LR_{\rightarrow} always mean the modified version.

Besides the use just adverted to, Curry's Lemma clearly shows that every derivable sequent has an *irredundant* derivation in the following sense: one containing no branch with a sequent Γ' below a sequent Γ of which it is a contraction.

We are finally ready to begin explicit talk about the decision procedure. Given a sequent Γ , one begins the test for derivability as follows (building

³⁸This is named (following [Anderson and Belnap, 1975]) after an analogous lemma in [Curry, 1950] in relation to classical (and intuitionistic) Gentzen systems. There, with free thinning available, Curry proves his lemma with $(\rightarrow \vdash)$ (in its singular version) stated as:

$$\frac{\Gamma, A \rightarrow B \vdash A \quad \Gamma, A \rightarrow B, B \vdash C}{\Gamma, A \rightarrow B \vdash C}.$$

This in effect *requires* the maximum contraction *permitted* in our statement of $(\rightarrow \vdash)$ above, but this is OK since items contracted 'too much' can always be thinned back in. Incidentally, our statement of $(\rightarrow \vdash)$ also differs somewhat from the statement of Anderson and Belnap [1975] or Belnap and Wallace [1961], in that we build in just the minimal amount of contraction needed to do the job.

a ‘complete proof search tree’): one places above Γ all possible premises or pairs of premises from which Γ follows by one of the rules. Note well that even with the little bit of contraction built into $(\rightarrow\vdash)$ this will still be only a finite number of sequents. Incidentally, one draws lines from those premises to Γ . One continues in this way getting a tree. It is reasonably clear that if a derivation exists at all, then it will be formed as a subtree of this ‘complete proof search there’, by the paragraph just above, the complete proof search tree can be constructed to be irredundant. But the problem is that the complete proof search tree may be infinite, which would tend to louse up the decision procedure. There is a well-known lemma which begins to come to the rescue:

KÖNIG’S LEMMA. *A tree is finite iff both (1) there are only finitely many points connected directly by lines to a given point (‘finite fork property’) and (2) each branch is finite (‘finite branch property’).*

By the ‘note well’ in the paragraph above, we have (1). The question remaining then is (2), and this is where an extremely ingenious lemma of Kripke’s plays a role. To state it we first need a notion from Kleene. Two sequents $\alpha \vdash A$ and $\alpha' \vdash A$ are *cognate* just when exactly the same formulas (not counting multiplicity) occur in α as in α' . Thus, e.g. all of the following are cognate to each other:

- (1) $X, Y \vdash A$
- (2) $X, X, Y \vdash A$
- (3) $X, Y, Y \vdash A$
- (4) $X, X, Y, Y \vdash A$
- (5) $X, X, X, Y, Y \vdash A$.

We call the class of all sequents cognate to a given sequent a *cognition class*.

KRIPKE’S LEMMA. *Suppose a sequence of cognate sequents $\Gamma_0, \Gamma_1, \dots$, is irredundant in the sense that for no Γ_i, Γ_j with $i < j$, is Γ_i a contraction of Γ_j . Then the sequence is finite.*

We postpone elaboration of Kripke’s Lemma until we see what use it is to the decision procedure. First we remark an obvious property of LR_{\rightarrow} that is typical of Gentzen systems (that lack Cut as a primitive rule):

SUBFORMULA PROPERTY. *If Γ is a derivable sequent of LR_{\rightarrow} , then any formula occurring in any sequent in the derivation is a subformula of some formula occurring in Γ .*

This means that the number of cognition classes occurring in any derivation (and hence in each branch) is finite. But Kripke’s Lemma further shows

that only a finite number of members of each cognation class occur in a branch (this is because we have constructed the complete proof search tree to be irredundant). So every branch is finite, and so both conditions of König's lemma hold. Hence the complete proof search tree is finite and so there is a decision procedure.

Figure 1. Sequents in the Plane

Returning now to Kripke's Lemma, we shall not present a proof (for which see [Belnap Jr. and Wallace, 1961] or [Anderson and Belnap, 1975]). Instead we describe how it can be geometrically visualised. For simplicity we consider sequents cognate to $X, Y \vdash A$ ((1), (2), (3), etc. above). Each such sequent can be represented as a point in the upper right-hand quadrant of the co-ordinate plane (where origin is labelled with 1 rather than 0 since (1) is the minimal sequent in the cognation class). See Figure 1. Thus, e.g. (5) gets represented as '3 X units' and '2 Y units'.

Now given any sequent, say

$$(\Gamma_0) \quad X, X, X, Y, Y \vdash A$$

as a starting point one might try to build an irredundant sequence by first building up the number of Y 's tremendously (for purposes of keeping on the page we let this be to six rather than say a million). But in so doing one

has to reduce the number of X 's (say, to be strategic, by one). The graph now looks like 2 for the first two members of the sequence Γ_0, Γ_1 .

Figure 2. Descending Regions

The purpose of the intersecting lines at each point is to mark off areas (shaded in the diagram) into which no further points of the sequence may be placed. Thus if Γ_2 were placed as indicated at the point (6, 5), it would reduce to Γ_0 . What this means is that each new point must march either one unit closer to the X axis or one unit closer to the Y axis. Clearly after a finite number of points one or the other of the two axes must be 'bumped', and then after a short while the other must be bumped as well. When this happens there is no space left to play without the sequence becoming redundant.

The generalisation to the case of n formulas in the antecedent to Euclidean n -space is clear (this is with n finite—with n infinite no axis need ever be bumped).

Incidentally, Kripke's Lemma (as Meyer discovered) is equivalent to a theorem of Dickson about prime numbers: Let M be a set of natural numbers all of which are composed out of the first m primes. Then every $n \in M$ is of the form $P_1^{n_1} \cdot P_2^{n_2} \cdot \dots \cdot P_k^{n_k}$, and hence (by unique decomposition) can be regarded as a sequence of the P_i 's in which each P_i is repeated n_i times. Divisibility corresponds then to contraction (at least neglecting the case

$n_i = 0$). Dickson's theorem says that if no member of M has a proper divisor in M , then M is finite.

Before going on to consider how the addition of connectives changes the complexity, let us call the reader's attention to a major open problem: It is still unknown whether the implication fragment of \mathbf{T} is decidable.

4.7 Implication–Negation Fragment

The idea of \mathbf{LR}_{\supset} is to accommodate the classical negation principles presenting \mathbf{R} in the same way that Gentzen [1934] accommodated them for classical logic: provide multiple right-hand sides for the sequents. This means that a sequent is of the form $\alpha \vdash \beta$, where α and β are (possible empty) finite sequences of formulas. One adds structural rules for Permutation and Contraction on the right-hand side, reformulates $(\vdash \rightarrow)$ and $(\rightarrow \vdash)$ as follows

$$(\vdash \rightarrow) \frac{\alpha, A \vdash B, \beta}{\alpha \vdash A \rightarrow B, \beta} \quad (\rightarrow \vdash) \frac{\alpha \vdash A, \gamma \quad \beta, B \vdash \delta}{\alpha, \beta, A \rightarrow B \vdash \gamma, \delta},$$

and adds 'flip and flop' rules for negation:

$$(\vdash \neg) \frac{\alpha, A \vdash \beta}{\alpha \vdash \neg A, \beta} \quad (\neg \vdash) \frac{\alpha \vdash A, \beta}{\alpha, \neg A \vdash \beta}.$$

\mathbf{LE}_{\supset} is the same except that in the rule $(\vdash \rightarrow)\beta$ must be empty and α must consist only of formulas whose main connective is \rightarrow . The decision procedure for \mathbf{LE}_{\supset} was worked out by Belnap and Wallace [1961] along basically the lines of the argument of Kripke just reported in the last section, and is clearly reported in [Anderson and Belnap, 1975, Section 13]. The modification to \mathbf{LR}_{\supset} is straightforward (indeed \mathbf{LR}_{\supset} is easier because one need not prove the theorem of p. 128 of [Anderson and Belnap, 1975], and so one can avoid all the apparatus there of 'squeezes'). McRobbie and Belnap [1979] have provided a nice reformulation of \mathbf{LR}_{\supset} in an analytic tableau style, and Meyer has extended this to give analytic tableau for linear logic and other systems in the vicinity of \mathbf{R} [Meyer *et al.*, 1995].

4.8 Implication–Conjunction Fragment, and \mathbf{R} Without Distribution

This work is to be found in [Meyer, 1966]. The idea is to add to $\mathbf{LR}_{\rightarrow}$ the Gentzen rules:

$$(\wedge \vdash) \frac{\alpha, A \vdash C}{\alpha, A \wedge B \vdash C} \quad \frac{\alpha, \beta \vdash C}{\alpha, A \wedge B \vdash C} \quad (\vdash \wedge) \frac{\alpha \vdash A \quad \alpha \vdash B}{\alpha \vdash A \wedge B}.$$

Again the argument for decidability is a simple modification of Kripke's.

Note that it is important that the rule $(\wedge \vdash)$ is stated in two parts, and not as one ‘Ketonen form’ rule:

$$(K\wedge \vdash) \quad \frac{\alpha, A, B \vdash C}{\alpha, A \wedge B \vdash C}.$$

The reason is that without thinning it is impossible to derive the rule(s) $(\wedge \vdash)$ from $(K\wedge \vdash)$.

Early on it was recognised that the distribution axiom

$$A \wedge (B \vee C) \rightarrow (A \vee B) \vee C$$

was difficult to derive from Gentzen-style rules for **E** and **R**. Thus Anderson [1963] saw this as the sticking point for developing Gentzen formulations, and Belnap [1960b, page 72] says with respect to LE_{\rightarrow} that ‘the standard rules for conjunction and disjunction could be added ... the Elimination Theorem (suitably modified) remaining provable. However, [since distribution would not be derivable], the game does not seem worth the candle’. Meyer [1966] carried out such an addition to LR_{\rightarrow} , getting a system he called LR_{\rightarrow} –, whose Hilbert-style version is precisely **R** without the distribution axiom. He showed using a Kripke-style argument that this system is decidable. This system is now called **LR**, for “lattice **R**”.

Meyer [1966] also showed how **LR** can be translated into $\mathbf{R}_{\rightarrow, \wedge}$ rather simply. Given a formula A in the language of \mathbf{LR}^+ , let V be the set of variables in A , and let two atomic propositions p_t and p_f not in V . Set $\neg A$ for the moment to be $A \rightarrow p_f$, to define a translation A' of A as follows.

$$\begin{aligned} p' &= p \\ t' &= p_t \\ (A \rightarrow B)' &= A' \rightarrow B' \\ (A \wedge B)' &= A' \wedge B' \\ (A \vee B)' &= \neg(\neg A' \wedge \neg B') \\ (A \circ B)' &= \neg(A' \rightarrow \neg B') \end{aligned}$$

then setting $t(A) = \bigwedge \{p_t \rightarrow (p \rightarrow p) : p \in V \cup \{p_t, p_f\}\}$ and $f(A) = \bigwedge \{\neg\neg p \rightarrow p : p \in V \cup \{p_t, p_f\}\}$, we get the following theorem:

TRANSLATION THEOREM (Meyer). *If A is a formula in \mathbf{LR}^+ then A is provable in \mathbf{LR}^+ if and only if $(t(A) \wedge f(A) \wedge p_t) \rightarrow A'$ is provable in $\mathbf{R}_{\rightarrow, \wedge}$.*

The proof is given in detail in [Urquhart, 1997], and we will not present it here.

Some recent work of Alasdair Urquhart has shown that although $\mathbf{R}_{\rightarrow, \wedge}$ is decidable, it is *only just* decidable [Urquhart, 1990; Urquhart, 1997].

More formally, Urquhart has shown that given any particular formula in the language of $\mathbf{R}_{\rightarrow, \wedge}$, there is no primitive recursive bound on either the time or the space taken by a computation of whether or not that formula is a theorem. Presenting the proof here would take us too far away from the *logic* to be worthwhile, however we can give the reader the kernel of the idea behind Urquhart's result.

Urquhart follows work of [Lincoln *et al.*, 1992] by using a propositional logic to encode the behaviour of a *branching counter machines*. A counter machine has a finite number of *registers* (say, r_i for suitable i) which each hold one non-negative integer, and some finite set of possible *states* (say, q_j for suitable j). Machines are coded with a list of instructions, which enable you to *increment* or *decrement* registers, and test for registers' being zero. A *branching* counter machine dispenses with the test instructions and allows instead for machines to take multiple execution paths, by way of *forking* instructions. The instruction $q_i + r_j q_k$ means "when in q_i , add 1 to register r_j and enter stage q_k ," and $q_i - r_j q_k$ means "when in q_i , subtract 1 to register r_j (if it is non-empty) and enter stage q_k ," and $q_i f q_j q_k$ is "when in q_i , fork into two paths, one taking state q_j and the other taking q_k ."

A machine configuration is a state, together with the values of each register. Urquhart uses the logic \mathbf{LR} to simulate the behaviour of a machine. For each register r_i , choose a distinct variable R_i , for each state q_j choose a distinct variable Q_j . The configuration $\langle q_i; n_1, \dots, n_l \rangle$, where n_i is the value of r_i is the formula

$$Q_i \circ R_1^{n_1} \circ \dots \circ R_l^{n_l}$$

and the instructions are modelled by sequents in the Gentzen system, as follows:

Instruction	Sequent
$q_i + r_j q_k$	$Q_i \vdash Q_k \circ R_j$
$q_i - r_j q_k$	$Q_i, R_j \vdash Q_k$
$q_i f q_j q_k$	$Q_i \vdash Q_j \vee Q_k$

Given a machine program (a set of instructions) we can consider what is provable from the sequents which code up those instructions. This set of sequents we can call the *theory* of the machine. $Q_i \circ R_1^{n_1} \circ \dots \circ R_l^{n_l} \vdash Q_j \circ R_1^{m_1} \circ \dots \circ R_l^{m_l}$ is intended to mean that from state configuration $\langle q_i; n_1, \dots, n_l \rangle$ all paths will go through configuration $\langle q_j; m_1, \dots, m_l \rangle$ after some number of steps.

A branching counter machine *accepts* an initial configuration if when run on that configuration, all branches terminate at the final state q_f , with all registers taking the value zero. The corresponding condition in \mathbf{LR} will be the provability of

$$Q_i \circ R_1^{n_1} \circ \dots \circ R_l^{n_l} \vdash Q_m$$

This will *nearly* do to simulate branching counter machines, except for the fact that in **LR** we have $A \vdash A \circ A$. This means that each of our registers can be incremented as much as you like, provided that they are non-zero to start with. This means that each of our machines need to be equipped with every instruction of the form $q_i > 0 + r_j q_i$, meaning “if in state q_i , add 1 to r_j , provided that it is already nonzero, and remain in state q_i .”

Given these definitions, Urquhart is able to prove that a configuration is accepted in branching counter machine, if and only if the corresponding sequent is provable from the theory of that machine. But this is equivalent to a formula

$$\bigwedge \text{Theory}(M) \wedge t \rightarrow (Q_1 \rightarrow Q_m)$$

in the language of **LR**. It is then a short step to our complexity result, given the fact that there is no primitive recursive bound on determining acceptability for these machines. Once this is done, the translation of **LR** into $\mathbf{R}_{\rightarrow \wedge}$ gives us our complexity result.

It is still unknown if \mathbf{R}_{\rightarrow} has similar complexity or whether it is a more tractable system.

Despite this complexity result, Kripke’s algorithm can be implemented with quite some success. The theorem prover **Kripke**, written by McRobbie, Thistlewaite and Meyer, implements Kripke’s decision procedure, together with some quite intelligent proof-search pruning, by means of finite models. If a branch is satisfiable in **RM3**, for example, there is no need to extend it to give a contradiction. This implementation *works* in many cases [Thistlewaite *et al.*, 1988]. Clearly, work must be done to see whether the horrific complexity of this problem in general can be transferred to results about *average case* complexity.

Finally, before moving to add distribution, we should mention that Linear Logic (see Section 5.5) also lacks distribution, and the techniques used in the theorem prover **Kripke** have application in that field also.

4.9 Positive **R**

In this section we will examine extensions of the Gentzen technique to cover all of positive relevance logic. We know (see Section 4.12) that this will not provide decidability. However, they provide another angle on **R** and cousins. Dunn and Minc independently developed a Gentzen-style calculus (with some novel features) for **R** without negation (\mathbf{LR}^+).³⁹ Belnap

³⁹Dunn’s result was presented by title at a meeting of the Association for Symbolic Logic, December, 1969 (see [Dunn, 1974]), and the full account is to be found in [Anderson and Belnap, 1975, Section 28.5]. Minc [1972, earliest presentation said to there to be February 24] obtained essentially the same results (but for the system with a necessity operator). See also [Belnap Jr. *et al.*, 1980].

[1960b] had already suggested the idea of a Gentzen system in which antecedents were sequences of sequences of formulas, rather than just the usual sequences of formulas (in this section ‘sequence’ always means *finite* sequence). The problem was that the Elimination Theorem was not provable. LR^+ goes a step ‘or two’ further, allowing an antecedent of a sequent instead to be a sequence of sequence of . . . sequences of formulas. More formally, we somehow distinguish two kinds of sequences, ‘intensional sequences’ and ‘extensional sequences’ (say prefix them with an ‘ I ’ or an ‘ E ’). an antecedent can then be an intensional sequence of formulas, an extensional sequence of the last mentioned, etc. or the same thing but with ‘intensional’ and ‘extensional’ interchanged. (We do not allow things to ‘pile up’, with, e.g. *intensional* sequences of *intensional* sequences—there must be alternation).⁴⁰ Extensional sequences are to be interpreted using ordinary ‘extensional’ conjunction \wedge , whereas intensional sequences are to be interpreted using ‘intensional conjunction’ \circ , which may be defined in the full system \mathbf{R} as $A \circ B = \neg(A \rightarrow \neg B)$, but here it is taken as primitive—see below).

We state the rules, using commas for extensional sequences, semicolons for intensional sequences, and asterisks ambiguously for either; we also employ an obvious substitution notation.⁴¹

$$\text{Permutation } \frac{\alpha[\beta * \gamma] \vdash A}{\alpha[\gamma * \beta] \vdash A} \quad \text{Contraction } \frac{\alpha[\beta * \beta] \vdash A}{\alpha[\beta] \vdash A}$$

$$\text{Thinning } \frac{\alpha[\beta] \vdash A}{\alpha[\beta, \gamma] \vdash A}, \quad \text{provided } \beta \text{ is non-empty.}$$

$$\frac{\alpha; A \vdash B}{\alpha \vdash A \rightarrow B} (\vdash \rightarrow) \quad \frac{\alpha \vdash A \quad \beta[B] \vdash C}{\beta[\alpha; A \rightarrow B] \vdash C} (\rightarrow \vdash)$$

$$\frac{\alpha \vdash A \quad \alpha \vdash B}{\alpha \vdash A \wedge B} (\vdash \wedge) \quad \frac{\alpha[A, B] \vdash C}{\alpha[A \wedge B] \vdash C} (\wedge \vdash)$$

⁴⁰This differs from the presentation of [Anderson and Belnap, 1975] which allows such ‘pile ups’, and then adds additional structural rules to eliminate them. Belnap felt this was a clearer, more explicit way of handling things and he is undoubtedly right, but Dunn has not been able to read his own section since he rewrote it, and so return to the simpler, more sloppy form here.

⁴¹With the understanding that substitutions do not produce ‘pile ups’. Thus, e.g. a ‘substitution’ of an intensional sequence for an item in an intensional sequence does not produce an intensional sequence with an element that is an intensional sequence formed by juxtaposition. Again this differs from the presentation of [Anderson and Belnap, 1975, cf. note 28].

$$\frac{\alpha \vdash A}{\alpha \vdash A \vee B} (\vdash \vee) \quad \frac{\alpha \vdash B}{\alpha \vdash A \vee B} (\vdash \vee) \quad \frac{\alpha[a] \vdash C \quad \alpha[B] \vdash C}{\alpha[A \vee B] \vdash C} (\vee \vdash)$$

$$\frac{\alpha \vdash A \quad \beta \vdash B}{\alpha; \beta \vdash A \circ B} (\vdash \circ) \quad \frac{\alpha[a; B] \vdash C}{\alpha \circ B] \vdash C} (\circ \vdash)$$

For technical reasons (see below) we add the sentential constant t with the axiom $\vdash t$ and the rule:

$$\frac{\alpha[B] \vdash A}{\alpha[\beta; t] \vdash A} (t \vdash)$$

The point of the two kind of sequences can now be made clear. Let us examine the classically (and intuitionistically) valid derivation:

- (1) $\frac{A \vdash A}{A \vdash A}$ Axiom
- (2) $\frac{A, B \vdash A}{A \vdash B \rightarrow A}$ Thinning
- (3) $A \vdash B \rightarrow A$ ($\vdash \rightarrow$).

It is indifferent whether (2) is interpreted as

- (2 \wedge) $(A \wedge B) \rightarrow A$, or
- (2 \rightarrow) $A \rightarrow (B \rightarrow A)$,

because of the principles of exportation and importation. In LR^+ however we may regard (2) as ambiguous between

- (2,) $A, B \vdash A$ (extensional), and
- (2;) $A; B \vdash A$ (intensional).

(2,) continues to be interpreted as (2 \wedge), but (2;) is interpreted as

- (2 \circ) $(A \circ B) \rightarrow A$.

Now in \mathbf{R} , exportation holds for \circ but not for \wedge (importation holds for both). Thus the move from (2;) to (3) is valid, but not from (2,) to (3). On the other hand, in \mathbf{R} , the inference from $A \rightarrow C$ to $(A \wedge B) \rightarrow C$ is valid, whereas the inference to $(A \circ B) \rightarrow C$ is not. Thus the move from (1) to (2,) is valid, but not the move from (1) to (2;). the whole point of LR^+ is to allow some thinning, but only in extensional sequences.

This allows the usual classical derivation of the distribution axiom to go through, since clearly

$$A \wedge (B \vee C) \vdash (A \wedge B) \vee C$$

can be derived with no need of any but the usual extensional sequence. The following sketch of a derivation of distribution in the consequent is even

more illustrative of the powers of LR^+ (permutations are left implicit; also the top half is left to the reader);

$$\begin{array}{c}
\frac{A, B \vdash (A \wedge B) \vee C \quad A, C \vdash (A \wedge B) \vee C}{X \vdash X \quad A, B \vee C \vdash (A \wedge B) \vee C} (\vee \vdash) \\
\frac{X \vdash X \quad A, (X; X \rightarrow B \vee C) \vdash (A \wedge B) \vee C}{(X; X \rightarrow A), (X; X \rightarrow A, X \rightarrow B \vee C) \vdash (A \wedge B) \vee C} (\rightarrow \vdash) \\
\frac{(X; X \rightarrow A), (X; X \rightarrow A, X \rightarrow B \vee C) \vdash (A \wedge B) \vee C}{X \rightarrow A, X \rightarrow B \vee C; X \vdash (A \wedge B) \vee C} \\
\frac{X \rightarrow A, X \rightarrow B \vee C; X \vdash (A \wedge B) \vee C}{(X \rightarrow A) \wedge (X \rightarrow B \vee C); X \vdash (A \wedge B) \vee C} \\
\frac{(X \rightarrow A) \wedge (X \rightarrow B \vee C); X \vdash (A \wedge B) \vee C}{\vdash (X \rightarrow A) \wedge (X \rightarrow B \vee C) \rightarrow [X \rightarrow (A \wedge B) \vee C]}
\end{array}$$

LR^+ is equivalent to R^+ in the sense that for any negation-free sentence A of R , $\vdash A$ is derivable in LR^+ iff A is a theorem of R . The proofs of both halves of the equivalence are complicated by technical details. Right-to-left (the interpretation theorem) requires the addition of intensional conjunction as primitive, and then a lemma, due to R. K. Meyer, to the effect that this is harmless (a conservative extension). Left-to-right (the Elimination Theorem) is what requires the addition of the constant true sentence t . This is because the ‘Cut’ rule is stated as:

$$\frac{\alpha \vdash A \quad \beta(A) \vdash B}{\beta(\alpha) \vdash B},$$

where $\beta(\alpha)$ is the result of replacing arbitrarily many occurrences of A in $\beta(A)$ by α if α is non-empty, and otherwise by t .⁴² Without this emendation of the Cut rule one could derive $B \vdash A$ whenever $\vdash A$ is derivable (for arbitrary B , relevant or not) as follows

$$\frac{\frac{A \vdash A}{\vdash A} \text{ Thinning} \quad A, B \vdash A}{B \vdash A} \text{ Cut}$$

Discussing decidability a bit, one problem seems to be that Kripke’s Lemma (appropriately modified) is just plain false. The following is a sequence of cognate sequents in just the two propositional variables X and Y which is irredundant in the sense that structural rules will not get you from a later member to an earlier member:

$$\frac{X; Y \vdash X \quad (X; Y), X \vdash X \quad ((X; Y), X); Y \vdash X \dots}{\vdash (X; Y) \rightarrow X} \text{ }^{43}$$

⁴²Considerations about the eliminability of occurrences of t are then needed to show the admissibility of *modus ponens*. This was at least the plan of [Dunn, 1974]. A different plan is to be found in [Anderson and Belnap, 1975, Section 28.5], where things are arranged so that sequents are never allowed to have empty left-hand sides (they have t there instead).

4.10 Systems Without Contraction

Gentzen systems without the contraction rule tend to be more amenable to decision procedures than those with it. Clearly, all of the work in Kripke's Lemma is in keeping contraction under control. So it comes as no surprise that if we consider systems without contraction for intensional structure, decision procedures are forthcoming. If we remove the contraction rule from **LR** we get the system which has been known as **LRW** (**R** without **W** without distribution), and which is equivalent to the additive and multiplicative fragment of Girard's linear logic [Girard, 1987]. It is well known that this system is decidable. In the Gentzen system, define the *complexity* of a sequent to be the number of connectives and commas which appear in it. It is trivial to show that complexity never increases in a proof and that as a result, from any given sequent there are only a finite number of sequents which could appear in a proof of the original sequent (if there is one). This gives rise to a simple decision procedure for the logic. (Once the work has already been done in showing that Cut is eliminable.)

If we add the extensional structure which appears in the proof theories of traditional relevance logics then the situation becomes more difficult. However, work by Giambrone has shown that the Gentzen systems for positive relevance logics without contraction do in fact yield decision procedures [Giambrone, 1985]. In these systems we do have extensional contraction, so such a simple minded measure of complexity as we had before will not yield a result. In the rest of this section we will sketch Giambrone's ideas, and consider some more recent extensions of them to include negation. For details, the reader should consult his paper. The results are also in the second volume of *Entailment* [Anderson *et al.*, 1992].

Two sequents are *equivalent* just when you can get from one to the other by means of the invertible structural rules (intensional commutativity, extensional commutativity, and so on). A sequent is *super-reduced* if no equivalent sequent can be the premise of a rule of extensional contraction. A sequent is *reduced* if for any equivalent sequents which are the premise of a rule of extensional contraction, the conclusion of that rule is super-reduced. So, intuitively, a super-reduced sequent has no duplication in it, and a reduced sequent can have one part of it 'duplicated', but no more. Clearly any sequent is equivalent to a super-reduced sequent. The crucial lemma is that any super-reduced sequent has a proof in which every sequent appearing is

⁴³Further, this is not just caused by a paucity of structural rules. Interpreting the sequents of formulas of \mathbf{R}^+ (\wedge for comma, \circ for semicolon, \rightarrow for \vdash) no later formula provably implies an earlier formula. Incidentally, one does need at least two variables (cf. R. K. Meyer [1970b]).

reduced. This is clear, for given any proof you can transform it into one in which every sequent is reduced without too much fuss.

As a result, we have gained as much control over extensional contraction as we need. Giambrone is able to show that only finitely many reduced sequents can appear in the proof of a given sequent, and as a result, the size of the proof-search tree is bounded, and we have decidability. This technique does not work for intensional contraction, as we do not have the result that every sequent is equivalent to an intensionally super-reduced sequent, in the absence of the mingle rule. While $A \wedge A \vdash B$ is equivalent to $A \vdash B$, we do not have the equivalence of $A \circ A \vdash B$ and $A \vdash B$, without mingle.

These methods can be extended to deal with negation. Brady [1991] constructs out of *signed* formulae TA and FA instead of formulae alone, and this is enough to include negation without spoiling the decidability property. Restall [1998] uses the techniques of Belnap's *Display Logic* (see Section 5.2) to provide an alternate way of modelling negation in sequent systems. These techniques show that the decidability of systems without intensional contraction are decidable, to a large extent independently of the other properties of the intensional structure.

4.11 Various Methods Used to Attack the Decision Problem

Decision procedures can basically be subdivided into two types: syntactic (proof-theoretic) and semantic (model-theoretical). A paradigm of the first type would be the use of Gentzen systems, and a paradigm of the second would be the development of the finite model property. It seems fair to say, looking over the previous sections, that syntactic methods have dominated the scene when nested implications have been afoot, and that semantical methods have dominated when the issue has been first-degree implications and first-degree formulas.⁴⁴

There are two well-known model-theoretic decision procedures used for such non-classical logics as the intuitionistic and modal logics. One is due to McKinsey and Tarski and is appropriate to algebraic models (matrices) (cf. [Lemmon, 1966, p. 56 ff.]), and the other (often called 'filtration') is due to Lemmon and Scott and is appropriate to Kripke-style models (cf. [Lemmon, 1966, p. 208 ff]). Actually these two methods are closely connected (equivalent?) in the familiar situation where algebraic model and Kripke models are duals. The problem is that neither seems to work with **E** and **R**. The difficulty is most clearly stated with **R** as paradigm. For the algebraic models the problem is given a de Morgan monoid $(M, \wedge, \vee, \neg, \circ)$

⁴⁴As something like 'the exception that proves the rule' it should be noted that Belnap's [1967a] work on first-degree formulas and slightly more complex formulas has actually been a subtle blend of model-theoretic (algebraic) and proof-theoretic methods.

and a finite de Morgan sublattice $(D, \wedge', \vee, -')$, how to define a new multiplicative operation \circ' on D so as to make it a de Morgan monoid and so for $x, y \in D$, if $x \circ y \in D$ then $x \circ y = x \circ' y$. the chief difficulty is in satisfying the associative law. For the Kripke-style models (say the Routley–Meyer variety) the problem is more difficult to state (especially if the reader has skipped Section 3.7) but the basic difficulty is in the satisfying of certain requirements on the three-placed accessibility relation once set-ups have been identified into a finite number of equivalence classes by ‘filtration’. Thus, e.g. the requirement corresponding to the algebraic requirement of associativity is $Rax \ \& \ Rbcy \Rightarrow \exists y(Raby \ \& \ Rycx)$ ⁴⁵ the problem in a nutshell is that after filtration one does not know that there exists the appropriate equivalence class \bar{y} needed to feed such an existentially hungry postulate.

The McKinsey-Tarski method has been used successfully by Maksimova [1967] with respect to a subsystem of **R**, which differs essentially only in that it replaces the nested form of the transitivity axiom

$$(A \rightarrow B) \rightarrow [(B \rightarrow C) \rightarrow (A \rightarrow C)]$$

by the ‘conjoined’ form

$$(A \rightarrow B) \wedge (B \rightarrow C) \rightarrow (A \rightarrow C).$$
⁴⁶

Perhaps the most striking positive solution to the decision problem for a relevance logic is that provided for **RM** by Meyer (see [Anderson and Belnap, 1975, Section 29.3], although the result was first obtained by Meyer [1968]).⁴⁷ Meyer showed that a formula containing n propositional variables is a theorem of **RM** iff it is valid in the ‘Sugihara matrix’ defined on the non-zero integers from $-n$ to $+n$. this result was extended by [Dunn, 1970] to show that every ‘normal’ extension of **RM** has some finite Sugihara matrix (with possibly 0 as an element) as a characteristic matrix. So clearly **RM** and its extensions have at least the finite model property. Cf. Section 3.10 for further information about **RM**.

Meyer [private communication] has thought that the fact that the decidability of **R** is equivalent to the solvability of the word problem for de Morgan monoids suggests that **R** might be shown to be undecidable by some suitable modification of the proof that the word problem for monoids is unsolvable. It turns out that this is technique is the one which pays off — although the proof is very complex. The complexity arises because there is an important disanalogy between monoids and de Morgan monoids in

⁴⁵This is suggestively written (following Meyer) as $Ra(bc)x \Rightarrow R(ab)cx$.

⁴⁷In fact neither McKinsey-Tarski methods nor filtration was used in this proof. We are no clearer now that they could not be used, and we think the place to start would be to try to apply filtration to the Kripke-style semantics for **RM** of [Dunn, 1976b], which uses a *binary* accessibility relation and seems to avoid the problems caused by ‘existentially hungry axioms’ for the ternary accessibility relation.

that in the latter the multiplicative operation is necessarily commutative (and the word problem for commutative monoids *is* solvable).⁴⁸ Still it has occurred to both Meyer and Dunn that it might be possible to define a new multiplication operation \times for both \circ and \wedge in such a way as to embed the free monoid into the free de Morgan monoid. This suspicion has turned out to be right, as we shall see in the next section.

4.12 \mathbf{R} , \mathbf{E} and Related Systems

As is quite well known by now, the principal systems of relevance logic, \mathbf{R} , \mathbf{E} and others, are undecidable. Alasdair Urquhart proved this in his ground breaking papers [Urquhart, 1983; Urquhart, 1984]. We have recounted earlier attempts to come to a conclusion on the decidability question. The insights that helped decide the issue came from an unexpected quarter — projective geometry. To see why projective geometry gave the necessary insights, we will first consider a simple case, the undecidability of the system \mathbf{KR} . \mathbf{KR} is given by adding $A \wedge \neg A \rightarrow B$ to \mathbf{R} . A \mathbf{KR} frame is one satisfying the following conditions (given by adding the clause that $a = a^*$ to the conditions for an \mathbf{R} frame).

$$\begin{array}{l} R0ab \text{ iff } a = b \quad Rabc \text{ iff } Rbac \text{ iff } Racb \text{ (total permutation)} \\ Raaa \text{ for each } a \quad R^2abcd \text{ only if } R^2acbd \end{array}$$

The clauses for the connectives are standard, with the proviso that $a \vDash \neg A$ iff $a \not\vDash A$, since $a = a^*$.

Urquhart's first important insight was that \mathbf{KR} frames are quite like projective spaces. A *projective space* \mathcal{P} is a set P of points, and a collection L of subsets of P called *lines*, such that any two distinct points are on exactly one line, and any two distinct lines intersect in exactly one point. But we can define projective spaces instead through the ternary relation of collinearity. Given a projective space \mathcal{P} , its collinearity relation C is a ternary relation satisfying the condition:

$$Cabc \text{ iff } a = b = c, \text{ or } a, b \text{ and } c \text{ are distinct and they lie on a common line.}$$

If \mathcal{P} is a projective space, then its collinearity relation C satisfies the following conditions,

$$Caaa \text{ for each } a. \quad Cabc \text{ iff } Cbac \text{ iff } Cacb. \quad C^2abcd \text{ only if } C^2acbd.$$

⁴⁸In this connection two things should be mentioned. First, Meyer [unpublished typescript, 1973] has shown that not all finitely generated de Morgan monoids are finitely presentable. Second, Meyer and Routley [1973c] have constructed a positive relevance logic \mathbf{Q}^+ (the algebraic semantics for which dispenses with commutativity) and shown it undecidable.

provided that every line has at least four points (this last requirement is necessary to verify the last condition). Conversely, if we have a set with a ternary relation C satisfying these conditions, then the space defined with the original set as points and the sets $l_{ab} = \{c : Cab\} \cup \{a, b\}$ where $a \neq b$ as lines is a projective space.

Now the similarity with **KR** frames becomes obvious. If \mathcal{P} is a projective space, the frame $\mathcal{F}(\mathcal{P})$ generated by \mathcal{P} is given by adjoining a new point 0, adding the conditions $C0aa$, $Ca0a$, and $Caa0$, and by taking the extended relation C to be the accessibility relation of the frame.

Projective spaces have a naturally associated undecidable problem. The problem arises when considering the *linear subspaces* of projective spaces. A subspace of a projective space is a subset which is also a projective space under its inherited collinearity relation. Given any two linear subspaces \mathcal{X} and \mathcal{Y} , the subspace $\mathcal{X} + \mathcal{Y}$ is the set of all points on lines through points in \mathcal{X} and points in \mathcal{Y} .

In **KR** frames there are propositions which play the role of linear subspaces in projective spaces. We need a convention to deal with the extra point 0, and we simply decree that 0 should be *in* every “subspace.” Then linear subspaces are equivalent to the *positive idempotents* in a frame. That is, they are the propositions X which are *positive* (so $0 \in X$) and *idempotent* (so $X = X \circ X$). Clearly for any sentence A and any **KR** model \mathcal{M} , the extension of A , $\|A\|$ in \mathcal{M} is a positive idempotent iff $0 \vDash A \wedge (A \leftrightarrow A \circ A)$. It is then not too difficult to show that if A and B are positive idempotents, so are $A \circ B$ and $A \wedge B$, and that t and \top are positive idempotents.

Given a projective space \mathcal{P} , the lattice algebra $\langle \mathcal{L}, \cap, + \rangle$ of all linear subspaces of the projective space, under intersection and $+$ is a modular geometric lattice. That is, it is a complete lattice, satisfying these conditions:

Modularity $a \geq c \Rightarrow (\forall b)(a \cap (b + c) \leq (a \cap b) + c)$

Geometricity Every lattice element is a join of atoms, and if a is an atom and X is a set where $a \leq \Sigma X$ then there's some finite $Y \subseteq X$, where $a \leq \Sigma Y$.

The lattice of linear subspaces of a projective space satisfies these conditions, and that in fact, any modular geometric lattice is isomorphic to the lattice of linear subspaces of some projective space. Furthermore the lattice of positive idempotents of any **KR** frame is also a modular geometric lattice.

The undecidable problem which Urquhart uses to prove the undecidability of **KR** is now simple to state. Hutchinson [1973] and Lipshitz [1974] proved that

The word problem for any class of modular lattices which includes the subspace lattice of an infinite dimensional projective space is undecidable.

Given an infinite dimensional projective space in which every line includes at least four points \mathcal{P} , the logic of the frame (\mathcal{P}) is said to be a *strong* logic. Our undecidability theorem then goes like this:

Any logic between **KR** and a strong logic is undecidable.

The proof is not too difficult. Consider a modular lattice problem

$$\text{If } v_1 = w_1 \dots v_n = w_n \text{ then } v = w$$

stated in a language with variables x_i ($i = 1, 2, \dots$) constants 1 and 0, and the lattice connectives \cap and $+$. Fix a map into the language of **KR** by setting $x_i^t = p_i$ for variables, $0^t = t$, $1^t = \top$, $(v \cap w)^t = v^t \wedge w^t$ and $(v + w)^t = v^t \circ w^t$. The translation of our modular lattice problem is then the **KR** sentence

$$(B \wedge (v_1^t \leftrightarrow w_1^t) \wedge \dots \wedge (v_n^t \leftrightarrow w_n^t) \wedge t) \rightarrow (v^t \leftrightarrow w^t)$$

where the sentence B is the conjunction of all sentences $p_i \wedge (p_i \leftrightarrow p_i \circ p_i)$ for each p_i appearing in the formulae v_j^t or w_j^t .

We will show that given a particular infinite dimensional projective space (with every line containing at least four points) \mathcal{P} , then the word problem is valid in the lattice of linear subspaces of \mathcal{P} if and only if its translation is provable in L , for any logic L intermediate between **KR** and the logic of the frame $\mathcal{F}(\mathcal{P})$.

If the translation of the word problem is valid in L , then it holds in the frame $\mathcal{F}(\mathcal{P})$. Consider the word problem. If it were invalid, then there would be linear subspaces x_1, x_2, \dots in the space \mathcal{P} such that each $v_i = w_i$ would be true while $v \neq w$. Construct a model on the frame $\mathcal{F}(\mathcal{P})$ as follows. Let the extension of p_i be the space x_i together with the point 0. It is then simple to show that $0 \vDash B$, as each p_i is a positive idempotent. In addition, $0 \vDash t$, and $0 \vDash v_i^t \leftrightarrow w_i^t$, for the extension of each v_i^t and w_i^t will be the spaces picked out by v_i and w_i (both with the obligatory 0 added). However, we would have $0 \not\vDash v^t \leftrightarrow w^t$, since the extensions of v^t and w^t were picked out to differ. This would amount to a counterexample to the translation of the word problem, which we said was valid. As a result, the word problem is valid in the space \mathcal{P} . The converse reasoning is similar.

Unfortunately, these techniques do not work for systems weaker than **KR**. The proof that positive idempotents are modular uses essentially the special properties of **KR**. Not every positive idempotent in **R** need be modular. But nonetheless, the techniques of the proof can be extended to apply to a much wider range of systems. Urquhart examined the structure of the modular lattice undecidability result, and he showed that you could make do with much less. You do not need to restrict your attention to modular lattices to construct an undecidable word problem. But to do that, you need to examine Lipshitz and Hutchinson's proof more carefully. In the rest of

this section, we will sketch the structure of Urquhart's undecidability proof. The techniques are quite involved, so we do not have the space to go into detail. For that, the reader is referred to Urquhart [1984].

Lipshitz and Hutchinson proved that the word problem for modular lattices was undecidable by embedding into that problem the already known undecidable word problem for semigroups. It is enough to show that a structure can define a "free associative binary operation", for then you will have the tools for representing arbitrary semigroup problems. (A semigroup is a set with an associative binary operation. An operation is a "free associative" operation if it satisfies those conditions satisfied by any associative operation but no more.) We will sketch how this can be done without resorting to a modular lattice.

The required structure is what is called a 0-structure, and a modular 4-frame defined within a 0-structure. A 0-structure is a set equipped with the following structure

- A semilattice with respect to \sqcap .
- With a binary operator $+$ which is associative and commutative.
- And $x \leq y \Rightarrow x + z \leq y + z$.
- $0 + x = x$.
- $y \geq 0 \Rightarrow x \sqcap (x + y) = x$.

A 4-frame in a 0-structure is a set $\{a_1, a_2, a_3, a_4\} \cup \{c_{ij} : i \neq j, i, j = 1, \dots, 4\}$ such that

- The a_i s are *independent*. If $G, H \subseteq \{a_1, \dots, a_4\}$ then $(\Sigma G) \sqcap (\Sigma H) = \Sigma(G \cap H)$ (where $\Sigma \emptyset = 0$)
- If $G \subseteq \{a_1, \dots, a_4\}$ then ΣG is modular
- $a_i + a_i = a_i$
- $c_{ij} = c_{ji}$
- $a_i + a_j = a_i + c_{ik}; c_{ij} \sqcap a_j = 0$, if $i \neq j$
- $(a_i + a_k) \sqcap (c_{ij} + c_{jk}) = c_{ik}$ for distinct i, j, k

Now, we are nearly at the point where we can define a semigroup structure. First, for each distinct i, j , we define the set L_{ij} to be $\{x : x + a_j = a_i + a_j \text{ and } x \sqcap a_j = 0\}$. Then if $b \in L_{ij}$ and $d \in L_{jk}$ where i, j, k are distinct, then we set $b \otimes d = (b + d) \sqcap (a_i + a_k)$, and it is not difficult to show that $b \otimes d \in L_{ik}$. Then, we can define a semigroup operation ' \cdot ' on L_{12} by setting

$$x \cdot y = (x \otimes c_{23}) \otimes (c_{31} \otimes y)$$

Now it is quite an involved operation to show that this is in fact an associative operation, but it can be done. And in fact, in certain circumstances, the operation is a free associative operation. Given a countably infinite-dimensional vector space \mathcal{V} , its lattice of subspaces is a 0-structure, and it is possible to define a modular 4-frame in this lattice of subspaces, such that any countable semigroup is isomorphic to a subsemigroup of L_{12} under the defined associative operation. (Urquhart gives the complete proof of this result [Urquhart, 1984].)

The rest of the work of the undecidability proof involves showing that this construction can be modelled in a logic. Perhaps surprisingly, it can all be done in a weak logic like $\mathbf{TW}[\wedge, \vee, \rightarrow, \top, \perp]$. We can do without negation by picking out a distinguished propositional atom f , and by defining $\neg A$ to be $A \rightarrow f$, t to be $\neg f$, and $A : B$ to be $\neg(A \rightarrow \neg B)$. A is a *regular* proposition iff $\neg\neg A \leftrightarrow A$ is provable. The regular propositions form an 0-structure, under the assumption of the formula $\Theta = \{R(t, f, \top, \perp), N(t, f, \top, \perp), \neg\top \leftrightarrow \perp\}$, where $R(A)$ is $\neg\neg A \leftrightarrow A$, $N(A)$ is $(t \rightarrow A) \rightarrow A$, and $R(A, B, \dots)$ is $R(A) \wedge R(B) \wedge \dots$ and similarly for N . In other words, we can show that the conditions for an 0-structure hold in the regular propositions, assuming Θ as an extra premise. To interpret the 0-structure conditions we interpret \sqcap by \wedge , $+$ by $:$ and 0 by t .

Now we need to model a 4-frame in the 0-structure. This can be done as we get just the modularity we need from another condition which is simple to state. Define $K(A)$ to be $R(A) \wedge (A \wedge \neg A \leftrightarrow \perp) \wedge (A \vee \neg A \leftrightarrow \top) \wedge (A : \neg A \leftrightarrow \neg A) \wedge (A \leftrightarrow A : A)$. Then we can show the following

$$K(A), R(B, C), C \rightarrow A \vdash A \wedge (B : C) \leftrightarrow (A \wedge B) : C$$

In other words, if $K(A)$, then A is modular in the class of regular propositions. Then the conditions for a 4-frame are simple to state. We pick out our atomic propositions A_1, \dots, A_4 and C_{12}, \dots, C_{34} which will do duty for a_1, \dots, a_4 and c_{12}, \dots, c_{34} . Then, for example, one independence axiom is

$$(A_1 : A_2 : A_3) \wedge (A_2 : A_3 : A_4) \leftrightarrow (A_2 : A_3)$$

and one modularity condition is

$$K(A_1 : A_3 : A_4)$$

We will let Π be the conjunction of the statements that express that the propositions A_i and C_{ij} form a 4-frame in the 0-structure of regular propositions. So, $\Theta \cup \Pi$ is a finite (but complex) set of propositions. In any algebra in which $\Theta \cup \Pi$ is true, the lattice of regular propositions is a 0-structure, and the denotations of the propositions A_i and C_{ij} form a 4-frame. Finally, when coding up a semigroup problem with variables x_1, x_2, \dots, x_m , we will need formulae in the language which do duty for these variables. Thus we

need a condition which picks out the fact that p_i (standing for x_i) is in L_{12} . We define $L(p)$ to be $(p : A_2 \leftrightarrow A_1 : A_2) \wedge (p \wedge A_2 \leftrightarrow t)$. Then the semigroup operation on elements of L_{12} can be defined in terms of \wedge and $:$ and the formulae A_i and C_{ij} . We assume that done, and we will simply take it that there is an operation \cdot on formulae which picks out the algebraic operation on L_{12} . This is enough for us to sketch the undecidability argument.

The deducibility problem for any logic between $\mathbf{TW}[\wedge, \vee, \rightarrow, \top, \perp]$ and \mathbf{KR} is undecidable.

Take a semigroup problem which is known to be undecidable. It may be presented in the following way

$$\text{If } v_1 = w_1 \dots v_n = w_n \text{ then } v = w$$

where each term v_i, w_i is a term in the language of semigroups, constructed out of the variables x_1, x_2, \dots, x_m for some m . The translation of that problem into the language of $\mathbf{TW}[\wedge, \vee, \rightarrow, \top, \perp]$ is the deducibility problem

$$\Theta, \Pi, L(p_1, \dots, p_m), v_1^t \leftrightarrow w_1^t, \dots, v_n^t \leftrightarrow w_n^t \vdash v^t \leftrightarrow w^t$$

where each the translation u^t of each term u is defined recursively by setting x_i^t to be p_i , and $(u_1.u_2)^t$ to be $u_1^t \cdot u_2^t$.

Now the undecidability result will be immediate once we show that for any logic between \mathbf{TW} and \mathbf{KR} the word problem in semigroups is valid if and only if its translation is valid in that logic.

For left to right, if the word problem is valid in the theory of semigroups, its translation must be valid, for given the truth of Θ and Π and $L(p_1, \dots, p_m)$, the operator \cdot is provably a semigroup operation on the propositions in L_{12} in the algebra of the logic, and the terms v_i and w_i satisfy the semigroup conditions. As a result, we must have v^t and w^t picking out the same propositions, hence we have a proof of $v^t \leftrightarrow w^t$.

Conversely, if the word problem is invalid, then it has an interpretation in the semigroup \mathcal{S} defined on L_{12} in the lattice of subspaces of an infinite dimensional vector space. The lattice of subspaces of this vector space is the 0-structure in our countermodel. However, we need a countermodel for our — the 0-structure is not a model of the whole of the logic, since it just models the regular propositions. How can we construct this? Consider the argument for \mathbf{KR} . There, the subspaces were the positive idempotents in the frame. The other propositions in the frame were *arbitrary* subsets of points. Something similar can work here. On the vector space, consider the subsets of points which are closed under multiplication (that is, if $x \in \alpha$, so is kx , where k is taken from the field of the vector space). This is a De Morgan algebra, defining conjunction and disjunction by means of intersection and union as is usual. Negation is modelled by set difference. The fusion $\alpha \circ \beta$ of two sets of points is the set $\{x + y : x \in \alpha \text{ and } y \in \beta\}$. It is not too difficult

to show that this is commutative and associative, and square increasing, when the vector space is in a field of characteristic other than 2, since if $x \in \alpha$ then $x = \frac{1}{2}x + \frac{1}{2}x \in \alpha \circ \alpha$. Then $\alpha \rightarrow \beta$ is simply $-(\alpha \circ -\beta)$. It is not too difficult to show that this is an algebraic model for **KR**, and that the regular propositions in this model are exactly the subspaces of the vector space. It follows that our counterexample in the 0-structure is a counterexample in a model of **KR** to the translation of the word problem. As a result, the translation is not provable in **KR** or in any weaker logic.

This result applies to systems between **TW** and **KR**, and it shows that the deducibility problem is undecidable for any of these systems. In the presence of the *modus ponens* axiom $A \wedge (A \rightarrow B) \wedge t \rightarrow B$, this immediately yields the undecidability of the *theoremhood* problem, as the deducibility problem can be rewritten as a single formula.

$$(\Theta \wedge \Pi \wedge L(p_1, \dots, p_m) \wedge (v_1^t \leftrightarrow w_1^t) \wedge \dots \wedge (v_n^t \leftrightarrow w_n^t) \wedge t) \rightarrow (v^t \leftrightarrow w^t)$$

As a result, the theoremhood problem for logics between **T** and **KR** is undecidable. In particular, **R**, **E** and **T** are all undecidable.

The restriction to **TW** is necessary in the theorem. Without the prefixing and suffixing axioms, you cannot show that the lattice of regular propositions is closed under the ‘fusion-like’ connective ‘:’.

Before moving on to our next section, let us mention that these geometric methods have been useful not only in proving the undecidability of logics, but also in showing that interpolation fails in **R** and related logics [Urquhart, 1993].

5 LOOKING ABOUT

A lot of the work in relevance logics taking place in the late 1980’s and in the 1990’s has not focussed on Anderson’s core problems. Now that these have been more or less resolved, work has proceeded apace in other directions. In this section we will give an undeniably indiosyncratic and personal overview of what we think are some of the strategic directions of this recent research. The first two sections in this part deal with generalisations — first of semantics, and second of proof theory — which situate relevance logic into a wider setting. The next sections deal with neighbouring formal theories, and we end with one philosophical application of the machinery of relevance logics.

5.1 Gaggle Theory

The fusion connective \circ has played an important part in the study of relevance logics. This is because fusion and implication are tied together by

the *residuation condition*

$$a \leq b \rightarrow c \text{ iff } a \circ b \leq c$$

In addition, in the frame semantics, fusion and implication are tied to the same ternary relation R , implication with the universal condition and fusion with the existential condition.

This is an instance of a generalised Galois connection. Galois studied connections between functions on partially ordered sets. A Galois connection between two partial orders \leq on A and \leq' on B is a pair of functions $f : A \rightarrow B$ and $g : B \rightarrow A$ such that

$$b \leq' f(a) \text{ iff } a \leq g(b)$$

The condition tying together fusion and implication is akin to that tying together f and g for Galois. So, gaggle theory (for 'ggl': *generalised Galois logic*) studies these connections in their generality, and it turns out that relevance logics like \mathbf{R} , \mathbf{E} and \mathbf{T} are a part of a general structure which not only includes other relevance logics, but also traditional modal logics, Jónsson and Tarski's Boolean algebras with operators [Jónsson and Tarski, 1951] and many other formal systems. Dunn has shown that if a logic has a family of n -ary connectives which are tied together with a generalised Galois connection, then the logic has a frame semantics in which those connectives are modelled using the one $n+1$ -ary relation, in the way that fusion and implication are modelled by the same ternary relation in relevance logics [Dunn, 1991; Dunn, 1993a; Dunn, 1994].

In general, an n -ary connective f has a *trace* $(\tau_1, \dots, \tau_n) \mapsto +$ if

- $f(c_1, \dots, \mathbf{1}, \dots, c_n) = \mathbf{1}$, if $\tau_i = +$ (where the $\mathbf{1}$ is in position i).
- $f(c_1, \dots, \mathbf{0}, \dots, c_n) = \mathbf{1}$, if $\tau_i = -$ (where the $\mathbf{0}$ is in position i).
- If $a \leq b$, and if $\tau_i = +$ then $f(c_1, \dots, a, \dots, c_n) \leq f(c_1, \dots, b, \dots, c_n)$.
- If $a \leq b$, and if $\tau_i = -$ then $f(c_1, \dots, b, \dots, c_n) \leq f(c_1, \dots, a, \dots, c_n)$.

We write this as $T(f) = (\tau_1, \dots, \tau_n) \mapsto +$. On the other hand, the connective f has *trace* $(\tau_1, \dots, \tau_n) \mapsto -$ if

- $f(c_1, \dots, \mathbf{1}, \dots, c_n) = \mathbf{0}$, if $\tau_i = +$ (where the $\mathbf{0}$ is in position i).
- $f(c_1, \dots, \mathbf{0}, \dots, c_n) = \mathbf{0}$, if $\tau_i = -$ (where the $\mathbf{1}$ is in position i).
- If $a \leq b$, and if $\tau_i = +$ then $f(c_1, \dots, b, \dots, c_n) \leq f(c_1, \dots, a, \dots, c_n)$.
- If $a \leq b$, and if $\tau_i = -$ then $f(c_1, \dots, a, \dots, c_n) \leq f(c_1, \dots, b, \dots, c_n)$.

We write this as $T(c) = (\tau_1, \dots, \tau_n) \mapsto -$. Here are a few examples of traces of connectives. Conjunction-like connectives tend to be $(-, -) \mapsto -$, disjunction-like connectives tend to be $(+, +) \mapsto +$, necessity-like connectives tend to be $+ \mapsto +$, possibility-like connectives tend to be $- \mapsto -$, and negations can be either $+ \mapsto -$ or $- \mapsto +$ (and in many cases they are both).

Now we are nearly able to state the abstract law of residuation. First, we define $S(f, a_1, \dots, a_n, b)$ as follows. If $T(f) = (\dots) \mapsto +$, then $S(f, a_1, \dots, a_n, b)$ is the condition $f(a_1, \dots, a_n) \leq b$. If, on the other hand, $T(f) = (\dots) \mapsto -$, then $S(f, a_1, \dots, a_n, b)$ is $b \leq f(a_1, \dots, a_n)$. Then, two connectives f and g are *contrapositives in place j* iff, if $T(f) = (\tau_1, \dots, \tau_j, \dots, \tau_n) \mapsto \tau$, then $T(g) = (\tau_1, \dots, -\tau, \dots, \tau_n) \mapsto -\tau_j$. (Where we define $-+$ as $-$ and $--$ as $+$.) Two operators f and g satisfy the *abstract law of residuation* iff f and g are contrapositives in place j , and $S(f, a_1, \dots, a_j, \dots, a_n, b)$ iff $S(g, a_1, \dots, b, \dots, a_n, a_j)$.

A collection of connectives in which there is some connective f such that every element of the collection satisfies the abstract law of residuation with f , is called a *founded family* of connectives. Dunn's major result is that if you have an algebra in which every connective is in a founded family, then the algebra is isomorphic to a subalgebra of the collection of propositions in a model in which each founded family of n -ary connectives shares an $n + 1$ -ary relation. The soundness and completeness of the Routley–Meyer ternary relational semantics is for the implication-fusion fragment of relevance logics is an instance of this more general result.

The gaggle theoretic account of negation in relevance logics is interesting. We do not automatically get negation modelled by the Routley star — instead, being a unary connective, negation is modelled with a *binary* relation. One way negation can be modelled along gaggle theoretic lines is as follows. The De Morgan negation connective has trace $- \mapsto +$, so the gaggle theoretic result is that there is a binary relation C between set-ups such that

- $x \vDash \neg A$ iff for each y where xCy , $y \not\vDash A$

This is the general semantic structure which models negation connectives with trace $- \mapsto +$. Given a relation C , which we may read as ‘compatibility’, we can define another negation connective \sim , using C 's converse:

- $x \vDash \sim A$ iff for each y where yCx , $y \not\vDash A$

Then it follows that $A \vdash \sim B$ iff $B \vdash \neg A$. For the De Morgan negation of relevance logics, \sim and \neg are the same, for the compatibility relation C is symmetric. But in more general settings, this need not hold.

The general perspective of gaggle theory not only opens up new formal systems to study — it also helps with interpreting the semantics. The

condition for \neg above can be read as follows: $\neg A$ is true at x iff for each y compatible with x , A is not true at y . This certainly sounds like a more palatable condition for negation than that using Routley star. We have an understanding of what it is for two set-ups (theories, worlds or situations) to be compatible, and the notion of compatibility is tied naturally to that of negation. Furthermore, the Routley star condition is an instance of this more general ‘compatibility’ condition. For any set-up a , a^* can be seen as the set-up which ‘wraps up’ all set-ups compatible with a . We can argue whether there is such an all-encompassing set-up, but if there is, then the semantics for negation in terms of the compatibility relation is equivalent to that of the Routley star. And in addition, we have another means of explaining it.

Furthermore, once we have this generalised position from which to view negation, we can tinker with the binary accessibility relation in just the same way that modal logics are studied. Clearly if Boolean negation (written ‘ \neg ’) is present, then $\neg A$ is simply $\Box \neg A$ for the positive modal operator \Box which uses C as its accessibility relation; and the study of these negation is dealt with using the techniques of modal logic. However, in relevance logics and other related systems, boolean negation is not present. And in this case the theory of negations arising from compatibility clauses like the one we have seen is a young and interesting subject in its own right. This perspective is pursued in Dunn [1994], and Restall [1999] develops a philosophical interpretation of the semantics.

5.2 Display Logic

Nuel Belnap has developed proof theoretical techniques which are quite similar to those from gaggle theory. Consider the general problem of providing a sequent calculus for logics like **R** and others. We have the choice of how to formulae sequents. If they are of the form $X \vdash A$, where X is a structured collection of formulae, and A is a formula, then we have the problem of how to state the introduction and elimination of negation rules in such a way as to make $\neg\neg A$ equivalent to A . It is unclear how to do this while maintaining that the succedent of every sequent is a single formula. On the other hand, if we allow that sequents are of the form $X \vdash Y$, where now both X and Y are structured complexes of formulae, it is unclear how to state a cut rule which is both valid and admits of a cut-elimination proof in the style of Gentzen. If we are restricted to single formulae in the succedent position the rule is easy to state:

$$\frac{X \vdash A \quad Y(A) \vdash B}{Y(X) \vdash B}$$

but in the presence of multiple succedents it is unclear how to state the rule generally enough to be eliminable yet strictly enough to be valid under

interpretation. If there is only one sort of structuring in the consequent this might be possible, in the way used in the proof theories of classical or linear logic, for example:

$$\frac{X \vdash A, Y \quad X', A \vdash Y'}{X, X' \vdash Y, Y'}$$

But if we have $X \vdash Y(A)$ and $X'(A) \vdash Y'$ where the indicated instances of A are buried under multiple sorts of structure, then what is the appropriate conclusion of a cut rule? $X'(X) \vdash Y(Y')$ will not do in general, for it is invalid in many instances. For example, in \mathbf{R} if $Y(A)$ is $A \wedge B$ and $X'(A)$ is $A \circ D$, then we have $A \wedge B \vdash A \wedge B$ and $A \circ D \vdash A \circ D$, but we don't have $(A \wedge B) \circ D \vdash (A \circ D) \wedge B$ in general. (Consider the case where $B = A$. $A \circ D$ needn't imply A .)

The alternative examined by Belnap is to make do with Cut where the cut formula is “displayed” in both premises of the rule.

$$\frac{X \vdash A \quad A \vdash Y}{X \vdash Y}$$

In order to get away with this, a system needs to be such that whenever you need to use a cut you can. The way Belnap does this is by requiring what he calls the “display condition”. The display condition is satisfied iff for every formula, every sequent including that formula is equivalent (using invertible rules) to one in which that formula is either the entire antecedent or the entire succedent of the sequent. For Belnap's original formulation, this is achieved by having a binary structuring connective \circ (not to be confused with the sentential connective \circ) and a unary connective $*$. The display rules were as follows:

$$\begin{aligned} X \circ Y \vdash Z &\iff X \vdash *Y \circ Z \\ X \vdash Y \circ Z &\iff X \circ *Y \vdash Z \iff X \vdash Z \circ Y \\ X \vdash Y &\iff *Y \vdash *X \iff **X \vdash Y \end{aligned}$$

A structure is in antecedent position if it is in the left under an even number of stars, or in the right under an odd number of stars. If it is not in antecedent position, it is in succedent position. The star is read as negation, and the circle is read as conjunction in antecedent position, and disjunction in succedent position. The display postulates are a reworking of conditions like the residuation condition for fusion and implication. Here we have the conditions that $a \circ b \leq c$ iff $a \leq \sim b + c$ (where $x + y$ is the *fission* of x and y).

Belnap's system allows that different families of structural connectives can be used for different families of connectives in the language. For example, when \circ and $*$ are read intensionally, we can have the following rules for

implication:

$$\frac{X \circ A \vdash B}{X \vdash A \rightarrow B} \quad \frac{X \vdash A \quad B \vdash Y}{A \rightarrow B \vdash *X \circ Y}$$

If the properties of \circ vary, so do the properties of the connective \rightarrow . We can give \circ properties of extensional conjunction in order to get a material conditional. Or conditions can be tightened, to give \rightarrow modal properties. It is clear that the family of structural connectives (here \circ and $*$) act in analogously to accessibility relations on frames. However, the connections with gaggle theory run deeper, however. It can be shown a connective introduced in with rules without side conditions, and in a way which ‘mimics’ structural connectives (just as here $A \rightarrow B$ mimics $*X \circ Y$ in consequent position) must have a definable trace. Any implication satisfying those rules will have trace $(-, +) \mapsto +$, for example. For more details of this connection and a general argument, see Restall’s paper [Restall, 1995a].

Display logic gives these systems a natural cut-free proof theory, for Belnap has shown that under a broad set of conditions, any proof theory with this structure will satisfy cut-elimination. So again, just as with gaggle theory, we have an example of the way that the study of relevance logics like **R** and **E** have opened up into a more general theory of logics with similar structures.

5.3 Paraconsistency

Relevance logics are paraconsistent, in that argument forms such as $A \wedge \neg A \vdash B$ are taken to be invalid. As a result, relevance logics have been seen to be important for the study of paraconsistent theories. [[See Priest’s article in this volume]]. Relevance logics are suited to applications for which a paraconsistent notion of consequence is needed however, not all logics are equal in this regard. For example, paraconsistentists have often considered the topic of naïve theories of sets and of truth (any predicate yields the set of things satisfying that predicate, the proposition p is true if and only if p). With a relevance logic at hand, you can avoid the inference to triviality from contradictions such as that arising from the liar

This proposition is not true.

(from which you can deduce that it is true, and hence that it isn’t) and Russell’s paradox ($\{x : x \notin x\}$ both is and is not a member of itself). However, the *Curried* forms of these paradoxes

If this proposition is true then there is a Santa Claus.

and $\{x : (x \in x) \rightarrow P\}$ are more difficult to deal with. These yield arguments for the existence of Santa Claus and the truth of P (which was

arbitrary) in logics like \mathbf{R} , or any others with theorems related to the rule of contraction. The theoremhood of propositions such as $(A \rightarrow (A \rightarrow B)) \rightarrow (A \rightarrow B)$ and $A \wedge (A \rightarrow B) \rightarrow B$ rule out a logic for service in the cause of paraconsistent theories like these [Meyer *et al.*, 1979].

However, this has not deterred some hardier souls in considering weaker relevance logics which do not allow one to deduce triviality in these theories. Some work has been done to show that in some logics these theories are consistent, and in others, though inconsistent, not everything is a theorem [Brady, 1989].

Another direction of paraconsistency in which techniques of relevance logics have borne fruit is in the more computational area of reasoning with inconsistent information. The techniques of first degree entailment have found a home in the study of “bilattices” by Melvin Fitting and others, who seen in them a suitable framework for reasoning under the possibility of inconsistent information [Fitting, 1989].

5.4 *Semantic Neighbours*

Another area in which research has grown in the recent years has been toward connections with other fields. It has turned out that seemingly completely unrelated fields have studied structures remarkably like those studied in relevance logics. These neighbours are helpful, not only for giving independent evidence for the fact that relevance logicians have been studying *something* worthwhile, but also because of the different insights they can bring to bear on theorising. In this section we will see just three of the neighbours which can shed light on work in relevance logics.

The first connection comes with Barwise and Perry’s situation semantics [1983]. For Barwise and Perry, utterances classify situations (parts of the world) which may be incomplete with regard to their semantic ‘content’. Consider the claim that Max saw Queensland win the Sheffield Shield”. How is this to be understood? For the Barwise and Perry of *Situations and Attitudes* [Barwise and Perry, 1983], this was to be parsed as expressing a relationship between Max and a *situation*, where a situation is simply a restricted part of the world. Situations are parts of the world and they support information. Max saw a situation and in this situation, Queensland won the Sheffield Shield. If, in this very situation, Queensland beat South Australia, then Max saw Queensland beat South Australia.

This shows why for this account situations have to be (in general) *restricted* bits of the world. The situation Max saw had better not be one in which Paul Keating lost the 1996 Federal Election, lest it follow from the fact that Max witnessed Queensland’s victory that he also witnessed Keating’s defeat, and surely *that* would be an untoward conclusion. Let’s denote this relationship between situations and the information they support as follows. We’ll abbreviate the claim that the situation s supports the

information that A by writing ' $s \vDash A$ ', and we'll write its negation, that s doesn't support the information that A by writing ' $s \not\vDash A$ '. This is standard in the situation theoretic literature. The information carried by these situations has, according to Barwise and Perry, a kind of logical coherence. For them, infons are closed under conjunction and disjunction, and $s \vDash A \wedge B$ if and only if $s \vDash A$ and $s \vDash B$, and $s \vDash A \vee B$ if and only if $s \vDash A$ or $s \vDash B$. However, negation is a different story — clearly situations don't support the traditional equivalence between $s \vDash \neg A$ and $s \not\vDash A$ (where $\neg A$ is the negation of A), for our situation witnessed by Max supports neither the infon "Keating won the 1996 election" nor its negation.

What to do? Well, Barwise and Perry suggest that negation interacts with conjunction and disjunction in the familiar ways — $\neg(A \vee B)$ is (equivalent to) $\neg A \wedge \neg B$, and $\neg(A \wedge B)$ is (equivalent to) $\neg A \vee \neg B$. And similarly, $\neg\neg A$ is (equivalent to) A . This gives us a logic of sorts of negation — it is *first degree entailment*. Now for Barwise and Perry, there are no *actual* situations in which $s \vDash A \wedge \neg A$ (the world is not self-contradictory). However, they agree that it is helpful to consider *abstract* situations which allow this sort of inconsistency. So, Barwise and Perry have an independent motivation for a semantic account of first-degree entailment. (More work has gone on to consider other connections between situation theory and relevance logics [Mares, 1997; Restall, 1994; Restall, 1995b].)

Another connection with a parallel field has come from completely different areas of research. The semantic structures of relevance logics have close cousins in the models for the Lambek Calculus and in Relation algebras. Let's consider relation algebras first.

A relation algebra is a Boolean algebra with some extra operations, a binary operation which denotes composition of relation, a unary operation \smile , for the converse of a relation, and a constant 1 for the identity relation. There is a widely accepted axiomatisation of the variety **RA** of relation algebras. A relation algebra is set R with operations $\wedge, \vee, -, 1, \circ, \smile$ such that

- $\langle R, \wedge, \vee, - \rangle$ is a boolean algebra.
- \smile is an automorphism on the algebra, satisfying $a^{\smile\smile} = a$, $(a \wedge b)^{\smile} = a^{\smile} \wedge b^{\smile}$, $-(a^{\smile}) = (-a)^{\smile}$.
- \circ is associative, with a left and right identity 1, satisfying $(a \vee b) \circ c = (a \circ c) \vee (b \circ c)$, $a \circ (b \vee c) = (a \circ b) \vee (a \circ c)$.
- \smile and \circ are connected by setting $(a \circ b)^{\smile} = b^{\smile} \circ a^{\smile}$.

These conditions are satisfied by the class of relations on any base set (that is, by any *concrete* relation algebra). However, not every algebra satisfying these equations is isomorphic to a subalgebra of a concrete relation algebra.

These algebras are quite similar to de Morgan monoids. If we define $\neg A$ to be $-(a)^\smile$ or $(-a)^\smile$ then the conjunction, disjunction, \neg , 1 fragment is that of first degree entailment. We do not have $a \leq b \vee \neg b$, and nor do we have $a \wedge \neg a \leq b$. Consider the relation a :

a	x	y
x	1	1
y	0	1

Then $\neg a$ is the following relation

a	x	y
x	0	1
y	0	0

So we don't have $b \leq a \vee \neg a$ for every b , and nor do we have $a \wedge \neg a \vee b$. (However, we do have $1 \leq a \vee \neg a$.)

The class of relation algebras have a natural form of implication to go along with the fusionlike connective \circ . If we define $a \rightarrow b$ to be $\neg(\neg b \circ a)$, then we have the residuation condition $a \circ b \leq c$ iff $a \leq b \rightarrow c$. However, that is not the only implication-like connective we may define. If we set $b \leftarrow a$ to be $\neg(a \circ \neg b)$, then $a \circ b \leq c$ iff $b \leq c \leftarrow a$. Since \circ is not, in general, commutative, we have two residuals.

In logics like **R** this is not possible, for the left and the right residuals of fusion are the same connective. However, in systems in the vicinity of **E**, these implication operations come apart. This is mirrored by the behaviour on frames, since we can define $B \leftarrow A$ by setting $x \vDash B \leftarrow A$ iff for each y, z where $Ryxz$ if $y \vDash A$ then $z \vDash B$. This will be another residual for fusion, and it will not agree with \rightarrow in the absence of commutativity of R (if $Rxyz$ then $Ryxz$).⁴⁹

It was hoped for some time that relation algebras would give an interesting model for logics like **R**. However, there does not seem to be a natural class of relations for which composition is commutative and square increasing. (The class of symmetric relations will not do. Even if $a = a^\smile$ and $b = b^\smile$, it does not follow that $a \circ b = b \circ a$. You merely get that $a \circ b = a^\smile \circ b^\smile = (b \circ a)^\smile$.) Considered as a logic, **RA** is a sublogic of **R** (ignoring boolean negation for the moment). It is not a sublogic of **E**, since in **RA**, $a = 1 \rightarrow a$. Another difference between **RA** and typical relevance logics is the behaviour of contraposition. We do not have $a \rightarrow b = \neg b \rightarrow \neg a$. Instead, $a \rightarrow b = \neg a \leftarrow \neg b$.

A final connection between **RA** and relevance logics is in the issue of semantics. As we stated earlier, not all relation algebras are representable as subalgebras of concrete relation algebras. However, Dunn has shown

⁴⁹We should flag here that in the relevance logic literature, [Meyer and Routley, 1972] seems to have been the first to consider both left- and right-residuals for fusion.

that all relation algebras *are* representable by algebras of propositions on a particular class of Routley–Meyer frames [Dunn, 1993b]. This is the first representation theorem for **RA**, and it shows that the semantical techniques of relevance logics have a wider scope than applications to **R**, **E** and their immediate neighbours.

In a similar vein, Dunn and Meyer [1997] have provided a Routley–Meyer style frame semantics for combinatory logic. The key idea here is that the ternary relation R satisfies *no* special conditions, but these properties are encoded by *combinators*, which are modelled by special propositions on frames.

Lambek’s *categorial grammar* is also similar to relevance logics, though this time it is introduced with frames, not algebras [Lambek, 1958; Lambek, 1961]. Here, the points in frames are pieces of syntax, and the ‘propositions’ are syntactic classifications of various kinds. For example, the classifications into noun phrases, verbs, and sentences. The interest comes with the way in which these classifications can be combined. For example $A \circ B$ can be defined, where we say $x \vDash A \circ B$ iff x is a concatenation of two strings y and z , where $y \vDash A$ and $z \vDash B$. We can also define ‘slicing’ operations, setting $x \vDash A \setminus B$ iff for each y where $y \vDash A$, $yx \vDash B$; and $x \vDash B / A$ iff for each y where $y \vDash A$, $xy \vDash B$. These are obviously analogues for \circ and \rightarrow in relevance logics, and again, we have a ‘left’ and ‘right’ residuals for fusion. In these frames $Rxyz$ iff $xy = z$. So the Lambek calculus gives us an independently motivated interpretation of a class of Routley–Meyer frames. This connection has been explored by Kurtonina [1995], which is a helpful sourcebook of some recent work on ternary frames in connection with the Lambek calculus and related logics.

If you like, you can enrich the logic of strings with conjunction and disjunction, and if you do it in the obvious way (using the same clauses as in relevance logics) you get a formal logic quite like **RA** [Restall, 1994]. But more importantly, the conditions for conjunction and disjunction may be independently motivated. A string is of type $A \vee B$ just when it is of type A or of type B . A string is of type $A \wedge B$ just when it is of type A and of type B . The resulting logic is clearly interpretable, but it was a number of years before a proof theory was found for it. Here the techniques for the Gentzenisation for positive relevance logics are appropriate, and the proof theory can be found by utilising the proof theory for **R**⁺, and removing the commutativity and contraction of the intensional bunching operation. The resulting proof theory captures exactly the Lambek calculus enriched with conjunction and disjunction. In addition, the techniques of Giambrone show that the resulting logic is decidable [Restall, 1994].

5.5 *Linear Logic*

The burgeoning phenomenon of linear logic is one which has a number of formal similarities to relevance logics [Girard, 1987; Troelstra, 1992]. Linear logic is the study of systems in the vicinity of **LRW** (**R** without contraction, without distribution). This is proof-theoretically a very stable system. It is simple to show that it is decidable. Girard’s innovation, however, is to extend the proof theory with a modal operator $!$ which allows intuitionistic logic to be modelled inside linear logic. This operation is given as follows, in single-succedent Gentzen systems.

$$\frac{X \vdash B}{X, !A \vdash B} \quad \frac{X; A \vdash B}{X; !A \vdash B} \quad \frac{!X \vdash B}{!X \vdash !B} \quad \frac{X, !A, !A \vdash B}{X, !A \vdash B}$$

Given this proof theory it is possible to show that $A \Rightarrow B$ defined as $!A \rightarrow B$ is an intuitionistic implication. This is similar to Meyer’s result that $A \wedge t \rightarrow B$ is an intuitionistic implication in **R** (indeed, $!A$ defined as $A \wedge t$ satisfies each of the conditions for $!$ above in **R**, but not in systems without contraction). However, nothing like it holds in relevance logics without contraction.

Linear logic also brings with it many new algebraic structures and models in category theory. None of these models have been mined to see if they can bring any ‘relevant’ insight. However, some transfer has gone on in the other direction — Allwein and Dunn [1993] have shown that the multiplicative and additive fragment of linear logic can be given a Routley–Meyer style semantics. This is not a simple job, as the absence of the distribution of (additive) conjunction over disjunction means that at least one of these connectives (in this case, disjunction) must take a non-standard interpretation.

5.6 *Relevant Predication*

There has been one major way in which relevance logics have been used in application to philosophical issues, and this application makes a good topic to end this article. The topic is Dunn’s work on relevant predication [Dunn, 1987].⁵⁰ The guiding idea is that a theory of relevant implication will give you some way of marking out the distinction between the way that Socrates’ wisdom is a property of Socrates, in the way that Socrates’ wisdom is not a property of Bill Clinton.

Classical first order logic is not good at marking out such a distinction, for if Wx stands for ‘ x is wise’, and s stands for Socrates, and c stands for

⁵⁰The reference [Dunn, 1987] is of course “Relevant Predication”: Of course all work has precursors, in this instance (largely unpublished) thoughts in the 1970’s by N. Belnap, J. Freeman, and most importantly R. K. Meyer and A. Urquhart (and Dunn). Cf. Sec. 9 of [Dunn, 1987] for some history.

Bill Clinton, then Wx is true of x iff it is wise, and $(Ws \wedge x = x) \vee Ws$ is true of something iff Socrates is wise. Why is one a ‘real’ property and the other not? The guiding idea for relevant predication is the following distinction. It is true that if x is Socrates then x is wise. However, it is not true that if x is Bill Clinton then Socrates is wise. At least, it is plausible that this conditional fail, when read ‘relevantly’. This can be cashed out formally as follows. F is a *relevant property of a* (written $(\rho xFx)a$) if and only if $(\forall x)(x = a \rightarrow Fx)$.

Given this definition, if F is a relevant property of a then Fa holds (quite clearly) and if F and G are relevant properties of a then so is their conjunction, and the disjunction of any relevant property with anything at all is still a relevant property.

Furthermore, one can define what it is for a relation to truly be a relation between objects. If Hx is ‘ x ’s height is over 1 meter’, and Ly is ‘ y is a logician’ then, it is true that Greg’s height is over 1 meter and Mike is a logician. However, it would be bizarre to hold that in this there is a real relation that holds between Greg and Mike because of this fact. We would have the following

$$\forall x \forall y (x = g \wedge y = m \rightarrow Hx \wedge Ly)$$

(assuming that $(\rho xHx)g$ and $(\rho yLy)m$) but it need not follow that

$$\forall x \forall y (x = g \rightarrow (y = m \rightarrow Hx \wedge Ly))$$

for there is no reason that Hx should follow from $y = m$, even given that $x = g$ holds. There is no connection between ‘ y ’s being m ’ and Hg . This latter proposition is a good candidate for expressing that there is a real relationship holding between g and m . In other words, we can define $(\rho xyLxy)ab$ to be

$$\forall x \forall y (x = a \rightarrow (y = b \rightarrow Lxy))$$

to express the holding of a relevant relation. For more on relevant predication, consult Dunn’s series of papers [Dunn, 1987; Dunn, 1990a; Dunn, 1990b]

Relevance logics are very good at telling you what follows from what as a matter of logic — and in this case, the logical structure of relevant predication and relations. However, more work needs to be done to see in what it consists to say that a relevant implication is *true*. For that, we need a better grip on how to understand the models of relevance logics. It is our hope that this chapter will help people in this aim, and to bring the technique of relevance logics to a still wider audience.

ACKNOWLEDGEMENTS

Dunn's acknowledgements from the first edition: I wish to express my thanks and deep indebtedness to a number of fellow toilers in the relevant vineyards, for information and discussion over the years. These include Richard Routley and Alasdair Urquhart and especially Nuel D. Belnap, Jr. and Robert K. Meyer, and of course Alan Ross Anderson, to whose memory I dedicate this essay. I also wish to thank Yong Auh for his patient and skilful help in preparing this manuscript, and to thank Nuel Belnap, Lloyd Humberstone, and Allen Hazen for corrections, although all errors and infelicities are to be charged to me.

Our acknowledgements from the second edition: Thanks to Bob Meyer, John Slaney, Graham Priest, Nuel Belnap, Richard Sylvan, Ed Mares, Rajeev Goré, Errol Martin, Chris Mortensen, Uwe Petersen and Pragati Jain for helpful conversations and correspondence on matters relevant to what is discussed here. Thanks too to Jane Spurr, who valiantly typed in the first edition of the article, to enable us to more easily create this version. This edition is dedicated to Richard Sylvan, who died while this essay was being written. Relevance (and *relevant*) logic has lost one of its most original and productive proponents.

QUANTUM LOGICS

1 INTRODUCTION

The official birth of quantum logic is represented by a famous article of Birkhoff and von Neumann “The logic of quantum mechanics” [Birkhoff and von Neumann, 1936]. At the very beginning of their paper, Birkhoff and von Neumann observe:

One of the aspects of quantum theory which has attracted the most general attention, is the novelty of the logical notions which it presupposes The object of the present paper is to discover what logical structures one may hope to find in physical theories which, like quantum mechanics, do not conform to classical logic.

In order to understand the basic reason why a non classical logic arises from the mathematical formalism of quantum theory (QT), a comparison with classical physics will be useful.

There is one concept which quantum theory shares alike with classical mechanics and classical electrodynamics. This is the concept of a mathematical “phase-space”. According to this concept, any physical system \mathcal{S} is at each instant hypothetically associated with a “point” in a fixed phase-space Σ ; this point is supposed to represent mathematically, the “state” of \mathcal{S} , and the “state” of \mathcal{S} is supposed to be ascertainable by “maximal” observations.

Maximal pieces of information about physical systems are called also *pure states*. For instance, in classical particle mechanics, a pure state of a single particle can be represented by a sequence of six real numbers $\langle r_1, \dots, r_6 \rangle$ where the first three numbers correspond to the *position*-coordinates, whereas the last ones are the *momentum*-components.

As a consequence, the phase-space of a single particle system can be identified with the set \mathbb{R}^6 , consisting of all sextuples of real numbers. Similarly for the case of compound systems, consisting of a finite number n of particles.

Let us now consider an *experimental proposition* \mathbf{P} about our system, asserting that a given physical quantity has a certain value (for instance: “the value of position in the x -direction lies in a certain interval”). Such

a proposition \mathbf{P} will be naturally associated with a subset X of our phase-space, consisting of all the pure states for which \mathbf{P} holds. In other words, the subsets of Σ seem to represent good mathematical representatives of experimental propositions. These subsets are called by Birkhoff and von Neumann *physical qualities* (we will say simply *events*). Needless to say, the correspondence between the set of all experimental propositions and the set of all events will be many-to-one. When a pure state p belongs to an event X , we will say that our system in state p *verifies* both X and the corresponding experimental proposition.

What about the structure of all events? As is well known, the power-set of any set is a *Boolean algebra*. And also the set $\mathcal{F}(\Sigma)$ of all measurable subsets of Σ (which is more tractable than the full power-set of Σ) turns out to have a Boolean structure. Hence, we may refer to the following Boolean algebra:

$$\mathcal{B} = \langle \mathcal{F}(\Sigma), \subseteq, \cap, \cup, -, \mathbf{1}, \mathbf{0} \rangle,$$

where:

- 1) $\subseteq, \cap, \cup, -$ are, respectively, the set-theoretic inclusion relation and the operations intersection, union, relative complement;
- 2) $\mathbf{1}$ is the total space Σ , while $\mathbf{0}$ is the empty set.

According to a standard interpretation, $\cap, \cup, -$ can be naturally regarded as a set-theoretic realization of the classical logical connectives *and*, *or*, *not*. As a consequence, we will obtain a classical semantic behaviour:

- a state p verifies a conjunction $X \cap Y$ iff $p \in X \cap Y$ iff p verifies both members;
- p verifies a disjunction $X \cup Y$ iff $p \in X \cup Y$ iff p verifies at least one member;
- p verifies a negation $-X$ iff $p \notin X$ iff p does not verify X .

To what extent can such a picture be adequately extended to QT? Birkhoff and von Neumann observe:

In quantum theory the points of Σ correspond to the so called “wave-functions” and hence Σ is ... a function-space, usually assumed to be Hilbert space.

As a consequence, we immediately obtain a basic difference between the quantum and the classical case. The *excluded middle principle* holds in

classical mechanics. In other words, pure states semantically decide any event: for any p and X ,

$$p \in X \text{ or } p \in -X.$$

QT is, instead, essentially probabilistic. Generally, pure states assign only probability-values to quantum events. Let ψ represent a pure state (a wave function) of a quantum system and let \mathbf{P} be an experimental proposition (for instance “the spin value in the x -direction is up”). The following cases are possible:

- (i) ψ assigns to \mathbf{P} probability-value 1 ($\psi(\mathbf{P}) = 1$);
- (ii) ψ assigns to \mathbf{P} probability-value 0 ($\psi(\mathbf{P}) = 0$);
- (iii) ψ assigns to \mathbf{P} a probability-value different from 1 and from 0 ($\psi(\mathbf{P}) \neq 0, 1$).

In the first two cases, we will say that \mathbf{P} is *true (false)* for our system in state ψ . In the third case, \mathbf{P} will be *semantically indeterminate*.

Now the question arises: what will be an adequate mathematical representative for the notion of quantum experimental proposition? The most important novelty of Birkhoff and von Neumann’s proposal is based on the following answer: “The mathematical representative of any experimental proposition is a closed linear subspace of Hilbert space” (we will say simply a *closed subspace*).¹ Let \mathcal{H} be a (separable) Hilbert space, whose *unitary vectors* correspond to possible wave functions of a quantum system. The closed subspaces of \mathcal{H} are particular instances of subsets of \mathcal{H} that are closed under linear combinations and Cauchy sequences. Why are mere subsets of the phase-space not interesting in QT? The reason depends on the *superposition principle*, which represents one of the basic dividing line between the quantum and the classical case. Differently from classical mechanics, in quantum mechanics, finite and even infinite linear combinations of pure states give rise to new pure states (provided only some formal conditions are satisfied). Suppose three pure states ψ, ψ_1, ψ_2 and let ψ be a linear combination of ψ_1, ψ_2 :

$$\psi = c_1\psi_1 + c_2\psi_2.$$

¹A *Hilbert space* is a vector space over a *division ring* whose elements are the real or the complex or the quaternionic numbers such that

- (i) An *inner product* (\cdot, \cdot) that transforms any pair of vectors into an element of the division ring is defined;
- (ii) the space is *metrically complete* with respect to the metrics induced by the inner product (\cdot, \cdot) .

A Hilbert space \mathcal{H} is called *separable* iff \mathcal{H} admits a countable basis.

According to the standard interpretation of the formalism, roughly this means that a quantum system in state ψ might verify with probability $|c_1|^2$ those propositions that are certain for state ψ_1 (and are not certain for ψ) and might verify with probability $|c_2|^2$ those propositions that are certain for state ψ_2 (and are not certain for ψ). Suppose now some pure states ψ_1, ψ_2, \dots each assigning probability 1 to a given experimental proposition \mathbf{P} , and suppose that the linear combination

$$\psi = \sum_i c_i \psi_i \quad (c_i \neq 0)$$

is a pure state. Then also ψ will assign probability 1 to our proposition \mathbf{P} . As a consequence, the mathematical representatives of experimental propositions should be closed under finite and infinite linear combinations. The closed subspaces of \mathcal{H} are just the mathematical objects that can realize such a role.

What about the algebraic structure that can be defined on the set $C(\mathcal{H})$ of all mathematical representatives of experimental propositions (let us call them *quantum events*)? For instance, what does it mean *negation*, *conjunction* and *disjunction* in the realm of quantum events? As to negation, Birkhoff and von Neumann's answer is the following:

The mathematical representative of the *negative* of any experimental proposition is the *orthogonal complement* of the mathematical representative of the proposition itself.

The orthogonal complement X' of a subspace X is defined as the set of all vectors that are orthogonal to all elements of X . In other words, $\psi \in X'$ iff $\psi \perp X$ iff for any $\phi \in X$: $(\psi, \phi) = 0$ (where (ψ, ϕ) is the inner product of ψ and ϕ). From the point of view of the physical interpretation, the orthogonal complement (called also *orthocomplement*) is particularly interesting, since it satisfies the following property: for any event X and any pure state ψ ,

$$\psi(X) = 1 \text{ iff } \psi(X') = 0;$$

$$\psi(X) = 0 \text{ iff } \psi(X') = 1;$$

In other words, ψ assigns to an event X probability 1 (0, respectively) iff ψ assigns to the orthocomplement of X probability 0 (1, respectively). As a consequence, one is dealing with an operation that *inverts* the two extreme probability-values, which naturally correspond to the truth-values *truth* and *falsity* (similarly to the classical truth-table of negation).

As to conjunction, Birkhoff and von Neumann notice that this can be still represented by the set-theoretic intersection (like in the classical case). For,

the intersection $X \cap Y$ of two closed subspaces is again a closed subspace. Hence, we will obtain the usual truth-table for the connective *and*:

ψ verifies $X \cap Y$ iff ψ verifies both members.

Disjunction, however, cannot be represented here as a set-theoretic union. For, generally, the union $X \cup Y$ of two closed subspaces is not a closed subspace. In spite of this, we have at our disposal another good representative for the connective *or*: the *supremum* $X \sqcup Y$ of two closed subspaces, that is the smallest closed subspace including both X and Y . Of course, $X \sqcup Y$ will include $X \cup Y$.

As a consequence, we obtain the following structure

$$\mathcal{C}(\mathcal{H}) = \langle C(\mathcal{H}), \sqsubseteq, \sqcap, \sqcup, ', \mathbf{1}, \mathbf{0} \rangle,$$

where \sqsubseteq, \sqcap are the set-theoretic inclusion and intersection; $\sqcup, '$ are defined as above; while $\mathbf{1}$ and $\mathbf{0}$ represent, respectively, the total space \mathcal{H} and the null subspace (the singleton of the null vector, representing the smallest possible subspace). An isomorphic structure can be obtained by using as a support, instead of $C(\mathcal{H})$, the set $P(\mathcal{H})$ of all *projections* P of \mathcal{H} . As is well known projections (i.e. *idempotent* and *self-adjoint linear operators*) and closed subspaces are in one-to-one correspondence, by the projection theorem. Our structure $\mathcal{C}(\mathcal{H})$ turns out to simulate a “quasi-Boolean behaviour”; however, it is not a Boolean algebra. Something very essential is missing. For instance, conjunction and disjunction are no more distributive. Generally,

$$X \sqcap (Y \sqcup Z) \neq (X \sqcap Y) \sqcup (X \sqcap Z).$$

It turns out that $\mathcal{C}(\mathcal{H})$ belongs to the variety of all *orthocomplemented orthomodular lattices*, that are not necessarily distributive.

The failure of distributivity is connected with a characteristic property of disjunction in QT. Differently from classical (bivalent) semantics, a quantum disjunction $X \sqcup Y$ may be true even if neither member is true. In fact, it may happen that a pure state ψ belongs to a subspace $X \sqcup Y$, even if ψ belongs neither to X nor to Y (see Figure 1).

Such a semantic behaviour, which may appear *prima facie* somewhat strange, seems to reflect pretty well a number of concrete quantum situations. In QT one is often dealing with alternatives that are semantically determined and true, while both members are, in principle, strongly indeterminate. For instance, suppose we are referring to some one-half spin particle (say an electron) whose spin may assume only two possible values: either *up* or *down*. Now, according to one of the *uncertainty principles*, the spin in the x direction ($spin_x$) and the spin in the y direction ($spin_y$) represent two strongly *incompatible* quantities that cannot be simultaneously

Figure 1. Failure of bivalence in QT

measured. Suppose an electron in state ψ verifies the proposition “ $spin_x$ is up”. As a consequence of the uncertainty principle both propositions “ $spin_y$ is up” and “ $spin_y$ is down” shall be strongly indeterminate. However the disjunction “either $spin_y$ is up or $spin_y$ is down” must be true.

Birkhoff and von Neumann’s proposal did not arouse any immediate interest, either in the logical or in the physical community. Probably, the quantum logical approach appeared too abstract for the foundational debate about QT, which in the Thirties was generally formulated in a more traditional philosophical language. As an example, let us only think of the famous discussion between Einstein and Bohr. At the same time, the work of logicians was still mainly devoted to classical logic.

Only twenty years later, after the appearance of George Mackey’s book *Mathematical Foundations of Quantum Theory* [Mackey, 1957], one has witnessed a “renaissance period” for the logico-algebraic approach to QT. This has been mainly stimulated by the contributions of Jauch, Piron, Varadarajan, Suppes, Finkelstein, Foulis, Randall, Greechie, Gudder, Beltrametti, Cassinelli, Mittelstaedt and many others. The new proposals are characterized by a more general approach, based on a kind of abstraction from the Hilbert space structures. The starting point of the new trends can be summarized as follows. Generally, any physical theory \mathbb{T} determines a class

of *event-state* systems $\langle \mathcal{E}, S \rangle$, where \mathcal{E} contains the events that may occur to our system, while S contains the states that a physical system described by the theory may assume. The question arises: what are the abstract conditions that one should postulate for any pair $\langle \mathcal{E}, S \rangle$? In the case of QT, having in mind the Hilbert space model, one is naturally led to the following requirement:

- the set \mathcal{E} of events should be a good abstraction from the structure of all closed subspaces in a Hilbert space. As a consequence \mathcal{E} should be at least a σ -complete orthomodular lattice (generally non distributive).
- The set S of states should be a good abstraction from the *statistical operators* in a Hilbert space, that represent possible states of physical systems. As a consequence, any state shall behave as a *probability measure*, that assigns to any event in \mathcal{E} a value in the interval $[0, 1]$. Both in the concrete and in the abstract case, states may be either *pure* (maximal pieces of information that cannot be consistently extended to a richer knowledge) or *mixtures* (non maximal pieces of information).

In such a framework two basic problems arise:

- I) Is it possible to capture, by means of some abstract conditions that are required for any event-state pair $\langle \mathcal{E}, S \rangle$, the behaviour of the concrete Hilbert space pairs?
- II) To what extent should the Hilbert space model be absolutely binding?

The first problem gave rise to a number of attempts to prove a kind of *representation theorem*. More precisely, the main question was: what are the necessary and sufficient conditions for a generic event-state pair $\langle \mathcal{E}, S \rangle$ that make \mathcal{E} isomorphic to the lattice of all closed subspaces in a Hilbert space?

Our second problem stimulated the investigation about more and more general quantum structures. Of course, looking for more general structures seems to imply a kind of discontent towards the standard quantum logical approach, based on Hilbert space lattices. The fundamental criticisms that have been moved concern the following items:

- 1) The standard structures seem to determine a kind of *extensional* collapse. In fact, the closed subspaces of a Hilbert space represent at the same time *physical properties* in an *intensional sense* and the *extensions* thereof (sets of states that certainly verify the properties in question). As happens in classical set theoretical semantics, there is no mathematical representative for physical properties in an intensional

sense. Foulis and Randall have called such an extensional collapse “the metaphysical disaster” of the standard quantum logical approach.

- 2) The lattice structure of the closed subspaces automatically renders the quantum proposition system closed under logical conjunction. This seems to imply some counterintuitive consequences from the physical point of view. Suppose two experimental propositions that concern two strongly incompatible quantities, like “the spin in the x direction is up”, “the spin in the y direction is down”. In such a situation, the intuition of the quantum physicist seems to suggest the following semantic requirement: the conjunction of our propositions has no definite meaning; for, they cannot be experimentally tested at the same time. As a consequence, the lattice proposition structure seems to be too strong.

An interesting weakening can be obtained by giving up the lattice condition: generally the *infimum* and the *supremum* are assumed to exist only for countable sets of propositions that are pairwise orthogonal. In the recent quantum logical literature an orthomodular partially ordered set that satisfies the above condition is simply called a *quantum logic*. At the same time, by *standard quantum logic* one usually means the complete orthomodular lattice based on the closed subspaces in a Hilbert space. Needless to observe, such a terminology that identifies a *logic* with a particular example of an algebraic structure turns out to be somewhat misleading from the strict logical point of view. As we will see in the next sections, different forms of quantum logic, which represent “genuine logics” according to the standard way of thinking of the logical tradition, can be characterized by convenient abstraction from the physical models.

2 ORTHOMODULAR QUANTUM LOGIC AND ORTHOLOGIC

We will first study two interesting examples of logic that represent a natural logical abstraction from the class of all Hilbert space lattices. These are represented respectively by *orthomodular quantum logic* (**OQL**) and by the weaker *orthologic* (**OL**), which for a long time has been also termed *minimal quantum logic*. In fact, the name “minimal quantum logic” appears today quite inappropriate, since a number of weaker forms of quantum logic have been recently investigated. In the following we will use **QL** as an abbreviation for both **OL** and **OQL**.

The language of **QL** consists of a denumerable set of sentential literals and of two primitive connectives: \neg (*not*), \wedge (*and*). The notion of *formula* of the language is defined in the expected way. We will use the following metavariables: p, q, r, \dots for sentential literals and $\alpha, \beta, \gamma, \dots$ for formulas.

The connective disjunction (\vee) is supposed defined via de Morgan's law:

$$\alpha \vee \beta := \neg (\neg \alpha \wedge \neg \beta).$$

The problem concerning the possibility of a well behaved conditional connective will be discussed in the next Section. We will indicate the basic metalogical constants as follows: *not*, *and*, *or*, \rightsquigarrow (*if...then*), *iff* (*if and only if*), \forall (for all), \exists (for at least one).

Because of its historical origin, the most natural characterization of **QL** can be carried out in the framework of an algebraic semantics. It will be expedient to recall first the definition of *ortholattice*:

DEFINITION 1 (Ortholattice). An *ortholattice* is a structure $\mathcal{B} = \langle B, \sqsubseteq, ', \mathbf{1}, \mathbf{0} \rangle$, where

- (1.1) $\langle B, \sqsubseteq, \mathbf{1}, \mathbf{0} \rangle$ is a bounded lattice, where $\mathbf{1}$ is the *maximum* and $\mathbf{0}$ is the *minimum*. In other words:
- (i) \sqsubseteq is a partial order relation on B (reflexive, antisymmetric and transitive);
 - (ii) any pair of elements a, b has an *infimum* $a \sqcap b$ and a *supremum* $a \sqcup b$ such that:
 $a \sqcap b \sqsubseteq a, b$ and $\forall c: c \sqsubseteq a, b \rightsquigarrow c \sqsubseteq a \sqcap b$;
 $a, b \sqsubseteq a \sqcup b$ and $\forall c: a, b \sqsubseteq c \rightsquigarrow a \sqcup b \sqsubseteq c$;
 - (iii) $\forall a: \mathbf{0} \sqsubseteq a; a \sqsubseteq \mathbf{1}$.
- (1.2) the 1-ary operation $'$ (called *orthocomplement*) satisfies the following conditions:
- (i) $a'' = a$ (double negation);
 - (ii) $a \sqsubseteq b \rightsquigarrow b' \sqsubseteq a'$ (contraposition);
 - (iii) $a \sqcap a' = \mathbf{0}$ (non contradiction).

Differently from Boolean algebras, ortholattices do not generally satisfy the distributive laws of \sqcap and \sqcup . There holds only

$$(a \sqcap b) \sqcup (a \sqcap c) \sqsubseteq a \sqcap (b \sqcup c)$$

and the dual form

$$a \sqcup (b \sqcap c) \sqsubseteq (a \sqcup b) \sqcap (a \sqcup c).$$

The lattice $\langle C(\mathcal{H}), \sqsubseteq, ', \mathbf{1}, \mathbf{0} \rangle$ of all closed subspaces in a Hilbert space \mathcal{H} is a characteristic example of a non distributive ortholattice.

DEFINITION 2 (Algebraic realization for **OL**). An *algebraic realization* for **OL** is a pair $\mathcal{A} = \langle \mathcal{B}, v \rangle$, consisting of an ortholattice $\mathcal{B} = \langle B, \sqsubseteq, ', \mathbf{1}, \mathbf{0} \rangle$ and a *valuation*-function v that associates to any formula α of the language an element (*truth-value*) in B , satisfying the following conditions:

- (i) $v(\neg\beta) = v(\beta)'$;
- (ii) $v(\beta \wedge \gamma) = v(\beta) \sqcap v(\gamma)$.

DEFINITION 3 (Truth and logical truth). A formula α is *true* in a realization $\mathcal{A} = \langle \mathcal{B}, v \rangle$ (abbreviated as $\models_{\mathcal{A}} \alpha$) iff $v(\alpha) = \mathbf{1}$; α is a *logical truth* of **OL** ($\models_{\mathbf{OL}} \alpha$) iff for any algebraic realization $\mathcal{A} = \langle \mathcal{B}, v \rangle$, $\models_{\mathcal{A}} \alpha$.

When $\models_{\mathcal{A}} \alpha$, we will also say that \mathcal{A} is a *model* of α ; \mathcal{A} will be called a *model* of a set of formulas T ($\models_{\mathcal{A}} T$) iff \mathcal{A} is a model of any $\beta \in T$.

DEFINITION 4 (Consequence in a realization and logical consequence). Let T be a set of formulas and let $\mathcal{A} = \langle \mathcal{B}, v \rangle$ be a realization. A formula α is a *consequence in \mathcal{A}* of T ($T \models_{\mathcal{A}} \alpha$) iff for any element a of \mathcal{B} : if for any $\beta \in T$, $a \sqsubseteq v(\beta)$ then $a \sqsubseteq v(\alpha)$. A formula α is a *logical consequence* of T ($T \models_{\mathbf{OL}} \alpha$) iff for any algebraic realization \mathcal{A} : $T \models_{\mathcal{A}} \alpha$.

Instead of $\{\alpha\} \models_{\mathbf{OL}} \beta$ we will write $\alpha \models_{\mathbf{OL}} \beta$. If T is finite and equal to $\{\alpha_1, \dots, \alpha_n\}$, we will obviously have: $T \models_{\mathbf{OL}} \alpha$ iff $v(\alpha_1) \sqcap \dots \sqcap v(\alpha_n) \sqsubseteq v(\alpha)$. One can easily check that $\models_{\mathbf{OL}} \alpha$ iff for any T , $T \models_{\mathbf{OL}} \alpha$.

OL can be equivalently characterized also by means of a Kripke-style semantics, which has been first proposed by [Dishkant, 1972]. As is well known, the algebraic semantic approach can be described as founded on the following intuitive idea: interpreting a language essentially means associating to any sentence α an abstract truth-value or, more generally, an abstract meaning (an element of an algebraic structure). In the Kripkean semantics, instead, one assumes that interpreting a language essentially means associating to any sentence α the set of the *possible worlds* or *situations* where α holds. This set, which represents the *extensional meaning* of α , is called the *proposition* associated to α (or simply *the proposition of α*). Hence, generally, a Kripkean realization for a logic **L** will have the form:

$$\mathcal{K} = \langle I, \vec{R}_i, \vec{o}_j, \Pi, \rho \rangle,$$

where

- (i) I is a non-empty set of possible worlds possibly correlated by relations in the sequence \vec{R}_i and operations in the sequence \vec{o}_j . In most cases, we have only one binary relation R , called *accessibility* relation.
- (ii) Π is a set of sets of possible worlds, representing possible propositions of sentences. Any proposition and the total set of propositions Π must satisfy convenient closure conditions that depend on the particular logic.
- (iii) ρ transforms sentences into propositions preserving the logical form.

The Kripkean realizations that turn out to be adequate for **OL** have only one accessibility relation, which is reflexive and symmetric. As is well known, many logics, that are stronger than *positive logic*, are instead characterized by Kripkean realizations where the accessibility relation is at least reflexive and transitive. As an example, let us think of *intuitionistic logic*. From an intuitive point of view, one can easily understand the reason why semantic models with a reflexive and symmetric accessibility relation may be physically significant. In fact, physical theories are not generally concerned with *possible evolutions of states of knowledge* with respect to a constant world, but rather with *sets of physical situations* that may be *similar*, where *states of knowledge* must single out some *invariants*. And similarity relations are reflexive and symmetric, but generally not transitive.

Let us now introduce the basic concepts of a Kripkean semantics for **OL**.
DEFINITION 5 (Orthoframe). An *orthoframe* is a relational structure $\mathcal{F} = \langle I, R \rangle$, where I is a non-empty set (called the set of *worlds*) and R (the *accessibility relation*) is a binary reflexive and symmetric relation on I .

Given an orthoframe, we will use i, j, k, \dots as variables ranging over the set of worlds. Instead of Rij (not Rij) we will also write $i \perp j$ ($i \perp j$).

DEFINITION 6 (Orthocomplement in an orthoframe). Let $\mathcal{F} = \langle I, R \rangle$ be an orthoframe. For any set of worlds $X \subseteq I$, the *orthocomplement* X' of X is defined as follows:

$$X' = \{i \mid \forall j(j \in X \rightsquigarrow j \perp i)\}.$$

In other words, X is the set of all worlds that are inaccessible to all elements of X' . Instead of $i \in X'$, we will also write $i \perp X$ (and we will read it as “ i is orthogonal to the set X ”). Instead of $i \notin X'$, we will also write $i \not\perp X$.

DEFINITION 7 (Proposition). Let $\mathcal{F} = \langle I, R \rangle$ be an orthoframe. A set of worlds X is called a *proposition* of \mathcal{F} iff it satisfies the following condition:

$$\forall i [i \in X \text{ iff } \forall j(i \not\perp j \rightsquigarrow j \not\perp X)].$$

In other words, a proposition is a set of worlds X that contains all and only the worlds whose accessible worlds are not inaccessible to X . Notice that the conditional $i \in X \rightsquigarrow \forall j(i \not\perp j \rightsquigarrow j \not\perp X)$ trivially holds for any set of worlds X .

Our definition of proposition represents a quite general notion of “possible meaning of a formula”, that can be significantly extended also to other logics. Suppose for instance, a Kripkean frame $\mathcal{F} = \langle I, R \rangle$, where the accessibility relation is at least reflexive and transitive (as happens in the Kripkean semantics for intuitionistic logic). Then a set of worlds X turns out to be a proposition (in the sense of Definition 7) iff it is *R-closed* (i.e.,

$\forall ij(i \in X \text{ and } Rij \leadsto j \in X)$). And R -closed sets of worlds represent precisely the possible meanings of formulas in the Kripkean characterization of intuitionistic logic.

LEMMA 8. *Let \mathcal{F} be an orthoframe and X a set of worlds of \mathcal{F} .*

$$(8.1) \quad X \text{ is a proposition of } \mathcal{F} \text{ iff } \forall i [i \notin X \leadsto \exists j (i \not\perp j \text{ and } j \perp X)]$$

$$(8.2) \quad X \text{ is a proposition of } \mathcal{F} \text{ iff } X = X''.$$

LEMMA 9. *Let $\mathcal{F} = \langle I, R \rangle$ be an orthoframe.*

$$(9.1) \quad I \text{ and } \emptyset \text{ are propositions.}$$

$$(9.2) \quad \text{If } X \text{ is any set of worlds, then } X' \text{ is a proposition.}$$

$$(9.3) \quad \text{If } C \text{ is a family of propositions, then } \bigcap C \text{ is a proposition.}$$

DEFINITION 10 (Kripkean realization for **OL**). A *Kripkean realization* for **OL** is a system $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$, where:

- (i) $\langle I, R \rangle$ is an orthoframe and Π is a set of propositions of the frame that contains \emptyset, I and is closed under the orthocomplement $'$ and the set-theoretic intersection \cap ;
- (ii) ρ is a function that associates to any formula α a proposition in Π , satisfying the following conditions:

$$\begin{aligned} \rho(\neg\beta) &= \rho(\beta)'; \\ \rho(\beta \wedge \gamma) &= \rho(\beta) \cap \rho(\gamma). \end{aligned}$$

Instead of $i \in \rho(\alpha)$, we will also write $i \models \alpha$ (or, $i \models_{\mathcal{K}} \alpha$, in case of possible confusions) and we will read: “ α is true in the world i ”. If T is a set of formulas, $i \models T$ will mean $i \models \beta$ for any $\beta \in T$.

THEOREM 11. *For any Kripkean realization \mathcal{K} and any formula α :*

$$i \models \alpha \text{ iff } \forall j \not\perp i \exists k \not\perp j (k \models \alpha).$$

Proof. Since the accessibility relation is symmetric, the left to right implication is trivial. Let us prove $i \not\models \alpha \leadsto \text{not} \forall j \not\perp i \exists k \not\perp j (k \models \alpha)$, which is equivalent to $i \notin \rho(\alpha) \leadsto \exists j \not\perp i \forall k \not\perp j (k \notin \rho(\alpha))$. Suppose $i \notin \rho(\alpha)$. Since $\rho(\alpha)$ is a proposition, by Lemma 8.1 there holds for a certain j : $j \not\perp i$ and $j \perp \rho(\alpha)$. Let $k \not\perp j$, and suppose, by contradiction, $k \in \rho(\alpha)$. Since $j \perp \rho(\alpha)$, there follows $j \perp k$, against $k \not\perp j$. Consequently, $\exists j \not\perp i \forall k \not\perp j (k \notin \rho(\alpha))$. ■

LEMMA 12. *In any Kripkean realization \mathcal{K} :*

$$(12.1) \quad i \models \neg\beta \text{ iff } \forall j \not\perp i (j \not\models \beta);$$

$$(12.2) \quad i \models \beta \wedge \gamma \text{ iff } i \models \beta \text{ and } i \models \gamma.$$

DEFINITION 13 (Truth and logical truth). A formula α is *true* in a realization $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$ (abbreviated $\models_{\mathcal{K}} \alpha$) iff $\rho(\alpha) = I$; α is a *logical truth* of **OL** ($\models_{\text{OL}} \alpha$) iff for any realization \mathcal{K} , $\models_{\mathcal{K}} \alpha$.

When $\models_{\mathcal{K}} \alpha$, we will also say that \mathcal{K} is a *model* of α . Similarly in the case of a set of formulas T .

DEFINITION 14 (Consequence in a realization and logical consequence).

Let T be a set of formulas and let \mathcal{K} be a realization. A formula α is a *consequence in \mathcal{K}* of T ($T \models_{\mathcal{K}} \alpha$) iff for any world i of \mathcal{K} , $i \models T \curvearrowright i \models \alpha$. A formula α is a *logical consequence* of T ($T \models_{\text{OL}} \alpha$) iff for any realization \mathcal{K} : $T \models_{\mathcal{K}} \alpha$. When no confusion is possible we will simply write $T \models \alpha$.

Now we will prove that the algebraic and the Kripkean semantics for **OL** characterize the same logic. Let us abbreviate the metalogical expressions “ α is a logical truth of **OL** according to the algebraic semantics”, “ α is a logical consequence in **OL** of T according to the algebraic semantics”, “ α is a logical truth of **OL** according to the Kripkean semantics”, “ α is a logical consequence in **OL** of T according to the Kripkean semantics”, by $\stackrel{\text{A}}{\models}_{\text{OL}} \alpha$, $T \stackrel{\text{A}}{\models}_{\text{OL}} \alpha$, $\stackrel{\text{K}}{\models}_{\text{OL}} \alpha$, $T \stackrel{\text{K}}{\models}_{\text{OL}} \alpha$, respectively.

THEOREM 15. $\stackrel{\text{A}}{\models}_{\text{OL}} \alpha$ iff $\stackrel{\text{K}}{\models}_{\text{OL}} \alpha$, for any α .

The Theorem is an immediate corollary of the following Lemma:

LEMMA 16.

(16.1) For any algebraic realization \mathcal{A} there exists a Kripkean realization $\mathcal{K}^{\mathcal{A}}$ such that for any α , $\models_{\mathcal{A}} \alpha$ iff $\models_{\mathcal{K}^{\mathcal{A}}} \alpha$.

(16.2) For any Kripkean realization \mathcal{K} there exists an algebraic realization $\mathcal{A}^{\mathcal{K}}$ such that for any α , $\models_{\mathcal{K}} \alpha$ iff $\models_{\mathcal{A}^{\mathcal{K}}} \alpha$.

Sketch of the proof

(16.1) The basic intuitive idea of the proof is the following: any algebraic realization can be canonically transformed into a Kripkean realization by identifying the set of worlds with the set of all non-null elements of the algebra, the accessibility-relation with the non-orthogonality relation in the algebra, and finally the set of propositions with the set of all *principal quasi-ideals* (i.e., the principal ideals, devoided of the zero-element). More precisely, given $\mathcal{A} = \langle \mathcal{B}, v \rangle$, the Kripkean realization $\mathcal{K}^{\mathcal{A}} = \langle I, R, \Pi, \rho \rangle$ is defined as follows:

$$\begin{aligned} I &= \{b \in B \mid b \neq \mathbf{0}\}; \\ Rij &\text{ iff } i \not\perp j'; \\ \Pi &= \{\{b \in B \mid b \neq \mathbf{0} \text{ and } b \sqsubseteq a\} \mid a \in B\}; \end{aligned}$$

$$\rho(p) = \{b \in I \mid b \sqsubseteq v(p)\}.$$

One can easily check that $\mathcal{K}^{\mathcal{A}}$ is a “good” Kripkean realization; further, there holds, for any α : $\rho(\alpha) = \{b \in B \mid b \neq \mathbf{0} \text{ and } b \sqsubseteq v(\alpha)\}$. Consequently, $\models_{\mathcal{A}} \alpha$ iff $\models_{\mathcal{K}^{\mathcal{A}}} \alpha$.

(16.2) Any Kripkean realization $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$ can be canonically transformed into an algebraic realization $\mathcal{A}^{\mathcal{K}} = \langle \mathcal{B}, v \rangle$ by putting:

$$\begin{aligned} B &= \Pi; \\ \text{for any } a, b \in B: & \quad a \sqsubseteq b \text{ iff } a \subseteq b; \\ a' &= \{i \in I \mid i \perp a\}; \\ \mathbf{1} &= I; \quad \mathbf{0} = \emptyset; \\ v(p) &= \rho(p). \end{aligned}$$

It turns out that \mathcal{B} is an ortholattice. Further, for any α , $v(\alpha) = \rho(\alpha)$. Consequently: $\models_{\mathcal{K}} \alpha$ iff $\models_{\mathcal{A}^{\mathcal{K}}} \alpha$. ■

THEOREM 17. $T \stackrel{\mathbf{A}}{\underset{\mathbf{OL}}{\models}} \alpha$ iff $T \stackrel{\mathbf{K}}{\underset{\mathbf{OL}}{\models}} \alpha$.

Proof. In order to prove the left to right implication, suppose by contradiction: $T \stackrel{\mathbf{A}}{\underset{\mathbf{OL}}{\models}} \alpha$ and $T \not\stackrel{\mathbf{K}}{\underset{\mathbf{OL}}{\models}} \alpha$. Hence there exists a Kripkean realization $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$ and a world i of \mathcal{K} such that $i \models T$ and $i \not\models \alpha$. One can easily see that \mathcal{K} can be transformed into $\mathcal{K}^{\circ} = \langle I, R, \Pi^{\circ}, \rho \rangle$ where Π° is the smallest subset of the power-set of I , that includes Π and is closed under infinitary intersection. Owing to Lemma 9.3, \mathcal{K}° is a “good” Kripkean realization for \mathbf{OL} and for any β , $\rho(\beta)$ turns out to be the same proposition in \mathcal{K} and in \mathcal{K}° . Consequently, also in \mathcal{K}° , there holds: $i \models T$ and $i \not\models \alpha$. Let us now consider $\mathcal{A}^{\mathcal{K}^{\circ}}$. The algebra \mathcal{B} of $\mathcal{A}^{\mathcal{K}^{\circ}}$ is complete, because Π° is closed under infinitary intersection. Hence, $\bigcap \{\rho(\beta) \mid \beta \in T\}$ is an element of B . Since $i \models \beta$ for any $\beta \in T$, we will have $i \in \bigcap \{\rho(\beta) \mid \beta \in T\}$. Thus there is an element of B , which is less or equal than $v(\beta)(= \rho(\beta))$ for any $\beta \in T$, but is not less or equal than $v(\alpha)(= \rho(\alpha))$, because $i \notin \rho(\alpha)$. This contradicts the hypothesis $T \stackrel{\mathbf{A}}{\underset{\mathbf{OL}}{\models}} \alpha$.

The right to left implication is trivial. ■

Let us now turn to a semantic characterization of \mathbf{OQL} . We will first recall the definition of orthomodular lattice.

DEFINITION 18 (Orthomodular lattice). An *orthomodular lattice* is an ortholattice $\mathcal{B} = \langle B, \sqsubseteq, ', \mathbf{1}, \mathbf{0} \rangle$ such that for any $a, b \in B$:

$$a \sqcap (a' \sqcup (a \sqcap b)) \sqsubseteq b.$$

Orthomodularity clearly represents a weak form of distributivity.

LEMMA 19. *Let \mathcal{B} be an ortholattice. The following conditions are equivalent:*

- (i) \mathcal{B} is orthomodular.
- (ii) For any $a, b \in B$: $a \sqsubseteq b \iff b = a \sqcup (a' \sqcap b)$.
- (iii) For any $a, b \in B$: $a \sqsubseteq b$ iff $a \sqcap (a \sqcap b)' = \mathbf{0}$.
- (iv) For any $a, b \in B$: $a \sqsubseteq b$ and $a' \sqcap b = \mathbf{0} \iff a = b$.

The property considered in (19(iii)) represents a significant weakening of the Boolean condition:

$$a \sqsubseteq b \text{ iff } a \sqcap b' = \mathbf{0}.$$

DEFINITION 20 (Algebraic realization for **OQL**). An *algebraic realization* for **OQL** is an algebraic realization $\mathcal{A} = \langle \mathcal{B}, v \rangle$ for **OL**, where \mathcal{B} is an orthomodular lattice.

The definitions of truth, logical truth and logical consequence in **OQL** are analogous to the corresponding definitions of **OL**.

Like **OL**, also **OQL** can be characterized by means of a Kripkean semantics.

DEFINITION 21 (Kripkean realization for **OQL**). A *Kripkean realization* for **OQL** is a Kripkean realization $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$ for **OL**, where the set of propositions Π satisfies the *orthomodular property*:

$$X \not\subseteq Y \iff X \cap (X \cap Y)' \neq \emptyset.$$

The definitions of *truth*, *logical truth* and *logical consequence* in **OQL** are analogous to the corresponding definitions of **OL**. Also in the case of **OQL** one can show:

THEOREM 22. $\stackrel{\mathbf{A}}{\underset{\mathbf{OQL}}{\equiv}} \alpha \text{ iff } \stackrel{\mathbf{K}}{\underset{\mathbf{OQL}}{\equiv}} \alpha.$

The Theorem is an immediate corollary of Lemma 16 and of the following lemma:

LEMMA 23.

- (23.1) If \mathcal{A} is orthomodular then $\mathcal{K}^{\mathcal{A}}$ is orthomodular;
- (23.2) If \mathcal{K} is orthomodular then $\mathcal{A}^{\mathcal{K}}$ is orthomodular.

Proof. (23.1) We have to prove $X \not\subseteq Y \iff X \cap (X \cap Y)' \neq \emptyset$ for any propositions X, Y of $\mathcal{K}^{\mathcal{A}}$. Suppose $X \not\subseteq Y$. By definition of proposition in $\mathcal{K}^{\mathcal{A}}$:

$$\begin{aligned} X &= \{b \mid b \neq \mathbf{0} \text{ and } b \sqsubseteq x\} \text{ for a given } x; \\ Y &= \{b \mid b \neq \mathbf{0} \text{ and } b \sqsubseteq y\} \text{ for a given } y; \end{aligned}$$

Consequently, $x \not\subseteq y$, and by Lemma 19: $x \sqcap (x \sqcap y)' \neq \mathbf{0}$, because \mathcal{A} is orthomodular. Hence, $x \sqcap (x \sqcap y)'$ is a world in $\mathcal{K}^{\mathcal{A}}$. In order to prove

$X \cap (X \cap Y)' \neq \emptyset$, it is sufficient to prove $x \sqcap (x \sqcap y)' \in X \cap (X \cap Y)'$. There holds trivially $x \sqcap (x \sqcap y)' \in X$. Further, $x \sqcap (x \sqcap y)' \in (X \cap Y)'$, because $(x \sqcap y)'$ is the generator of the quasi-ideal $(X \cap Y)'$. Consequently, $x \sqcap (x \sqcap y)' \in X \cap (X \cap Y)'$.

(23.2) Let \mathcal{K} be orthomodular. Then for any $X, Y \in \Pi$:

$$X \not\subseteq Y \rightsquigarrow X \cap (X \cap Y)' \neq \emptyset.$$

One can trivially prove:

$$X \cap (X \cap Y)' \neq \emptyset \rightsquigarrow X \not\subseteq Y.$$

Hence, by Lemma 19, the algebra \mathcal{B} of $\mathcal{A}^{\mathcal{K}}$ is orthomodular. \blacksquare

As to the concept of logical consequence, the proof we have given for **OL** (Theorem 17) cannot be automatically extended to the case of **OQL**. The critical point is represented by the transformation of \mathcal{K} into \mathcal{K}° whose set of propositions is closed under infinitary intersection: \mathcal{K}° is trivially a “good” **OL**-realization; at the same time, it is not granted that \mathcal{K}° preserves the orthomodular property. One can easily prove:

THEOREM 24. $T \stackrel{\mathbf{K}}{\underset{\mathbf{OQL}}{=} } \alpha \rightsquigarrow T \stackrel{\mathbf{A}}{\underset{\mathbf{OQL}}{=} } \alpha$.

The inverse relation has been proved by [Minari, 1987]:

THEOREM 25. $T \stackrel{\mathbf{A}}{\underset{\mathbf{OQL}}{=} } \alpha \rightsquigarrow T \stackrel{\mathbf{K}}{\underset{\mathbf{OQL}}{=} } \alpha$.

Are there any significant structural relations between \mathcal{A} and $\mathcal{K}^{\mathcal{A}^{\mathcal{K}}}$ and between \mathcal{K} and $\mathcal{A}^{\mathcal{K}^{\mathcal{A}}}$? The question admits a very strong answer in the case of \mathcal{A} and $\mathcal{K}^{\mathcal{A}^{\mathcal{K}}}$.

THEOREM 26. $\mathcal{A} = \langle \mathcal{B}, v \rangle$ and $\mathcal{A}^{\mathcal{K}^{\mathcal{A}}} = \langle \mathcal{B}^*, v^* \rangle$ are isomorphic realizations.

Sketch of the proof Let us define the function $\psi : B \rightarrow B^*$ in the following way:

$$\psi(a) = \{b \mid b \neq \mathbf{0} \text{ and } b \sqsubseteq a\} \text{ for any } a \in B.$$

One can easily check that: (1) ψ is an isomorphism (from \mathcal{B} onto \mathcal{B}^*); (2) $v^*(p) = \psi(v(p))$ for any atomic formula p . \blacksquare

At the same time, in the case of \mathcal{K} and $\mathcal{K}^{\mathcal{A}^{\mathcal{K}}}$, there is no natural correspondence between I and Π . As a consequence, one can prove only the weaker relation:

THEOREM 27. Given $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$ and $\mathcal{K}^{\mathcal{A}^{\mathcal{K}}} = \langle I^*, R^*, \Pi^*, \rho^* \rangle$, there holds:

$$\rho^*(\alpha) = \{X \in \Pi \mid X \subseteq \rho(\alpha)\}, \text{ for any } \alpha.$$

In the class of all Kripkean realizations for **QL**, the realizations \mathcal{K}^A (which have been obtained by canonical transformation of an algebraic realization A) present some interesting properties, which are summarized by the following theorem.

THEOREM 28. *In any $\mathcal{K}^A = \langle I, R, \Pi, \rho \rangle$ there is a one-to-one correspondence ϕ between the set of worlds I and the set of propositions $\Pi - \{\emptyset\}$ such that:*

- (28.1) $i \in \phi(i)$;
- (28.2) $i \not\perp j$ iff $\phi(i) \not\subseteq \phi(j)'$;
- (28.3) $\forall X \in \Pi: i \in X$ iff $\forall k \in \phi(i) (k \in X)$.

Sketch of the proof Let us take as $\phi(i)$ the quasi-ideal generated by i . ■

Theorem 28 suggests to isolate, in the class of all \mathcal{K} , an interesting subclass of Kripkean realizations, that we will call *algebraically adequate*.

DEFINITION 29. A Kripkean realization \mathcal{K} is *algebraically adequate* iff it satisfies the conditions of Theorem 28.

When restricting to the class of all algebraically adequate Kripkean realizations one can prove:

THEOREM 30. $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$ and $\mathcal{K}^{A^K} = \langle I^*, R^*, \Pi^*, \rho^* \rangle$ are isomorphic realizations; i.e., there exists a bijective function ψ from I onto I^* such that:

- (30.1) Rij iff $R^*\psi(i)\psi(j)$, for any $i, j \in I$;
- (30.2) $\Pi^* = \{\psi(X) \mid X \in \Pi\}$, where $\psi(X) := \{\psi(i) \mid i \in X\}$;
- (30.3) $\rho^*(p) = \psi(\rho(p))$, for any atomic formula p .

One can easily show that the class of all algebraically adequate Kripkean realizations determines the same concept of logical consequence that is determined by the larger class of all possible realizations.

The Kripkean characterization of **QL** turns out to have a quite natural physical interpretation. As we have seen in the Introduction, the mathematical formalism of quantum theory (QT) associates to any *physical system* \mathcal{S} a Hilbert space \mathcal{H} , while the *pure states* of \mathcal{S} are mathematically represented by unitary vectors ψ of \mathcal{H} . Let us now consider an elementary sublanguage \mathcal{L}^Q of QT, whose atomic formulas represent possible measurement reports (i.e., statements of the form “the value for the observable Q lies in the Borel set Δ ”) and suppose \mathcal{L}^Q closed under the quantum logical connectives. Given a physical system \mathcal{S} (whose associated Hilbert space is \mathcal{H}), one can define a natural Kripkean realization for the language \mathcal{L}^Q as follows:

$$\mathcal{K}^{\mathcal{S}} = \langle I, R, \Pi, \rho \rangle,$$

where:

- I is the set of all pure states ψ of \mathcal{S} .
- R is the non-orthogonality relation between vectors (in other words, two pure states are accessible iff their inner product is different from zero).
- Π is the set of all propositions that is univocally determined by the set of all closed subspaces of \mathcal{H} (one can easily check that the set of all unitary vectors of any subspace is a proposition).
- For any atomic formula p , $\rho(p)$ is the proposition containing all the pure states that assign to p probability-value 1.

Interestingly enough, the accessibility relation turns out to have the following physical meaning: Rij iff j is a pure state into which i can be transformed after the performance of a physical measurement that concern an observable of the system.

3 THE IMPLICATION PROBLEM

Differently from most weak logics, **QL** gives rise to a critical “implication-problem”. All conditional connectives one can reasonably introduce in **QL** are, to a certain extent, anomalous; for, they do not share most of the characteristic properties that are satisfied by the *positive conditionals* (which are governed by a logic that is at least as strong as *positive logic*). Just the failure of a well-behaved conditional led some authors to the conclusion that **QL** cannot be a “real” logic. In spite of these difficulties, these days one cannot help recognizing that **QL** admits a set of different implicational connectives, even if none of them has a *positive* behaviour. Let us first propose a general semantic condition for a logical connective to be classified as an implication-connective.

DEFINITION 31. In any semantics, a binary connective $\overset{*}{\rightarrow}$ is called an *implication-connective* iff it satisfies at least the two following conditions:

$$(31.1) \quad \alpha \overset{*}{\rightarrow} \alpha \text{ is always true (identity);}$$

$$(31.2) \quad \text{if } \alpha \text{ is true and } \alpha \overset{*}{\rightarrow} \beta \text{ is true then } \beta \text{ is true (modus ponens).}$$

In the particular case of **QL**, one can easily obtain:

LEMMA 32. *A sufficient condition for a connective $\overset{*}{\rightarrow}$ to be an implication-connective is:*

- (i) *in the algebraic semantics: for any realization $\mathcal{A} = \langle \mathcal{A}, v \rangle$, $\models_{\mathcal{A}} \alpha \overset{*}{\rightarrow} \beta$ iff $v(\alpha) \sqsubseteq v(\beta)$;*

- (ii) *in the Kripkean semantics: for any realization $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$,*
 $\models_{\mathcal{K}} \alpha \overset{*}{\rightarrow} \beta$ *iff* $\rho(\alpha) \subseteq \rho(\beta)$.

In **QL** it seems reasonable to assume the sufficient condition of Lemma 32 as a minimal condition for a connective to be an implication-connective.

Suppose we have independently defined two different implication-connectives in the algebraic and in the Kripkean semantics. When shall we admit that they represent the “same logical connective”? A reasonable answer to this question is represented by the following convention:

DEFINITION 33. Let $\overset{A}{*}$ be a binary connective defined in the algebraic semantics and $\overset{K}{*}$ a binary connective defined in the Kripkean semantics: $\overset{A}{*}$ and $\overset{K}{*}$ represent the *same logical connective* iff the following conditions are satisfied:

- (33.1) given any $\mathcal{A} = \langle \mathcal{B}, v \rangle$ and given the corresponding $\mathcal{K}^{\mathcal{A}} = \langle I, R, \Pi, \rho \rangle$, $\rho(\alpha \overset{K}{*} \beta)$ is the quasi-ideal generated by $v(\alpha \overset{A}{*} \beta)$;
- (33.2) given any $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$ and given the corresponding $\mathcal{A}^{\mathcal{K}} = \langle \mathcal{B}, v \rangle$, there holds: $v(\alpha \overset{A}{*} \beta) = \rho(\alpha \overset{K}{*} \beta)$.

We will now consider different possible semantic characterizations of an implication-connective in **QL**. Differently from classical logic, in **QL** a material conditional defined by *Philo-law* ($\alpha \rightarrow \beta := \neg\alpha \vee \beta$), does not give rise to an implication-connective. For, there are algebraic realizations $\mathcal{A} = \langle \mathcal{B}, v \rangle$ such that $v(\neg\alpha \vee \beta) = \mathbf{1}$, while $v(\alpha) \not\sqsubseteq v(\beta)$. Further, ortholattices and orthomodular lattices are not, generally, *pseudocomplemented* lattices: in other words, given $a, b \in B$, the maximum c such that $a \sqcap c \sqsubseteq b$ does not necessarily exist in B . In fact, one can prove [Birkhoff, 1995] that any pseudocomplemented lattice is distributive.

We will first consider the case of *polynomial conditionals*, that can be defined in terms of the connectives \wedge, \vee, \neg . In the algebraic semantics, the minimal requirement of Lemma 32 restricts the choice only to five possible candidates [Kalmbach, 1983]. This result follows from the fact that in the orthomodular lattice freely generated by two elements there are only five polynomial binary operations \circ satisfying the condition $a \sqsubseteq b$ iff $a \circ b = \mathbf{1}$. These are our five candidates:

- (i) $v(\alpha \rightarrow_1 \beta) = v(\alpha)' \sqcup (v(\alpha) \sqcap v(\beta))$.
- (ii) $v(\alpha \rightarrow_2 \beta) = v(\beta) \sqcup (v(\alpha)' \sqcap v(\beta)')$.
- (iii) $v(\alpha \rightarrow_3 \beta) = (v(\alpha)' \sqcap v(\beta)) \sqcup (v(\alpha) \sqcap v(\beta)) \sqcup (v(\alpha)' \sqcap v(\beta)')$.
- (iv) $v(\alpha \rightarrow_4 \beta) = (v(\alpha)' \sqcap v(\beta)) \sqcup (v(\alpha) \sqcap v(\beta)) \sqcup ((v(\alpha)' \sqcup v(\beta)) \sqcap v(\beta)')$.

$$(v) \quad v(\alpha \rightarrow_5 \beta) = (v(\alpha)' \sqcap v(\beta)) \sqcup (v(\alpha)' \sqcap v(\beta)') \sqcup (v(\alpha) \sqcap (v(\alpha)' \sqcup v(\beta))).$$

The corresponding five implication-connectives in the Kripkean semantics can be easily obtained. It is not hard to see that for any i ($1 \leq i \leq 5$), \rightarrow_i represents the same logical connective in both semantics (in the sense of Definition 33).

THEOREM 34. *The polynomial conditionals \rightarrow_i ($1 \leq i \leq 5$) are implication-connectives in **OQL**; at the same time they are not implication-connectives in **OL**.*

Proof. Since \rightarrow_i represent the same connective in both semantics, it will be sufficient to refer to the algebraic semantics. As an example, let us prove the theorem for $i = 1$ (the other cases are similar). First we have to prove $v(\alpha) \sqsubseteq v(\beta)$ iff $\mathbf{1} = v(\alpha \rightarrow_1 \beta) = v(\alpha)' \sqcup (v(\alpha) \sqcap v(\beta))$, which is equivalent to $v(\alpha) \sqsubseteq v(\beta)$ iff $v(\alpha) \sqcap (v(\alpha) \sqcap v(\beta))' = \mathbf{0}$. From Lemma 19, we know that the latter condition holds for any pair of elements of B iff \mathcal{B} is orthomodular. This proves at the same time that \rightarrow_1 is an implication-connective in **OQL**, but cannot be an implication-connective in **OL**. ■

Interestingly enough, each polynomial conditional \rightarrow_i represents a good weakening of the classical material conditional. In order to show this result, let us first introduce an important relation that describes a “Boolean mutual behaviour” between elements of an orthomodular lattice.

DEFINITION 35 (Compatibility).

Two elements a, b of an orthomodular lattice \mathcal{B} are *compatible* iff

$$a = (a \sqcap b') \sqcup (a \sqcap b).$$

One can prove that a, b are compatible iff the subalgebra of \mathcal{B} generated by $\{a, b\}$ is Boolean.

THEOREM 36. *For any algebraic realization $\mathcal{A} = \langle \mathcal{B}, v \rangle$ and for any α, β :*

$$v(\alpha \rightarrow_i \beta) = v(\alpha)' \sqcup v(\beta) \text{ iff } v(\alpha) \text{ and } v(\beta) \text{ are compatible.}$$

As previously mentioned, Boolean algebras are pseudocomplemented lattices. Therefore they satisfy the following condition for any a, b, c :

$$c \sqcap a \sqsubseteq b \text{ iff } c \sqsubseteq a \rightsquigarrow b,$$

where: $a \rightsquigarrow b := a' \sqcup b$.

An orthomodular lattice \mathcal{B} turns out to be a Boolean algebra iff for any algebraic realization $\mathcal{A} = \langle \mathcal{B}, v \rangle$, any i ($1 \leq i \leq 5$) and any α, β the following *import-export* condition is satisfied:

$$v(\gamma) \sqcap v(\alpha) \sqsubseteq v(\beta) \text{ iff } v(\gamma) \sqsubseteq v(\alpha \rightarrow_i \beta).$$

In order to single out a unique polynomial conditional, various weakenings of the import-export condition have been proposed. For instance the following condition (which we will call *weak import-export*):

$$v(\gamma) \sqcap v(\alpha) \sqsubseteq v(\beta) \text{ iff } v(\gamma) \sqsubseteq v(\alpha) \rightarrow_i v(\beta), \\ \text{whenever } v(\alpha) \text{ and } v(\beta) \text{ are compatible.}$$

One can prove [Hardegree, 1975; Mittelstaedt, 1972] that a polynomial conditional \rightarrow_i satisfies the weak import-export condition iff $i = 1$. As a consequence, we can conclude that \rightarrow_1 represents, in a sense, the best possible approximation for a material conditional in quantum logic. This connective (often called *Sasaki-hook*) was originally proposed by [Mittelstaedt, 1972] and [Finch, 1970], and was further investigated by [Hardegree, 1976] and other authors. In the following, we will usually write \rightarrow instead of \rightarrow_1 and we will neglect the other four polynomial conditionals.

Some important positive laws that are violated by our quantum logical conditional are the following:

$$\begin{aligned} &\alpha \rightarrow (\beta \rightarrow \alpha); \\ &(\alpha \rightarrow (\beta \rightarrow \gamma)) \rightarrow ((\alpha \rightarrow \beta) \rightarrow (\alpha \rightarrow \gamma)); \\ &(\alpha \rightarrow \beta) \rightarrow ((\beta \rightarrow \gamma) \rightarrow (\alpha \rightarrow \gamma)); \\ &(\alpha \wedge \beta \rightarrow \gamma) \rightarrow (\alpha \rightarrow (\beta \rightarrow \gamma)); \\ &(\alpha \rightarrow (\beta \rightarrow \gamma)) \rightarrow (\beta \rightarrow (\alpha \rightarrow \gamma)). \end{aligned}$$

This somewhat “anomalous” behaviour has suggested that one is dealing with a kind of *counterfactual conditional*. Such a conjecture seems to be confirmed by some important physical examples. Let us consider again the class of the Kripkean realizations of the sublanguage $\mathcal{L}^{\mathbf{Q}}$ of QT (whose atomic sentences express measurement reports). And let $K^{\mathcal{S}} = \langle I, R, \Pi, \rho \rangle$ represent a Kripkean realization of our language, which is associated to a physical system \mathcal{S} . As [Hardegree, 1975] has shown, in such a case the conditional \rightarrow turns out to receive a quite natural counterfactual interpretation (in the sense of Stalnaker). More precisely, one can define, for any formula α , a partial *Stalnaker-function* f_α in the following way:

$$f_\alpha : \text{Dom}(f_\alpha) \rightarrow I,$$

where:

$$\text{Dom}(f_\alpha) = \{i \in I \mid i \not\perp \rho(\alpha)\}.$$

In other words, f_α is defined for all and only the states that are not orthogonal to the proposition of α .

If $i \in \text{Dom}(f_\alpha)$, then:

$$f_\alpha(i) = j^{P_{\rho(\alpha)}i},$$

where $P_{\rho(\alpha)}$ is the projection that is uniquely associated with the closed subspace determined by $\rho(\alpha)$, and $j^{P_{\rho(\alpha)}i}$ is the normalized vector determined by $P_{\rho(\alpha)}i$. There holds:

$$i \models \alpha \rightarrow \beta \text{ iff either } \forall j \not\perp i (j \not\models \alpha) \text{ or } f_\alpha(i) \models \beta.$$

From an intuitive point of view, one can say that $f_\alpha(i)$ represents the “pure state nearest” to i , that verifies α , where “nearest” is here defined in terms of the metrics of the Hilbert space \mathcal{H} . By definition and in virtue of one of the basic postulates of QT (von Neumann’s *collapse of the wave function*), $f_\alpha(i)$ turns out to have the following physical meaning: it represents the transformation of state i after the performance of a measurement concerning the physical property expressed by α , provided the result was positive. As a consequence, one obtains: $\alpha \rightarrow \beta$ is true in a state i iff either α is impossible for i or the state into which i has been transformed after a positive α -test, verifies α .

Another interesting characteristic of our connective \rightarrow , is a *weak non monotonic* behaviour. In fact, in the algebraic semantics the inequality

$$v(\alpha \rightarrow \gamma) \sqsubseteq v(\alpha \wedge \beta \rightarrow \gamma)$$

can be violated (a counterexample can be easily obtained in the orthomodular lattice based on \mathbb{R}^3). As a consequence:

$$\alpha \rightarrow \gamma \not\models \alpha \wedge \beta \rightarrow \gamma.$$

Polynomial conditionals are not the only significant examples of implication-connectives in **QL**. In the framework of a Kripkean semantic approach, it seems quite natural to introduce a conditional connective \multimap , that represents a kind of *strict implication*. Given a Kripkean realization $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$ one would like to require:

$$i \models \alpha \multimap \beta \text{ iff } \forall j \not\perp i (j \models \alpha \rightsquigarrow j \models \beta).$$

However such a condition does not automatically represent a correct semantic definition, because it is not granted that $\rho(\alpha \multimap \beta)$ is an element of Π . In order to overcome this difficulty, let us first define a new operation in the power-set of an orthoframe $\langle I, R \rangle$.

DEFINITION 37 (Strict-implication operation ($\boxed{\multimap}$)). Given an orthoframe $\langle I, R \rangle$ and $X, Y \subseteq I$:

$$X \boxed{\multimap} Y := \{i \mid \forall j (i \not\perp j \text{ and } j \in X \rightsquigarrow j \in Y)\}.$$

If X and Y are sets of worlds in the orthoframe, then $X \boxed{\dashv} Y$ turns out to be a proposition of the frame.

When the set Π of \mathcal{K} is closed under $\boxed{\dashv}$, we will say that \mathcal{K} is a realization for a *strict-implication language*.

DEFINITION 38 (Strict implication (\dashv)). If $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$ is a realization for a strict-implication language, then

$$\rho(\alpha \dashv \beta) := \rho(\alpha) \boxed{\dashv} \rho(\beta).$$

One can easily check that \dashv is a “good” conditional. There follows immediately:

$$i \models \alpha \dashv \beta \text{ iff } \forall j \not\models i (j \models \alpha \curvearrowright j \models \beta).$$

Another interesting implication that can be defined in **QL** is represented by an entailment-connective.

DEFINITION 39 (Entailment (\Rightarrow)). Given $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$,

$$\rho(\alpha \Rightarrow \beta) := \begin{cases} I, & \text{if } \rho(\alpha) \subseteq \rho(\beta); \\ \emptyset, & \text{otherwise.} \end{cases}$$

Since $I, \emptyset \in \Pi$, the definition is correct. One can trivially check that \Rightarrow is a “good” conditional. Interestingly enough, our strict implication and our entailment represent “good” implications also for **OL**.

The general relations between \rightarrow , \dashv and \Rightarrow are described by the following theorem:

THEOREM 40. *For any realization \mathcal{K} for a strict-implication language of **OL**:*

$$\models_{\mathcal{K}} (\alpha \Rightarrow \beta) \Rightarrow (\alpha \dashv \beta).$$

*For any realization \mathcal{K} for a strict-implication language of **OQL**:*

$$\models_{\mathcal{K}} (\alpha \Rightarrow \beta) \Rightarrow (\alpha \rightarrow \beta); \quad \models_{\mathcal{K}} (\alpha \dashv \beta) \Rightarrow (\alpha \rightarrow \beta).$$

But the inverse relations do not generally hold!

Are the connectives \dashv and \Rightarrow definable also in the algebraic semantics? The possibility of defining \Rightarrow is straightforward.

DEFINITION 41 (Entailment in the algebraic semantics). Given $\mathcal{A} = \langle \mathcal{B}, v \rangle$,

$$v(\alpha \Rightarrow \beta) := \begin{cases} \mathbf{1}, & \text{if } v(\alpha) \sqsubseteq v(\beta); \\ \mathbf{0}, & \text{otherwise.} \end{cases}$$

One can easily check that \rightarrow represents the same connective in the two semantics. As to \rightarrow , given $\mathcal{A} = \langle \mathcal{B}, v \rangle$, one would like to require:

$$v(\alpha \rightarrow \beta) = \bigsqcup \{b \in B \mid b \neq \mathbf{0} \text{ and } \forall c(c \neq \mathbf{0} \text{ and } b \not\sqsubseteq c' \text{ and } c \sqsubseteq v(\alpha) \curvearrowright c \sqsubseteq v(\beta))\}.$$

However such a definition supposes the algebraic completeness of \mathcal{B} . Further we can prove that \rightarrow represents the same connective in the two semantics only if we restrict our consideration to the class of all algebraically adequate Kripkean realizations.

4 METALOGICAL PROPERTIES AND ANOMALIES

Some metalogical distinctions that are not interesting in the case of a number of familiar logics weaker than classical logic turn out to be significant for **QL** (and for non distributive logics in general).

We have already defined (both in the algebraic and in the Kripkean semantics) the concepts of *model* and of *logical consequence*. Now we will introduce, in both semantics, the notions of *quasi-model*, *weak consequence* and *quasi-consequence*. Let T be any set of formulas.

DEFINITION 42 (Quasi-model).

Algebraic semantics

A realization $\mathcal{A} = \langle \mathcal{B}, v \rangle$
is a quasi-model of T iff
 $\exists a[a \in B \text{ and } a \neq \mathbf{0} \text{ and}$
 $\forall \beta \in T(a \sqsubseteq v(\beta))]$.

Kripkean semantics

A realization $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$
is a *quasi-model* of T iff
 $\exists i(i \in I \text{ and } i \models T)$.

The following definitions can be expressed in both semantics.

DEFINITION 43 (Realizability and verifiability). T is *realizable* ($\text{Real } T$) iff it has a quasi-model; T is *verifiable* ($\text{Verif } T$) iff it has a model.

DEFINITION 44 (Weak consequence). A formula α is a *weak consequence* of T ($T \equiv \alpha$) iff any model of T is a model of α .

DEFINITION 45 (Quasi-consequence). A formula α is a *quasi-consequence* of T ($T \approx \alpha$) iff any quasi-model of T is a quasi-model of α .

One can easily check that the algebraic notions of verifiability, realizability, weak consequence and quasi-consequence turn out to coincide with the corresponding Kripkean notions. In other words, T is Kripke-realizable iff T is algebraically realizable. Similarly for the other concepts.

In both semantics one can trivially prove the following lemmas.

LEMMA 46. $\text{Verif } T \curvearrowright \text{Real } T$.

LEMMA 47. $\text{Real } T$ iff for any contradiction $\beta \wedge \neg\beta$, $T \not\models \beta \wedge \neg\beta$.

LEMMA 48. $T \models \alpha \curvearrowright T \equiv \alpha$; $T \models \alpha \curvearrowright T \approx \alpha$.

LEMMA 49. $\alpha \equiv \beta$ iff $\neg\beta \approx \neg\alpha$.

Most familiar logics, that are stronger than positive logic, turn out to satisfy the following metalogical properties, which we will call *Herbrand–Tarski*, *verifiability* and *Lindenbaum*, respectively.

- *Herbrand–Tarski*

$$T \models \alpha \text{ iff } T \equiv \alpha \text{ iff } T \approx \alpha$$

- *Verifiability*

$$\text{Ver } T \text{ iff Real } T$$

- *Lindenbaum*

$$\text{Real } T \curvearrowright \exists T^* [T \subseteq T^* \text{ and Compl } T^*], \text{ where}$$

$$\text{Compl } T \text{ iff } \forall \alpha [\alpha \in T \text{ or } \neg\alpha \in T].$$

The Herbrand–Tarski property represents a semantic version of the deduction theorem. The Lindenbaum property asserts that any semantically non-contradictory set of formulas admits a semantically non-contradictory complete extension. In the algebraic semantics, canonical proofs of these properties essentially use some versions of Stone-theorem, according to which any *proper filter* F in an algebra \mathcal{B} can be extended to a *proper complete filter* F^* (such that $\forall a(a \in F^* \text{ or } a' \in F^*)$). However, Stone-theorem does not generally hold for non distributive orthomodular lattices! In the case of ortholattices, one can still prove that every proper filter can be extended to an *ultrafilter* (i.e., a *maximal filter* that does not admit any extension that is a proper filter). However, differently from Boolean algebras, ultrafilters need not be complete.

A counterexample to the Herbrand–Tarski property in **OL** can be obtained using the “non-valid” part of the distributive law. We know that (owing to the failure of distributivity in ortholattices):

$$\alpha \wedge (\beta \vee \gamma) \not\equiv (\alpha \wedge \beta) \vee (\alpha \wedge \gamma).$$

At the same time

$$\alpha \wedge (\beta \vee \gamma) \equiv (\alpha \wedge \beta) \vee (\alpha \wedge \gamma),$$

since one can easily calculate that for any realization $\mathcal{A} = \langle \mathcal{B}, v \rangle$ the hypothesis $v(\alpha \wedge (\beta \vee \gamma)) = \mathbf{1}$, $v((\alpha \wedge \beta) \vee (\alpha \wedge \gamma)) \neq \mathbf{1}$ leads to a contradiction ².

²In **OQL** a counterexample in two variables can be obtained by using the failure of the contraposition law for \rightarrow . One has: $\alpha \rightarrow \beta \not\equiv \neg\beta \rightarrow \neg\alpha$. At the same time $\alpha \rightarrow \beta \equiv \neg\beta \rightarrow \neg\alpha$; since for any realization $\mathcal{A} = \langle \mathcal{B}, v \rangle$ the hypothesis $v(\alpha \rightarrow \beta) = \mathbf{1}$, implies $v(\alpha) \sqsubseteq v(\beta)$ and therefore $v(\neg\beta \rightarrow \neg\alpha) = v(\beta) \sqcup (v(\alpha)' \sqcap v(\beta)') = v(\beta) \sqcup v(\beta)' = \mathbf{1}$.

A counterexample to the verifiability-property is represented by the negation of the *a fortiori* principle for the quantum logical conditional \rightarrow :

$$\gamma := \neg(\alpha \rightarrow (\beta \rightarrow \alpha)) = \neg(\neg\alpha \vee (\alpha \wedge (\neg\beta \vee (\alpha \wedge \beta)))).$$

This γ has an algebraic quasi-model. For instance the realization $\mathcal{A} = \langle \mathcal{B}, v \rangle$, where \mathcal{B} is the orthomodular lattice determined by all subspaces of the plane (as shown in Figure 2). There holds: $v(\gamma) = v(\alpha) \neq \mathbf{0}$. But one can easily check that γ cannot have any model, since the hypothesis that $v(\gamma) = \mathbf{1}$ leads to a contradiction in any algebraic realization of **QL**.

Figure 2. Quasi-model for γ

The same γ also represents a counterexample to the Lindenbaum-property. Let us first prove the following lemma.

LEMMA 50. *If T is realizable and $T \subseteq T^*$, where T^* is realizable and complete, then T is verifiable.*

Sketch of the proof Let us define a realization $\mathcal{A} = \langle \mathcal{B}, v \rangle$ such that

(i) $B = \{1, 0\}$;

(ii)

$$v(\alpha) = \begin{cases} 1, & \text{if } T^* \models \alpha; \\ 0, & \text{otherwise.} \end{cases}$$

Since T^* is realizable and complete, \mathcal{A} is a good realization and is trivially a model of T . ■

Now, one can easily show that γ violates Lindenbaum. Suppose, by contradiction, that γ has a realizable and complete extension. Then, by Lemma 50, γ must have a model, and we already know that this is impossible.

The failure of the metalogical properties we have considered represents, in a sense, a relevant “anomaly” of quantum logics. Just these anomalies suggest the following conjecture: the distinction between *epistemic logics* (characterized by Kripkean models where the accessibility relation is at least reflexive and transitive) and *similarity logics* (characterized by Kripkean models where the accessibility relation is at least reflexive and symmetric) seems to represent a highly significant dividing line in the class of all logics that are weaker than classical logic.

5 A MODAL INTERPRETATION OF **OL** AND **OQL**

QL admits a modal interpretation [Goldblatt, 1974; Dalla Chiara, 1981] which is formally very similar to the modal interpretation of intuitionistic logic. Any modal interpretation of a given non-classical logic turns out to be quite interesting from the intuitive point of view, since it permits us to associate a classical meaning to a given system of non-classical logical constants. As is well known, intuitionistic logic can be translated into the modal system **S4**. The modal basis that turns out to be adequate for **OL** is instead the logic **B**. Such a result is of course not surprising, since both the **B**-realizations and the **OL**-realizations are characterized by frames where the accessibility relation is reflexive and symmetric.

Suppose a modal language L^M whose alphabet contains the same sentential literals as **QL** and the following primitive logical constants: the classical connectives \sim (*not*), \wedge (*and*) and the modal operator \Box (*necessarily*). At the same time, the connectives \vee (*or*), \supset (*if ... then*), \equiv (*if and only if*), and the modal operator \Diamond (*possibly*) are supposed defined in the standard way.

The modal logic **B** is semantically characterized by a class of Kripkean realizations that we will call **B**-realizations.

DEFINITION 51. A **B**-realization is a system $\mathcal{M} = \langle I, R, \Pi, \rho \rangle$ where:

- (i) $\langle I, R \rangle$ is an orthoframe;
- (ii) Π is a subset of the power-set of I satisfying the following conditions:
 - $I, \emptyset \in \Pi$;
 - Π is closed under the set-theoretic relative complement $-$, the set-theoretic intersection \cap and the modal operation \Box , which is defined as follows:

for any $X \subseteq I$, $\Box X := \{i \mid \forall j (Rij \leadsto j \in X)\}$;

- (iii) ρ associates to any formula α of $L^{\mathbf{M}}$ a proposition in Π satisfying the conditions: $\rho(\sim \beta) = -\rho(\beta)$; $\rho(\beta \wedge \gamma) = \rho(\beta) \cap \rho(\gamma)$; $\rho(\Box \beta) = \Box \rho(\beta)$.

Instead of $i \in \rho(\alpha)$, we will write $i \models \alpha$. The definitions of truth, logical truth and logical consequence for \mathbf{B} are analogous to the corresponding definitions in the Kripkean semantics for \mathbf{QL} .

Let us now define a translation τ of the language of \mathbf{QL} into the language $L^{\mathbf{B}}$.

DEFINITION 52 (Modal translation of \mathbf{OL}).

- $\tau(p) = \Box \Diamond p$;
- $\tau(\neg \beta) = \Box \sim \tau(\beta)$;
- $\tau(\beta \wedge \gamma) = \tau(\beta) \wedge \tau(\gamma)$.

In other words, τ translates any atomic formula as the necessity of the possibility of the same formula; further, the quantum logical negation is interpreted as the necessity of the classical negation, while the quantum logical conjunction is interpreted as the classical conjunction. We will indicate the set $\{\tau(\beta) \mid \beta \in T\}$ by $\tau(T)$.

THEOREM 53. *For any α and T of \mathbf{OL} : $T \models_{\mathbf{OL}} \alpha$ iff $\tau(T) \models_{\mathbf{B}} \tau(\alpha)$*

Theorem 53 is an immediate corollary of the following Lemmas 54 and 55.

LEMMA 54. *Any \mathbf{OL} -realization $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$ can be transformed into a \mathbf{B} -realization $\mathcal{M}^{\mathcal{K}} = \langle I^*, R^*, \Pi^*, \rho^* \rangle$ such that: $I^* = I$; $R^* = R$;
 $\forall i (i \models_{\mathcal{K}} \alpha$ iff $i \models_{\mathcal{M}^{\mathcal{K}}} \tau(\alpha)$).*

Sketch of the proof Take Π^* as the smallest subset of the power-set of I that contains $\rho(p)$ for any atomic formula p and that is closed under $I, \emptyset, -, \cap, \Box$. Further, take $\rho^*(p)$ equal to $\rho(p)$. ■

LEMMA 55. *Any \mathbf{B} -realization $\mathcal{M} = \langle I, R, \Pi, \rho \rangle$ can be transformed into a \mathbf{OL} -realization $\mathcal{K}^{\mathcal{M}} = \langle I^*, R^*, \Pi^*, \rho^* \rangle$ such that: $I^* = I$; $R^* = R$;
 $\forall i (i \models_{\mathcal{K}^{\mathcal{M}}} \alpha$ iff $i \models_{\mathcal{M}} \tau(\alpha)$).*

Sketch of the proof Take Π^* as the smallest subset of the power-set of I that contains $\rho(\Box \Diamond p)$ for any atomic formula p and that is closed under $I, \emptyset, ', \cap$ (where for any set X of worlds, $X' := \{j \mid \text{not } Rij\}$). Further take $\rho^*(p)$ equal to $\rho(\Box \Diamond p)$. The set $\rho^*(p)$ turns out to be a proposition in the orthoframe $\langle I^*, R^* \rangle$, owing to the \mathbf{B} -logical truth: $\Box \Diamond \alpha \equiv \Box \Diamond \Box \Diamond \alpha$. ■

The translation of **OL** into **B** is technically very useful, since it permits us to transfer to **OL** some nice metalogical properties such as *decidability* and the *finite-model property*.

Does also **OQL** admit a modal interpretation? The question has a somewhat trivial answer. It is sufficient to apply the technique used for **OL** by referring to a convenient modal system **B^o** (stronger than **B**) which is founded on a modal version of the orthomodular principle. Semantically **B^o** can be characterized by a particular class of realizations. In order to determine this class, let us first define the concept of *quantum proposition* in a **B**-realization.

DEFINITION 56. Given a **B**-realization $\mathcal{M} = \langle I, R, \Pi, \rho \rangle$ the set Π_Q of all *quantum propositions* of \mathcal{M} is the smallest subset of the power-set of I which contains $\rho(\Box \Diamond p)$ for any atomic p and is closed under $'$ and \cap .

LEMMA 57. *In any **B**-realization $\mathcal{M} = \langle I, R, \Pi, \rho \rangle$, there holds $\Pi_Q \subseteq \Pi$.*

Sketch of the proof The only non-trivial point of the proof is represented by the closure of Π under $'$. This holds since one can prove: $\forall X \in \Pi (X' = \Box - X)$. ■

LEMMA 58. *Given $\mathcal{M} = \langle I, R, \Pi, \rho \rangle$ and $\mathcal{K}^{\mathcal{M}} = \langle I, R, \Pi^*, \rho^* \rangle$, there holds $\Pi_Q = \Pi^*$.*

LEMMA 59. *Given $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$ and $\mathcal{M}^{\mathcal{K}} = \langle I, R, \Pi^*, \rho^* \rangle$, there holds $\Pi \supseteq \Pi_Q^*$.*

DEFINITION 60. A **B^o**-realization is a **B**-realization $\langle I, R, \Pi, \rho \rangle$ that satisfies the orthomodular property:

$$\forall X, Y \in \Pi_Q : X \not\subseteq Y \quad \curvearrowright \quad X \cap (X \cap Y)' \neq \emptyset.$$

We will also call the **B^o**-realizations *orthomodular realizations*.

THEOREM 61. *For any T and α of **OQL**: $T \models_{\mathbf{OL}} \alpha$ iff $\tau(T) \models_{\mathbf{B}^o} \tau(\alpha)$.*

The Theorem is an immediate corollary of Lemmas 54, 55 and of the following Lemma:

LEMMA 62.

(62.1) *If \mathcal{K} is orthomodular then $\mathcal{M}^{\mathcal{K}}$ is orthomodular.*

(62.2) *If \mathcal{M} is orthomodular then $\mathcal{K}^{\mathcal{M}}$ is orthomodular.*

Unfortunately, our modal interpretation of **OQL** is not particularly interesting from a logical point of view. Differently from the **OL**-case, **B^o** does not correspond to a familiar modal system with well-behaved metalogical properties. A characteristic logical truth of this logic will be a modal version of orthomodularity:

$$\alpha \wedge \sim \beta \supset \Diamond [\alpha \wedge \Box \sim (\alpha \wedge \beta)],$$

where α, β are modal translations of formulas of **OQL** into the language L^M .

6 AN AXIOMATIZATION OF OL AND OQL

QL is an axiomatizable logic. Many axiomatizations are known: both in the Hilbert-Bernays style and in the Gentzen-style (*natural deduction* and *sequent-calculi*).³ We will present here a **QL**-calculus (in the natural deduction style) which is a slight modification of a calculus proposed by [Goldblatt, 1974]. The advantage of this axiomatization is represented by the fact that it is formally very close to the algebraic definition of ortholattice; further it is independent of any idea of quantum logical implication.

Our calculus (which has no axioms) is determined as a set of *rules*. Let T_1, \dots, T_n be finite or infinite (possibly empty) sets of formulas. Any rule has the form

$$\frac{T_1 \vdash \alpha_1, \dots, T_n \vdash \alpha_n}{T \vdash \alpha}$$

(if α_1 has been inferred from T_1, \dots, α_n has been inferred from T_n , then α can be inferred from T). We will call any $T \vdash \alpha$ a *configuration*. The configurations $T_1 \vdash \alpha_1, \dots, T_n \vdash \alpha_n$ represent the *premisses* of the rule, while $T \vdash \alpha$ is the *conclusion*. As a limit case, we may have a rule, where the set of premisses is empty; in such a case we will speak of an *improper rule*. Instead of $\frac{\emptyset}{T \vdash \alpha}$ we will write $T \vdash \alpha$; instead of $\emptyset \vdash \alpha$, we will write $\vdash \alpha$.

Rules of OL

(OL1)	$T \cup \{\alpha\} \vdash \alpha$	(identity)
(OL2)	$\frac{T \vdash \alpha, T^* \cup \{\alpha\} \vdash \beta}{T \cup T^* \vdash \beta}$	(transitivity)
(OL3)	$T \cup \{\alpha \wedge \beta\} \vdash \alpha$	(\wedge -elimination)
(OL4)	$T \cup \{\alpha \wedge \beta\} \vdash \beta$	(\wedge -elimination)
(OL5)	$\frac{T \vdash \alpha, T \vdash \beta}{T \vdash \alpha \wedge \beta}$	(\wedge -introduction)
(OL6)	$\frac{T \cup \{\alpha, \beta\} \vdash \gamma}{T \cup \{\alpha \wedge \beta\} \vdash \gamma}$	(\wedge -introduction)

³Sequent calculi for different forms of quantum logic will be described in Section 17.

- (OL7) $\frac{\{\alpha\} \vdash \beta, \{\alpha\} \vdash \neg\beta}{\neg\alpha}$ (absurdity)
- (OL8) $T \cup \{\alpha\} \vdash \neg\neg\alpha$ (weak double negation)
- (OL9) $T \cup \{\neg\neg\alpha\} \vdash \alpha$ (strong double negation)
- (OL10) $T \cup \{\alpha \wedge \neg\alpha\} \vdash \beta$ (Duns Scotus)
- (OL11) $\frac{\{\alpha\} \vdash \beta}{\{\neg\beta\} \vdash \neg\alpha}$ (contraposition)

DEFINITION 63 (Derivation). A *derivation* of **OL** is a finite sequence of configurations $T \vdash \alpha$, where any element of the sequence is either the conclusion of an improper rule or the conclusion of a proper rule whose premisses are previous elements of the sequence.

DEFINITION 64 (Derivability). A formula α is *derivable* from T ($T \vdash_{\text{OL}} \alpha$) iff there is a derivation such that the configuration $T \vdash \alpha$ is the last element of the derivation.

Instead of $\{\alpha\} \vdash_{\text{OL}} \beta$ we will write $\alpha \vdash_{\text{OL}} \beta$. When no confusion is possible, we will write $T \vdash \alpha$ instead of $T \vdash_{\text{OL}} \alpha$.

DEFINITION 65 (Logical theorem). A formula α is a *logical theorem* of **OL** ($\vdash_{\text{OL}} \alpha$) iff $\emptyset \vdash_{\text{OL}} \alpha$.

One can easily prove the following syntactical lemmas.

LEMMA 66. $\alpha_1, \dots, \alpha_n \vdash \alpha$ iff $\alpha_1 \wedge \dots \wedge \alpha_n \vdash \alpha$.

LEMMA 67. *Syntactical compactness.*

$T \vdash \alpha$ iff $\exists T^* \subseteq T$ (T^* is finite and $T^* \vdash \alpha$).

LEMMA 68. $T \vdash \alpha$ iff $\exists \alpha_1, \dots, \alpha_n$ ($\alpha_1 \in T$ and ... and $\alpha_n \in T$ and $\alpha_1 \wedge \dots \wedge \alpha_n \vdash \alpha$).

DEFINITION 69 (Consistency). T is an *inconsistent* set of formulas if $\exists \alpha (T \vdash \alpha \wedge \neg\alpha)$; T is *consistent*, otherwise.

DEFINITION 70 (Deductive closure). The *deductive closure* \overline{T} of a set of formulas T is the smallest set which includes the set $\{\alpha \mid T \vdash \alpha\}$. T is called *deductively closed* iff $T = \overline{T}$.

DEFINITION 71 (Syntactical compatibility). Two sets of formulas T_1 and T_2 are called *syntactically compatible* iff

$$\forall \alpha (T_1 \vdash \alpha \curvearrowright T_2 \not\vdash \neg\alpha).$$

The following theorem represents a kind of “weak Lindenbaum theorem”.

THEOREM 72. *Weak Lindenbaum theorem.*

If $T \not\vdash \neg\alpha$, then there exists a set of formulas T^ such that T^* is compatible with T and $T^* \vdash \alpha$.*

Proof. Suppose $T \not\vdash \neg\alpha$. Take $T^* = \{\alpha\}$. There holds trivially: $T^* \vdash \alpha$. Let us prove the compatibility between T and T^* . Suppose, by contradiction, T and T^* incompatible. Then, for a certain β , $T^* \vdash \beta$ and $T \vdash \neg\beta$. Hence (by definition of T^*), $\alpha \vdash \beta$ and by contraposition, $\neg\beta \vdash \neg\alpha$. Consequently, because $T \vdash \neg\beta$, one obtains by transitivity: $T \vdash \neg\alpha$, against our hypothesis. ■

We will now prove a soundness and a completeness theorem with respect to the Kripkean semantics.

THEOREM 73. *Soundness theorem.*

$$T \vdash \alpha \quad \curvearrowright \quad T \models \alpha.$$

Proof. Straightforward. ■

THEOREM 74. *Completeness theorem.*

$$T \models \alpha \quad \curvearrowright \quad T \vdash \alpha.$$

Proof. It is sufficient to construct a *canonical model* $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$ such that:

$$T \vdash \alpha \text{ iff } T \models_{\mathcal{K}} \alpha.$$

As a consequence we will immediately obtain:

$$T \not\vdash \alpha \quad \curvearrowright \quad T \not\models_{\mathcal{K}} \alpha \quad \curvearrowright \quad T \not\models \alpha.$$

Definition of the canonical model

- (i) I is the set of all consistent and deductively closed sets of formulas;
- (ii) R is the compatibility relation between sets of formulas;
- (iii) Π is the set of all propositions in the frame $\langle I, R \rangle$;
- (iv) $\rho(p) = \{i \in I \mid p \in i\}$.

In order to recognize that \mathcal{K} is a “good” **OL**-realization, it is sufficient to prove that: (a) R is reflexive and symmetric; (b) $\rho(p)$ is a proposition in the frame $\langle I, R \rangle$.

The proof of (a) is immediate (reflexivity depends on the consistency of any i , and symmetry can be shown using the weak double negation rule).

In order to prove (b), it is sufficient to show (by Lemma 8.1): $i \notin \rho(p) \curvearrowright \exists j \not\vdash i (j \perp \rho(p))$. Let $i \notin \rho(p)$. Then (by definition of $\rho(p)$): $p \notin i$; and, since i is deductively closed, $i \not\vdash p$. Consequently, by the weak Lindenbaum theorem (and by the strong double negation rule), for a certain j : $j \not\vdash i$ and $\neg p \in j$. Hence, $j \perp \rho(p)$.

LEMMA 75. *Lemma of the canonical model.*

$$\text{For any } \alpha \text{ and any } i \in I, i \models \alpha \text{ iff } \alpha \in i.$$

Sketch of the proof By induction on the length of α . The case $\alpha = p$ holds by definition of $\rho(p)$. The case $\alpha = \neg\beta$ can be proved by using Lemma 12.1 and the weak Lindenbaum theorem. The case $\alpha = \beta \wedge \gamma$ can be proved using the \wedge -introduction and the \wedge -elimination rules. ■

Finally we can show that $T \vdash \alpha$ iff $T \models_{\mathcal{K}} \alpha$. Since the left to right implication is a consequence of the soundness-theorem, it is sufficient to prove: $T \not\vdash \alpha \curvearrowright T \not\models_{\mathcal{K}} \alpha$. Let $T \not\vdash \alpha$; then, by Duns Scotus, T is consistent. Take $i := \overline{T}$. There holds: $i \in I$ and $T \subseteq i$. As a consequence, by the Lemma of the canonical model, $i \models T$. At the same time $i \not\models \alpha$. For, should $i \models \alpha$ be the case, we would obtain $\alpha \in i$ and by definition of i , $T \vdash \alpha$, against our hypothesis. ■

An axiomatization of **OQL** can be obtained by adding to the **OL**-calculus the following rule:

$$\text{(OQL)} \quad \alpha \wedge \neg(\alpha \wedge \neg(\alpha \wedge \beta)) \vdash \beta. \quad \text{(orthomodularity)}$$

All the syntactical definitions we have considered for **OL** can be extended to **OQL**. Also Lemmas 66, 67, 68 and the weak Lindenbaum theorem can be proved exactly in the same way. Since **OQL** admits a material conditional, we will be able to prove here a *deduction theorem*:

THEOREM 76. $\alpha \vdash_{\text{OQL}} \beta$ iff $\vdash_{\text{OQL}} \alpha \rightarrow \beta$.

This version of the deduction-theorem is obviously not in contrast with the failure in **QL** of the semantical property we have called Herbrand-Tarski. For, differently from other logics, here the syntactical relation \vdash does not correspond to the weak consequence relation!

The soundness theorem can be easily proved, since in any orthomodular realization \mathcal{K} there holds:

$$\alpha \wedge \neg(\alpha \wedge \neg(\alpha \wedge \beta)) \models_{\mathcal{K}} \beta.$$

As to the completeness theorem, we need a slight modification of the proof we have given for ‘**OL**. In fact, should we try and construct the canonical model \mathcal{K} , by taking Π as the set of all possible propositions of the

frame, we would not be able to prove the orthomodularity of \mathcal{K} . In order to obtain an orthomodular canonical model $\mathcal{K} = \{I, R, \Pi, \rho\}$, it is sufficient to define Π as the set of all propositions X of \mathcal{K} such that $X = \rho(\alpha)$ for a certain α . One immediately recognizes that $\rho(p) \in \Pi$ and that Π is closed under $'$ and \cap . Hence \mathcal{K} is a “good” **OL**-realization. Also for this \mathcal{K} one can easily show that $i \models \alpha$ iff $\alpha \in i$. In order to prove the orthomodularity of \mathcal{K} , one has to prove for any propositions $X, Y \in \Pi$, $X \not\subseteq Y \leadsto X \cap (X \cap Y)' \neq \emptyset$; which is equivalent (by Lemma 19) to $X \cap (X \cap (X \cap Y)')' \subseteq Y$. By construction of Π , $X = \rho(\alpha)$ and $Y = \rho(\beta)$ for certain α, β . By the orthomodular rule there holds $\alpha \wedge \neg(\alpha \wedge \neg(\alpha \wedge \beta)) \vdash \beta$. Consequently, for any $i \in I$, $i \models \alpha \wedge \neg(\alpha \wedge \neg(\alpha \wedge \beta)) \leadsto i \models \beta$. Hence, $\rho(\alpha) \cap (\rho(\alpha) \cap (\rho(\alpha) \cap \rho(\beta))')' \subseteq \rho(\beta)$.

Of course, also the canonical model of **OL** could be constructed by taking Π as the set of all propositions that are “meanings” of formulas. Nevertheless, in this case, we would lose the following important information: the canonical model of **OL** gives rise to an algebraically complete realization (closed under infinitary intersection).

7 THE INTRACTABILITY OF ORTHOMODULARITY

As we have seen, the proposition-ortholattice in a Kripkean realization $\mathcal{K} = \langle I, R, \Pi, \rho \rangle$ does not generally coincide with the (algebraically) *complete* ortholattice of *all* propositions of the orthoframe $\langle I, R \rangle$.⁴ When Π is the set of all propositions, \mathcal{K} will be called *standard*. Thus, a *standard orthomodular Kripkean realization* is a standard realization, where Π is orthomodular. In the case of **OL**, every non standard Kripkean realization can be naturally extended to a standard one (see the proof of Theorem 17). In particular, Π can be always embedded into the complete ortholattice of all propositions of the orthoframe at issue. Moreover, as we have learnt from the completeness proof, the canonical model of **OL** is standard. In the case of **OQL**, instead, there are various reasons that make significant the distinction between standard and non standard realizations:

- (i) Orthomodularity is not elementary [Goldblatt, 1984]. In other words, there is no way to express the orthomodular property of the ortholattice Π in an orthoframe $\langle I, R \rangle$ as an elementary (first-order) property.
- (ii) It is not known whether every orthomodular lattice is embeddable into a complete orthomodular lattice.
- (iii) It is an open question whether **OQL** is characterized by the class of all standard orthomodular Kripkean realizations.

⁴For the sake of simplicity, we indicate briefly by Π the ortholattice $\langle \Pi, \sqsubseteq, ', \mathbf{1}, \mathbf{0} \rangle$. Similarly, in the case of other structures dealt with in this section.

- (iv) It is not known whether the *canonical model* of **OQL** is standard. Try and construct a canonical realization for **OQL** by taking Π as the set of all possible propositions (similarly to the **OL**-case). Let us call such a realization a *pseudo canonical realization*. Do we obtain in this way an **OQL**-realization, satisfying the orthomodular property? In other words, is the pseudo canonical realization a model of **OQL**?

In order to prove that **OQL** is characterized by the class of all standard Kripkean realizations it would be sufficient to show that the canonical model belongs to such a class. Should orthomodularity be elementary, then, by a general result proved by Fine, this problem would amount to showing the following statement: there is an elementary condition (or a set thereof) implying the orthomodularity of the standard pseudo canonical realization. Result (i), however, makes this way definitively unpracticable.

Notice that a positive solution to problem (iv) would automatically provide a proof of the full equivalence between the algebraic and the Kripkean consequence relation ($T \stackrel{A}{\models}_{\mathbf{OQL}} \alpha$ iff $T \stackrel{K}{\models}_{\mathbf{OQL}} \alpha$). If **OQL** is characterized by a standard canonical model, then we can apply the same argument used in the case of **OL**, the ortholattice Π of the canonical model being orthomodular. By similar reasons, also a positive solution to problem (ii) would provide a direct proof of the same result. For, the orthomodular lattice Π of the (not necessarily standard) canonical model of **OQL** would be embeddable into a complete orthomodular lattice.

We will now present Goldblatt's result proving that orthomodularity is not elementary. Further, we will show how orthomodularity leaves defeated one of the most powerful embedding technique: the MacNeille completion method.

Orthomodularity is not elementary

Let us consider a first-order language L^2 with a single predicate denoting a binary relation R . Any frame $\langle I, R \rangle$ (where I is a non-empty set and R any binary relation) will represent a classical realization of L^2 .

DEFINITION 77 (Elementary class).

- (i) Let Γ be a class of frames. A possible property P of the elements of Γ is called *first-order* (or *elementary*) iff there exists a sentence η of L^2 such that for any $\langle I, R \rangle \in \Gamma$:

$$\langle I, R \rangle \models \eta \text{ iff } \langle I, R \rangle \text{ has the property } P.$$

- (ii) Γ is said to be an *elementary class* iff the property of being in Γ is an elementary property of Γ .

Thus, Γ is an elementary class iff there is a sentence η of L^2 such that

$$\Gamma = \{\langle I, R \rangle \mid \langle I, R \rangle \models \eta\}.$$

DEFINITION 78 (Elementary substructure). Let $\langle I_1, R_1 \rangle, \langle I_2, R_2 \rangle$ be two frames.

(a) $\langle I_1, R_1 \rangle$ is a *substructure* of $\langle I_2, R_2 \rangle$ iff the following conditions are satisfied:

- (i) $I_1 \subseteq I_2$;
- (ii) $R_1 = R_2 \cap (I_1 \times I_1)$;

(b) $\langle I_1, R_1 \rangle$ is an *elementary substructure* of $\langle I_2, R_2 \rangle$ iff the following conditions hold:

- (i) $\langle I_1, R_1 \rangle$ is a substructure of $\langle I_2, R_2 \rangle$;
- (ii) For any formula $\alpha(x_1, \dots, x_n)$ of L^2 and any i_1, \dots, i_n of I_1 :

$$\langle I_1, R_1 \rangle \models \alpha[i_1, \dots, i_n] \text{ iff } \langle I_2, R_2 \rangle \models \alpha[i_1, \dots, i_n].$$

In other words, the elements of the “smaller” structure satisfy exactly the same L^2 -formulas in both structures. The following Theorem [Bell and Slomson, 1969] provides a useful criterion to check whether a substructure is an elementary substructure.

THEOREM 79. *Let $\langle I_1, R_1 \rangle$ be a substructure of $\langle I_2, R_2 \rangle$. Then, $\langle I_1, R_1 \rangle$ is an elementary substructure of $\langle I_2, R_2 \rangle$ iff whenever $\alpha(x_1, \dots, x_n, y)$ is a formula of L^2 (in the free variables x_1, \dots, x_n, y) and i_1, \dots, i_n are elements of I_1 such that for some $j \in I_2$, $\langle I_2, R_2 \rangle \models \alpha[i_1, \dots, i_n, j]$, then there is some $i \in I_1$ such that $\langle I_2, R_2 \rangle \models \alpha[i_1, \dots, i_n, i]$.*

Let us now consider a *pre-Hilbert space*⁵ \mathcal{H} and let $\mathcal{H}^+ := \{\psi \in \mathcal{H} \mid \psi \neq \underline{0}\}$, where $\underline{0}$ is the null vector. The pair

$$\langle \mathcal{H}^+, \perp \rangle$$

is an orthoframe, where $\forall \psi, \phi \in \mathcal{H}^+$: $\psi \not\perp \phi$ iff the inner product of ψ and ϕ is different from the null vector $\underline{0}$ (i.e., $(\psi, \phi) \neq \underline{0}$). Let $\Pi(\mathcal{H})$ be the ortholattice of all propositions of $\langle \mathcal{H}^+, \perp \rangle$, which turns out to be isomorphic to the ortholattice $\mathcal{C}(\mathcal{H})$ of all (not necessarily closed) subspaces of \mathcal{H} (a proposition is simply a subspace devoided of the null vector). The following deep Theorem, due to Amemiya and Halperin [Varadarajan, 1985] permits

⁵A *pre-Hilbert space* is a vector space over a division ring whose elements are the real or the complex or the quaternionic numbers such that an inner product (which transforms any pair of vectors into an element of the ring) is defined. Differently from Hilbert spaces, pre-Hilbert spaces need not be metrically complete.

us to characterize the class of all Hilbert spaces in the larger class of all pre-Hilbert spaces, by means of the orthomodular property.

THEOREM 80 (Amemiya–Halperin Theorem). *$\mathcal{C}(\mathcal{H})$ is orthomodular iff \mathcal{H} is a Hilbert space.*

In other words, $\mathcal{C}(\mathcal{H})$ is orthomodular iff \mathcal{H} is metrically complete.

As is well known [Bell and Slomson, 1969], the property of “being metrically complete” is not elementary. On this basis, it will be highly expected that also the orthomodular property is not elementary. The key-lemma in Goldblatt’s proof is the following:

LEMMA 81. *Let Y be an infinite-dimensional (not necessarily closed) subspace of a separable Hilbert space \mathcal{H} . If α is any formula of L^2 and ψ_1, \dots, ψ_n are vectors of Y such that for some $\phi \in \mathcal{H}$, $\langle \mathcal{H}^+, \perp \rangle \models \alpha[\psi_1, \dots, \psi_n, \phi]$, then there exists a vector $\psi \in Y$ such that $\langle \mathcal{H}^+, \perp \rangle \models \alpha[\psi_1, \dots, \psi_n, \psi]$.*

As a consequence one obtains:

THEOREM 82. *The orthomodular property is not elementary.*

Proof. Let \mathcal{H} be any *metrically incomplete* pre-Hilbert space. Let $\overline{\mathcal{H}}$ be its metric completion. Thus \mathcal{H} is an infinite-dimensional subspace of the Hilbert space $\overline{\mathcal{H}}$. By Lemma 81 and by Theorem 79, $\langle \mathcal{H}^+, \perp \rangle$ is an elementary substructure of $\langle \overline{\mathcal{H}}^+, \perp \rangle$. At the same time, by Amemiya–Halperin’s Theorem, $\mathcal{C}(\mathcal{H})$ cannot be orthomodular, because \mathcal{H} is metrically incomplete. However, $\mathcal{C}(\overline{\mathcal{H}})$ is orthomodular. As a consequence, orthomodularity cannot be expressed as an elementary property. ■

The embeddability problem

As we have seen in Section 2, the class of all propositions of an orthoframe is a complete ortholattice. Conversely, the representation theorem for ortholattices states that every ortholattice $\mathcal{B} = \langle B, \sqsubseteq, ', \mathbf{1}, \mathbf{0} \rangle$ is embeddable into the complete ortholattice of all propositions of the orthoframe $\langle B^+, \perp \rangle$, where: $B^+ := B - \{\mathbf{0}\}$ and $\forall a, b \in B$: $a \perp b$ iff $a \not\sqsubseteq b'$. The embedding is given by the map

$$h : a \mapsto \langle a \rangle,$$

where $\langle a \rangle$ is the quasi-ideal generated by a . In other words: $\langle a \rangle = \{b \neq \mathbf{0} \mid b \sqsubseteq a\}$.

One can prove the following Theorem:

THEOREM 83. *Let $\mathcal{B} = \langle B, \sqsubseteq, ', \mathbf{1}, \mathbf{0} \rangle$ be an ortholattice. $\forall X \subseteq B$, X is a proposition of $\langle B^+, \perp \rangle$ iff $X = l(u(X))$, where:*

$$u(Y) := \{b \in B^+ \mid \forall a \in Y : a \sqsubseteq b\} \text{ and } l(Y) := \{b \in B^+ \mid \forall a \in Y : b \sqsubseteq a\}.$$

Accordingly, the complete ortholattice of all propositions of the orthoframe $\langle B^+, \perp \rangle$ is isomorphic to the *MacNeille completion* (or *completion by cuts*) of \mathcal{B} [Kalmbach, 1983].⁶ At the same time, orthomodularity (similarly to distributivity and modularity) is not preserved by the MacNeille completion, as the following example shows [Kalmbach, 1983].

Let $\mathcal{C}_{(2)}^0(\mathbb{R})$ be the class of all continuous complex-valued functions f on \mathbb{R} such that

$$\int_{-\infty}^{+\infty} |f(x)|^2 dx < \infty$$

Let us define the following bilinear form $(\cdot, \cdot) : \mathcal{C}_{(2)}^0(\mathbb{R}) \times \mathcal{C}_{(2)}^0(\mathbb{R}) \rightarrow \mathbb{C}$ (representing an inner product):

$$(f, g) = \int_{-\infty}^{+\infty} f^*(x)g(x)dx,$$

where $f^*(x)$ is the complex conjugate of $f(x)$. It turns out that $\mathcal{C}_{(2)}^0(\mathbb{R})$, equipped with the inner product (\cdot, \cdot) , gives rise to a metrically incomplete infinite-dimensional pre-Hilbert space. Thus, by Amemiya–Halperin’s Theorem (Theorem 80), the algebraically complete ortholattice $\mathcal{C}(\mathcal{C}_{(2)}^0(\mathbb{R}))$ of all subspaces of $\mathcal{C}_{(2)}^0(\mathbb{R})$ cannot be orthomodular. Now consider the sublattice \mathcal{FI} of $\mathcal{C}(\mathcal{C}_{(2)}^0(\mathbb{R}))$, consisting of all finite or cofinite dimensional subspaces. It is not hard to see that \mathcal{FI} is orthomodular. One can prove that $\mathcal{C}(\mathcal{C}_{(2)}^0(\mathbb{R}))$ is *sup-dense* in \mathcal{FI} ; in other words, any $X \in \mathcal{C}(\mathcal{C}_{(2)}^0(\mathbb{R}))$ is the *sup* of a set of elements of \mathcal{FI} . Thus, by a theorem proved by McLaren [Kalmbach, 1983], the MacNeille completion of $\mathcal{C}(\mathcal{C}_{(2)}^0(\mathbb{R}))$ is isomorphic to the MacNeille completion of \mathcal{FI} . Since $\mathcal{C}(\mathcal{C}_{(2)}^0(\mathbb{R}))$ is algebraically complete, the MacNeille completion of $\mathcal{C}(\mathcal{C}_{(2)}^0(\mathbb{R}))$ is isomorphic to $\mathcal{C}(\mathcal{C}_{(2)}^0(\mathbb{R}))$ itself. As a consequence, \mathcal{FI} is orthomodular, while its MacNeille completion is not.

8 HILBERT QUANTUM LOGIC AND THE ORTHOMODULAR LAW

As we have seen, the prototypical models of **OQL** that are interesting from the physical point of view are based on the class \mathbb{H} of all Hilbert lattices, whose support is the set $\mathcal{C}(\mathcal{H})$ of all closed subspaces of a Hilbert space \mathcal{H} . Let us call *Hilbert quantum logic* (**HQL**) the logic that is semantically characterized by \mathbb{H} . A question naturally arises: do **OQL** and **HQL** represent one and the same logic? As proved by [Greechie, 1981],⁷ this question

⁶The *MacNeille completion* of an ortholattice $\mathcal{B} = \langle B, \sqsubseteq, ', \mathbf{1}, \mathbf{0} \rangle$ is the lattice whose support consists of all $X \subseteq B$ such that $X = l(u(X))$, where: $u(Y) := \{b \in B \mid \forall a \in Y : a \sqsubseteq b\}$ and $l(Y) := \{b \in B \mid \forall a \in Y : b \sqsubseteq a\}$. Clearly the only difference between the proposition-lattice of the frame $\langle B^+, \perp \rangle$ and the Mac Neille completion of \mathcal{B} is due to the fact that propositions do not contain $\mathbf{0}$.

⁷See also [Kalmbach, 1983].

has a negative answer: there is a lattice-theoretical equation (the so-called *orthoarguesian law*) that holds in \mathbb{H} , but fails in a particular orthomodular lattice. As a consequence, **OQL** does not represent a faithful logical abstraction from its quantum theoretical origin.

DEFINITION 84. Let Γ be a class of orthomodular lattices. We say that **OQL** is *characterized* by Γ iff for any T and any α the following condition is satisfied:

$$T \models_{\text{OQL}} \alpha \text{ iff for any } \mathcal{B} \in \Gamma \text{ and any } \mathcal{A} = \langle \mathcal{B}, v \rangle : T \models_{\mathcal{A}} \alpha.$$

In order to formulate the orthoarguesian law in an equational way, let us first introduce the notion of *Sasaki projection*.

DEFINITION 85 (The Sasaki projection).

Let \mathcal{B} be an orthomodular lattice and let a, b be any two elements of \mathcal{B} . The *Sasaki projection* of a onto b , denoted by $a \pitchfork b$, is defined as follows:

$$a \pitchfork b := (a \sqcup b') \sqcap b.$$

It is easy to see that two elements a, b of an orthomodular lattice are compatible ($a = (a \sqcap b') \sqcup (a \sqcap b)$) iff $a \pitchfork b = a \sqcap b$. Consequently, in any Boolean lattice, \pitchfork coincides with \sqcap .

DEFINITION 86 (The orthoarguesian law).

$$a \sqsubseteq b \sqcup \{(a \pitchfork b') \sqcap [(a \pitchfork c') \sqcup ((b \sqcup c) \sqcap ((a \pitchfork b') \sqcup (a \pitchfork c')))]\} \quad (\text{OAL})$$

Greechie has proved that (OAL) holds in \mathbb{H} but fails in a particular finite orthomodular lattice. In order to understand Greechie's counterexample, it will be expedient to illustrate the notion of *Greechie diagram*.

Let us first recall the definition of *atom*.

DEFINITION 87 (Atom). Let $\mathcal{B} = \langle B, \sqsubseteq, \mathbf{1}, \mathbf{0} \rangle$ any bounded lattice. An *atom* is an element $a \in B - \{\mathbf{0}\}$ such that:

$$\forall b \in B : \mathbf{0} \sqsubseteq b \sqsubseteq a \curvearrowright b = \mathbf{0} \text{ or } a = b.$$

Greechie diagrams are *hypergraphs* that permits us to represent particular orthomodular lattices. The representation is essentially based on the fact that a finite Boolean algebra is completely determined by its atoms. A Greechie diagram of an orthomodular lattice \mathcal{B} consists of points and lines. Points are in one-to-one correspondence with the atoms of \mathcal{B} ; lines are in one-to-one correspondence with the maximal Boolean subalgebras⁸ of \mathcal{B} . Two lines are crossing in a common atom. For example, the Greechie diagram pictured in Figure 3. represents the orthomodular lattice \mathcal{G}_{12} (Figure 4).

Figure 3. The Greechie diagram of \mathcal{G}_{12} Figure 4. The orthomodular lattice \mathcal{G}_{12}

Figure 5. The Greechie diagram of \mathcal{B}_{30}

Let us now consider a particular finite orthomodular lattice, called \mathcal{B}_{30} , whose Greechie diagram is pictured in Figure 3.

THEOREM 88. (OAL) fails in \mathcal{B}_{30} .

Proof. There holds: $a \frown b' = (a \sqcup b) \sqcap b' = s' \sqcap b' = e$, $a \frown c' = (a \sqcup c) \sqcap c' = n' \sqcap c' = i$ and $b \sqcup c = l'$. Thus,

$$\begin{aligned}
 & b \sqcup \{ (a \frown b') \sqcap [(a \frown c') \sqcup ((b \sqcup c) \sqcap ((a \frown b') \sqcup (a \frown c')))] \} \\
 &= b \sqcup \{ e \sqcap [i \sqcup (l' \sqcap (e \sqcup i))] \} \\
 &= b \sqcup \{ e \sqcap [i \sqcup (l' \sqcap g')] \} \\
 &= b \sqcup (e \sqcap (i \sqcup \mathbf{0})) \\
 &= b \sqcup (e \sqcap i) \\
 &= b \\
 &\not\sqsubseteq a.
 \end{aligned}$$

■

Hence, there are two formulas α and β (whose valuations in a convenient realization represent the left- and right- hand side of (OAL), respectively) such that $\alpha \not\equiv_{\mathbb{H}} \beta$. At the same time, for any $\mathcal{C}(\mathcal{H}) \in \mathbb{H}$ and for any realization $\mathcal{A} = \langle \mathcal{C}(\mathcal{H}), v \rangle$, there holds: $\alpha \models_{\mathcal{A}} \beta$.

As a consequence, **OQL** is not characterized by \mathbb{H} . Accordingly, **HQL** is definitely stronger than **OQL**. We are faced with the problem of finding

⁸A *maximal Boolean subalgebra* of an ortholattice \mathcal{B} is a Boolean subalgebra of \mathcal{B} , that is not a proper subalgebra of any Boolean subalgebra of \mathcal{B} .
