The classical results of Gentzen [1935] on cut elimination in sequent systems can be recast in the finite-valued logic setting. In [Carnielli, 1991] it is observed that the existence of cut-free sequent proofs follows from the completeness of many-valued tableaux and the duality between sequent and tableau calculi, while [Baaz *et al.*, 1994] give a direct and constructive cut

elimination algorithm for singleton signed calculi.

6.5 Exploiting Duality Theory

If a truth value set is equipped with a partial order that defines the connectives and quantifiers of a logic, one can exploit dual representations of ordered structures to improve its calculi. Consider, for example, Birkhoff's well-known representation theorem for finite distributive lattices saying that each element of a finite distributive lattice either is the top (bottom) element or it can be uniquely represented as a meet (join) of meet-(join-)irreducible elements.

THEOREM 28 (Birkhoff). *Let \mathbf{L} be a finite distributive lattice; then \mathbf{L} is isomorphic to $\mathcal{O}(\mathcal{J}(\mathbf{L}))$, where \mathcal{O} is ordered by set inclusion.*

Moreover, if $i \in L$, let M be the minimal elements of $\mathcal{M}(\mathbf{L}) \cap \uparrow i$ and J the maximal elements of $\mathcal{J}(\mathbf{L}) \cap \downarrow i$. Then $i = \prod M = \bigsqcup J$ (using the convention $\prod\{\} = \top$ and $\bigsqcup\{\} = \perp$).

EXAMPLE 29. Consider the distributive lattice \mathbf{L} on the left of Figure 10. $\mathcal{J}(\mathbf{L})$ is drawn in the middle, and $\mathcal{O}(\mathcal{J}(\mathbf{L}))$ on the right.

Figure 10. Illustration of Example 29.

Birkhoff's and other representation theorems [Davey and Priestley, 1990; Goldblatt, 1989; Sofronie-Stokkermans, 2000] allow to replace truth value sets as signs with elements j of $\mathcal{J}(\mathbf{L})$.¹⁴ Formally, using interpretations $\mathbf{I}^* : \Sigma \rightarrow \mathcal{O}(\mathcal{J}(\mathbf{L}))$, the following—quasi-classical—semantic conditions hold provided that A_\vee and A_\wedge are the lattice operations:

- (44) $\mathbf{I}^* \models j:p$ iff $j \in \mathbf{I}^*(p)$
- (45) $\mathbf{I}^* \models j:(\varphi \vee \psi)$ iff $\mathbf{I}^* \models j:\varphi$ or $\mathbf{I}^* \models j:\psi$
- (46) $\mathbf{I}^* \models j:(\varphi \wedge \psi)$ iff $\mathbf{I}^* \models j:\varphi$ and $\mathbf{I}^* \models j:\psi$

¹⁴In general, the dual space of \mathbf{L} may be more complicated. I use $\mathcal{J}(\mathbf{L})$, which is valid for the case of finite distributive lattices, by way of illustration.

These give directly rise to almost classical tableau and sequent rule schemata. An additional advantage is that $\mathcal{J}(\mathbf{L})$ is often much smaller than \mathbf{L} .

A logic solely based on lattice operators is not very interesting, but the representation theorems hold as well, if one adds, for example, monotone operations m and anti-monotone operations a on $\mathcal{J}(\mathbf{L})$. These induce lattice morphisms f_m and anti-morphisms g_a on \mathbf{L} . The latter can be added to the logical language as additional unary connectives F_m and G_a :

$$(47) \quad \mathbf{I}^* \models j:F_m(\varphi) \quad \text{iff} \quad \mathbf{I}^* \models m(j):\varphi$$

$$(48) \quad \mathbf{I}^* \models j:G_a(\varphi) \quad \text{iff} \quad \mathbf{I}^* \not\models a(j):\varphi$$

The last equivalence is realized in a rule like

$$\frac{j:G_a(\varphi)}{a(j):\varphi} .$$

Hence, the signs used in calculi are $\mathcal{J}(\mathbf{L}) \cup \{\bar{j} \mid j \in \mathcal{J}(\mathbf{L})\}$. Keeping in mind that $\mathcal{J}(\mathbf{L})$ is isomorphic to the prime ideals of \mathbf{L} ordered by set inclusion via $f : j \mapsto (L - \uparrow j)$ [Davey and Priestley, 1990, Prop. 9.4], one can see that the duals of the family of regular signs (35) are exactly the signs required for $N = \{0, \frac{1}{n-1}, \dots, 1\}$. In the general, non-linearly ordered case, not all regular signs are required, because join-irreducible elements alone suffice to construct the dual representation.

To arrive at sound and complete calculi, two more ingredients are required: encoding validity by signed formulas and closure rule schemata. Assume the designated values are $D = \{1\}$, then φ is valid iff $\mathbf{I}^*(\varphi) = N$ for all \mathbf{I}^* iff never $\mathbf{I}^*(\varphi) \neq N = \bigsqcup \mathcal{J}(\mathbf{L})$ iff $\bigvee_{j \in \mathcal{J}(\mathbf{L})} j:\varphi$ has a closed tableau. The single closure rule schema is obviously $\{j:\varphi, \bar{j}:\varphi\}$.

The logics based on finite chains and obtained from regular signs with monotone and anti-monotone unary operators were investigated under the label **regular logic** in [Hähnle, 1991b; Hähnle, 1994a]. It was suggested in [Lehmke, 1995; Lehmke, 1996] to take signs from the dual space of a lattice; the totally ordered chain $[0, 1]$ is discussed in detail.

A systematic treatment of the idea to use dual spaces for lattice-based logics is [Sofronie-Stokkermans, 1997]. In [Sofronie-Stokkermans, 1999b; Sofronie-Stokkermans, to appear, 2000] this is further generalized to ordered relational structures, which can be considered as classes of possible world models, see also Bull and Segerberg's chapter in Volume 3 of this *Handbook* and Section 10 below.

One can express (44)–(48) along with the theory of partially ordered signs in classical propositional (for finite N) or in first-order logic [Sofronie-Stokkermans, 1998; Beckert *et al.*, 1999; Sofronie-Stokkermans, to appear, 2000]. For example, (45) becomes

$$(\forall j)(p_{\varphi \vee \psi}(j) \leftrightarrow p_{\varphi}(j) \vee p_{\psi}(j)) .$$

In [Sofronie-Stokkermans, 1999a] translations into classical logic of this kind were used to show decidability of certain non-classical logics that happen to fall in decidable fragments of first-order logic. The idea is pushed one step further in [Ganzinger and Sofronie-Stokkermans, 2000], where suitable translations into of dual space representations classical logic are shown to be a special case of the classical first-order logic with transitive relations that can be efficiently handled with so-called ordered chaining [Bachmair and Ganzinger, 1998]. Thus, refinements based on literal orderings and selection functions that are available for classical logic become directly applicable to many-valued logics. For example, a stronger version of regular negative hyperresolution as discussed below (56), is obtained. In addition, highly sophisticated theorem provers for classical logic become applicable to many-valued logics.

Recall that the many-valued quantifiers \forall and \exists are defined via \min and \max just like \wedge and \vee are. Given the above treatment of binary connectives based on lattice operators, it is not surprising that quantifiers Π and Σ defined via \sqcap and \sqcup in finite (distributive) lattices possess elegant generic tableau and sequent rules [Hähnle, 1996a; Salzer, 1996b; Hähnle, 1998].

The use of duality theory for automated deduction in many-valued logics has just about started. One could try to base Sofronie-Stokkermans' approach, for example, on Martínez' Priestley-type duality theory, which is available for a wide class of algebraic structures related to many-valued logic, including MV-algebras, linear Heyting algebras, and implicative lattices [Martínez, 1990; Martínez, 1994; Martínez, 1996]. Interestingly, computation of the associated dual spaces can even largely be mechanized [Martínez and Priestley, to appear, 2000].

6.6 Normal form computation

Many practically relevant calculi, such as resolution (see Section 6.8), are only defined (or efficient) for formulas in conjunctive normal form.

Up to the right notion of literals, CNF is obviously achieved by repeated application of Theorems 21 and 22, pushing quantifiers in front, if necessary. The details are straightforward and, for the monosigned case, can be found in [Baaz and Fermüller, 1995b].

It is well-known that the naive computation of a CNF of a classical propositional formula is in general exponential in size with respect to the input. This can be avoided using **structure preserving CNF translations** [Tseitin, 1970; Plaisted and Greenbaum, 1986]. The basic idea is to introduce a predicate $p_\psi(x_1, \dots, x_r)$ for each non-atomic subformula ψ of φ with free variables x_1, \dots, x_r , and then replace each occurrence of ψ with its predicate symbol. Of course, one must state that p_ψ and ψ are equivalent.

For each $\psi = \theta(\rho_1, \dots, \rho_m)$ one obtains the formula

$$(49) \quad (\forall x_1) \cdots (\forall x_r) (p_\psi(x_1, \dots, x_r) \leftrightarrow \theta(p_{\rho_1}, \dots, p_{\rho_m})) \ .$$

Together with the negation of φ , the conjunction of these lines states that φ is unsatisfiable. As each formula (49) has constant depth two, its CNF is of length linear in $|\varphi|$ (not constant, because of the free variables). There is a linear number of subformulas of φ . Together, one has a quadratic length, satisfiability equivalent¹⁵ CNF of φ . Exactly the same trick is used in the proof of Theorem 16(1).

This idea works for signed formulas just as well, including optimizations based on the polarity of subformula occurrences [Hähnle, 1994d]. The role of classical literals, of course, is taken over by signed atoms: a **signed CNF formula** has the form $(\forall x_1) \cdots (\forall x_r) \bigwedge_{k=1}^M \bigvee_{l=1}^{J_k} S_{kl}:p_{kl}$, in which the $S_j:p_j$ are signed atoms and $\{x_1, \dots, x_l\}$ are the free variables in the scope. For any $1 \leq k \leq M$, the expression

$$(50) \quad (\forall y_1) \cdots (\forall y_m) (S_{k1}:p_{k1} \vee \cdots \vee S_{kJ_k}:p_{kJ_k})$$

where $\{y_1, \dots, y_m\}$ are the free variables in the scope, is a **signed clause**. Like in classical logic, the quantifier prefix is often not written explicitly and a signed CNF formula is identified with the set of its clauses.

Any signed formula in any finite-valued first-order logic has an at most polynomially larger signed CNF, which is satisfiability equivalent.

Signed clauses are used as if they were sets of signed atoms, which is justified by commutativity, associativity, and idempotency of disjunction. As for sequents, various notations for signed clauses occur in the literature, starting with [Lee and Chang, 1971; Morgan, 1976; Orłowska, 1978].

Like in classical logic, a signed clause is satisfiable if at least one of its literals is satisfiable, a signed CNF formula is satisfiable if all instances of all its clauses are simultaneously satisfiable. The **empty signed clause** has no literals and is denoted with \square . By definition, it is unsatisfiable.

Exactly like the tableau and sequent rules (see Section 6.5), the translation process can be improved by working with dual representations in the case of truth value lattices [Sofronie-Stokkermans, to appear, 2000].

In [Murray and Rosenthal, 1991b] **signed negation normal form** (NNF) formulas are defined: these are negation-free propositional formulas constructed with \wedge, \vee and with signed atoms as literals. Its relevance is based on the following observation: if, for each connective θ occurring in $D:\varphi$ and all signs S of a family of signs complete with respect to D , the number of occurrences of subformulas in a CNF or DNF representation for $S:\theta(\rho_1, \dots, \rho_m)$ is not greater than in $S:\theta(\rho_1, \dots, \rho_m)$ itself, then one obtains a linear size signed NNF equivalent of $D:\varphi$ by repeated substitution

¹⁵The CNF of φ computed this way has not the same models as φ , because the signature was extended.

of signed subformulas with their CNF or DNF equivalents. This generalizes the well-known fact that classical NNF can be computed in linear time, if no equivalence connectives are present in the input. There are calculi that are specialized for signed NNF, see Section 6.9.

In [Thiele and Lehmke, 1994; Lehmke, 1996] it is observed that every formula of infinite-valued Łukasiewicz logic can be expressed in signed NNF provided that Łukasiewicz sum \oplus_L and product \odot_L are used instead of classical disjunction and conjunction, but it can blow up a formula exponentially. They call this **hierarchical normal form**. Again, by using abbreviations for complex subformulas, this can be improved to convert any propositional Łukasiewicz formula into a CNF over so-called bold clauses (see end of Section 6.8).

An internal (in the sense of Section 2.4) DNF was obtained for Łukasiewicz logic in [Mundici, 1996] based on [Mundici, 1991], see also Section 4.1. Clauses are based on \odot_L instead of \wedge ; as Łukasiewicz product is not idempotent, a more complex notion of literal is required: formulas φ such that f_φ is a strictly monotone McNaughton function in one variable. Satisfiability of such functions can be characterized with a regular signed atom, that is, a signed atom of the form $\uparrow i:p$ or $\downarrow i:p$. As a consequence, the resolution calculus of [Mundici and Olivetti, 1998] based on this notion of literal does not go beyond signed resolution which is discussed in Section 6.8.

It is non-trivial to prove a McNaughton Theorem for the above notion of literals, that is, to characterize the Łukasiewicz formulas that are literals. This is done in [Aguzzoli, 1998b; Aguzzoli, 1999].

6.7 Signed Clause Logic

By virtue of the results of Section 6.6, it is no loss of generality for the purpose of validity checking of formulas in finite-valued first-order logic to work with signed CNF formulas.

Signed CNF formulas are generic or “logic-free” in the sense that their syntax and semantics are fixed and independent of the logic, out of which the translation started. Signed CNF formulas do not contain *any* many-valued connective and are simply a generic and flexible language for denoting many-valued interpretations.

In addition, signed CNF formulas can be motivated from the point of view of **constraint programming (CP)** and **annotated logic programming (ALP)**.

If N is equipped with an ordering, there is a natural notion of a Horn formula. Recall that in classical logic a CNF formula is a **Horn formula** iff each clause contains at most one positive literal. Signed atoms are, in general, neither positive nor negative in any sense, but a natural notion of **polarity** is present in regular signs (35): literals of the form $\uparrow i:p$ are **positive** while literals of the form $\overline{\uparrow} i:p$ are **negative**. With this convention,

a **regular Horn formula** is defined exactly as in the classical case. Some calculi based on this formula class are discussed in Section 7.2.

The particular case, when N is lattice-ordered and S is an order filter is investigated in annotated logic programming [Kifer and Subrahmanian, 1992] (there, S is called an *annotation*). Annotated logic programs can be considered as particular signed CNF formulas, see Section 7.3.

On the other hand, $S:p$ can be read as “ p is constrained to values from S ” and, hence, as an instance of finite-domain constraint programming [Lu *et al.*, 1997; Castell and Fargier, 1998; Hähnle *et al.*, 2000]. Applications in this spirit are reported for Assumption-Based Reasoning [Haenni and Lehmann, 1998a; Haenni and Lehmann, 1998b].

It is also possible to embed propositional signed CNF formulas into classical monadic first-order logic over finite domains by representing a signed atom $S:p$, where $S = \{i_1, \dots, i_r\}$, with the following classical formula:

$$(\exists p)(S(p)) \wedge (\forall x)(S(x) \leftrightarrow (S(i_1) \vee \dots \vee S(i_r)))$$

6.8 Resolution

A **resolution rule** is a pair $\langle \mathcal{C}, \varphi \rangle$, where \mathcal{C} is a non-empty set of formula schemata, the **premiss** or **parent formulas**, and φ is a formula schema called **resolvent** (of \mathcal{C}). A **termination rule** is a non-empty set of formula schemata. A **resolution calculus** \mathcal{RK} is a finite set of resolution rules and a termination rule.

Each resolution calculus \mathcal{RK} induces a **provability relation** $\vdash_{\mathcal{RK}}$ between sets of formulas Ψ and formulas φ .

- (1) If $\varphi \in \Psi$, then $\Psi \vdash_{\mathcal{RK}} \varphi$.
- (2) If $\Psi \vdash_{\mathcal{RK}} \varphi_i$ for $1 \leq i \leq n$, and there is an instance of a resolution rule in \mathcal{RK} with parent formulas $\varphi_1, \dots, \varphi_n$ and resolvent φ , then $\Psi \vdash_{\mathcal{RK}} \varphi$.

If $\Psi \vdash_{\mathcal{RK}} \varphi$ and φ is an instance of a formula schema in the termination rule of \mathcal{RK} , then Ψ is **refuted** (in \mathcal{RK}). Obviously, resolution calculi can be considered as Hilbert calculi with an empty set of axioms (up to refutation).

The formula schemata in many-valued resolution calculi are typically restricted to signed clauses of the form (50). In this case, the termination rule contains exactly \square and it is only possible to refute signed CNF formulas. A resolution calculus is **complete** if every unsatisfiable set of formulas can be refuted and it is **sound** if only unsatisfiable sets of formulas can be refuted.

Only propositional calculi are discussed here, because lifting to first-order logic is done *exactly* like in classical logic and does not provide any insights specific to many-valued logic.

Recall that classical resolution is based on combining clauses that contain unsatisfiable literal sets (closure rule schemata in a tableau framework). Many-valued resolution does exactly the same:

$$(51) \quad \frac{S_1:p \vee C_1 \quad \cdots \quad S_m:p \vee C_m}{C_1 \vee \cdots \vee C_m} \quad \text{if} \quad \bigcap_{1 \leq i \leq m} S_i = \emptyset$$

Compare this to the tableau closure rule defined in Section 6.3. In contrast to classical logic, unsatisfiable literal sets in general are required to admit more than two elements.

EXAMPLE 30. The signed CNF formula $\Gamma = \{\{0, \frac{1}{2}\}:p, \{0, 1\}:p, \{\frac{1}{2}, 1\}:p\}$ is clearly unsatisfiable, but there is no refutation, if (51) is restricted to $m \leq 2$.

There is a complete binary resolution rule for signed logic, though:

$$(52) \quad \frac{S:p \vee C \quad S':p \vee C'}{(S \cap S'):p \vee C \vee C'} \quad \frac{\emptyset:p \vee C}{C}$$

Rule (51) can be simulated by several applications of rules (52). On the other hand, (52) has (intermediate) resolvents which cannot be obtained with (51). Let us call (51) **many-valued hyperresolution** and (52) **many-valued binary resolution**. The literal $(S \cap S'):p$ in the binary rule is called a **residue**, the rule on the right in (52) is called **reduction rule**.

Similar as for tableau and sequent calculi, historically the monosigned restriction of (52) came first [Lee and Chang, 1971; Lee, 1972; Morgan, 1976; Baaz and Fermüller, 1992]. Orłowska [1978] and Schmitt [1986; 1989] implicitly considered truth value sets as signs in a specialized context.

Rule (51) appeared first in [Hähnle, 1993] and, independently, a close variant in [Haenni and Lehmann, 1998b]; rule (52) is due to [Murray and Rosenthal, 1991b; Murray and Rosenthal, 1993b]. All of the earlier systems included a **many-valued merging** rule

$$(53) \quad \frac{S_1:p \vee \cdots \vee S_m:p \vee C}{(S_1 \cup \cdots \cup S_m):p \vee C}$$

but [Hähnle, 1996b] proved that either of (51) and (52) alone is complete with implicit merging of only identical literals.

It is easy to prove [Murray and Rosenthal, 1994; Hähnle, 1996b] that every CNF formula over signed atoms is logically equivalent to one in which only regular signs (for any given total order) occur. Such a formula is called a **regular formula**. Again using the trick to introduce abbreviations for subformulas (see Section 6.6), one can even show that each signed CNF formula can be reduced to a satisfiability equivalent regular formula, which is only polynomially larger [Beckert *et al.*, 2000b].

In the case of monosigned and regular CNF formulas over a totally ordered truth value set, non-empty residues cannot occur, hence (52) simplifies to

$$(54) \quad \frac{S_1:p \vee C \quad S_2:p \vee C'}{C \vee C'} \quad \text{if } S_1 \cap S_2 = \emptyset$$

which is called **monosigned** or **regular binary resolution**, depending on the form of the signs. Completeness of binary resolution, as well as of ordered resolution and hyperresolution, for monosigned CNF formulas is shown in [Baaz and Fermüller, 1995b]. If N is totally ordered, one obtains the hyperresolution-like refinements (55) and (56) of regular binary resolution by combining several applications of rule (54) into one [Hähnle, 1994d; Hähnle, 1996b].

$$(55) \quad \frac{\uparrow i_1:p \vee C_1 \quad \cdots \quad \uparrow i_m:p \vee C_m \quad \downarrow j:p \vee C}{C_1 \vee \cdots \vee C_m \vee C} \quad \text{if } \left(\max_{1 \leq k \leq m} i_k \right) > j$$

regular resolution

Taking the *maximal* i_k in the rule above is not strictly necessary: admitting *any* $i_k > j$ yields a sound and complete calculus, but may lead to longer proofs. For regular formulas, (55) with $m = 1$ is the same as (54).

EXAMPLE 31. Let $N = \{0, \frac{1}{2}, 1\}$ and Γ the following regular formula:

$$\{\downarrow 0:p_1 \vee \downarrow \frac{1}{2}:p_2, \uparrow \frac{1}{2}:p_1 \vee \downarrow 0:p_2, \downarrow 0:p_1 \vee \uparrow 1:p_3, \\ \uparrow 1:p_2 \vee \uparrow \frac{1}{2}:p_3, \uparrow 1:p_2 \vee \downarrow 0:p_3\}$$

The last three clauses resolve to $\downarrow 0:p_1 \vee \uparrow 1:p_2$ by (55), which in turn resolves to $\downarrow 0:p_1$ with the first clause (by either rule (55) or (54)). From there, one obtains $\downarrow 0:p_2$ with the second clause. In three more steps the empty clause can be derived.

$$(56) \quad \frac{\downarrow i_1:p \vee C_1 \quad \cdots \quad \downarrow i_m:p \vee C_m \quad \uparrow j_1:p \vee \cdots \vee \uparrow j_m:p \vee C}{C_1 \vee \cdots \vee C_m \vee C}$$

if $m \geq 1$, $i_l < j_l$ for $1 \leq l \leq m$,
 C_1, \dots, C_m, C contain only negative literals

regular negative hyperresolution

In [Sofronie-Stokkermans, 1998; Sofronie-Stokkermans, to appear, 2000] it is shown that, if N is a distributive lattice and signs are its prime ideals and their complements, then an analogue of rule (56) is complete, where signs in positive literals are prime ideals and those in negative literals their complements. The \bar{U} -resolution rule of [Leach *et al.*, 1998] is a special case of Sofronie-Stokkermans' [to appear, 2000] framework.

If N is a lattice, the following calculus is complete [Beckert *et al.*, 1999]:

$$(57) \quad \frac{\uparrow i:p \vee C \quad \overline{\uparrow j}:p \vee C'}{C \vee C'} \quad \text{if } i \geq j \quad \text{lattice-regular binary resolution} \quad \frac{\uparrow i:p \vee C \quad \uparrow j:p \vee C'}{\uparrow(i \sqcup j):p \vee C \vee C'} \quad \text{if } i, j \text{ incomparable} \quad \text{lattice-regular reduction}$$

Note that, when N is totally ordered, the left rule of (57) is the same as (54) for regular formulas.

Regarding techniques to prove completeness of the above-mentioned resolution calculi, one can say that semantic tree arguments [Robinson, 1968] retain much of their clarity. The most straightforward approach is to use $|N|$ -ary semantic trees [Hähnle, 1994d]. Just as in classical resolution theory, more complex refinements are often better handled by inductive construction of a proof, where the number of atoms or atom occurrences in a formula supplies the induction parameter [Hähnle, 1996b]. Alternatively, via translation of signed logics into classical first-order logic with transitive relations [Ganzinger and Sofronie-Stokkermans, 2000] many completeness results are inherited from classical logic. In fact, where this works, one usually obtains strengthened versions (based on literal orderings and selection functions) of the calculi discussed here.

The restriction of binary resolution to **unit resolution** (the case when one input clause is a unit) is at the heart of the **Davis–Putnam–Loveland procedure** [Davis *et al.*, 1962], together with a case splitting rule (a so-called *pure* rule that discards irrelevant clauses and is not needed for completeness, but for efficiency, is not displayed):

$$(58) \quad \frac{S:p \quad S':p \vee C}{(S \cap S'):p \vee C} \quad \frac{\emptyset:p \vee C}{C} \quad \frac{S_1:p \mid \cdots \mid S_r:p}{(S_j)_{1 \leq j \leq r} \text{ generates } 2^N}$$

This many-valued version was introduced for regular formulas (with total order) in [Hähnle, 1996b]. Regular-DPL was analyzed and improved in [Manyà, 1996; Manyà *et al.*, 1998; Béjar and Manyà, 1999b].

Several resolution-based calculi were also given for logic programs based on signed formulas. They are discussed in Section 7.

Lehmke, in [1995; 1996] describes a resolution system for so-called **weighted bold clauses**. These are signed formulas over \mathbf{L}_L^0 , where the formula part is a **bold clause**: a finite multiset M of literals plus a “conjunctive correction” $\delta \in \mathbb{R}$ that determines, whether M is interpreted as \oplus_L or \odot_L :

$$\mathbf{I}(\langle M, \delta \rangle) = \max\{0, \min\{1, \sum_{L \in M} \mathbf{I}(L) - \delta\}\} .$$

Signs are either prime filters of $[0, 1]$ (that is, open intervals of the form $(i, 1]$ and closed intervals of the form $[i, 1]$) or again bold clauses. In the first case, the interpretation is as before, see Definition 19. Otherwise, $\mathbf{I} \models \varphi : \varphi'$ iff $\mathbf{I}(\varphi') \geq \mathbf{I}(\varphi)$.

Once again, the trick of introducing abbreviations for complex subformulas (see Section 6.6) is employed to show that any satisfiability problem of Łuksiewicz logic can be expressed with a finite set of weighted bold clauses (the necessity for bold clauses as signs comes from the abbreviations). A sound and complete resolution calculus for weighted bold clauses exists [Lehmke, 1995]. Due to the many parameters of the language (conjunctive correction, two kinds of signs), its rules are quite technical.

The **non-clausal resolution** rule for classical propositional logic takes any two formulas φ and φ' as premisses, in which $p \in \Sigma$ occurs, and computes the formula $\varphi\{p/0\} \vee \varphi'\{p/1\}$ as resolvent (the clausal rule is obtained, if φ and φ' are clauses, p occurs positively in φ and negatively in φ'). Together with simplification rules of the form $p \wedge 0 \mapsto 0$ etc., for getting rid of 0 and 1, this is a sound and complete calculus for \mathcal{L}_c^0 [Murray, 1982]. In a finite-valued logic \mathcal{L}^0 one can, in principle, use a straightforward generalization: resolve formulas φ_i , $i \in N$, to $\bigvee_{i \in N} \varphi_i\{p/i\}$. In practice, some obstacles must be cleared away first:

- (1) the truth values i might not be definable in \mathcal{L}^0 ;
- (2) \vee might not be definable in \mathcal{L}^0 .

Truth values can be replaced by the elements of a suitable subalgebra of the Lindenbaum algebra of \mathcal{L}^0 , so-called **verifiers** [Stachniak, 1988]. One can show that a finite, although in the worst case exponential in N , number of verifiers is sufficient [Stachniak and O'Hearn, 1990]. The theory of many-valued non-clausal resolution is fully developed in [Stachniak, 1996].

6.9 Other Calculi

One deduction method which, like non-clausal resolution, avoids to compute any normal form altogether is the **dissolution rule**. It is available both for classical [Murray and Rosenthal, 1993a] and finite-valued logics [Murray and Rosenthal, 1991b; Murray and Rosenthal, 1994].

Many-valued dissolution operates on formulas in signed NNF (see Section 6.6). The dissolution rule selects in a signed NNF formula an implicitly conjunctively connected pair of signed atoms $S:p$, $S':p$, and restructures the formula in such a way that at least one conjoint occurrence of $S:p$, $S':p$ is replaced with $(S \cap S'):p$. Producing $\emptyset:p$ leads to obvious simplifications like in (52). Every unsatisfiable signed NNF formula is reduced to the empty formula by a finite number of dissolution steps.

A **regular implicate** of a signed NNF formula φ is a clause C of a regular formula such that $\varphi \models C$. A **regular prime implicate** of φ is a regular implicate C' of φ such that there is no regular implicate $C \neq C'$ with $C' \models C$. The set of prime implicates of a formula is important to know in many applications of classical and many-valued logic, such as diagnosis, circuit minimization, or truth maintenance systems. For some applications it is crucial to avoid computing clause normal form [Ramesh *et al.*, 1997a]. An algorithm for computing regular prime implicates of signed NNF formulas based on many-valued dissolution that avoids normal form is discussed in [Ramesh and Murray, 1994; Ramesh and Murray, 1997].

A conjunctively connected pair $S:p, S':p$ of signed atoms with $S \neq S'$ in a signed NNF formula φ can be seen as a generalization of the tableau closure rule and (52). The dual notion, a disjunctively connected pair such that $S \cap S' \neq \emptyset$, indicates the presence of certain redundancies of φ in representing f_φ (if $\mathbf{I}(p) \in (S \cap S')$). Such a pair of signed atoms is called an **anti-link** [Ramesh *et al.*, 1997b]. Anti-links can be systematically removed from formulas by a similar rule as dissolution. This can dramatically speed up the computation of irredundant representations of f_φ . The signed NNF case is handled in [Beckert *et al.*, 1998]. An implementation is described in [Geiß, 1997]. The technique of anti-links can improve the methods based on dissolution mentioned above.

In contrast to dissolution, the so-called **TAS method** [Aguilera Venegas *et al.*, 1995] computes a simplified DNF of a given formula in NNF. The input formula is unsatisfiable iff the result is the empty formula. Before each application of the distributive laws towards computing a DNF, unitary models of subformulas are computed and used for simplification. The generalization of the TAS method to signed NNF formulas was done in [Aguilera Venegas *et al.*, 1997] and improved in [Aguilera Venegas *et al.*, 1999].

Both, dissolution and the TAS method can, in principle, be lifted to first-order logic, although the technical difficulties are considerable.

The **connection method** [Bibel, 1987] is another non-clausal deduction system for full first-order logic closely related to tableaux. In [Lee, 1997] a version of the connection method for propositional regular formulas is given.

In [Orłowska, 1991b] a relationship between certain non-classical logics and relation algebras [Tarski, 1941] was established and the concept of **relational proof system** was derived from it. There exist relational proof systems in the spirit of [Rasiowa and Sikorski, 1963] for various many-valued logics including generic ones for arbitrary finite-valued logics [Morgan and Orłowska, 1993; Orłowska, 1991a; Konikowska *et al.*, 1998].

Algorithms based on **local search** outperform deductive decision procedures for checking satisfiability of CNF formulas on some problem classes. In particular, this holds for satisfiable hard random 3-SAT instances, which the fastest implementations of DPL cannot solve within a reasonable time

limit [Selman *et al.*, 1994].

Regular-GSAT [Béjar and Manyà, 1999a] is an extension of the classical GSAT procedure [Selman *et al.*, 1992]. It works as follows: first, it tries to find a satisfying interpretation for a regular formula Γ (with a total order on truth values) performing a greedy local search through the space of interpretations. It starts with a randomly generated interpretation \mathbf{I} . If \mathbf{I} does not satisfy Γ , then it creates a set $\mathcal{P} \subseteq \Sigma \times N$, formed by those variable-value pairs $\langle p, i \rangle$ that give rise to a maximal decrease (possibly zero or negative) in the total number of unsatisfied clauses of Γ when the truth value of \mathbf{I} at p is changed to i . Next, a propositional variable p' appearing in \mathcal{P} and then a truth value i' from $\{i \mid \langle p', i \rangle \in \mathcal{P}\}$ are randomly chosen. Finally, \mathbf{I} is updated to i' at p' . Such changes are repeated until either a satisfying interpretation is found or a preset maximum number of changes is reached. The whole process is repeated up to fixed number of times, if no satisfying interpretation is found before.

The superiority of classical local search algorithms over decision procedures such as DPL for certain hard combinatorial problems was found for Regular-GSAT and Regular-DPL [Béjar and Manyà, 1999a] as well. There is experimental evidence that Regular-GSAT outperforms other, including classical, approaches on certain classes of problems [Béjar and Manyà, 1999c].

7 LOGIC PROGRAMMING AND DEDUCTIVE DATABASES

This section requires familiarity with the basic notions of Logic Programming as found, for example, in [Lloyd, 1987]. Once again, the discussion is at the propositional level, because lifting to first-order is standard for signed CNF formulas.

7.1 Signed Formula Logic Programs

Logic programs are obtained from classical CNF formulas by specifying a preferred direction of evaluation within clauses, which are then called **rule**. Syntactically, rules can be considered as sequents over literals, where the succedent has length one or zero. Traditionally, rules are written in the reverse direction of sequents.

Formally, a **signed formula logic program**¹⁶ (SFLP) [Lu, 1996] is a finite set of **signed rules** of the form

$$(59) \quad S:p \leftarrow S_1:\varphi_1, \dots, S_m:\varphi_m,$$

where $S:p$ is a signed atom and the $S_i:\varphi_i$ are signed formulas of a finite-valued logic. A signed rule is satisfiable iff $S:p$ is satisfiable or one of $\overline{S_j}:\varphi_j$,

¹⁶Not be confused with *signed logic programs*, a totally different concept [Turner, 1994].

$1 \leq j \leq m$, is satisfiable. $S:p$ is the **head** of the rule, $S_1:\varphi_1, \dots, S_m:\varphi_m$ its **body**, and $S_j:\varphi_j$ its **body literals**.

In the light of the results on the existence of a signed CNF of $S_i:\varphi_i$ (see Section 6.6), one may assume without loss of generality that the φ_i are atomic as well [Lu, 1996]. Similar as in classical logic, if $S = \emptyset$, write

$$(60) \quad \leftarrow S_1:\varphi_1, \dots, S_m:\varphi_m \text{ ,}$$

and call such a rule **signed query**. If $m = 0$, write

$$(61) \quad S:p$$

and say **signed fact**. If $m = 0$ and $S = \emptyset$ one has the empty clause \square . As usual in logic programming, the goal is to prove $P \models \bigwedge_{L \in Q} L$ for a logic program P and literal set Q , and this is established by showing $P \cup \{\leftarrow Q\}$ to be unsatisfiable.

The sign N is not excluded from SFLPs, but it is assumed that any body literal of the form $N:p$ is automatically deleted; this is justified by the reduction rule in (52).

Unrestricted SFLPs are not easier to solve than general signed CNF formulas (and, hence, as classical CNF formulas): any signed clause (50) can be rewritten into one of the signed rules

$$S_j:p_j \leftarrow \overline{S_1}:p_1, \dots, \overline{S_{j-1}}:p_{j-1}, \overline{S_{j+1}}:p_{j+1}, \dots, \overline{S_m}:p_m$$

for $1 \leq j \leq m$. So one cannot expect straight SLD-style (Prolog-like) or unit resolution to be complete for SFLP as it is for classical logic programs. SFLPs encompass the complexities of classical disjunctive logic programming [Lobo *et al.*, 1992] and more.

In this context, two directions for meaningful investigations were suggested:

- (1) define a signed SLD-like resolution calculus for SFLPs, and characterize semantically the valid queries it approximates;
- (2) restrict the language of SFLP so that complete calculi can be defined (analogous to classical logic, where one works with *definite* or *normal* logic programs).

The key tool for the first part are power interpretations, defined in Section 6.2, with the small modification that $\mathbf{I}^+(p) = \emptyset$ is admitted, hence, $\mathbf{I}^+ \rightarrow \mathcal{P}(N)$. Following [Lu, 1996], we speak of an **extended interpretation**. An extended interpretation that satisfies an SFLP P is called **extended model** of P . Extended interpretations are naturally ordered according to their “definiteness”: $\mathbf{I}_1^+ \preceq \mathbf{I}_2^+$ iff $\mathbf{I}_1^+(p) \supseteq \mathbf{I}_2^+(p)$ for all $p \in \Sigma$. Let \mathcal{I}^+ be the family of all extended interpretations (for fixed N and Σ),

then $\langle \mathcal{I}^+, \preceq \rangle$ is a bounded distributive lattice of finite height generated by “definite” extended interpretations $\mathbf{I}_I^+(p) = \{\mathbf{I}(p)\}$. Consider the interpretation

$$(62) \quad \mathcal{E}_P(p) = \bigcup_{\mathbf{I}^+ \models P} \mathbf{I}^+(p)$$

defined for each SFLP P . One can show that it is the **minimal extended model** of P with respect to \preceq [Lu, 1996]. Moreover, \mathcal{E}_P can be effectively computed:

$$(63) \quad \frac{S:p \quad L \leftarrow L_1, \dots, S':p, \dots, L_m}{L \leftarrow L_1, \dots, (\overline{S \cap S'}) : p, \dots, L_m} \quad \text{signed unit resolution} \qquad \frac{S:p \quad S':p}{(S \cap S') : p} \quad \text{signed unit reduction}$$

Both rules are special cases of the left-hand side of (52).

THEOREM 32. *For every SFLP P : $\mathcal{E}_P \models S:p$ iff $S:p$ can be derived from P with rules (63).*

The theorem follows immediately from Theorems 2.18 and 2.19 in [Lu, 1996], where also the top-down version of (63) was shown to be a complete SLD-style resolution calculus for SFLP:¹⁷

$$(64) \quad \frac{S:p \leftarrow C \quad \leftarrow L_1, \dots, S':p, \dots, L_m}{\leftarrow L_1, \dots, (\overline{S \cap S'}) : p, C, \dots, L_m} \quad \text{signed SLD resolution}$$

THEOREM 33. *For every SFLP P and signed query $\leftarrow Q$: $\mathcal{E}_P \models \bigwedge_{L \in Q} L$ iff \square can be derived from P starting with $\leftarrow Q$ and using rule (64).*

EXAMPLE 34. For the SFLP $P = \{\{1\}:p \leftarrow \{0\}:q, \{1\}:p \leftarrow \{1\}:q, \{1\}:q \leftarrow \{1\}:p\}$, one has $\mathcal{E}_P \equiv N = \{0, 1\}$. Nothing definite can be said about any atom, indeed, no rule in (63) is applicable, and only the empty query succeeds with (64). This is not surprising, since P corresponds to a non-Horn classical CNF formula.

If we add $\{0\}:q$ to P , then $\mathcal{E}_P(p) = \{1\}$, but $\mathcal{E}_P(q) = \emptyset$. This means P is not satisfiable by any standard interpretation; indeed, the corresponding classical CNF formula is unsatisfiable. \mathcal{E}_P , however, gives more information than mere unsatisfiability, for example, $\mathcal{E}_P \not\models \{0\}:q$. It is possible to reconstruct paraconsistent logic programming [Kifer and Lozinskii, 1992] within SFLP [Lu, 1996].

¹⁷Theorems 5.4 and 5.8; there is a mistake in the statement of the latter, which is corrected in Theorem 33 below.

Every SFLP is satisfied by the **trivial extended model** that constantly assigns \emptyset .

For $P' = \{\{a, 0\}:p, \{b, 0\}:p\}$ one has $\mathcal{E}_P(p) = \{0\}$, which is “definite”.

Note, that SLD resolution is optimized for first-order logic and not very efficient on the propositional level.

7.2 Regular Logic Programs

The second direction of research into SFLP starts by restricting the language. The key property of classical definite logic programs is that they are Horn formulas. If N is totally ordered, regular Horn formulas inherit many properties of their classical counterparts, such as model theoretic characterizations [Hähnle, 1996b].

Complete refinements of regular binary resolution (54) for regular Horn formulas over a *totally* ordered truth value set are **regular unit resolution** [Hähnle, 1994d] (the case $C = \square$ in rule (54)) and also **regular positive unit resolution** [Manyà, 1996] (where, in addition, the unit input clause must be a positive literal).

A slightly different strand of development, sometimes encountered under the label **fuzzy logic programming**, is (selectively) represented by the papers [Klawonn and Kruse, 1994; Escalada-Imaz and Manyà, 1995; Yasui and Mukaidono, 1996; Vojtáš and Paulik, 1996; Vojtáš, 1998]. Signs are used here in a more restrictive way in that they are attached to rules, not to single literals. On the other hand, instead of the classical \vee , \wedge , and \rightarrow , connectives \oplus_t , \odot_t , and \rightarrow_t based on various continuous t -norms over $[0, 1]$ are admitted. Most of the cited papers define sound and complete versions of SLD-resolution.

Another possibility to generalize is to consider non-linear orderings. [Beckert *et al.*, 1999] show that the rules below are complete for regular Horn formulas, if N is a finite upper semi-lattice.

(65)

$$\frac{\uparrow i:p \quad \overline{\uparrow j:p} \vee C}{C} \qquad \frac{\uparrow i:p \quad \uparrow j:p}{\uparrow (i \sqcup j):p}$$

if $i \geq j$

i, j incomparable

lattice-regular positive unit resolution **lattice-regular unit reduction**

The discussion on duality in Section 6.5 shows that for distributive lattices further improvements are possible, for example, using only prime filters and their complements as signs [Sofronie-Stokkermans, 1998]. The opposite direction, to consider more general orderings than lattices, requires more thought: a core feature of any efficient deduction procedure for Horn formulae is the possibility to represent the conjunction of two unit clauses as a

single unit clause as witnessed by lattice-regular unit reduction (65). This means that the set of signs must be closed under intersection:

$$(66) \quad \text{For all } i, j \in N \text{ there is a } k \in N \text{ such that } \uparrow i \cap \uparrow j = \uparrow k$$

Every non-empty, finite partially ordered set satisfying (66) is, however, already an upper semi-lattice. Therefore, it is inevitable to generalize the language of signs if one wants to go beyond lattices. The most natural choice is to work with upsets of N that need not be filters, in other words, signs of the form $\uparrow S$, where $S \subseteq N$. Details are in [Beckert *et al.*, 1999].

We defined regular signs as the non-trivial order filters of N generated by single elements and their complements (35) and this is the definition most of the work on regular signs is based upon. If N is totally ordered, then (35) is equivalent to (in fact, this was the original definition in [Hähnle, 1994a]):

$$(67) \quad \mathcal{S}_{\text{regular}}^* = \{\uparrow i \mid i \in N, \uparrow i \neq N\} \cup \{\downarrow i \mid i \in N, \downarrow i \neq N\} .$$

The set of signs $\mathcal{S}_{\text{regular}}^*$ differs from $\mathcal{S}_{\text{regular}}$ in the non-linear case; it is less expressive than the latter and not suitable for defining a Horn fragment, because it is not closed under set complement. See also Table 1 below for complexity results for associated satisfiability problems.

7.3 Annotated and Paraconsistent Logic Programs

An **annotated logic program** (ALP) [Kifer and Subrahmanian, 1992], sometimes called **paraconsistent logic program**, has the same form as (59), but all occurring signs are positive regular signs and N is a complete lattice. It should be clear then, that an ALP is simply a regular Horn formula (based on lattice-orders) in rule notation. In this sense, ALP is a special case of SFLP [Lu *et al.*, 1993; Lu *et al.*, 1998].

It is possible to go the other way round: for a truth value set N , let $\mathbf{2}^n$ be the inverted power set lattice of N , that is, \emptyset is on top. Now each sign $S \subseteq N$ generates an order filter in $\mathbf{2}^n$ that is comprised of all subsets of S , that is, values of extended interpretations satisfying S [Lu, 1996].

Historically, ALPs preceded regular Horn formulas [Kifer and Lozinskij, 1989; Kifer and Lozinskii, 1992]. They were motivated by Belnap's paraconsistent logic [Belnap Jr., 1977], which is based on the truth sublattice of *FOUR* discussed in Section 2.5. The logic based on this lattice was modeled with Petri Nets [Murata *et al.*, 1991]. Various calculi for ALPs were developed and partly implemented [Blair and Subrahmanian, 1989; Lu *et al.*, 1991; Kifer and Subrahmanian, 1992; Messing and Stackelberg, 1995; Leach and Lu, 1996; Lu, 1996]. Non-monotonic ALP is considered in [Bell *et al.*, 1994], while [Lu and Rosenthal, 1997] is an overview of generalized logic programming.

Remarkably, the general theory of annotated logic programs [Kifer and Subrahmanian, 1992] allows for variables and function symbols to occur in the signs, thus blurring the distinction between truth values and terms. Variables in signs are also admitted in [Hähnle *et al.*, 2000].

7.4 *Deductive Databases & Knowledge Representation*

Relational databases correspond to recursion-free, safe Datalog logic programs (no function symbols) [Ullman, 1988]. Expressiveness of queries, respectively, conciseness of the data can be improved by allowing recursion or admitting function symbols or non-Horn rules. All of these drastically increase computational cost (the first two relaxations even imply undecidability), in contrast to SFLP and annotated logic programming ALP. Therefore, signed logic techniques have been suggested to enhance deductive database technology [Lakshmanan and Sadri, 1994; Subrahmanian, 1994; Ng and Subrahmanian, 1993] and knowledge representation systems [Messing, 1997].

Deductive tasks in databases differ from satisfiability checking: while consistency of a database is important, it is often guaranteed by non-deductive means and rarely performed.

More important tasks are query answering, updates, and query optimization. **Query answering** means to decide whether a conjunction of atoms logically follows from a given logic program. It is important for such algorithms that they can take advantage from the fact that a logic program does not change between subsequent queries, that is, there should be some sort of compilation. This compilation process should be incremental in order to allow **database updates**. As these requirements are fulfilled by standard logic programming techniques, one looks for deductive algorithms in signed logic that closely resemble those for classical logic programming [Leach and Lu, 1996; Messing and Stackelberg, 1995; Messing, 1995]. Another topic derived from classical database theory is the optimization of queries [Lakshmanan and Sadri, 1994].

The expert system architecture Milord II [Puyol-Gruart, 1996] makes essential use of regular Horn formulas. Large knowledge bases are split into modules, each equipped with a local many-valued logic [Agustí-Cullell *et al.*, 1991; Agustí-Cullell *et al.*, 1994]. A mapping determines the global truth degree from the truth degrees computed by each module.

In [Arieli and Avron, 1998] it is argued that the *bilattice FOUR* (Section 2.5) plays a similar role as the two-valued Boolean algebra in the realm of reasoning with incomplete and uncertain information, rather than Belnap's [Belnap Jr., 1977] four-valued truth lattice.

7.5 Many-Valued Semantics of Logic Programs

The knowledge lattice $\langle \{F, T, \perp, \top\}, \leq_k \rangle$ of the bilattice \mathcal{FOUR} (Definition 10) is a key tool for characterizing the declarative semantics of SLDNF-resolution of general logic programs.

Observe that both sublattices of \mathcal{FOUR} are compatible in the sense that prime filters/ideals (that is: regular signs) in one lattice have the same status in the other. It is possible, therefore, to handle connectives from both lattices with the same set of regular signs in \mathcal{FOUR} . In fact, even $\uparrow_k F$ and $\uparrow_k T$ suffice.

The operational semantics of general logic programs P can be modeled with the signed formula $\uparrow_k T:P$, if the operators in P are defined by a suitable \mathcal{FOUR} -valued matrix. One possibility is: define $A_{\leftarrow}(i, j) = T$ iff $j \leq_k i$ and $A_{\leftarrow}(i, j) = F$ otherwise, that is, rules propagate knowledge and have a two-valued definite result; combination of rules and body literals is done simply by \sqcap in the truth lattice; to model negation as failure, think of \top to encompass both F and T and \perp none of them. Now negation just switches support of T and F , thus: $A_{\neg}(F) = T$, $A_{\neg}(T) = F$, and $A_{\neg}(i) = i$ otherwise. It is straightforward to transform the signed formula $\uparrow_k T:P$ into a regular Horn formula or annotated logic program over \mathcal{FOUR} . At that point, the results stated in Section 7.1 apply.

The model of classical general logic programming sketched above is essentially due to [Stärk, 1991; Plaza, 1996]. The latter shows that SLDNF-resolution is faithfully captured therein. The idea to use three- and four-valued logics to model the semantics of logic programs with negation is due to [Fitting, 1985; Kunen, 1987; Fitting, 1991a].

8 MANY-VALUED LOGIC IN CIRCUIT DESIGN

8.1 Usage of Many-Valued Logic in Circuit Design

The idea to generalize binary logic technology in hardware designs to many-valued logic is natural and has been intensely explored for at least 30 years. A closer look reveals that many-valued logic can be put to use in quite different ways:

Many-Valued Hardware. One can build genuinely many-valued hardware that internally works typically with 2^n voltage levels, where $n \geq 2$. The most important advantage is that a higher integration can be achieved, because a 2^n -valued gate or cell is only slightly larger than a two-valued one.

- Many-valued technology is used in various commercially available memory devices [Bauer *et al.*, 1995]. Besides larger storage capacity on the

same area, they offer faster access as well. The need to map binary addresses to many-valued cells affords slightly more complicated periphery, otherwise, existing manufacturing techniques scale up well. A nice overview is [Gulak, 1998].

- The design of complex arithmetic and logic circuits has been proven to be technologically feasible as well. In addition to smaller size, they consume less power and have fewer internal connections [Kawahito *et al.*, 1994]. On the other hand, many-valued design tools of comparable quality to binary ones are not yet available. Together with the higher complexity of many-valued circuits, this leads so far to comparatively higher development cost. As a consequence, complex many-valued circuits did not yet make a commercial impact, which may change as physical barriers are in sight for binary technology.

Modeling below the Gate Level. Switch-level models (SLM) [Bryant, 1984; Hayes, 1986] are a well-established formal framework for modeling properties of *binary* circuits on the transistor level in considerable detail. SLMs are used to model phenomena such as propagation and resolution of undefined values, hazard detection, degradation effects, varying capacities, pull-up transistors or depletion mode transistors, see [Eveking, 1991] for a very exhaustive list. It is important to note, however, that all dimensions are symbolic values.

It has been demonstrated that many-valued logic is an appropriate modeling language at the switch-level [Hayes, 1986; Eveking, 1991], which makes it possible to verify designs as well [Bryant and Seger, 1991; Hähnle and Kernig, 1993].

Representation, Minimization, Synthesis. Just as in the binary case, it is important to represent, minimize and optimize many-valued functions, that is, to express them in a given logical language with a minimal number of connectives, which is the basis for a realization in hardware. For representation of binary and many-valued functions decision diagrams (Section 8.2) are mostly used in modern design tools.

A large number of many-valued minimization methods can be found in the literature. They fall into two categories:

- *heuristic methods*, for example, ESPRESSO-MV [Rudell and Sangiovanni-Vincentelli, 1987]; [Rudell and Sangiovanni-Vincentelli, 1987]; these are used in practice, because
- *systematic methods* often cannot deal efficiently enough with larger designs [Sasao, 1999], but are successful in certain special contexts, such as designs using field programmable gate arrays (FPGA).

What seems surprising at first is that many-valued minimization can be used for optimizing *binary* designs as well [Sasao, 1981; Sasao, 1993b]. For instance, a single 2^n -valued signed atom can encode n binary literals. Accordingly, a signed CNF formula (with truth values in $\{1, \dots, 2^n\}$) represents a so-called programmable logic array (PLA) with n -bit decoder.

It is outside the scope of this article to present technical details of many-valued circuits. Instead, I would like to point out some connections between many-valued switching theory and proof theory of many-valued logics.

8.2 Decision Diagrams

Decision diagrams (DD) are a family of data structures originally developed for efficient representation and manipulation of Boolean formulas, but now successfully used for many purposes in computer science, in particular in circuit design tools [Burch *et al.*, 1990]. A standard reference for binary decision diagrams (BDD) is [Bryant, 1986], a survey of BDDs is contained in [Bryant, 1992] and, more recently and exhaustively, in [Sasao and Fujita, 1996; Minato, 1996]. An introduction to BDDs from the point of view of automated theorem proving is [Strother Moore, 1994]. DDs in many-valued logic are discussed in [Kam *et al.*, 1998].

BDDs are a representation of two-valued (Boolean) functions based on the three-place **if-then-else** operator $\text{if } i \text{ then } j \text{ else } k \equiv (i \wedge j) \vee (\neg i \wedge k)$, where

$$A_{\text{if-then-else}}(i, j, k) = \begin{cases} j & \text{if } i = 1 \\ k & \text{if } i = 0 \end{cases} .$$

Every Boolean function can be expressed with a formula that contains no connective but **if-then-else**, logical constants 0 and 1, and where variables occur exactly as the first argument of **if-then-else** connectives. For instance,

$$(68) \quad p \rightarrow q \equiv \text{if } p \text{ then } (\text{if } q \text{ then } 1 \text{ else } 0) \text{ else } 1 .$$

Such a representation is called an **if-then-else normal form**, a **BDD**, or a **Shannon tree**. A systematic way to obtain a BDD representation of a formula or logical function φ is provided by the so-called **Shannon expansion**.¹⁸ Assume that p is a variable occurring in φ , then:

$$(69) \quad \varphi \equiv \text{if } p \text{ then } \varphi\{p/1\} \text{ else } \varphi\{p/0\} .$$

Recursive application of (69) to $\varphi\{p/i\}$ ($i = 0, 1$) and the variables in it, plus replacement of variable-free formulas with their valuation, obviously

¹⁸In the BDD and function minimization literature this equation is often attributed to Shannon [1938] or Akers [1978], however, it appears already in [Boole, 1854]. Expansions are sometimes called **decomposition**.

yields a BDD representation of φ , see Figure 11 (top right) for the example in (68) in tree notation.

By definition of **if-then-else**, the right-hand side of the equivalence (69) is valid iff the signed atom $\{1\}:p$ and $\varphi\{p/1\}$ are valid or the signed atom $\{0\}:p$ and $\varphi\{p/0\}$ are valid.

Usually, BDDs are assumed to be reduced and ordered, abbreviated **ROBDD**. **Reduced** means that the syntax tree of a BDD representation is turned into a directed acyclic graph by identifying isomorphic subtrees and applying the following simplification rule, wherever possible:

$$(\text{if } i \text{ then } j \text{ else } j) \equiv j .$$

Ordered means that relative to a given total ordering \prec on variables, whenever q occurs in the body of **if** $p \dots$ **then** $p \prec q$ must hold. An important property of ROBDDs is that for a given variable ordering the ROBDD representation of any formula is unique, rendering ROBDDs a **canonical normal form** for Boolean functions. This property is crucial for the implementation of BDD manipulation packages, because it allows BDDs to be hashed, which helps to avoid redundant computations.

BDDs are extended to a **many-valued decision diagram** or **MDD** for finite-valued logics in a natural way using an $(n + 1)$ -ary **switch** connective in n -valued logic:

$$A_{\text{switch}}(i, j_0, \dots, j_{n-1}) = \begin{cases} j_0 & \text{if } i = 0 \\ j_1 & \text{if } i = \frac{1}{n-1} \\ \dots & \dots \\ j_{n-1} & \text{if } i = 1 \end{cases}$$

Orłowska [1967] gave a proof procedure for propositional Post logic based on an MDD-like structure, using a different (and slightly cryptic) notation. ROMDDs were defined first by [Thayse *et al.*, 1979] and were rediscovered in connection with the growing interest in BDD methods by [Srinivasan *et al.*, 1990], now called **canonical function graph**. Like their binary counterparts n -valued MDDs are functionally complete, an ROMDD representation is a canonical normal form for any n -valued function, and they can be computed with the help of a generalized Shannon expansion:

$$(70) \quad \varphi \equiv \begin{cases} \text{switch } i \\ \text{case } 0 : & \varphi\{p/0\}; \\ \text{case } \frac{1}{n-1} : & \varphi\{p/\frac{1}{n-1}\}; \\ \dots & \dots \\ \text{case } 1 : & \varphi\{p/1\} \end{cases}$$

Obviously, the right-hand side of this equivalence is valid iff for some $i \in N$ both the signed atom $\{i\}:p$ and the formula $\varphi\{p/i\}$ are valid.

Figure 11. Partitioning tableau rules and DDs.

DDs and partitioning DNF representations (Definition 27) bear a close relationship. Consider the partitioning tableau rule for $\{1\}:(p \rightarrow q)$ and the ROBDD for $p \rightarrow q$ depicted in the top row of Figure 11. Edges corresponding to **then** and **else** branches are labeled with 1 and 0, respectively, in the ROBDD. An edge labeled with i going out of a node p can be seen as an assertion of the truth value i to p , in other words, as the signed formula $\{i\}:p$. The following relationship between classical signed tableaux with partitioning rules and (RO)BDDs holds [Posegga, 1993]: if B is the set of signed atoms corresponding to the edges on a path ending with 1 in a (RO)BDD for φ , then there is an open branch in any tableau for $\{1\}:\varphi$ with partitioning rules containing exactly B as signed atoms and vice versa.

This relationship generalizes to many-valued signed tableaux with partitioning rules and (RO)MDDs. Let B be the set of signed atoms corresponding to edges on a path ending with $j \in S$ in a (RO)MDD for φ . Then there is an open branch in any signed tableau with partitioning rules for $S:\varphi$ containing signed atoms B' such that for each $\{i\}:p \in B$ there is $S':p \in B'$ with $i \in S'$.

Conversely, if B' are the signed atoms on an open branch in a signed tableau with partitioning rules for $S:\varphi$, then there is $j \in S$ and a path in a (RO)MDD for φ ending with j and set B of signed atoms corresponding to its edges, such that for each $S':p \in B'$ one has $\{i\}:p \in B$ for some $i \in S'$.

For instance, an ROMDD for $p \rightarrow_L q$ is displayed in Figure 11 (bottom right—this time, variable q was expanded first); the paths ending with values from $\{0, \frac{1}{2}\}$ correspond to the extensions of the partitioning tableau rule for $\{0, \frac{1}{2}\}:(p \rightarrow_L q)$ depicted on the left.

The relationship between open tableau branches and paths in MDDs is more straightforward, if one admits *set-valued edges* in DDs, which correspond directly to atoms signed with truth value sets. Such diagrams,

however, are not a canonical representation and, hence, less important in practice.

Yet another way to look at DDs is as a non-clausal version of the (signed) DPL procedure (58), whose splitting rule in the singleton sign case is exactly generalized Shannon expansion (70). The main difference is that DPL-proofs are trees and not DAGs.

We stress that DD methods are essentially confined to the ground case, because total ordering of non-ground atoms is not compatible with applying substitutions to them, hence the canonicity property is lost [Posegga and Schmitt, 1995].

Implementations of MDDs are reported in [Srinivasan *et al.*, 1990; Sasao, 1996; Kam *et al.*, 1998].

8.3 Polynomial Expressions

The set of paths in a BDD or MDD can be seen as a Boolean polynomial over signed atoms with truth values as coefficients. Let us write a signed atom of the form $\{i\}:p$ as p^i , “ \wedge ” as “ \cdot ”, and “ \vee ” as “ $+$ ”. Then, by (69), for example,

$$\begin{aligned}
 p \rightarrow q &\equiv p^1 \cdot (1 \rightarrow q) + p^0 \cdot (0 \rightarrow q) \\
 &\equiv p^1 \cdot (q^1 \cdot (1 \rightarrow 1) + q^0 \cdot (1 \rightarrow 0)) + \\
 &\quad p^0 \cdot (q^1 \cdot (0 \rightarrow 1) + q^0 \cdot (0 \rightarrow 0)) \\
 &\equiv p^1 \cdot q^1 \cdot 1 + p^1 \cdot q^0 \cdot 0 + p^0 \cdot q^1 \cdot 1 + p^0 \cdot q^0 \cdot 1 \\
 (\text{reduction: } &\equiv p^1 \cdot q^1 \cdot 1 + p^0 \cdot 1) \text{ ,}
 \end{aligned}$$

where the last line can also be read off the paths (ending with 1) in the ROBDD in Figure 11. In switching theory [Hachtel and Somenzi, 1996; Sasao, 1999], such a polynomial expression is known as **sum-of-products expression** or **SOP**, the products $p_1^{i_1} \cdots p_k^{i_k}$ of the non-reduced form are called **minterm**, and the coefficients 0, 1 **discriminant**. Many readers will have realized that an SOP simply is a DNF.¹⁹

Replacing disjunction “ $+$ ” with exclusive or “ \oplus ” yields a so-called **exclusive-or-of-products expression** **ESOP**, which is of great practical value [Hachtel and Somenzi, 1996; Sasao, 1999]. We saw that the Shannon expansion yields SOP expressions. Because of $p \wedge q \equiv 0$ iff $p \oplus q \equiv p \vee q$, one obtains ESOP expressions in the same way. There are many kinds of polynomial representations. Most of them, for example, general SOPs and ESOPs are not canonical (that is, more than one (E)SOP has the same ROBDD). On the other hand, certain restrictions of (E)SOPs are canonical: an ESOP, in which only positive signed atoms of the form p^1 occur,

¹⁹(Signed) NNF formulas (Section 6.6) are known in switching theory as well under the name **factored expression**.

and where each product occurs at most once is called **positive polarity Reed-Muller** (PPRM) expression and is of considerable practical interest in circuit synthesis. The relevance of polynomial expressions comes from the fact that they can be immediately realized with two-level networks. In addition, many kinds of (E)SOP expressions can be read off decision diagrams (based on suitable expansions), which gives directly a method for synthesis of the corresponding circuits. One drawback is that the (E)SOPs produced by DDs are not necessarily of minimal size.

In the many-valued case one may, of course, consider arbitrary signed atoms $S:p$ in minterms. Written p^S , they are known in logic design under the name **set literal** or **universal literal** [Sasao, 1981; Dueck and Butler, 1994]. On the other hand, there is no reason to restrict oneself to unary functions as an expansion base for a polynomial representation: recall that (70) can alternatively be written as

$$\varphi \equiv \sum_{i \in N} (p^i \cdot \varphi\{p/i\}) ,$$

which can be generalized to

$$(71) \quad \varphi \equiv \sum_{i \in I} (\Psi_i \cdot \varphi_i) ,$$

for a certain base of Boolean-valued functions $(\Psi_i)_{i \in I}$ over the variables of φ and certain many-valued functions φ_i depending on the Ψ_i . One needs, of course, to impose restrictions on the Ψ_i to make this work. Examples of generalized expansions are Löwenheim's *orthonormal expansions*, see [Brown, 1990]. Expansions for many-valued logic were investigated in many papers, see [Perkowski, 1992] for an overview and attempt at systematizing the plethora of existing expansions. The complexity of expressions in terms of minimal length is compared in many papers.

Some expansions, for example (70), correspond to partitioning DNF representations (Definition 27), but in general, expansions are a much more general mechanism. With DNF representations and, hence, tableau and sequent rules, the usual point of view taken is that one eliminates a connective by applying it, whereas expansion schemata as used in switching theory often eliminate a variable. Through many-valued cut rules both notions are linked.

9 COMPLEXITY AND DECIDABILITY

As it is the case for classical logic and other non-standard logics, a variety of complexity-related questions can be asked in the context of many-valued logic. Some questions, such as the complexity of the sets of satisfiable and valid formulas in various logics, are completely standard; others, such as the maximal size of DNF/CNF representations of many-valued operators, only make sense in a many-valued context. We assume the reader to be

familiar with standard concepts from complexity [Papadimitriou, 1994] and recursion theory [Soare, 1987].

9.1 Satisfiability and Validity

Given an N -valued (propositional or first-order) logic \mathcal{L} , a truth value set $D \subseteq N$, denote with $D\text{-SAT}_{\mathcal{L}}$ the D -satisfiable formulas and with $D\text{-VAL}_{\mathcal{L}}$, the D -valid formulas of \mathcal{L} . Further, let $\text{SAT}_{\mathcal{L}=\{1\}}\text{-SAT}_{\mathcal{L}}$ and $\text{VAL}_{\mathcal{L}=\{1\}}\text{-VAL}_{\mathcal{L}}$.

THEOREM 35. *$\text{SAT}_{\mathcal{L}}$ is NP-complete and $\text{VAL}_{\mathcal{L}}$ co-NP-complete, whenever $\mathcal{L} \in \{\mathcal{L}_c^0, \mathcal{L}_G^0, \mathcal{L}_L^0, \mathcal{L}_H^0\}$ for any choice of N .*

Proof. (Sketch) For \mathcal{L}_c^0 this is, of course, Cook's Theorem.

For hardness of the problems associated to a logic $\mathcal{L}^0 \in \{\mathcal{L}_G^0, \mathcal{L}_L^0, \mathcal{L}_H^0\}$, first observe that by virtue of equations (1), (3) one may assume that \mathbf{L}^0 contains all classical formulas $\varphi \in \mathbf{L}_c^0$. Now it is sufficient to define for each $\varphi \in \mathbf{L}_c^0$ an \mathbf{L}^0 -formula φ^* that restricts \mathcal{L}^0 -interpretations of φ to values in $\{0, 1\}$. Then $\varphi \in \text{SAT}_{\mathcal{L}_c^0}$ iff $\varphi \wedge \varphi^* \in \text{SAT}_{\mathcal{L}^0}$. In the case of \mathcal{L}_L^0 , for example, one can use $\varphi^* = \bigwedge_{p \text{ occurs in } \varphi} (p \vee \neg p)$, in the other logics similar formulas work.

For finite-valued logics, NP-, respectively, co-NP-easiness is straightforward, so assume $N = [0, 1]$ for the remaining cases.

$\text{SAT}_{\mathcal{L}_c^0} = \text{SAT}_{\mathcal{L}_H^0} = \text{SAT}_{\mathcal{L}_G^0}$ is shown by giving straightforward polynomial-size embeddings of the latter into the former [Hájek, 1998].

$\text{VAL}_{\mathcal{L}_G^0}$ [Baaz *et al.*, 1998a]: assume there is an interpretation \mathbf{I} of $\varphi \in \mathbf{L}_G^0$ over variables p_1, \dots, p_m such that $\mathbf{I}(\varphi) < 1$. There is a trivial order-isomorphism o mapping $\mathbf{I}(p_1), \dots, \mathbf{I}(p_m)$ into $\mathbf{m} + \mathbf{2} = \{0, \frac{1}{m+1}, \dots, \frac{m}{m+1}, 1\}$. All Gödel operations f have the property that $f(i_1, \dots, i_{\alpha(f)}) \in \{i_1, \dots, i_{\alpha(f)}\} \cup \{0, 1\}$, hence, $o(\mathbf{I})(\varphi) < 1$; now it suffices to guess such an interpretation over $\mathbf{m} + \mathbf{2}$ and check that $o(\mathbf{I})(\varphi) < 1$, which can obviously be done in polynomial time.

$\text{VAL}_{\mathcal{L}_H^0}$: there is a polynomial embedding of \mathcal{L}_H^0 into \mathcal{L}_L^0 , see [Baaz *et al.*, 1998a].

$\text{VAL}_{\mathcal{L}_L^0}, \text{SAT}_{\mathcal{L}_L^0}$: an immediate consequence of Theorem 16(1). ■

REMARK 36. Co-NP-completeness of $\text{VAL}_{\mathcal{L}_L^0}$ was shown by Mundici [1987]. The polynomial embedding of MIP-representable logics described in Section 4.2 also yields NP-easiness of Gödel logic and of the extension of Łukasiewicz logic that is characterized by piecewise linear functions with rational coefficients (discussed at the end of Section 4.3). In [Hájek, 1998] also the complexity of the sets $N \setminus \{0\}\text{-SAT}_{\mathcal{L}}$ and $N \setminus \{0\}\text{-VAL}_{\mathcal{L}}$ is considered.

While the decision problems of propositional infinite-valued Łukasiewicz, Gödel and product logic have the same complexity as two-valued logic, the situation changes drastically in the first-order case:

THEOREM 37. *$VAL_{\mathcal{L}_G}$ is Σ_1 -complete and $VAL_{\mathcal{L}}$ is Π_2 -complete, whenever $\mathcal{L} \in \{\mathcal{L}_L, \mathcal{L}_\Pi\}$, if $N = [0, 1]$.*

The proofs are rather technical and must be omitted (they can be found in [Hájek, 1998]). Π_2 -completeness of \mathcal{L}_L was first shown in [Scarpellini, 1962; Ragaz, 1981]. An embedding of \mathcal{L}_L into \mathcal{L}_G [Hájek, 1998] can be used to show Π_2 -completeness of the latter. Σ_1 -easiness follows from the existence of a complete first-order axiomatization [Hájek, 1998]. Surprisingly, $VAL_{\mathcal{L}_G}$ is *not* recursively enumerable anymore, for example, over the truth value set $N_* = \{\frac{1}{n+1} \mid n \in \mathbb{N}\} \cup \{0\}$ [Baaz *et al.*, 1996]. So the order type of the truth value set can drastically change the complexity of infinite-valued first-order logic.

More fine-grained investigations were made into the complexity of satisfiability problems associated with signed CNF formulas (50). Let CNF-SAT be the set of satisfiable propositional signed formulas, let 2-CNF-SAT be the restriction of CNF-SAT, where signed clauses contain exactly two signed atoms, and let HORN-SAT be the satisfiable regular Horn formulas (defined in Section 7.2). If the truth value set N , together with a partial order, is fixed, this is denoted with CNF-SAT $_N$, 2-CNF-SAT $_N$, and HORN-SAT $_N$.

Similar to the classical case, CNF-SAT is NP-complete, but some of its sub-classes are polynomially solvable. NP-hardness of CNF-SAT is trivial, because classical SAT is the same as CNF-SAT $_{\{0,1\}}$ up to notation; NP-easiness of the problem CNF-SAT for all finite N is straightforward, see above. Further results are summarized in Table 1 and are collected in [Beckert *et al.*, 2000b].

2-CNF-SAT $_N$ for any $|N| \geq 3$ and, therefore, 2-CNF-SAT was shown to be NP-hard in [Manyà, 1996; Manyà, 2000] (in contrast to classical 2-CNF-SAT that can be solved in linear time) by embedding the 3-colorability problem of graphs. A direct embedding of classical CNF-SAT into 2-CNF-SAT is given in [Beckert *et al.*, 1999].

Even *regular* 2-CNF-SAT is NP-complete, which can be shown by embedding (general) 2-CNF-SAT into regular 2-CNF-SAT [Beckert *et al.*, 2000a]. Under certain restrictions, however, membership in regular 2-CNF-SAT can be checked in polynomial time: for totally ordered N , [Manyà, 1996; Manyà, 2000] gives a quadratic-time procedure by a version of signed DPL (58) for regular formulas. A generalization is proven in [Beckert *et al.*, 2000a] for the case when N is a lattice and all occurring signs are of the form $\uparrow i$ or $\downarrow i$. A linear-time procedure for solving monosigned 2-CNF-SAT is described in [Manyà, 2000].

If N is totally ordered, the problem of deciding whether a regular Horn formula Γ is satisfiable can be solved in time linear in $|\Gamma|$ in case $|N|$ is fixed, and in $|\Gamma| \log |\Gamma|$ time, otherwise [Hähnle, 1996b]. An algorithm for a particular subclass of regular Horn formulas appeared before in [Escalada-Imaz and Manyà, 1994].

Table 1. Known complexity results for signed SAT problems

	CNF	2-CNF	HORN
<i>classical</i>	NPC	linear [Even <i>et al.</i> , 1976]	linear [Dowling and Gallier, 1984]
<i>monosigned</i>	NPC	linear [Manyà, 2000]	—
<i>regular, N totally ord.</i>	NPC	polynomial [Manyà, 1996]	$ \Gamma \log \Gamma $ [Hähnle, 1996b]
<i>regular, N distr. lattice, signs of form $\uparrow i$ and $\overline{\uparrow i}$</i>	NPC	NPC [Beckert <i>et al.</i> , 2000a]	$ \Gamma N ^2$ [Sofronie-Stokkermans, 1998]
<i>regular, N lattice, signs of form $\uparrow i$ and $\overline{\uparrow i}$</i>	NPC	NPC	polynomial [Beckert <i>et al.</i> , 1999]
<i>regular, N lattice, signs of form $\uparrow i$ and $\downarrow i$</i>	NPC	polynomial [Beckert <i>et al.</i> , 2000a]	—
<i>regular (arbitrary)</i>	NPC	NPC	—
<i>signed (arbitrary)</i>	NPC	NPC [Manyà, 1996]	—

If N is a finite lattice, regular HORN-SAT is decidable in time linear in the length of the formula and polynomial in the cardinality of N via a reduction to classical HORN-SAT [Beckert *et al.*, 1999]. For distributive lattices, the more precise bound $|\Gamma| \cdot |N|^2$ was found independently in [Sofronie-Stokkermans, 1998], which contains also some results on decidable first-order fragments of regular CNF formulas. A closer inspection of the proofs in the cited papers yields immediately that all regular HORN-SAT $_N$ versions have linear complexity.

If the partial order of N is no lattice, then regular Horn formulas need to be based on signs of the form $\uparrow S$, where $S \subseteq N$ (see end of Section 7.2). This more general notion of regular HORN-SAT is still decidable in time linear in the length of the formula, but exponential in the cardinality of N [Beckert *et al.*, 1999] provided that N possesses a maximal element.

If N is infinite, then regular HORN-SAT is decidable provided that N is a **locally finite lattice**, that is, every sub-lattice generated by a finite subset is finite [Beckert *et al.*, 1999].

A set of on-line (that is: incremental) algorithms for Horn formulas with numerical uncertainties has been proposed and studied in [Ausiello and Giaccio, 1997]. The resulting complexities are (at most cubic) polynomials, also in the infinite-valued case.

The NP-complete satisfiability problems for regular formulas and Regular-DPL exhibit the phase transition phenomena encountered in many decision

procedures for NP-complete problems [Mitchell *et al.*, 1992]: (i) there is a sharp increase (phase transition) of the percentage of unsatisfiable random CNF-SAT instances around a certain point when the ratio $\frac{c}{v}$ between the number c of clauses and the number v of variables is varied; (ii) there is an easy-hard-easy pattern in the computational difficulty of solving problem instances as $\frac{c}{v}$ is varied—the hard instances tend to be found near the crossover point [Manyà *et al.*, 1998; Béjar and Manyà, 1999b].

The complexity of deciding logical consequence depends on the availability and form of deduction theorems (such as Theorem 9) for a given logic.

On the CNF level, some authors used many-valued semantics to approximate classical propositional consequence. In some cases this lead to polynomial decision procedures and results of this kind were used in knowledge representation [Patel-Schneider, 1990]. An overview of results in this area is in [Cadoli and Schaerf, 1996].

9.2 Representations

The size of representations and tableau/sequent rules for many-valued operators (see Section 6) is closely related to the deterministic complexity of decision problems, because the size of rules determines the size of sequent/tableau proofs, and the latter immediately yield upper bounds of the complexity of VAL and CNF-SAT by virtue of the Completeness Theorem 25.

Representations (Theorem 21) and expansions (Section 8.2) do also determine the size of various normal forms for many-valued logic formulas in an essential way.

In [Rousseau, 1967; Rousseau, 1970; Zach, 1993; Hähnle, 1994a; Baaz and Fermüller, 1995b] the following results on the maximal size of signed CNF-/DNF-representations of finite-valued connectives θ are stated and proven:

$n = N , r = \alpha(\theta)$	DNF	CNF
monosigned	n^r	n^{r-1}
general	n^{r-1}	n^{r-1}

All bounds are tight. The r -ary Łukasiewicz sum \oplus_L^r serves in the proof of all cases,; it is defined as $\oplus_L^r(p_1, \dots, p_r) \equiv p_1 \oplus_L \dots \oplus_L p_r$.

The method described in Section 6.6 for translating formulas of any finite-valued logic into signed CNF limits the latter's size to be in $\mathcal{O}(n^R|\varphi|)$, where $R = \max\{\alpha(\theta) \mid \theta \in \Theta, \theta \text{ occurs in } \varphi\}$ [Hähnle, 1994d]. For logics defined by distributive lattices, up to exponentially better results are possible by using the dual space representations discussed in Section 6.5. General complexity results for this case and many concrete examples are in [Sofronie-Stokkermans, to appear, 2000].

The branching factor of signed tableau rules for quantifiers (the number of disjuncts in Theorem 22) is at most $2^n - 2$. For the dual sequent rules the slightly better bound 2^{n-1} can be obtained [Baaz and Fermüller, 1995b], which is sharp as well.

A slightly different question is to ask how many different signs are needed in general to build a sound and complete signed tableau or sequent calculus for a given n -valued logic. It is shown in [Baaz *et al.*, 1998b] for families of signs fulfilling condition (40) that this number is logarithmic in n (and the bound is tight).

One of the results relating to infinite-valued Łukasiewicz logic is that every \mathbf{L}_L^0 -formula over just one variable can be polynomially translated into a regular signed atom with respect to the natural order on $N = [0, 1]$ [Mundici and Olivetti, 1998]. The complexity of McNaughton functions in one variable is investigated in [Aguzzoli, 1998a; Aguzzoli, 1999]. In [Mundici, 1987] it is shown that a \mathbf{L}_L^0 -formula φ is valid in infinite-valued \mathcal{L}_L^0 iff it is valid in $(2^{(2^{|\varphi|})} + 1)$ -valued \mathcal{L}_L^0 . This bound was later improved to $(2^{|\varphi|} + 1)$ values [Aguzzoli and Ciabattoni, 2000; Ciabattoni, 2000b]. An analogous result is established for logical consequence.

Space complexity of various kinds of MDDs (Section 8.2) is discussed, for example, in [Sasao, 1993b], where further pointers to the literature can be found. In fact, every known kind of MDD has exponential worst-case space complexity. Increased space complexity is frequently traded in for more efficient computation in practice.

The worst-case, best-case and relative space complexity of various kinds of polynomial representations of finite-valued functions is investigated in many papers, for example, [Sasao and Butler, 1997].

10 INTERACTION WITH OTHER NON-CLASSICAL LOGICS

Interaction between many-valued and other non-classical logics can take place in several ways. I start by mentioning general *logical frameworks* such as Gabbay's labeled deductive systems (LDS) [Gabbay, 1996], which can accommodate several non-classical logics, including MVL, at the same time. The development of a general tableau-based deductive framework for LDS was started in [D'Agostino and Gabbay, 1994].

Fibring of logics, suggested in [Pfalzgraf, 1991], and developed further by Gabbay [1999], is a general methodology to break up logical systems into simpler components and recombine them. This is exploited in [Beckert and Gabbay, 1998] who provide precise conditions on logics that guarantee modular combination of sound and complete tableau calculi.

The matrix-based semantics defined in Section 2.1 and used throughout this article is a very straightforward and natural generalization of classical semantics. Moreover, it is perfectly adequate for characterizing many-valued

logics. There exist, however, several other kinds of semantics that not only cover certain many-valued logics, but other logics (modal, relevant, etc.) as well. Advantages of taking an alternative approach are that it admits a direct comparative analysis of the logics in question and often gives additional insights.

One semantical framework is the **possible-translation semantics** or **non-deterministic semantics** of Carnielli [2000]. It works with sets of matrices, and formulas are satisfiable, if they are satisfiable in certain subsets of these matrices. There are logics that can be characterized by a finite subset of finite matrices, even though there is no single finite characteristic matrix. Possible-translation semantics can be generalized to offer an alternative to logical fibring [Carnielli and Coniglio, 1999].

The so-called **society semantics** [Carnielli and Lima-Marques, 1999] is an agent-oriented semantics and can be seen as a special case of possible-translation semantics.

The book [Epstein, 1996] develops **set-assignment semantics**, an addition to matrix semantics that allows elegant characterization of a great variety of non-classical logics, including modal logics, intuitionistic logic, paraconsistent logics, and many-valued logics.

In parallel to the semantical frameworks just mentioned, there exist at least two mainly proof theoretical frameworks that allow to compare a variety of non-classical logics, including many-valued ones. These are hypersequent calculi (see Section 6.1) [Pottinger, 1983; Avron, 1987; Avron, 1996] and display sequent calculi [Belnap, 1982]

On the other hand, many-valued logic can also be combined with other logics in a “bottom-up” style, which sometimes allows to prove stronger results than can be obtained within general frameworks. Many-valued modal logics of various sorts were considered in [Fitting, 1991b; Fitting, 1992; Iturrioz, 1993; Fitting, 1995; Baaz and Fermüller, 1996], many-valued temporal logic in [Thiele and Kalenka, 1993; Baaz and Zach, 1994; Baaz *et al.*, 1996], sometimes with surprising results such as *propositional* infinite-valued temporal logic being undecidable [Wagner, 1997]. Sorted, many-valued higher-order logic was used for modeling partial functions [Kerber and Kohlhase, 1994; Kerber and Kohlhase, 1997].

Consider signed formulas $S:\varphi$ in some many-valued logic \mathcal{L}^0 with truth values N and family of signs $\mathcal{S} \subseteq 2^N$. It is straightforward to define a two-valued possible world semantics, if one considers \mathcal{S} as the set of possible worlds and by forcing φ in i , whenever $S:\varphi$ is satisfiable in \mathcal{L}^0 . The question, of course, is: are there any interesting operators to relate possible worlds? In some cases, this is indeed so, for example, the common possible worlds semantics of Gödel, intuitionistic and certain temporal logics was used to prove undecidability results about the latter [Baaz *et al.*, 1996]. The paper [Orłowska and Iturrioz, 1999] provides a link between Łukasiewicz logic and modal logic.

The converse direction, from modal logic to MVL, is interesting as well, because many-valued logics permit efficient deduction procedures (see Section 6). Any modal logic with set of possible worlds N and accessibility relation $R \subseteq N \times N$ can be trivially re-interpreted as a 2^N -valued logic by encoding a possible world interpretation $\mathbf{I}^* : \Sigma \times N \rightarrow \{0, 1\}$ as a many-valued interpretation $\mathbf{I} : \Sigma \rightarrow 2^N$. For modal logics with the finite model property this construction yields finite-valued proof systems characterizing those modal logics [Caferra and Zabel, 1990]. More interesting results are obtained from duality theory of distributive lattices: possible world frames of certain modal logics turn out to be the dual spaces of suitable distributive lattices, not necessarily finite. The technique explained in Section 6.5 due to Sofronie-Stokkermans [1999a; to appear, 2000] leads to proof theoretical characterization of such modal logics in terms of regular logic and, ultimately, first-order classical logic.

Finally, an interesting connection is the usage of many-valued signs to make deduction in intuitionistic and modal logic more efficient [Miglioli *et al.*, 1994; Miglioli *et al.*, 1995; Avellone *et al.*, 1999].

11 MVL RESOURCES

REMARK 38. In the present section I collected various resources to draw upon for learning about MVL. For the reader's convenience URLs are supplied, whenever appropriate. Information of this kind is likely to change, so I maintain a web page²⁰ containing this section in updated and expanded form.

Books Classic, but dated, monographs on MVL in general are [Rosser and Turquette, 1952; Rescher, 1969]; the same holds for the collections [Dunn and Epstein, 1977; Rine, 1984].

[Malinowski, 1993] is recommended as a more recent and compact introduction into MVL. Another concise introduction, strong on algebraic aspects, is [Panti, 1998]. The volumes [Bolc and Borowik, 1992; Bolc and Borowik, 2000] are comprehensive and fairly recent, but at least the first part is, unfortunately, seriously flawed by many inaccuracies, see [Hájek and Zach, 1994].

The book [Gottwald, 1989] is comprehensive, but only available in German; a much expanded English edition [Gottwald, 2000] is likely to become the standard monograph on MVL. The work [Hájek, 1998] is broader than its title may suggest—both books were of invaluable help in preparing this chapter. Substantial bibliographies are contained in [Iturrioz, 2000; Iturrioz *et al.*, 2000; Gottwald, 2000]

²⁰<http://www.cs.chalmer.se/~reiner/mvl-web>

There are, of course, books on more specialized areas within MVL: Among the many books on fuzzy logic I only mention [Novák, 1989; Zimmermann, 1991; Gottwald, 1993; Kruse *et al.*, 1994; Hájek, 1998; Turunen, 1999] and the collections [Marks, 1994; Klir and Yuan, 1996], which contain material on fuzzy logic in the narrow sense. The definitive book on t -norm theory is [Klement *et al.*, 2000]. Deductive aspects of MVL are the topic of [Hähnle, 1994a; Stachniak, 1996; Baaz *et al.*, to appear, 2000]. An overview of algebraic structures related to many-valued logics is [Iturrioz *et al.*, 2000]. Algebraic aspects of Łukasiewicz logic are treated in depth in [Cignoli *et al.*, 1999], while philosophical aspects of MVL are discussed in [Zinov'ev, 1963; Haack, 1974; Haack, 1996]. For many-valued switching theory look at [Muzio and Wesselkamper, 1986] and the collections [Sasao, 1993a; Sasao and Fujita, 1996].

Journals There is one journal publishing articles on all aspects of many-valued logic: *Multiple-Valued Logic: an International Journal*²¹, published by Gordon & Breach.

Journals with a strong emphasis on one or more aspects of MVL are *Soft Computing: A Fusion of Foundations, Methodologies and Applications*²², published by Springer-Verlag; *Mathware & Soft Computing*²³, published by Universitat Politècnica de Catalunya; *Fuzzy Sets and Systems*²⁴, published by Elsevier.

Mainstream logic journals with an editorial interest in many-valued logic include *Studia Logica*²⁵, published by Kluwer; *Journal of Applied Non-Classical Logics*²⁶, published by Hermès; *Journal of Logic and Computation*²⁷, published by Oxford University Press; *Journal of Language, Logic and Computation*²⁸, published by Kluwer.

Organizations and Meetings *IEEE Computer Society*²⁹ has a *Technical Committee on MVL*³⁰ [Kameyama, 1997], which also organizes the only annual conference devoted exclusively to MVL. The meeting is called *International Symposium on Multiple-Valued Logic*, the proceedings are published by the IEEE Computer Society Press. Papers in MVL are, of course, also presented in other *logic-related conferences*³¹. A research network called

*Many-Valued Logics for Computer Science Applications*³² sponsored as a COST Action by the European Community existed between 1995 and 1999 [Tassart *et al.*, 1995]. Its final report [Iturrioz, 2000] contains a bibliography of recent work on MVL with over 600 entries.

ACKNOWLEDGEMENTS

For preprints of unpublished books and articles I am indebted to Lluís Godo, Siegfried Gottwald, Daniele Mundici, and Alasdair Urquhart. For constructive criticism and many helpful remarks I am grateful to Walter A. Carnielli (the second reader of this chapter), Agata Ciabattoni, Roberto Cignoli, Siegfried Gottwald, João Marcos, and Daniele Mundici.

The meetings of EC COST Action 15 “Many-Valued Logics for Computer Science Applications” between 1995–1999 were a great source of inspiration. I am deeply grateful to all who contributed to these meetings—without you this chapter simply could not have been written.

Chalmers University of Technology, Gothenburg, Sweden.

PREFACE TO THE SECOND EDITION

It is with great pleasure that we are presenting to the community the second edition of this extraordinary handbook. It has been over 15 years since the publication of the first edition and there have been great changes in the landscape of philosophical logic since then.

The first edition has proved invaluable to generations of students and researchers in formal philosophy and language, as well as to consumers of logic in many applied areas. The main logic article in the Encyclopaedia Britannica 1999 has described the first edition as ‘the best starting point for exploring any of the topics in logic’. We are confident that the second edition will prove to be just as good.!

The first edition was the second handbook published for the logic community. It followed the North Holland one volume *Handbook of Mathematical Logic*, published in 1977, edited by the late Jon Barwise. The four volume *Handbook of Philosophical Logic*, published 1983–1989 came at a fortunate temporal junction at the evolution of logic. This was the time when logic was gaining ground in computer science and artificial intelligence circles.

These areas were under increasing commercial pressure to provide devices which help and/or replace the human in his daily activity. This pressure required the use of logic in the modelling of human activity and organisation on the one hand and to provide the theoretical basis for the computer program constructs on the other. The result was that the *Handbook of Philosophical Logic*, which covered most of the areas needed from logic for these active communities, became their bible.

The increased demand for philosophical logic from computer science and artificial intelligence and computational linguistics accelerated the development of the subject directly and indirectly. It directly pushed research forward, stimulated by the needs of applications. New logic areas became established and old areas were enriched and expanded. At the same time, it socially provided employment for generations of logicians residing in computer science, linguistics and electrical engineering departments which of course helped keep the logic community thriving. In addition to that, it so happens (perhaps not by accident) that many of the Handbook contributors became active in these application areas and took their place as time passed on, among the most famous leading figures of applied philosophical logic of our times. Today we have a handbook with a most extraordinary collection of famous people as authors!

The table below will give our readers an idea of the landscape of logic and its relation to computer science and formal language and artificial intelligence. It shows that the first edition is very close to the mark of what was needed. Two topics were not included in the first edition, even though

they were extensively discussed by all authors in a 3-day Handbook meeting. These are:

- a chapter on non-monotonic logic
- a chapter on combinatory logic and λ -calculus

We felt at the time (1979) that non-monotonic logic was not ready for a chapter yet and that combinatory logic and λ -calculus was too far removed.¹ Non-monotonic logic is now a very major area of philosophical logic, alongside default logics, labelled deductive systems, fibring logics, multi-dimensional, multimodal and substructural logics. Intensive re-examinations of fragments of classical logic have produced fresh insights, including at time decision procedures and equivalence with non-classical systems.

Perhaps the most impressive achievement of philosophical logic as arising in the past decade has been the effective negotiation of research partnerships with fallacy theory, informal logic and argumentation theory, attested to by the Amsterdam Conference in Logic and Argumentation in 1995, and the two Bonn Conferences in Practical Reasoning in 1996 and 1997.

These subjects are becoming more and more useful in agent theory and intelligent and reactive databases.

Finally, fifteen years after the start of the Handbook project, I would like to take this opportunity to put forward my current views about logic in computer science, computational linguistics and artificial intelligence. In the early 1980s the perception of the role of logic in computer science was that of a specification and reasoning tool and that of a basis for possibly neat computer languages. The computer scientist was manipulating data structures and the use of logic was one of his options.

My own view at the time was that there was an opportunity for logic to play a key role in computer science and to exchange benefits with this rich and important application area and thus enhance its own evolution. The relationship between logic and computer science was perceived as very much like the relationship of applied mathematics to physics and engineering. Applied mathematics evolves through its use as an essential tool, and so we hoped for logic. Today my view has changed. As computer science and artificial intelligence deal more and more with distributed and interactive systems, processes, concurrency, agents, causes, transitions, communication and control (to name a few), the researcher in this area is having more and more in common with the traditional philosopher who has been analysing

¹I am really sorry, in hindsight, about the omission of the non-monotonic logic chapter. I wonder how the subject would have developed, if the AI research community had had a theoretical model, in the form of a chapter, to look at. Perhaps the area would have developed in a more streamlined way!

such questions for centuries (unrestricted by the capabilities of any hardware).

The principles governing the interaction of several processes, for example, are abstract and similar to principles governing the cooperation of two large organisations. A detailed rule based effective but rigid bureaucracy is very much similar to a complex computer program handling and manipulating data. My guess is that the principles underlying one are very much the same as those underlying the other.

I believe the day is not far away in the future when the computer scientist will wake up one morning with the realisation that he is actually a kind of formal philosopher!

The projected number of volumes for this Handbook is about 18. The subject has evolved and its areas have become interrelated to such an extent that it no longer makes sense to dedicate volumes to topics. However, the volumes do follow some natural groupings of chapters.

I would like to thank our authors and readers for their contributions and their commitment in making this Handbook a success. Thanks also to our publication administrator Mrs J. Spurr for her usual dedication and excellence and to Kluwer Academic Publishers for their continuing support for the Handbook.

Dov Gabbay
King's College London

Logic	IT			
	Natural language processing	Program control specification, verification, concurrency	Artificial intelligence	Logic programming
Temporal logic	Expressive power of tense operators. Temporal indices. Separation of past from future	Expressive power for recurrent events. Specification of temporal control. Decision problems. Model checking.	Planning. Time dependent data. Event calculus. Persistence through time—the Frame Problem. Temporal query language. temporal transactions.	Extension of Horn clause with time capability. Event calculus. Temporal logic programming.
Modal logic. Multi-modal logics	generalised quantifiers	Action logic	Belief revision. Inferential databases	Negation by failure and modality
Algorithmic proof	Discourse representation. Direct computation on linguistic input	New logics. Generic theorem provers	General theory of reasoning. Non-monotonic systems	Procedural approach to logic
Non-monotonic reasoning	Resolving ambiguities. Machine translation. Document classification. Relevance theory	Loop checking. Non-monotonic decisions about loops. Faults in systems.	Intrinsic logical discipline for AI. Evolving and communicating databases	Negation by failure. Deductive databases
Probabilistic and fuzzy logic	logical analysis of language	Real time systems	Expert systems. Machine learning	Semantics for logic programs
Intuitionistic logic	Quantifiers in logic	Constructive reasoning and proof theory about specification design	Intuitionistic logic is a better logical basis than classical logic	Horn clause logic is really intuitionistic. Extension of logic programming languages
Set theory, higher-order logic, λ-calculus, types	Montague semantics. Situation semantics	Non-well-founded sets	Hereditary finite predicates	λ -calculus extension to logic programs

Imperative vs. declarative languages	Database theory	Complexity theory	Agent theory	Special comments: A look to the future
Temporal logic as a declarative programming language. The changing past in databases. The imperative future	Temporal databases and temporal transactions	Complexity questions of decision procedures of the logics involved	An essential component	Temporal systems are becoming more and more sophisticated and extensively applied
Dynamic logic	Database updates and action logic	Ditto	Possible actions	Multimodal logics are on the rise. Quantification and context becoming very active
Types. Term rewrite systems. Abstract interpretation	Abduction, relevance	Ditto	Agent's implementation rely on proof theory.	
	Inferential databases. Non-monotonic coding of databases	Ditto	Agent's reasoning is non-monotonic	A major area now. Important for formalising practical reasoning
	Fuzzy and probabilistic data	Ditto	Connection with decision theory	Major area now
Semantics for programming languages. Martin-Löf theories	Database transactions. Inductive learning	Ditto	Agents constructive reasoning	Still a major central alternative to classical logic
Semantics for programming languages. Abstract interpretation. Domain recursion theory.		Ditto		More central than ever!

Classical logic. Classical fragments	Basic background language	Program synthesis	A basic tool	
Labelled deductive systems	Extremely useful in modelling		A unifying framework. Context theory.	Annotated logic programs
Resource and substructural logics	Lambek calculus		Truth maintenance systems	
Fibring and combining logics	Dynamic syntax	Modules. Combining languages	Logics of space and time	Combining features
Fallacy theory				
Logical Dynamics	Widely applied here			
Argumentation theory games		Game semantics gaining ground		
Object level/metalevel			Extensively used in AI	
Mechanisms: Abduction, default relevance			ditto	
Connection with neural nets				
Time-action-revision models			ditto	

	Relational databases	Logical complexity classes	The workhorse of logic	The study of fragments is very active and promising.
	Labelling allows for context and control.		Essential tool.	The new unifying framework for logics
Linear logic			Agents have limited resources	
	Linked databases. Reactive databases		Agents are built up of various fibred mechanisms	The notion of self-fibring allows for self-reference
				Fallacies are really valid modes of reasoning in the right context.
			Potentially applicable	A dynamic view of logic
				On the rise in all areas of applied logic. Promises a great future
			Important feature of agents	Always central in all areas
			Very important for agents	Becoming part of the notion of a logic
				Of great importance to the future. Just starting
			A new theory of logical agent	A new kind of model

ROBERT BULL AND KRISTER SEGERBERG

BASIC MODAL LOGIC

Historical Part

1 HISTORICAL OVERVIEW

It is popular practice to borrow metaphors between different fields of thought. When it comes to evaluating modal logic it is tempting to borrow from the anthropologists who seem to agree that our civilisation has lived through two great waves of change in the past, the Agricultural Revolution and the Industrial Revolution. Where we stand today, where the world is going, is difficult to say. If there is a deeper pattern fitting all that is happening today, then many of us do not see it. All we know, really, is that history is pushing on.

The history of modal logic can be written in similar terms, if on a less global scale. Already from the beginning—corresponding to the stage of hunter-gatherer cultures in anthropology—insights into the logic of modality has been gathered, by Aristotle, the Megarians, the Stoics, the medievals, and others. But systematic work only began when pioneers found or forged tools that enabled the to plough and cultivate where their predecessors had had to be content to forage. This was the First Wave, and as with agriculture it started in several places, more or less independently: C. I. Lewis, Jan Łukasiewicz, Rudolf Carnap. These cultures grew slowly, from early this century till the end of the sixth decade, a period of more than 50 years. Then something happened that can well be described as a Second Wave. What brought it out spectacularly was the achievements of the teenage genius of Saul Kripke, but he was not alone, more strictly speaking the first of his kind: the names of Arthur Prior, Stig Kanger, and Jaakko Hintikka must also be mentioned, perhaps also those of J. C. C. McKinsey and Alfred Tarski. Now modal logic became an industry. In the quarter of a century that has passed since, this industry has seen steady growth and handsome returns on invested capital.

Where we stand today is difficult to say. Is the picture beginning to break up, or is it just the contemporary observer's perennial problem of putting his own time into perspective? For a long while one attraction of modal logic was that it was, comparatively speaking, so easy to do—now it is becoming as difficult as the more mature branches of logic. And the sheer bulk of published material is making it difficult to survey. But there is also the increasing differentiation of interests and the subsequent tendency

towards fragmentation. In addition to more traditional pursuits we are now seeing phenomena as diverse as the application of modal predicate logic to philosophical problems at a new level of sophistication (Fine [1977; 1977a; 1980]), the analysis of conditionals started by Stalnaker [1968], Lewis [1973], the generalisation of model theory with modal notions (Mortimer [1974], Bowen [1978]), in-depth studies of the so-called provability interpretation (see Boolos [1979]; see also Craig Smoryński's Chapter in this *Handbook*), the advent of dynamic logic (see Pratt [1980] and David Harel's Chapter in this *Handbook*) and Montague grammar (see Montague [1974]).

This is not the place to go deeply into the history of modal logic, even though we will say something about it in the next few sections. A reader who would like to know more about the beginnings of the discipline is referred to Prior [1962], Kneale and Kneale [1962], and Lemmon [1977]. For the discipline itself, as distinct from its history, the reader may consult a number of textbooks or monographs, from E. J. Lemmon's and Dana Scott's fragment Lemmon [1977], and Hughes and Cresswell [1968]. Schütte [1968], Makinson [1971], Segerberg [1971], Snyder [1971], Zeman [1973], and Gabbay [1976] to the recent and very readable Rautenberg [1979] and Chellas [1980]. Notable journal collections of papers on modal logic include 'Proceedings of a colloquium on modal and many-valued logics' (*Acta Philosophica Fennica*, **16**, 1963), 'In memory of Arthur Prior' (*Theoria*, **36**, 1970), and 'Trends in modal logic' (*Studia Logica*, **39**, 1980). Good bibliographies of early work are found in Feys [1965], Hughes and Cresswell [1968] and Zeman [1973]. Among survey papers from the last few years we recommend Montague [1968], Belnap [1981], Bull [1982; 1983], and Føllesdal [1989].

All writing of history is to some extent arbitrary. The historian, in his quest for order, imposes structure. A favourite stratagem is the imposition of n -chotomies. As long as the arbitrary element is recognised, the procedure seems perfectly legitimate. This admitted we should like to impose a trichotomy on early modal logic: modern modal logic derives from three fountain-heads which may be classified according to their relation to semantics. The *syntactic* tradition is the oldest and is characterised by the lack of explicit semantics. Then we have the *algebraic* tradition with a semantics of sorts in algebraic terms. Finally there is the *model theoretic* tradition, the youngest one, whose semantics is in terms of models. Possible worlds semantics is the dominating kind of model theoretic semantics, perhaps even, if we take advantage of the vagueness of this term and stretch it a little, the only kind. In the next few sections we propose to give a brief account of each of the three traditions.

2 THE SYNTACTIC TRADITION

Modern modal logic began in 1912 when C. I. Lewis filed a complaint in *Mind* to the effect that classical logic fails to provide a satisfactory analysis of implication, ‘the ordinary “implies” of ordinary valid inference’, [Lewis, 1912]. Roughly it is the paradoxes of material implication that Lewis worries about, but his subtle argument goes beyond the vulgar objections, implication is not the only connective that worries him. In fact, his very first analysis concerns disjunction. Consider, he says the following two propositions:

1. Either Caesar died, or the moon is made of green cheese.
2. Either Matilda does not love me, or I am beloved.

If we disregard the complication that there is also an exclusive reading of ‘or’, classical logic will consider that both these propositions are of the form

- (i) $A \vee B$.

Yet, Lewis argues, there are more important differences between the two. For example, we know that (1) is true since we know that, as it happens, Caesar is dead, but we know that (2) is true without knowing which of the disjuncts is true. Thus (2) exhibits a ‘purely logical or formal character’ and an ‘independence of facts’ that is lacking in (1).

This much all can agree. But disagreement arises over how to account for the difference between (1) and (2). One possibility would be to hold that while both (1) and (2) are of the same form, viz. (i) they differ in that only (2) satisfies the further condition

- (ii) $\vdash A \vee B$,

where the turnstile \vdash stands for assertability or provability in some suitable system. But Lewis embraces another possibility. The difference between (1) and (2), he feels, is a difference in meaning. More specifically, he feels that there is a connection between the disjuncts of (2) which is part of the meaning of (2). On this view, the ‘or’ of (1) and the ‘or’ of (2) are different kinds of disjunction, and Lewis proposes to call the former *extensional* and the latter *intensional*. While extensional disjunction is rendered by the traditional, truth-value functional operator \vee , a novel sort of operator is needed to render intensional disjunction. Lewis himself never introduced a symbol for it, but E. M. Curley, in a recent historical study, uses the symbol \boxplus [Curley, 1975]. Thus, while (1) is of the form (i), we may say that, according to Lewis, (2) is of the form

- (iii) $A \boxplus B$.

The same problem also concerns other connectives. In the case of implication there is, according to Lewis, an extensional kind which is adequately rendered by the ‘arrow’, \rightarrow , the material implication of ordinary truth-value functional logic. But there is also an intensional kind of implication, called *strict implication* by Lewis, and for this he introduces a new symbol, the ‘fish-hook’, $\rightarrow\!\!\!\rightarrow$. The latter is not found, nor definable, in classical logic, and so Lewis proposes to develop a calculus of strict implication.

Thus there is a triad corresponding to (1)–(iii), viz.,

$$(i') \quad A \rightarrow B,$$

$$(ii') \quad \vdash A \rightarrow B,$$

$$(iii') \quad A \rightarrow\!\!\!\rightarrow B.$$

(The condition $A \vdash B$ is logically equivalent to (ii'); Lewis would also have regarded the condition $\vdash A \rightarrow\!\!\!\rightarrow B$ as equivalent to (ii').) The reader should notice the difference in theoretical status between \rightarrow and $\rightarrow\!\!\!\rightarrow$ on the one hand, and \vdash on the other. In both cases the first two are, or name, operators belonging to the object language, while the turnstile is part of the metalanguage, standing for provability or deducibility. (Provability may of course be seen as a special case of deducibility, viz. deducibility from the empty set of premises.)

Evidently the crucial question is whether the logical difference between (1) and (2) should be expressed in the object language or not—is it a feature *about* logic or *in* logic? Gerhard Gentzen is often regarded as having opted for the former alternative (although see [Shoemith and Smiley, 1978, p. 33f] concerning the historicity of this view). It is hard to say whether Lewis was aware that there was a choice. However, looking back on his work we must represent him as having favoured (iii) over (ii) and (iii') over (ii') as the logical form of certain propositions. he has been much criticised for this. It has been maintained that his whole enterprise rests on a violation of the use/mention distinction and is hopelessly confused. this is not the place to go into that discussion, all we can do is to refer the reader to [Scott, 1971] which contains what is probably the deepest discussion of this matter and certainly the most constructive one.

The method chosen by Lewis in his search for a calculus of strict implication was the axiomatic one. Lewis' intuitive understanding of logical necessity, logical possibility and related notions was of course (at least) as good as any man's, but he never tried to give it direct systematic expression; what there is, is what is implicit in the axiom systems, plus scattered informal remarks. In other words, there is no formal semantics in Lewis' work; semantics is left at an informal level. In mathematics, there is an important and time-honoured way to proceed, ultimately going back on Euclid. In the case of logic the method may be described as follows. A formal language

is defined. Formulas from this language are understood to be meaningful. A number of them are somehow selected for testing against one's intuition. Some are accepted as valid, some are rejected as nonvalid, some may be difficult to decide. The valid ones one tries to axiomatise so as to give a finite description of an infinite scene. In Lewis' case, the first effort was presented in [Lewis, 1918], a calculus which has since become known as the Survey System. However, if your semantics is only intuitive, as Lewis' was, and consequently vague, then you have a completeness problem: even if you are satisfied that the theses of your system are acceptable, how do you know that your axiom system captures as theses all the formulas that you would find acceptable? The answer is that you do not, and it did not take long for other systems to emerge with, apparently, as good a claim as the Survey System to the title conferred upon it in [Lewis, 1918] as *the* System of Strict Implication. In [Lewis and Langford, 1959] several more were defined and others hinted at. Here Lewis himself defined five systems called **S1**, **S2**, **S3**, **S4**, and **S5**, the survey system coinciding with **S3**. Later **S6** was introduced by Miss Alban and **S7** by Halldén, but in effect there were contemplated already by Lewis [Alban, 1943; Halldén, 1949]. The series of **S**-systems has been extended even further, but those mentioned are the principal ones.

Of modal logicians working in the same vein as Lewis, Oskar Becker is remembered for his early treatise [Becker, 1930], but perhaps it is G. H. Von Wright who should be named the second most important author in the syntactic tradition. In his influential monograph [von Wright, 1951] he remarks that, strictly speaking, modal logic is the logic of the modes of being. In this work and the related paper [von Wright, 1951a], Von Wright sets out to explore modal logic in a wider sense, the logic of the modes of knowledge, belief, norms and similar concepts; this wider sense of the term has since gained currency. These two works marked the beginning of much work in epistemic, doxastic, and deontic logic. Some studies of the same kind had already been published, such as [Mally, 1926] and [Hofstadter and McKinsey, 1955] (see [Follesdal and Hilpinen, 1971] or Von Wright [1968; 1981] for more of the prehistory of deontic logic), but Von Wright's work becomes seminal, especially in deontic logic. (For epistemic and doxastic logic the real trigger was a book written some ten years later by Von Wright's one time student Jaakko Hintikka, but this work [Hintikka, 1962] was written in what we call the model theoretic tradition and so does not belong in this section.)

There are two other subtraditions that should be mentioned under the present heading. One is the development of entailment and relevance logic associated with the names of Alan Ross Anderson and Nuel D. Belnap. This movement concentrated on C. I. Lewis' concern to develop a logic of strict implication, that is, to give a syntactic characterisation of 'the ordinary "implies" of ordinary valid inference'. Early contributions in the axiomatic style were given by [Church, 1951a] and [Ackerman, 1956], but it was only

with Anderson and Belnap and their many students that the project got off the ground. Algebraic and model theoretic semantics came later to this kind of logic than to modal logic, and it is perhaps fair to say that the efforts towards finding an explicit semantics have led to results that are less natural than in modal logic. This may have to do with the fact that while model logicians aim at *improving* classical logic, entailment/relevance logicians wish to *replace* it. Students interested in this subtradition will find the powerful tome [Anderson and Belnap, 1975] a rich source of information. (Cf. also Dunn, in a later volume of this *Handbook*.)

The other subtradition that should be mentioned is that of proof theory. Gentzen methods have never really flourished in modal logic, but some work has been done, mostly on sequent formulations. Early references are [Curry, 1950; Ridder, 1955; Kanger, 1957; Ohnishi and Matsumoto, 1957/59]. A monograph in this tradition is [Zeman, 1973]. In the field of natural deduction [Fitch, 1952] would seem to be the pioneer with [Prawitz, 1965] the classical reference. The recent interest in the provability interpretation of modal logic has spurred renewed interest in the proof theory of particular systems (for example [Boolos, 1979; Leivant, 1981]). In Section 9 we return to this topic.

Finally, let it be remarked that the syntactic tradition in Lewis' spirit is by no means dead. For a recent declaration of allegiance to it by a distinguished logician, see [Grzegorzcyk, 1981].

3 THE ALGEBRAIC TRADITION

That classical logic is truth-functional is enormously impressive! As shown by the existence of intuitionistic and other dissenting logics, it is by no means self-evident that it should be possible to understand the usual propositional operators in terms of simple truth-conditions (the familiar truth-tables). But given the success of classical logic it is natural to ask if the same treatment can be extended to other operators of interest, for example, modal ones. It is immediately clear that such an extension is not straight-forward, if it exists at all. There are four unary truth-functions (identity, negation, tautology, and contradiction), so if necessity or possibility is to be truth-functional, it would have to be one of them, which is absurd.

But if one insists, nevertheless, that it must be possible to give a truth-functional analysis of 'necessary' and 'possible'? Bright idea: perhaps there are more truth-values than the ordinary two—three, say. This idea occurred to Jan Łukasiewicz around 1918. His first effort was to supplement the ordinary truth-values 1 (truth) and 0 (falsity) with a third truth-value $\frac{1}{2}$ (possibility (of some kind)). his new truth-tables were as follows:

\wedge	1	$\frac{1}{2}$	0	\vee	1	<i>half</i>	0	\rightarrow	1	$\frac{1}{2}$	0
1	1	$\frac{1}{2}$	0	1	1	1	1	1	1	$\frac{1}{2}$	0
$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	0	$\frac{1}{2}$	1	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{1}{2}$	1	1	$\frac{1}{2}$
0	0	0	0	0	1	$\frac{1}{2}$	0	0	1	1	1
\neg				\square				\diamond			
1	0			1	1			1	1		
$\frac{1}{2}$	$\frac{1}{2}$			$\frac{1}{2}$	0			$\frac{1}{2}$	1		
0	1			0	0			0	0		

With 1 singled out as the sole designated truth value, the concept of validity is clear: a formula is valid if and only if it takes the value 1 under all (three-valued) truth-value assignments to its propositional letters. Let the resulting logic be called L_3 . It is an immediate corollary that L_3 is a subsystem of the classical propositional calculus; for if everything to do with the new truth-value $\frac{1}{2}$ is deleted from the truth-tables, then we get the old, classical ones back.

Exactly what sort of possibility would $\frac{1}{2}$ represent? the inspiration for his new logic Łukasiewicz had got from Aristotle's discussion of the theoretical status of propositions concerning the future. It is an interesting suggestion that a new truth-value is needed to analyse propositions of type 'there will be a sea-battle tomorrow'; for it might be held that there are points in time when such propositions are meaningful, yet neither true nor false. In other words, if one is not a determinist—and Łukasiewicz definitely was not one—then one will agree that there are propositions P such that, today, P is possible and also $\neg P$ is possible; that is, that both $\diamond P$ and $\diamond \neg P$ are true. This is in agreement with Łukasiewicz's matrix, for if P has value $\frac{1}{2}$, then $\diamond P$ and $\diamond \neg P$ take the value 1. So far, so good, but here a difficulty lurks. For under the matrix $\diamond(P \wedge \neg P)$ gets the value 1 which is absurd intuitively: whatever the future may bring, it will not be both a sea-battle and not a sea-battle tomorrow. The counter-example is flagrant, and it is interesting that Łukasiewicz was not moved by it. What is at issue is evidently whether one can accept a modal logic which validates all instances of the type

$$\diamond A \wedge \diamond B \rightarrow \diamond(A \wedge B).$$

Our counter-example would appear to settle this question in the negative—cf. [Lewis and Langford, 1959, p. 167]—but Łukasiewicz was not impressed. In a paper published only a few years before his death he states that he cannot find any example that refutes the schema in question: 'on the contrary, all seem to support its correctness' [Łukasiewicz, 1953]. He goes on to intimate that when people disagree over questions of this sort, they have different concepts of necessity and possibility in mind.

Once invented, this game admits of endless variation. Even among three-valued logics, \mathbb{L}_3 is not the only possibility, and there is literally no end to how many truth-values you may introduce. Łukasiewicz himself extended his ideas first to n -valued logic, for any finite n , and then to infinitely-valued logic, where infinite could mean either denumerably infinite or even non-denumerably infinite. In this way the notion of matrix was developed. ([Malinowski, 1977] is a compact and informative reference on Łukasiewicz and his work. For Łukasiewicz's own papers non-Polish speaking readers are referred to the collections [Łukasiewicz, 1970] and [McCall, 1967].)

A *matrix* is given if you have (i) a set of objects, called *truth-values*, (ii) a subset of these, called the *designated* truth-values, and (iii) for every n -ary propositional operator \star in your object language, a truth-table for \star (essentially, an n -place function from truth-values to truth-values). In tuple talk, if $\star_0, \dots, \star_{k-1}$ are all your propositional operators, the matrix can be thought of as a $(k+2)$ -tuple $\langle A, D, \mathfrak{M}(\star_0), \dots, \mathfrak{M}(\star_{k-1}) \rangle$, where A is a non-empty set, D a non-empty subset of A , and, for each $i < k$, $\mathfrak{M}(\star_i)$ is a function from the Cartesian product A^{n_i} to A , where n_i is the arity of \star_i . It is easy to see how this can be generalised to any number of operators.

Opinions may be divided over what philosophical importance to attach to the logics that Łukasiewicz introduce. However, there can be no doubt that he started or tied in with a line of development which is of great mathematical importance. the matrices that he invented became generalised in two steps. the first one seems like a mere change of terminology: the introduction of the concept of an *algebra* as a tuple $\langle A, f_0, \dots, f_{k-1} \rangle$, where A is a non-empty set and f_0, \dots, f_{k-1} are operations on A ; that is, for each $i < k$ there is a non-negative number n_i such that f_i is a function from A^{n_i} to A . As before, the generalisation to infinitely many functions is obvious. The connection with the concept of matrix is patent. Roughly speaking, it is only the set of designated elements that has been omitted; and as far as logic is concerned, that concept is needed for the definition of validity, not for the assignment of values of A to formulas. The most important thing about the new definition of algebra is perhaps that it encourages the study of these structures independently of their connection with logic.

The second step of generalisation was to consider *classes of algebras* rather than one matrix or algebra at the time. Thus, whereas at first algebraic structures (matrices) were introduced in order to study logic, later on logic was used to study algebra. The person who more than anyone deserves credit for this whole development is Alfred Tarski, a student and collaborator of Łukasiewicz. Some papers by Tarski written jointly with J. C. C. McKinsey or Bjarni Jónsson rank with the most important in the history of modal logic.

Among early results stemming from the algebraic tradition are that Lewis' five systems are distinct [Parry, 1934]; the analysis of **S2** and **S4** along with a proof that they are decidable [McKinsey, 1941]; that no logic between **S1**

and **S5**, inclusively, can be viewed as an n -valued logic, for any finite n [Dugundj, 1940]; that even though **S5** is not a finitely-valued logic, all its proper extensions are [Scroggs, 1951].

It does not seem as if anyone had ever worked out exactly what the relation is between abstract algebras and the intended applications. But the idea must have been something like this. We are told to think of the elements of a matrix as *truth-values*, but in the case of an algebra one should perhaps rather think of the elements as *propositions* (identifying propositions that are logically equivalent). The class of all propositions, if it exists, would presumably form one gigantic, complicated, universal algebra. But in a given context only a subclass of propositions are at issue, and they will form a simpler, more manageable algebra.

A particularly interesting paper with implications for modal logic is [Jónsson and Tarski, 1951]. If it had been widely read when it was published, the history of modal logic might have looked different. the scope of the paper is quite broad, but we should like to mention one or two results of particular relevance to modern modal logic. First, according to M. H. Stone's famous representation theorem, every Boolean algebra is isomorphic to a set of algebra. In other words, if $\mathfrak{A} = \langle A, 0, 1, -, \cap, \cup \rangle$ is any Boolean algebra, then there exists a certain set U and a set B of subsets of U , closed under the Boolean operations, such that \mathfrak{A} is isomorphic to the Boolean algebra $\mathfrak{B} = \langle B, \emptyset, U, -, \cap, \cup \rangle$. (See [Rasiowa and Sikorski, 1963] for a good presentation of this and related results.) Jónsson and Tarski extend this result to Boolean algebras with operations (that is, functions from A^n to A , for any n). If this does not sound too exciting, wait.

Suppose that U is any non-empty set, and let F be a family of subsets of U closed under the Boolean operations. Let $\mathbf{l}, \mathbf{m} : F \rightarrow F$ be functions satisfying the following conditions:

$$\begin{array}{ll} \text{(l1)} & \mathbf{l}U = U, & \text{(m1)} & \mathbf{m}\emptyset = \emptyset, \\ \text{(l2)} & \mathbf{l}(X \cap Y) = \mathbf{l}X \cap \mathbf{l}Y, & \text{(m2)} & \mathbf{m}(X \cup Y) = \mathbf{m}X \cup \mathbf{m}Y, \\ \text{(lm)} & \mathbf{m}X = U - \mathbf{l}(U - X), & \text{(ml)} & \mathbf{l}X = U - \mathbf{m}(U - X). \end{array}$$

Then, according to Jónsson and Tarski, there exists a uniquely defined binary relation R on U —that is $R \subseteq U \times U$ —such that

$$\begin{array}{ll} \text{(lR)} & \mathbf{l}X = \{x \in U : \forall y(xRy \Rightarrow y \in X)\}, \\ \text{(mR)} & \mathbf{m}X = \{x \in U : \exists y(xRy \& y \in X)\}; \end{array}$$

moreover, of the following conditions, (i1), (i2), and (i3) are mutually equivalent, for $i = r, s, t$:

$$(r1) \quad (\forall X \in F)(\mathbf{l}X \subseteq X),$$

$$(r2) \quad (\forall X \in F)(X \subseteq \mathbf{m}X),$$

- (r3) R is reflexive with field U ;
- (s1) $(\forall X, Y \in F)(Y \cup \mathbf{l}X = U \text{ iff } X \cup \mathbf{l}Y = U)$,
- (s2) $(\forall X, Y \in F)(Y \cap \mathbf{m}X = \emptyset \text{ iff } X \cap \mathbf{m}Y = \emptyset)$,
- (s3) R is symmetric;
- (t1) $(\forall X \in F)(\mathbf{l}X \subseteq \mathbf{l}\mathbf{l}X)$,
- (t2) $(\forall X \in F)(\mathbf{m}\mathbf{m}X \subseteq \mathbf{m}X)$,
- (t3) R is transitive.

Conversely, if R is any binary relation on U , then $(\mathbf{l}R)$ and $(\mathbf{m}R)$ define functions $\mathbf{l}, \mathbf{m} : F \rightarrow F$ such that again (i1), (i2), and (i3) are mutually equivalent, for $i = r, s, t$.

Putting all this together we arrive at the following picture. If we are analysing a class of propositions satisfying certain conditions, then we may try to cast them as an algebra $\mathfrak{B} = \langle B, 0, 1, -, \cap, \cup, \mathbf{l}, \mathbf{m} \rangle$ where $\langle B, 0, 1, -, \cap, \cup \rangle$ is a Boolean algebra and \mathbf{l} and \mathbf{m} are two additional unary operations. (If an element $a \in B$ is taken to represent a proposition, then $\mathbf{l}a$ and $\mathbf{m}a$ would represent the propositions ‘ a is necessary’ and ‘ a is possible’, respectively.) By the representation theorem, there exists a set U such that \mathfrak{B} is isomorphic to an algebra $\mathfrak{A} = \langle A, \emptyset, U, -, \cap, \cup, \mathbf{l}, \mathbf{m} \rangle$, where A is a set of subsets of U and $-, \cap, \cup$ are the usual set theoretical operations. Note that it is not claimed that every subset of U corresponds to a proposition, but that the converse claim is made: to every proposition $a \in B$ a subset $\|a\| \subseteq U$ corresponds. Under the intended interpretation it seems reasonable that \mathbf{l} and \mathbf{m} should satisfy conditions (l1), (l2), (lm) and (m1), (m2), (ml) above. Consequently Jónsson’s and Tarski’s result applies, and so \mathbf{l} and \mathbf{m} are completely determined by a certain binary relation R . Thus \mathfrak{A} is completely determined by U, R , and P , where P is the set of elements $\|P\|$ such that P is an atomic proposition. In this sense, \mathfrak{A} is equivalent to the triple $\langle U, R, P \rangle$. Moreover, in the special case that the closure of P under \mathbf{l} and \mathbf{m} equals $\mathfrak{B}u$, \mathfrak{A} is in the same sense equivalent to the pair $\langle U, R \rangle$. In view of later developments this is a striking result.

The reader is asked to keep the following observations in mind when readings Sections 4 and 10 below: for all $a, b \in B$ and $x \in U$,

$$\begin{aligned}
 x \in \|-a\| & \text{ if } x \notin \|a\|, \\
 x \in \|a \cap b\| & \text{ iff } x \in \|a\| \text{ and } x \in \|b\|, \\
 x \in \|a \cup b\| & \text{ iff } x \in \|a\| \text{ or } x \in \|b\|, \\
 x \in \|\mathbf{l}a\| & \text{ iff } \forall y \in U (xRy \rightarrow y \in \|a\|), \\
 x \in \|\mathbf{m}a\| & \text{ iff } \exists y \in U (xRy \& y \in \|a\|).
 \end{aligned}$$

4 THE MODEL THEORETIC TRADITION

If algebraic semantics is discounted, then Rudolf Carnap was the first to provide a semantics for modal logic. Three of the all time greats came together in him. From Frege he got his interest in semantics and, more specifically, learnt to distinguish between intension and extension; and he attributes to Leibniz the notion that necessity is to be analysed as truth in all possible worlds. Moreover, he credits Wittgenstein with some ideas that formed the starting point for part of his own work (Carnap [1942; 1947]).

By a *state-description* let us understand a set of atomic propositions (propositional letters). If S is a state-description, then we may say what it means that a formula A holds in S , which in symbols we write $\vDash_S A$:

$$\begin{aligned} \vDash_S P &\text{ iff } P \in S, \text{ if } P \text{ is an atomic proposition,} \\ \vDash_S \neg A &\text{ iff not } \vDash_S A, \\ \vDash_S A \wedge B &\text{ iff } \vDash_S A \text{ and } \vDash_S B, \\ \vDash_S A \vee B &\text{ iff } \vDash_S A \text{ or } \vDash_S B, \\ \vDash_S A \rightarrow B &\text{ iff if } \vDash_S A \text{ then } \vDash_S B. \end{aligned}$$

If one is considering a definite collection C of state-descriptions, then also the following conditions become meaningful:

$$\begin{aligned} \vDash_S \Box A &\text{ iff, for all } T \in C, \vDash_T A, \\ \vDash_S \Diamond A &\text{ iff, for some } T \in C, \vDash_T A. \end{aligned}$$

Let us say that a formula is *valid in C* if it holds in every state-description in C , and simply *valid* if it is valid in every collection of state-descriptions. This definition singles out a well-defined subset from the set of all formulas. Interestingly enough, this subset is the same as the set of theses of Lewis' system **S5**. Is this a coincidence? On the surface of it, Carnap's characterisation of **S5** looks very different from the original one due to Lewis.

This still does not look like modern modal logic: possible worlds are missing. According to Hintikka [1975], 'Carnap came extremely close to the basic ideas of possible-worlds semantics, and yet apparently did not formulate them, not even to himself'. This is drawing a very fine line, at least on the level of propositional logic. Carnap does talk about possible worlds. He is quite clear that he wants to latch on to Leibniz' suggestion that a necessary truth is one that holds in all possible worlds. Moreover, he says that his state-descriptions 'represent' possible worlds, which would seem to indicate that the former are (partial) descriptions of the latter. Thus from a formal point of view—Hintikka agrees with this—instead of the collections of state-descriptions that appear in the preceding paragraph, we could just as well have collections of possible worlds, provided only that we find a way of dealing with the first clause in the definition of 'holds in'. One virtue of state-descriptions, not shared by possible worlds, is that it is at once

clear what it means that a given atomic proposition hold in a given state-description. What we need, it seems, is a new primitive to perform this service. This leads us to re-cast Carnap's semantics in the following terms. We call $\langle U, V \rangle$ a *Carnap-model* if U is any set (of *possible worlds*) and V (the *valuation*) is a function assigning to each atomic proposition P and possible world x a truth-value $V(P, x)$ which is either T (truth) or F (falsity). In the definition of 'holds at' the first clause is replaced by this condition:

$$\models_x P \text{ iff } V(P, x) = \text{T, if } P \text{ is an atomic proposition.}$$

The other conditions are changed accordingly. In particular, those concerning the modal formulas become

$$\begin{aligned} \models_x \Box A &\text{ iff } \forall y \in U \models_y A, \\ \models_x \Diamond A &\text{ iff } \exists y \in U \models_y A. \end{aligned}$$

All this is no improvement on Carnap, but it brings us into line with modern terminology. It should be added that the picture of Carnap given here is a pale one since so much of importance in his work is found at the level of predicate logic, which is not considered in this article.

The next step of importance within the semantic tradition was taken by Arthur Prior. both Lewis and Carnap had been concerned with the analysis of modal concepts in the strict sense, but, as remarked in Section 2, some authors have also tried to model concepts which are called modal in the wide sense (imperative, deontic, etc.). The efforts of the latter had been syntactic, but Prior, whose interests lay in temporal notions, gave an algebraic flavoured analysis which in effect was a model theoretic one. In his book, Prior [1957], he models time as the set ω of natural numbers. Thus instead of Carnap models we now meet with structures $\langle \omega, V \rangle$ which we might call *Prior models* and in which the unspecified collection U of possible worlds of a Carnap model $\langle U, V \rangle$ is replaced by the special set ω representing a set of points of time.

With the help of Prior models many new operators are definable. In [Prior, 1957] attention is focused on the operators defined by the conditions

$$\begin{aligned} \models_t \Box A &\text{ iff } \forall u \geq t \models_u A, \\ \models_t \Diamond A &\text{ iff } \exists u \geq t \models_u A. \end{aligned}$$

Later Prior was to consider also the related operators defined by the conditions

$$\begin{aligned} \models_t \Box A &\text{ iff } \forall u > t \models_u A, \\ \models_t \Diamond A &\text{ iff } \exists u > t \models_u A. \end{aligned}$$

There is almost no end to the number of new operators thus definable. Already in [Prior, 1957] one finds conditions like

$$\begin{aligned} \models_t \Box A &\text{ iff } \models_t A \text{ and } \models_{t+1} A, \\ \models_t \Diamond A &\text{ iff } \models_t A \text{ or } \models_{t+1} A; \end{aligned}$$

and later developments have seen a host of others.

Once Prior had shown how to do tense logic, much activity followed. For example, it is natural to study Prior models in which the set ω of natural numbers is replaced by the set ξ of all integers, or the set η of rational numbers, or the set λ of real numbers. Much attention was also devoted to studying the interaction of several temporal and other operators in multi-modal systems. (One among many good references in tense logic is [Rescher and Urquhart, 1971].) Prior's work paved the way for Kamp [1968] where for the first time exact definitions of the notion of tense were offered. For example, according to Kamp, an n -place tense in discrete time is a function f from $(\mathfrak{B}\xi)^n$ to $\mathfrak{B}\xi$; and an n -ary operators \star will express this tense if, for all $t \in \xi$,

$$\models_t \star(A_0, \dots, A_{n-1}) \text{ iff } t \in f(\{u : \models_u A_0\}, \dots, \{u : \models_u A_{n-1}\}).$$

With Kamp [1968] tense logic achieved a new level of sophistication. However, much of the early interest concerned more basic problems, for example, that of characterising the operators defined by the first of the three definitions given above. This logic, the so-called Diodorean logic, is not as strong as **S5**, yet stronger than **S4**, as pointed out by Hintikka, Dummett and others. Its true identity was finally settled by S. A. Kripke and R. A. Bull, independently [Bull, 1965]. For an entertaining account of this, see [Prior, 1967, Chapter 2].

All of this is sorted out in the chapter on tense logic (see the chapter by Burgess in a later volume of this *Handbook*. What is important here is that Prior replaces Carnap's *unordered* set of possible worlds (actually, state-descriptions) by an *ordered* set of possible worlds (actually, points of time). In order to stress this difference we should perhaps have introduced the Prior models as triples $\langle \omega, \leq, V \rangle$, where \leq is the ordinary less-than-or-equal-to ordering of the natural numbers. Thus in retrospect it seems that Carnap and Prior between them supplied all the necessary ingredients for modal logic as we know it at present. Already Jónsson and Tarski had explored the mathematics that is needed, and in Carnap and Prior there was sufficient philosophical underpinning to get modern modal logic going. The modern notion of a model is a triple $\langle U, R, V \rangle$, where U is a set (of *possible worlds*, or, more neutrally, *indices*, or even just *points*), R a binary relation on U (the *accessibility* relation (Geach) or the *alternativeness* relation (Hintikka)), and V a valuation. As we say the elements U and V were contributed by Carnap, and the relation R is obtained by generalising ever so slightly over Prior: instead of working with his special cases, we keep as the one general requirement that R is a binary relation, not necessarily an ordering.

But this is not the way history is usually written. So-called possible worlds semantics or Kripke semantics is commonly attributed to S. A.

Kripke, who laid down the foundations of modern propositional and predicate modal logic in several influential papers (Kripke [1959; 1963; 1963a; 1965]). Relatively less influential were the papers by Jaakko Hintikka and Stig Kanger (Hintikka [1957; 1961; 1963]; Kanger [1957; 1957a; 1957b; 1957c]). Actually the three seem to have been independent of one another; but Kanger published first. Kanger's writings are difficult to decipher, and this fact, paired with the unassuming mode of their publication, may have been what has deprived him of some of the recognition due to him (cf. Hintikka's generous review, [Hintikka, 1969a]). Hintikka has had more impact, especially on the philosophers.

The reason his work has been less important for the formal development of modal logic than that of Kripke is perhaps his style of presentation which tones down mathematical aspects and skips proofs.

5 OTHER TRADITIONS

In the preceding sections we have described what seems to us to be the main developments in early modal logic. no history is ever complete, and starts not recorded here have been made without their developing into what we regard as a major tradition. In this section we will briefly mention five or six such starts.

First there is the so-called provability interpretation(s) of modal logic, the embryo of which is found in [Gödel, 1933]. In view of recent development one may perhaps say that this is expanding into a new tradition right now. Via Montague [1963], Friedman [1975] and Solovay [1976] it has begun to generate a literature of its won. For more information on this, see [Boolos, 1979] and Smoryński's chapter in a later volume of this *Handbook*.

Another start, more suggestive than seminal, was made by J. C. C. McKinsey who described what is now known as McKinsey's syntactic interpretation of modal logic [McKinsey, 1945]; McKinsey's idea was perhaps foreshadowed in Fitch [1937; 1939], it is taken up again in [Morgan, 1979]. A third start was made by Alonzo Church in a series of papers ([1946; 1951; 1973–74]); recent contributions to this area are Parsons [1982] and C. A. Anderson [1980]. (Cf. also his chapter in volume 4 of this *Handbook*.) A fourth start worth mentioning was made with the appearance of Arthur Prior's three-valued modal logic **Q**. many-valued modal logic is not a vast field and in any case mainly falls under what we have called the algebraic tradition, but **Q**, first defined in [Prior, 1957], seems to be of particular philosophical interest; see, for example, [Fine, 1977].

Finally there ought to be a tradition called intuitionistic modal logic, but it is debatable whether today even a subtradition can be found under that heading. Perhaps Ditch [1948], Curry [1950] and Prawitz [1965] can be regarded as starts, but they are not very illuminating as analyses of

modality; and work on semantics has, to date, been in the classical spirit (Bull [1965a], Fischer Servi [1977; 1981]). Why intuitionistically minded logicians have not been attracted to this area is not clear, and surely it would be interesting to see an intuitionistic-logical analysis of knowledge (including extra-mathematical knowledge), obligation, imperative, perception, and other notions which are modal in the wide sense.

Systematic Part

6 LOGICS AND DEDUCIBILITY RELATIONS

In the preceding sections our primary concern has been historical. It is now time to being a more systematic exposition. In this section we will give a number of concepts which are useful when it comes to classifying modal logics. First we give a family of (more or less) traditional definitions, and then we develop similar definitions of a slightly more general nature.

Modal logics are often defined as sets of formulas of a certain kind. One might begin by defining a *logic* as a set \mathbf{L} of formulas satisfying the following conditions:

- (tf) $A \in \mathbf{L}$, whenever A is a tautology in the sense of classical propositional logic;
- (mp) if $A \rightarrow B \in \mathbf{L}$ and $A \in \mathbf{L}$, then $B \in \mathbf{L}$;
- (sb) if $A \in \mathbf{L}$, then $sA \in \mathbf{L}$, if sA is the result of uniform substitution of formulas for propositional letters in A .

Then one might perhaps go on to say that a logic \mathbf{L} is *classical modal* if it contains the formulas

$$\mathbf{K}. \quad \Box(P \rightarrow Q) \rightarrow (\Box P \rightarrow \Box Q),$$

$$*. \quad \Box T,$$

(where P, Q are two propositional letters and T is either primitive or some chosen tautology) and in addition is closed under replacement of tautological equivalents:

- (rte) If A and B are tautologically equivalent and C and C^* are identical except that one occurrence of A in C has been replaced by an occurrence of B to give C^* , then $C \in \mathbf{L}$ iff $C^* \in \mathbf{L}$.

This is a very weak conception of classical modal logic (incidentally, differing from that in [Seegerberg, 1971]), and usually one would require much more, for example, closure under congruence (cgr), monotonicity (mon), or necessitation (nec):

- (cgr) if $A \leftrightarrow B \in \mathbf{L}$, then $\Box A \leftrightarrow \Box B \in \mathbf{L}$;
(mon) if $A \rightarrow B \in \mathbf{L}$, then $\Box A \rightarrow \Box B \in \mathbf{L}$;
(nec) if $A \in \mathbf{L}$, then $\Box A \in \mathbf{L}$.

A modal logic satisfying (cgr) ((mon), (nec)) would be called *congruential (regular, normal)*. Moreover, a modal logic would be *quasi-congruential (quasi-regular, quasi-normal)* if it contained some congruential (regular, normal) modal logic. (A logic containing a classical modal logic is of course itself classical modal.) Notice that normality implies regularity implies congruentiality. If \Box is the only non-Boolean operator, then congruentiality implies replacement of tautological equivalents. (Our terminology is not completely standard, but at least the definitions of ‘logic’, ‘regular’, ‘normal’, and ‘quasi-normal’ appear to be.)

So far tradition. however, there is also a more roundabout way to arriving at similar definitions which begins with deducibility relations instead of with logics. It may be instructive to offer these slightly more general definitions as well. In this paper—and here we offer less than full generality—a *deducibility relation* R is a set of ordered pairs $\langle \Gamma, A \rangle$, where Γ is a set of formulas and A is a formula. If $\langle \Gamma, A \rangle \in R$ we say that Γ *yields* A and write $\Gamma \vdash_R A$, or even $\Gamma \vdash A$ when suppression of the subscript does not lead to confusion. If $\Gamma \vdash A$ and $\Gamma = \emptyset$ we write $\vdash A$ and say that A is a *thesis* of R . The set of theses of R is denoted by $\text{Th } R$. We usually write $A_0, \dots, A_{n-1} \vdash B$ instead of $\{A_0, \dots, A_{n-1}\} \vdash B$; also $A_0, \dots, A_{n-1}, \Gamma \vdash B$ instead of $\{A_0, \dots, A_{n-1}\}, \Gamma \vdash B$. If $A \vdash B$ and $B \vdash A$ we write $A \dashv\vdash B$.

Common conditions on deducibility relations re reflexivity (RX), (left) monotonicity (LM), cut (CUT), and substitutivity (SB):

- (RX) $A \vdash A$;
(LM) if $\Gamma \vdash A$ and $\Gamma \subseteq \Delta$, then $\Delta \vdash A$;
(CUT) if $\Gamma \vdash C$ and $C, \Gamma \vdash A$, then $\Gamma \vdash A$;
(SB) if $\Gamma \vdash A$, then $s\Gamma \vdash sA$, if $s\Gamma$ and sA are the result of uniform substitution in Γ and A , respectively, of formulas for propositional letters.

A deducibility relation is *Boolean* if it also satisfies the conditions in Table 1 (we assume a truth-value functionally complete set of Boolean operators). A deducibility relation is *compact* if, wherever $\Gamma \vdash B$, there are some $A_0, \dots, A_{n-1} \in \Gamma$, for some $n \geq 0$, such that $A_0, \dots, A_{n-1} \vdash B$. Notice that two compact Boolean deducibility relations coincide if they agree on their theses: $\text{Th}R = \text{Th}R'$ implies that $R = R'$.

The concepts defined above for logics may now be given analogous definitions in the context of deducibility relations. first, let us say that a deducibility relation is *n-modal* if

(n -M) if Γ tautologically implies A , then $\Box^n \Gamma \vdash \Box^n \Gamma \Box^n A$, provided that $\Gamma \neq \emptyset$.

Table 1.

(\wedge E)	If $\Gamma \vdash A \wedge B$, then $\Gamma \vdash A$ and $\Gamma \vdash B$.
(\wedge I)	If $\Gamma \vdash A$ and $\Gamma \vdash B$, then $\Gamma \vdash A \wedge B$.
(\vee E)	If $\Gamma \vdash A \vee B$ and $A, \Gamma \vdash C$ and $B, \Gamma \vdash C$, then $\Gamma \vdash C$.
(\vee I)	If $\Gamma \vdash A$ or $\Gamma \vdash B$, then $\Gamma \vdash A \vee B$.
(\rightarrow E)	If $\Gamma \vdash A \rightarrow B$ and $\Gamma \vdash A$, then $\Gamma \vdash B$.
(\rightarrow I)	If $A, \Gamma \vdash B$, then $\Gamma \vdash A \rightarrow B$.
(\neg E)	If $\Gamma \vdash \neg A$ and $\Gamma \vdash A$, then $\Gamma \vdash B$.
(\neg I)	If $A, \Gamma \vdash \neg A$, then $\Gamma \vdash \neg A$.
(RAA)	If $\neg A, \Gamma \vdash A$, then $\Gamma \vdash A$.

(Here $\Box^n A$ is the formula consisting of the formula A preceded by a string of n occurrences of \Box , while $\Box^n \Gamma = \{\Box^n B : B \in \Gamma\}$. Let us say that a Boolean deducibility relation is *modal* if it is 1-modal, and *strongly modal* if it is n -modal for all n .)

Next, let us say that a deducibility relation is *classical* if it is closed under the following condition of replacement under tautological equivalents:

(RTE) If A and B are tautologically equivalent, and C and C^* are identical except that one occurrence of A in C has been replaced by an occurrence of B to give C^* , then $C \dashv\vdash C^*$.

Finally, let us say that a deducibility relation is *congruential* (*regular*, *normal*) if it satisfies (CGR)((SC1), (SC2)):

(CGR) If $A \dashv\vdash B$, then $\Box A \dashv\vdash \Box B$;

(SC1) If $\Gamma \vdash A$, then $\Box \Gamma \vdash \Box A$, provided that $\Gamma \neq \emptyset$;

(SC2) If $\Gamma \vdash A$, then $\Box \Gamma \vdash \Box A$.

(Conditions (SC1) and (SC2) are due to Dana Scott, whence the notation.)

Let us now review the situation. It is readily seen that every Boolean deducibility relation R determines a unique logic, viz. Th \mathbf{R} . Conversely, every logic \mathbf{L} determines a compact Boolean deducibility relation Rel \mathbf{L} in a natural manner: $\Gamma \vdash B$ iff there are $A_0, \dots, A_{n-1} \in \Gamma$, for some $n \geq 0$, such that $((A_0 \wedge \dots \wedge A_{n-1}) \rightarrow B) \in \mathbf{L}$. Note that

$\mathbf{L} = \text{Th Rel } \mathbf{L}$, for every logic \mathbf{L} ,

$\mathbf{R} = \text{Rel Th } \mathbf{R}$, for every compact, Boolean deducibility relation \mathbf{R} .

Moreover, note that if \mathbf{L} is classical modal (and also congruential, regular, or normal, respectively), in the sense of logics, then so is Rel \mathbf{L} , in the sense

of deducibility relations; and if a compact Boolean deducibility relation is classical modal (and also congruential, regular, or normal, respectively), in the sense of deducibility relations, then so is $\text{Th } \mathbf{R}$, in the sense of logics. In view of a preceding remark we know that $\text{Rel } \mathbf{L}$ is the only compact deducibility relation with \mathbf{L} as its set of theses. Therefore, evidently, if, as in this paper, one is only interested in compact deducibility relations, it is harmless to restrict oneself to the study of logics; which is what one has usually done traditionally.

For some recent works in which deducibility is seen as primary, rather than thesishood, see [Scott, 1971; Kuhn, 1977; Shoesmith and Smiley, 1978; Gabbay, 1981; Segerberg, 1982]. Ultimately this approach seems to derive from two quite different sources, Gentzen and Tarski.

7 A CATALOGUE OF MODAL LOGICS

Almost all recent work in modal logic has been concerned with normal logics. At least from a technical point of view, non-normal, regular or quasi-regular logics—a class which includes $\mathbf{S2}$, $\mathbf{S3}$, $\mathbf{S6}$ and $\mathbf{S7}$ —seem to offer little of interest beyond what normal logics offer, and for that reason we will not treat them here but refer the reader to [Kripke, 1965] and [Lemmon, 1957; Lemmon, 1966]. Among logics that are not even quasi-regular, the congruential merit some attention, and in Section 21 below some are implicit. But with this exception the purview of this paper is normal modal logics.

Over the years an almost astronomical number of modal logics have been put forward. Under such circumstances, naming or identifying logics becomes a problem. The best nomenclature is perhaps the one proposed by E. J. Lemmon in [Lemmon, 1977], and here we will usually employ a variant of it. The smallest normal logic we designate by ‘ \mathbf{K} ’ (in honour of Kripke who, curiously enough, seems never to have dealt with this particular logic). If ‘ \mathbf{X}_0 ’, \dots , ‘ \mathbf{X}_{m-1} ’ name any formulas, then ‘ $\mathbf{KX}_0, \dots, \mathbf{X}_{m-1}$ ’ is the *Lemmon code* for the smallest normal logic that contains $\mathbf{X}_0, \dots, \mathbf{X}_{m-1}$. Note that, by definition, this logic is closed under substitution.

Lemmon’s convention presupposes that formulas have names. Here is a list of formulas with names that either are more or less standard, or else in the opinion of the authors deserves to be:

D.	$\Box P \rightarrow \Diamond P,$
T.	$\Box P \rightarrow P,$
4.	$\Box P \rightarrow \Box \Box P,$
E.	$\Diamond P \rightarrow \Box \Diamond P,$
B.	$P \rightarrow \Box \Diamond P,$
Tr.	$\Box P \leftrightarrow P,$
V.	$\Box P,$
M.	$\Box \Diamond P \rightarrow \Diamond \Box P,$
G.	$\Diamond \Box P \rightarrow \Box \Diamond P,$
H.	$(\Diamond P \wedge \Diamond Q) \rightarrow (\Diamond(P \wedge Q) \vee \Diamond(P \wedge \Diamond Q) \vee \Diamond(Q \wedge \Diamond P)),$
Grz.	$\Box(\Box(P \rightarrow \Box P) \rightarrow P) \rightarrow P,$
Dum.	$\Box(\Box(P \rightarrow \Box P) \rightarrow P) \rightarrow (\Diamond \Box P \rightarrow P),$
W.	$\Box(\Box P \rightarrow P) \rightarrow \Box P.$

the following remarks will make it easier to remember these names. ‘**D**’ stands for deontic, ‘**T**’ comes from ‘**t**’, a name invented by Feys, **4** is the characteristic axiom of Lewis’ **S4**, ‘**E**’ stands for Euclidean, ‘**B**’ for Brouwer, ‘**Tr**’ for trivial, ‘**V**’ for *verum*, ‘**M**’ for McKinsey, ‘**F**’ for Geach, ‘**H**’ for Hintikka, ‘**Grz**’ for Grzegorzczuk, ‘**Dum**’ for Dummett, and ‘**W**’ for (anti-)well-ordered. The strangest of these names is perhaps ‘**B**’ for Brouwer, as the father of mathematical intuitionism was never known to harbour much sympathy for logic, let alone modal logic. The name hails back to Oskar Becker who saw a similarity between the logic **KTB** and intuitionistic logic [Becker, 1930].

Of the many logics that can be defined in terms of the above formulas we list the following:

KT = T = the Gödel/Feys/Von Wright system,
KT4 = S4
KT4B = KT4E = S5
KD = deontic T ,
KD4 = deontic S4 ,
KD4E = deontic S5 ,
KTB = the Brouwer system (‘the em Brouwersche system’),
KT4M = S4.1 ,
KT4G = S4.2 ,
KT4H = S4.3 ,
KT4Dum = D = Prior’s Diodorean logic,
KT4Grz = KGrz = Grzegorzczuk’s system,
K4W = KW = Löb’s system,
KTr = KT4BM = the trivial system,
KV = the <i>verum</i> system.

There is no upper bound to the number of normal modal logics, and many—perhaps too many—have found their way into the literature. But the given catalogue includes many of the most studied systems.

If the inconsistent logic, the set of all formulas, is accepted as a normal modal logic—and under the definition given here it must be—then the set of all normal modal logics forms a distributive lattice under the operations g.l.b. $(\mathbf{L}, \mathbf{L}') =$ the greatest normal logic to be contained in both \mathbf{L} and \mathbf{L}' (which is the same as $\mathbf{L} \cap \mathbf{L}'$) and l.u.b. $(\mathbf{L}, \mathbf{L}') =$ the smallest normal logic to extend both \mathbf{L} and \mathbf{L}' (which is *not* the same as $\mathbf{L} \cup \mathbf{L}'$). Much effort has gone into exploring the nature of this enormously complicated lattice. Early contributions were made by Scroggs who mapped out all the extensions of **S5** [Scroggs, 1951]; by Bull who did the same for the extensions of **S4.3** [Bull, 1966]; by Makinson who showed that the trivial system and the *verum* system are the two dual atoms of this lattice [Makinson, 1971]; and by McKinsey and Tarski who showed that there are non-normal extensions of **S4** [McKinsey and Tarski, 1948]. Kit Fine and Wim Block have done more than anyone else to complete the picture, and some of their work is described below. Schumm [1981] sums up some of the things that are known about the elements of the big lattice. Readers interested in the geography of modal logic are also referred to Hansson and Gärdenfors [1973].

8 SEMANTIC TABLEAUX AND HINTIKKA SYSTEMS

The deductive systems given in the preceding sections are of so-called Hilbert type, strict on rules and soft on axioms. Most of the deductive systems in the modal logic literature are of this type. From a metamathematical point of view such systems have much to offer. But if one's interest lies in proving theorems *in* a system rather than *about* it, then they are not terribly accommodating. Yet in modal logic they have had relatively little competition from other kinds of deductive systems. The most common system of a different kind is no doubt the procedure due to Hintikka and Kripke (similar ideas in a less developed form are found in [Guillaume, 1958]). Hintikka's work on model system [1957; 1961; 1962; 1963] and Kripke's on semantic tableaux [1963; 1963a] were independent, and even though the two methods are equivalent they are not identical. It would take us too far here to discuss both, and here we will follow Hintikka. For classical logic the general references are the classic works [Beth, 1959] and [Hintikka, 1955] as well as the later monograph [Smullyan, 1968]. an elementary and particularly readable account is given in [Jeffrey, 1990].

We define a set Σ of formulas as *downward saturated* if it satisfies the following conditions:

- (C \neg) If $\neg A \in \Sigma$, then $A \notin \text{Sigma}$.
- (C \wedge) If $A \wedge B \in \Sigma$, then $A \in \Sigma$ and $B \in \text{Sigma}$.
- (C \vee) If $A \vee B \in \Sigma$, then $A \in \Sigma$ or $B \in \Sigma$,
- (C \rightarrow) If $A \rightarrow B \in \Sigma$, then $A \in \Sigma$ only if $B \in \Sigma$.
- (C $\neg\neg$) If $\neg\neg A \in \Sigma$, then $A \in \Sigma$.
- (C $\neg\wedge$) If $\neg(A \wedge B) \in \Sigma$, then $\neg A \in \Sigma$ or $\neg B \in \Sigma$.
- (C $\neg\vee$) If $\neg(A \vee B) \in \Sigma$, then $\neg A \in \Sigma$ and $\neg B \in \Sigma$.
- (C $\neg\rightarrow$) If $\neg(A \rightarrow B) \in \Sigma$, then $A \in \Sigma$ and $\neg B \in \Sigma$.

The seven last conditions define an effective procedure: given any finite set Σ it is possible to add a finite number of new formulas to it to obtain a set Σ^* which satisfies all the conditions except perhaps (C \neg); this would be to *embed* Σ in Σ^* . Notice that Σ^* is downwards saturated only if also (C \neg) holds. The latter condition is evidently of a different character from the others: they *prescribe* membership under *some* conditions, whereas (C \neg) *proscribes* it under *all*. That is to say, (C \neg) is a consistency condition.

We are now able to define a deducibility relation as follows: $\Gamma \vdash B$ if and only if the set $\Gamma \cup \{\neg B\}$ cannot be embedded in a downwards saturated set. Specifically, if Γ is finite,

- (*) $A_0, \dots, A_{n-1} \vdash B$ iff, for every downwards saturated set Σ ,
if $A_0, \dots, A_{n-1} \in \Sigma$, then $\neg B \notin \Sigma$.

The reason this deducibility relation is of interest is that it coincides with classical logic: $\Gamma \vdash A$ iff Γ tautologically implies A . Furthermore, by the compactness theorem of classical propositional logic, $\Gamma \vdash B$ only if for some $n \geq 0$ and some $A_0, \dots, A_{n-1} \in \Gamma$ we have $A_0, \dots, A_{n-1} \vdash B$.

The question arises, how to extend this analysis to modal logic. From a syntactic point of view, all that would be needed is two additional rules, (C \Box) and (C $\neg\Box$) of a similar kind. By ‘similar’ is meant that the rules would have to be such that the Augmented set of rules would again define a (not necessarily effective) procedure. It turns out that in order to do this we have to widen the perspective. What both Hintikka and Kripke did was to consider not just downward saturated sets (respectively, semantic tableaux) but systems of such sets (respectively, tableaux). Let us call a triple $\langle \Sigma_0, U, R \rangle$ a *Hintikka system* if the following is true. First, U is a set of downward saturated sets of which Σ_0 is one; and R is a binary relation over U (called the *alternativeness relation* by Hintikka) which generates U from Σ_0 in the sense that, for each $\Sigma \in U$, there are some sets $\Sigma_1, \Sigma_2, \dots, \Sigma_k \in U$, for some $k \geq 0$, such that $\Sigma_i R \Sigma_{i+1}$, for all $k < k$, and $\Sigma_k = \Sigma$. Second, for every $\Sigma \in U$ the following conditions are satisfied:

- (C \Box) If $\Box A \in \Sigma$, then $A \in \Sigma'$, for all $\Sigma' \in U$ such that $\Sigma R \Sigma'$.
- (C $\neg\Box$) If $\neg\Box A \in \Sigma$, then $\neg A \in \Sigma'$, for some $\Sigma' \in U$ such that $\Sigma R \Sigma'$.

We are now able to define a deducibility relation for modal logic: $\Gamma \vdash A$ iff the set $\Gamma \cup \{\neg A\}$ cannot be embedded in a Hintikka system (in the obvious sense: there is no Hintikka system $\langle \Sigma_0, U, R \rangle$ such that $\Gamma \cup \{\neg A\} \subseteq \Sigma_0$). As Hintikka and Kripke proved (and, in effect, Kanger had proved before them), the deducibility relation thus introduced will coincide with the famous modal logics **T**, **S4**, and **S5**, respectively, if special conditions are placed on the alternativeness relation, viz. reflexivity; reflexivity and transitivity; reflexivity, transitivity, and symmetry; respectively. These are no doubt the most celebrated of all results in modal logic, and much of the success of the new semantics is probably due to the fact that the three most important systems of modal logic can be given such a simple characterisation in these new terms. Other conditions than those mentioned can also be considered, and it turns out that for practically all systems in the literature that have been proposed for their philosophical virtues, a similar model theoretic characterisation is possible.

What we have so far is just a procedure. Primarily it is a disproof procedure (successful if an appropriate Hintikka system is found). Secondly it is also (the beginning of) a proof procedure (successful if it can be shown that no appropriate Hintikka system can be found). In general neither procedure need be effective, though, for the new rule ($C-\Box$) may introduce new formula sets, and the implicit procedure may therefore not terminate. In other words, given some conditions on the alternativeness relation and formulas A_0, \dots, A_{n-1}, B , there is no guarantee that one will ever be able to settle the question whether $A_0, \dots, A_{n-1} \vdash B$ (even though, as it turns out, in many cases such a guarantee can be given).

From a philosophical point of view it should be noted that what we have above is not yet a semantics in any but a combinatorial sense of the word. As in the case of Carnap—there is of course a close connection between state-descriptions and a downward saturated set—a real semantics is obtained if possible worlds are postulated and downward saturated sets are identified as partial descriptions of them.

We shall append two observations which are of some interest. Let us say that a set of formulas is *upward saturated* if the converses of the above C -conditions for the classical operators are satisfied, and *maximal consistent* if it is saturated both upward and downward. The first observation is a familiar one: we again get classical propositional logic by stipulating that $\Gamma \vdash B$ iff $\Gamma \cup \{\neg B\}$ cannot be embedded in a maximal consistent set. Specifically, if Γ is finite,

(§) $A_0, \dots, A_{n-1} \vdash B$ iff, for every maximal consistent set Σ , if $A_0, \dots, A_{n-1} \in \Sigma$, then $B \in \Sigma$.

This statement, which is nothing but the famous Lindenbaum's Lemma, should be compared to (*) above.

Suppose now that we call a set $\langle \Sigma_0, U, R \rangle$ of maximal consistent sets a *Henkin system* if U is a set of maximal consistent sets of which Σ_0 is one, and R is a binary relation on U such that $(C\Box)$ and $(C\neg\Box)$ as well as their converses are satisfied by every $\Sigma \in U$. Then once again we get a deducibility relation by stipulating that $\Gamma \vdash A$ iff $\Gamma \cup \{\neg A\}$ cannot be embedded in a Henkin system (in the obvious sense: there is no Henkin system $\langle \Sigma_0, U, R \rangle$ such that $\Gamma \cup \{\neg A\} \subseteq \Sigma_0$). This suggests the second observation, viz. that the relation between downward saturated sets and maximal consistent sets in classical logic is, in some sense, the same as that between Hintikka systems and Henkin systems in modal logic. In fact, Henkin systems have been more used than Hintikka systems in the study of modern modal logic. They were introduced independently by Makinson [1966], Cresswell [1967], Schütte [1968] and perhaps others. Dana Scott had similar ideas a little earlier and exerted a powerful influence even though he did not publish; cf. Kaplan [1966] and Lemmon [1966; 1977]. Another early reference in this context is [Bayart, 1959].

9 NATURAL DEDUCTION IN MODAL LOGIC

Seen in a grand perspective, the Hintikka/Kripke deductive technique is an extension to modal logic of ideas introduced into the study of classical logic by P. Hertz and G. Gentzen. However, some have proposed a more straightforward extension of those ideas. In this section we will consider to what extent such an effort is likely to succeed.

Perhaps the most important work in the latter tradition is Prawitz [1965]. We will begin by giving a standard system of natural deduction for classical propositional logic which is similar to one found there. First there are the *inference rules* listed in Table 2. here ‘E’ and ‘I’ stand for ‘elimination’ and ‘introduction’ respectively, while ‘RAA’ is short for ‘*reductio ad absurdum*’.

Next we should give the *deduction rules*, that is, rules which legislate how inference rules may be used to produce deductions. But deduction rules are cumbersome to state in full detail. Therefore we will make a short-cut. (Readers who are led astray by this short-cut should consult [Prawitz, 1965].)

As usual, $\Gamma \vdash A$ is defined to mean that there is a deduction where A is the conclusion (‘the bottom formula’) and where Γ contains all premises (‘undischarged top formulas’). It is immediate that the deducibility relation \vdash will satisfy the common conditions (RX), (LM), (CUT), and (SB) defined in Section 6. Now we declare—this is the short-cut—that the deduction rules are exactly what it takes to make certain that the conditions of Table 1 of the same section to be satisfied; thus \vdash is a Boolean deducibility relation. Notice that there is a one-to-one correspondence between the conditions of Table 1 and the inference rules of Table 2. In order to stress the connection we have used the same name for both condition and inference rule: in effect

Table 2.

$(\wedge E) \quad \frac{A \wedge B}{A} \quad \frac{A \wedge B}{B} \quad (B)$	$(\wedge I) \quad \frac{A \quad B}{A \wedge B}$
$(\vee E) \quad \frac{A \vee B \quad C \quad C}{c}$	$(\vee I) \quad \frac{A}{A \vee B} \quad \frac{B}{A \vee B}$
$(\rightarrow E) \quad \frac{A \rightarrow B \quad A}{B}$	$(\rightarrow I) \quad \frac{(A) \quad B}{A \rightarrow B}$
$(\neg E) \quad \frac{\neg A \quad A}{B}$	$(\neg I) \quad \frac{(A) \quad \neg A}{\neg A}$
	$(RAA) \quad \frac{(\neg A) \quad A}{A}$

the condition explains how the inference rule is to be applied. This is needed, especially in the case of the so-called improper inference rules, that is, those containing parentheses: $(\vee E)$, $(\rightarrow I)$, $(\neg I)$, (RAA) . What is at issue here is on exactly what premises a conclusion *depends*, and this can be gathered from the observations.

The interest in the system thus presented is that the deducibility relation it defines coincides with that of classical logic: $\Gamma \vdash A$ iff Γ tautologically implies A . In order to generalise it to modal logic, the most direct course is to try and devise rules for \Box of the same kind as those governing the classical operators; in other words, to force the classical pattern on the modal operator. Thus one elimination and one introduction rule are called for, and their form is obvious:

$$(\Box E) \quad \frac{\Box A}{A} \quad (\Box I) \quad \frac{A}{\Box A}$$

This is what Prawitz does. He considers $(\Box E)$ a proper rule, which means that

$$(\Box E) \quad \text{If } \Gamma \vdash \Box A, \text{ then } \Gamma \vdash A.$$

By contrast, $(\Box I)$ is very much improper: taking it as a proper rule would literally trivialise modal logic. That is, if one accepts

$$(\Box I) \quad \text{If } \Gamma \vdash A, \text{ then } \Gamma \vdash \Box A,$$

then the resulting deducibility relation coincides with the trivial system defined in Section 7. Thus in all interesting cases the deduction rule for $(\Box I)$ will have to contain some proviso if the trivial system is to be avoided. Prawitz discusses two possibilities. In one case every premise must be of the form $\Box A$, in the other of the form either $\Box A$ or $\neg\Box A$. If we adopt the convention according to which $\star^n\Sigma = \{\star^n A : A \in \Sigma\}$, where \star is any unary propositional operator, then we can give Prawitz's rules the following formulation:

$(\Box I)_{S4}$ If $\Gamma \vdash A$, then $\Gamma \vdash \Box A$, provided that, for some set Δ , $\Gamma = \Box\Delta$.

$(\Box I)_{S5}$ If $\Gamma \vdash A$, then $\Gamma \vdash \Box A$, provided that, for some sets Δ_0 and Δ_1 , $\Gamma = \Box\Delta_0 \cup \neg\Box\Delta_1$.

The indexing of the rules is not fortuitous: Prawitz's two systems really coincide with Lewis' **S4** and **S5**. However, it has proved difficult to extend this sort of analysis to the great multitude of other systems of modal logic. It seems fair to say that a deductive treatment congenial to modal logic is yet to be found, for Hilbert systems are not suited for the purpose of actual deduction, and in Hintikka/Kripke systems the alternativeness relation introduces an alien element which, moreover, can become quite unmanageable in special cases.

The situation has given rise to various suggestions. One is that the Gentzen format, which works so well for truth-functional operators, should not be expected to work for intensional operators, which are far from truth-functional. (But then Gentzen works well for intuitionistic logic which is not truth-functional either.) Another suggestion is that the great proliferation of modal logics is an epidemic from which modal logic ought to be cured: Gentzen methods work for the important systems, and the other should be abolished. 'No wonder natural deduction does not work for unnatural systems!' We will now present a deductive system which explores a third alternative: trying to achieve generality at the expense of modifying the Gentzen format (there will be no special E- or I-rules for \Box). As far as we know, this system is new; there is a forerunner for some special cases in Segerberg [Segerberg, 1989].

Let us begin by trying to learn from the success of the Hintikka/Kripke venture. This success can perhaps be attributed to a certain division of labour: in Hintikka systems of downward saturated sets the classical conditions govern the relationship between the sets. How can this feature be imitated in the setting of natural deduction? The crux of the matter seems to be that any classically valid argument should remain valid *in any modal context*; the difficulty is to explicate the italicised phrase. The solution seems to be to require that whenever Γ tautologically implies A , then also $\Box^n\Gamma \vdash \Box^n A$. This condition we recognise from Section 6 where it was introduced as the condition that the deducibility relation be strongly modal.

The condition of strong modality may of course be adopted as a new rule in a sequent formulation of our logic. But as a proof-theoretic analysis such a move would not go very far: sequent theories, it would appear, are most naturally understood as meta-logics (theories about deductive systems). However that may be, here is the promised system. First there are the *inference rules* list in Table 3. For each rule in the old system there are now infinitely many rules. It is almost as if each power of \Box would be an independent operator. As before, we do not state the *deduction rules* but are content to make a number of observations from which they can be reconstructed. We introduce the convention

$${}^n\sqrt{\Gamma} = \{A : \Box^n A \in \Gamma\}.$$

Table 3.

	$\frac{\Box^n(A \wedge B)}{\Box^n A}$	$\frac{\Box^n(A \wedge B)}{\Box^n B}$		$(\wedge I)^n$	$\frac{\Box^n A \Box^n B}{\Box^n(A \wedge B)}$
$(\wedge E)^n$		$(a)_n \quad (b)_n$			
	$\frac{\Box^n(A \vee B)}{\Box^n B}$	$\frac{C \quad C}{\Box^n B}$		$(\vee I)^n$	$\frac{\Box^n A \quad \Box^n B}{\Box^n(A \vee B)}$
	$\frac{\Box^n(A \rightarrow B) \Box^n A}{\Box^n B}$			$(\rightarrow I)^n$	$\frac{(A)_n \quad B}{\Box^n(A \rightarrow B)}$
$(\rightarrow E)^n$				$(\neg I)^n$	$\frac{(A)_n \quad \neg A}{\Box^n \neg A}$
	$\frac{\Box^n(\neg A) \Box^n A}{\Box^n B}$				
$(\neg E)^n$				$(RAA)^n$	$\frac{(\neg A)_n \quad A}{\Box^n A}$

Notice that the new rules (Table 3) have ‘ $()_n$ ’, where the old (Table 2) have ‘ $()$ ’. this new notation also is explained by the observations listed in Table 4. It is easy to check that the deducibility relation defined by this system is classical if \Box is the only non-Boolean operator. Nor is it difficult to prove that it also satisfies Scott’s Rule (SC2): if $\Gamma \vdash A$, then $\Box \Gamma \vdash \Box A$. In fact, the system coincides with the minimal normal system \mathbf{K} .

The given system looks more complicated than the Hilbert type formulation of \mathbf{K} in Section 6. But for deductive purposes it may be an alternative. If one would like to general modal logic within this framework, different logics would have to be characterised by special axioms. This means giving up the idea of finding characteristic rules for those systems. This is perhaps

Table 4.

$(\wedge E)^n$	If $\Gamma \vdash \Box^n(A \wedge B)$, then $\Gamma \vdash \Box^n A$ and $\Gamma \vdash \Box^n B$.
$(\wedge I)^n$	If $\Gamma \vdash \Box^n A$ and $\Gamma \vdash \Box^n B$, then $\Gamma \vdash \Box^n(A \wedge B)$.
$(\vee E)^n$	If $\Gamma \vdash \Box^n(A \vee B)$ and ${}^n\sqrt{\Gamma}, A \vdash C$ and ${}^n\sqrt{\Gamma}, B \vdash C$, then $\Gamma \vdash \Box^n C$.
$(\vee I)^n$	If $\Gamma \vdash \Box^n A$ or $\Gamma \vdash \Box^n B$, then $\Gamma \vdash \Box^n(A \vee B)$.
$(\rightarrow E)^n$	If $\Gamma \vdash \Box^n(A \rightarrow B)$ and $\Gamma \vdash \Box^n A$, then $\Gamma \vdash \Box^n B$.
$(\rightarrow I)^n$	If ${}^n\sqrt{\Gamma}, A \vdash B$, then $\Gamma \vdash \Box^n(A \rightarrow B)$.
$(\neg E)^n$	If $\Gamma \vdash \Box^n(\neg A)$ and $\Gamma \vdash \Box^n A$, then $\Gamma \vdash \Box^n B$.
$(\neg I)^n$	If ${}^n\sqrt{\Gamma}, A \vdash \neg A$, then $\Gamma \vdash \Box^n \neg A$.
$(RAA)^n$	If ${}^n\sqrt{\Gamma}, \neg A \vdash A$, then $\Gamma \vdash \Box^n A$.

a price worth paying, for—as remarked before—only exceptional systems would seem to be characterisable in terms of reasonably simple rules.

The same point can perhaps be put in the following way. When we go to systems of traditional modal logic stronger than \mathbf{K} , we should like to preserve classicalness, usually also Scott's Rule. The best way to do this appears to be to add more in the way of axioms rather than rules. In this manner, modal propositional logics become a bit like theories of ordinary predicate logic. Let Σ be any set of modal formulas closed under substitution (that is, $A^* \in \Sigma$ whenever A^* is a substitution instance of some $A \in \Sigma$). Then we define $\mathbf{L}(\Sigma)$ as the logic got by adopting Σ as a set of new axioms: $\Gamma \vdash A$ in $\mathbf{L}(\Sigma)$ iff $\Gamma \cup \Sigma \vdash A$ in the basic system. It is obvious that $\mathbf{L}(\Sigma)$ will always be classical. Moreover, if Σ is closed also under necessitation (that is, if $\Box \Sigma \subseteq \Sigma$), then $\mathbf{L}(\Sigma)$ is a normal logic. In this fashion we preserve more of the Gentzen/Prawitz flavour than the Hintikka/Kripke procedure does, while retaining full generality.

10 MODAL ALGEBRAS, FRAMES, GENERAL FRAMES

The sections which follow survey the mainstream of technical modal logic. It is felt that the major results have been fairly represented. However, the selection of secondary results has been decidedly subjective, and another writer might well have chosen different topics. The best unified and detailed presentation in the area is [Goldblatt, 1976], which extends his PhD thesis of 1974 to account for the work of other logicians of that period. A good picture of an earlier stage is given in [Seegerberg, 1971]. The startling difference of content between these two 'monographs' reflects the great increase of mathematical sophistication in technical modal logic at that time. This trend was led by Kit Fine, S. K. Thomason and R. I. Goldblatt. A more recent exploitation of algebra in the work of W. J. Blok will not be discussed in detail in this survey.

A *modal algebra* $\mathfrak{A} = \langle A, 0, 1, -, \cap, \cup, \mathbf{l}, \mathbf{m} \rangle$ consists of a set A including 0 and 1, with functions $-, \cap, \cup, \mathbf{l}, \mathbf{m}$ on it which satisfies the conditions that $\langle A, -, 1, -, \cap, \cup \rangle$ is a Boolean algebra and

$$\mathbf{l}1 = 1, \mathbf{l}(a \cap b) = \mathbf{l}a \cap \mathbf{l}b, \mathbf{m}a = -\mathbf{l} - a,$$

or, equivalently, that

$$\mathbf{m}0 = 0, \mathbf{m}(a \cup b) = \mathbf{m}a \cup \mathbf{m}b, \mathbf{l}a = -\mathbf{m} - a.$$

A valuation v on \mathfrak{A} is a function from the propositional formulas to the elements of the algebra which satisfies the conditions

$$\begin{aligned} v(\neg A) &= -v(A), \\ v(A \wedge B) &= v(A) \cap v(B), \\ v(A \vee B) &= v(A) \cup v(B), \\ v(\Box A) &= \mathbf{l}v(A), \\ v(\Diamond A) &= \mathbf{m}v(A). \end{aligned}$$

An algebraic ‘model’ $\langle \mathfrak{A}, v \rangle$ is a modal algebra with a valuation on it, and A is true or verified in this ‘model’ iff $v(A) = 1$. A formula is true in a modal algebra iff it is true in all ‘models’ on that algebra (cf. Section 3).

A *frame* $\mathfrak{F} = \langle W, R \rangle$ consists of a set W and a binary relation R on W . A valuation V on \mathfrak{F} is a function such that $V(A, x) \in \{T, F\}$ for each propositional formula A and $x \in W$, which satisfies the conditions

$$\begin{aligned} V(\neg A, x) &= T \text{ iff } V(A, x) = F, \\ V(A \wedge B, x) &= T \text{ iff } V(A, x) = T \text{ and } V(B, x) = T, \\ V(A \vee B, x) &= T \text{ iff } V(A, x) = T \text{ or } V(B, x) = T, \\ V(\Box A, x) &= T \text{ iff } \forall y(xRy \rightarrow V(A, y) = T), \\ V(\Diamond A, x) &= T \text{ iff } \exists y(xRy \wedge V(A, y) = T). \end{aligned}$$

A model $\langle \mathfrak{F}, V \rangle$ is a frame with a valuation on it, and A is satisfied in it iff

$$V(A, x) = T \text{ for some } x \in W,$$

and is true or verified in it iff

$$V(A, x) = T \text{ for each } x \in @.$$

A formula is true or verified in a frame iff it is true in all models on that frame. (Cf. Section 4.)

A modal logic is *normal* iff it includes all tautologies and the axiom

$$\vdash \Box(P \rightarrow Q) \rightarrow (\Box P \rightarrow \Box Q),$$

and is closed under the rules of substitution for variables, modus ponens, and necessitation,

$$\text{if } \vdash A \text{ then } \vdash \Box A.$$

An alternative to this axiom and necessitation is to take

$$\begin{aligned} &\vdash \Box(P \rightarrow P) \\ &\vdash (\Box P \wedge \Box Q) \rightarrow \Box(P \wedge Q) \end{aligned}$$

and the rule

$$\text{if } \vdash A \rightarrow B \text{ then } \vdash \Box A \rightarrow \Box B,$$

from which

$$\vdash \Box(P \wedge Q) \rightarrow (\Box P \wedge \Box Q)$$

is derivable. (Cf. Section 6.) The minimal normal modal logic is called **K**, and its formulas are true in every modal logic and frame. Well-known formulas which are true in every modal algebra satisfying a corresponding equation, and every frame satisfying a corresponding first-order condition on its relation, are shown in Table 5. Here $a \leq b$ is an abbreviation for $a \cap b = a$ or $a \cup b = b$. It is convenient to label the extension of **K** with certain axioms by concatenating **K** with their labels, so that the extension of **K** with **T** and **4** is **KT4**, except that **KT** has usually been replaced by **S**. (Cf. Section 7.) Note that the modal algebras verifying **S4** satisfy $\mathbf{1}a \leq$ and $\mathbf{1}a = \mathbf{1}a$, being the closure algebras or interior algebras of McKinsey and Tarski [1944].

When added to **K4**, the formulas in Table 4 are true in every transitive frame satisfying the corresponding condition on its relation. (Here the condition for **·3** is known as connectedness, and the condition for **M** asserts that after each point x there is a ‘second last’ point y .) (Of these formulas, **M** was introduced in [McKinsey, 1945], **·3** in [Dummett and Lemmon, 1959], and **Grz** in [Sobinciński, 1964], where it is shown that **T** and **M** are derivable in **K4G4z**. In fact **4** is derivable in **KGrz** by [van Benthem and Blok, 1978].)

A frame $\mathfrak{F} = \langle W, R \rangle$ determines a modal algebra \mathfrak{F}^+ with carrier $\mathfrak{B}(W)$, where $0 = \emptyset$ and $1 = W$, $-, \cap, \cup$ are the usual set-theoretic operations, $\mathfrak{B}(W)$ is the set of subsets of W , and

$$\begin{aligned} \mathbf{1}_R a &= \{x : \forall y (xRy \rightarrow y \in a)\}, \\ \mathbf{m}_R a &= \{x : \exists y (xRy \wedge y \in a)\}. \end{aligned}$$

Writing $v(A)$ for $\{x : V(A, x) = T\}$, each valuation V on \mathfrak{F} determines a subset $\{v(A) : A \text{ a formula}\}$ of $\mathfrak{B}(W)$. This subset is in fact the carrier of a subalgebra of \mathfrak{F}^+ . For many purposes this is the most important point of a valuation, so that it is often preferable to consider *general frames* $\langle W, R, P \rangle$, where P is the carrier of a subalgebra of $\langle W, R \rangle^+$. A formula is true or verified in a general frame $\langle W, R, P \rangle$ iff it is true in each model $\langle W, R, V \rangle$ for which v is a function into P . (General frames were introduced in [Thomason, 1972], though they are foreshadowed in [Makinson, 1970] and in the secondary models of [Bull, 1969; Fine, 1970] and [Kaplan, 1970] for modal

logics with propositional quantifiers.) The construction $^+$ can be extended to general frames $\mathfrak{F} = \langle W, R, P \rangle$ by taking the carrier of \mathfrak{F}^+ to be P instead of $\mathfrak{B}(W)$.

Table 5.

Label	Formula	Equation	Condition on R
T	$\Box P \rightarrow P$	$\mathbf{1}a \leq a$	$\forall x(xRx)$
B	$\Diamond \Box P \rightarrow P$	$\mathbf{m}1a \leq a$	$\forall x \forall y (xRy \rightarrow yRx)$
4	$\Box P \rightarrow \Box \Box P$	$\mathbf{1}a \leq \mathbf{1}1a$	$\forall x \forall y \forall z ((xRy \wedge yRz) \rightarrow xRz)$

Table 6.

Label	Formula	Condition on R
3	$\Box(\Box P \rightarrow \Box Q) \vee \Box(\Box Q \rightarrow \Box P)$	$\forall x \forall y \forall z ((xRy \wedge xRz) \rightarrow (yRz \vee zRy))$
M	$\Box \Diamond P \rightarrow \Diamond \Box P$	$\forall x \exists y (xRy \wedge \forall z \forall w ((yRz \wedge yRw) \rightarrow z = -w))$
Grz	$\Box(\Box(P \rightarrow \Box P) \rightarrow P) \rightarrow P$	There is no infinite chain x_0, x_1, x_2, \dots with $x_i R x_{i+1}$ and $x_i \neq x_{i+1}$, for all i .

A modal algebra \mathfrak{A} determines a general frame $\mathfrak{A}_+ = \langle W_{\mathfrak{A}}, R_{\mathfrak{A}}, P_{\mathfrak{A}} \rangle$, where $W_{\mathfrak{A}}$ is the set of ultrafilters of \mathfrak{A} ,

$$xR_{\mathfrak{A}}y \text{ iff } \forall a(a \in y \rightarrow \mathbf{m}a \in x)$$

or, equivalently,

$$\begin{aligned} xR_{\mathfrak{A}}y \text{ iff } & \forall a(\mathbf{1}a \in x \rightarrow a \in y), \\ P_{\mathfrak{A}} = & \{ \{x : a \in x\} : a \in A \}, \end{aligned}$$

i.e. for each element of the modal algebra we take the set of ultrafilters x containing it. (The filters of \mathfrak{A} are the subsets F of A which satisfy the conditions

$$\begin{aligned} & 1 \in F \text{ and not } 0 \in F, \\ & \text{if } a, b \in F \text{ then } a \cap b \in F, \\ & \text{if } a \in F \text{ and } a \leq b \text{ then } b \in F, \end{aligned}$$

and the ultrafilters F also satisfy

$$\text{for each } a \in A, \text{ either } a \in F \text{ or } -a \in F$$

(note that also not both $a \in F$ and $-a \in F$.) Here we write $\mathfrak{A}_{\#}$ for the underlying frame $\langle W_{\mathfrak{A}}, R_{\mathfrak{A}} \rangle$. Note that if \mathfrak{A} is finite then $P_{\mathfrak{A}}$ is $\mathfrak{B}(W_{\mathfrak{A}})$, and \mathfrak{A}_+ and $\mathfrak{A}_{\#}$ coincide.

Clearly a formula is true in a model $\langle \mathfrak{F}, V \rangle$ iff it is true in the algebraic ‘model’ $\langle \mathfrak{F}^+, v \rangle$ and hence true in \mathfrak{F} iff it is true in \mathfrak{F}^+ , since they have the same valuations. It can also be shown that a formula is true in an algebraic ‘model’ $\langle \mathfrak{A}, v \rangle$ iff it is true in $\langle \mathfrak{A}_\sharp, V \rangle$, where

$$V(A, x) = T \text{ iff } v(A) \in x.$$

(These constructions and results are due to Lemmon [1966], though they would also have been easy consequences of [Jónsson and Tarski, 1951].) In fact, each modal algebra \mathfrak{A} is isomorphic to $(\mathfrak{A}_+)^+$ by similar arguments. Let us consider the properties of \mathfrak{A}_+ . A set $X \subseteq A$ has the f.i.p. (finite intersection property) iff

$$a_1 \cap \dots \cap a_n \neq 0, \text{ for each } a_1, \dots, a_n \in X.$$

Each set X with the f.i.p. can easily be extended to a filter, which can in turn be extended to a maximal filter by Zorn’s Lemma. Conversely each subset of a filter has the f.i.p. As a lemma, if X has the f.i.p. but $X \cup \{-a\}$ does not, then $a \in F$, for each filter F with $X \subseteq F$. It follows immediately that each maximal filter is an ultrafilter. As a second lemma following from the first, $b \in F$, for each ultrafilter F with $X \subseteq F$, iff

$$a_1 \cap \dots \cap a_n \leq b, \text{ for some } a_1, \dots, a_n \in X.$$

In both the results above we are concerned with the function $\phi : A \rightarrow P_{\mathfrak{A}}$ with

$$\phi(a) = \{F : F \text{ an ultrafilter on } \mathfrak{A} \text{ with } a \in F\}.$$

The crucial point is to show that

$$\exists G(FR_{\mathfrak{A}}G \wedge G \in \phi(a)) \text{ iff } F \in \phi(\mathbf{m}a),$$

in order to establish the properties of $V(\Diamond A, x)$ on \mathfrak{A}_+ , and the properties of $\mathbf{m}_{R_{\mathfrak{A}}}$ in $(\mathfrak{A}_+)^+$. This is immediate from left to right, using the definition

$$FR_{\mathfrak{A}}G \text{ iff } \forall b(b \in G \rightarrow \mathbf{m}b \in F).$$

Going from right to left, suppose that the left-hand side is false, so that

$$\forall G(FR_{\mathfrak{A}}G \rightarrow -a \in G),$$

for the ultrafilter F . Using the alternative definition

$$FR_{\mathfrak{A}}G \text{ if } \forall b(\mathbf{l}b \in F \rightarrow b \in G)$$

and taking $X = \{b : \mathbf{l}b \in F\}$, each ultrafilter G with $X \subseteq G$ has $-a \in G$. Applying the second lemma above to X it is easy to show that $\mathbf{l}(-a) \in F$, and hence not $F \in \phi(\mathbf{m}a)$, as required.

However, $(\mathfrak{F}^+)_+$ is not in general ‘isomorphic’ to \mathfrak{F} , for a general frame \mathfrak{F} . Therefore we need a subclass of the general frames which will include all the general frames \mathfrak{A}_+ and be closed under this pair of operations. In the terminology of [Goldblatt, 1976], given a general frame $\langle W, R, P \rangle$ write

$$\begin{aligned} Px &= \{S \in P : x \in S\}, \\ MPx &= \{\mathbf{m}_R S : x \in S \wedge S \in P\}. \end{aligned}$$

Then Thomason [1972] defines the conditions

$$\begin{aligned} \text{if } Px = Py \text{ then } x = y & \quad (1\text{-refinement}), \\ \text{if } MPy \subseteq Px \text{ then } xRy & \quad (2\text{-refinement}), \end{aligned}$$

and calls a general frame *refined* when it satisfies both of them. In effect a general frame $\langle W, R, P \rangle$ has enough propositions in P to determine W when it is 1-refined, and enough propositions in P to determine R when it is 2-refined. (Kit Fine independently introduced analogous conditions differentiated, tight, and natural for models.) Clearly each general frame \mathfrak{A}_+ determined by a modal algebra \mathfrak{A} is refined.

As Thomason [1972] shows, for each general frame $\langle W, R, P \rangle$ there is a refined general frame for which precisely the same formulas are true. One first replaces R by R' with

$$xR'y \text{ iff } (\forall S \in P)(y \in S \rightarrow \mathbf{m}_R S \in x),$$

so that $\langle W, R', P \rangle^+$ is the same as $\langle W, R, P \rangle^+$ but 2-refinement is satisfied. Then an equivalence relation \simeq is defined on W by taking

$$x \simeq y \text{ iff } (\forall S \in P)(x \in S \equiv y \in S).$$

This is a congruence on $\langle W, R', P \rangle$ in the sense that

$$\text{if } x_1 \simeq x_2 \text{ and } y_1 \simeq y_2 \text{ then } x_1 R' y_1 = x_2 R' y_2.$$

Now the quotient general frame $\langle W / \simeq, R' / \simeq, P / \simeq \rangle$ with

$$\begin{aligned} W / \simeq &= \{[x] : x \in W\}, \\ [x]R' / \simeq [y] &\text{ iff } xR'y, \\ P / \simeq &= \{\{[x] : x \in S\} : S \in P\}, \end{aligned}$$

is refined, and $\langle W / \simeq, R' / \simeq, P / \simeq \rangle^+$ is isomorphic to $\langle W, R', P \rangle^+$. Thus these two steps yield a refined general frame with an associated modal algebra which is isomorphic to that for the given general frame.

Fine [1975] introduces saturation or compactness conditions on models analogous to $\cap F \neq \emptyset$, for each ultrafilter F of $\langle W, R, P \rangle^+$, and

$$\cap \{\mathbf{m}_R S : S \in F\} \subseteq \mathbf{m}_R(\cap F) \quad (2\text{-saturation}).$$

Since each $x \in W$ generates an ultrafilter Px , this first condition is equivalent to

$$F = Px, \text{ for some } x \in W \text{ (1-saturation)}$$

for each ultrafilter F of $\langle W, R, P \rangle^+$. Note that applying 2-saturation to the ultrafilter Px yields

$$\text{if } MPy \subseteq Px \text{ then } \exists z(xRz \wedge Pz = Py) \text{ (2'-saturation).}$$

In Goldblatt [1976] it is shown that 2'-saturation is equivalent to 2-saturation in the presence of 1-saturation, and equivalent to 2-refinement in the presence of 1-refinement. Goldblatt [1976] then introduces the *descriptive* general frames as the refined general frames which also satisfy 1-saturation and, hence, 2-saturation. For each modal algebra \mathfrak{A} the general frame \mathfrak{A}_+ is descriptive. To see that 1-saturation is satisfied we must consider each ultrafilter F of $\langle W_{\mathfrak{A}}, R_{\mathfrak{A}}, P_{\mathfrak{A}} \rangle^+$, i.e. of $P_{\mathfrak{A}}$ with members

$$\phi(a) = \{F : F \text{ an ultrafilter of } \mathfrak{A} \text{ with } a \in F\},$$

for each $a \in A$. The required $x \in W_{\mathfrak{A}}$ with $F = P_{\mathfrak{A}}x$ is $\{a : \phi(a) \in F\}$.

It can also be shown that each descriptive general frame \mathfrak{F} is 'isomorphic' to $(\mathfrak{F}^+)_+$, so that the descriptive frames are the required 'duals' of the modal algebras. In Goldblatt [1976] this duality is expressed in terms of category theory, which involves the appropriate morphisms between structures as well as the structures themselves. The appropriate frame morphisms are a slight extension of the pseudo-epimorphisms of Segerberg [1968], which have to be onto. Given frames $\mathfrak{F} = \langle W, R \rangle$ and $\mathfrak{F}' = \langle W', R' \rangle$, $\phi : W \rightarrow W'$ is a *frame morphism* iff

$$\begin{aligned} &\text{if } xRy \text{ then } \phi(x)R'\phi(y), \\ &\text{if } \phi(x)R'z \text{ then } \exists y(xRy \wedge \phi(y) = z). \end{aligned}$$

Frame morphisms are extended to models $\langle W, R, V \rangle$ and general frames $\langle W, R, P \rangle$ by taking

$$v(P) = \phi^{-1}[v'(P)] = \{x \in W : \phi(x) \in v'(P)\},$$

for each propositional variable P ,

$$\text{if } S \in P' \text{ then } \phi^{-1}[S] = \{x \in W : \phi(x) \in S\} \in P.$$

As in Segerberg [1968],

$$V(A, x) = T \text{ iff } V'(A', \phi(x)) = T,$$

by an easy induction on the construction of A . The induction basis uses the condition above on V' . For the step on \Box , the first condition on frame

morphisms shows that if $V(\Box B, x) = F$, then $V'(\Box B, \phi(x)) = F$, and the second condition shows that if $V'(\Box B, \phi(x)) = F$ then $V(\Box B, x) = F$.

Now the descriptive frames \mathfrak{F} and $(\mathfrak{F}^+)_+$ can be shown to be frame isomorphic. For each descriptive frame $\mathfrak{F} = \langle W, R, P \rangle$, the function $\theta : W \rightarrow W^{\mathfrak{F}^+}$ with

$$\theta(x) = Px, \text{ for each } x \in W,$$

is a one-one frame morphism from \mathfrak{F} onto $(\mathfrak{F}^+)_+$. To see this, θ is one-one because \mathfrak{F} is 1-refined, and not because \mathfrak{F} is 1-saturated. Also, by the definition of l_R and 2-refinement, xRy iff $(\forall S \in P)((S \in Py \rightarrow \mathbf{m}_R S \in Px)$ iff $PxR_{\mathfrak{F}^+}Py$ iff $\theta(x)R_{\mathfrak{F}^+}\theta(y)$. To complete the proof that \mathfrak{F} and $(\mathfrak{F}^+)_+$ are frame isomorphic, i.e. that θ and θ^{-1} are general frame morphisms, it can be shown that $S \in P$ iff $\theta[S] \in P\mathfrak{F}^+$.

To establish the category-theoretic contravariant duality, correspondences must be established between homomorphisms of modal algebras and general frame morphisms of descriptive general frames, with the functions applied in opposite directions. Given general frames $\mathfrak{F} = \langle U, R, P \rangle$, $\mathfrak{G} = \langle V, S, Q \rangle$ and a general frame morphism $\phi : \mathfrak{F} \rightarrow \mathfrak{G}$, define $\phi^+ : \mathfrak{G}^+ \rightarrow \mathfrak{F}^+$ by

$$\phi^+(S) = \phi^{-1}[S], \text{ for each } S \in Q,$$

where $\phi^{-1}[S] \in P$ by the third condition. It is easy to show that ϕ^+ is a homomorphism. Given modal algebras $\mathfrak{A}, \mathfrak{B}$ and a homomorphism $\psi : \mathfrak{A} \rightarrow \mathfrak{B}$, define $\psi_+ : \mathfrak{B}_+ \rightarrow \mathfrak{A}_+$ by

$$\psi_+(x) = \{a \in A : \psi(a) \in x\}, \text{ for each } x \in W_{\mathfrak{B}}.$$

This set is an ultrafilter in $W_{\mathfrak{A}}$, and ψ_+ satisfies the conditions on general frame morphisms. For the first condition, if $xR_{\mathfrak{B}}y$ and $\mathbf{1}_a \in \psi_+(x)$ then $a \in \psi_+(y)$. For the second condition, if $\psi_+(x)R_{\mathfrak{A}}z$ then $\{a : Bla \in x\} \cup \{\psi(b) : b \in z\}$ can be shown to have the f.i.p. Therefore it can be extended to an ultrafilter y , which satisfies $xR_{\mathfrak{B}}y$ and $\psi_+(y) = z$. For the third condition, if

$$S = \{F : F \text{ an ultrafilter of } \mathfrak{A} \text{ with } a \in F\}$$

in $P_{\mathfrak{A}}$, then

$$\psi_+^{-1}[S] = \{G : G \text{ an ultrafilter of } \mathfrak{B} \text{ with } \psi(a) \in G\}$$

in $P_{\mathfrak{B}}$.

The category of modal algebras is a variety, and varieties are characterised by being closed under homomorphic images, subalgebras and direct products. So what are the corresponding constructions in the contravariantly dual category of descriptive frames? Frame-morphic images correspond to sub-algebras.

Subframes correspond to homomorphic images, where $\langle W', R', P' \rangle$ is a *subframe* of $\langle W, R, P \rangle$ iff W' is a subset of W satisfying the condition

$$\text{if } x \in W' \text{ and } xRy \text{ then } y \in W',$$

R' is the restriction of R to W' , and P' is $\{S \cap W' : S \in P\}$. The generated submodels $\langle W_x, R_x, V_x \rangle$ of Segerberg [1970] are a special case of subframes. Here, for $x \in W$,

$$W_x = \{y_n : xRy_1 \wedge \dots \wedge y_{n-1}Ry_n, \text{ for some } y_1, \dots, y_{n-1}\},$$

and R_x, V_x are the restrictions of R, V to W_x . (In the context of Segerberg [1970] R is transitive, so that it suffices to take $W_x = \{y : xRy\}$.) Clearly a formula is true in $\langle W, R, V \rangle$ iff it is true in all the generated submodels $\langle W_x, R_x, V_x \rangle$, a surprisingly important fact as we shall see. Note that if $\langle W, R, P \rangle$ is refined or descriptive, then so is each $\langle W_x, R_x, P_x \rangle$. For 1-saturation use the fact that the ultrafilters of $\langle W_x, R_x, P_x \rangle^+$ are the restrictions of the ultrafilters of $\langle W, R, P \rangle^+$ to subsets of W_x .

Disjoint unions correspond to direct products, in which we consider a set of general frames $\langle W_i, R_i, P_i \rangle$, for $i \in I$, for which each W_i and W_j are disjoint. (This can always be achieved by attaching indices.) The disjoint union $\langle W, R, P \rangle$ then has $W = \cup_{i \in I} W_i, R = \cup_{i \in I} R_i$, and

$$S \in P \text{ iff } S \cap W_i \in P_i, \text{ for each } i \in I.$$

It is easy to show that if each $\langle W_i, R_i, P_i \rangle$ is refined, then so is their disjoint union. Goldblatt [1976, Section 9] shows that the disjoint union preserves 1-saturation if I is finite, but not if it is infinite. The attempt to characterise the class of descriptive frames in terms dual to the usual characterisation of varieties fails in view of this point. (Category-theoretic duality is not always as good as it might sound!)

Section 12 of [Goldblatt, 1976] solves this problem by using another characterisation of varieties, as being closed under homomorphic images, subalgebras, finite direct products, and unions of chains. Onto inverse limits correspond to unions of chains, where the inverse limit of a directed set of descriptive frames is a complex construction set out in Section 11 of [Goldblatt, 1976].

Another important construction in varieties is Birkhoff's subdirect product, \mathfrak{A} being a subdirect product of the modal algebras \mathfrak{A}_i with $i \in I$ iff it is isomorphic to a subalgebra of their direct product which has the following property. Since \mathfrak{A} is a subalgebra of $\prod_{i \in I} \mathfrak{A}_i$, there is a one-one homomorphism ι from \mathfrak{A} into $\prod_{i \in I} \mathfrak{A}_i$. For each $i \in I$ there is a projection π_i from $\prod_{i \in I} \mathfrak{A}_i$ onto \mathfrak{A}_i . The condition on the subdirect product is that the homomorphisms $\pi_i \circ \iota$ from \mathfrak{A} into each \mathfrak{A}_i be onto, so that each \mathfrak{A}_i is a homomorphic image of \mathfrak{A} . Using this condition it is easy to show that a

formula is true in \mathfrak{A} iff it is true in each \mathfrak{A}_i . Each homomorphic image of a modal algebra \mathfrak{A} is isomorphic to a quotient \mathfrak{A}/F , where F is an open filter of \mathfrak{A} , i.e. a filter satisfying the condition

$$\text{if } a \in F \text{ then } \mathbf{1}a \in F.$$

The quotient is defined by taking the equivalence relation

$$a \simeq b \text{ iff } (-a) \cup (a \cup (-b)) \in F$$

and then taking \mathfrak{A}/F to be $\{[a] : a \in A\}$ with $\mathbf{1}[a] = [1a]$, etc. In view of this we can restrict attention to \mathfrak{A}_i 's of the form \mathfrak{A}/F_i for F_i an open filter of \mathfrak{A} .

Birkhoff defined a modal algebra \mathfrak{A} to be *subdirectly reducible* iff it is a subdirect product of quotients \mathfrak{A}/F_i with F_i nontrivial, and showed that every modal algebra is subdirectly reducible to subdirectly irreducible algebras. If some nonunit element a of \mathfrak{A} is in every nontrivial open filter F then $[a] = [1]$ in each \mathfrak{A}/F_i , so that \mathfrak{A} cannot be a subalgebra of $\prod_{i \in I} \mathfrak{A}/F_i$. Thus v is subdirectly irreducible already. Otherwise each non-unit member a of \mathfrak{A} lies outside some nontrivial open filter, and applying Zorn's Lemma yields a (nontrivial) maximal open filter F_a among those not containing a . Now \mathfrak{A} is subdirectly reducible to the \mathfrak{A}/F_a 's, noting that if $b \neq c$ and $a = ((-b) \cup c) \cap (b \cup (-c)) \neq 1$ then $[b] \neq [c]$ in \mathfrak{A}/F_a . Here each \mathfrak{A}/F_a is subdirectly irreducible, since $[a] \in F$ for each nontrivial filter F of \mathfrak{A}/F_a by the maximality of F_a among the open filters of \mathfrak{A} not containing a .

In view of Birkhoff's theorem, we can restrict attention to modal algebras with some nonunit element in every nontrivial open filter, when verifying formulas in a modal logic. (The importance of this result in modal logic lies in its use in the recent work of W. J. Blok.) In a closure or interior algebra, an open filter is determined by its open elements, so that a closure or interior algebra is subdirectly irreducible iff it has a maximum nonunit open element, or equivalently, a minimum nonzero closed element. In such an algebra,

$$\text{if } \mathbf{1}a \cup \mathbf{1}b = 1 \text{ then } \mathbf{1}a = 1 \text{ or } \mathbf{1}b = 1,$$

a condition we shall use later. It is easy to see that a modal algebra $\langle W, R \rangle^+$ is subdirectly reducible to the algebras $\langle W_x, R_x \rangle^+$ for $x \in W$, which are subdirectly irreducible.

In view of the contravariant duality between modal algebras and descriptive general frames, what theorem for the latter corresponds to Birkhoff's Theorem? Note that the lack of a disjoint union of infinitely many descriptive frames will block a dualisation of Birkhoff's proof. Let us say that a general frame \mathfrak{F} is the subdirect sum of general frames \mathfrak{F}_i with $i \in I$ iff it is a frame-morphic image of their disjoint union $\Sigma_{i \in I} \mathfrak{F}_i$ which has the following property. Since \mathfrak{F} is a frame-morphic image of $\Sigma_{i \in I} \mathfrak{F}_i$ there is a frame

morphism ϕ from $\Sigma_{i \in I} \mathfrak{F}_i$ onto \mathfrak{F} . For each $i \in I$ there is embedding frame morphism ι_i from \mathfrak{F}_i into $\Sigma_{i \in I} \mathfrak{F}_i$. The condition on the subdirect sums is that the frame morphisms $\phi \circ \iota_i$ from each \mathfrak{F}_i into \mathfrak{F} be embedding, so that each \mathfrak{F}_i is isomorphic to a subframe of \mathfrak{F} . In view of this we can restrict attention to \mathfrak{F}_i 's which are subframes of \mathfrak{F} . Again it is easy to show that a formula is true in \mathfrak{F} iff it is true in each \mathfrak{F}_i . Say that a general frame is subdirectly reducible iff it is a subdirect sum of its proper subframes. Then it is clear that a general frame is subdirectly reducible to its generated subframes, and that these are subdirectly irreducible. So although the disjoint union of descriptive frames is not usually descriptive, Birkhoff's deep result for modal algebras is analogous to the easy, known result that a formula is true in a descriptive general frame iff it is true in its generated subframes, which are again descriptive!

11 CANONICAL STRUCTURES

So far we have not constructed any modal algebras or frames. given a normal modal logic \mathbf{L} , define an equivalence relation $\simeq_{\mathbf{L}}$ on formulas by taking

$$B \simeq_{\mathbf{L}} C \text{ iff } \vdash_{\mathbf{L}} B \equiv C.$$

Then the *canonical modal algebra* $\mathfrak{A}_{\mathbf{L}}$ is constructed by taking

$$\begin{aligned} A_{\mathbf{L}} &= \{[B]_{\mathbf{L}} : B \text{ a formula}\}, \\ 0 &= [P \wedge \neg P]_{\mathbf{L}} \text{ and } 1 = [(\neg P) \vee P]_{\mathbf{L}}, \\ \neg[B]_{\mathbf{L}} &= [\neg B]_{\mathbf{L}}, \\ [B]_{\mathbf{L}} \cap [C]_{\mathbf{L}} &= [B \wedge C]_{\mathbf{L}}, \\ [B]_{\mathbf{L}} \cup [C]_{\mathbf{L}} &= [B \vee C]_{\mathbf{L}}, \\ l[B]_{\mathbf{L}} &= [\Box B]_{\mathbf{L}}, \\ \mathbf{m}[B]_{\mathbf{L}} &= [\Diamond B]_{\mathbf{L}}. \end{aligned}$$

That $\mathfrak{A}_{\mathbf{L}}$ is indeed a modal algebra is easily shown using the defining axioms and rules of normal modal logics. Defining a valuation $v_{\mathbf{L}}$ by

$$v_{\mathbf{L}}(B) = [B]_{\mathbf{L}}, \text{ for each formula } B,$$

we have

$$v_{\mathbf{L}}(B) = 1 \text{ iff } B \in \mathbf{L},$$

so that the canonical algebraic 'model' $\langle \mathfrak{A}_{\mathbf{L}}, v_{\mathbf{L}} \rangle$ characterises the normal modal logic \mathbf{L} . Further, for each valuation v on $\mathfrak{A}_{\mathbf{L}}$, $v(B)$ is $[C]_{\mathbf{L}}$ for some substitution instance C of B , so that B is true in $\mathfrak{A}_{\mathbf{L}}$ iff it is in \mathbf{L} .

Given a normal modal logic \mathbf{L} , a set X of formulas is inconsistent iff $\vdash_{\mathbf{L}} \neg(A_1 \wedge \dots \wedge A_n)$, for some $A_1, \dots, A_n \in X$, and is consistent otherwise. (Note the analogy between consistency and the f.i.p. The existence of maximal

consistent sets is proved with Zorn's Lemma, just as for that of maximal filters. However, if \mathbf{L} has only countably many propositional variables, then a more elementary construction due to Henkin can be used.) Define the *canonical frame* $\langle W_{\mathbf{L}}, R_{\mathbf{L}} \rangle$ by taking $W_{\mathbf{L}}$ to be the set of maximal consistent set of formulas, and taking

$$FR_{\mathbf{L}}G \text{ iff } \forall A(A \in G \rightarrow \diamond A \in F)$$

or, equivalently,

$$FR_{\mathbf{L}}G \text{ iff } \forall A(\Box A \in F \rightarrow A \in G).$$

Note the analogy with the construction of the frame $\mathfrak{A}_{\mathfrak{A}}$ from a modal algebra \mathfrak{A} . Define a valuation $v_{\mathbf{L}}$ by taking

$$v_{\mathbf{L}}(B, F) = T \text{ iff } B \in F, \text{ for each formula } B,$$

a definition which is shown to be sound by an induction on the construction of B . For the induction step on $B = \diamond C$ it must be shown that

$$\exists G(FR_{\mathbf{L}}G \wedge G \in v_{\mathbf{L}}(C)) \text{ iff } F \in v_{\mathbf{L}}(\diamond C).$$

This proof is exactly analogous to the one used when showing that $(\mathfrak{A}_+)^+$ is isomorphic to \mathfrak{A} , using the defining axioms and rules of normal modal logics. Now

$$v_{\mathbf{L}}(B, F) = T, \text{ for each } F \in W_{\mathbf{L}}, \text{ iff } B \in \mathbf{L},$$

since each consistent set of formulas can be extended to a member of $W_{\mathbf{L}}$, so that the canonical model $\langle W_{\mathbf{L}}, R_{\mathbf{L}}, v_{\mathbf{L}} \rangle$ characterises the normal modal logic \mathbf{L} . Taking

$$P_{\mathbf{L}} = \{v_{\mathbf{L}}(B) : B \text{ a formula}\}$$

gives the canonical general frame $\langle W_{\mathbf{L}}, R_{\mathbf{L}}, P_{\mathbf{L}} \rangle$. For each valuation V on this frame, $v(B)$ is $v_{\mathbf{L}}(C)$, for some substitution instance C of B , so that B is true in $\langle W_{\mathbf{L}}, R_{\mathbf{L}}, P_{\mathbf{L}} \rangle$ iff it is in \mathbf{L} . In fact $\langle W_{\mathbf{L}}, R_{\mathbf{L}}, P_{\mathbf{L}} \rangle$ is $\mathfrak{A}_{\mathbf{L}+}$, so that it has a descriptive general frame characterising \mathbf{L} .

It does not follow that the canonical frame $\langle W_{\mathbf{L}}, R_{\mathbf{L}} \rangle$ itself characterises the normal modal logic \mathbf{L} . Nonetheless, in a number of cases it can be shown that $R_{\mathbf{L}}$ satisfies some condition for frames to verify \mathbf{L} , so that $\langle W_{\mathbf{L}}, R_{\mathbf{L}} \rangle$ does characterise \mathbf{L} . In particular, the canonical frames for **KT**, **KB**, **K4**, and the logics obtained by combining these axioms, satisfy the first-order conditions on R given in Section 10. (These completeness proofs were given independently in [Lemmon, 1977], written in 1966, and in [Makinson, 1966].) These partial results suggest a number of important problems which have provided the main motivation for modal logic in the 1970s. Under what conditions is a formula true on the underlying frame $\langle W, R \rangle$ when it is true on a model $\langle W, R, V \rangle$ or a general frame $\langle W, R, P \rangle$? Are there logics which

are not characterised by the ordinary frames which verify them? What is the relationship between modal axioms and first-order conditions on R in the frames $\langle W, R \rangle$? Are there formulas not characterised by the class of frames satisfying some first-order condition? Generalising the problem of completeness, often a problem can be easily solved for descriptive general frames by their duality with the variety of modal algebras, and the difficulty lies in transferring the problem to the underlying frames. We shall return to answers to these questions after studying various particular logics which have attracted attention.

12 THE F. M. P. AND FILTRATIONS

A logic \mathbf{L} is said to have the *f.m.p.* (*finite model property*) iff, for each formula A , $\vdash_{\mathbf{L}} A$ iff A is true in each finite modal algebra or frame which verifies the formulas of \mathbf{L} . Thus in showing that \mathbf{L} has the f.m.p. we must find, for each nonthesis A , a finite modal algebra or frame which verifies \mathbf{L} but does not verify A . Note that modal algebras and frames are interchangeable here. For if \mathfrak{F} is a finite frame, then of course \mathfrak{F}^+ is a finite modal algebra, and if \mathfrak{A} is a finite modal algebra, then $\mathfrak{A}_\# = \mathfrak{A}_+$ is a finite frame. The f.m.p. is important, among other reasons, for giving decidability to a finitely axiomatised normal modal logic. For as Harrop pointed out, we can construct the countably many finite models in some order, checking each one for verifying the finitely many axioms and the given formula A . Again a problem of independence is raised, which will be considered in a later section: are there logics which are characterised by frames, but not by the finite frames which verify them? (The position of the logics characterised by one finite model in the lattice of modal logics is investigated in detail in [Blok, 1980]. The normal modal logics immediately below these, which also have the f.m.p., are the subject of [Block, 1980a].)

We now consider a pair of methods for constructing finite modal algebras and frames from given structures, both known as filtration. Consider an algebraic ‘model’ $\langle \mathfrak{A}, v \rangle$ and a formula A with $v(A) \neq 1$. Let $\{A_1, \dots, A_n\}$ be a finite set of formulas including A and closed under subformulas, and let $\langle B, 0, 1, -, \cap, \cup \rangle$ be the subalgebra of $\langle A, 0, 1, -, \cap, \cup \rangle$ generated by $\{v(A_1), \dots, v(A_n)\}$, noting that it is non-trivial and finite. (Usually A_1, \dots, A_n are A and its subformulas, but sometimes some larger set is preferable.) This Boolean algebra is extended to a finite modal algebra $\mathfrak{B} = \langle B, 0, 1, -, \cap, \mathbf{l}', \mathbf{m}' \rangle$ by taking

$$\begin{aligned} \mathbf{l}'b &= \cup \{ \mathbf{l}a \in B : a \in B \wedge a \leq b \}, \\ \mathbf{m}'b &= \cap \{ \mathbf{m}c \in B : c \in B \wedge b \leq c \}, \end{aligned}$$

(In the case of a closure or interior algebra \mathfrak{A} , \mathbf{m} is determined by the closed elements of \mathfrak{A} and \mathbf{l} by the open elements. Therefore it suffices to take $\mathbf{l}'b$

to be the union of the open elements of B contained by b , and take $\mathbf{m}'b$ to be the intersection of the closed elements of B containing b .) In particular,

$$\begin{aligned} \text{if } \mathbf{l}b \in B \text{ then } \mathbf{l}'b &= \mathbf{l}b, \\ \text{if } \mathbf{m}b \in B \text{ then } \mathbf{m}'b &= \mathbf{m}b, \end{aligned}$$

for each $b \in B$. Now \mathfrak{B} is indeed a modal algebra, satisfying

$$\begin{aligned} \mathbf{l}'1 &= 1 \text{ and } \mathbf{l}'(a \cap b) = \mathbf{l}'a \cap \mathbf{l}'b, \\ \mathbf{m}'0 &= 0 \text{ and } \mathbf{m}'(a \cup b) = \mathbf{m}'a \cup \mathbf{m}'b, \end{aligned}$$

using distributivity and the fact that \mathfrak{A} satisfies these conditions. Construct a valuation w on \mathfrak{B} by taking $w(P) = v(P) \cap B$, for each propositional variable P in A_1, \dots, A_n , and applying the defining conditions for valuations. We now have

$$a(A_i) = v(A_i) \text{ for } i = 1, \dots, n,$$

so that $w(A) \neq 1$ in the *filtered* algebraic ‘model’ $\langle \mathfrak{B}, w \rangle$.

It is not in general true that $\langle \mathfrak{B}, w \rangle$, let alone \mathfrak{B} , verifies a logic \mathbf{L} verified by \mathfrak{A} . Nonetheless, in a number of cases it can be shown that each filtration \mathfrak{B} of \mathfrak{A} satisfies some condition for modal algebras to verify \mathbf{L} . In particular, filtrations of algebraic ‘models’ verifying \mathbf{KT} , \mathbf{KB} , \mathbf{Kr} , and the logics obtained by combining these axioms, again satisfy the equations given in Section 10. It follows that these logics have the f.m.p. and are decidable, being characterised by the filtrations of their canonical modal algebras. (This technique was introduced in [McKinsey, 1941], and extended in [Lemmon, 1966], to establish many decidability results.)

Now consider a model $\langle W, R, V \rangle$ and a formula A with $v(A) \neq W$. Again let $\{A_1, \dots, A_n\}$ be a finite set of formulas including A and closed under subformulas. Define an equivalence relation \simeq on W by taking

$$x \simeq y \text{ iff } V(A_i, x) = V(A_i, y), \text{ for } i = 1, \dots, n,$$

so that W is partitioned into a finite set W' of equivalence classes $[x]$ under \simeq . Consider finite frames $\langle W', R' \rangle$ satisfying the conditions

$$\begin{aligned} \text{if } xRy \text{ then } [x]R'[y], \\ \text{if } [x]R; [y] \text{ then [if } V(A_i, x) = T, \text{ for } A_i = \Box A_j, \\ \text{then } V(A_j, y) = T], \text{ for } i = 1, \dots, n. \end{aligned}$$

(A suitable condition in terms of \diamond could equally well be used.) There are a number of relations R' on W' which satisfy these conditions, e.g. \bar{R} with

$$\begin{aligned} [x]\bar{R}[y] \text{ iff [if } V(A_i, x) = T, \text{ for } A_i = \Box A_j, \\ \text{then } V(A_j, y) = T], \text{ for } i = 1, \dots, n. \end{aligned}$$

This relation satisfies the first conditions, since if xRy then the right-hand side of the defining condition holds for all formulas $B = \Box C$. This is in fact

the largest such relation R' . The smallest is the intersection \underline{R} of all such relations, which again satisfies the two conditions. Construct a valuation V' on $\langle W', R' \rangle$ by taking $V'; (P, [x]) = V(P, x)$ for each propositional variable P in A_1, \dots, A_n , and applying the defining conditions for valuations. It can now be shown that

$$V'(A_i, [x]) = V(A_i, x), \text{ for } i = 1, \dots, n,$$

by induction on the construction of formulas, so that $v'(A) \neq W'$ in the *filtered* model $\langle W', R', V' \rangle$. for the induction step on \Box , consider $A_i = \Box A_j$. If $V(\Box A_j, x) = T$ and $[x]R'[y]$ then $V(A_j, y) = T$ by the second condition on R' , and $V'(A_j[y]) = T$ by the induction hypothesis. Applying this to each $[y]$ we have $V'(\Box A_j, [x]) = T$. If $V'(\Box A_j, [x]) = T$ and xy , then $[x]R'[y]$ by the first condition on R , so that $V'(A_j, [y]) = T$ and $V(A_j, y) = T$ by the induction hypothesis. Applying this to each y we have $V(\Box A_j, x) = T$.

Again it is not in general true that $\langle W', R', V' \rangle$, let alone $\langle W', R' \rangle$, verifies a logic **L** verified by $\langle W, R, V \rangle$. Nonetheless, in a number of cases it can be shown that R' satisfies some condition for frames to verify **L**. In particular filtrations $\langle W', \bar{R}, \bar{V} \rangle$ of models verifying **KT**, **KB**, **K4**, and the logics obtained by combining these axioms, again satisfy the first-order conditions on R given in Section 10. This gives alternative proofs of the decidability of these logics. (The construction $\langle W', \bar{R}, \bar{V} \rangle$ was introduced in [Lemmon, 1977] and was generalised to $\langle W', R', V' \rangle$ in [Seegerberg, 1968].) In many more cases a further step after filtration, or a variation on the construction $\langle W', \bar{R}, \bar{V} \rangle$ to suit the axioms involved, will yield a finite frame $\langle W', R' \rangle$ verifying the logic concerned. We shall see some of these techniques in the following sections.

13 UNRAVELLING AND BULLDOZING

(The technique of unravelling was introduced in [Dummett and Lemmon, 1959] and used extensively in [Sahlqvist, 1975], apparently without knowledge of the earlier paper.) Consider a frame $\langle W, R \rangle$ which is generated by $w_0 \in W$, so that $w_0 R w_1, \dots, w_{n-1} R w_n$, for some w_1, \dots, w_{n-1} , for each other $w_n \in W$. Construct a new frame $\langle W^*, R^* \rangle$ by taking

$$\begin{aligned} \langle w_0, \dots, w_n \rangle \in W^* &\text{ iff} \\ w_1, \dots, w_n \in W &\text{ and } w_0 R w_1, \dots, w_{n-1} R w_n, \\ \langle w_0, \dots, w_m \rangle R^* \langle w_0, \dots, w_n \rangle &\text{ iff} \\ \langle w_0, \dots, w_n = \langle w_0, \dots, w_m \rangle * \langle w_n \rangle. \end{aligned}$$

Thus R has been unravelled in the sense that if $u_{n-1} R w_n$ and $v_{n-1} R w_n$ then w_n is replaced by $\langle w_0, \dots, u_{n-1}, w_n \rangle$ and $\langle w_0, \dots, v_{n-1}, w_n \rangle$ with $\langle w_0, \dots, u_{n-1} \rangle R^* \langle w_0, \dots, u_{n-1}, w_n \rangle$ and $\langle w_0, \dots, v_{n-1} \rangle R^* \langle w_0, \dots, v_{n-1}, w_n \rangle$.

Unravelling is extended to models $\langle W, R, V \rangle$ by taking $V^*(P, \langle w_0, \dots, w_n \rangle) = V(P, w_n)$ for each propositional variable P , and applying the defining conditions for valuations. It is easy to show that

$$V^*(A, \langle w_0, \dots, w_n \rangle) = V(A, w_n), \text{ for each formula } A,$$

by induction on the construction of A . Since \mathbf{K} is characterised by the finite frames using filtrations, it is now characterised by the unravelled frames. Note that these unravelled frames are irreflexive, asymmetrical, and intransitive. Therefore none of these conditions characterise a proper extension of \mathbf{K} .

A frame $\langle W, R \rangle$ could be defined to be a tree iff there is $w_0 \in W$ and a relation S on W satisfying the conditions, for each $w_n \in W$ other than w_0 , only one $w_{n-1} \in W$ with $w_{n-1}Sw_n$, for some $w_1, \dots, w_{n-1} \in W$; there is only one $w_{n-1} \in W$ with $w_{n-1}Sw_n$ and w_nRw_{n-1} if $w_nSw_{m+1}, \dots, w_{n-1}Sw_n$, for some $w_{m+1}, \dots, w_{n-1} \in W$. A tree could be reflexive or irreflexive. Then trees could be obtained by taking the transitive closures of unravelled frames, with or without the reflexive closure as required. (Sahlqvist [1975] uses a more general notion of tree, and proves a number of results concerning them.)

The *clusters* of a transitive frame $\langle W, R \rangle$ are defined in [Segeberberg, 1971] to be the equivalence classes of W under the equivalence relation

$$x \simeq y \text{ iff } (xRy \wedge yRx) \vee x = y.$$

Clusters are divided into three kinds: proper, with at least two elements, all reflexive; simple, with one reflexive element; and degenerate with one irreflexive element. Note that when a nondegenerate cluster is unravelled, it will give rise to many branches of $\langle W^*, R^* \rangle$ in which the members of the cluster are repeated. Thus unravelling imposes asymmetry on frames, sometimes without losing the property of characterising a given logic.

Another technique for removing nondegenerate clusters and so imposing asymmetry is the bulldozing of Segerberg [1970]. Let us suppose that the logic concerned is an extension of $\mathbf{K4}$ which has countably many propositional variables P_0, P_1, P_2, \dots and consider a generated transitive frame $\langle W, R \rangle$. Construct a new frame $\langle W^0, R^0 \rangle$ by first replacing each nondegenerate cluster C of W by

$$C^0 = \{ \langle x, i \rangle : x \in C \wedge i = 0, 1, 2, \dots \},$$

and replacing each degenerate cluster $C = \{x\}$ of W by $\{ \langle x, 0 \rangle \}$, to obtain W^0 . Define R^0 on W^0 by taking

$$\begin{aligned} \langle x, i \rangle R^0 \langle y, j \rangle \text{ iff either not } x \simeq y \text{ and } xRy \\ \text{or } x \simeq y \text{ and } i < j \text{ or } x \simeq y \text{ and } i = j \text{ and } xR_C y, \end{aligned}$$

where r_C is an arbitrary strict ordering of the proper cluster C with $x, y \in C$. Thus each nondegenerate cluster C of W is ‘bulldozed’ into an infinite set C^0 on which R^0 is a strict linear ordering. In $\langle C^0, R^0 \rangle$ a copy $\langle y, j \rangle$ of y occurs after each copy $\langle x, i \rangle$ of x , for each $x, y \in C$. If $\langle W, R \rangle$ is reflexive, so that there are no degenerate clusters, modify the construction as follows to make $\langle W^0, R^0 \rangle$ reflexive as well. Form C^0 as above only for proper clusters C , and replace simple clusters $C = \{x\}$ by $C^0 = (\langle x, 0 \rangle)$; and add the clause ‘or $x = y$ ’ to the right-hand side of the definition of R_0^0 . In this case each proper cluster C is ‘bulldozed’ into an infinite set C_0 on which R_0 is a linear ordering.

Bulldozing is extended to models $\langle W, R, V \rangle$ by taking

$$V^0(p_j, \langle x, i \rangle) = V(P_j, x), \text{ for } j = 0, 1, 2, \dots,$$

and applying the defining conditions for valuations. Now

$$V^0(A, \langle x, i \rangle) = V(A, x), \text{ for each formula } A$$

by induction on the construction of A . (For the induction step on $\Box, V^0(\Box B, \langle x, i \rangle) = F$ iff $V^0(B, \langle y, j \rangle) = F$, for some $\langle y, j \rangle \in W^0$ with $\langle x, i \rangle R^0 \langle y, j \rangle$, iff $V(B, y) = F$, for some $y \in W$ with $\langle x, i \rangle R^0 \langle y, j \rangle$, (by the induction hypothesis) iff $V(B, y) = F$, for some $y \in W$ with xRy , (by the definition of R^0 if not $x \simeq y$, and by a remark above if $x \simeq y$) iff $V(\Box B, x) = F$.)

Now consider any normal modal logic \mathbf{L} containing **S4.3**. First we shall use

$$\vdash_{\mathbf{L}} \Box(\Box A \rightarrow \Box B) \vee \Box(\Box B \rightarrow \Box A)$$

to show that the canonical frame $\langle W_{\mathbf{L}}, R_{\mathbf{L}} \rangle$ is connected with

$$\forall x \forall y \forall z ((xR_{\mathbf{L}}y \wedge xR_{\mathbf{L}}z) \rightarrow (yR_{\mathbf{L}}z \vee zR_{\mathbf{L}}y)).$$

Let us suppose that we have maximal consistent sets F, G, H of \mathbf{L} with $FR_{\mathbf{L}}G$, $FR_{\mathbf{L}}H$ but not $GR_{\mathbf{L}}H$ and not $HR_{\mathbf{L}}G$, and obtain a contradiction. Since not $GR_{\mathbf{L}}H$ there is some $\Box A \in G$ with not $A \in H$, and since not $HR_{\mathbf{L}}G$ there is some $\Box B \in H$ with not $B \in G$. Just as maximal filters are ultrafilters, it can be shown that a maximal consistent set F satisfies

$$A \in F \text{ or } \neg A \in F, \text{ for each formula } A.$$

It is easy to deduce that

$$\text{if } A \vee B \in F \text{ then } A \in F \text{ or } B \in F, \text{ for all formulas } A, B.$$

Therefore

$$\begin{aligned} &\vdash_{\mathbf{L}} \Box(\Box A \rightarrow \Box B) \vee \Box(\Box B \rightarrow \Box A) \\ &\text{implies } \Box(\Box A \rightarrow \Box B) \in F \text{ or } \Box(\Box B \rightarrow \Box A) \in F \\ &\text{implies } \Box A, \Box A \rightarrow \Box B \in G \text{ or } \text{square}B, \Box B \rightarrow \Box A \in H \\ &\text{implies } \Box B \in G \text{ or } \Box A \in H \\ &\text{implies } B \in G \text{ or } A \in H \end{aligned}$$

(since $\vdash_{\mathbf{L}} \Box P \rightarrow P$)—the required contradiction.

The canonical frame for \mathbf{L} is also reflexive and transitive. Clearly its generated subframes $\langle W_{\mathbf{L}}, R_{\mathbf{L}x} \rangle$ satisfy $\forall y \forall z (yRz \vee zRy)$, and bulldozing adds

$$\forall y \forall z (y \neq z \rightarrow \neg(yRz \wedge zRy))$$

to these conditions in $\langle W_{\mathbf{L}z}^0, R_{\mathbf{L}x}^0 \rangle$, so that $R_{\mathbf{L}x}^0$ is a linear ordering in the full sense. Often such frames still verify \mathbf{L} , so that they characterise it, in particular when \mathbf{L} is **S4.3** itself. (Segerberg [1970] proves the analogous result for extensions \mathbf{L} of **K4.3**, using filtrations of the canonical frame which are connected although the canonical frame itself is not. Many other results along these lines are obtained in [Segerberg, 1970; Segerberg, 1971] and [Sahlqvist, 1975].)

14 S4.1 AND S4GRZ

(**K4.1** = **K4M** and **S4.1** = **KT4M** were shown to be characterised by frames satisfying the appropriate conditions in [Lemmon, 1977], written in 1966, and **S4.1** was shown to be characterised by the appropriate finite frames in [Segerberg, 1968]. Independently Bull [1967] gave an algebraic proof of the f.m.p. for **S4.1**, and described a characteristic frame for it. The extension **S4 Grz** of **S4.1** was shown to be characterised by the appropriate finite frames in [Segerberg, 1971].)

Bull [1967] begins by showing that **S4.1** can also be axiomatised by extending **S4** with either of the rules

$$\begin{aligned} &\text{if } \vdash \Diamond A, \vdash \Diamond B \text{ then } \vdash \Diamond(A \wedge B), \\ &\text{if } \vdash \Diamond A, \text{ then } \vdash \Diamond \Box A. \end{aligned}$$

Although a filtration \mathfrak{B} of the canonical modal algebra for **S4.1** may not verify these rules, an extension \mathfrak{B}^+ of \mathfrak{B} can be constructed which does. (Thinking in terms of $\langle W, R \rangle^+$, where R satisfies the conditions in Section 10 for verifying **S4.1**, we need to isolate the R -last points of W . This is achieved by the following trick.) Taking $a_B = \cup\{\mathbf{m}b - b : b \in B\}$, where the join and \mathbf{m} are that of $\mathfrak{A}_{\mathbf{S4.1}}$, we shall consider separately what happens in a_B and what happens in $-a_B$ (the set of R -last points, in effect). Let $\langle B^+, 0, 1, -, \cap, \cup, \mathbf{l}', \mathbf{m}' \rangle$ be the filtration of $\mathfrak{A}_{\mathbf{S4.1}}$ generated by $B \cup \{a_B\}$, and define

$$\begin{aligned} \mathbf{l}^+b &= (\mathbf{l}'b \cap a_B) \cup (b - a_B), \\ \mathbf{m}^+b &= (\mathbf{m}'b \cap a_B) \cup (b - a_B), \end{aligned}$$

for each $b \in \mathfrak{B}^+$. The required modal algebra \mathfrak{B}^+ is $\langle B^+, 0, 1, -, \cap, \cup, \mathbf{l}^+, \mathbf{m}^+ \rangle$. The canonical modal algebra $\mathfrak{A}_{\mathbf{S4.1}}$ and the filtrations of it are closure or interior algebras, and it can be shown that \mathfrak{B}^+ is as well. Using the fact

that $\mathfrak{A}_{\mathbf{S4.1}}$ verifies the first rule above, it can be shown that $\mathbf{I}^+ a_B = 0$. From this it follows that

$$\text{if } \mathbf{I}^- b = 0 \text{ then } \mathbf{I}^+ \mathbf{m}^+ b = 0,$$

so that the second rule above is indeed verified by \mathfrak{B}^+ . Finally it can be shown that $\mathbf{I}^+ b = \mathbf{I} b$ and $\mathbf{m}^+ b = \mathbf{m} b$ if these are in B , so that \mathfrak{B}^+ rejects the given formula A rejected by \mathfrak{B} . Thus $\mathbf{S4.1}$ is characterised by these finite closure or interior algebras \mathfrak{B}^+ .

For the reflexive and transitive frames which verify $\mathbf{S4}$, the condition given in Section 10 for $\langle W, R \rangle$ to verify \mathbf{M} becomes

$$\forall x \exists y (x R y \wedge \forall z (y R z \rightarrow y = z)),$$

i.e. that each point x has an R -last point y after it. For finite frames it suffices that each final cluster be simple. It is well-known that in $\mathbf{S4}$ the only non-equivalent formulas obtained by applying \neg, \Box, \Diamond to P are P itself, $\Box P, \Box \Diamond \Box P, \Box \Diamond P$ and $\Diamond \Box P, \Diamond \Box \Diamond P, \Diamond P$, and the negations of these. Thus in $\mathbf{S4.1}$ there are only 10 of these ‘modalities’. In forming a filtration $\langle W', \bar{R}, \bar{V} \rangle$ let us take $\{A_1, \dots, A_n\}$ to be the finite closure of A and its subformulas under these modalities of $\mathbf{S4.1}$. Now these filtrations of the canonical model $\langle W_{\mathbf{S4.1}}, R_{\mathbf{S4.1}}, V_{\mathbf{S4.1}} \rangle$ have all their final clusters simple, and so characterise $\mathbf{S4.1}$. For consider $[F], [G] \in W'_{\mathbf{S4.1}}$ in a final cluster of such a frame $\langle W'_{\mathbf{S4.1}}, \bar{R}_{\mathbf{S4.1}} \rangle$, with $A_i \in F$. Since $[F]$ is in a final cluster, for each $[H]$ with $[F] \bar{R}_{\mathbf{S4.1}} [H]$ we have $[H] R_{\mathbf{S4.1}} [F]$, and so $\Diamond A_i \in H$. Therefore $\Box \Diamond A_i \in F$, as well as $\Box \Diamond A_i \rightarrow \Diamond \Box A_i \in F$, so that $\Diamond \Box A_i \in F$. Now there must be an H with $[F] \bar{R}_{\mathbf{S4.1}} [H]$ and $\Box A_i \in H$. But since R is transitive and this is a final cluster, $[H] \bar{R}_{\mathbf{S4.1}} [G]$ and so $A_i \in G$. We have shown that if $A_i \in F$ then $A_i \in G$, so that extending the argument yields

$$A_i \in F \text{ iff } A_i \in G, \text{ for } i = 1, \dots, n,$$

i.e. $[F] = [G]$, as required.

For finite reflexive and transitive frames, to satisfy the condition given in Section 10 for $\langle W, R \rangle$ to satisfy \mathbf{Grz} , it suffices that each cluster be simple. Unfortunately filtrations $\langle W', \bar{R}, \bar{V} \rangle$ of the canonical model for $\mathbf{S4 Grz}$ may not have this property, and it is necessary to replace \bar{R} by a suitable asymmetric R' . Given a cluster C of reflexive, transitive $\langle W'_{\mathbf{Grz}}, \bar{R}_{\mathbf{Grz}}, \bar{V}_{\mathbf{Grz}} \rangle$, say that $x \in C$ is ‘virtually last’ in C iff there is some $F_x \in x$ with

$$\forall G ((F_x R_{\mathbf{Grz}} G \wedge [G] \in C) \rightarrow x = [G]).$$

It is clear that the member of a simple cluster of this frame is virtually last. In [Seegerberg, 1971, Chapter II, Section 3], it is shown by a difficult argument that each proper cluster has a virtually last element as well.

Assuming this result, define $R'_{\mathbf{Grz}}$ on $W'_{\mathbf{Grz}}$ by taking $x R'_{\mathbf{Grz}} y$ iff either not $x \simeq y$ and $x \bar{R}_{\mathbf{Grz}} y$ or $x \simeq y$ and $x r_C y$, where r_C is an arbitrary ordering

of C in which the r_C -last member of finite C is virtually last in C . Now $R'_{\mathbf{Grz}} \subseteq \bar{R}_{\mathbf{Grz}}$, and $\langle W'_{\mathbf{Grz}}, R'_{\mathbf{Grz}} \rangle$ has only simple clusters and so verifies **S4Grz**. Define $V'_{\mathbf{Grz}}$ on $\langle W'_{\mathbf{Grz}}, R'_{\mathbf{Grz}} \rangle$ by taking $V'_{\mathbf{Grz}}(P, [F]) = V_{\mathbf{Grz}}(P, F)$ for each propositional variable P in $\{A_1, \dots, A_n\}$, and applying the defining conditions for valuations. It can be shown that

$$V'_{\mathbf{Grz}}(A, [F]) = \bar{V}_{\mathbf{Grz}}(A_i, [F]), \text{ for } i = 1, \dots, n,$$

by induction on their construction, so that $\langle W'_{\mathbf{Grz}}, R'_{\mathbf{Grz}}, V'_{\mathbf{Grz}} \rangle$ rejects the given formula as well. For the induction step on \Box , consider $A_i = \Box A_j$, one direction being easy with $R'_{\mathbf{Grz}} \subseteq \bar{R}_{\mathbf{Grz}}$. For the difficult direction take x to be a cluster C with y virtually last in C , and then

$$\begin{aligned} & \bar{V}_{\mathbf{Grz}}(\Box A_j, x) = F \\ & \text{implies } \bar{V}_{\mathbf{Grz}}(\Box A_j, y) = F \\ & \text{implies } V_{\mathbf{Grz}}(\Box A_j, F_y) = F \text{ and} \\ & \quad \forall G((F_y R_{\mathbf{Grz}} G \wedge [G] \in C) \rightarrow y = [G]) \\ & \text{implies } V_{\mathbf{Grz}}(A_j, G) = F, \text{ for some } G \text{ with either} \\ & \quad F_y R_{\mathbf{Grz}} G \text{ and not } [G] \in C \text{ or } y = [G] \in C, \\ & \text{implies } V'_{\mathbf{Grz}}(A_j, [G]) = F \text{ and either not } y \simeq [G] \\ & \quad \text{and } y \bar{R}_{\mathbf{Grz}} [G] \text{ or } y \simeq [G] \text{ and } y r_C [G] \\ & \text{implies } V'_{\mathbf{Grz}}(A_j, [G]) = F \text{ and } x R'_{\mathbf{Grz}} y \text{ and } y R'_{\mathbf{Grz}} [G] \\ & \text{implies } V'_{\mathbf{Grz}}(\Box A_j, x) = F. \end{aligned}$$

With what natural axiom can **S4.1** be extended to **S4Grz**? Clearly we need a formula A such that **S4A** is characterised by the finite reflexive-and-transitive frames in which all but the final clusters are simple. Segerberg [1971, Chapter II, Section 3] shows that

$$\mathbf{Dum}.\diamond\Box P \rightarrow (\Box(\Box(P \rightarrow \Box P) \rightarrow P) \rightarrow P)$$

(i.e. $\diamond\Box P \rightarrow \mathbf{Grz}$) has this property, so that **S4Grz** is **S4.1Dum**.

15 THE TRANSITIVE LOGICS OF FINITE DEPTH

Given a frame $\langle W, R \rangle$, say that $x_1, \dots, x_r \in W$ form a *chain* iff $x_i R x_{i+1}$ and $x_i \neq x_{i+1}$ and not $x_{i+1} R x_i$, for $i = 1, \dots, r-1$. (Thus x_1, \dots, x_r come from a chain of distinct clusters. We include $\langle x_1 \rangle$ as a chain.) Say that x_1 has a rank r in $\langle W, R \rangle$ iff there is a chain $\langle x_1, \dots, x_r \rangle$ but no chain $\langle x_1, \dots, x_r, x_{r+1} \rangle$. And say that $\langle W, R \rangle$ itself has rank r iff each element in it has a rank which is $\leq r$, and some element in it has rank r . In this section (which is derived from work in [Segerberg, 1971]) we study normal extensions of **K4** with characteristic frames of finite depth in this sense.

Define formulas B_n , for $n = 1, 2, 3, \dots$ by taking

$$\begin{aligned} B_1 &= B = \diamond\Box P_1 \rightarrow P_1, \\ B_{n+1} &= \diamond(\Box P_{n+1} \wedge \neg B_n) \rightarrow P_{n+1}. \end{aligned}$$

Then transitive $\langle W, R \rangle$ verifies B_n iff it has rank $\leq n$. For it is easy to show that $\langle W, R, V \rangle$ rejects B_n at $x_0 \in W$ iff there exists $x_1, \dots, x_n \in W$ with $x_i R x_{i+1}$ and

$$\begin{aligned} V(P_{n-i}, x_i) &= F, \\ v(B_{n-i}, x_i) &= F, \\ v(\Box P_{n-i}, x_{i+1}) &= T, \end{aligned}$$

for $i = 0, \dots, n-1$, by induction from $n-1$ to 0. And it can be checked that these conditions can hold iff x_0, \dots, x_n satisfy the conditions for being a chain.

We shall see that any normal logic \mathbf{L} which contains $\mathbf{K4B}_n$ has the f.m.p. Consider a formula A with propositional variables from P_1, \dots, P_m , and take r to be maximum of m and n . Taking \mathbf{L}_r to be the restriction of \mathbf{L} to P_1, \dots, P_r , it is clear that $\vdash_{\mathbf{L}} A$ iff $\vdash_{\mathbf{L}_r} A$. Suppose that A is a nonthesis of both logics. The canonical general frame $\langle W_{\mathbf{L}_r}, R_{\mathbf{L}_r}, P_{\mathbf{L}_r} \rangle$ verifies \mathbf{L} and rejects A , and we shall see that it is finite.

Firstly $\langle W_{\mathbf{L}_r}, R_{\mathbf{L}_r} \rangle$ has rank $\leq n$. For if it has a chain F_0, \dots, F_n then there must be formulas A_1, \dots, A_n with

$$\Box A_{n-1} \in F_{i+1} \text{ and not } A_{n-1} \in F_i, \text{ for } i = 0, \dots, n-1.$$

Then it is easy to show that the formula B'_n obtained from B_n by substituting A_i for $P_i, i = 1, \dots, n$, has not $B'_n \in F_0$, in contradiction to the properties of $W_{\mathbf{L}_r}$.

Now $W_{\mathbf{L}_r}$ has finitely many maximal consistent sets of rank i , by induction from $i = 1$ to $i = n$. Say that a formula is modally atomic iff it is a propositional variable or of the form $\Box C$ or $\Diamond C$. Since a maximal consistent set F , like an ultrafilter, satisfies the conditions

$$\begin{aligned} \neg A \in F &\text{ iff not } A \in F, \\ A \wedge B \in F &\text{ iff } A \in F \text{ and } B \in F, \\ A \vee B \in F &\text{ iff } A \in F \text{ or } B \in F, \end{aligned}$$

it is determined by its modally atomic formulas. Note that if F is a maximal consistent set in $W_{\mathbf{L}_r}$ of rank i then $\Box C \in F$ iff

$$C \in \cap \{G : F \simeq G \vee (FR_{\mathbf{L}_r} G \wedge G \text{ has rank } < i)\}$$

and $\Diamond C \in F$ iff

$$C \in \cup \{G : F \simeq G \vee (FR_{\mathbf{L}_r} G \wedge G \text{ has rank } < i)\}.$$

By the induction hypothesis there are finitely many sets of maximal consistent sets G with $(FR_{\mathbf{L}_r} G \wedge G \text{ has rank } < i)$. There are finitely many ways of allocating P_1, \dots, P_r to the maximal consistent sets G with $F \simeq G$. Once these items are fixed, the members of each maximal consistent set in the

cluster including F are determined (by an easy induction on the construction of formulas). In particular the number of maximal consistent sets in the cluster is at most the number of ways of allocating P_1, \dots, P_r to those sets. It follows that there are finitely many possible sets of modally atomic formulas for F , and hence finitely many maximal consistent sets F of rank i in $\langle W_{\mathbf{L}_r}, R_{\mathbf{L}_r} \rangle$.

16 THE NORMAL EXTENSIONS OF **S4.3**

(Bull [1966] gives an algebraic proof that every normal extension of **4.3** has the f.m.p. Fine [1971] gives a frame-theoretic proof, together with a description of the lattice of these logics. Both proofs are rather elegant.)

Let \mathbf{L} be any normal modal logic containing **S4.3**. by what we have seen in Section 10, \mathbf{L} is characterised by the subdirectly irreducible closure or interior algebras which verify it. Let \mathfrak{A} be such an algebra. Since \mathfrak{A} verifies $\Box(\Box P \rightarrow \Box Q) \vee \Box(\Box Q \rightarrow \Box P)$ and satisfies the condition

$$\text{if } \mathbf{1}a \cup \mathbf{1}b = 1 \text{ then } \mathbf{1}a = 1 \text{ or } \mathbf{1}b = 1,$$

it is well-connected in the sense that

$$\mathbf{1}a \leq \mathbf{1}b \text{ or } \mathbf{1}b \leq \mathbf{1}a.$$

It also satisfies the condition

$$\text{if } \mathbf{1}a < \mathbf{1}b \text{ then } \mathbf{1}(a \cup (-\mathbf{1}b)) = \mathbf{1}a,$$

where $\mathbf{1}a < \mathbf{1}b$ is $(\mathbf{1}a \leq \mathbf{1}b) \wedge \mathbf{1}a \neq \mathbf{1}b$. This is shown by first applying the same argument to $\Box(\Box P \rightarrow \Box Q) \vee \Box(\Box(\Box P \rightarrow \Box Q) \rightarrow \Box Q)$, which can be shown to be a thesis of **S4.3**, so that $\mathbf{1}b \leq \mathbf{1}a$ or $\mathbf{1}((-\mathbf{1}b) \cup \mathbf{1}a) \leq \mathbf{1}a$. But if $\mathbf{1}a < \mathbf{1}b$ then not $\mathbf{1}b \leq \mathbf{1}a$, and in any interior algebra it can be shown that $\mathbf{1}a \leq \mathbf{1}((-\mathbf{1}b) \cup \mathbf{1}a) = \mathbf{1}((-\mathbf{1}b) \cup a)$. dualising these results, we have

$$\mathbf{m}a \leq \mathbf{m}b \text{ or } \mathbf{m}b \leq \mathbf{m}a, \text{ if } \mathbf{m}b < \mathbf{m}a \text{ then } \mathbf{m}(a - \mathbf{m}b) = \mathbf{m}a,$$

for each $a, b \in A$.

Given a nonthesis A of \mathbf{L} and an algebraic ‘model’ $\langle \mathfrak{A}, v \rangle$ which rejects it, let A_1, \dots, A_m be A and its subformulas and let $\mathfrak{B} = \langle B, 0, 1, -, \cap, \cup \rangle$ be the finite subalgebra of $\langle A, 0, 1, -, \cap, \cup \rangle$ generated by $\{v(A_1), \dots, v(A_m)\}$. Take W to be the set $\{b_1, \dots, b_n\}$ of atoms of the atomic Boolean algebra \mathfrak{B} and define R on W by taking

$$b_i R b_j \text{ iff } b_i \leq \mathbf{m}b_j.$$

Now $\langle W, R \rangle^+$ is a finite closure or interior algebra, such that there is an isomorphism ϕ from \mathfrak{B} onto the underlying Boolean algebra of $\langle W, R \rangle^+$ on

$\mathfrak{B}(W)$. (Note that $\langle W, R \rangle^+$ is not a filtration of \mathfrak{A} in the usual sense.) Define a valuation V' on $\langle W, R \rangle$ by taking

$$v; (P) = \phi v(P), \text{ for each propositional variable } P \text{ in } A,$$

and applying the conditions on valuations. We have

$$v'(A_i) = \phi v(A_i), \text{ for } i = 1, \dots, n,$$

because ϕ is a Boolean isomorphism and

$$x \in \phi(\mathbf{m}b) \text{ iff } \exists y(xRy \wedge y \in \phi(b)),$$

for each $b \in \mathfrak{B}$. For taking $b = x_1 \cup \dots \cup x_r$ for atoms x_1, \dots, x_r of \mathfrak{B} , we have

$$\begin{aligned} x \in \phi(\mathbf{m}b) & \\ \text{iff } x &\leq \mathbf{m}(x_1 \cup \dots \cup x_r) \\ \text{iff } x &\leq \mathbf{m}x_1 \cup \dots \cup \mathbf{m}x_r \\ \text{iff } x &\leq \mathbf{m}(x_1 \text{ or } \dots \text{ or } x_r) \\ \text{iff } xR &x_1 \text{ or } \dots \text{ or } xRx_r \\ \text{iff } \exists y &(xRy \wedge y \in \phi(b)). \end{aligned}$$

In particular $\langle W, R \rangle^+$ rejects A .

To show that $\langle W, R \rangle^+$ verifies **L**, it is sufficient to construct an embedding homomorphism θ from $\langle W, r \rangle^+$ into \mathfrak{A} . Suppose that b_1, \dots, b_n are indexed so that, in their indexed order, $\mathbf{m}b_{k(1)} = \dots = \mathbf{m}b_{k(2)-1} < \dots < \mathbf{m}b_{k(s)} = \dots = \mathbf{m}b_{k(s+1)-1}$ in \mathfrak{A} , where $1 = k(1) < \dots < k(s+1) = n+1$. Set $b_{k(0)} = 0$ and note that $\mathbf{m}b_{k(1)} - \mathbf{m}b_{k(0)}, \dots, \mathbf{m}b_{k(s)} - \mathbf{m}b_{k(s-1)}$ is a disjoint cover of 1. Define θ by taking

$$\theta(\phi) = 0;$$

for $i = 1, \dots, s$,

$$\theta(\{b_{k(i)}\}) = \mathbf{m}b_{k(i)} = b_{k(i)+1} \cup \dots \cup b_{k(i+1)-1} - \mathbf{m}b_{k(i-1)};$$

for $i = 1, \dots, s$ and $k(i) + j = k(i) + 1, \dots, k(i+1) - 1$,

$$\begin{aligned} \theta(\{b_{k(i)+j}\}) &= b_{b(i)+j} - \mathbf{m}b_{k(i+1)}; \\ \theta(\{b_{i(1)}, \dots, b_{i(r)}\}) &= \theta(\{b_{i(1)}\}) \cup \dots \cup \theta(\{b_{i(r)}\}). \end{aligned}$$

It is clear that θ is an embedding homomorphism of the underlying Boolean algebras. It can also be shown that

$$\begin{aligned} \mathbf{m}\theta(\{b_{k(i)}\}) &= \mathbf{m}(b_{k(i)} - \mathbf{m}b_{k(i-1)}), \\ \mathbf{m}\theta(\{b_{k(i)+j}\}) &= \theta(\{b_1, \dots, b_{k(i+1)-1}\}), \end{aligned}$$

for $i = 1, \dots, s$ and $k(i) + j = k(i), \dots, k(i+1) - 1$. (The second result uses the first and the lemma of the first paragraph.) But $\{b_1, \dots, b_{k(i+1)-1}\}$

is the closure of $\{b_{k(i)+j}\}$ in $\langle W, R \rangle^+$, so that θ is now easily seen to be a homomorphism w.r.t. \mathbf{m} as well.

Alternatively, \mathbf{L} is characterised by the generated submodels $\langle W_{\mathbf{L}x}, R_{\mathbf{L}x}, V_{\mathbf{L}x} \rangle$ of its canonical model. We know from Section 13 that these satisfy the condition

$$\forall y \forall z (y R_{\mathbf{L}x} z \vee z R_{\mathbf{L}x} y).$$

So, given a nonthesis A of \mathbf{L} , let $\langle W, R, V \rangle$ be a model which satisfies this condition and rejects A . Let $\{A_1, \dots, A_n\}$ be $\Diamond A$ and its subformulas, and consider the filtration $\langle W; \bar{R}, \bar{V} \rangle$ determined by this set of formulas.

Let us first try to prove that finite $\langle W', \bar{R} \rangle$ verifies each formula verified by $\langle W, R, V \rangle$ and, hence, \mathbf{L} , which would establish the f.m.p. for \mathbf{L} . We must first reduce any model $\langle W', \bar{R}, V'' \rangle$ to $\langle W', \bar{R}, \bar{V} \rangle$. Say a subset of W' is definable in $\langle W, \bar{R}, \bar{V} \rangle$ iff it is $\bar{v}(B)$, for some formula B ; that $\langle W', \bar{P}\bar{R}, v'' \rangle$ is a definable variant of $\langle W', \bar{R}, \bar{V} \rangle$ iff $\bar{v}''(P)$ is definable in $\langle W', \bar{R}, \bar{V} \rangle$, for each propositional variable P ; and that $\langle W', \bar{R}, \bar{V} \rangle$ is differentiated iff $\{[w]\}$ is definable, for each $[w] \in W'$ (cf. 1- refinement). It is easy to show that finite $\langle W', \bar{R}, \bar{V} \rangle$ is differentiated; that therefore each $\langle W', \bar{R}, V'' \rangle$ is a definable variant of it' and that therefore if $\langle W', \bar{R}, \bar{V} \rangle$ verifies \mathbf{L} then so does each W', \bar{R}, V'' . To show that $\langle W', \bar{R}, \bar{V} \rangle$ verifies \mathbf{L} , it would clearly suffice to show that

$$\begin{aligned} &\text{if } xRy \text{ then } [x]\bar{R}[y], \\ &\text{if } [x]\bar{R}[y] \text{ then } \exists z(xRz \wedge z \in [y]). \end{aligned}$$

The first condition is of course true, but unfortunately it is quite possible that the second could fail.

In view of this set-back, let us try to eliminate elements β for which the second condition fails. given $\alpha, \beta \in W'$, define β sub α to hold iff

$$\exists x(x \in \alpha \wedge \forall y(y \in \beta \rightarrow \neg xRy)).$$

Note that if this holds then yRx , since $\langle W, R \rangle$ is connected and so $\beta \bar{R} \alpha$. Say that β is *eliminable*' iff there is some α with $\alpha \bar{R} \beta$ and β sub α . (Note the similarity of the conditions 'virtually last' and 'eliminable' on the members of a cluster in a filtration.) Take U to be the set of noneliminable elements of V , and form $\langle U, \bar{R}, \bar{V} \rangle$ by restricting \bar{R}, \bar{V} to U . It is easy to show that

$$\bar{V}(A_i, [x]) = T \text{ iff } A_i \in x, \text{ for } i = 1, \dots, n \text{ and each } [x] \in U,$$

once the lemma of the following paragraph is proved. It follows that $\langle U, \bar{R}, \bar{V} \rangle$ rejects the given formula A and is differentiated.

The lemma is that, for each formula $\Diamond B$ in $\{A_1, \dots, A_n\}$, if $\Diamond B \in x$ then there is some y with $B \in y$ such that $[x]\bar{R}[y]$ and y is not eliminable. This is done by constructing a sequence $\alpha_0, \alpha_1, \alpha_2, \dots$ in W' by taking $\alpha_0 = [x]$,

and for each $i = 1, 2, 3, \dots$,

$$\begin{aligned} \alpha_{2i-1} & \text{ is some } [z] \text{ with } B \in z \text{ and not } [z] \text{ sub } \alpha_{2i-2}, \\ \alpha_{2i} & \text{ is some } [z] \text{ with } [z]\bar{R}\alpha_{2i-1} \text{ and } \alpha_{2i-1} \text{ sub } [z]. \end{aligned}$$

It is easy to see that $B \in \alpha_{2i-1}$ and $\diamond B \in \alpha_{2i}$, for $i = 1, 2, 3, \dots$. It can be shown that this sequence must terminate, but that it cannot terminate at any α_{2i} . the required y is the z with $B \in z$ such that the sequence terminates at $\alpha_{2j-1} = [z]$.

To complete the argument it will suffice to set up a frame morphism ϕ from some definable variant of $\langle W, R, V \rangle$ onto $\langle U, \bar{R}, \bar{V} \rangle$. Fro then $\langle U, \bar{R}, \bar{V} \rangle$ will verify L , as shown in Section 10, and so will each variant of differentiated $\langle U, \bar{R}, \bar{V} \rangle$, as in the original ‘proof’. Define $\phi : W \rightarrow U$ by taking

$$\begin{aligned} \phi(x) & = [x], \text{ if } [x] \in U, \\ & = \text{ the first element in some arbitrary ordering of } U \text{ which is} \\ & \quad \bar{R}\text{-first in } \{\alpha : [x]\bar{R}\alpha\}, \text{ otherwise} \end{aligned}$$

—noting that ϕ is onto U . If xRy then $[x]\bar{R}[y]$ and $[y]\bar{R}\phi(y)$ yield $\phi(x)\bar{R}\phi(y)$. If $\phi(x)\bar{R}\phi(y)$ then we must have some $z \in \phi(y)$ with xRz , otherwise $\phi(y)$ sub $\phi(x)$ and $\phi(y)$ would be eliminable. Now $\phi(y) = \phi(z)$ and xRz as required. Thus ϕ is an onto frame morphism. Define a valuation V' on $\langle W, R \rangle$ by taking $V'(P, x) = \bar{V}(P, \phi(x))$, for each propositional variable P , and applying the conditions on valuations. Then it is easy to show that $\langle W, R, V' \rangle$ is a definable variant of $\langle W, R, V \rangle$ and to extend ϕ to a morphism of models.

(What is the relationship between these two proofs? Take $\langle W, R, V \rangle$ to be a generated sub model of the canonical model of \mathbf{L} , and take $\langle \mathfrak{A}, v \rangle$ to be $\langle \langle W, R \rangle^+, v \rangle$, for the same valuation. Thus \mathfrak{A} is indeed a subdirectly irreducible closure or interior algebra verifying \mathbf{L} . Relabelling the finite frame $\langle W, R \rangle$ of the first proof as $\langle W', R' \rangle$, W' is the usual set obtained from $\{v(A_1), \dots, v(A_n)\}$ in a filtration, but from

$$\alpha R' \vee \text{ iff } \forall x(x \in \alpha \rightarrow \exists y(xRy \wedge y \in \beta)).$$

Since a one-one homomorphism θ from $\langle W', R' \rangle^+$ into $\langle W, R \rangle^+$ is the dual of a frame morphism ϕ from $\langle W, R \rangle$ onto $\langle W', R' \rangle$, we would expect that all the elements in W' are noneliminable. To see that this is indeed true, suppose that $\alpha R' \beta$ and β sub α and try to obtain a contradiction. In this case there is some $x \in \alpha$ with $\forall y(y \in \beta \rightarrow \neg xRy)$ by the definition of β sub α . then the definition of $\alpha R' \beta$ give us some $y \in \beta$ with xRy —the required contradiction. Unfortunately, the other condition on frame morphisms, that if xRy then $[x]R'[y]$, is not satisfied by this construction. and indeed the frame morphism ϕ of which θ is the dual, is not $\phi(x) = [x]$, for each $x \in W$, but a more complicated function which can be constructed from the definition of θ above.)

Say that a nonempty sequence of positive integers is a list. A finite frame $\langle W, R \rangle$ which verifies **S4.3** must consist of a finite chain of finite clusters, so that it is described by the list of numbers of elements in successive clusters. Say that a list t contains a list $s = \langle A_1, \dots, a_m \rangle$ when there is a subsequence $\langle b_{i_1}, \dots, b_{i_m} \rangle$ of t with $a_1 \leq b_{i_1}, \dots, a_m \leq b_{i_m}$. And that $t = \langle b_1, \dots, b_n \rangle$ covers s iff t contains s and $a_m \leq b_n$. Given finite frames $\langle W, R \rangle$ and $\langle U, S \rangle$ which verify **S4.3**, described by lists t and s , it is easy to show that if t covers than in each infinite sequence t_1, t_2, t_3, \dots of lists there is an infinite subsequence $t_{i_1}, t_{i_2}, t_{i_3}, \dots$, such that if $h < k$ then t_{i_h} is covered by t_{i_k} . From this it is easy to deduce that there is no infinite increasing sequence $\mathbf{L}_1 \subset \mathbf{L}_2 \subset \mathbf{L}_3 \subseteq \dots$ of normal modal logics containing **S4.3**. For take A_i to be a formula in \mathbf{L}_{i+1} but not in \mathbf{L}_i , and take t_i to be the list describing a suitable finite frame which rejects A_i . Then the result yields a t_j with $i < j$ which covers t_i , and now A_i is also not in \mathbf{L}_j with $i + 1 \leq j$, a contradiction.

17 THE PRETABULAR EXTENSIONS OF **S4**

(A normal modal logic is said to be tabular iff it is characterised by a single finite structure, and to be pretabular iff all its proper extensions are tabular. Thus the well-known [Scroggs, 1951] shows that **S5** = **S4B** is a pretabular logic. Maksimova [1975] and [Esaia and Meskhi, 1977] independently prove the very pretty result that there are precisely five pretabular extensions of **S4**. The work of the last four sections provides the background needed for [Esaia and Meskhi, 1977]. The pretabular extensions of **K4** are a much more difficult topic, dealt with by [Block, 1980a]. This paper takes as its starting point the very strong results of [Jónsson, 1967] on the subdirectly irreducible algebras in a variety.)

Consider the finite, generated, reflexive-and-transitive frames $\langle W, R \rangle$. Which parameters of these frames can be left unrestricted by the formulas that they verify? It turns out that there are precisely five of them.

1. *The maximum number of points in any final cluster.*
2. *the maximum number of points in any non-final cluster.*

A cluster $[z]$ is a successor of $[x]$ iff xRz but $[x] \neq [z]$, and an immediate success for iff, further, there is no cluster $[y]$ such that $[z]$ is a successor of $[y]$ and $[y]$ is a successor of $[x]$. Say that the external branching of a cluster is the number of final clusters which are immediate successors of it. And that the internal branching of a cluster is the number of non-final clusters which are immediate successors of it.

3. *The maximum of the external branching of the clusters.*
4. *The maximum of the internal branchings of the clusters.*

5. *The maximum number of clusters in any chain of cluster*, i.e. the rank of $\langle W, R \rangle$ in the sense of Section 15.

It is clear that once all five parameters are bounded, the class of reflexive- and- transitive frames satisfying those bounds is finite. Thus if \mathbf{L} is determined by such a class of frames then it is determined by a single finite frame, namely the finite disjoint union of these finite frames.

For each of the five parameters, given a finite frame $\langle W, R \rangle$ of the kind being considered, a frame $\langle W_i, R_i \rangle$ of a certain kind can be constructed, which has the same value of that parameter. The constructions needed are subframes and frame-morphic images. We saw in Section 10 that a class of frames verifying a normal modal logic \mathbf{L} is closed under them. The five kinds of simple frames and their constructions are as follows.

1. $\langle W_1, R_1 \rangle$ *has one cluster*. Take the largest final cluster of $\langle W, R \rangle$, which is a subframe and has the required properties.
2. $\langle W_2, R_2 \rangle$ *has two clusters, of which the final one is simple*. Take the largest nonfinal cluster $[x]$ of $\langle W, R \rangle$ and form $\langle W_x, R_x \rangle$. Take $W_2 = [x] \cup \{\omega\}$ and define R_2 on it by taking xR_2y iff $x \simeq y \vee y = \omega$. Define a frame morphism ϕ_2 from W_x onto W_2 by taking $\phi_2(y) = y$ if $x \simeq y$, $\phi_2(y) = \omega$ otherwise.
3. $\langle W_3, R_3 \rangle$ *has* $W_3 = \{0, 1, \dots, n\}$ *with* xR_3y *iff* $x = y \vee x = 0$. Take $[x]$ to have the maximal external branching in $\langle W, R \rangle$ with final clusters $[y_1], \dots, [y_n]$ immediately succeeding it. Form $\langle W_x, R_x \rangle$ and define a frame morphism ϕ_3 from W_x onto W_3 by taking $\phi_3(y) = 0$ if $y \in [x]$, $\phi_3(y) = i$ if $y \in [y_i]$, for $i = 1, \dots, n$, $\phi_3(y) = 1$ otherwise.
4. $\langle W_4, R_4 \rangle$ *has* $W_4 = \{0, 1, \dots, n, \omega\}$ *with* xR_4y *iff* $x = y \vee x = 0 \vee y = \omega$. Take $[x]$ to have the maximal internal branching in $\langle W, R \rangle$, with nonfinal clusters $[y_1], \dots, [y_n]$ immediately succeeding it. Form $\langle W_x, R_x \rangle$ and define a frame morphism ϕ_4 from W_x onto W_4 by taking $\phi_4(y) = 0$ if $y \in [x]$, $\phi_4(y) = i$ if $y \in [y_i]$, for $i = 1, \dots, n$, $\phi_4(y) = \omega$ otherwise.
5. $\langle W_5, R_5 \rangle$ *has* $W_5 = \{2, \dots, n\}$ *with* iR_5j *iff* $i \leq j$. Suppose that $\langle W, R \rangle$ has rank n , with a maximal chain $\langle x_1, \dots, x_n \rangle$. Define a frame morphism ϕ_5 from W onto W_5 by taking $\phi_5(y) = i$ if $x_i \simeq y$, for $i = 1, \dots, n-1$, $\phi_5(y) = n$ otherwise.

Each of these five sets of simple frames characterises a normal modal logic, as follows:

1. **S4B**, known as **S5**.
2. **S4.3B₂M**
3. **S4GrzB₂**.

4. **S4GrzB₃** plus $\diamond\Box\diamond P \rightarrow \Box\diamond P$.

5. **S4 · 3Grz**.

For each of these extensions of **S4B_n** or **S4 · 3** has the f.m.p. by Sections 15 and 16, and it is easy to check the class of finite generated frames which verifies each logic. Any pretabular extension **L** of **S4** must be one of these logics. For pretabular **L** must have the f.m.p. with a class of finite frames in which one of the five parameters is not bounded, as we saw above. Its class of finite frames must therefore include one of the five sets of simple frames. Therefore **L** must be contained in one of the five corresponding logics. But every proper extension of pretabular **L** must be tabular, so that **L** has to be identical with one of these logics.

Finally it can be shown that any nontabular logic is contained in a pretabular logic, and hence in one of these five. But these five logics are pairwise incomparable, so that they must all be pretabular logics.

18 THE TRANSITIVE LOGICS OF FINITE WIDTH

(The work of this section is taken from Fine [1974a; 1974b], which extend the ideas of [Fine, 1971] to a wider set of logics.)

Given a frame $\langle W, R \rangle$ say that points $x, y \in W$ are incomparable iff $x \neq y$ and not xRy and not yRx . The frame $\langle W, R \rangle$ is of width n if it has n pairwise incomparable points but does not have $n + 1$ incomparable points. (In particular, for transitive frames, $\langle W, R \rangle$ is connected iff it is of width 1.) For $i = 1, \dots, n$ take **I_n** to be the formula

$$\bigwedge_{i=0}^n P \rightarrow \bigvee_{0 \leq i \neq j \leq n} \diamond(P_i \wedge (P_j \vee \diamond P_j)).$$

It is easy to see that a generated frame verifies **I_n** iff it is of width $\leq n$.

Various of the nice properties of the connected frames break down at greater widths. As an example of this, there is an infinite increasing chain of normal extensions of **S4I₂**. Indeed there are continuum many distinct normal extensions of **S4I₂**. This is shown by defining certain frames $\mathfrak{F}_1, \mathfrak{F}_2, \mathfrak{F}_3, \dots$ of width 2, and proving that distinct subsets of this set of frames characterise distinct logics. Each frame $\mathfrak{F}_n = \langle W_n, R_n \rangle$ is defined by taking $W_n = \{0, \dots, 2n + 4\}$ and taking R_n to be the restriction to W_n of R with

$$\begin{aligned} iRj \text{ iff either } & i = 0 \\ & \text{or } i \text{ is odd, } j \text{ is odd, and } i > j \\ & \text{or } i \text{ is odd, } j \text{ is even, and } i > j + 2 \\ & \text{or } i \text{ is odd, } j \text{ is odd, and } i > j + 4 \end{aligned}$$

For example, \mathfrak{F}_2 is depicted in Figure 1.

Figure 1.

The result will follow if it can be shown that each \mathfrak{F}_n rejects a formula $\neg A_n$ which is verified by every other \mathfrak{F}_m . In each case A_n is taken to be the frame formula for \mathfrak{F}_n , in the following sense.

The frame formula $A_{\mathfrak{F}}$ for any finite reflexive-and-transitive frame $\mathfrak{F} = \langle \{0, \dots, r\}, R \rangle$ generated by 0 is the conjunction of the formulas P_0 and

$$\begin{aligned} & \Box(P_0 \vee \dots \vee P_r), \\ & \Box(P_i \rightarrow \neg P_j), \text{ for each } i \neq j, \\ & \Box(P_i \rightarrow \Diamond P_j), \text{ whenever } iRj, \\ & \Box(P_i \rightarrow \neg \Diamond P_j), \text{ whenever not } iRj. \end{aligned}$$

In general, frame formulas have the property that $A_{\mathfrak{F}}$ can be satisfied in a frame $\mathfrak{S} = \langle U, S \rangle$ iff, for some $u \in U$, there is a frame morphism ϕ from \mathfrak{S}_u onto \mathfrak{F} . We know from Section 10 that if this condition holds then each formula satisfied in \mathfrak{F} can be satisfied at u in \mathfrak{S} . but $A_{\mathfrak{F}}$ is satisfied in \mathfrak{F} when V is defined on $\{0, \dots, r\}$ by taking

$$V(P_{i,j}) = T \text{ iff } i = j, \text{ for each } i = 0, \dots, r,$$

which yields $V(A_{\mathfrak{F}}, 0) = T$. For the converse, suppose that there is a $u \in U$ and a valuation V' on \mathfrak{S} with $V'(A_{\mathfrak{F}}, u) = T$. Then define a function ϕ from U_u into $\{0, \dots, r\}$ by taking

$$\phi(x) = i \text{ iff } V'(P_i, x) = T,$$

for each x with uSx and $i = 0, \dots, r$. It is straightforward to show, using the construction of $A_{\mathfrak{F}}$, that ϕ is an onto frame morphism.

Therefore, to show that $\neg A_n$ is verified by \mathfrak{F}_m , i.e. A_n is not satisfied by \mathfrak{F}_m , it suffices to show that there is no frame morphism from $\mathfrak{F}_{m,k}$ onto \mathfrak{F}_n unless $m = n$ and $k = 0$. Clearly, if $m < n$ or $1 \leq k \leq 2n + 6$ then $\mathfrak{F}_{m,k}$ does not have enough points for there to be a frame morphism from it onto \mathfrak{F}_n . (Compare $\mathfrak{F}_{2,k}$ with \mathfrak{F}_0 .) So suppose that $m > n$ and $k = 0$ or $k \geq 2n + 7$, and that ϕ is a frame morphism from $\mathfrak{F}_{m,k}$ onto \mathfrak{F}_n , and try to obtain a contradiction. Firstly it can be shown that $\phi(1)$ and $\phi(2)$ are distinct final points of \mathfrak{F}_n , say $\phi(1) = 1$ and $\phi(2) = 2$. Then it can be shown

that $\phi(i) = i$, for $i \geq 1$, in $\mathfrak{F}_{m,k}$, by induction on odd or even $i = 1, 2, \dots$. Now $i = 2n + 5$ or $i = 2n + 6$ is in $\mathfrak{F}_{m,k}$ but not in \mathfrak{F}_n , so that \mathfrak{F}_n does not have enough points for ϕ to map $\mathfrak{F}_{m,k}$ but not in \mathfrak{F}_n , so that \mathfrak{F}_n does not have enough points for ϕ to map $\mathfrak{F}_{m,k}$ into it. (Compare $\mathfrak{F}_{1,0}, \mathfrak{F}_{2,7}, \mathfrak{F}_{2,8}$ with \mathfrak{F}_0 .) (Check why this argument cannot be used on a connected frame!)

Nonetheless, each normal extension of $\mathbf{K4I}_n$ is characterised by the transitive frames of width $\leq n$ which verify it. The proof of this major result is difficult, and all that will be given here is a brief glance at the ideas involved. Let \mathbf{L} be any normal extension of $\mathbf{K4I}_n$. The big difference from the second half of Section 16 is that we are working with infinite $\langle W_{\mathbf{L}_r}, R_{\mathbf{L}_r}, F_{\mathbf{L}_r} \rangle$ instead of with a finite filtration of $\langle W_{\mathbf{L}}, R_{\mathbf{L}}, V_{\mathbf{L}} \rangle$. (Here \mathbf{L}_r is the restriction of \mathbf{L} to the propositional variables P_1, \dots, P_r .) Therefore the problem comes at a different point. It is now immediate that $\langle W_{\mathbf{L}_r}, R_{\mathbf{L}_r}, V_{\mathbf{L}_r} \rangle$ verifies \mathbf{L} , but since this differentiated model is not finite, it is no longer true that each variant of it is definable. (Note that just as the canonical general frame is refined, the canonical model is not only differentiated but natural. That is, it satisfies the condition that if $V(\Box A, x) = T \rightarrow V(A, y) = T$, for each formula A , then xRy .)

As before it is necessary to eliminate certain points from the given frame. Say $x \in W_{\mathbf{L}_r}$ is eliminable iff, for each formula A ,

$$\text{if } V(a, x) = T \text{ then } \exists y(xR_{\mathbf{L}_r}y \wedge \neg yR_{\mathbf{L}_r}x \wedge V_{\mathbf{L}_r}(A, y) = T).$$

A reduced canonical model is not formed on the noneliminable points. It must be shown that there are enough noneliminable points, i.e. that if $V_{\mathbf{L}_r}(A, x) = T$ then there is some noneliminable y with $xR_{\mathbf{L}_r}y$ and $V_{\mathbf{L}_r}(A, y) = T$, and that they are definable. The proof that the reduced canonical frame verifies \mathbf{L} , because the definable variants of the reduced canonical model do, uses the facts that $\langle W_{\mathbf{L}_r}, R_{\mathbf{L}_r}, V_{\mathbf{L}_r} \rangle$ is natural and that $\langle W_{\mathbf{L}_r}, R_{\mathbf{L}_r} \rangle$ has no infinite ascending R -chains. (So does the proof of the definability of the noneliminable points.) So a crucial step in the argument is the lengthy proof that a differentiated model which is transitive and of finite width has no such chains.

19 THE VEILED RECESSION FRAME

The *recession frame* $\langle \omega, R \rangle$ is defined on $\omega = \{0, 1, 2, \dots\}$ by taking

$$mRn \text{ iff } m \leq n + 1 \text{ for each } m, n \in \omega.$$

Thus R is reflexive, and transitive for increasing numbers, but is not transitive for decreasing numbers, when only mRn iff $m = n + 1$. For any valuation V on $\langle \omega, R \rangle$,

$$v(\Box A) = [m, \infty) = \{n : m \leq n\} \text{ and } v(\Box\Box A) = [m + 1, \infty),$$

where $[m-1, \infty)$ is the ‘largest unbroken interval in $v(A)$ ’. It is easy to verify that the recession frame verifies **KT** · **3**. The *veiled* recession frame $\langle \omega, R, P \rangle$ is the general frame defined on the recession frame by taking P to consist of the finite and cofinite subsets of ω . (Cofinite subsets are the complements of the finite ones.) In fact Blok has shown that it characterises **KT** · **3M** plus $\Box(P \rightarrow \Box P) \rightarrow (\Diamond P \rightarrow P)$ and two further axioms, all of which correspond to certain first-order conditions on frames; see [van Benthem, 1978]. The recession frame was introduced in [Makinson, 1969] to show that a certain logic does not have the f.m.p. the veiled recession frame was introduced in [Thomason, 1974] to show that a certain logic is not characterised by frames. Two similar but sharper examples were produced in [van Benthem, 1978]. These four results are discussed in this section. Thomason [1972a] uses the finite fragments of the recession frame with one point added. It shows that a certain formula (10) is verified by any frame verifying a certain infinite set of axioms, of which each finite subset is verified by a frame rejecting (10). It follows that whatever finitary rules are used, a logic with these axioms is not characterised by the frames which verify it. Finally Blok [1980] uses variations on the veiled recession frame to show that there is a continuum of distinct extensions of **KT** which are all verified by the same class of frames! This paper takes as its starting point the very strong results of [Jónsson, 1967] on the subdirectly irreducible algebras in a variety.

These results are usually described as incompleteness theorems, but they are better thought of as showing the independence of various notions of consequence. In each case we have a logic **L** and a formula F . Firstly there is modal *logical consequence* $\mathbf{L} \vdash F$, using the rules of normal modal logics. then for each class S of structures there is a corresponding notion of *semantic consequence*, with $\mathbf{L} \vDash F$ iff F is verified by each structure in S which verifies **L**. We know from Sections 10, 11, 12 that finite semantic consequence is as strong as (frame) semantic consequence, which is as strong as general (frame) semantic consequence, which is equivalent to algebraic ‘semantic’ consequence and modal logical consequence. The problem is to show that these relative strengths are strict. The method is to show by example that some formula F is a consequence of **L** in the first sense but not in the second sense.

In order to show that finite semantic consequence is strictly stronger than semantic consequence, take **L** to be **KT** plus

$$(\Box P \wedge \neg \Box^2 P) \rightarrow \Diamond(\Box^2 P \wedge \neg \Box^3 P),$$

and take F to be 4. If the recession frame verifies this formula, it will show that 4 is not a semantic consequence of this **L**. It is clear that if a valuation V on $\langle \omega, R \rangle$ rejects this formula m then

$$\begin{aligned} V(\Box P, m) &= T, V(\Box^2 P, m) = F, \\ V(\Box^2 P, m+1) &= F \text{ or } V(\Box^3 P, m+1) = T. \end{aligned}$$

In the second case, $(m+1)Rm$ yields $V(\Box P, m) = T$ and a contradiction. The first case requires some n with $m \leq n$ such that $V(\Box P, n) = F$, and some k with $n < k+1$ such that $V(P, k) = F$. Now $m \leq k+1$ and so $V(\Box P, m) = F$, another contradiction.

To show that 4 is a finite semantic consequence of this \mathbf{L} , it is sufficient to show that if a model $\langle W, R, V \rangle$ verifying \mathbf{L} rejects 4 then W is infinite. But in a model which rejects 4 we have $v(\Box^2 P) \subset v(\Box P)$, which serves as the induction basis for an inductive proof that $v(\Box^{n+1} P) \subset v(\Box^n P)$, for $n \geq 1$. The induction step uses the fact that

$$\begin{aligned} &\text{if } v(\Box^k P) - v(\Box^{k+1} P) \neq 0, \\ &\text{then } v(\Box^{k+1} P) - v(\Box^{k+2} P) \neq 0, \end{aligned}$$

from the verification of $(\Box P \wedge \neg \Box^2 P), \Diamond(\Box^2 P \wedge \neg \Box^3 P)$. The argument can be sharpened to prove the existence of an infinite ascending R -chain if

$$(P \wedge \Diamond^2 Q) \rightarrow (\Diamond Q \vee \Diamond^2(Q \wedge \Diamond P))$$

is added to \mathbf{L} . For suppose that $\langle W, R \rangle$ verifies this formula and rejects 4, having $x, y, z \in W$ such that xRy and yRz but not xRz . Then taking $v(P) = \{x\}$ and $v(Q) = \{z\}$ we have $V(P, x) = T, V(\Diamond^2 Q, x) = T, V(\Diamond Q, x) = F$, so that $V(\Diamond^2(Q \wedge \Diamond P), x) = T$. It follows that $V(\Diamond P, z) = T$, which can only hold if zRx . This fact, that if xRy and yRz but not xRz then zRx , can be used to construct an infinite ascending R -chain from the decreasing sequence $v(\Box P), v(\Box^2 P), v(\Box^3 P), \dots$ of subsets of W .

Note that this additional formula is also verified by the recession frame. For if $V(P, m) = T, V(\Diamond^2 Q, m) = T, V(\Diamond Q, m) = F$ then $V(Q, m-2) = T, V(Q \wedge \Diamond P, m-2) = T$, and $V(\Diamond^2(Q \wedge \Diamond P), m) = T$. To show that semantic consequence is strictly stronger than general semantic consequence, it only remains to find a formula A which is verified by the veiled recession frame but is rejected by any frame with an infinite ascending R -chain. Thomason [1974] does give a complicated formula A with this property. Now, for each frame verifying the extension of \mathbf{KT} with the two formulas of recent paragraphs, rejection of 4 implies the rejection of A , so that verification of A requires the verification of 4. Taking \mathbf{L} to be the extension of \mathbf{KT} with the two stated formulas and A , 4 is a semantic consequence of \mathbf{L} but not a general semantic consequence of it.

Another proof that semantic consequence is strictly stronger than general semantic consequence goes as follows. Take \mathbf{L} to be $\mathbf{KT} \cdot \mathbf{3M}$ plus

$$\Box(P \rightarrow \Box P) \rightarrow (\Diamond P \rightarrow P),$$

and take F to be $P \rightarrow \Box P$. This formula reduces the modal operators to triviality, with the corresponding condition on R that if xRy then $x = y$.

Define $xR^n y$ on a frame $\langle W, R \rangle$, for $n \geq 0$, taking

$$\begin{aligned} xR^0 y &\text{ iff } x = y, \\ xR^1 y &\text{ iff } xRy, \\ xR^{n+1} y &\text{ iff } xRz_1, \dots, z_n R y, \text{ for some } z_1, \dots, z_n \in W. \end{aligned}$$

Given a frame $\langle W, R \rangle$ and $x, y \in W$ such that xRy but not $yR^n x$, for $n \geq 0$, define V on $\langle W, R \rangle$ by taking $V(P, z) = T$ iff $yR^n z$, for some $n \geq 0$. It is easy to show that $V(\Box(P \rightarrow \Box P), x) = T$, $V(\Diamond P \rightarrow P, x) = F$. Therefore in any frame $\langle W, R \rangle$ which verifies $\Box(P \rightarrow \Box P) \rightarrow (\Diamond P \rightarrow P)$ we have

(*) if xRy then $yR^n x$, for some $n \geq 0$.

It can be shown that any reflexive frame $\langle W, R \rangle$ which verifies $\cdot 3$ satisfies the condition

$$\forall x \forall y \forall z ((xRy \wedge xRz) \rightarrow (\forall u (yRu \rightarrow zRu) \vee \forall v (zRv \rightarrow yRv))).$$

Call this condition strong connectedness, noting that connectedness is the special case with $u = y$ and $v = z$, and that this condition can be derived from the ordinary one and transitivity. It can be shown that if a reflexive, strongly connected frame $\langle W, R \rangle$ satisfies condition (*), then it verifies $\Box(P \rightarrow \Box P) \rightarrow (\Diamond P \rightarrow P)$. As an application of this result, the recession frame verifies this formula. Thus the veiled recession frame verifies **L** but not $P \rightarrow \Box P$.

Suppose that $\langle W, R \rangle$ is a reflexive, strongly connected frame which satisfies condition (*). It can be shown that if $\langle W, R \rangle$ also verifies M then xRy implies $x = y$, so that any frame which verifies **L** also verifies $P \rightarrow \Box P$. For given any $x \in W$, define

$$S_n = \{y : yR^n x \wedge \neg \exists m (m < n \wedge yR^m x)\},$$

for $n \geq 0$, and define V on $\langle W, R \rangle$ by taking

$$V(P, y) = T \text{ iff } \exists m (y \in S_{2m}), \text{ for each } y \in W.$$

Now it can be shown that $V(\Box \Diamond P, x) = T$, so that $V(\Diamond \Box P, x) = T$ by the verification of M . From this it can be deduced that $V(\Box P, x) = T$. Finally we suppose that xRy and $x \neq y$, and obtain a contradiction. For in this case we have $V(P, y) = T$, so that $y \in S_{2m}$, for some $m \leq 1$, and there are some $z_1, \dots, z_{2m-1} \in W$ with $yRz_1, \dots, z_{2m-1} R x$ and not $z_1 R x$. Thus xRy, xRz_1, yRz_1 but not xRz_1, xRz_1 but not yRz_1 —which contradicts strong connectedness when we put x for z, z_1 for u , and x for v .

A third proof that semantic consequence is strictly stronger than general semantic consequence takes **L** to be **KT** plus

$$\Box(\Box(P \rightarrow \Box P) \rightarrow \Box^3 P) \rightarrow P$$

and takes F to be 4 again. for it can be shown that the veiled recession frame verifies this axiom of \mathbf{L} , but that each frame which verifies it is transitive. The interest of this example lies in the fact that the extension of $\mathbf{S4}$ with this axiom is precisely $\mathbf{S4Grz}$.

Given a frame $\langle W, R \rangle$, consider the evaluation of any formula A in any model on $\langle W, R \rangle$. Our definition of valuations determines $V(A, x)$ in terms of first-order logic applied to propositions of the form yRz and $V(P, y) = T$ for propositional variables P . Replace each yRz by an atomic proposition $R(y, z)$, and each $V(P, y) = T$ by an atomic proposition $P(y)$. Now the truth of A in $\langle W, R \rangle$ can be expressed by a formula in second-order predicate logic with unary predicate parameters P, Q , etc. and one binary parameter R . This formula is known as the standard translation $ST(A)$ of A . As we have seen, $ST(A)$ is often equivalent to a first-order predicate formula in R alone, but this is not always the case. If we take some axiom system for second-order predicate logic then we can introduce yet another notion of consequence. Say that F is a second-order logical consequence of L iff $ST(F)$ is derivable from the standard translations of the formulas of \mathbf{L} . In fact whenever we have shown that F is a semantic consequence of \mathbf{L} , we have used an argument in some unspecified, informal second-order logic to show that F is a second-order logical consequence of \mathbf{L} . Clearly semantic consequence is as strong as second-order logical consequence, which is as strong as modal logical consequence.

Van Benthem [1978; 1979a] discuss whether second-order logical consequence is strictly stronger than modal logical consequence. History added point to this question, in that transitivity was derived from $ST(\mathbf{Grz})$ before 4 was derived in $\mathbf{KG4z}$. Of course the answer will depend on the axiomatisation used for second-order predicate logic. For example, close inspection of the informal argument for $P \rightarrow \Box P$ being a second-order logical consequence of $\mathbf{KT} \cdot \mathbf{3M}$ plus $\Box(P \rightarrow \Box P) \rightarrow (\Diamond P \rightarrow P)$, shows that it involves an Axiom of Choice. It turns out that if this is dropped, then a second-order derivation is no longer possible. Consider the axiomatic second-order logic with just the weak second-order substitution axiom

$$\forall PA \rightarrow S_P^B(A), \text{ for first-order formulas } B.$$

(Here $S_P^B(A)$ is obtained from A by substituting $S_x^t(B)$ for $P(t)$ throughout, under suitable conditions.) the proof that $P \rightarrow \Box P$ is not a general semantic consequence of this modal logic used the veiled recession frame, for which the possible values of formulas are the finite and cofinite subsets of ω . It can be shown that these are precisely the subsets of ω definable by first-order formulas with $=$ and R as their only predicate parameters. Since these are the subsets of ω to which the weak second-order substitution axiom applies, the same argument shows that $P \rightarrow \Box P$ is not a second-order logical consequence of this modal logic.

The normal modal logic **k** plus $\Box(\Box P \rightarrow P) \rightarrow P$ is easily shown to be inconsistent. Define a general frame $\langle \omega \cup \{\infty\}, R, P \rangle$ by taking

$$xRy \text{ iff } x > y \vee x = \infty,$$

and taking P to consist of the finite subsets of ω and their complements in $\omega \cup \{\infty\}$. Then it is easy to show that $\Box(\Box P \rightarrow P) \rightarrow P$ is satisfied at ∞ by each valuation on $\langle \omega \cup \{\infty\}, R, P \rangle$ (but not of course verified). So consider the non-normal logic **K** plus $\Box(\Box P \rightarrow P)$, from which the rule of necessitation has been dropped. Now $P \wedge \neg P$ is a second-order logical consequence of this logic, but not a modal logical consequence of it. Van Benthem [1979a] shows how to adopt this argument to give a normal modal logic **L** and a formula F , such that F is a second-order logical consequence of **L** but not a modal logical consequence of it.

20 INDEPENDENCE RESULTS ABOVE S4

None of the logics used in the previous section is an extension of **S4** (though **KT** · **3M** plus $\Box(P \rightarrow \Box P) \rightarrow (\Diamond P \rightarrow P)$ is a very strong logic in a sense, with no frames between it and triviality). Further, the methods of that section cannot be applied to extensions of **S4**, since transitivity reduces the recession frame to a frame verifying **S5**. For independence results above **S4** we turn to a brief description of the complicated constructions of [Fine, 1972; Fine, 1974a].

In showing that finite semantic consequence is strictly stronger than semantic consequence, **L** is taken to be **S4** plus a certain axiom $Y \rightarrow Z$, and F is taken to be $\neg Y$. The frame used to show that $\neg Y$ is not a consequence of **S4** plus $Y \rightarrow Z$ consists of three chains of points a_i, b_i, c_i , for $i \geq 0$, with R a lattice on them, and a final related pair of points d, e . This frame is illustrated in Figure 2 with R going from left to right. The points in these chains are described by corresponding formulas A_i, B_i, C_i , for $i \geq 0$, with $A_0 = P, B_0 = Q, C_0 = R$. Each A_{i+1} is

$$\Diamond A_i \wedge \Diamond B_i \wedge \neg \Diamond C_i,$$

expressing the fact that

$$a_{i+1}Ra_i \wedge a_{i+1}Rb_i \wedge \neg a_{i+1}Rc_i$$

and similarly for B_{i+1}, C_{i+1} . (Remember the frame formulas of the first half of Section 18.) Because of this construction there are theses of **S4** describing the relations between the points. For example, not a_iRb_i and not a_iRc_i , and $\vdash_{\mathbf{S4}} \Box(A_i \rightarrow (\neg \Diamond B_i \wedge \neg \Diamond C_i))$.

The formula Y is simply a description of a_0, b_0, c_0, d in these terms, so that if V is defined on this frame by taking $V(P) = \{a_0\}, V(Q) = \{b_0\}$,

$V(R) = \{c_0\}, V(S) = \{d\}$, then $V(Y, d) = T$. Thus $V(\neg Y, d) = F$ and $\neg Y$ is rejected on this frame as required. but it is also true that if V is a valuation on this frame with $V(Y, x) = T$ then x is d or e and $V(P), V(Q), V(R)$ are a permutation of $\{a_i\}, \{b_i\}, \{c_i\}$, for some $i \geq 0$. The formula Z describes a property of four such points, so that again $V(Z, x) = T$. Thus $V(Y \rightarrow Z, x) = T$, for each $x \in W$ and each valuation V , so that this frame verifies $Y \rightarrow Z$ as required.

Figure 2.

These formulas also have the property that any frame $\langle W, R \rangle$ which verifies $Y \rightarrow Z$ and has a valuation V which satisfies Y must be infinite. First it can be shown that if $V(Y, x) = T$ then $V(\Diamond A_i, x) = T$, for $i \geq 0$, by an induction on i . The induction basis with $i = 0$ uses $V(Y, x) = T$, the induction step from $i = 1$ uses $V(Y \rightarrow Z, x) = T$, and the other induction steps use theses of **S4** as above and $V(Y' \rightarrow Z', x) = T$, for substitution instances Y', Z' of Y, Z . Then it can be shown that $\vdash_{\mathbf{S4}} A_i \rightarrow A_{i-j}$, for each $0 < j < i$, by an induction using theses of **S4** above. It follows that there must be points a_i with xRa_i and $V(A_i, a_i) = T$, for $i \geq 0$, and with $a_i \neq a_j$, for $i \neq j$. Thus any finite frame which verifies **S4** plus $Y \rightarrow Z$ must reject $\neg Y$, for otherwise it would satisfy Y and be infinite.

A similar strategy is used to show that semantic consequence is strictly stronger than general semantic consequence. At first sight Fine [1974] is not about general semantic consequence at all. Instead $\langle W, R, V \rangle$ strongly verifies A iff all substitution instances of A are true in $\langle W, R, V \rangle$. But this is clearly equivalent to A being true on $\langle W, R, P \rangle$, where $P = \{v(B) : B \text{ a formula}\}$. Unfortunately there are a number of omissions and other typographical slips in this paper. See Bull [1982; 1983]. Again **L** is **S4** plus certain axioms $E \rightarrow F$ and H , and the other formula is $\neg E$. The underlying frame used in showing that $\neg E$ is not a general semantic consequence of this logic has two descending R -chains of points b_m, c_m , for $m \geq 0$, with R a

lattice on them. It also has a sequence of unrelated points a_m linked to an ascending R -chain of points d_m , for $m \geq 0$. (Note that because of the unrelated a_m 's, this frame is not of finite width.) This frame is illustrated in Figure 3 with R going from left to right. (As the page is finite, the ascending and descending parts have been overlapped. Each d_n should be linked to its a_n from the left, so that $d_m R a_n$ for each $m \leq n$.) The points in the first three sequences are described by corresponding formulas A_m, B_m, C_m , for $m \geq 0$, with $B_0 = Q_0, B_1 = Q_1, C_0 = R_0, C_1 = R_1$. Each A_m is

$$\Diamond B_{m+1} \wedge \Diamond C_{m+1} \wedge \neg \Diamond B) m + 2 \wedge \neg \Diamond C_{m+2},$$

expressing the fact that

$$a_m R b_{m+1} \wedge a_m R c_{m+1} \wedge \neg a_m R b_{m+2} \wedge \neg a_m R c_{m+2},$$

and so on. Because of this construction there are theses of **S4** describing the relations between the points. For example, $b_{i+1} R b_i$ but not $b_{i+1} R c_i$, and

$$\vdash_{\mathbf{S4}} \Box (B_{i+1} \rightarrow (\Diamond B_i \wedge \neg \Diamond C_i)).$$

Figure 3.

The formula E is a description, from the viewpoint of d_0 , of the frame given in Figure 4, together with the fact that there is an R -chain after it. Thus E is rejected at d_0 on this frame by taking

$$\begin{aligned} v(P_0) &= \{d_{2m} : m \geq 0\}, & V(P_1) &= \{d_{2m+1} : m \geq 0\}, \\ V(Q_0) &= \{b_0\}, & V(Q_1) &= \{b_1\}, \\ V(R_0) &= \{c_0\}, & V(R_1) &= \{c_1\}. \end{aligned}$$

But it is also true that if V is a valuation on this frame with $V(E, x) = T$ then V must give the propositional variables values which are points in this

configuration. Thus x must be some d_n . The formula F describes the R -chain beginning at d_1 from the viewpoint of d_0 , so that again $V(F, x) = T$. Thus $V(E \rightarrow F, x) = T$, for each $x \in W$ and each valuation V , so that this

Figure 4.

frame verifies $E \rightarrow F$.

These formulas also have the property that any frame $\langle W, R \rangle$ which verifies $E \rightarrow F$ and has a valuation V which satisfies E at $x \in W$ must have an infinite ascending R -chain after x . To see this, write E_n, F_n for the formulas obtained from E, F by replacing A_0, A_1 with A_n, A_{n+1} , and so on. It can be shown by an induction on n that there is an R -chain $\langle x = y_0, \dots, y_n \rangle$ such that $V(E_n, y_n) = T$, for $n \geq 0$. (Think of y_0, \dots, y_n as d_m, \dots, d_{m+n} .) The induction step uses $V(E_n \rightarrow F_n, y_n) = T$ and these of **S4** as above. The crucial point is that

$$F_n = \diamond((P_0 \vee P_1) \wedge \neg \diamond A_n \wedge \diamond A_{n+1})$$

sends us from y_n with $V(F_n, y_n) = T$ to some y_{n+1} with $y_n R y_{n+1}$ and $V(\diamond A_{n+1}, y_{n+1}) = T$. Using this infinite ascending R -chain after x , it is easy to reject

$$H = S \wedge \Box(S \rightarrow \diamond((\neg S \wedge T) \wedge \diamond((\neg S \wedge \neg T) \wedge \diamond S)))$$

at x with a suitable valuation. Thus any frame which verifies **S4** plus $E \rightarrow F$ and H must reject $\neg E$.

Finally, consider again the frame illustrated in Figure 4 above, and the valuation V on it used to satisfy E at d_0 . This valuation determines a general frame on it, in which P is the set of values $v(B)$ of all formulas B . We already know that $E \rightarrow F$ is verified by this general frame and that $\neg E$ is rejected by it, so it only remains to show that it verifies H . Suppose then that $V(\neg H', x) = T$, for some $x \in W$, and some substitution instance H' of H , and try to obtain a contradiction. It is clear that x must be d_m , for some $m \geq 0$, for H can only be rejected on a proper cluster or an infinite ascending R -chain. Note that H' is constructed from three incompatible propositions $a, \neg A \wedge B, \neg A \wedge \neg B$. Further, A and B are constructed from propositional variables and formulas $\Box C_1, \dots, \Box C_k$ with \neg, \wedge, \vee . Note that

after some d_n , the formulas $\Box C_1, \dots, \Box C_k$ must have fixed truth values $V(\Box C_i, d_j)$. Consider j_1, j_2, j_3 with $n \leq j_1, j_2, j_3$ and

$$V(A, d_{j_1}) = V(\neg A \wedge B, d_{j_2}) = V(\neg A \wedge \neg B, d_{j_3}) = T.$$

At least one pair of these j 's must have an even difference, e.g. j_2 and j_3 . In this case

$$V(\neg A \wedge \neg B, d_{j_2}) = V(\neg A \wedge B, d_{j_2}) = T,$$

using the construction of each $V(P_i, d_j)$ and the fact about each $V(\Box C_i, d_j)$. But this contradicts the mutual incompatibility of these three formulas.

21 NEIGHBOURHOOD FRAMES

A *neighbourhood frame* $\langle U, N \rangle$ consists of a set U and a function $N : U \rightarrow \mathfrak{B}(\mathfrak{B}(U))$. Thus each value $N(x)$ of N is a subset of $\mathfrak{B}(U)$, the subsets of U in $N(x)$ being known as the neighbourhoods of x . Valuations V and models on $\langle U, N \rangle$ are defined as for ordinary frames except that

$$V(\Box A, x) = T \text{ iff } V(A) \in N(x).$$

The canonical neighbourhood model $\langle U_L, N_L, V_L \rangle$ for a logic \mathbf{L} is defined as for ordinary frames except that

$$S \in N(F) \text{ iff } \exists A(\Box A \in F \wedge S = \{G : A \in G\}).$$

Satisfaction, verification, and neighbourhood semantic consequence are defined as for ordinary frames. The minimal normal modal logic \mathbf{K} is characterised by the class of neighbourhood frames $\langle U, N \rangle$ in which each $N(x)$ is a filter on U . Such a neighbourhood frame is said to be normal, and determines a modal algebra on $\mathfrak{B}(U)$. Each ordinary frame $\langle W, R \rangle$ determines a normal neighbourhood frame $\langle W, N \rangle$ by taking

$$N(x) = \{S : \{y : xRy\} \subseteq S\}, \text{ for each } x \in W.$$

Here $\langle W, N \rangle$ verifies the same formula as $\langle W, R \rangle$. Also each normal neighbourhood frame $\langle U, N \rangle$ determines an ordinary frame $\langle U, R \rangle$ by taking

$$xRy \text{ iff } y \in \bigcap N(x), \text{ for each } x, y \in U.$$

But here $\langle U, R \rangle$ may not be equivalent to $\langle U, N \rangle$, so that we must ask whether semantic consequence is strictly stronger than normal neighbourhood semantic consequence.

(Neighbourhood frames seem to have been created independently by Dana Scott and Montague. See [Seegerberg, 1971] for a full discussion of

them. Gerson [1975] established that normal neighbourhood semantic consequence was strictly stronger than general semantic consequence, while Gerson [1976; 1975a] established that ordinary semantic consequence was strictly stronger than it.)

In showing that normal neighbourhood semantic consequence is strictly stronger than general semantic consequence, the arguments of Thomason [1974] and Fine [1974] can be taken over with only slight alterations. These come when showing that each normal neighbourhood frame which verifies the logic concerned also verifies the other formula 4 or E . For the first case, if $\langle U, N \rangle$ verifies S. K. Thomason's axiom

$$(P \wedge \diamond^2 Q) \rightarrow (\diamond Q \vee \diamond^2(Q \wedge \diamond P)),$$

and there are $R, S, T \subseteq U$ with $R \subseteq \mathbf{m}S$ and $S \subseteq \mathbf{m}T$ but not $R \subseteq \mathbf{m}T$, then $T \cap \mathbf{m}R$ is nonempty. Now the proof that, if $\langle W, R \rangle$ verifies Makinson's axiom

$$(\Box P \wedge \neg \Box^2 P) \rightarrow \diamond(\Box^2 P \wedge \neg \Box^3 P)$$

but rejects 4 then it must be infinite, can be sharpened as follows. If $\langle U, N \rangle$ verifies both these axioms but rejects 4 then U contains an infinite sequence of distinct subsets W_1, W_2, W_3, \dots with $W_i \subseteq \mathbf{m}W_j$ if $i < j$. S. K. Thomason's second axiom A can be rejected on any $\langle U, N \rangle$ with this property, so that if a normal neighbourhood frame verifies the logic of [Thomason, 1974] then it verifies 4.

For the second case, suppose that $\langle U, N \rangle$ verifies $E \rightarrow F$ and has valuation V which satisfies RE at $u \in U$. Then it can be shown that U contains an infinite sequence of distinct subsets W_1, W_2, W_3, \dots with $u \in W_i$, for $i \geq 0$, and $W_i \subseteq \mathbf{m}W_j$ if $i < j$, taking $W_i = v(E_i)$, for $i \geq 0$. Using this finite sequence of sets it is easy to reject $\neg H$ with V at u , so that if a normal neighbourhood frame verifies $\mathbf{S4}$ plus $E \rightarrow F$ and H then it verifies $\neg E$.

Gerson [1976] uses a minor variation on the logic \mathbf{L} of the 'noncompactness' proof in [Thomason, 1972a]. A very complicated argument shows that this logic is verified by a certain normal neighbourhood frame, which is largely determined by an ordinary frame consisting of all finite fragments of the recession frame, with one point added. A further three points are then added and their neighbourhoods specified. Otherwise the argument is like that of [Thomason, 1972a]. Gerson [1975a] uses a version \mathbf{L}' of the logic \mathbf{L} of [Fine, 1974], with $E \rightarrow F_n$ for $n \geq 1$. That any ordinary frame which verifies \mathbf{L}' also verifies $\neg E$ goes as before. A complicated argument shows that \mathbf{L}' is verified by a certain normal neighbourhood frame, which is largely determined by an ordinary frame similar to that of [Fine, 1974] illustrated above. The difference is that the infinite ascending R -chain of d_m 's has been replaced by an infinity of finite ascending R -chains $\langle d_{m,1}, \dots, d_{m,m} \rangle$ for $m \geq 1$. A further two points are then added and their neighbourhood specified. Otherwise the argument is fairly similar to that of [Fine, 1974].

22 ELEMENTARY EQUIVALENCE AND D -PERSISTENCE

Consider the first-order predicate logic with binary predicate constants $=$ and R . Write $\mathfrak{F} \models A$ iff the formula A of predicate logic is true of the frame \mathfrak{F} , and similarly for $\mathfrak{F} \models \Gamma$, where Γ is a set of predicate formulas. A class X of frames is *elementary* iff

$$X = \{\mathfrak{F} : \mathfrak{F} \models A\}, \text{ for some formula } A \text{ of predicate logic,}$$

Δ -*elementary* iff it is an intersection of elementary classes, Σ -*elementary* iff it is a union of elementary classes, and $\Sigma\Delta$ -*elementary* iff it is an intersection of Σ -elementary classes. Note that X is Δ -elementary iff it is axiomatic, with

$$X = \{\mathfrak{F} : \mathfrak{F} \models \Gamma\}, \text{ for some set } \Gamma \text{ of formulas of predicate logic.}$$

And X is $\Sigma\Delta$ -elementary iff it is closed under elementary equivalence, where \mathfrak{F} and \mathfrak{G} are *elementarily equivalent* iff

$$\mathfrak{F} \models A \text{ iff } \mathfrak{G} \models A, \text{ for each formula } A \text{ of predicate logic.}$$

The importance of elementarily equivalent frames for modal logic lies in the following lemma. Given a general frame $\mathfrak{F} = \langle W, R, P \rangle$, there is a general frame $\mathfrak{F}' = \langle W', R', P' \rangle$ such that \mathfrak{F}' is 1- and 2'-saturated (see Section 10), \mathfrak{F}^+ and \mathfrak{F}'^+ are isomorphic, $\langle W, R \rangle$ and $\langle W', R' \rangle$ are elementarily equivalent, and there is a frame morphism from $\langle W', R' \rangle$ onto $(\mathfrak{F}^+)_2$.

Alternatively, consider modal logic as usual, again writing $\langle \mathfrak{F}, V \rangle \models A$ iff the formula A of modal logic is true in the model $\langle \mathfrak{F}, V \rangle$, and so on. A class X of frames is *modal elementary* iff

$$X = \{\mathfrak{F} : \mathfrak{F} \models A\}, \text{ for some formula } A \text{ of modal logic,}$$

and is *modal axiomatic* iff

$$X = \{\mathfrak{F} : \mathfrak{F} \models \Gamma\}, \text{ for some set } \Gamma \text{ of formulas of modal logic.}$$

Again modal axiomatic is equivalent to modal Δ -elementary. A set Γ of formulas of modal logic is *c-persistent* iff $\langle W_{K\Gamma}, R_{K\Gamma} \rangle \models \Gamma$ (the canonical frame for the normal modal logic K plus Γ), *d-persistent* iff if $\langle \mathfrak{F}, P \rangle \models \Gamma$ then $\mathfrak{F} \models \Gamma$, for each descriptive general frame $\langle v, P \rangle$, and *r-persistent* iff if $\langle \mathfrak{F}, P \rangle \models \Gamma$ then $\mathfrak{F} \models \Gamma$, for each refined general frame $\langle \mathfrak{F}, P \rangle$. Note that *r-persistent* implies *d-persistent*, implies *c-persistent*, implies characterised by frames. Many proofs that a logic is characterised by frames involve *c-persistence*. However \mathbf{K} plus $\Box(\Box P \rightarrow P) \rightarrow \Box P$ is characterised by frames but is not *c-persistent* (see [Seegerberg, 1971; van Benthem, 1979]).

A class of frames verifies a *d-persistent* set of formulas iff it is closed under subframes, frame-morphic images, disjoint unions, and both it and

its complement are closed under the construction $(\mathfrak{F}^+)_{\sharp}$. We know from Section 10 that the class of frames verifying a set of formulas is closed under subframes and frame-morphic images, and that any frame \mathfrak{F} is frame-isomorphic to a subframe of $(\mathfrak{F}^+)_{\sharp}$. The latter point can be extracted from the proof that a descriptive frame \mathfrak{F} is isomorphic to $(\mathfrak{F}^+)_{+}$, and shows that the complement of a class of frames verifying a set of formulas is closed under the construction $(\mathfrak{F}^+)_{\sharp}$. It is easy to show that the class of frames verifying a set of formulas is closed under disjoint unions. If a frame \mathfrak{F} verifies a set Γ of formulas then so do the modal algebra \mathfrak{F}^+ and the descriptive general frame $(\mathfrak{F}^+)_{+}$, by Section 10. If Γ is a d -persistent set of formulas then $(\mathfrak{F}^+)_{\sharp}$ also verifies Γ , so that the class of frames verifying a d -persistent set of formulas is closed under the construction $(\mathfrak{F}^+)_{\sharp}$.

Conversely, suppose that a class X of frames satisfies these closure conditions. Consider the class

$$X^+ = \{\mathfrak{F}^+ : \mathfrak{F} \in X\}$$

of modal algebras and the set

$$\Gamma = \{A : \mathfrak{F}^+ \models A, \text{ for each } \mathfrak{F}^+ \in X^+\}$$

of formulas. If $\mathfrak{F} \in X$ then $\mathfrak{F}^+ \models \Gamma$ and so $\mathfrak{F} \models \Gamma$ by Section 10. For the other direction, suppose that $\mathfrak{F} \models \Gamma$ and so $\mathfrak{F}^+ \models \Gamma$. The set Γ of formulas is closely analogous to the set of equations in modal algebra verified by X^+ , so that the set of all modal algebras verifying Γ is the variety generated by X^+ . Using a theorem of Birkhoff's on varieties, a modal algebra \mathfrak{F}^+ verifies Γ iff it is a homomorphic image of a subalgebra of a direct product of modal algebras $\{\mathfrak{F}_i^+ : i \in I\}$ in X^+ . Checking the definition of the disjoint union $\Sigma_{i \in I} \mathfrak{F}_i \in X$, the direct product $\Pi_{i \in I} \mathfrak{F}_i^+$ is isomorphic to $(\Sigma_{i \in I} \mathfrak{F}_i)^+$. Taking the carrier of the subalgebra to be P , this subalgebra is $\langle \Sigma_{i \in I} \mathfrak{F}_i, P \rangle^+$. Thus there is a homomorphism from $\langle \Sigma_{i \in I} \mathfrak{F}_i \rangle^+$ onto \mathfrak{F}^+ . As in Section 10, we can dualise from the category of modal algebras to the category of descriptive frames, with homomorphic images going to subframes and subalgebras going to frame-morphic images. Thus $(\mathfrak{F}^+)_{+}$ is frame-isomorphic to a subframe of $(\langle \Sigma_{i \in I} \mathfrak{F}_i, P \rangle^+)_{+}$, and $(\langle \Sigma_{i \in I} \mathfrak{F}_i, P \rangle^+)_{+}$ is a frame-morphic image of $((\Sigma_{i \in I} \mathfrak{F}_i)^+)_{+}$, and $((\Sigma_{i \in I} \mathfrak{F}_i)^+)_{+}$ is a frame-morphic image of $((\Sigma_{i \in I} \mathfrak{F}_i)^+)_{\sharp}$. Going to the underlying frames, $(\mathfrak{F}^+)_{\sharp}$ is frame-isomorphic to a subframe of a frame-morphic image of $((\Sigma_{i \in I} \mathfrak{F}_i)^+)_{\sharp}$. Since $\Sigma_{i \in I} \mathfrak{F}_i \in X$ and X is closed under subframes, frame-morphic images, and the construction $(\mathfrak{F}^+)_{\sharp}$, we have $(\mathfrak{F}^+)_{\sharp} \in X$. Since the complement of X is also closed under the construction $(\mathfrak{F}^+)_{\sharp}$, we have $\mathfrak{F} \in X$. Thus $\mathfrak{F} \models \Gamma$ iff $\mathfrak{F} \in X$, so that X is the class of frames verifying Γ .

It remains to show that Γ is d -persistent. Supposing that a descriptive frame $\langle \mathfrak{F}, P \rangle$ verifies Γ , and repeating the previous argument with $\langle \mathfrak{F}, P \rangle^+$ in place of \mathfrak{F}^+ , will show that $(\langle \mathfrak{F}, P \rangle^+)_{\sharp} \in X$. But the descriptive frame

$\langle \mathfrak{F}, P \rangle$ is frame-isomorphic to $(\langle \mathfrak{F}, P \rangle^+)_+$ by Section 10, so that going to the underlying frames yields that \mathfrak{F} is frame-isomorphic to $(\langle \mathfrak{F}, P \rangle^+)_\sharp$. Thus $\mathfrak{F} \in X$ and, hence, \mathfrak{F} verifies Γ , so that Γ is d -persistent.

Consider a set of formulas Γ characterised by the class X of frames which verify it. Then Γ is d -persistent iff X is closed under the construction $(\mathfrak{F}^+)_\sharp$. If Γ is d -persistent then one direction of the result applies, and yields X closed under the construction $(\mathfrak{F}^+)_\sharp$. If X is the class of frames verifying Γ and is closed under the construction $(\mathfrak{F}^+)_\sharp$, then the other direction of the result applies. In this case it yields that X is the class of frames verifying some d -persistent set of formulas. Inspection of the proof shows that this is the set of semantic consequences of Γ . But since Γ is characterised by frames, it equals its set of semantic consequences so that Γ is a d -persistent set of formulas.

Combining our lemmas elementary equivalence and d -persistence yields two important theorems. Firstly, if a set Γ of formulas is characterised by the class X of frames which verify it and X is closed under elementary equivalence, then Γ is d -persistent. For then X is closed under the construction $(\mathfrak{F}^+)_\sharp$ by the first lemma, and so Γ is d -persistent by the second lemma. Secondly, given a class X of frames closed under elementary equivalence, X is modal axiomatic iff it is closed under subframes, frame -morphic images, disjoint unions, and its complement is closed under the construction $(\mathfrak{F}^+)_\sharp$. We have already seen that a modal axiomatic class of frames has these closure properties. If X is closed under elementary equivalence and these conditions then it satisfies all the closure properties of the theorem on d -persistent sets, using the first lemma. Thus X is modal axiomatic; indeed it is determined by a d -persistent set of formulas.

The presentation here has followed the elegant van Benthem [1979]. The first paper in this area was the important [Fine, 1975]. It defined notions of modal saturation and persistence, and introduced the lemma on classes of frames closed under elementary equivalence. (It worked in terms of models rather than of general frames, but the analogy is close.) It proved the slightly weaker result, that if a set Γ of formulas is characterised by the class X of frames which verify it and X is closed under elementary equivalence, then Γ is c -persistent. The theorem giving the closure conditions for a class X of frames, which is closed under elementary equivalence, to be axiomatic, is Goldblatt's contribution to Goldblatt and Thomason [1975]. The proof was roughly similar to the one here but more complicated. It too started with the duality between varieties of modal algebras and classes of descriptive frames, and used Fine's lemma and the properties of $(\mathfrak{F}^+)_\sharp$ to bridge the gap between the frames and descriptive frames. Fine [1975] used classical modal theory to show that if a set Γ of formulas is r -persistent then the class X of frames which verify Γ is Δ -elementary (and of course characterises the normal modal logic \mathbf{K} plus Γ). It also gives counter-examples to the converse of both its theorems. In the second case the counter-example is

S4·3M. We know that it is characterised by the elementary class of frames determined by certain conditions. and it is verified by the refined general frame $\langle \omega, \leq, P \rangle$, where P is the set of finite and cofinite subsets of ω , but $\langle \omega, \leq \rangle$ rejects M .

23 MODAL ELEMENTARY AND AXIOMATIC CLASSES

The main construction for this topic is the ultraproduct of frames. Consider frames $\mathfrak{F}_i \langle W_i, R_i \rangle$ for $i \in I$, and an ultrafilter G on I . Remember that the members f of the direct product $\prod_{i \in I} W_i$ are the functions $f : I \rightarrow \cup_{i \in I} W_i$ such that $f(i) \in W_i$, for each $i \in I$. Define an equivalence relation \simeq on $\prod_{i \in I} W_i$ by taking

$$f \simeq g \text{ iff } \{i : f(i) = g(i)\} \in G$$

and consider the equivalence classes $[f]$ under \simeq . The *ultraproduct* $\mathfrak{F}_G = \prod_{i \in I} \mathfrak{F}_i / G = \langle W_G, R_G \rangle$ is defined by taking

$$W_G = \prod_{i \in I} W_i / G = \{[f] : f \in \prod_{i \in I} W_i\},$$

$$[f] R_G [g] \text{ iff } \{i : f(i) R_i g(i)\} \in G.$$

To extend this definition to general frames $\langle F_i, P_i \rangle$, for $i \in I$, it can first be shown that

$$\text{if } f \simeq g \text{ then } \{i : f(i) \in S(i)\} \in G \equiv \{i : g(i) \in S(i)\} \in G,$$

$$S \simeq T \text{ iff } \forall f (\{i : f(i) \in S(i)\} \in G \equiv \{i : f(i) \in T(i)\} \in G),$$

for $f, g \in \prod_{i \in I} W_i$ and $S, T \in \prod_{i \in I} P_i$. This justifies defining

$$[S] = \{[f] : \{i : f(i) \in S(i)\} \in G\},$$

for each $S \in \prod_{i \in I} P_i$, and taking

$$P_G = \left\{ [S] : S \in \prod_{i \in I} P_i \right\}.$$

Here the definition of a general frame requires that P_G be a subalgebra of $(\prod_{i \in I} \mathfrak{F}_i / G)^+$. for the case \mathbf{m}_{R_G} we need

$$\mathbf{m}_{R_G} [S] = [\mathbf{m}S],$$

where

$$(\mathbf{m}S)(i) = \mathbf{m}_{R_i}(S(i)), \text{ for each } i \in I,$$

for each $S \in \Pi_{i \in I} P_i$. We have

$$\begin{aligned}
 & [f] \in \mathbf{m}_{R_G}[S] \\
 & \text{iff } [f]R_G[g], \text{ for some } [g] \in [S], \\
 & \text{iff } \{i : f(i)R_i g(i)\} \in G \text{ and } \{i : g(i) \in S(i)\} \in G, \\
 & \quad \text{for some } g \in \Pi_{i \in I} W_i, \\
 & \text{iff } \{i : f(i)R_u g(i) \wedge g(i) \in S(i)\} \in G, \text{ for some } g \in \Pi_{i \in I} W_i, \\
 & \text{iff } \{i : f(i) \in \mathbf{m}_{R_i}(S(i))\} \in G \\
 & \text{iff } \{i : f(i) \in (\mathbf{m}S)(i)\} \in G \\
 & \text{iff } [f] \in [\mathbf{m}S].
 \end{aligned}$$

Given a valuation V_i on each general frame $\mathfrak{F}_i = \langle W_i, R_i, P_i \rangle$, for each $i \in I$, define a valuation V_G on $\mathfrak{F}_G = \langle W_G, R_G, P_G \rangle$ by taking

$$V_G(P, [f]) = T \text{ iff } [f] \in [V_G(P)] \text{ iff } \{i : V_i(P, f(i)) = T\} \in G,$$

for each propositional variable P , and apply the defining conditions for valuations. Then the argument like that of the previous paragraph shows that

$$V_G(A, [f]) = T \text{ iff } \{i : V_i(A, f(i)) = T\} \in G,$$

for each formula A . It is now easy to show that

$$\mathfrak{F}_G \vDash A \text{ iff } \{i : \mathfrak{F}_i \vDash A\} \in G.$$

Going from left to right, note that if not $\{i : \mathfrak{F}_i \vDash A\} \in G$ then $\{i : \text{not } \mathfrak{F}_i \vDash A\} \in G$, since G is an ultrafilter. Now use valuations V_i and points $f(i)$ with $V_i(A, f(i)) = F$, for each i in the member of G . Note that taking $P_i = \mathfrak{B}(W_i)$, for each $i \in I$, does not yield $P_G = \mathfrak{B}(\Pi_{i \in I} W_i/G)$, so that $\Pi_{i \in I} \langle \mathfrak{F}_i, \mathfrak{B}(W_i) \rangle / G$ is not the same as $\Pi_{i \in I} \mathfrak{F}_i / G$. Therefore this result for ultraproducts of general frames yields only

$$\text{if } \mathfrak{F}_G \vDash A \text{ then } \{i : \mathfrak{F}_i \vDash A\} \in G,$$

for ultraproducts of ordinary frames. (As we shall note later, M is a counterexample to the converse.) It follows that if X is a modal elementary class of frames, then its complement is closed under ultraproducts. Similarly, if X is a modal axiomatic class of frames then its complement is closed under ultrapowers. Here an ultrapower \mathfrak{F}^I/G is the ultraproduct $\Pi_{i \in I} \mathfrak{F}_i/G$ for which $\mathfrak{F}_i = \mathfrak{F}$, for each $i \in I$.

Classical model theory proves the following characterisations of the various kinds of elementary classes. A class X of frames is elementary iff X and $\neg X$ are closed under frame isomorphism and ultraproducts. Class X is Δ -elementary iff X is closed under frame isomorphism and ultraproducts, and $\neg X$ is closed under ultrapowers. Class X is Σ -elementary iff X is closed under ultrapowers, and $\neg X$ is closed under frame isomorphism and

ultraproducts. Class X is $\Sigma\Delta$ -elementary iff X and $\neg X$ are closed under isomorphism and ultrapowers. Combining the results so far, it is easy to show that a modal elementary class of frames is elementary if it is closed under ultraproducts. And a modal axiomatic class is Δ -elementary iff it is closed under ultraproducts.

Further, a class X of frames closed under frame isomorphism, subframes, disjoint unions, and ultrapowers is also closed under ultraproducts. For, given $\mathfrak{F}_i \in X$, for $i \in I$, it is easy to show that $\prod_{i \in I} \mathfrak{F}_i / G$ is isomorphic to a subframe of $(\sum_{i \in I} \mathfrak{F}_i)^I / G$. Now it is easy to show that for a modal elementary class X of frames, all the following conditions are equivalent: X is elementary, X is Σ -elementary, X is Δ -elementary, X is $\Sigma\Delta$ -elementary, X is closed under ultrapowers, X is closed under ultraproducts. For a modal axiomatic class X of frames, the conditions elementary and Σ -elementary are equivalent, and the following conditions are equivalent: X is Δ -elementary, X is $\Sigma\Delta$ -elementary, X is closed under ultrapowers, X is closed under ultraproducts.

Ultraproducts of frames were introduced in [Goldblatt, 1975], and are described in detail in [Goldblatt, 1976]. Goldblatt [1975] obtained some of the results above, and gave a complicated example of frames which verify M but have an ultraproduct which does not. It follows that the class of frames verifying M is not (first-order) axiomatic, although [Fine, 1975] shows that **KM** is characterised by the class of frames verifying it. (Therefore this class of frames is characterised by some formula of second-order predicate logic, as in the last part of Section 19.) This result was also proved independently in [van Benthem, 1975], by a direct method. Van Benthem [1976] proved more of the results above, the published version using Goldblatt's ultraproducts. The picture was completed in [Goldblatt, 1976], where there is also a more detailed explanation of the ultraproduct of frames which verify M .

24 TWO FURTHER RESULTS

We have found closure conditions for a modal axiomatic class of frames, provided that it is closed under elementary equivalence and, hence, includes enough saturated frames. Can closure conditions for axiomatic classes of frames still be found when this condition is dropped? A rather complicated answer is provided in [Goldblatt and Thomason, 1975] (originally part of [Thomason, 1975]). Given a frame $\langle W, R \rangle$, choosing a general frame $\langle W, R, P \rangle$ represents a choice of which 'propositions' are to be considered. In then forming $\langle U, S \rangle = (\langle W, R, P \rangle^+)_\#$, the members of U are the ultrafilters on P , representing 'states-of-affairs', i.e. maximal consistent sets of 'propositions'. The natural definition of S on these 'states-of-affairs' is, as usual,

$$uSv \text{ iff } (\forall X \in \mathcal{U})(X \in v \rightarrow \mathbf{m}_R X \in u).$$

Under what conditions will $\langle U, s \rangle$ again verify the formulas verified by $\langle W, R \rangle$? Firstly, there must be no ‘new propositions’ in $\langle U, S \rangle$, i.e.

$$(\forall Y \subseteq U)(\exists X \in P)(Y = \phi(X)),$$

where $\phi(X) = \{u \in U : X \in u\}$, or

$$(\forall Y \subseteq U)(\exists X \in P)(u \in Y \rightarrow X \in u).$$

Secondly, to carry out the necessary induction step on the value of $\diamond A$, we must have

$$(\forall u \in U)(\forall X \in P)(\mathbf{m}_R X \in u \rightarrow (\exists v \in u)(uSv \wedge X \in v)).$$

If $\langle U, S \rangle$ satisfies these conditions for the carrier P of some subalgebra of $\langle W, R \rangle^+$, then we say that $\langle U, S \rangle$ is SA-based on $\langle W, R \rangle$.

It can be shown, by a fairly difficult proof, that $\langle U, S \rangle$ is frame-isomorphic to a frame SA-based on $\langle W, R \rangle$ iff $\langle U, S \rangle^+$ is a homomorphic image of a subalgebra of $\langle W, R \rangle^+$. Now a class of frames is modal axiomatic if it is closed under frame isomorphism, nontrivial disjoint unions, and the construction of $\langle U, S \rangle$ SA-based on $\langle W, R \rangle$. It is easy to show that a modal axiomatic class is closed under these conditions. For the converse, suppose that a class X of frames is closed under these conditions. As in the theorem in Section 23 on the closure conditions for the class of frames verifying a d -persistent set of formulas, we take

$$\begin{aligned} X^+ &= \{\mathfrak{F}^+ : \mathfrak{F} \in X\}, \\ \Gamma &= \{A : \mathfrak{F}^+ \models A \wedge \mathfrak{F}^+ \in X^+\}, \end{aligned}$$

and show that X is the class of frames verifying Γ . Again \mathfrak{F}^+ verifies Γ iff it is a homomorphic image of a subalgebra for a direct product of modal algebras $\{\mathfrak{F}_i^+ : i \in I\}$ in X^+ , where the direct product is isomorphic to $(\sum_{i \in I} \mathfrak{F}_i)^+$ for $\sum_{i \in I} \mathfrak{F}_i \in X$. By the lemma stated above \mathfrak{F} must be SA-based on $\sum_{i \in I} \mathfrak{F}_i$, and so $\mathfrak{F} \in X$. Thus if $\mathfrak{F} \models \Gamma$ then $\mathfrak{F} \in X$, and the converse is clear.

We are familiar with the duality between modal algebras and descriptive frames, and with the fact that we must shift from frames to descriptive frames before a duality can be established. Can we, as an alternative, shift to some other kind of algebra and then establish a duality with frames proper? This is done in [Thomason, 1975]. The appropriate algebras are the complete atomic modal algebras, i.e. modal algebras based on complete atomic Boolean algebras with

$$\begin{aligned} \mathbf{l} \cap \{b_i : i \in I\} &= \cap \{\mathbf{l}b_i : i \in I\}, \\ \mathbf{m} \cup \{b_i : i \in I\} &= \cup \{\mathbf{m}b_i : i \in I\}. \end{aligned}$$

An atom of a Boolean algebra $\mathfrak{B} = \langle B, 0, 1, -, \cap, \cup \rangle$ is an element $a \in B$ with

$$a \leq b \vee a \cap b = 0, \text{ for each } b \in B.$$

Then \mathfrak{B} is atomic iff

$$\forall b \exists a (a \text{ an atom} \wedge a \leq b),$$

and is complete iff it is closed under the operations \cap and \cup for arbitrary subsets $\{b_i : i \in I\}$ of B . In a complete atomic Boolean algebra, each element b is determined by the set of atoms a with $a \leq b$. the appropriate morphisms for the category of complete atomic modal algebras are the complete homomorphisms, i.e. the homomorphisms ϕ with

$$\phi(\cup\{b_i : i \in I\}) = \cup\{\phi(b_i) : i \in I\}.$$

this category is dual to the category of frames and frame morphisms. As far as the structures go, for each frame \mathfrak{F} the usual modal algebra \mathfrak{F}^+ on $\mathfrak{B}(W)$ is complete and atomic. For each complete atomic modal algebra \mathfrak{A} with set of atoms $\text{At}(\mathfrak{A})$, we take the frame $\mathfrak{A}_+ = \langle \text{At}(\mathfrak{A}), R \rangle$ with

$$xRy \text{ iff } x \leq \mathbf{m}y, \text{ for each } x, y \in \text{At}(\mathfrak{A}).$$

For the morphisms, given frames $\mathfrak{F} = \langle W, R \rangle, \mathfrak{F}' = \langle W', R' \rangle$ and a frame morphism $\psi : \mathfrak{F} \rightarrow \mathfrak{F}'$, define $\psi^+ : \mathfrak{F}'^+ \rightarrow \mathfrak{F}^+$ by taking

$$\psi^+(S) = \psi^{-1}[S], \text{ for each } S \in \mathfrak{B}(W')$$

as before. In the other direction a new definition is needed. given complete atomic modal algebras $\mathfrak{A}, \mathfrak{B}$ and a complete homomorphism $\phi : \mathfrak{A} \rightarrow \mathfrak{B}$, define $\phi_+ : \mathfrak{B}_+ \rightarrow \mathfrak{A}_+$ by taking

$$\phi_+(y) = x \text{ iff } y \leq \phi(x), \text{ for each } x \in \text{At}(\mathfrak{A}), y \in \text{At}(\mathfrak{B}).$$

To see that this definition is valid, note that $\{\phi(x) : x \in \text{At}(\mathfrak{A})\}$ is a disjoint cover of B , since $\text{At}(\mathfrak{A})$ is a disjoint cover of A and ϕ is a complete homomorphism. It can be checked that each frame \mathfrak{F} is 'isomorphic' to $(\mathfrak{F}^+)_+$, and that each complete atomic modal algebra \mathfrak{A} is isomorphic to $(\mathfrak{A}_+)^+$, so that these categories are contravariantly dual to each other.

ACKNOWLEDGEMENTS

This chapter is the result of collaboration on the following terms. Segerberg wrote Section 1–9, Bull Sections 10–24. Although the authors met and together planned the paper, each wrote his part independently of the other will little *ex post script* discussion.

Seeger wishes to thank S. K. Thomason (who conveniently spent part of his sabbatical 1982 at the University of Auckland) for a number of very useful critical comments.

ADVANCED MODAL LOGIC

This chapter is a continuation of the preceding one, and we begin it at the place where the authors of *Basic Modal Logic* left us about fifteen years ago. Concluding his historical overview, Krister Segerberg wrote: “Where we stand today is difficult to say. Is the picture beginning to break up, or is it just the contemporary observer’s perennial problem of putting his own time into perspective?” So, where did modal logic of the 1970s stand? Where does it stand now? Modal logicians working in philosophy, computer science, artificial intelligence, linguistics or some other fields would probably give different answers to these questions. Our interpretation of the history of modal logic and view on its future is based upon understanding it as part of mathematical logic.

Modal logicians of the First Wave constructed and studied modal systems trying to formalize a few kinds of necessity-like and possibility-like operators. The industrialization of the Second Wave began with the discovery of a deep connection between modal logics on the one hand and relational and algebraic structures on the other, which opened the door for creating many new systems of both artificial and natural origin. Other disciplines—the foundations of mathematics, computer science, artificial intelligence, etc.—brought (or rediscovered¹) more. “This framework has had enormous influence, not only just on the logic of necessity and possibility, but in other areas as well. In particular, the ideas in this approach have been applied to develop formalisms for describing many other kinds of structures and processes in computer science, giving the subject applications that would have probably surprised the subject’s founders and early detractors alike” [Barwise and Moss 1996]. Even two or three mathematical objects may lead to useful generalizations. It is no wonder then that this huge family of logics gave rise to an abstract notion (or rather notions) of a modal logic, which in turn put forward the problem of developing a general theory for it.

Big classes of modal systems were considered already in the 1950s, say extensions of **S5** [Scroggs 1951] or **S4** [Dummett and Lemmon 1959]. Completeness theorems of Lemmon and Scott [1977],² Bull [1966b] and Segerberg [1971] demonstrated that many logics, formerly investigated “piecewise”, have in fact very much in common and can be treated by the same methods. A need for a uniting theory became obvious. “There are two main lacunae in recent work on modal logic: a lack of general results and a lack of negative results. This or that logic is shown to have such and such a property, but very little is known about the scope or bounds of the property.

¹One of the celebrities in modal logic—the Gödel–Löb provability logic **GL**—was first introduced by Segerberg [1971] as an “artificial” system under the name **K4W**.

²This book was written in 1966.

Thus there are numerous results on completeness, decidability, finite model property, compactness, etc., but very few general or negative results”, wrote Fine [1974c]. The creation of duality theory between relational and algebraic semantics ([Lemmon 1966a,b], [Goldblatt 1976a,b]), originated actually by Jónsson and Tarski [1951], the establishment of the connection between modal logics and varieties of modal algebras ([Kuznetsov 1971], Maksimova and Rybakov [1974], [Blok 1976]), and between modal and first and higher order languages ([Fine 1975b], [van Benthem 1983]) added those mathematical ingredients that were necessary to distinguish modal logic as a separate branch of mathematical logic.

On the other hand, various particular systems became subjects of more special disciplines, like provability logic, deontic logic, tense logic, etc., which has found reflection in the corresponding chapters of this Handbook.

In the 1980s and 1990s modal logic was developing both “in width” and “in depth”, which made it more difficult for us to select material for this chapter. The expansion “in width” has brought in sight new interesting types of modal operators, thus demonstrating again the great expressive power of propositional modal languages. They include, for instance, polyadic operators, graded modalities, the fixed point and difference operators. We hope the corresponding systems will be considered in detail elsewhere in the *Handbook*; in this chapter they are briefly discussed in the appendix, where the reader can find enough references.

Instead of trying to cover the whole variety of existing types of modal operators, we decided to restrict attention mainly to the classes of normal (and quasi-normal) uni- and polymodal logics and follow “in depth” the way taken by Bull and Segerberg in *Basic Modal Logic*, the more so that this corresponds to our own scientific interests.

Having gone over from considering individual modal systems to big classes of them, we are certainly interested in developing general methods suitable for handling modal logics *en masse*. This somewhat changes the standard set of tools for dealing with logics and gives rise to new directions of research. First, we are almost completely deprived of proof-theoretic methods like Gentzen-style systems or natural deduction. Although proof theory has been developed for a number of important modal logics, it can hardly be extended to reasonably representative families. (Proof theory is discussed in the chapter *Sequent systems for modal logics* in a later volume of this *Handbook*; some references to recent results can be found in the appendix.)

In fact, modern modal logic is primarily based upon the frame-theoretic and algebraic approaches. The link connecting syntactical representations of logics and their semantics is general completeness theory which stems from the pioneering results of Bull [1966b], Fine [1974c], Sahlqvist [1975], Goldblatt and Thomason [1974]. Completeness theorems are usually the first step in understanding various properties of logics, especially those that have semantic or algebraic equivalents. A classical example is Maksimova’s

[1979] investigation of the interpolation property of normal modal logics containing **S4**, or decidability results based on completeness with respect to “good” classes of frames. Completeness theory provides means for axiomatizing logics determined by given frame classes and characterizes those of them that are modal axiomatic.

Standard families of modal logics are endowed with the lattice structure induced by the set-theoretic inclusion. This gives rise to another line of studies in modal logic, addressing questions like “what are co-atoms in the lattice?” (i.e., what are maximal consistent logics in the family?), “are there infinite ascending chains?” (i.e., are all logics in the family finitely axiomatizable?), etc. From the algebraic standpoint a lattice of logics corresponds to a lattice of subvarieties of some fixed variety of modal algebras, which opens a way for a fruitful interface with a well-developed field in universal algebra.

A striking connection between “geometrical” properties of modal formulas, completeness, axiomatizability and \bigwedge -prime elements in the lattice of modal logics was discovered by Jankov [1963, 1969], Blok [1978, 1980b] and Rautenberg [1979]. These observations gave an impetus to a project of constructing frame-theoretic languages which are able to characterize the “geometry” and “topology” of frames for modal logics ([Zakharyashev 1984, 1992], [Wolter 1996c]) and thereby provide new tools for proving their properties and clarifying the structure of their lattices.

One more interesting direction of studies, arising only when we deal with big classes of logics, concerns the algorithmic problem of recognizing properties of (finitely axiomatizable) logics. Having undecidable finitely axiomatizable logics in a given class [Thomason 1975a; Shehtman 1978c], it is tempting to conjecture that non-trivial properties of logics in this class are undecidable. However, unlike Rice’s Theorem in recursion theory, some important properties turn out to be decidable, witness the decidability of interpolation above **S4** [Maksimova 1979]. The machinery for proving the undecidability of various properties (e.g. Kripke completeness and decidability) was developed in [Thomason 1982] and [Chagrova 1990b,c].

Thomason [1982] proved the undecidability of Kripke completeness first in the class of polymodal logics and then transferred it to that of unimodal ones. In fact, Thomason’s embedding turns out to be an isomorphism from the lattice of logics with n necessity operators onto an interval in the lattice of unimodal logics, preserving many standard properties [Kracht and Wolter 1999]. Such embeddings are interesting not only from the theoretical point of view but can also serve as a vehicle for reducing the study of one class of logics to another. Perhaps the best known example of such a reduction is the Gödel translation of intuitionistic logic and its extensions into normal modal logics above **S4** [Maksimova and Rybakov 1974; Blok 1976; Esakia 1979a,b]. We will take advantage of this translation to give a brief survey of results in the field of superintuitionistic logics which actually were always

studied in parallel with modal logics (see also Section 5 of *Intuitionistic Logic* in volume 7 of this *Handbook*).

Listed above are the most important general directions in mathematical modal logic we are going to concentrate on in this chapter. They, of course, do not cover the whole discipline. Other topics, for instance, modal systems with quantifiers, the relationship between the propositional modal language and the first (or higher) order classical language, or proof theory are considered in other chapters of this *Handbook*.

It should be emphasized once again that the reader will find no discussions of particular modal systems in this chapter. Modal logic is presented here as a mathematical theory analyzing big families of logics and thereby providing us with powerful methods for handling concrete ones. (In some cases we illustrate technically complex methods by considering concrete logics; for instance Rybakov's [1994] technique of proving the decidability of the admissibility problem for inference rules is explained only for **GL**.)

1 UNIMODAL LOGICS

We begin by considering normal modal logics with one necessity operator, which were introduced in Section 6 of *Basic Modal Logic*. Recall that each such logic is a set of modal formulas (in the language with the primitive connectives $\wedge, \vee, \rightarrow, \perp, \Box$) containing all classical tautologies, the modal axiom

$$\Box(p \rightarrow q) \rightarrow (\Box p \rightarrow \Box q),$$

and closed under substitution, modus ponens and necessitation $\varphi/\Box\varphi$.

1.1 The lattice \mathbf{NExtK}

First let us have a look at the class of normal modal logics from a purely syntactic point of view. Given a normal modal logic L_0 , we denote by $\mathbf{NExt}L_0$ the family of its **n**ormal **e**xtensions. \mathbf{NExtK} is thus the class of all normal modal logics. Each logic L in $\mathbf{NExt}L_0$ can be obtained by adding to L_0 a set of modal formulas Γ and taking the closure under the inference rules mentioned above; in symbols this is denoted by

$$L = L_0 \oplus \Gamma.$$

Formulas in Γ are called *additional* (or *extra*) *axioms of L over L_0* . Formulas φ and ψ are said to be *deductively equivalent* in $\mathbf{NExt}L_0$ if $L_0 \oplus \varphi = L_0 \oplus \psi$. For instance, $\Box p \rightarrow p$ and $p \rightarrow \Diamond p$ are deductively equivalent in \mathbf{NExtK} , both axiomatizing **T**, however $(\Box p \rightarrow p) \leftrightarrow (p \rightarrow \Diamond p) \notin \mathbf{K}$. (For more information on the relation between these formulas see [Chellas and Segerberg 1994] and [Williamson 1994].)

We distinguish between two kinds of derivations from assumptions in a logic $L \in \text{NExt}\mathbf{K}$. For a formula φ and a set of formulas Γ , we write $\Gamma \vdash_L \varphi$ if there is a derivation of φ from formulas in L and Γ with the help of only modus ponens. In this case the standard deduction theorem— $\Gamma, \psi \vdash_L \varphi$ iff $\Gamma \vdash_L \psi \rightarrow \varphi$ —holds. The fact of derivability of φ from Γ in L using both modus ponens and necessitation is denoted by $\Gamma \vdash_L^* \varphi$; in such a case we say that φ is *globally derivable*³ from Γ in L . For this kind of derivation we have the following variant of the deduction theorem which is proved by induction on the length of derivations in the same manner as for classical logic.

THEOREM 1 (Deduction). *For every logic $L \in \text{NExt}\mathbf{K}$, all formulas φ and ψ , and all sets of formulas Γ ,*

$$\Gamma, \psi \vdash_L^* \varphi \text{ iff } \exists m \geq 0 \Gamma \vdash_L^* \Box^{\leq m} \psi \rightarrow \varphi,$$

where $\Box^{\leq m} \psi = \Box^0 \psi \wedge \dots \wedge \Box^m \psi$ and $\Box^n \psi$ is ψ prefixed by n boxes.

It is to be noted that in general no upper bound for m can be computed even for a decidable L (see Theorem 194). However, if the formula

$$\mathbf{tra}_n = \Box^{\leq n} p \rightarrow \Box^{n+1} p$$

is in L —such an L is called *n -transitive*—then we can clearly take $m = n$. In particular, for every $L \in \text{NExt}\mathbf{K4}$, $\Gamma, \psi \vdash_L^* \varphi$ iff $\Gamma \vdash_L^* \Box^+ \psi \rightarrow \varphi$, where $\Box^+ \psi = \psi \wedge \Box \psi$. Moreover, a sort of conversion of this observation holds.

THEOREM 2. *The following conditions are equivalent for every logic L in $\text{NExt}\mathbf{K}$:*

- (i) L is n -transitive, for some $n < \omega$;
- (ii) there exists a formula $\chi(p, q)$ such that, for any φ, ψ and Γ ,

$$\Gamma, \psi \vdash_L^* \varphi \text{ iff } \Gamma \vdash_L^* \chi(\psi, \varphi).$$

Proof. The implication (i) \Rightarrow (ii) is clear. To prove the converse, observe first that $\chi(p, q) \vdash_L^* \chi(p, q)$ and so $\chi(p, q), p \vdash_L^* q$. By Theorem 1, we then have $\chi(p, q) \vdash_L^* \Box^{\leq n} p \rightarrow q$, for some n . Let $q = \Box^{n+1} p$. Then

$$\chi(p, \Box^{n+1} p) \vdash_L^* \Box^{\leq n} p \rightarrow \Box^{n+1} p.$$

And since $p \vdash_L^* \Box^{n+1} p$, $\chi(p, \Box^{n+1} p) \in L$. Consequently, $\mathbf{tra}_n \in L$. ■

REMARK. Note also that (i) is equivalent to the algebraic condition: the variety of modal algebras for L has equationally definable principal congruences. For more information on this and close results consult [Blok and Pigozzi 1982].

³This name is motivated by the semantical characterization of \vdash_L^* to be given in Theorem 19.

The *sum* $L_1 \oplus L_2$ and *intersection* $L_1 \cap L_2$ of logics $L_1, L_2 \in \text{NExt}L_0$ are clearly logics in $\text{NExt}L_0$ as well. The former can be axiomatized simply by joining the axioms of L_1 and L_2 . To axiomatize the latter we require the following definition. Given two formulas $\varphi(p_1, \dots, p_n)$ and $\psi(p_1, \dots, p_m)$ (whose variables are in the lists p_1, \dots, p_n and p_1, \dots, p_m , respectively), denote by $\varphi \underline{\vee} \psi$ the formula $\varphi(p_1, \dots, p_n) \vee \psi(p_{n+1}, \dots, p_{n+m})$.

THEOREM 3. *Let $L_1 = L_0 \oplus \{\varphi_i : i \in I\}$ and $L_2 = L_0 \oplus \{\psi_j : j \in J\}$. Then*

$$L_1 \cap L_2 = L_0 \oplus \{\Box^m \varphi_i \underline{\vee} \Box^n \psi_j : i \in I, j \in J, m, n \geq 0\}.$$

Proof. Denote by L the logic in the right-hand side of the equality to be established and suppose that $\chi \in L_1 \cap L_2$. Then for some $m, n \geq 0$ and some finite I' and J' such that all φ'_i and ψ'_j , for $i \in I', j \in J'$, are substitution instances of some $\varphi_{i'}$ and $\psi_{j'}$, for $i' \in I, j' \in J$, we have

$$\Box^{\leq m} \bigwedge_{i \in I'} \varphi'_i \rightarrow \chi \in L_0, \quad \Box^{\leq n} \bigwedge_{j \in J'} \psi'_j \rightarrow \chi \in L_0,$$

from which

$$\bigwedge_{\substack{i \in I', j \in J' \\ 0 \leq k, l \leq m+n}} (\Box^k \varphi'_i \vee \Box^l \psi'_j) \rightarrow \chi \in L_0$$

and so $\chi \in L$ because $\Box^k \varphi'_i \vee \Box^l \psi'_j$ is a substitution instance of $\Box^k \varphi_{i'} \underline{\vee} \Box^l \psi_{j'}$. Thus, $L_1 \cap L_2 \subseteq L$. The converse inclusion is obvious. \blacksquare

Although the sum of logics differs in general from their union, these two operations have a few common important properties.

THEOREM 4. *The operation \oplus is idempotent, commutative, associative and distributes over \cap ; the operation \cap distributes over (infinite) sums, i.e.,*

$$L \cap \bigoplus_{i \in I} L_i = \bigoplus_{i \in I} (L \cap L_i).$$

It follows that $(\text{NExt}L_0, \oplus, \cap)$ is a complete distributive lattice, with L_0 and the inconsistent logic, i.e., the set **For** of all modal formulas, being its zero and unit elements, respectively, and the set-theoretic \subseteq its corresponding lattice order. Note, however, that \oplus does not in general distribute over infinite intersections of logics. For otherwise we would have

$$(\mathbf{K} \oplus \neg \Box \perp) \oplus \bigcap_{1 \leq n < \omega} (\mathbf{K} \oplus \Box^n \perp) = \bigcap_{1 \leq n < \omega} (\mathbf{K} \oplus \neg \Box \perp \oplus \Box^n \perp),$$

which is a contradiction, since the logic in the left-hand side is consistent (**D**, to be more precise), while that in the right-hand side is not.

If we are interested in finding a simple (in one sense or another) syntactic representation of a logic $L \in \text{NExt}L_0$, we can distinguish *finite*, *recursive* and *independent axiomatizations of L over L_0* . The former two notions mean that $L = L_0 \oplus \Gamma$, for some finite or, respectively, recursive Γ , and a set of axioms Γ is independent over L_0 if $L \neq L_0 \oplus \Delta$ for any proper subset Δ of Γ . In the case when L_0 is \mathbf{K} or any other finitely axiomatizable over \mathbf{K} logic, we may omit mentioning L_0 and say simply that L is finitely (recursively, independently) axiomatizable.

It is fairly easy to see that L is not finitely axiomatizable over L_0 iff there is an infinite sequence of logics $L_1 \subset L_2 \subset \dots$ in $\text{NExt}L_0$ such that $L = \bigoplus_{i>0} L_i$. This observation is known as *Tarski's criterion*. (It is worth noting that finite axiomatizability is not preserved under \cap . For example, using Tarski's criterion, one can show that $\mathbf{D} \cap (\mathbf{K} \oplus \Box p \vee \Box \neg p)$ is not finitely axiomatizable.) The recursive axiomatizability of a logic L , as was observed by Craig [1953], is equivalent to the recursive enumerability of L . As for independent axiomatizability, an interesting necessary condition can be derived from [Kleyman 1984]. Suppose a normal modal logic L_1 has an independent axiomatization. Then, for every finitely axiomatizable normal modal logic $L_2 \subset L_1$, the interval of logics

$$[L_2, L_1] = \{L \in \text{NExt}\mathbf{K} : L_2 \subseteq L \subseteq L_1\}$$

contains an immediate predecessor of L_1 . Using this condition Chagrov and Zakharyashev [1995a] constructed various logics in $\text{NExt}\mathbf{K4}$, $\text{NExt}\mathbf{S4}$ and $\text{NExt}\mathbf{Grz}$ without independent axiomatizations.

To understand the structure of the lattice $\text{NExt}L_0$ it may be useful to look for a set Γ of formulas which is *complete* in the sense that its formulas are able to axiomatize all logics in the class, and *independent* in the sense that it contains no complete proper subsets. Such a set (if it exists) may be called an *axiomatic basis* of $\text{NExt}L_0$. The existence of an axiomatic basis depends on whether every logic in the class can be represented as the sum of "indecomposable" logics. A logic $L \in \text{NExt}L_0$ is said to be \bigoplus -*irreducible* in $\text{NExt}L_0$ if for any family $\{L_i : i \in I\}$ of logics in $\text{NExt}L_0$, $L = \bigoplus_{i \in I} L_i$ implies $L = L_i$ for some $i \in I$. L is \bigoplus -*prime* if for any family $\{L_i : i \in I\}$, $L \subseteq \bigoplus_{i \in I} L_i$ only if there is $i \in I$ such that $L \subseteq L_i$. It is not hard to see (using Theorem 4) that a logic is \bigoplus -irreducible iff it is \bigoplus -prime. This does not hold, however, for the dual notions of \bigcap -irreducible and \bigcap -prime logics. We have only one implication in general: if L is \bigcap -prime (i.e., $\bigcap_{i \in I} L_i \subseteq L$ only if $L_i \subseteq L$, for some $i \in I$) then it is \bigcap -irreducible (i.e., $L = \bigcap_{i \in I} L_i$ only if $L = L_i$, for some $i \in I$). A formula φ is said to be *prime* in $\text{NExt}L_0$ if $L_0 \oplus \varphi$ is \bigoplus -prime in $\text{NExt}L_0$.

PROPOSITION 5. *Suppose a set of formulas Γ is complete for $\text{NExt}L_0$ and contains no distinct deductively equivalent in $\text{NExt}L_0$ formulas. Then Γ is an axiomatic basis for $\text{NExt}L_0$ iff every formula in Γ is prime.*

Although the definitions above seem to be quite simple, in practice it is not so easy to understand whether a given logic is \oplus - or \cap -prime, at least at the syntactical level. However, these notions turn out to be closely related to the following lattice-theoretic concept of splitting for which in the next section we shall provide a semantic characterization.

A pair (L_1, L_2) of logics in $\text{NExt}L_0$ is called a *splitting pair* in $\text{NExt}L_0$ if it divides the lattice $\text{NExt}L_0$ into two disjoint parts: the filter $\text{NExt}L_2$ and the ideal $[L_0, L_1]$. In this case we also say that L_1 *splits* and L_2 *cosplits* $\text{NExt}L_0$.

THEOREM 6. *A logic L_1 splits $\text{NExt}L_0$ iff it is \cap -prime in $\text{NExt}L_0$, and L_2 cosplits $\text{NExt}L_0$ iff it is \oplus -prime in $\text{NExt}L_0$. Moreover, the following conditions are equivalent:*

- (i) (L_1, L_2) is a splitting pair in $\text{NExt}L_0$;
- (ii) L_1 is \cap -prime in $\text{NExt}L_0$ and $L_2 = \bigcap\{L \in \text{NExt}L_0 : L \not\subseteq L_1\}$;
- (iii) L_2 is \oplus -prime in $\text{NExt}L_0$ and $L_1 = \bigoplus\{L \in \text{NExt}L_0 : L \not\subseteq L_2\}$.

Splittings were first introduced in lattice theory by Whitman [1943] and McKenzie [1972] (see also [Day 1977], [Jipsen and Rose 1993]). Jankov [1963, 1968b, 1969], Blok [1976] and Rautenberg [1977] started using splittings in non-classical logic.

A few standard normal modal logics are listed in Table 1. Note that our notations are somewhat different from those used in *Basic Modal Logic*. (\mathbf{A}^* was introduced by Artemov; see [Shavrukov 1991]. The formulas B_n bounding depth of frames are defined in Section 15 of *Basic Modal Logic*.)

1.2 Semantics

The algebraic counterpart of a logic $L \in \text{NExt}\mathbf{K}$ is the variety of modal algebras validating L (for definitions consult Section 10 of *Basic Modal Logic*). Conversely, each variety (equationally definable class) \mathcal{V} of modal algebras determines the normal modal logic $\text{Log}\mathcal{V} = \{\varphi : \forall \mathfrak{A} \in \mathcal{V} \mathfrak{A} \models \varphi\}$. Thus we arrive at a dual isomorphism between the lattice $\text{NExt}\mathbf{K}$ and the lattice of varieties of modal algebras, which makes it possible to exploit the apparatus of universal algebra for studying modal logics.

It is often more convenient, however, to deal not with modal algebras directly but with their relational representations discovered by Jónsson and Tarski [1951] and now known as general frames. Each *general frame* $\mathfrak{F} = \langle W, R, P \rangle$ is a hybrid of the usual Kripke frame $\langle W, R \rangle$ and the modal algebra

$$\mathfrak{F}^+ = \langle P, \emptyset, W, -, \cap, \cup, \Box, \Diamond \rangle$$

in which the operations \Box and \Diamond are uniquely determined by the accessibility relation R : for every $X \in P \subseteq 2^W$,

$$\Box X = \{x \in W : \forall y (xRy \rightarrow y \in X)\}, \quad \Diamond X = -\Box - X.$$

Table 1. A list of standard normal modal logics.

D	=	$\mathbf{K} \oplus \Box p \rightarrow \Diamond p$
T	=	$\mathbf{K} \oplus \Box p \rightarrow p$
KB	=	$\mathbf{K} \oplus p \rightarrow \Box \Diamond p$

K5	=	$\mathbf{K} \oplus \Diamond \Box p \rightarrow \Box p$
Alt_n	=	$\mathbf{K} \oplus \Box p_1 \vee \Box(p_1 \rightarrow p_2) \vee \cdots \vee \Box(p_1 \wedge \cdots \wedge p_n \rightarrow p_{n+1})$
D4	=	$\mathbf{K4} \oplus \Diamond \top$
S4	=	$\mathbf{K4} \oplus \Box p \rightarrow p$
GL	=	$\mathbf{K4} \oplus \Box(\Box p \rightarrow p) \rightarrow \Box p$
Grz	=	$\mathbf{K} \oplus \Box(\Box(p \rightarrow \Box p) \rightarrow p) \rightarrow p$
K4.1	=	$\mathbf{K4} \oplus \Box \Diamond p \rightarrow \Diamond \Box p$
K4.2	=	$\mathbf{K4} \oplus \Diamond(p \wedge \Box q) \rightarrow \Box(p \vee \Diamond q)$
K4.3	=	$\mathbf{K4} \oplus \Box(\Box^+ p \rightarrow q) \vee \Box(\Box^+ q \rightarrow p)$
S4.1	=	$\mathbf{S4} \oplus \Box \Diamond p \rightarrow \Diamond \Box p$
S4.2	=	$\mathbf{S4} \oplus \Diamond \Box p \rightarrow \Box \Diamond p$
S4.3	=	$\mathbf{S4} \oplus \Box(\Box p \rightarrow q) \vee \Box(\Box q \rightarrow p)$
Triv	=	$\mathbf{K4} \oplus \Box p \leftrightarrow p$
Verum	=	$\mathbf{K4} \oplus \Box p$
S5	=	$\mathbf{S4} \oplus p \rightarrow \Box \Diamond p$
K4B	=	$\mathbf{K4} \oplus p \rightarrow \Box \Diamond p$
A*	=	$\mathbf{GL} \oplus \Box \Box p \rightarrow \Box(\Box^+ p \rightarrow q) \vee \Box(\Box^+ q \rightarrow p)$
Dum	=	$\mathbf{S4} \oplus \Box(\Box(p \rightarrow \Box p) \rightarrow p) \rightarrow (\Diamond \Box p \rightarrow p)$
K4BW_n	=	$\mathbf{K4} \oplus \bigwedge_{i=0}^n \Diamond p_i \rightarrow \bigvee_{0 \leq i \neq j \leq n} \Diamond(p_i \wedge (p_j \vee \Diamond p_j))$
K4BD_n	=	$\mathbf{K4} \oplus B_n$
K4_{n,m}	=	$\mathbf{K4} \oplus \Box^n p \rightarrow \Box^m p, \text{ for } 1 \leq m < n$

So, using general frames we can take advantage of both relational and algebraic semantics. To simplify notation, we denote general frames of the form $\mathfrak{F} = \langle W, R, 2^W \rangle$ by $\mathfrak{F} = \langle W, R \rangle$. Such frames will be called *Kripke frames*. Given a class of frames \mathcal{C} , we write $\text{Log}\mathcal{C}$ to denote the logic determined by \mathcal{C} , i.e., the set of formulas that are valid in all frames in \mathcal{C} ; it is called the *logic of \mathcal{C}* . If \mathcal{C} consists of a single frame \mathfrak{F} , we write simply $\text{Log}\mathfrak{F}$.

Basic facts about duality between frames and algebras can be found in the chapters *Basic Modal Logic* and *Correspondence Theory* in this volume. Here we remind the reader of the definitions that will be important in what follows.

A frame $\mathfrak{G} = \langle V, S, Q \rangle$ is said to be a *generated subframe* of a frame $\mathfrak{F} = \langle W, R, P \rangle$ if $V \subseteq W$ is *upward closed* in \mathfrak{F} , i.e., $x \in V$ and xRy imply $y \in V$, $S = R \upharpoonright V$ and $Q = \{X \cap V : X \in P\}$. The smallest generated subframe \mathfrak{G} of \mathfrak{F} containing a set $X \subseteq W$ is called the *subframe generated by X* . A frame \mathfrak{F} is *rooted* if there is $x \in W$ —a *root* of \mathfrak{F} —such that the subframe of \mathfrak{F} generated by $\{x\}$ is \mathfrak{F} itself.

A map f from W onto V is a *reduction* (or *p -morphism*) of a frame $\mathfrak{F} = \langle W, R, P \rangle$ to $\mathfrak{G} = \langle V, S, Q \rangle$ if the following three conditions are satisfied for all $x, y \in W$ and $X \in Q$

- (R1) xRy implies $f(x)Sf(y)$;
- (R2) $f(x)Sf(y)$ implies $\exists z \in W (xRz \wedge f(z) = f(y))$;
- (R3) $f^{-1}(X) \in P$.

The operations of reduction and generating subframes are relational counterparts of the algebraic operations of forming subalgebras and homomorphic images, respectively, and so preserve validity.

A frame $\mathfrak{F} = \langle W, R, P \rangle$ is *differentiated* if, for any $x, y \in W$,

$$x = y \text{ iff } \forall X \in P (x \in X \leftrightarrow y \in X).$$

\mathfrak{F} is *tight* if

$$xRy \text{ iff } \forall X \in P (x \in \Box X \rightarrow y \in X).$$

Those frames that are both differentiated and tight are called *refined*. A frame \mathfrak{F} is said to be *compact* if every subset \mathcal{X} of P with the finite intersection property (i.e., with $\bigcap \mathcal{X}' \neq \emptyset$ for any finite subset \mathcal{X}' of \mathcal{X}) has non-empty intersection. Finally, refined and compact frames are called *descriptive*. A characteristic property of a descriptive \mathfrak{F} is that it is isomorphic to its bidual $(\mathfrak{F}^+)_+$. The classes of all differentiated, tight, refined and descriptive frames will be denoted by \mathcal{DF} , \mathcal{T} , \mathcal{R} and \mathcal{D} , respectively.

When representing frames in the form of diagrams, we denote by \bullet irreflexive points, by \circ reflexive ones, and by $\textcircled{\circ\circ}$ two-point clusters. An arrow from x to y means that y is accessible from x . If the accessibility relation is transitive, we draw arrows only to the immediate successors of x .

Figure 1.

EXAMPLE 7. (Van Benthem 1979) Let $\mathfrak{F} = \langle W, R, P \rangle$ be the frame whose underlying Kripke frame is shown in Fig. 1 ($\omega + 1$ sees only ω and the subframe generated by ω is transitive) and $X \subseteq W$ is in P iff either X is finite and $\omega \notin X$ or X is cofinite in W and $\omega \in X$. It is easy to see that P is closed under \cap , $-$ and \diamond . Clearly, \mathfrak{F} is refined. Suppose \mathcal{X} is a subset of P with the finite intersection property. If \mathcal{X} contains a finite set then obviously $\bigcap \mathcal{X} \neq \emptyset$. And if \mathcal{X} consists of only infinite sets then $\omega \in \bigcap \mathcal{X}$. Thus, \mathfrak{F} is descriptive.

A frame \mathfrak{F} is said to be \varkappa -generated, \varkappa a cardinal, if its dual \mathfrak{F}^+ is a \varkappa -generated algebra.⁴ Each modal logic L is determined by the free finitely generated algebras in the corresponding variety, i.e., by the Tarski–Lindenbaum (or canonical) algebras $\mathfrak{A}_L(n)$ for L in the language with $n < \omega$ variables. Their duals are denoted by $\mathfrak{F}_L(n) = \langle W_L(n), R_L(n), P_L(n) \rangle$ and called the *universal frames of rank n for L* . Analogous notation and terminology will be used for the free algebras $\mathfrak{A}_L(\varkappa)$ with \varkappa generators. Note that $\langle W_L(\varkappa), R_L(\varkappa) \rangle$ is (isomorphic to) the canonical Kripke frame for L with \varkappa variables (defined in Section 11 of *Basic Modal Logic*) and $P_L(\varkappa)$ is the collection of the truth-sets of formulas in the corresponding canonical model. Unless otherwise stated, we will assume in what follows that the language of the logics under consideration contains ω variables.

An important property of the universal frame of rank \varkappa for L is that every descriptive \varkappa' -generated frame for L , $\varkappa' \leq \varkappa$, is a generated subframe of $\mathfrak{F}_L(\varkappa)$. Thus, the more information about universal frames for L we have, the deeper our knowledge about the structure of arbitrary frames for L and thereby about L itself.

Although in general universal frames for modal logics are very complicated, considerable progress was made in clarifying the structure of the upper part (points of finite depth) of the universal frames of finite rank for logics in NExt**K4**. The studies in this direction were started actually by Segerberg [1971]. Shehtman [1978a] presented a general method of constructing the universal frames of finite rank for logics in NExt**S4** with the finite model property. Later similar results were obtained by other authors; see e.g. [Bellissima 1985]. The structure of free finitely generated algebras

⁴An algebra is said to be \varkappa -generated if it contains a set X of cardinality $\leq \varkappa$ such that the closure of X under the algebra's operations coincides with its universe.

for **S4** was investigated by Blok [1976].

Let us try to understand first the constitution of an arbitrary transitive refined frame $\mathfrak{F} = \langle W, R, P \rangle$ with n generators $G_1, \dots, G_n \in P$. Define \mathfrak{V} to be the valuation of the set of variables $\Sigma = \{p_1, \dots, p_n\}$ in \mathfrak{F} such that $x \models p_i$ iff $x \in G_i$. Say that points x and y are Σ -equivalent, $x \sim_\Sigma y$ in symbols, if the same variables in Σ are true at them; for $X, Y \subseteq W$ we write $X \sim_\Sigma Y$ if every point in X is Σ -equivalent to some point in Y and vice versa. Let $d(\mathfrak{F})$ denote the *depth*⁵ of \mathfrak{F} ; if \mathfrak{F} is of infinite depth, we write $d(\mathfrak{F}) = \infty$. For $d < d(\mathfrak{F})$, $W^{=d}$ and $W^{>d}$ are the sets of all points in \mathfrak{F} of depth d and $> d$, respectively; $W^{<d}$, $W^{\leq d}$, etc. are defined analogously. $\mathfrak{F}^{\leq d}$ is the subframe of \mathfrak{F} generated by $W^{\leq d}$. The set of all successors (predecessors) of points in a set $X \subseteq W$ is denoted by $X\uparrow$ (respectively, $X\downarrow$); in the transitive case $X\downarrow = X\uparrow \cup X$ and $X\uparrow = X\downarrow \cup X$ are then the upward and downward closure operations. A set X is said to be a *cover* for a set Y in \mathfrak{F} if $Y \subseteq X\downarrow$. A point x is called an *atom* in \mathfrak{F} if $\{x\} \in P$.

THEOREM 8. *Suppose $\mathfrak{F} = \langle W, R, P \rangle$ is a transitive refined n -generated frame, for some $n < \omega$. Then*

- (i) *each cluster in \mathfrak{F} contains $\leq 2^n$ points;*
- (ii) *for every finite $d \leq d(\mathfrak{F})$, $W^{=d}$ is a cover for $W^{\geq d}$ and contains at most $c_n(d)$ distinct clusters, where*

$$c_n(1) = 2^n + 2^{2^n} - 1, \quad c_n(m+1) = c_n(1) \cdot 2^{c_n(1) + \dots + c_n(m)};$$

- (iii) *every point of finite depth in \mathfrak{F} is an atom.*

Proof. (i) follows from the differentiatedness of \mathfrak{F} and the obvious fact that precisely the same formulas (in p_1, \dots, p_n) are true under \mathfrak{V} at Σ -equivalent points in the same cluster.

The proof of (ii) proceeds by induction on d . Let $x \in W^{>d}$. Since \mathfrak{F} is transitive and $W^{\leq d}$ is finite (by the induction hypothesis), there exists a non-empty upward closed in $W^{>d}$ set X (i.e., $X = X\uparrow \cap W^{>d}$) such that $x \in X\downarrow$, points in X see exactly the same points of depth $\leq d$ and either

$$(1) \quad \forall u, v \in X \exists w \in u\uparrow \cap X \quad w \sim_\Sigma v$$

or

$$(2) \quad \forall u, v \in X \quad (u \sim_\Sigma v \wedge \neg uRv).$$

Such a set X is called *d-cyclic*; it is *nondegenerate* if (1) holds and *degenerate* otherwise. One can readily show that the same formulas are true at Σ -equivalent points in X . Since \mathfrak{F} is refined, X is then a cluster of depth $d+1$. Thus, $W^{>d} \subseteq W^{=d+1}\downarrow$. The upper bound for the number of distinct

⁵In Section 15 of *Basic Modal Logic* $d(\mathfrak{F})$ was called the rank of \mathfrak{F} .

clusters of depth $d + 1$ follows from the differentiatedness of \mathfrak{F} and the definition of d -cyclic sets.

To establish (iii), for every point x of depth $d + 1$ one can construct by induction on d a formula (expressing the definition of the d -cyclic set containing x) which is true in \mathfrak{F} under \mathfrak{V} only at x . For details consult [Chagrova and Zakharyashev 1997]. ■

It is fairly easy now to construct the (generated) subframe $\mathfrak{F}_{\mathbf{K4}}^{\leq \infty}(n)$ of the universal frame of rank n for $\mathbf{K4}$ consisting of finite depth points. Indeed, $\mathfrak{F}_{\mathbf{K4}}(n)$ is n -generated, refined and so has the form as described in Theorem 8. On the other hand, it is universal and contains any n -generated descriptive frame as a generated subframe, which means roughly that it contains all possible points of finite depth that can exist in n -generated refined frames.

More precisely, assuming that each point is assigned the set of variables in Σ that are true at it, we begin constructing a frame $\mathfrak{G}_{\mathbf{K4}}(n)$ by putting at depth 1 in it 2^n non- Σ -equivalent degenerate clusters and $2^{2^n} - 1$ non- Σ -equivalent non-degenerate clusters with $\leq 2^n$ non- Σ -equivalent points. Suppose that $\mathfrak{G}_{\mathbf{K4}}^{\leq d}(n)$ is already constructed. Then for every antichain \mathfrak{a} of clusters in $\mathfrak{G}_{\mathbf{K4}}^{\leq d}(n)$ containing at least one cluster of depth d and different from a singleton with a non-degenerate cluster, we add to $\mathfrak{G}_{\mathbf{K4}}^{\leq d}(n)$ copies of all $2^n + 2^{2^n} - 1$ clusters of depth 1 so that they would be inaccessible from each other and could see only the clusters in \mathfrak{a} and their successors. And for every singleton $\mathfrak{a} = \{C\}$ with a non-degenerate cluster C , we add to $\mathfrak{G}_{\mathbf{K4}}^{\leq d}(n)$ copies of those clusters of depth 1 which are not Σ -equivalent to any subset of C (otherwise the frame will not be refined) so that again they would be mutually inaccessible and could see only C and its successors in $\mathfrak{G}_{\mathbf{K4}}^{\leq d}(n)$.

Let $\mathfrak{M}_{\mathbf{K4}}(n) = \langle \mathfrak{G}_{\mathbf{K4}}(n), \mathfrak{U}_{\mathbf{K4}}(n) \rangle$ be the resulting model (the relational component of $\mathfrak{G}_{\mathbf{K4}}(n)$ is completely determined by the construction and its set of possible values is the collection of the truth-sets of formulas in $\mathfrak{G}_{\mathbf{K4}}(n)$ under $\mathfrak{U}_{\mathbf{K4}}(n)$). It is not hard to show that $\mathfrak{G}_{\mathbf{K4}}(n)$ is atomic. Moreover, for every point x in this frame one can construct a formula $\varphi(p_1, \dots, p_n)$ such that $x \not\models \varphi$ and, for any frame \mathfrak{F} , $\mathfrak{F} \models \varphi$ iff there is a generated subframe of \mathfrak{F} reducible to the subframe of $\mathfrak{G}_{\mathbf{K4}}(n)$ generated by x . It follows in particular that $\mathfrak{G}_{\mathbf{K4}}(n)$ is refined. Thus, every $\mathfrak{G}_{\mathbf{K4}}^{\leq d}(n)$ is a generated subframe of $\mathfrak{F}_{\mathbf{K4}}(n)$. On the other hand, by Theorem 8, $\mathfrak{F}_{\mathbf{K4}}(n)$ contains no clusters of depth $\leq d$ different from those in $\mathfrak{G}_{\mathbf{K4}}^{\leq d}(n)$ and so $\mathfrak{F}_{\mathbf{K4}}^{\leq \infty}(n)$ is isomorphic to $\mathfrak{G}_{\mathbf{K4}}(n)$. It worth noting also that, since $\mathbf{K4}$ has the finite model property, it is characterized by $\mathfrak{F}_{\mathbf{K4}}^{\leq \infty}(n)$, and so $\mathfrak{F}_{\mathbf{K4}}(n)$ is isomorphic to the bidual of $\mathfrak{F}_{\mathbf{K4}}^{\leq \infty}(n)$.

The universal frame $\mathfrak{F}_L(n)$ for an arbitrary consistent logic L in $\text{NExt}\mathbf{K4}$ is a generated subframe of $\mathfrak{F}_{\mathbf{K4}}(n)$. It can be constructed by removing from $\mathfrak{F}_{\mathbf{K4}}(n)$ those points at which some formulas in L are refuted (under

Figure 2.

$\mathfrak{V}_{\mathbf{K}_4}(n)$. For example, $\mathfrak{F}_{\mathbf{S}_4}^{\leq \infty}(n)$ is obtained by removing from $\mathfrak{F}_{\mathbf{K}_4}^{\leq \infty}(n)$ all irreflexive points and their predecessors. In other words, $\mathfrak{F}_{\mathbf{S}_4}^{\leq \infty}(n)$ can be constructed in the same way as $\mathfrak{F}_{\mathbf{K}_4}^{\leq \infty}(n)$ but using only non-degenerate clusters. $\mathfrak{F}_{\mathbf{S}_4}^{\leq 2}(1)$ (the corresponding model, to be more exact) is shown in Fig. 2, where \heartsuit denotes the cluster with two points at one of which p_1 is true. To construct $\mathfrak{F}_{\mathbf{Grz}}^{\leq \infty}(n)$ and $\mathfrak{F}_{\mathbf{GL}}^{\leq \infty}(n)$, we take only simple clusters and degenerate clusters, respectively.

In general, this method of constructing universal frames does not work for logics with nontransitive frames. However, using the fact that \mathbf{K} is characterized by the class of finite intransitive irreflexive trees (see Section 13 of *Basic Modal Logic*), in the same manner as above one can construct an intransitive irreflexive model characterizing \mathbf{K} and such that $\mathfrak{F}_{\mathbf{K}}(n)$ is isomorphic to the bidual of the frame associated with this model.

Let us consider now the semantical meaning of splittings. In view of the following observation we focus attention only on splittings by the logics of finite rooted frames.

THEOREM 9. *If L_1 splits $\text{NExt}L_0$ and L_0 has the finite model property then $L_1 = \text{Log}\mathfrak{F}$, for some finite rooted frame \mathfrak{F} validating L_0 .*

Proof. Since L_2 in the splitting pair (L_1, L_2) is a proper extension of L_0 , there is a finite frame \mathfrak{G} such that $\mathfrak{G} \models L_0$ and $\mathfrak{G} \not\models L_2$. It follows that $\text{Log}\mathfrak{G} \subseteq L_1$. As we shall see later (Corollary 86), every extension of a tabular logic is also tabular. So $L_1 = \text{Log}\mathfrak{F}$ for some finite $\mathfrak{F} \models L_0$. And since L_1 is \bigwedge -prime, \mathfrak{F} must be rooted. \blacksquare

We say that a frame \mathfrak{F} *splits* $\text{NExt}L_0$ if $\text{Log}\mathfrak{F}$ splits $\text{NExt}L_0$. The logic L_2 of the splitting pair $(\text{Log}\mathfrak{F}, L_2)$ is denoted by L_0/\mathfrak{F} and called the *splitting* of $\text{NExt}L_0$ by \mathfrak{F} . This notation reflects the fact that L_2 is the smallest logic in $\text{NExt}L_0$ which is not validated by \mathfrak{F} .

EXAMPLE 10. We show that $\mathbf{D} = \mathbf{K}/\bullet$. Recall that $\mathbf{D} = \mathbf{K} \oplus \diamond\top$ is characterized by the class of serial frames (in which every point has a suc-

cessor). So if $\bullet \models L$ then $L \subseteq \text{Log}\bullet$; otherwise no frame for L has a dead end, which means that $\diamond\top \in L$ and $\mathbf{D} \subseteq L$. The inconsistent logic **For** can be represented as \mathbf{D}/\circ .

To illustrate some applications of splittings we require a few definitions. Given $L \in \text{NExt}L_0$, we say that the *axiomatization problem* for L above L_0 is decidable if the set $\{\varphi : L_0 \oplus \varphi = L\}$ is recursive. L is *strictly Kripke complete* above L_0 if no other logic in $\text{NExt}L_0$ has exactly the same Kripke frames as L . If all frames in a set \mathcal{F} split $\text{NExt}L_0$, we call the logic $\bigoplus\{L_0/\mathfrak{F} : \mathfrak{F} \in \mathcal{F}\}$ the *union-splitting* of $\text{NExt}L_0$ and denote it by L_0/\mathcal{F} .

EXAMPLE 11. **Grz** is not a splitting of $\text{NExt}\mathbf{S4}$. However, it is a union-

splitting: $\mathbf{Grz} = \mathbf{S4}/\{\overset{\circ}{\circ\circ}, \overset{\circ}{\circ\circ}\}$. $\mathbf{S4.1} = \mathbf{S4}/\overset{\circ}{\circ\circ}$. A frame may split the lattice $\text{NExt}L_0/\mathcal{F}$ but not $\text{NExt}L_0$: e.g. \circ splits $\text{NExt}\mathbf{K}/\bullet$ but does not split $\text{NExt}\mathbf{K}$.

THEOREM 12. Suppose $L \in \text{NExt}L_0$ and $L = (\dots(L_0/\mathcal{F}_1)/\dots)/\mathcal{F}_n$, for a sequence $\mathcal{F}_1, \dots, \mathcal{F}_n$ of sets of finite rooted frames.

(i) If $\mathcal{F} = \bigcup_{i=1}^n \mathcal{F}_i$ is finite and L is decidable then the axiomatization problem for L above L_0 is decidable. More precisely,

$$\{\varphi : L_0 \oplus \varphi = L\} = \{\varphi \in L : \forall \mathfrak{F} \in \mathcal{F} \mathfrak{F} \not\models \varphi\}.$$

(ii) If L is Kripke complete then L is strictly Kripke complete above L_0 .

(iii) The immediate predecessors of L in $\text{NExt}L_0$ are precisely the logics $L \cap \text{Log}\mathfrak{F}$, for $\mathfrak{F} \in \mathcal{F}$ such that \mathfrak{F} is not a reduct of a generated subframe of another frame in \mathcal{F} .

Proof. (i) is left to the reader as an easy exercise.

(ii) Let L' be a logic in $\text{NExt}L_0$ with the same Kripke frames as L . Then obviously $L' \subseteq L$. On the other hand, the frames in \mathcal{F} do not validate L' and so $L \subseteq L'$.

(iii) If L' is an immediate predecessor of L in $\text{NExt}L_0$ then $\mathfrak{F} \models L'$, for some $\mathfrak{F} \in \mathcal{F}$. Therefore, $L' \subseteq L \cap \text{Log}\mathfrak{F} \subset L$ and so $L' = L \cap \text{Log}\mathfrak{F}$. Suppose now that \mathfrak{F} is not a reduct of a generated subframe of another frame in \mathcal{F} and $L \cap \text{Log}\mathfrak{F} \subseteq L' \subset L$. Then $L' \subseteq \text{Log}\mathfrak{F}'$ for some $\mathfrak{F}' \in \mathcal{F}$, and hence $\mathfrak{F}' = \mathfrak{F}$, $L' = L \cap \text{Log}\mathfrak{F}$. \blacksquare

As follows from Theorem 12 and Example 10, **For** has exactly two immediate predecessors in $\text{NExt}\mathbf{K}$: **Verum** = $\text{Log}\bullet$ and **Triv** = $\text{Log}\circ$ (and each consistent normal modal logic is contained in one of them). This result is known as Makinson's [1971] Theorem. Moreover, the axiomatization problem for **For** is decidable, i.e., there is an algorithm which decides, given a formula φ whether $\mathbf{K} \oplus \varphi$ is consistent. Likewise, since $\mathbf{D} = \mathbf{K} \oplus \diamond\top$ is decidable, there is an algorithm recognizing, given φ , whether $\mathbf{D} = \mathbf{K} \oplus \varphi$.

We shall see later in Section 4.4 that in fact not so many properties of logics are decidable (e.g. the axiomatization problem for $\mathbf{K} \oplus \neg\Diamond\top$ is undecidable; see Theorem 207) and that Theorem 12 (i) provides the main method for proving decidability results of this type.

To determine whether a finite rooted frame $\mathfrak{F} = \langle W, R \rangle$ splits $\text{NExt}L_0$, we need the formulas defined below:

$$\begin{aligned} \Delta_{\mathfrak{F}} &= \{p_x \rightarrow \Diamond p_y : x, y \in W, xRy\} \cup \\ &\quad \{p_x \rightarrow \neg\Diamond p_y : x, y \in W, \neg xRy\} \cup \\ &\quad \{p_x \rightarrow \neg p_y : x, y \in W, x \neq y\}, \\ \sigma_{\mathfrak{F}} &= \bigwedge \Delta_{\mathfrak{F}}, \quad \delta_{\mathfrak{F}} = \sigma_{\mathfrak{F}} \wedge \bigvee \{p_x : x \in W\}. \end{aligned}$$

The meaning of $\delta_{\mathfrak{F}}$ is explained by the following lemma, in which

$$\Box^{<\omega} \varphi = \{\Box^n \varphi : n < \omega\}.$$

LEMMA 13. *For any finite \mathfrak{F} with root r , the set of formulas $\{p_r\} \cup \Box^{<\omega} \delta_{\mathfrak{F}}$ is satisfiable in a frame \mathfrak{G} iff there is a generated subframe \mathfrak{H} of \mathfrak{G} reducible to \mathfrak{F} . Moreover, if \mathfrak{F} is cycle free (i.e., contains no path from a point to itself) then ω can be replaced by $n = d(\mathfrak{F}) + 1$.*

Proof. (\Rightarrow) Suppose $\{p_r\} \cup \Box^{<\omega} \delta_{\mathfrak{F}}$ is satisfied at a point u in \mathfrak{G} . It is not hard to check that the map f defined by $f(v) = x$ iff $v \models p_x$ is a reduction of the subframe \mathfrak{H} of \mathfrak{G} generated by u to \mathfrak{F} . If \mathfrak{F} is cycle free and $\{p_r\} \cup \Box^{<\omega} \delta_{\mathfrak{F}}$ is satisfied at u then $d(\mathfrak{H}) = d(\mathfrak{F})$. For otherwise an ascending chain of $n+1$ points starts from u and so \mathfrak{F} must contain a cycle.

(\Leftarrow) Let f be a reduction of \mathfrak{H} to \mathfrak{F} . Define a valuation in \mathfrak{G} so that $v \models p_x$ iff $v \in f^{-1}(x)$. The reader can readily verify that under this valuation $\{p_r\} \cup \Box^{<\omega} \delta_{\mathfrak{F}}$ is true at any point in $f^{-1}(r)$. \blacksquare

LEMMA 14. *For every logic $L \in \text{NExt}\mathbf{K}$ and every finite rooted frame \mathfrak{F} , $\mathfrak{F} \models L$ iff $\forall n < \omega \Box^{\leq n} \delta_{\mathfrak{F}} \rightarrow \neg p_r \notin L$.*

Proof. The implication (\Rightarrow) follows from Lemma 13. Suppose now that $\Box^{\leq n} \delta_{\mathfrak{F}} \rightarrow \neg p_r \notin L$, for every $n < \omega$. Then the set $\{p_r\} \cup \Box^{<\omega} \delta_{\mathfrak{F}}$ is L -consistent and so it is satisfied in a frame \mathfrak{G} for L . By Lemma 13, a generated subframe of \mathfrak{G} is reducible to \mathfrak{F} , and hence $\mathfrak{F} \models L$. \blacksquare

We are now in a position to characterize finite frames that split $\text{NExt}L_0$ and to axiomatize splittings.

THEOREM 15. *Suppose \mathfrak{F} is a finite frame with root r and $L_0 \in \text{NExt}\mathbf{K}$. Then \mathfrak{F} splits $\text{NExt}L_0$ iff there is $n < \omega$ such that, for every frame $\mathfrak{G} \models L_0$, $\Box^{\leq n} \delta_{\mathfrak{F}} \wedge p_r$ is satisfiable in \mathfrak{G} only if $\Box^{\leq m} \delta_{\mathfrak{F}} \wedge p_r$ is satisfiable in \mathfrak{G} for every $m > n$. In this case $L_0/\mathfrak{F} = L_0 \oplus \Box^{\leq n} \delta_{\mathfrak{F}} \rightarrow \neg p_r$.*

Proof. (\Rightarrow) Suppose otherwise and consider a sequence $\{\mathfrak{G}_n : n < \omega\}$ of frames for L_0 such that $\Box^{\leq n} \delta_{\mathfrak{F}} \wedge p_r$ is satisfiable in \mathfrak{G}_n but $\Box^{\leq m} \delta_{\mathfrak{F}} \wedge p_r$ is not satisfied, for some $m > n$. By Lemma 14, the former condition implies $\bigcap_{n < \omega} \text{Log} \mathfrak{G}_n \subseteq \text{Log} \mathfrak{F}$, while the latter means that $\mathfrak{F} \not\models \text{Log} \mathfrak{G}_n$, for every $n < \omega$, contrary to $\text{Log} \mathfrak{F}$ being \bigcap -prime.

(\Leftarrow) We show that $L_0/\mathfrak{F} = L_0 \oplus \Box^{\leq n} \delta_{\mathfrak{F}} \rightarrow \neg p_r$. Suppose $L \not\subseteq \text{Log} \mathfrak{F}$. Then, by Lemma 14, there is $m < \omega$ such that $\Box^{\leq m} \delta_{\mathfrak{F}} \rightarrow \neg p_r \in L$. It follows that $\Box^{\leq n} \delta_{\mathfrak{F}} \rightarrow \neg p_r \in L$ and so $L_0 \oplus \Box^{\leq n} \delta_{\mathfrak{F}} \rightarrow \neg p_r \subseteq L$. ■

For more general versions of this criterion consult [Kracht 1990] and [Wolter 1993].

COROLLARY 16 (Rautenberg 1980). *Suppose that $L_0 \in \text{NExt}(\mathbf{K} \oplus \text{tra}_n)$, for some $n < \omega$. Then every finite rooted frame \mathfrak{F} for L_0 splits $\text{NExt} L_0$ and $L_0/\mathfrak{F} = L_0 \oplus \Box^{\leq n} \delta_{\mathfrak{F}} \rightarrow \neg p_r$.*

In particular, every transitive finite rooted frame splits $\text{NExt} \mathbf{K4}$. This result may also be obtained using the fact that all finite subdirectly irreducible algebras split the lattice of subvarieties of a variety with equationally definable principal congruences (see [Blok and Pigozzi 1982]). However, not every frame splits $\text{NExt} \mathbf{K}$.

THEOREM 17 (Blok 1978). *A finite rooted frame \mathfrak{F} splits $\text{NExt} \mathbf{K}$ iff it is cycle free. In this case $\mathbf{K}/\mathfrak{F} = \mathbf{K} \oplus \Box^{\leq n} \delta_{\mathfrak{F}} \rightarrow \neg p_r$, where $n = d(\mathfrak{F})$.*

Proof. That frames with cycles do not split $\text{NExt} \mathbf{K}$ follows from the fact that \mathbf{K} is characterized by cycle free finite rooted frames. And the converse is an immediate consequence of Lemma 13 and Theorem 15. ■

An element $x \neq 0$ of a complete lattice \mathfrak{L} is called an *atom* in \mathfrak{L} if the zero element 0 in \mathfrak{L} is the immediate predecessor of x , i.e., there is no y such that $0 < y < x$. Splittings turn out to be closely related to the existence of atoms in finitely generated free algebras; see [Blok 1976], [Bellissima 1984, 1991] and [Wolter 1997c]. We demonstrate the use of splittings by the following

THEOREM 18 (Blok 1980a). *The lattice $\text{NExt} \mathbf{K}$ has no atoms.*

Proof. If a logic L is an atom in $\text{NExt} \mathbf{K}$, it is \bigoplus -prime. It follows that L cosplits $\text{NExt} \mathbf{K}$ and the logic $L' = \text{Log} \mathfrak{F}$ in the splitting pair (L', L) has no proper predecessor that splits $\text{NExt} \mathbf{K}$. Add a new irreflexive root to \mathfrak{F} . By Theorem 17, the resulting frame \mathfrak{G} splits $\text{NExt} \mathbf{K}$, and clearly $\text{Log} \mathfrak{G} \subset \text{Log} \mathfrak{F}$, which is a contradiction. ■

A logic is linked with its semantics via completeness theorems. The most general completeness theorem states that every consistent normal modal logic is characterized by the class of (descriptive) frames validating it. Or, if we want to characterize the consequence relations \vdash_L and \vdash_L^* , we can use the following

THEOREM 19. (i) For $L \in \text{NExt}\mathbf{K}$, $\Gamma \vdash_L \varphi$ iff for any model \mathfrak{M} based on a frame for L and any point x in \mathfrak{M} , $x \models \Gamma$ implies $x \models \varphi$.

(ii) For $L \in \text{NExt}\mathbf{K}$, $\Gamma \vdash_L^* \varphi$ iff for any model \mathfrak{M} based on a frame for L , $\mathfrak{M} \models \Gamma$ implies $\mathfrak{M} \models \varphi$.

However, usually more specific completeness results are required. What is the “geometry” of frames for a given logic? Are Kripke or even finite frames enough to characterize it? Questions of this sort will be addressed in the next several sections.

1.3 Persistence

The structure of Kripke frames for many standard modal logics can be described by rather simple conditions on the accessibility relation which are expressed in the first order language with equality and a binary (accessibility) predicate R . (This observation was actually the starting point of investigations in *Correspondence Theory* studying the relation between modal and first (or higher) order languages; see Chapter 4 of this volume.) Moreover, in many cases it turns out that the universal frame $\mathfrak{F}_L(\omega)$ for such a logic L also satisfies the corresponding first order condition ϕ . Since ϕ says nothing about sets of possible values in $P_L(\omega)$, it follows immediately that the canonical (Kripke) frame $\kappa\mathfrak{F}_L(\omega)$ also satisfies ϕ and so characterizes L . Thus we obtain a completeness theorem of the form:

$$\varphi \in L \text{ iff } \mathfrak{F} \models \varphi \text{ for every Kripke frame } \mathfrak{F} \text{ satisfying } \phi.$$

This method of establishing Kripke completeness, known as the *method of canonical models*, is based essentially upon two facts: first, that L is characterized by its universal frame $\mathfrak{F}_L(\omega)$ and second, that L is “persistent” under the transition from $\mathfrak{F}_L(\omega)$ to its underlying Kripke frame. Of course, instead of $\mathfrak{F}_L(\omega)$ we can take any other class of frames \mathcal{C} with respect to which L is complete and try to show that L is \mathcal{C} -persistent in the sense that, for every $\mathfrak{F} = \langle W, R, P \rangle$ in \mathcal{C} , if $\mathfrak{F} \models L$ then $\kappa\mathfrak{F} = \langle W, R \rangle$ validates L as well.

PROPOSITION 20. *If a logic is both \mathcal{C} -complete and \mathcal{C} -persistent, then it is complete with respect to the class $\{\kappa\mathfrak{F} : \mathfrak{F} \in \mathcal{C}\}$ of Kripke frames.*

It follows in particular that L is Kripke complete whenever it is \mathcal{DF} -, or \mathcal{R} -, or \mathcal{D} -persistent. Since every descriptive frame for L is a generated subframe of a suitable universal frame for L , L is \mathcal{D} -persistent iff it is persistent with respect to the class of its universal frames. It is an open problem, however, whether *canonicity*, i.e., $\mathfrak{F}_L(\omega)$ -persistence, implies \mathcal{D} -persistence. Here are two simple examples.

THEOREM 21 (van Benthem 1983). *A logic is persistent with respect to the class of all general frames iff it is axiomatizable by a set of variable free formulas.*

It is easily checked that a Kripke frame validates \mathbf{Alt}_n iff no point in it has more than n distinct successors (see [Segerberg 1971]).

THEOREM 22 (Bellissima 1988). *Every $L \in \mathbf{NExtAlt}_n$ is \mathcal{DF} -persistent, for any $n < \omega$.*

Proof. The proof is based on the fact that, for any differentiated frame $\mathfrak{F} = \langle W, R, P \rangle$, any finite $X \subseteq W$, and any $y \in X$, there is $Y \in P$ such that $X \cap Y = \{y\}$. It follows that at most n distinct points are accessible from every point in a differentiated frame for L ; in particular, \mathbf{Alt}_n is \mathcal{DF} -persistent. Suppose now that a formula $\varphi \in L$ is refuted at a point x under a valuation \mathfrak{V} in $\kappa\mathfrak{F}$, \mathfrak{F} a differentiated frame for L . Let X be the set of points accessible from x in $\leq md(\varphi)$ steps.⁶ Since X is finite, there is a valuation \mathfrak{U} in \mathfrak{F} such that $\mathfrak{U}(p) \cap X = \mathfrak{V}(p)$, for every variable p . Consequently, φ is false in \mathfrak{F} at x under \mathfrak{U} , which is a contradiction. ■

The proof of Fine's [1974c] Theorem that all logics of finite width, i.e., logics in $\mathbf{NExtK4BW}_n$, for $n < \omega$, are Kripke complete (a sketch can be found in Section 18 of *Basic Modal Logic*) may also be regarded as a proof of persistence. Recall that a point x in a transitive frame $\mathfrak{F} = \langle W, R, P \rangle$ is called *non-eliminable* (relative to R) if there is $X \in P$ such that $x \in X$ but no proper successor of x is in X (in other words, x is *maximal* in X); in this case we write $x \in \max_R X$. Denote by W_r the set of all non-eliminable points in \mathfrak{F} and put $\mathfrak{F}_r = \langle W_r, R_r, P_r \rangle$, where $R_r = R \upharpoonright W_r$, $P_r = \{X \cap W_r : X \in P\}$. (Fine called the frame \mathfrak{F}_r *reduced*.)

THEOREM 23 (Fine 1985). *Let $\mathfrak{F} = \langle W, R, P \rangle$ be a transitive descriptive frame and $x \in X \in P$. Then (i) there exists a point $y \in \max_R X \cap x \uparrow$ and (ii) \mathfrak{F}_r is a refined frame whose dual \mathfrak{F}_r^+ is isomorphic to \mathfrak{F}^+ .*

Proof. (i) Suppose otherwise, i.e., there is no maximal point in $X \cap x \uparrow$. Let Y be a maximal chain of points in $X \cap x \uparrow$ (that it exists follows from Zorn's Lemma) and $\mathcal{X} = \{Z \in P : \exists y \in Y \ y \uparrow \cap Y \subseteq Z\}$. Clearly, \mathcal{X} is non-empty and has the finite intersection property (because $X \cap x \uparrow$ has no maximal point). By compactness, we then have a point z in $\bigcap \mathcal{X}$ which, by tightness, is maximal in Y , contrary to $X \cap x \uparrow$ having no maximal point. (ii) is a consequence of (i). ■

It follows that to establish the Kripke completeness of a logic $L \in \mathbf{NExtK4}$ it is enough to show that it is persistent with respect to the class

$$\mathcal{RE} = \{\mathfrak{F}_r : \mathfrak{F} \text{ a finitely generated descriptive frame}\}.$$

That is what Fine [1974c] actually did for logics of finite width.

⁶Here $md(\varphi)$, the *modal degree* of φ , is the length of the longest chain of nested modal operators in φ .

THEOREM 24 (Fine 1974c). *All logics of finite width are \mathcal{RE} -persistent and so Kripke complete.*

Let us return, however, to the method of canonical models. Having tried it for a number of standard systems, Lemmon and Scott [1977] found a rather general sufficient condition for its applicability and put forward a conjecture concerning a further extension (which was proved by Goldblatt [1976b]). This direction of completeness (and correspondence) theory culminated in the theorem of Sahlqvist [1975] who proved an optimal (in a sense) generalization of the condition of [Lemmon and Scott 1977]. To formulate it we require the following definition. Say that a formula is *positive* (*negative*) if it is constructed from variables (negated variables) and the constants \top , \perp using \wedge , \vee , \diamond and \square .

THEOREM 25 (Sahlqvist 1975). *Suppose φ is a formula which is equivalent in \mathbf{K} to a formula of the form $\square^k(\psi \rightarrow \chi)$, where $k \geq 0$, χ is positive and ψ is constructed from variables and their negations, \perp and \top with the help of \wedge , \vee , \square and \diamond in such a way that no ψ 's subformula of the form $\psi_1 \vee \psi_2$ or $\diamond\psi_1$, containing an occurrence of a variable without \neg , is in the scope of some \square . Then one can effectively construct a first order formula $\phi(x)$ in R and $=$ having x as its only free variable and such that, for every descriptive or Kripke frame \mathfrak{F} and every point a in \mathfrak{F} ,*

$$(\mathfrak{F}, a) \models \varphi \text{ iff } \mathfrak{F} \models \phi(x)[a].$$

(Here $(\mathfrak{F}, a) \models \varphi$ means that φ is true at a in \mathfrak{F} under any valuation.)

Proof. We present a sketch of the proof found by Sambin and Vaccaro [1989]. Given a formula $\varphi(p_1, \dots, p_n)$, a frame $\mathfrak{F} = \langle W, R, P \rangle$ and sets $X_1, \dots, X_n \in P$, denote by $\varphi(X_1, \dots, X_n)$ the set of points in \mathfrak{F} at which φ is true under the valuation \mathfrak{V} defined by $\mathfrak{V}(p_i) = X_i$, i.e., $\varphi(X_1, \dots, X_n) = \mathfrak{V}(\varphi)$. Using this notation, we can say that

$$(\mathfrak{F}, x) \models \varphi(p_1, \dots, p_n) \text{ iff } \forall X_1, \dots, X_n \in P \ x \in \varphi(X_1, \dots, X_n).$$

EXAMPLE 26. Let us consider the formula $\square p \rightarrow p$ and try to extract a first order equivalent for it in the class of tight frames directly from the equivalence above and the condition of tightness. For every tight frame $\mathfrak{F} = \langle W, R, P \rangle$ we have:

$$\begin{aligned} (\mathfrak{F}, x) \models \square p \rightarrow p & \text{ iff } \forall X \in P \ x \in (\square X \rightarrow X) \\ & \text{ iff } \forall X \in P \ (x \in \square X \rightarrow x \in X) \\ & \text{ iff } \forall X \in P \ (x \uparrow \subseteq X \rightarrow x \in X). \end{aligned}$$

To eliminate the variable X ranging over P , we can use two simple observations. The first one is purely set-theoretic:

$$(3) \quad \forall X \in P (Y \subseteq X \rightarrow x \in X) \text{ iff } x \in \bigcap \{X \in P : Y \subseteq X\}.$$

And the second one is just a reformulation of the characteristic property of tight frames:

$$(4) \quad \bigcap \{X \in P : x \uparrow \subseteq X\} = x \uparrow.$$

With the help of (3) and (4) we can continue the chain of equivalences above with two more lines:

$$\begin{aligned} (\mathfrak{F}, x) \models \Box p \rightarrow p & \text{ iff } \dots \\ & \text{ iff } x \in \bigcap \{X \in P : x \uparrow \subseteq X\} \\ & \text{ iff } x \in x \uparrow. \end{aligned}$$

Thus, $\mathfrak{F} \models \Box p \rightarrow p$ iff $\forall x \ x \in x \uparrow$ iff $\forall x \ x R x$.

The proof of Sahlqvist's Theorem is a (by no means trivial) generalization of this argument. Define by induction $x \uparrow^0 = \{x\}$, $x \uparrow^{n+1} = (x \uparrow^n) \uparrow$, and notice that in (4) we can replace $x \uparrow$ by any term of the form $x_1 \uparrow^{n_1} \cup \dots \cup x_k \uparrow^{n_k}$, thus obtaining the equality

$$(5) \quad \bigcap \{X \in P : x_1 \uparrow^{n_1} \cup \dots \cup x_k \uparrow^{n_k} \subseteq X\} = x_1 \uparrow^{n_1} \cup \dots \cup x_k \uparrow^{n_k}$$

which holds for every descriptive frame $\mathfrak{F} = \langle W, R, P \rangle$, all $x_1, \dots, x_k \in W$ and all $n_1, \dots, n_k \geq 0$.

A frame-theoretic term $x_1 \uparrow^{n_1} \cup \dots \cup x_k \uparrow^{n_k}$ with (not necessarily distinct) world variables x_1, \dots, x_k will be called an *R-term*. It is not hard to see that for any *R-term* T , the relation $x \in T$ on $\mathfrak{F} = \langle W, R, P \rangle$ is first order expressible in R and $=$. Consequently, we obtain

LEMMA 27. *Suppose $\varphi(p_1, \dots, p_n)$ is a modal formula and T_1, \dots, T_n are *R-terms*. Then the relation $x \in \varphi(T_1, \dots, T_n)$ is expressible by a first order formula (in R and $=$) having x as its only free variable.*

Syntactically, *R-terms* with a single world variable correspond to modal formulas of the form $\Box^{m_1} p_1 \wedge \dots \wedge \Box^{m_k} p_k$ with not necessarily distinct propositional variables p_1, \dots, p_k . Such formulas are called *strongly positive*. By induction on the construction of φ , one can prove the following

LEMMA 28. *Suppose $\varphi(p_1, \dots, p_n)$ is a strongly positive formula containing all the variables p_1, \dots, p_n and $\mathfrak{F} = \langle W, R, P \rangle$ is a frame. Then one can effectively construct *R-terms* T_1, \dots, T_n (with one variable x) such that for any $x \in W$ and any $X_1, \dots, X_n \in P$,*

$$x \in \varphi(X_1, \dots, X_n) \text{ iff } T_1 \subseteq X_1 \wedge \dots \wedge T_n \subseteq X_n.$$

Now, trying to extend the method of Example 26 to a wider class of formulas, we see that it still works if we replace the antecedent $\Box p$ in $\Box p \rightarrow p$

with an arbitrary strongly positive formula ψ . As to generalizations of the consequent, let us take first an arbitrary formula χ instead of p and see what properties it should satisfy to be handled by our method.

Thus, for a modal formula $(\psi \rightarrow \chi)(p_1, \dots, p_n)$ with strongly positive ψ and a descriptive frame $\mathfrak{F} = \langle W, R, P \rangle$, we have:

$$\begin{aligned} (\mathfrak{F}, x) \models \psi \rightarrow \chi &\text{ iff } \forall X_1, \dots, X_n \in P \ (x \in \psi(X_1, \dots, X_n) \rightarrow \\ &\quad x \in \chi(X_1, \dots, X_n)) \\ &\text{ iff } \forall X_1, \dots, X_n \in P \ (T_1 \subseteq X_1 \wedge \dots \wedge T_n \subseteq X_n \rightarrow \\ &\quad x \in \chi(X_1, \dots, X_n)) \\ &\text{ iff } \forall X_1, \dots, X_{n-1} \in P \ (T_1 \subseteq X_1 \wedge \dots \wedge T_{n-1} \subseteq X_{n-1} \rightarrow \\ &\quad \forall X_n \in P \ (T_n \subseteq X_n \rightarrow x \in \chi(X_1, \dots, X_n))). \end{aligned}$$

(3) does not help us here, but we can readily generalize it to

$$\begin{aligned} \forall X \in P \ (Y \subseteq X \rightarrow x \in \chi(\dots, X, \dots)) &\text{ iff} \\ (6) \quad x \in \bigcap \{ \chi(\dots, X, \dots) : Y \subseteq X \in P \}. \end{aligned}$$

So

$$\begin{aligned} (\mathfrak{F}, x) \models \psi \rightarrow \chi &\text{ iff } \forall X_1, \dots, X_{n-1} \in P \ (T_1 \subseteq X_1 \wedge \dots \wedge T_{n-1} \subseteq X_{n-1} \rightarrow \\ &\quad x \in \bigcap \{ \chi(X_1, \dots, X_n) : T_n \subseteq X_n \in P \}). \end{aligned}$$

But now (4) and (5) are useless. In fact, what we need is the equality

$$\begin{aligned} \bigcap \{ \chi(\dots, X, \dots) : T \subseteq X \in P \} = \\ (7) \quad \chi(\dots, \bigcap \{ X \in P : T \subseteq X \}, \dots) \end{aligned}$$

which, with the help of (5), would give us

$$(8) \quad \bigcap \{ \chi(\dots, X, \dots) : T \subseteq X \in P \} = \chi(\dots, T, \dots).$$

Of course, (7) is too good to hold for an arbitrary χ , but suppose for a moment that our χ satisfies it. Then we can eliminate step by step all the variables X_1, \dots, X_n like this:

$$\begin{aligned} (\mathfrak{F}, x) \models \psi \rightarrow \chi &\text{ iff } \forall X_1, \dots, X_{n-1} \in P \ (T_1 \subseteq X_1 \wedge \dots \wedge T_{n-1} \subseteq X_{n-1} \rightarrow \\ &\quad x \in \chi(X_1, \dots, X_{n-1}, T_n)) \\ &\text{ iff } \dots \text{ (by the same argument)} \\ &\text{ iff } x \in \chi(T_1, \dots, T_n). \end{aligned}$$

And the last relation can be effectively rewritten in the form of a first order formula $\phi(x)$ in R and $=$ having x as its only free variable. So, finally we shall have $\mathfrak{F} \models \psi \rightarrow \chi$ iff $\forall x \phi(x)$.

Now, to satisfy (7), χ should have the property that all its operators distribute over intersections. Clearly, \rightarrow and \neg are not suitable for this goal. But all the other operators turn out to be good enough at least in descriptive and Kripke frames. So we can take as χ any positive modal formula. The main property of a positive formula $\varphi(\dots, p, \dots)$ is its *monotonicity* in every variable p which means that, for all sets X, Y of worlds in a frame, $X \subseteq Y$ implies $\varphi(\dots, X, \dots) \subseteq \varphi(\dots, Y, \dots)$.

To prove that all positive formulas satisfy (7) in Kripke frames and descriptive frames, recall that \Box distributes over arbitrary intersections in any frame. As to \Diamond , we have the following lemma in which a family \mathcal{X} of non-empty subsets of some space W is called *downward directed* if for all $X, Y \in \mathcal{X}$ there is $Z \in \mathcal{X}$ such that $Z \subseteq X \cap Y$.

LEMMA 29 (Esakia 1974). *Suppose $\mathfrak{F} = \langle W, R, P \rangle$ is a descriptive frame. Then for every downward directed family $\mathcal{X} \subseteq P$,*

$$\Diamond \bigcap_{X \in \mathcal{X}} X = \bigcap_{X \in \mathcal{X}} \Diamond X.$$

Using Esakia's Lemma, by induction on the construction of φ one can prove

LEMMA 30. *Suppose that $\mathfrak{F} = \langle W, R, P \rangle$ is a Kripke or descriptive frame and $\varphi(p, \dots, q, \dots, r)$ is a positive formula. Then for every $Y \subseteq W$ and all $U, \dots, V \in P$,*

$$(9) \quad \bigcap \{ \varphi(U, \dots, X, \dots, V) : Y \subseteq X \in P \} = \varphi(U, \dots, \bigcap \{ X \in P : Y \subseteq X \}, \dots, V).$$

It follows from this lemma and considerations above that Sahlqvist's Theorem holds for formulas $\varphi = \psi \rightarrow \chi$ with strongly positive ψ and positive χ . The remaining part of the proof is purely syntactic manipulations with modal and first order formulas.

Notice that using the monotonicity of positive formulas, equivalence (6) can be generalized to the following one: for every $\mathfrak{F} = \langle W, R, P \rangle$, every positive $\chi_i(\dots, p, \dots)$ and every $x_i \in W$,

$$(10) \quad \forall X \in P (Y \subseteq X \rightarrow \bigvee_{i \leq n} x_i \in \chi_i(\dots, X, \dots)) \text{ iff } \bigvee_{i \leq n} x_i \in \bigcap \{ \chi_i(\dots, X, \dots) : Y \subseteq X \in P \}.$$

Say that a modal formula ψ is *untied* if it can be constructed from negative formulas and strongly positive ones using only \wedge and \Diamond . If $\nu(p_1, \dots, p_n)$ is negative then $\neg\nu(p_1, \dots, p_n)$ is clearly equivalent in \mathbf{K} to a positive formula; we denote it by $\nu^*(\neg p_1, \dots, \neg p_n)$.

LEMMA 31. *Let $\psi(p_1, \dots, p_n)$ be an untied formula and $\mathfrak{F} = \langle W, R, P \rangle$ a frame. Then for every $x \in W$ and all $X_1, \dots, X_n \in P$,*

$$x \in \psi(X_1, \dots, X_n) \text{ iff } \exists y_1, \dots, y_l (\vartheta \wedge \bigwedge_{i \leq n} T_i \subseteq X_i \wedge \bigwedge_{j \leq m} z_j \in \nu_j(X_1, \dots, X_n))$$

where the formula in the right-hand side, effectively constructed from ψ , has only one free individual variable x , ϑ is a conjunction of formulas of the form uRv , T_i are suitable R -terms and $\nu_j(p_1, \dots, p_n)$ are negative formulas.

We are ready now to prove Sahlqvist's Theorem. To construct a first order equivalent for $\Box^k(\psi \rightarrow \chi)$ supplied by the formulation of our theorem, we observe first that one can equivalently reduce ψ to a disjunction $\psi_1 \vee \dots \vee \psi_m$ of untied formulas, and hence $\Box^k(\psi \rightarrow \chi)$ is equivalent in \mathbf{K} to the formula

$$\Box^k(\psi_1 \rightarrow \chi) \wedge \dots \wedge \Box^k(\psi_m \rightarrow \chi).$$

So all we need is to find a first order equivalent for an arbitrary formula $\Box^k(\psi \rightarrow \chi)$ with untied ψ and positive χ . Let p_1, \dots, p_n be all the variables in ψ and χ and $\mathfrak{F} = \langle W, R, P \rangle$ a descriptive or Kripke frame. Then, for any $x \in W$, we have:

$$\begin{aligned} (\mathfrak{F}, x) \models \Box^k(\psi \rightarrow \chi) &\text{ iff } \forall X_1, \dots, X_n \in P \ x \in \Box^k(\psi \rightarrow \chi)(X_1, \dots, X_n) \\ &\text{ (by Lemma 31) iff } \forall X_1, \dots, X_n \in P \ \forall y \ (xR^k y \rightarrow (\exists y_1, \dots, y_l \ (\vartheta \wedge \\ &\quad \bigwedge_{i \leq n} T_i \subseteq X_i \wedge \bigwedge_{j \leq m} z_j \in \nu_j(X_1, \dots, X_n)) \rightarrow \\ &\quad y \in \chi(X_1, \dots, X_n))) \\ &\text{ iff } \forall X_1, \dots, X_n \in P \ \forall y, y_1, \dots, y_l \ (\vartheta' \wedge \bigwedge_{i \leq n} T_i \subseteq X_i \wedge \\ &\quad \bigwedge_{j \leq m} z_j \in \nu_j(X_1, \dots, X_n) \rightarrow y \in \chi(X_1, \dots, X_n)) \end{aligned}$$

where $\vartheta' = xR^k y \wedge \vartheta$. Let $\pi_j(p_1, \dots, p_n) = \nu_j^*(\neg p_1, \dots, \neg p_n)$. We continue this chain of equivalences as follows:

$$\begin{aligned} \text{iff } \forall y, y_1, \dots, y_l \ (\vartheta' \rightarrow \forall X_1, \dots, X_n \in P \ (\bigwedge_{i \leq n} T_i \subseteq X_i \rightarrow \\ \bigvee_{j \leq m+1} z_j \in \pi_j(X_1, \dots, X_n))) \end{aligned}$$

(where $\pi_{m+1}(p_1, \dots, p_n) = \chi(p_1, \dots, p_n)$ and $z_{m+1} = y$)

$$\text{iff } \forall y, y_1, \dots, y_l \ (\vartheta' \rightarrow \bigvee_{j \leq m+1} z_j \in \pi_j(T_1, \dots, T_n)),$$

as follows from (10), Lemma 30 and equality (5). It remains to use Lemma 27. ■

The formulas φ defined in the formulation of Theorem 25 are called *Sahlqvist formulas*. It follows from this theorem that if L is a \mathcal{D} -persistent logic and Γ a set of Sahlqvist formulas then $L \oplus \Gamma$ is also \mathcal{D} -persistent. Moreover, $L \oplus \Gamma$ is *elementary* (in the sense that the class of Kripke frames for it coincides with the class of all models for some set of first order formulas in R and $=$) whenever L is so.

Other proofs of Sahlqvist's Theorem were found by Kracht [1993] and Jónsson [1994] (the latter is based upon the algebraic technique developed in [Jónsson and Tarski 1951]). Venema [1991] extended Sahlqvist's Theorem to logics with non-standard inference rules, like Gabbay's [1981a] irreflexivity rule. In [Chagro and Zakharyashev 1995b] it is shown that there is a continuum of Sahlqvist logics above **S4** and that not all of them have the finite model property (above **T** such a logic was constructed by Hughes and Cresswell [1984]). As we shall see later in this chapter, there are even undecidable finitely axiomatizable Sahlqvist logics in **NExtK**. It would be of interest to find out whether such logics exist above **K4** or **S4**.

Kracht [1993] described syntactically the set of first order equivalents of Sahlqvist formulas. To formulate his criterion we require the fragment \mathcal{S} of first order logic defined inductively as follows. Formulas of the form $xR^m y$ are in \mathcal{S} for all variables x, y and every $m < \omega$; besides, if ϕ, ϕ' are in \mathcal{S} then the formulas

$$\forall x \in y \uparrow^m \phi, \exists x \in y \uparrow^m \phi, \phi \wedge \phi', \text{ and } \phi \vee \phi'$$

are also in \mathcal{S} . For simplicity we assume that all occurrences of quantifiers in a formula bind pairwise distinct variables. Call a variable y in a formula $\phi \in \mathcal{S}$ *inherently universal* if either all occurrences of y are free in ϕ or ϕ contains a subformula $\forall y \in x \uparrow^m \phi'$ which is not in the scope of \exists .

THEOREM 32 (Kracht 1993). *For every first order formula $\phi(x)$ (in R and $=$) with one free variable x , the following conditions are equivalent:*

- (i) $\phi(x)$ is classically equivalent to a formula $\phi'(x) \in \mathcal{S}$ such that any subformula of the form $yR^m z$ of $\phi'(x)$ contains at least one inherently universal variable;
- (ii) $\phi(x)$ corresponds to a Sahlqvist formula in the sense of Theorem 25.

Condition (i) is satisfied, for example, by the formula

$$\forall u \in x \uparrow \forall v \in x \uparrow \exists z \in u \uparrow vRz$$

which corresponds to $\diamond \Box p \rightarrow \Box \diamond p$. On the other hand,

$$\phi(x) = \exists y \in x \uparrow \forall z \in y \uparrow zR^0 y$$

does not satisfy (i). In fact, even relative to **S4** the condition expressed by $\phi(x)$ does not correspond to any Sahlqvist formula. Notice, however, that

$\mathbf{S4} \oplus \Box\Diamond p \rightarrow \Diamond\Box p$ is a \mathcal{D} -persistent logic whose frames are precisely the transitive and reflexive frames validating $\forall x\phi(x)$.

We conclude this section by mentioning two more important results connecting persistence and elementarity (the idea of the proof was discussed in Section 22 of *Basic Modal Logic*.)

THEOREM 33.

- (i) (Fine 1975b, van Benthem 1980) *If a logic L is characterized by a first order definable class of Kripke frames then L is \mathcal{D} -persistent.*
- (ii) (Fine 1975b) *If L is \mathcal{R} -persistent then the class of Kripke frames for L is first order definable.*

It is an open problem whether every \mathcal{D} -persistent logic is determined by a first order definable class of Kripke frames; for more information about this and related problems consult [Goldblatt 1995].

1.4 The degree of Kripke incompleteness

All known logics in \mathbf{NExtK} of “natural origin” are complete with respect to Kripke semantics. On the other hand, there are many examples of “artificial” logics that cannot be characterized by any class of Kripke frames (see Sections 19, 20 of *Basic Modal Logic* or the examples below). To understand the phenomenon of Kripke incompleteness Fine [1974b] proposed to investigate how many logics may share the same Kripke frames with a given logic L . The number of them is called the *degree of Kripke incompleteness* of L . Of course, this number depends on the lattice of logics under consideration. The degree of Kripke incompleteness of logics in \mathbf{NExtK} was comprehensively studied by Blok [1978]. In this section we present the main results of that paper following [Chagrov and Zakharyashev 1997].

By Theorem 12, all Kripke complete union-splittings of \mathbf{NExtK} have degree of incompleteness 1. And it turns out that no other union-splitting exists.

THEOREM 34 (Blok 1978). *Every union-splitting of \mathbf{NExtK} has the finite model property.*

Proof. Let \mathcal{F} be a class of finite rooted cycle free frames. We prove that $L = \mathbf{K}/\mathcal{F}$ has the finite model property using a variant of filtration, which is applied to an n -generated refined frame $\mathfrak{F} = \langle W, R, P \rangle$ for L refuting a formula $\varphi(p_1, \dots, p_n)$ under a valuation \mathfrak{V} .

Since \mathfrak{F} is differentiated, for every $m \geq 1$ there are only finitely many points x in \mathfrak{F} such that $x \models \Box^m \perp \wedge \neg \Box^{m-1} \perp$; we shall call them *points of type m* . Given $\Delta \subseteq \mathbf{Sub}\varphi$, $\mathbf{Sub}\varphi$ the set of all subformulas in φ , we put $m_\Delta = m$ if m is the minimal number such that a point in \mathfrak{F} is of type $\leq m$

Figure 3.

whenever $x \models \Delta$ and the formulas in $\mathbf{Sub}\varphi - \Delta$ are false at x (under \mathfrak{M}); if no such m exists, we put $m_\Delta = 0$. Let

$$k = \max\{m_\Delta : \Delta \subseteq \mathbf{Sub}\varphi\}, \quad \Gamma = \mathbf{Sub}(\varphi \wedge \Box^k \perp).$$

Now we divide \mathfrak{F} into two parts: W_1 consisting of points of type $\leq k$ and $W_2 = W - W_1$. For $x, y \in W$, put $x \sim y$ if either $x, y \in W_1$ and $x = y$ or $x, y \in W_2$ and exactly the same formulas in Γ are true at x and y . Let $\mathfrak{N} = \langle \mathfrak{G}, \mathfrak{U} \rangle$ be the smallest filtration (see Section 12 of *Basic Modal Logic*) of $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ through Γ with respect to \sim . Since W_1 is finite, \mathfrak{G} is also finite and, by the Filtration Theorem, $(\mathfrak{M}, x) \models \psi$ iff $(\mathfrak{N}, [x]) \models \psi$, for every $\psi \in \Gamma$. So it remains to show that $\mathfrak{G} \models L$. Notice that $[x]$ in \mathfrak{G} is of type $m \leq k$ iff x has type m in \mathfrak{F} . Moreover, there is no $[x]$ of type $l > k$. For otherwise $x \not\models \Box^k \perp$ and $m_\Delta = 0$ for $\Delta = \{\psi \in \mathbf{Sub}\varphi : x \models \psi\}$, which means that arbitrary long chains (of not necessarily distinct points) start from $[x]$, contrary to $[x]$ being of type l . Thus \mathfrak{G} consists of two parts: points of type $\leq k$, which form the generated subframe $\langle W_1, R \upharpoonright W_1 \rangle$ of \mathfrak{F} , and points involved in cycles. Since $\mathfrak{F} \models L$ and frames in \mathcal{F} are cycle free, it follows from Lemma 13 and Theorem 17 that $\mathfrak{G} \models L$. ■

THEOREM 35 (Blok 1978). *If a logic L is inconsistent or a union-splitting of \mathbf{NExtK} , then L is strictly Kripke complete. Otherwise L has degree of Kripke incompleteness 2^{\aleph_0} in \mathbf{NExtK} .*

Proof. That **For** is strictly complete follows from Example 10 and Theorem 12. Suppose now that a consistent L is not a union-splitting and L' is the greatest union-splitting contained in L . Since L' has the finite model property, there is a finite rooted frame $\mathfrak{F} = \langle W, R \rangle$ for L' refuting some $\varphi \in L$ and such that every proper generated subframe of \mathfrak{F} validates L . Clearly, \mathfrak{F} is not cycle free. Let $x_1 R x_2 R \dots R x_n R x_1$ be the shortest cycle in \mathfrak{F} and $k = md(\varphi) + 1$. We construct a new frame \mathfrak{F}' by extending the cycle x_1, \dots, x_n, x_1 as is shown in Fig. 3 ((a) for $n = 1$ and (b) for $n > 1$). More precisely, we add to \mathfrak{F} copies x_i^1, \dots, x_i^k of x_i for each $i \in \{1, \dots, n\}$, organize them into the nontransitive cycle shown in Fig. 3 and draw an arrow from x_i^j to $y \in W - \{x_1, \dots, x_n\}$ iff $x_i R y$. Denote the resulting frame

Figure 4.

by $\mathfrak{F}' = \langle W', R' \rangle$ and let $x' = x_n^k$. By the construction, \mathfrak{F} is a reduct of \mathfrak{F}' . Therefore, for every models $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ and $\mathfrak{M}' = \langle \mathfrak{F}', \mathfrak{V}' \rangle$ such that

$$\mathfrak{V}'(p) = \mathfrak{V}(p) \cup \{x_i^j : x_i \in \mathfrak{V}(p), j < k\}$$

and for every $x \in W$, $\psi \in \mathbf{Sub}\varphi$, we have $(\mathfrak{M}, x) \models \psi$ iff $(\mathfrak{M}', x) \models \psi$. So we can hook some other model on x' , and points in W will not feel its presence by means of φ 's subformulas. The frame to be hooked on x' depends on whether $\bullet \models L$ or $\circ \models L$. We consider only the former alternative.

Fix some $m > |W'|$. For each $I \subseteq \omega - \{0\}$, let $\mathfrak{F}_I = \langle W_I, R_I, P_I \rangle$ be the frame whose diagram is shown in Fig. 4 (d_0 sees the root of \mathfrak{F}' , all points e_i and e'_j and is seen from x' ; the subframes in dashed boxes are transitive, $e'_i \in W_I$ iff $i \in I$, and P_I consists of sets of the form $X \cup Y$ such that X is a finite or cofinite subset of $W_I - \{b, a_i : i < \omega\}$ and Y is either a finite subset of $\{a_i : i < \omega\}$ or is of the form $\{b\} \cup Y'$, where Y' is a cofinite subset of $\{a_i : i < \omega\}$. It is not hard to see that the points a_i , c , e_i and e'_i are characterized by the variable free formulas

$$\alpha_0 = \diamond(\delta_m \wedge \diamond(\delta_{m-1} \wedge \cdots \wedge \diamond\delta_0) \cdots) \wedge \neg\delta^2(\delta_m \wedge \diamond(\delta_{m-1} \wedge \cdots \wedge \diamond\delta_0) \cdots),$$

$$\alpha_{i+1} = \diamond\alpha_i \wedge \neg\delta^2\alpha_i, \quad \gamma = \diamond^2\alpha_0 \wedge \neg\delta\alpha_0,$$

$$\epsilon_0 = \diamond\gamma, \quad \epsilon_{i+1} = \diamond\epsilon_i \wedge \neg\delta^2\epsilon_i, \quad \epsilon'_{i+1} = \diamond\epsilon_i \wedge \neg\delta^+\epsilon_{i+1},$$

(in the sense that $x \models \alpha_i$ iff $x = a_i$, etc.), where

$$\delta_0 = \diamond\Box\perp, \quad \delta_1 = \diamond\delta_0 \wedge \neg\delta_0, \quad \delta_2 = \diamond\delta_1 \wedge \neg\delta_1 \wedge \neg\delta^+\delta_0,$$

$$\delta_{k+1} = \diamond\delta_k \wedge \neg\delta_k \wedge \neg\delta^+\delta_{k-1} \wedge \cdots \wedge \neg\delta^+\delta_0.$$

Define L_I to be the logic determined by the class of frames for L and \mathfrak{F}_I , i.e., $L_I = L \cap \text{Log}\mathfrak{F}_I$. Since $\neg(\epsilon'_i \wedge \diamond^{m+6}\neg\varphi) \in L_J - L_I$ for $i \in I - J$ (φ is refuted at the root of \mathfrak{F}'), $|\{L_I : I \subseteq \omega - \{0\}\}| = 2^{\aleph_0}$.

Let us show now that L_I has the same Kripke frames as L . Since $L_I \subseteq L$, we must prove that every Kripke frame for L_I validates L . Suppose there is a rooted Kripke frame \mathfrak{G} such that $\mathfrak{G} \models L_I$ but $\mathfrak{G} \not\models \psi$, for some $\psi \in L$. Since ψ is in L , it is valid in all frames for L , in particular, $\bullet \models \psi$. And since $\psi \notin L_I$, ψ is refuted in \mathfrak{F}_I . Moreover, by the construction of \mathfrak{F}_I , it is refuted at a point from which the root of \mathfrak{F}' can be reached by a finite number of steps. Therefore, the following formulas are valid in \mathfrak{F}_I and so belong to L_I and are valid in \mathfrak{G} :

$$(11) \quad \neg\psi \rightarrow \bigvee_{i=0}^l \diamond^i \gamma,$$

$$(12) \quad \neg\psi \rightarrow \bigwedge_{i=0}^l \square^i (\gamma \rightarrow \square(\square_0(\square_0 p \rightarrow p) \rightarrow p)),$$

where p does not occur in ψ and l is a sufficiently big number so that any point in \mathfrak{F}_I is accessible by $\leq l$ steps from every point in the selected cycle and every point at which ψ may be false, and $\square_0 \chi = \square(\diamond \alpha_0 \rightarrow \chi)$. According to (11), \mathfrak{G} contains a point at which γ is true. By the construction of γ , this point has a successor y at which, by (12), $\square_0(\square_0 p \rightarrow p) \rightarrow p$ is true under any valuation in \mathfrak{G} and $y \models \diamond \alpha_0$. Define a valuation \mathfrak{U} in \mathfrak{G} by taking $\mathfrak{U}(p) = y \uparrow$. Then $y \models \square_0(\square_0 p \rightarrow p)$, from which $y \models p$ and so $y \in y \uparrow$. Now define another valuation \mathfrak{U}' so that $\mathfrak{U}'(p) = y \uparrow - \{y\}$. Since y is reflexive, we again have $y \models \square_0(\square_0 p \rightarrow p)$, whence $y \models p$, which is a contradiction. \blacksquare

This construction can be used to obtain one more important result.

THEOREM 36 (Blok 1978). *Every union-splitting \mathbf{K}/\mathcal{F} has $\varkappa \leq \aleph_0$ immediate predecessors in $\text{NExt}\mathbf{K}$, where \varkappa is the number of frames in \mathcal{F} which are not reducts of generated subframes of other frames in \mathcal{F} . Every consistent logic different from union-splittings has 2^{\aleph_0} immediate predecessors in $\text{NExt}\mathbf{K}$. (For has 2 immediate predecessors in $\text{NExt}\mathbf{K}$.)*

Proof. The former claim follows from Theorem 12. To establish the latter, we continue the proof of Theorem 35. One can show that L is finitely axiomatizable over L_I (the proof is rather technical, and we omit it here). Then, by Zorn's Lemma, $\text{NExt}L_I$ contains an immediate predecessor L'_I of L . Besides, $L_I \oplus L_J = L$ whenever $I \neq J$. Indeed,

$$L_I \oplus L_J = (L \cap \text{Log}\mathfrak{F}_I) \oplus (L \cap \text{Log}\mathfrak{F}_J) = L \cap (\text{Log}\mathfrak{F}_I \oplus \text{Log}\mathfrak{F}_J)$$

and if $i \in I - J$ then, for every $\chi \in L$ and a sufficiently big l ,

$$\neg \bigvee_{k=0}^l \diamond^k \epsilon'_i \rightarrow \chi \in \text{Log}\mathfrak{F}_I, \quad \neg \epsilon'_i \in \text{Log}\mathfrak{F}_J,$$

from which $\chi \in \text{Log}\mathfrak{F}_I \oplus \text{Log}\mathfrak{F}_J$ and so $L \subseteq \text{Log}\mathfrak{F}_I \oplus \text{Log}\mathfrak{F}_J$. It follows that $L'_I \neq L'_J$ whenever $I \neq J$. ■

It is worth noting that tabular logics, proper extensions of **D** and extensions of **K4** are not union-splittings in $\text{NExt}\mathbf{K}$. Similar results hold for the lattices $\text{NExt}\mathbf{D}$ and $\text{NExt}\mathbf{T}$, where every consistent logic has degree of incompleteness 2^{\aleph_0} (see [Blok 1978, 1980b]). It would be of interest to describe the behavior of this function in $\text{NExt}\mathbf{K4}$, $\text{NExt}\mathbf{GL}$, $\text{NExt}\mathbf{S4}$, $\text{NExt}\mathbf{Grz}$ (where Theorem 34 does not hold and where every tabular logic has finitely many immediate predecessors) and other lattices of logics to be considered later in this chapter.

1.5 Stronger forms of Kripke completeness

In the two preceding sections we were considering the problem of characterizing logics $L \in \text{NExt}\mathbf{K}$ by classes of Kripke frames. The same problem arises in connection with the two consequence relations \vdash_L and \vdash_L^* as well. Theorem 19 shows a way of introducing the corresponding concepts of completeness.

With each Kripke frame \mathfrak{F} let us associate a consequence relation $\models_{\mathfrak{F}}$ by putting, for any formula φ and any set Γ of formulas, $\Gamma \models_{\mathfrak{F}} \varphi$ iff $(\mathfrak{M}, x) \models \Gamma$ implies $(\mathfrak{M}, x) \models \varphi$ for every model \mathfrak{M} based on \mathfrak{F} and every point x in \mathfrak{F} . Clearly, a modal logic L is Kripke complete iff, for any *finite* set of formulas Γ and any formula φ , $\Gamma \not\vdash_L \varphi$ only if there is a Kripke frame \mathfrak{F} for L such that $\Gamma \not\models_{\mathfrak{F}} \varphi$. Now, let us call L *strongly Kripke complete*⁷ if this implication holds for arbitrary sets Γ . In other words, L is strongly complete if every L -consistent set of formulas holds at some point in a model based on a Kripke frame for L . Another reformulation: L is strongly complete iff L is Kripke complete and the relation $\bigcap\{\models_{\mathfrak{F}}: \mathfrak{F} \text{ is a Kripke frame for } L\}$ is finitary. It follows from the construction of the canonical models that every canonical (in particular, \mathcal{D} -persistent) logic is strongly complete, which provides us with many examples of such logics in $\text{NExt}\mathbf{K}$.

By Theorem 33, all logics characterized by first order definable classes of Kripke frames are strongly complete. The converse does not hold: there exist strongly complete logics which are not canonical. The simplest is the bimodal logic of the frame $\langle \mathbb{R}, <, > \rangle$; see Example 144 below. By applying the Thomason simulation (to be introduced in Section 2.3) to this logic we obtain a logic in $\text{NExt}\mathbf{K}$ with the same properties; see Theorem 123. Moreover, in contrast to \mathcal{D} -persistence, strong Kripke completeness is not preserved under finite sums of logics (see [Wolter 1996b]). It is an open problem, however, whether such logics exist in $\text{NExt}\mathbf{K4}$.

⁷Fine [1974c] calls such logics *compact*, which does not agree with the use of this term by Thomason [1972].

Perhaps the simplest examples of Kripke complete logics which are not strongly complete are **GL** and **Grz** (use Theorem 58 and the fact that these logics are not elementary; see *Correspondence Theory*). It is much more difficult to prove that the McKinsey logic $\mathbf{K} \oplus \Box\Diamond p \rightarrow \Diamond\Box p$ is not strongly complete; the proof can be found in [Wang 1992]. For other examples of modal logics that are not strongly complete see Section 3.4. It is worth noting also that, as was shown in [Fine 1974c], every finite width logic in a *finite* language turns out to be strongly Kripke complete, though this is not the case for logics in an infinite language, witness

$$\mathbf{GL.3} = \mathbf{GL} \oplus \Box(\Box^+ p \rightarrow q) \vee \Box(\Box^+ q \rightarrow p).$$

For the consequence relation \vdash_L^* , we should take the “global” version $\models_{\mathfrak{F}}^*$ of $\models_{\mathfrak{F}}$. Namely, we put $\Gamma \models_{\mathfrak{F}}^* \varphi$ if $\mathfrak{M} \models \Gamma$ implies $\mathfrak{M} \models \varphi$ for any model \mathfrak{M} based on \mathfrak{F} . A modal logic L is called *globally Kripke complete* if for any finite set of formulas Γ and any formula φ , $\Gamma \not\vdash_L^* \varphi$ only if there is a frame \mathfrak{F} for L such that $\Gamma \not\models_{\mathfrak{F}}^* \varphi$. L is *strongly globally complete* if this holds for arbitrary (not only finite) Γ . We also say that L has the *global finite model property* if for every finite Γ and every φ , $\Gamma \not\vdash_L^* \varphi$ only if there is a finite frame \mathfrak{F} for L such that $\Gamma \not\models_{\mathfrak{F}}^* \varphi$.

The global finite model property (FMP, for short) of many standard logics can be proved by filtration. Say that a logic L *strongly admits filtration* if for every generated submodel \mathfrak{M} of the canonical model \mathfrak{M}_L and every finite set of formulas Σ closed under subformulas, there is a filtration of \mathfrak{M} through Σ based on a frame for L .

PROPOSITION 37 (Goranko and Passy 1992). *If L strongly admits filtration then L has global FMP.*

Proof. Suppose that $\Gamma \not\vdash_L^* \varphi$, Γ finite. Then $\Box^{<\omega} \bigwedge \Gamma \not\vdash_L \varphi$ and so the set $\Delta = \Box^{<\omega} \bigwedge \Gamma \cup \{\neg\varphi\}$ is L -consistent. It remains to filtrate through $\mathbf{Sub}\Gamma \cup \mathbf{Sub}\varphi$ the submodel of \mathfrak{M}_L generated by a maximal L -consistent set containing Δ . ■

It follows in particular that **K**, **T**, **D**, **KB** have global FMP.

PROPOSITION 38. *Suppose L is globally complete (has global FMP) and Γ is a finite set of variable free formulas. Then $L \oplus \Gamma$ is globally complete (has global FMP) as well.*

Proof. Let $L' = L \oplus \Gamma$ and $\Delta \not\vdash_{L'}^* \varphi$, Δ finite. Then $\Gamma \cup \Delta \not\vdash_L^* \varphi$ and so there exists a (finite) Kripke frame \mathfrak{F} for L such that $\Gamma \cup \Delta \not\models_{\mathfrak{F}}^* \varphi$. Since Γ contains no variables, $\mathfrak{F} \models L'$. ■

For n -transitive logics L the global consequence relation \vdash_L^* is reducible to the “local” \vdash_L and so L is Kripke complete (has FMP, is strongly complete)

iff L is globally complete (has global FMP, is strongly globally complete). In general the global properties are stronger than the “local” ones. Although L is globally complete (has global FMP) only if L is complete (has FMP), the converse does not hold (see [Wolter 1994a] and [Kracht 1999]).

EXAMPLE 39. Let $L = \mathbf{Alt}_3 \oplus p \rightarrow \Box \Diamond p \oplus (\Box p \wedge \neg p) \rightarrow \neg(\Diamond q \wedge \Diamond \neg q)$. A Kripke frame \mathfrak{F} validates L iff no point in \mathfrak{F} has more than three successors, \mathfrak{F} is symmetric, and irreflexive points in it have at most one successor. By Proposition 22, L is Kripke complete. The class of Kripke frames for L is closed under (not necessarily generated) subframes. So, by Proposition 59 to be proved below, L has FMP. We show now that it does not have global FMP. To this end we require the formulas:

$$\alpha_1 = q_1 \wedge \neg q_2 \wedge \neg q_3, \quad \alpha_2 = \neg q_1 \wedge q_2 \wedge \neg q_3, \quad \alpha_3 = \neg q_1 \wedge \neg q_2 \wedge q_3,$$

$$\varphi = \Box p \wedge \neg p \wedge \alpha_1, \quad \psi = \bigwedge \{ \alpha_i \rightarrow \Diamond \alpha_{i+1} : i = 1, 2 \} \wedge \alpha_3 \rightarrow \Diamond \alpha_1.$$

Let $\mathfrak{F} = \langle W, R \rangle$, where $W = \omega$ and

$$R = \{ \langle m, m \rangle : m > 0 \} \cup \{ \langle m, m+1 \rangle : m < \omega \} \cup \{ \langle m, m-1 \rangle : m > 0 \}.$$

We then have $\psi \not\models_{\mathfrak{F}}^* \neg \varphi$. In fact, φ is true at 0 and ψ is true everywhere under the valuation \mathfrak{V} defined by $\mathfrak{V}(p) = W - \{0\}$ and $\mathfrak{V}(q_i) = \{3n + i : n < \omega\}$. Clearly, $\mathfrak{F} \models L$ and so $\psi \not\models_L^* \neg \varphi$. Suppose now that $(\mathfrak{N}, x_0) \models \varphi$ and $\mathfrak{N} \models \psi$, for a model \mathfrak{N} based on a Kripke frame $\mathfrak{G} = \langle V, S \rangle$ for L . Then we can find a sequence x_j , $j < \omega$, such that $x_j S x_{j+1}$ and $x_{3j+i} \models \alpha_{i+1}$, for $j < \omega$ and $i = 1, 2, 3$. The reader can verify that all points x_j are distinct.

Let us consider now the algebraic meaning of the notions introduced above. A logic L is Kripke complete iff the variety $\mathbf{Alg}L$ of modal algebras for L is generated by the class $\mathbf{Kr}L = \{ \mathfrak{F}^+ : \mathfrak{F} \text{ is a Kripke frame for } L \}$. By Birkhoff’s Theorem (see e.g. [Mal’cev 1973]), this means that

$$\mathbf{Alg}L = \mathbf{HSPKr}L,$$

(i.e., $\mathbf{Alg}L$ is obtained by taking the closure of $\mathbf{Kr}L$ under direct products, then the closure of the result under (isomorphic copies of) subalgebras and finally under homomorphic images). Clearly, L is globally complete iff precisely the same quasi-identities hold in $\mathbf{Kr}L$ and $\mathbf{Alg}L$. And since the quasi-variety generated by a class of algebras \mathcal{C} is $\mathbf{SPP}_U \mathcal{C}$ (where \mathbf{P}_U denotes the closure under ultraproducts; see [Mal’cev 1973]), L is globally complete iff

$$\mathbf{Alg}L = \mathbf{SPP}_U \mathbf{Kr}L.$$

Goldblatt [1989] calls the variety $\mathbf{Alg}L$ *complex* if $\mathbf{Alg}L = \mathbf{SKr}L$, or, equivalently, if $\mathbf{Alg}L = \mathbf{SPKr}L$ (this follows from the fact that the dual of the disjoint union of a family of Kripke frames $\{ \mathfrak{F}_i : i \in I \}$ is isomorphic

to the product $\prod_{i \in I} \mathfrak{F}_i^+$). We say a logic L is \varkappa -complex, \varkappa a cardinal, if every modal algebra for L with $\leq \varkappa$ generators is a subalgebra of \mathfrak{F}^+ for some Kripke frame $\mathfrak{F} \models L$. As was shown in [Wolter 1993], this notion turns out to be the algebraic counterpart of both strong completeness and strong global completeness of logics in *infinite languages* with \varkappa variables.

THEOREM 40. *For every normal modal logic L in an infinite language with \varkappa variables the following conditions are equivalent:*

- (i) L is strongly Kripke complete;
- (ii) L is globally strongly complete;
- (iii) L is \varkappa -complex.

Proof. (i) \Rightarrow (iii) Suppose the cardinality of $\mathfrak{A} \in \text{Alg}L$ does not exceed \varkappa . Denote by \mathfrak{L} the algebra of modal formulas over \varkappa propositional variables and take some homomorphism h from \mathfrak{L} onto \mathfrak{A} . For each ultrafilter ∇ in \mathfrak{A} , the set $h^{-1}(\nabla)$ is maximal L -consistent. Since L is strongly complete, there is a model $\mathfrak{M}_\nabla = \langle \mathfrak{F}_\nabla, \mathfrak{V}_\nabla \rangle$ with root x_∇ based on a Kripke frame \mathfrak{F}_∇ for L and such that $(\mathfrak{M}_\nabla, x_\nabla) \models h^{-1}(\nabla)$. Without loss of generality we may assume that the frames \mathfrak{F}_∇ for distinct ∇ are disjoint. Let \mathfrak{F} be the disjoint union of all of them. Define a homomorphism \mathfrak{V} from \mathfrak{L} into \mathfrak{F}^+ by taking

$$\mathfrak{V}(p) = \bigcup \{ \mathfrak{V}_\nabla(p) : \nabla \text{ is an ultrafilter in } \mathfrak{A} \}.$$

Then $\mathfrak{V}(\mathfrak{L})$ is a subalgebra of $\mathfrak{F}^+ \in \text{Alg}L$ isomorphic to \mathfrak{A} .

The implication (iii) \Rightarrow (ii) is trivial. To prove (ii) \Rightarrow (i), consider an L -consistent set of formulas Γ of cardinality $\leq \varkappa$ and put

$$\Delta = \{p\} \cup \{\Box^n(p \rightarrow \varphi) : n < \omega, \varphi \in \Gamma\},$$

where the variable p does not occur in formulas from Γ . It is easily checked that all finite subsets of Δ are L -consistent, so Δ is L -consistent too. It follows that $\{p \rightarrow \varphi : \varphi \in \Gamma\} \not\models_L^* \neg p$. And since L is globally strongly complete, there exists a model \mathfrak{M} based on a Kripke frame for L such that $\mathfrak{M} \models \{p \rightarrow \varphi : \varphi \in \Gamma\}$ and $(\mathfrak{M}, x) \models p$, for some x . But then $(\mathfrak{M}, x) \models \Gamma$. ■

1.6 Canonical formulas

The main problem of completeness theory in modal logic is not only to find a sufficiently simple class of frames with respect to which a given logic L is complete but also to characterize the constitution of frames for L (in this class). The first order approach to the characterization problem, discussed in Section 1.3 in connection with Sahlqvist's Theorem, comes across two obstacles. First, there are formulas whose Kripke frames cannot be described in the first order language with R and $=$. The best known example

is probably the *Löb axiom*

$$\mathbf{la} = \Box(\Box p \rightarrow p) \rightarrow \Box p.$$

$\mathfrak{F} \models \mathbf{la}$ iff \mathfrak{F} is transitive, irreflexive (i.e., a strict partial order) and *Noetherian* in the sense that it contains no infinite ascending chain of distinct points. And as is well known, the condition of Noetherianness is not a first order one. The second obstacle is that this approach deals only with logics that are Kripke complete; it does not take into account sets of possible values.

There is another, purely frame-theoretic method of characterizing the structure of frames. For instance, a frame \mathfrak{G} validates \mathbf{K}/\mathfrak{F} iff \mathfrak{G} does not contain a generated subframe reducible to \mathfrak{F} . It was shown in [Zakharyashev 1984, 1988, 1992] that in a similar manner one can describe *transitive* frames validating an arbitrary modal formula. It is not clear whether characterizations of this sort can be extended to the class of all frames (an important step in this direction would be a generalization to n -transitive frames). That is why all frames in this section are assumed to be transitive. First we illustrate this method by a simple example.

EXAMPLE 41. Suppose a frame $\mathfrak{F} = \langle W, R, P \rangle$ refutes \mathbf{la} under some valuation. Then the set $V = \{x \in W : x \not\models \mathbf{la}\}$ is in P and $V \subseteq V\downarrow$. It follows from the former that $\mathfrak{G} = \langle V, R \upharpoonright V, \{X \cap V : X \in P\} \rangle$ is a frame—we call it the *subframe of \mathfrak{F} induced by V* . And the latter condition means that \mathfrak{G} is reducible to the single reflexive point \circ which is the simplest refutation frame for \mathbf{la} . Moreover, one can readily check that the converse also holds: if there is a subframe \mathfrak{G} of \mathfrak{F} reducible to \circ then $\mathfrak{F} \not\models \mathbf{la}$.

This example motivates the following definitions. Given frames $\mathfrak{F} = \langle W, R, P \rangle$ and $\mathfrak{G} = \langle V, S, Q \rangle$, a partial (i.e., not completely defined, in general) map f from W onto V is called a *subreduction* of \mathfrak{F} to \mathfrak{G} if it satisfies the reduction conditions (R1)–(R3) for all x and y in the domain of f and all $X \in Q$. The domain of f will be denoted by $\text{dom}f$. In other words, an f -subreduct of \mathfrak{F} is a reduct of the subframe of \mathfrak{F} induced by $\text{dom}f$. A frame $\mathfrak{G} = \langle V, S, Q \rangle$ is a *subframe* of $\mathfrak{F} = \langle W, R, P \rangle$ if $V \subseteq W$ and the identity map on V is a subreduction of \mathfrak{F} to \mathfrak{G} , i.e., if $S = R \upharpoonright V$ and $Q \subseteq P$. Note that a generated subframe \mathfrak{G} of \mathfrak{F} is not in general a subframe of \mathfrak{F} , since V may be not in P .

Thus, the result of Example 41 can be reformulated like this: $\mathfrak{F} \not\models \mathbf{la}$ iff \mathfrak{F} is subreducible to \circ .

A subreduction f of \mathfrak{F} to \mathfrak{G} is called *cofinal* if

$$\text{dom}f \uparrow \subseteq \text{dom}f \bar{\downarrow}.$$

This important notion can be motivated by the following observation: \mathfrak{F} refutes $\Diamond \top$ iff \mathfrak{F} is cofinally subreducible to \bullet (a plain subreduction is not enough).

THEOREM 42. *Every refutation frame $\mathfrak{F} = \langle W, R, P \rangle$ for $\varphi(p_1, \dots, p_n)$ is cofinally subreducible to a finite rooted refutation frame for φ containing at most $c_\varphi = 2^n \cdot (c_n(1) + \dots + c_n(2^{|\mathbf{Sub}\varphi|}))$ points.⁸*

Proof. Suppose φ is refuted in \mathfrak{F} under a valuation \mathfrak{V} . Without loss of generality we can assume \mathfrak{F} to be generated by $\mathfrak{V}(p_1), \dots, \mathfrak{V}(p_n)$. Let X_1, \dots, X_m be all distinct maximal 0-cyclic sets in \mathfrak{F} . Clearly, $m \leq c_n(1)$ but unlike Theorem 8, \mathfrak{F} is not in general refined and so these sets are not necessarily clusters of depth 1. However, they can be easily reduced to such clusters. Define an equivalence relation \sim on W by putting $x \sim y$ iff $x = y$ or $x, y \in X_i$, for some $i \in \{1, \dots, m\}$, and $x \sim_\Sigma y$ (as before $\Sigma = \{p_1, \dots, p_n\}$). Let $[x]$ be the equivalence class under \sim generated by x and $[X] = \{[x] : x \in X\}$, for $X \in P$. By the definition of cyclic sets, xRy iff $[x] \subseteq [y] \downarrow$. So the map $x \mapsto [x]$ is a reduction of \mathfrak{F} to the frame $\mathfrak{F}'_1 = \langle W'_1, R'_1, P'_1 \rangle$ which results from \mathfrak{F} by “folding up” the 0-cyclic sets X_i into clusters of depth 1 and leaving the other points untouched: $W'_1 = [W]$, $[x]R'_1[y]$ iff $[x] \subseteq [y] \downarrow$ and $P'_1 = \{[X] : X \in P\}$. (Roughly, we refine that part of \mathfrak{F} which gives points of depth 1.) Put $\mathfrak{V}'_1(p_i) = [\mathfrak{V}(p_i)]$. Then by the Reduction (or P-morphism) Theorem, we have $x \models \psi$ iff $[x] \models \psi$, for every $\psi \in \mathbf{Sub}\varphi$.

Let X be the set of all points in \mathfrak{F}'_1 of depth > 1 having $\mathbf{Sub}\varphi$ -equivalent successors of depth 1. It is not hard to see that $X \in P'_1$. Denote by $\mathfrak{F}_1 = \langle W_1, R_1, P_1 \rangle$ the subframe of \mathfrak{F}'_1 induced by $W'_1 - X$ and let \mathfrak{V}_1 be the restriction of \mathfrak{V}'_1 to \mathfrak{F}_1 . By induction on the construction of $\psi \in \mathbf{Sub}\varphi$ one can readily show that ψ has the same truth-values at common points in \mathfrak{F}'_1 and \mathfrak{F}_1 (under \mathfrak{V}'_1 and \mathfrak{V}_1 , respectively) and so $\mathfrak{F}_1 \not\models \varphi$. The partial map $x \mapsto [x]$, for $[x] \in W_1$, is a cofinal subreduction of \mathfrak{F} to \mathfrak{F}_1 .

Then we take the maximal 1-cyclic sets in \mathfrak{F}_1 , “fold” them up into clusters of depth 2 and remove those points of depth > 2 that have $\mathbf{Sub}\varphi$ -equivalent successors of depth 2. The resulting frame \mathfrak{F}_2 will be a cofinal subreduct of \mathfrak{F}_1 and so of \mathfrak{F} as well. After that we form clusters of depth 3, and so forth. In at most $2^{|\mathbf{Sub}\varphi|}$ steps of that sort we shall construct a cofinal subreduct of \mathfrak{F} refuting φ and containing $\leq c_\varphi$ points. It remains to select in it a suitable rooted generated subframe. ■

For the majority of standard modal axioms the converse also holds. However, not for all. The simplest counterexample is the density axiom $\mathbf{den} = \Box\Box p \rightarrow \Box p$. It is refuted by the chain \mathfrak{H} of two irreflexive points but becomes valid if we insert between them a reflexive one. In fact, $\mathfrak{F} \not\models \mathbf{den}$ iff there is a subreduction f of \mathfrak{F} to \mathfrak{H} such that $f(x\uparrow) = \{a\}$, for no point x in $\text{dom}f\uparrow - \text{dom}f$, where a is the final point in \mathfrak{H} .

Loosely, every refutation frame for formulas like \mathbf{la} can be constructed by adding new points to a frame \mathfrak{G} that is reducible to some finite refutation

⁸The function $c_n(m)$ was defined in Section 1.2.

frame of fixed size. For formulas like $\diamond\top$ we have to take into account the cofinality condition and do not put new points “above” \mathfrak{G} . And formulas like *den* impose another restriction: some places inside \mathfrak{G} may be “closed” for inserting new points. These “closed domains” can be singled out in the following way.

Suppose $\mathfrak{N} = \langle \mathfrak{H}, \mathfrak{U} \rangle$ is a model and \mathfrak{a} an antichain in \mathfrak{H} . Say that \mathfrak{a} is an *open domain* in \mathfrak{N} relative to a formula φ if there is a pair $t_{\mathfrak{a}} = (\Gamma_{\mathfrak{a}}, \Delta_{\mathfrak{a}})$ such that $\Gamma_{\mathfrak{a}} \cup \Delta_{\mathfrak{a}} = \mathbf{Sub}\varphi$, $\bigwedge \Gamma_{\mathfrak{a}} \rightarrow \bigvee \Delta_{\mathfrak{a}} \notin \mathbf{K4}$ and

- $\Box\psi \in \Gamma_{\mathfrak{a}}$ implies $\psi \in \Gamma_{\mathfrak{a}}$,
- $\Box\psi \in \Gamma_{\mathfrak{a}}$ iff $a \models \Box^+\psi$ for all $a \in \mathfrak{a}$.

Otherwise \mathfrak{a} is called a *closed domain* in \mathfrak{N} relative to φ . A reflexive singleton $\mathfrak{a} = \{a\}$ is always open: just take

$$t_{\mathfrak{a}} = (\{\psi \in \mathbf{Sub}\varphi : a \models \psi\}, \{\psi \in \mathbf{Sub}\varphi : a \not\models \psi\}).$$

It is easy to see also that antichains consisting of points from the same clusters are open or closed simultaneously; we shall not distinguish between such antichains.

For a frame \mathfrak{H} and a (possibly empty) set \mathfrak{D} of antichains in \mathfrak{H} , we say a subreduction f of \mathfrak{F} to \mathfrak{H} satisfies the *closed domain condition* for \mathfrak{D} if

$$(\text{CDC}) \quad \neg\exists x \in \text{dom}f \uparrow - \text{dom}f \exists \mathfrak{d} \in \mathfrak{D} \ f(x\uparrow) = \mathfrak{d}\uparrow.$$

Notice that the cofinal subreduction f of \mathfrak{F} to the resulting finite rooted frame \mathfrak{H} in the proof of Theorem 42 satisfies (CDC) for the set \mathfrak{D} of closed domains in the corresponding model \mathfrak{N} on \mathfrak{H} refuting φ . Indeed, every $x \in \text{dom}f \uparrow - \text{dom}f$ has a $\mathbf{Sub}\varphi$ -equivalent successor $y \in \text{dom}f$, and so an antichain \mathfrak{d} such that $f(x\uparrow) = \mathfrak{d}\uparrow$ is open, since we can take

$$t_{\mathfrak{d}} = (\{\psi \in \mathbf{Sub}\varphi : y \models \psi\}, \{\psi \in \mathbf{Sub}\varphi : y \not\models \psi\}).$$

On the other hand, we have

PROPOSITION 43. *Suppose $\mathfrak{N} = \langle \mathfrak{H}, \mathfrak{U} \rangle$ is a finite countermodel for φ and \mathfrak{D} the set of all closed domains in \mathfrak{N} relative to φ . Then $\mathfrak{F} \not\models \varphi$ whenever there is a cofinal subreduction f of \mathfrak{F} to \mathfrak{H} satisfying (CDC) for \mathfrak{D} . Moreover, if φ is negation free (i.e., contains no \perp , \neg , \diamond) then a plain subreduction satisfying (CDC) for \mathfrak{D} is enough.*

Proof. If f is cofinal and $\mathfrak{F} = \langle W, R, P \rangle$ then we can assume $\text{dom}f \uparrow = W$. Define a valuation \mathfrak{V} in \mathfrak{F} as follows. If $x \in \text{dom}f$ then we take $x \models p$ iff $f(x) \models p$, for every variable p in φ . If $x \notin \text{dom}f$ then $f(x\uparrow) \neq \emptyset$, since f is cofinal. Let \mathfrak{a} be an antichain in \mathfrak{H} such that $\mathfrak{a}\uparrow = f(x\uparrow)$. By (CDC), \mathfrak{a} is an open domain in \mathfrak{N} , and we put $y \models p$ iff $p \in \Gamma_{\mathfrak{a}}$, for every $y \notin \text{dom}f$ such that $f(y\uparrow) = f(x\uparrow)$. One can show that \mathfrak{V} is really a valuation in \mathfrak{F} and,

for every $\psi \in \mathbf{Sub}\varphi$, $x \models \psi$ iff $f(x) \models \psi$ in the case $x \in \text{dom}f$, and $x \models \psi$ iff $\psi \in \Gamma_{\mathfrak{a}}$, where \mathfrak{a} is the open domain in \mathfrak{M} associated with x , in the case $x \notin \text{dom}f$.

If φ is negation free and f is a plain subreduction then $f(x\uparrow)$ may be empty. In such a case we just put $x \models p$, for all variables p . ■

Now let us summarize what we have got. Given an arbitrary formula φ , we can effectively construct a finite collection of finite rooted frames $\mathfrak{F}_1, \dots, \mathfrak{F}_n$ (underlying all possible rooted countermodels for φ with $\leq c_\varphi$ points) and select in them sets $\mathfrak{D}_1, \dots, \mathfrak{D}_n$ of antichains (open domains in those countermodels) such that, for any frame \mathfrak{F} , $\mathfrak{F} \not\models \varphi$ iff there is a cofinal subreduction of \mathfrak{F} to \mathfrak{F}_i , for some i , satisfying (CDC) for \mathfrak{D}_i . If φ is negation free then a plain subreduction satisfying (CDC) is enough.

This general characterization of the constitution of refutation transitive frames can be presented in a more convenient form if with every finite rooted frame $\mathfrak{F} = \langle W, R \rangle$ and a set \mathfrak{D} of antichains in \mathfrak{F} we associate formulas $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ and $\alpha(\mathfrak{F}, \mathfrak{D})$ such that $\mathfrak{G} \not\models \alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ ($\mathfrak{G} \not\models \alpha(\mathfrak{F}, \mathfrak{D})$) iff there is a cofinal (respectively, plain) subreduction of \mathfrak{G} to \mathfrak{F} satisfying (CDC) for \mathfrak{D} . For instance, one can take

$$\alpha(\mathfrak{F}, \mathfrak{D}, \perp) = \bigwedge_{a_i R a_j} \varphi_{ij} \wedge \bigwedge_{i=0}^n \varphi_i \wedge \bigwedge_{\mathfrak{d} \in \mathfrak{D}} \varphi_{\mathfrak{d}} \wedge \varphi_{\perp} \rightarrow p_0$$

where a_0, \dots, a_n are all points in \mathfrak{F} and a_0 is its root,

$$\begin{aligned} \varphi_{ij} &= \Box^+(\Box p_j \rightarrow p_i), \\ \varphi_i &= \Box^+(\left(\bigwedge_{\neg a_i R a_k} \Box p_k \wedge \bigwedge_{j=0, j \neq i}^n p_j \rightarrow p_i\right) \rightarrow p_i), \\ \varphi_{\mathfrak{d}} &= \Box^+(\bigwedge_{a_i \in W - \mathfrak{d}\uparrow} \Box p_j \wedge \bigwedge_{i=0}^n p_i \rightarrow \bigvee_{a_j \in \mathfrak{d}} \Box p_j), \\ \varphi_{\perp} &= \Box^+(\bigwedge_{i=0}^n \Box^+ p_i \rightarrow \perp). \end{aligned}$$

$\alpha(\mathfrak{F}, \mathfrak{D})$ results from $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ by deleting the conjunct φ_{\perp} . $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ and $\alpha(\mathfrak{F}, \mathfrak{D})$ are called the *canonical* and *negation free canonical formulas* for \mathfrak{F} and \mathfrak{D} , respectively. It is not hard to check that if $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ is refuted in $\mathfrak{G} = \langle V, S, Q \rangle$ under some valuation then the partial map defined by $x \mapsto a_i$ if the premise of $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ is true at x and p_i false is a cofinal subreduction of \mathfrak{G} to \mathfrak{F} satisfying (CDC) for \mathfrak{D} ; and conversely, if f is such a subreduction then the valuation \mathfrak{U} defined by $\mathfrak{U}(p_i) = V - f^{-1}(a_i)$ refutes $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ at any point in $f^{-1}(a_0)$.

THEOREM 44. *There is an algorithm which, given a formula φ , returns canonical formulas $\alpha(\mathfrak{F}_1, \mathfrak{D}_1, \perp), \dots, \alpha(\mathfrak{F}_n, \mathfrak{D}_n, \perp)$ such that*

$$\mathbf{K4} \oplus \varphi = \mathbf{K4} \oplus \alpha(\mathfrak{F}_1, \mathfrak{D}_1, \perp) \oplus \dots \oplus \alpha(\mathfrak{F}_n, \mathfrak{D}_n, \perp).$$

So the set of canonical formulas is complete for the class NExtK4 . If φ is negation free then one can use negation free canonical formulas.

It is not hard to see that $\mathbf{K4} \oplus \varphi$ is a splitting of NExtK4 iff φ is deductively equivalent in NExtK4 to a formula of the form $\alpha(\mathfrak{F}, \mathfrak{D}^\#, \perp)$, where $\mathfrak{D}^\#$ is the set of all antichains in \mathfrak{F} (in this case $\mathbf{K4}/\mathfrak{F} = \mathbf{K4} \oplus \alpha(\mathfrak{F}, \mathfrak{D}^\#, \perp)$). Such formulas are known as *Jankov formulas* (Jankov [1963] introduced them for intuitionistic logic), or *frame formulas* (cf. [Fine 1974a]), or *Jankov–Fine formulas*. Since \mathbf{GL} is not a union-splitting of NExtK4 , this class of logics has no axiomatic basis.

We conclude this section by showing in Table 2 canonical axiomatizations of some standard modal logics in the field of $\mathbf{K4}$. For brevity we write $\alpha(\mathfrak{F}, \perp)$ instead of $\alpha(\mathfrak{F}, \emptyset, \perp)$ and $\alpha^\#(\mathfrak{F}, \perp)$ instead of $\alpha(\mathfrak{F}, \mathfrak{D}^\#, \perp)$. Each $*$ in the table is to be replaced by both \circ and \bullet .

For more information about the canonical formulas the reader is referred to [Zakharyashev 1992, 1997b].

1.7 Decidability via the finite model property

Although, for cardinality reason, there are “much more” undecidable logics than decidable ones, almost all “natural” propositional systems close to those we deal with in this chapter turn out to be decidable. Relevant and linear logics are probably the best known among very few exceptions (see [Urquhart 1984], [Lincoln *et al.* 1992]).

The majority of decidability results in modal logic was obtained by means of establishing the finite model property. FMP by itself does not ensure yet decidability (there is a continuum of logics with FMP); some additional conditions are required to be satisfied. For instance, to prove the decidability of **S4** McKinsey [1941] used two such conditions: that the logic under consideration is characterized by an effective class of finite frames (or algebras, matrices, models, etc.) and that there is an effective (exponential in the case of **S4**) upper bound for the size of minimal refutation frames. Under these conditions, a formula belongs to the logic iff it is validated by (finite) frames in a finite family which can be effectively constructed. Another sufficient condition of decidability is provided by the following well known

THEOREM 45 (Harrop 1958). *Every finitely axiomatizable logic with FMP is decidable.*

Here we need not to know a priori anything about the structure of frames for a given logic. This information is replaced by checking the validity of its

Table 2. Canonical axioms of standard modal logics

D4	=	K4 \oplus $\alpha(\bullet, \perp)$
S4	=	K4 \oplus $\alpha(\bullet)$
GL	=	K4 \oplus $\alpha(\circ)$

K4.2	=	K4 \oplus $\alpha(\overset{\bullet}{\downarrow}, \perp) \oplus \alpha(\overset{\circ}{\downarrow}, \perp) \oplus \alpha(\overset{*}{\downarrow}, \perp)$ (8 axioms)
K4.3	=	K4 \oplus $\alpha(\overset{*}{\downarrow}, \overset{*}{\downarrow})$ (6 axioms)
Dum	=	S4 \oplus $\alpha(\overset{\circ\circ}{\downarrow}, \overset{\circ}{\downarrow}) \oplus \alpha(\overset{\circ}{\downarrow}, \overset{\circ\circ}{\downarrow})$
K4BW_n	=	K4 \oplus $\alpha(\overset{n+1}{\downarrow}, \overset{*}{\downarrow})$ ($2n + 4$ axioms)
K4BD_n	=	K4 \oplus $\alpha(\overset{*}{\downarrow}, \overset{n}{\downarrow}, 0)$ (2^{n+1} axioms)
K4_{n,m}	=	K4 \oplus $\alpha(\overset{\bullet}{\downarrow}, \overset{1}{\downarrow}, \overset{m}{\downarrow}, \mathcal{D}^\sharp)$

axioms in finite frames, and the restriction of the size of refutation frames is replaced by constructing all possible derivations: in a finite number of steps we either separate a tested formula from the logic or derive it. Note that unlike the previous case now we cannot estimate the time required to complete this algorithm.

The condition of finite axiomatizability in Harrop's Theorem cannot be weakened to that of recursive axiomatizability. For there is a logic of depth 3 in $\text{NExt}\mathbf{K4}$ (i.e., a logic in $\text{NExt}\mathbf{K4BD}_3$) with an infinite set of independent axioms; so the logic of depth 3 axiomatizable by some recursively enumerable but not recursive sequence of formulas in this set is undecidable and has FMP. On the other hand there are examples of undecidable logics characterized by decidable classes of finite frames (see e.g. [Chagrov and Zakharyashev 1997]). Yet one can generalize Harrop's Theorem in the following way. A logic is decidable iff it is recursively enumerable and characterized by a recursive class of recursive algebras. However, this criterion is absolutely useless in its generality. In this connection we note two open problems posed by Kuznetsov [1979]. Is every finitely axiomatizable logic characterized by recursive algebras? Is every finitely axiomatizable logic, characterized by recursive algebras, decidable? (That *finite* axiomatizability is essential here is explained by the following fact: if a lattice of logics contains a logic with a continuum of immediate predecessors then there is no countable sequence of algebras such that every logic in the lattice is characterized by one of its subsequences. For details see [Chagrov and Zakharyashev 1997].)

FMP of almost all standard systems was proved using various forms of filtration (consult Section 12 *Basic Modal Logic* and [Gabbay 1976]). However, the method of filtration is rather capricious; one needs a special craft to apply it in each particular case (for instance, to find a suitable "filter"). In this and two subsequent sections we discuss other methods of proving FMP which are applicable to families of logics and provide in fact sufficient conditions of FMP. (It is to be noted that the families of Kripke complete logics considered in Section 1.3 contain logics without FMP.) A pair of such conditions was already presented in *Basic Modal Logic*:

THEOREM 46 (Seegerberg 1971). *Each logic in $\text{NExt}\mathbf{K4}$ characterized by a frame of finite depth (or, which is equivalent, containing $\mathbf{K4BD}_n$, for some $n < \omega$) has FMP.*

THEOREM 47 (Bull 1966b, Fine 1971). *Each logic in $\text{NExt}\mathbf{S4.3}$ has FMP and is finitely axiomatizable (and so decidable).*

The former result, covering a continuum of logics, follows immediately from the description of finitely generated refined frames for $\mathbf{K4}$ in Section 1.2 and the latter is a consequence of Theorem 52 and Example 54 below. It is worth noting also that since $\mathfrak{F}_L(n)$ is finite for every logic $L \in \text{NExt}\mathbf{K4}$ of finite depth and every $n < \omega$, there are only finitely many pairwise

non-equivalent in L formulas with n variables. Logics with this property are called *locally tabular* (or *locally finite*). Moreover, as was observed by Maksimova [1975a], the converse is also true: if $L \in \text{NExt}\mathbf{K4}$ has frames of any depth $< \omega$ then the formulas in the sequence $\varphi_1 = p$, $\varphi_{n+1} = p \vee \Box(p \rightarrow \Box\varphi_n)$ are not equivalent in L . Thus, a logic in $\text{NExt}\mathbf{K4}$ is locally tabular iff it is of finite depth. For $L \in \text{NExt}\mathbf{S4}$ this criterion can be reformulated in the following way: L is not locally tabular iff $L \subseteq \mathbf{Grz.3}$, where $\mathbf{Grz.3} = \mathbf{S4.3} \oplus \mathbf{Grz}$. Likewise, $L \in \text{NExt}\mathbf{GL}$ is not locally tabular iff $L \subseteq \mathbf{GL.3}$. Nagle and Thomason [1985] showed that all normal extensions of $\mathbf{K5}$ are locally tabular.

Uniform logics Fine [1975a] used a modal analog of the full disjunctive normal form for constructing finite models and proving FMP of a family of logics in $\text{NExt}\mathbf{D}$ (containing in particular the McKinsey system $\mathbf{K} \oplus \Box\Diamond p \rightarrow \Diamond\Box p$ which had resisted all attempts to prove its completeness by the method of canonical models and filtration). Let us notice first that every formula $\varphi(p_1, \dots, p_m)$ is equivalent in \mathbf{K} either to \perp or to a disjunction of normal forms (in the variables p_1, \dots, p_m) of degree $md(\varphi)$, which are defined inductively in the following way. \mathbf{NF}_0 , the set of *normal forms of degree 0*, contains all formulas of the form $\neg_1 p_1 \wedge \dots \wedge \neg_m p_m$, where each \neg_i is either blank or \neg . \mathbf{NF}_{n+1} , the set of *normal forms of degree $n+1$* , consists of formulas of the form

$$\theta \wedge \neg_1 \Diamond \theta_1 \wedge \dots \wedge \neg_k \Diamond \theta_k,$$

where $\theta \in \mathbf{NF}_0$ and $\theta_1, \dots, \theta_k$ are all distinct normal forms in \mathbf{NF}_n . Put $\mathbf{NF} = \bigcup_{n < \omega} \mathbf{NF}_n$. Using the fact that $\bigvee \{\Diamond \theta : \theta \in \mathbf{NF}_n\} \in \mathbf{D}$ it is not hard to see also that in \mathbf{D} every formula φ with $md(\varphi) \leq n$ is equivalent either to \perp or to a disjunction of normal forms of degree n such that at least one of \neg_1, \dots, \neg_k in the inductive step of the definition above is blank. Such normal forms are called *\mathbf{D} -suitable*.

It should be clear that, for any distinct $\theta', \theta'' \in \mathbf{NF}_n$, $\neg(\theta' \wedge \theta'') \in \mathbf{K}$. Consequently, for every $\theta \in \mathbf{NF}_n$ and every $\varphi(p_1, \dots, p_m)$ with $md(\varphi) \leq n$, we have either $\theta \rightarrow \varphi \in \mathbf{K}$ or $\theta \rightarrow \neg\varphi \in \mathbf{K}$.

With each \mathbf{D} -suitable normal form θ we associate a model $\mathfrak{M}_\theta = \langle \mathfrak{F}_\theta, \mathfrak{V}_\theta \rangle$ on a frame $\mathfrak{F}_\theta = \langle W_\theta, R_\theta \rangle$ by taking

$$W_\theta = \{\top\} \cup \{\theta' \in \mathbf{NF} : \theta' <^n \theta, \text{ for some } n \geq 0\},$$

$$\theta' < \theta'' \text{ iff } \Diamond \theta' \text{ is a conjunct of } \theta'',$$

$$\theta' R_\theta \theta'' \text{ iff either } \theta' > \theta'' \text{ or } md(\theta') = 0 \text{ and } \theta'' = \top,$$

$$\mathfrak{V}_\theta(p) = \{\theta' \in W_\theta : p \text{ is a conjunct of } \theta'\}.$$

According to the definition, \top is the reflexive last point in \mathfrak{F}_θ and so \mathfrak{F}_θ is serial. By a straightforward induction on the degree of $\theta' \in W_\theta$ one can

readily show that $(\mathfrak{M}_\theta, \theta') \models \theta'$. It follows immediately that \mathbf{D} has FMP. Indeed, given $\varphi \notin \mathbf{D}$, we reduce $\neg\varphi$ to a disjunction of \mathbf{D} -suitable normal forms with at least one disjunct θ , and then $(\mathfrak{M}_\theta, \theta) \models \theta$.

It turns out that in the same way we can prove FMP of all logics in $\text{NExt}\mathbf{D}$ axiomatizable by *uniform formulas*, which are defined as follows. Every φ without modal operators is a *uniform formula of degree 0*; and if $\varphi = \psi(\bigcirc_1\chi_1, \dots, \bigcirc_m\chi_m)$, where $\bigcirc_i \in \{\Box, \Diamond\}$, $md(\psi(p_1, \dots, p_m)) = 0$ and χ_1, \dots, χ_m are uniform formulas of degree n , then φ is a *uniform formula of degree $n+1$* . A remarkable property of uniform formulas is the following:

PROPOSITION 48. *Suppose φ is a uniform formula of degree n and $\mathfrak{M}, \mathfrak{N}$ are models based upon the same frame and such that, for some point x , $(\mathfrak{M}, y) \models p$ iff $(\mathfrak{N}, y) \models p$ for every $y \in x\uparrow^n$ and every variable p in φ . Then $(\mathfrak{M}, x) \models \varphi$ iff $(\mathfrak{N}, x) \models \varphi$.*

Given a logic L , we call a normal form θ *L -suitable* if $\mathfrak{F}_\theta \models L$.

THEOREM 49 (Fine 1975a). *Every logic $L \in \text{NExt}\mathbf{D}$ axiomatizable by uniform formulas has FMP.*

Proof. It suffices to prove that each formula φ with $md(\varphi) \leq n$ is equivalent in L either to \perp or to a disjunction of L -suitable normal forms of degree n . And this fact will be established if we show that every \mathbf{D} -suitable normal form θ such that $\theta \rightarrow \perp \notin L$ is L -suitable. Suppose otherwise. Let θ be an L -consistent and \mathbf{D} -suitable normal form of the least possible degree under which it is not L -suitable. Then there are a uniform formula $\psi \in L$ of some degree m and a model $\mathfrak{M} = \langle \mathfrak{F}_\theta, \mathfrak{M} \rangle$ such that $(\mathfrak{M}, \theta) \not\models \psi$.

For every variable p in ψ , let $\Gamma_p = \{\theta' \in \theta\uparrow^m : (\mathfrak{M}, \theta') \models p\}$ and let $\delta_p = \bigvee \Gamma_p$ (if $\Gamma_p = \emptyset$ then $\delta_p = \perp$). Observe that for every $\theta' \in \theta\uparrow^m$ we have $(\mathfrak{M}_\theta, \theta') \models \delta_p$ iff $\theta' \in \Gamma_p$ iff $(\mathfrak{M}, \theta') \models p$. Therefore, by Proposition 48, the formula ψ' which results from ψ by replacing each p with δ_p is false at θ in \mathfrak{M}_θ . Now, if $md(\psi') > n$ then $m > n$ and so $\delta_p = \perp$ for every p in ψ , i.e., ψ' is variable free. But then ψ' is equivalent in \mathbf{D} to \top or \perp , contrary to $\mathfrak{F}_\theta \not\models \psi'$ and L being consistent. And if $md(\psi') \leq n$ then either $\theta \rightarrow \psi' \in \mathbf{K}$, which is impossible, since $(\mathfrak{M}_\theta, \theta) \not\models \theta \rightarrow \psi'$, or $\theta \rightarrow \neg\psi' \in \mathbf{K}$, from which $\psi' \rightarrow \neg\theta \in \mathbf{K}$ and so $\neg\theta \in L$, contrary to θ being L -consistent. \blacksquare

Logics with $\Box\Diamond$ -axioms Another result, connecting FMP of logics with the distribution of \Box and \Diamond over their axioms, is based on the following

LEMMA 50. *For any φ and ψ , $\Diamond\varphi \leftrightarrow \Diamond\psi \in \mathbf{S5}$ iff $\Box\Diamond\varphi \leftrightarrow \Box\Diamond\psi \in \mathbf{K4}$.*

Proof. Suppose $\Box\Diamond\varphi \rightarrow \Box\Diamond\psi \notin \mathbf{K4}$. Then there is a finite model \mathfrak{M} , based on a transitive frame, and a point x in it such that $x \models \Box\Diamond\varphi$ and $x \not\models \Box\Diamond\psi$. It follows from the former that every final cluster accessible from x , if any, is non-degenerate and contains a point where φ is true. The latter means

that x sees a final cluster C at all points of which ψ is false. Now, taking the generated submodel of \mathfrak{M} based on C , we obtain a model for **S5** refuting $\diamond\varphi \rightarrow \diamond\psi$. The rest is obvious, since $\diamond p \leftrightarrow \diamond\Box p$ is in **S5** and **K4** \subseteq **S5**. ■

Formulas in which every occurrence of a variable is in the scope of a modality $\Box\Diamond$ will be called $\Box\Diamond$ -formulas.

THEOREM 51 (Rybakov 1978). *If a logic $L \in \text{NExtK4}$ is decidable (or has FMP) and ψ is a $\Box\Diamond$ -formula then $L \oplus \psi$ is also decidable (has FMP).*

Proof. Let $\psi = \psi'(\Box\Diamond\chi_1, \dots, \Box\Diamond\chi_n)$, for some formula $\psi'(q_1, \dots, q_n)$. If $\varphi(p_1, \dots, p_m) \in L \oplus \psi$ then there exists a derivation of φ in $L \oplus \psi$ in which substitution instances of ψ contain no variables different from p_1, \dots, p_m . Each of these instances has the form $\psi'(\Box\Diamond\chi'_1, \dots, \Box\Diamond\chi'_n)$, where every χ'_i is some substitution instance of χ_i containing only p_1, \dots, p_m . By Lemma 50 and in view of the local tabularity of **S5** (it is of depth 1), there are finitely many pairwise non-equivalent in **K4** substitution instances of $\Box\Diamond\chi_i$ of that sort (the reader can easily estimate the number of them). So there exist only finitely many pairwise non-equivalent in **K4** substitution instances of ψ containing p_1, \dots, p_m , say ψ_1, \dots, ψ_k , and we can effectively construct them. Then, by the Deduction Theorem,

$$\varphi \in L \oplus \psi \text{ iff } \psi_1, \dots, \psi_k \vdash_L^* \varphi \text{ iff } \Box^+(\psi_1 \wedge \dots \wedge \psi_k) \rightarrow \varphi \in L$$

and so $L \oplus \psi$ is decidable (or has FMP) whenever L is decidable (has FMP). ■

It should be noted that by adding to L with FMP infinitely many $\Box\Diamond$ -formulas we can construct an incomplete logic. For a concrete example see [Rybakov 1977]. By adding a variable free formula to a logic in NExtK with FMP one can get a logic without FMP. However, $\mathbf{K} \oplus \varphi$, φ variable free, has FMP, as can be easily shown by the standard filtration through the set $\mathbf{Sub}\varphi \cup \mathbf{Sub}\psi$, where $\psi \notin \mathbf{K} \oplus \varphi$. Infinitely many variable free formulas can axiomatize a normal extension of **K4** without FMP (for a concrete example see [Chagrov and Zakharyashev 1997]).

1.8 Subframe and cofinal subframe logics

A very useful source of information for investigating various properties of logics in NExtK4 is their canonical axioms. Notice, for instance, that the canonical axioms of all logics in Table 2, save **A*** and **K4_{n,m}**, contain no closed domains. Canonical and negation free canonical formulas of the form $\alpha(\mathfrak{F})$ and $\alpha(\mathfrak{F}, \perp)$ are called *subframe* and *cofinal subframe formulas*, respectively, and logics in NExtK4 axiomatizable by them are called *subframe* and *cofinal subframe logics*. The classes of such logics will be denoted by \mathcal{SF}

and \mathcal{CSF} . Subframe and cofinal subframe logics in $\text{NExt}\mathbf{K4}$ were studied by Fine [1985] and Zakharyashev [1984, 1988, 1996].

THEOREM 52. *All logics in \mathcal{SF} and \mathcal{CSF} have FMP.*

Proof. Suppose $L = \mathbf{K4} \oplus \{\alpha(\mathfrak{F}_i, \perp) : i \in I\}$ and $\varphi \notin L$. By Theorem 44, without loss of generality we may assume that φ is a canonical formula, say, $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$. Now consider two cases. (1) For no $i \in I$, \mathfrak{F} is cofinally subreducible to \mathfrak{F}_i . Then $\mathfrak{F} \models L$, $\mathfrak{F} \not\models \alpha(\mathfrak{F}, \mathfrak{D}, \perp)$, and we are done. (2) \mathfrak{F} is cofinally subreducible to $\alpha(\mathfrak{F}_i, \perp)$, for some $i \in I$. In this case we have $\alpha(\mathfrak{F}, \mathfrak{D}, \perp) \in \mathbf{K4} \oplus \alpha(\mathfrak{F}_i, \perp) \subseteq L$, which is a contradiction. Indeed, suppose $\mathfrak{G} \not\models \alpha(\mathfrak{F}, \mathfrak{D}, \perp)$. Then there is a cofinal subreduction of \mathfrak{G} to \mathfrak{F} . And since the composition of (cofinal) subreductions is again a (cofinal) subreduction, \mathfrak{G} is cofinally subreducible to \mathfrak{F}_i , which means that $\mathfrak{G} \not\models \alpha(\mathfrak{F}_i, \perp)$. Subframe logics are treated analogously. ■

The names “subframe logic” and “cofinal subframe logic” are explained by the following frame-theoretic characterization of these logics. A subframe $\mathfrak{G} = \langle V, S, Q \rangle$ of a frame \mathfrak{F} is called *cofinal* if $V \uparrow \subseteq V \downarrow$ in \mathfrak{F} . Say that a class \mathcal{C} of frames is *closed under (cofinal) subframes* if every (cofinal) subframe of \mathfrak{F} is in \mathcal{C} whenever $\mathfrak{F} \in \mathcal{C}$.

THEOREM 53. *$L \in \text{NExt}\mathbf{K4}$ is a (cofinal) subframe logic iff it is characterized by a class of frames that is closed under (cofinal) subframes.*

Proof. Suppose $L \in \mathcal{CSF}$. We show that the class of all frames for L is closed under cofinal subframes. Let $\mathfrak{G} \models L$ and \mathfrak{H} be a cofinal subframe of \mathfrak{G} . If $\mathfrak{H} \not\models \alpha(\mathfrak{F}, \perp)$, for some $\alpha(\mathfrak{F}, \perp) \in L$, then (since \mathfrak{G} is cofinally subreducible to \mathfrak{H}) $\mathfrak{G} \not\models \alpha(\mathfrak{F}, \perp)$, which is a contradiction. So $\mathfrak{H} \models L$.

Now suppose that L is characterized by some class of frames \mathcal{C} closed under cofinal subframes. We show that $L = L'$, where

$$L' = \mathbf{K4} \oplus \{\alpha(\mathfrak{F}, \perp) : \mathfrak{F} \not\models L\}.$$

If \mathfrak{F} is a finite rooted frame and $\mathfrak{F} \not\models L$ then $\alpha(\mathfrak{F}, \perp) \in L$, for otherwise $\mathfrak{G} \not\models \alpha(\mathfrak{F}, \perp)$ for some $\mathfrak{G} \in \mathcal{C}$, and hence there is a cofinal subframe \mathfrak{H} of \mathfrak{G} which is reducible to \mathfrak{F} ; but $\mathfrak{H} \in \mathcal{C}$ and so, by the Reduction Theorem, \mathfrak{F} is a frame for L , which is a contradiction. Thus, $L' \subseteq L$. To prove the converse, suppose $\alpha(\mathfrak{F}, \mathfrak{D}, \perp) \in L$. Then $\mathfrak{F} \not\models L$, and hence $\alpha(\mathfrak{F}, \perp) \in L'$, from which $\alpha(\mathfrak{F}, \mathfrak{D}, \perp) \in L'$.

Subframe logics are considered in the same way. ■

It follows in particular that $\mathcal{SF} \subset \mathcal{CSF}$ (**K4.1** and **K4.2** are cofinal subframe logics but not subframe ones). One can easily show also that \mathcal{CSF} is a complete sublattice of $\text{NExt}\mathbf{K4}$ and \mathcal{SF} a complete sublattice of \mathcal{CSF} .

EXAMPLE 54. Every normal extension of **S4.3** is axiomatizable by canonical formulas which are based on chains of non-degenerate clusters and so have no closed domains. Therefore, $\text{NExt}\mathbf{S4.3} \subset \mathcal{CSF}$.

The classes \mathcal{SF} and $\mathcal{CSF} - \mathcal{SF}$ contain a continuum of logics. And yet, unlike $\text{NExt}\mathbf{K}$ or $\text{NExt}\mathbf{K4}$, their structure and their logics are not so complex. For instance, it is not hard to see that every logic in \mathcal{CSF} is uniquely axiomatizable by an independent set of cofinal subframe formulas and so these formulas form an axiomatic basis for \mathcal{CSF} .

The concept of subframe logic was extended in [Wolter 1993] to the class $\text{NExt}\mathbf{K}$ by taking the frame-theoretic characterization of Theorem 53 as the definition. Namely, we say that $L \in \text{NExt}\mathbf{K}$ is a *subframe logic* if the class of frames for L is closed under subframes. In other words, subframe logics are precisely those logics whose axioms “do not force the existence of points”. For example, **K**, **KB**, **K5**, **T**, and **Alt_n** are subframe logics. To give a syntactic characterization of subframe logics we require the following formulas.

For a formula φ and a variable p not occurring in φ , define a formula φ^p inductively by taking

$$\begin{aligned} q^p &= q \wedge p, \quad q \text{ an atom,} \\ (\psi \odot \chi)^p &= \psi^p \odot \chi^p, \quad \text{for } \odot \in \{\wedge, \vee, \rightarrow\}, \\ (\Box\psi)^p &= \Box(p \rightarrow \psi^p) \wedge p \end{aligned}$$

and put $\varphi^{sf} = p \rightarrow \varphi^p$.

LEMMA 55. *For any frame \mathfrak{F} , $\mathfrak{F} \models \varphi^{sf}$ iff φ is valid in all subframes of \mathfrak{F} .*

Proof. It suffices to notice that if \mathfrak{M} is a model based on \mathfrak{F} , \mathfrak{M}' a model based on the subframe of \mathfrak{F} induced by $\{y : (\mathfrak{M}, y) \models p\}$ and $(\mathfrak{M}, x) \models q$ iff $(\mathfrak{M}', x) \models q$, for all variables q , then $(\mathfrak{M}, x) \models \varphi^p$ iff $(\mathfrak{M}', x) \models \varphi$. ■

PROPOSITION 56. *The following conditions are equivalent for any modal logic L :*

- (i) L is a subframe logic;
- (ii) $L = \mathbf{K} \oplus \{\varphi^{sf} : \varphi \in \Gamma\}$, for some set of formulas Γ ;
- (iii) L is characterized by a class of frames closed under subframes.

Proof. The implication (i) \Rightarrow (iii) is trivial; (iii) \Rightarrow (ii) and (ii) \Rightarrow (i) are consequences of Lemma 55. ■

It follows that the class of subframe logics forms a complete sublattice of $\text{NExt}\mathbf{K}$. However, not all of them have FMP and even are Kripke complete.

EXAMPLE 57. Let L be the logic of the frame \mathfrak{F} constructed in Example 7. Since every rooted subframe \mathfrak{G} of \mathfrak{F} is isomorphic to a generated subframe of \mathfrak{F} , L is a subframe logic. We show that L has the same Kripke frames

as **GL.3**. Suppose \mathfrak{G} is a rooted Kripke frame for **GL.3** refuting $\varphi \in L$. Then clearly \mathfrak{G} contains a finite subframe \mathfrak{H} refuting φ . Since \mathfrak{H} is a finite chain of irreflexive points, it is isomorphic to a generated subframe of \mathfrak{F} , contrary to $\mathfrak{F} \not\models \varphi$. Thus $\mathfrak{G} \models L$. Conversely, suppose \mathfrak{G} is a Kripke frame for L . Then \mathfrak{G} is irreflexive. For otherwise \mathfrak{G} refutes the formula $\varphi = \Box^2(\Box p \rightarrow p) \wedge \Box(\Box p \rightarrow p) \rightarrow \Box p$, which is valid in \mathfrak{F} . Let us show now that \mathfrak{G} is transitive. Suppose otherwise. Then \mathfrak{G} refutes the formula $\Box p \rightarrow \Box(\Box p \vee (\Box q \rightarrow q))$, which is valid in \mathfrak{F} because ω is a reflexive point. Finally, since $\mathfrak{G} \models \varphi$, \mathfrak{G} is Noetherian and since \mathfrak{F} is of width 1, we may conclude that $\mathfrak{G} \models \mathbf{GL.3}$. It follows that the subframe logic L is Kripke incomplete. Indeed, it shares the same class of Kripke frames with **GL.3** but $\Box p \rightarrow \Box \Box p \in \mathbf{GL.3} - L$.

The following theorem provides a frame-theoretic characterization of those complete subframe logics in \mathbf{NExtK} that are elementary, \mathcal{D} -persistent and strongly complete. Say that a logic L has the *finite embedding property* if a Kripke frame \mathfrak{F} validates L whenever all finite subframes of \mathfrak{F} are frames for L .

THEOREM 58 (Fine 1985). *For each Kripke complete subframe logic L the following conditions are equivalent:*

- (i) L is universal;⁹
- (ii) L is elementary;
- (iii) L is \mathcal{D} -persistent;
- (iv) L is strongly Kripke complete;
- (v) L has the finite embedding property.

Proof. The implications (i) \Rightarrow (ii) and (iii) \Rightarrow (iv) are trivial; (ii) \Rightarrow (iii) follows from Fine's [1975b] Theorem formulated in Section 1.3 and (v) \Rightarrow (i) from [Tarski 1954]. Thus it remains to show that (iv) \Rightarrow (v). Suppose \mathfrak{F} is a Kripke frame with root r such that $\mathfrak{F} \not\models L$ but all finite subframes of \mathfrak{F} validate L . Then it is readily checked that all finite subsets of $\Gamma = \{p_r\} \cup \Box^{<\omega} \Delta_{\mathfrak{F}}$ are L -consistent. Hence the whole set Γ is L -consistent. On the other hand, similarly to the proof of Lemma 13 one can show that Γ is satisfiable in a Kripke frame iff the frame is subreducible to \mathfrak{F} . So Γ cannot be satisfied in a Kripke frame for L and L is not strongly complete. ■

A similar criterion for the cofinal subframe logics in $\mathbf{NExtK4}$ can be found in [Zakharyashev 1996]. Note, however, that they are not in general universal and certainly do not have the finite embedding property, but (ii), (iii) and (iv) are still equivalent.

PROPOSITION 59. *Every subframe logic $L \in \mathbf{NExtAlt}_n$ has FMP.*

⁹I.e., universal is the class of Kripke frames for L considered as models of the first order language with R and $=$.

Figure 5.

Proof. Suppose $\varphi \notin L$. By Theorem 22, there is a Kripke frame \mathfrak{F} for L refuting φ at a point x . Denote by X the set of points in \mathfrak{F} accessible from x by $\leq md(\varphi)$ steps. Clearly, X is finite and the subframe of \mathfrak{F} induced by X validates L and refutes φ . ■

To understand the place of incomplete logics in the lattice of subframe logics we call a subframe logic L *strictly sf-complete* if it is Kripke complete and no other subframe logic has the same Kripke frames as L . Example 57 shows that **GL.3** is not strictly sf-complete. However, the logics **T**, **S4** and **Grz** turn out to be strictly sf-complete. The following result clarifies the situation. It is proved by applying the splitting technique to lattices of subframe logics.

THEOREM 60. *A subframe logic L containing **K4** is strictly sf-complete iff $L \not\subseteq \mathbf{GL.3}$. All subframe logics in $\mathbf{NExtAlt}_n$ are strictly sf-complete. A subframe logic is tabular iff there are only finitely many subframe logics containing it.*

1.9 More sufficient conditions of FMP

As follows from Theorem 52, a logic in $\mathbf{NExtK4}$ does not have FMP only if at least one of its canonical axioms contains closed domains. We illustrate their role by a simple example.

EXAMPLE 61. Consider the logic $L = \mathbf{K4.3} \oplus \alpha^\sharp(\mathfrak{F}, \perp)$ and the formula $\alpha(\mathfrak{F}, \perp)$, where \mathfrak{F} is the frame depicted in Fig. 5 (a). The frame \mathfrak{G} in Fig. 5 (b) separates $\alpha(\mathfrak{F}, \perp)$ from L . Indeed, \mathfrak{F} is a cofinal subframe of \mathfrak{G} and so $\mathfrak{G} \not\models \alpha(\mathfrak{F}, \perp)$. To show that $\mathfrak{G} \models \alpha^\sharp(\mathfrak{F}, \perp)$, suppose f is a cofinal subreduction of \mathfrak{G} to \mathfrak{F} . Then $f^{-1}(1)$ contains only one point, say x ; $f^{-1}(0)$ also contains only one point, namely the root of \mathfrak{G} . So the infinite set of points between x and the root is outside $\text{dom}f$, which means that f does not satisfy (CDC) for $\{\{1\}\}$. On the other hand, if \mathfrak{H} is a finite refutation frame of width 1 for $\alpha(\mathfrak{F}, \perp)$ then \mathfrak{H} contains a generated subframe reducible to \mathfrak{F} , from which $\mathfrak{H} \not\models L$. Thus, L fails to have FMP. In the same manner the reader can prove that **A*** in Table 2 does not have FMP either.

We show now two methods developed in [Zakharyashev 1997a] for establishing FMP of logics whose canonical axioms contain closed domains. One of them uses the following lemma, which is an immediate consequence of the refutability criterion for the canonical formulas.

LEMMA 62. *Suppose $\alpha(\mathfrak{F}, \mathfrak{D})$ and $\alpha(\mathfrak{G}, \mathfrak{E})$ ($\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ and $\alpha(\mathfrak{G}, \mathfrak{E}, \perp)$) are canonical formulas such that there is a (cofinal) subreduction f of \mathfrak{G} to \mathfrak{F} satisfying (CDC) for \mathfrak{D} and an antichain $\epsilon \subseteq \text{dom} f \uparrow$ is in \mathfrak{E} whenever $f(\epsilon \uparrow) = \vartheta \uparrow$ for some $\vartheta \in \mathfrak{D}$. Then $\alpha(\mathfrak{G}, \mathfrak{E}) \in \mathbf{K4} \oplus \alpha(\mathfrak{F}, \mathfrak{D})$ (respectively, $\alpha(\mathfrak{G}, \mathfrak{E}, \perp) \in \mathbf{K4} \oplus \alpha(\mathfrak{F}, \mathfrak{D}, \perp)$).*

THEOREM 63. *$L = \mathbf{K4} \oplus \{\alpha(\mathfrak{F}_i, \mathfrak{D}_i, \perp) : i \in I\} \oplus \{\alpha(\mathfrak{F}_j, \mathfrak{D}_j) : j \in J\}$ has FMP provided that either all frames \mathfrak{F}_i , for $i \in I \cup J$, are irreflexive or all of them are reflexive.*

Proof. Suppose all \mathfrak{F}_i are irreflexive and $\alpha(\mathfrak{G}, \mathfrak{E}, \perp)$ is an arbitrary canonical formula. We construct from \mathfrak{G} a new finite frame \mathfrak{H} by inserting into it new *reflexive* points. Namely, suppose ϵ is an antichain in \mathfrak{G} such that $\epsilon \notin \mathfrak{E}$. Suppose also that C_1, \dots, C_n are all clusters in \mathfrak{G} such that $\epsilon \subseteq C_i \uparrow$ and $\epsilon \cap C_i = \emptyset$, for $i = 1, \dots, n$, but no successor of C_i possesses this property. Then we insert in \mathfrak{G} new reflexive points x_1, \dots, x_n so that each x_i could see only the points in ϵ and their successors and could be seen only from the points in C_i and their predecessors. The same we simultaneously do for all antichains ϵ in \mathfrak{G} of that sort. The resulting frame is denoted by \mathfrak{H} . Since no new point was inserted just below an antichain in \mathfrak{E} , $\mathfrak{H} \not\models \alpha(\mathfrak{G}, \mathfrak{E}, \perp)$.

Suppose now that $\alpha(\mathfrak{G}, \mathfrak{E}, \perp) \notin L$ and show that $\mathfrak{H} \models L$. If this is not so then either $\mathfrak{H} \not\models \alpha(\mathfrak{F}_i, \mathfrak{D}_i, \perp)$, for some $i \in I$, or $\mathfrak{H} \not\models \alpha(\mathfrak{F}_j, \mathfrak{D}_j)$, for some $j \in J$. We consider only the former case, since the latter one is treated similarly. Thus, we have a cofinal subreduction f of \mathfrak{H} to \mathfrak{F}_i satisfying (CDC) for \mathfrak{D}_i . Since \mathfrak{F}_i is irreflexive, no point that was added to \mathfrak{G} is in $\text{dom} f$. So f may be regarded as a cofinal subreduction of \mathfrak{G} to \mathfrak{F}_i satisfying (CDC) for \mathfrak{D}_i . We clearly may assume also that the subframe of \mathfrak{G} generated by $\text{dom} f$ is rooted. Let ϵ be an antichain in \mathfrak{G} belonging to $\text{dom} f \uparrow$ and such that $f(\epsilon \uparrow) = \vartheta \uparrow$ for some $\vartheta \in \mathfrak{D}_i$. If $\epsilon \notin \mathfrak{E}$ then there is a reflexive point x in \mathfrak{H} such that $x \in \text{dom} f \uparrow$ and x sees only $\epsilon \uparrow$ and, of course, itself. But then $f(x \uparrow) = f(\epsilon \uparrow) = \vartheta \uparrow$ and so, by (CDC), $x \in \text{dom} f$, which is impossible. Therefore, $\epsilon \in \mathfrak{E}$ and so, by Lemma 62, $\alpha(\mathfrak{G}, \mathfrak{E}, \perp) \in L$, contrary to our assumption.

In the case of reflexive frames *irreflexive* points are inserted. ■

EXAMPLE 64. According to Theorem 63, the logic

$$L = \mathbf{K4} \oplus \alpha\left(\begin{array}{c} \bullet \quad \bullet \\ \diagdown \quad \diagup \\ \bullet \end{array}, \{\{1\}, \{1, 2\}\} \right)$$

has FMP. However, Artemov's logic $\mathbf{A}^* = L \oplus \mathbf{GL}$ does not enjoy this property. So FMP is not in general preserved under sums of logics.

The scope of the method of inserting points is not bounded only by canonical axioms associated with homogeneous (irreflexive or reflexive) frames. It can be applied, for instance, to normal extensions of **K4** with modal reduction principles, i.e., formulas of the form $Mp \rightarrow Np$, where M and N are strings of \Box and \Diamond (for first order equivalents of modal reduction principles see [van Benthem 1976]). One can show that each such logic is either of finite depth, or can be axiomatized by $\Box\Diamond$ -formulas and canonical formulas based upon almost homogeneous frames (containing at most one reflexive point), for which the method works as well. So we have

THEOREM 65. *All logics in NExt**K4** axiomatizable by modal reduction principles have FMP and are decidable.*

One of the most interesting open problems in completeness theory of modal logic is to prove an analogous theorem for logics in NExt**K** or to construct a counter-example. It is unknown, in particular, whether the logics of the form $\mathbf{K} \oplus \Box^m p \rightarrow \Box^n p$ have FMP; the same concerns the logics $\mathbf{K} \oplus \mathit{tra}_n$.

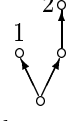

The second method of proving FMP uses the more conventional technique of removing points. Suppose that $L = \mathbf{K4} \oplus \{\alpha(\mathfrak{G}_i, \mathfrak{D}_i, \perp) : i \in I\}$ and $\alpha = \alpha(\mathfrak{H}, \mathfrak{E}, \perp) \notin L$. Then there exists a frame \mathfrak{F} for L such that $\mathfrak{F} \not\models \alpha$, i.e., there is a cofinal subreduction h of \mathfrak{F} to \mathfrak{H} satisfying (CDC) for \mathfrak{E} . Construct the countermodel $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ for α as it was done in Section 1.6. Without loss of generality we may assume that $\text{dom}h\uparrow = \text{dom}h\downarrow = \mathfrak{F}$ and that \mathfrak{F} is generated by the sets $\mathfrak{V}(p_i)$, p_i a variable in α .

Actually, the step-wise refinement procedure with deleting points having **Suba**-equivalent successors, used in the proof of Theorem 42, establishes FMP of L when all \mathfrak{D}_i are empty, i.e., L is a cofinal subframe logic. To tune it for L with non-empty \mathfrak{D}_i , we should follow a subtler strategy of deleting points, preserving those that are “responsible” for validating the axioms of L . Suppose we have already constructed a model $\mathfrak{M}'_n = \langle \mathfrak{F}'_n, \mathfrak{V}'_n \rangle$ by “folding up” $n - 1$ -cyclic sets into clusters of depth n (we use the same notations as in the proof of Theorem 42). Now we throw away points of two sorts.

First, for every proper cluster C of depth n such that some $x \in C$ has a **Suba**-equivalent successor of depth $< n$, we remove from C all points except x . Second, call a point x of depth $> n$ *redundant* in \mathfrak{M}'_n if it has a **Suba**-equivalent successor of depth $\leq n$ and, for every $i \in I$ and every cofinal subreduction g of $(\mathfrak{F}'_n)^{\leq n}$ to the subframe of \mathfrak{G}_i generated by some $\mathfrak{d} \in \mathfrak{D}_i$ such that $\mathfrak{d} \subseteq g(x\uparrow)$ and g satisfies (CDC) for \mathfrak{D}_i , there is a point $y \in x\uparrow$ of depth $\leq n$ such that $g(y\uparrow) = \mathfrak{d}\uparrow$. Let X be the maximal set of redundant points in \mathfrak{M}'_n which is upward closed in $(W'_n)^{>n}$. We define $\mathfrak{M}_{n+1} = \langle \mathfrak{F}_{n+1}, \mathfrak{V}_{n+1} \rangle$ as the submodel of \mathfrak{M}'_n resulting from it by removing all points in X as well. Since all deleted points have **Suba**-equivalent successors, $\mathfrak{M}_{n+1} \not\models \alpha$. And since we keep in \mathfrak{F}_{n+1} points which

violate (CDC) for \mathfrak{D}_i of possible cofinal subreductions to \mathfrak{G}_i , $\mathfrak{F}_{n+1} \models L$. So FMP of L will be established if we manage to prove that this process eventually terminates.

EXAMPLE 66. Let $L = \mathbf{S4} \oplus \alpha(\mathfrak{G}, \{\{1, 2\}\}, \perp)$, where \mathfrak{G} is , and assume that our “algorithm”, when being applied to \mathfrak{F} , α and L , works infinitely long. Then the frame $\mathfrak{F}_\omega = \langle W_\omega, R_\omega \rangle$, where

$$W_\omega = \bigcup_{0 < i < \omega} W_i^{\leq i}, \quad R_\omega = \bigcup_{0 < i < \omega} R_i^{\leq i}, \quad \mathfrak{F}_i = \langle W_i, R_i, P_i \rangle,$$

is of infinite depth. By König’s Lemma, there is an infinite descending chain $\dots x_i R_\omega x_{i-1} \dots R_\omega x_2 R_\omega x_1$ in \mathfrak{F}_ω such that x_i is of depth i . Since there are only finitely many pairwise non-**Sub** α -equivalent points, there must be some $n > 0$ such that, for every $k \geq n$, each point in $C(x_k)$ has a **Sub** α -equivalent successor in $\mathfrak{F}_k^{\leq k}$. And since $\mathfrak{F}_1^{\leq 1}$ is finite, there is $m \geq n$ starting from which all x_i see the same points of depth 1. Let us consider now \mathfrak{F}_m and ask why points in the m -cyclic set X , folded at step $m + 1$ into $C(x_{m+1})$, were not removed at step m . X is upward closed in $W_m^{\geq m}$ and every point in it has a **Sub** α -equivalent successor in $\mathfrak{F}_m^{\leq m}$. So the only reason for keeping some $x \in X$ is that $\mathfrak{F}_m^{\leq m}$ is cofinally subreducible to $\mathfrak{G}^{\leq 1}$, x sees inverse images of both points in $\mathfrak{G}^{\leq 1}$ but none of its successors in $\mathfrak{F}_m^{\leq m}$ does. By the cofinality condition, these inverse images can be taken from $\mathfrak{F}_1^{\leq 1}$. But then they are also seen from x_m , which is a contradiction. Thus sooner or later our algorithm will construct a finite frame separating L from α , which proves that L has FMP.

The reason why we succeeded in this example is that inverse images of points in the closed domain $\{1, 2\}$ can be found at a fixed finite depth in \mathfrak{F}_ω , and so points violating (CDC) for it can also be found at finite depth (that was not the case in Example 61). The following definitions describe a big family of frames and closed domains of that sort.

A point x in a frame \mathfrak{G} is called a *focus* of an antichain \mathfrak{a} in \mathfrak{G} if $x \notin \mathfrak{a}$ and $x \uparrow = \{x\} \cup \mathfrak{a} \uparrow$. Suppose \mathfrak{G} is a finite frame and \mathfrak{D} a set of antichains in \mathfrak{G} . Define by induction on n notions of *n -stable point* in \mathfrak{G} (relative to \mathfrak{D}) and *n -stable antichain* in \mathfrak{D} . A point x is *1-stable* in \mathfrak{G} iff either x is of depth 1 in \mathfrak{G} or the cluster $C(x)$ is proper. A point x is *$n + 1$ -stable* in \mathfrak{G} (relative to \mathfrak{D}) iff it is not *m -stable*, for any $m \leq n$, and either there is an *n -stable point* in \mathfrak{G} (relative to \mathfrak{D}) which is not seen from x or x is a focus of an antichain in \mathfrak{D} containing an *$n - 1$ -stable point* and no *n -stable point*. And we say an antichain \mathfrak{d} in \mathfrak{D} is *n -stable* iff it contains an *n -stable point* in the subframe \mathfrak{G}' of \mathfrak{G} generated by \mathfrak{d} (relative to \mathfrak{D}) and no *m -stable point* in \mathfrak{G}' (relative to \mathfrak{D}), for $m > n$. A point or an antichain is *stable* if

Figure 6.

it is n -stable for some n . It should be clear that if a point in an antichain is stable then the rest points in the antichain are also stable.

EXAMPLE 67.

- (1) Suppose \mathfrak{G} is a finite rooted generated subframe of one of the frames shown in Fig. 6 (a)–(c). Then, regardless of \mathfrak{D} , each point in \mathfrak{G} different from its root is n -stable, where n is the number located near the point. Every antichain \mathfrak{d} in \mathfrak{G} , containing at least two points, is also n -stable, with n being the maximal degree of stability of points in \mathfrak{d} .
- (2) If \mathfrak{G} is a rooted generated subframe of the frame depicted in Fig. 6 (d) and \mathfrak{D} is the set of all two-point antichains in \mathfrak{G} then every point in \mathfrak{G} is n -stable (relative to \mathfrak{D}), where n stays near the point. However, for $\mathfrak{D} = \emptyset$ no point in \mathfrak{G} , save those of depth 1, is stable.
- (3) If \mathfrak{G} is a finite tree of clusters then every antichain in \mathfrak{G} , different from a non-final singleton, is either 1- or 2-stable in \mathfrak{G} regardless of \mathfrak{D} . Every antichain containing a point x with proper $C(x)$ is 1- or 2-stable as well, whatever \mathfrak{G} and \mathfrak{D} are.
- (4) Every antichain is stable in every irreflexive frame \mathfrak{G} relative to the set \mathfrak{D}^\sharp of all antichains in \mathfrak{G} . However, this is not so if \mathfrak{G} contains reflexive points (for reflexive singletons are open domains and do not belong to \mathfrak{D}^\sharp).

The sufficient condition of FMP below is proved by arguments that are similar to those we used in Example 66.

THEOREM 68. *If $L = \mathbf{K4} \oplus \{\alpha(\mathfrak{G}_i, \mathfrak{D}_i, \perp) : i \in I\}$ and there is $d > 0$ such that, for any $i \in I$, every closed domain $\mathfrak{d} \in \mathfrak{D}_i$ is n -stable in \mathfrak{G}_i (relative to \mathfrak{D}_i), for some $n \leq d$, then L has FMP.*

Example 67 shows many applications of this condition. Moreover, using it one can prove the following

THEOREM 69. *Every normal extension of $\mathbf{S4}$ with a formula in one variable has FMP and is decidable.*

Note that, as was shown by Shehtman [1980], a formula with two variables or an infinite set of one-variable formulas can axiomatize logics in $\mathbf{NExtS4}$ without FMP (and even Kripke incomplete).

1.10 The reduction method

That a logic does not have FMP (or is Kripke incomplete) is not yet an evidence of its undecidability: it is enough to recall that the majority of decidability results for classical theories was proved without using any analogues of the finite model property (see e.g. [Rabin 1977], [Ershov 1980]). The first example of a decidable finitely axiomatizable modal logic without FMP was constructed by Gabbay [1971].

It seems unlikely that the methods of classical model theory can be applied directly for proving the decidability of propositional modal logics. However, sometimes it is possible to *reduce* the decision problem for a given modal logic L to that for a knowingly decidable first or higher order theory whose language is expressive enough for describing the structure of frames characterizing L . The most popular tools used for this purpose are Büchi's [1962] Theorem on the decidability of the weak monadic second order theory of the successor function on natural numbers and Rabin's [1969] Tree Theorem. Below we illustrate the use of Rabin's Theorem following [Gabbay 1975] and [Cresswell 1984].

Let ω^* be the set of all finite sequences of natural numbers and \prec the lexicographic order on it. For $x \in \omega^*$ and $i < \omega$, put $r_i(x) = x * i$, where $*$ denotes the usual concatenation operation. Besides, define the following predicates $<_i$ on ω^* , for $0 \leq i \leq 2$,

$$x <_i y \text{ iff } y = x * (3n + i) \text{ for some } n < \omega.$$

It follows from [Rabin 1969] that the monadic second order theory $\mathbf{S}\omega\mathbf{S}$ of the model $\langle \omega^*, \{r_i : i < \omega\}, \{<_i : 0 \leq i \leq 2\}, \prec, \emptyset \rangle$ (\emptyset denotes the empty sequence) is decidable.

The theory $\mathbf{S}\omega\mathbf{S}$ has a very strong expressive power which makes it possible to effectively describe semantical definitions of many modal (as well as some other) logics and thereby prove their decidability. In this way Gabbay [1975] established the decidability of, for instance,

$$\mathbf{K} \oplus \Box^m \Diamond p \rightarrow \Diamond p, \quad \mathbf{K} \oplus \Diamond^m \Box p \rightarrow \Box p,$$

$$\mathbf{K} \oplus \Box^m p \rightarrow \Diamond^n p, \quad \mathbf{K} \oplus \Diamond^m p \rightarrow \Box^n p.$$

By Sahlqvist's Theorem, all these logics are Kripke complete; however, we do not know whether they have FMP. General frames can also be described by means of $\mathbf{S}\omega\mathbf{S}$.

EXAMPLE 70. The frame $\mathfrak{F} = \langle W, R, P \rangle$ constructed in Example 7 can be represented in the language of $\mathcal{S}\omega\mathcal{S}$ as follows. Let us encode each $n < \omega$ by the sequence $\langle 3n \rangle$, while ω and $\omega + 1$ by $r_1(\emptyset)$ and $r_2(\emptyset)$, respectively. Then we have

$$\begin{aligned} x \in W & \text{ iff } \emptyset <_0 x \vee x = r_1(\emptyset) \vee x = r_2(\emptyset), \\ xRy & \text{ iff } (\emptyset <_0 x \wedge \emptyset <_0 y \wedge y \prec x \wedge x \neq y) \vee \\ & (x = r_1(\emptyset) \wedge \emptyset <_0 y) \vee x = y = r_1(\emptyset) \vee \\ & (x = r_2(\emptyset) \wedge y = r_1(\emptyset)), \\ X \in P & \text{ iff } \forall x (x \in X \rightarrow x \in W) \wedge ((Fin(X) \wedge r_1(\emptyset) \notin X) \vee \\ & \forall Y (\forall y (y \in Y \leftrightarrow (y \in W \wedge y \notin X)) \rightarrow Fin(Y) \wedge r_1(\emptyset) \notin Y)), \end{aligned}$$

where $x = y$ means $x \prec y \wedge y \prec x$ and

$$Fin(X) = \exists x \forall y (y \in X \rightarrow y \prec x).$$

It follows that the logic $\text{Log}\mathfrak{F}$ is decidable. Indeed, for every formula $\varphi(p_1, \dots, p_n)$, we have $\varphi \in \text{Log}\mathfrak{F}$ iff the second order formula

$$\forall x \forall X_1, \dots, X_n (X_1 \in P \wedge \dots \wedge X_n \in P \wedge x \in W \rightarrow ST(\varphi(X_1, \dots, X_n)))$$

belongs to $\mathcal{S}\omega\mathcal{S}$. Here $ST(\varphi(X_1, \dots, X_n))$, the *standard translation* of φ , is defined inductively in the following way (see also *Correspondence Theory*):

$$ST(X) = x \in X, \quad ST(\perp) = \perp,$$

$$ST(X \odot Y) = ST(X) \odot ST(Y), \text{ for } \odot \in \{\wedge, \vee, \rightarrow\},$$

$$ST(\Box X) = \forall y (xRy \rightarrow ST(X)\{y/x\}).$$

Recall that, as was shown in Example 57, $\text{Log}\mathfrak{F}$ is Kripke incomplete.

Also, it is not hard to find examples of applications of this technique for proving the decidability of finitely axiomatizable quasi-normal unimodal and normal polymodal (in particular, tense) logics which do not have Kripke frames at all; perhaps, the simplest one is Solovay's logic **S**.

Sobolev [1977a] found another way of proving decidability by applying methods of automata theory on infinite sequences. Using the results of [Büchi and Siefkes 1973] he showed that all finitely axiomatizable superintuitionistic logics of finite width (see Section 3.4) containing the formula

$$(((p \rightarrow q) \rightarrow p) \rightarrow p) \vee (((q \rightarrow p) \rightarrow q) \rightarrow q).$$

are decidable. By the preservation theorem of Section 3.3, this result can be transferred to the corresponding extensions of **S4**.

If a logic is known to be complete with respect to a suitable class of frames, the methods discussed above are usually applicable to it in a rather

straightforward manner. A relative disadvantage of this approach is that the resulting decision algorithms inherit the extremely high complexity of the decision algorithms for $\mathcal{S}\omega\mathcal{S}$ or other “rich theories” used to prove decidability. On the other hand, the logic \mathbf{S} , for instance, turns out to be decidable by an algorithm of the same complexity as that for \mathbf{GL} (see Example 75), in particular, the derivability problem in \mathbf{S} is *PSPACE*-complete. The logic of the frame \mathfrak{F} in Example 7 is “almost trivial”—it is polynomially equivalent to classical propositional logic, which follows from the fact that every formula φ refutable by \mathfrak{F} can be also refuted in \mathfrak{F} under a valuation giving the same truth-value to all variables in φ at all points i such that $|\mathbf{Sub}\varphi| < i < \omega$ (see Section 4.6). Actually, this sort of decidability proofs (ignoring “inessential” parts of infinite frames) was used already by Kuznetsov and Gerchik [1970] for studying some superintuitionistic logics.

Recently more general semantical methods of obtaining decidability results without turning to “rich theories” have been developed. We demonstrate them in the next section by establishing the decidability of all finitely axiomatizable logics in $\mathbf{NExtK4.3}$, which according to Example 61 do not in general have FMP. We show, however, that those logics are complete with respect to recursively enumerable classes of recursive frames in which the validity of formulas can be effectively checked—it was this rather than the finiteness of frames that we used in the proof of Harrop’s Theorem. In Section 2.5 this result will be extended to linear tense logics which in general are not even Kripke complete. Our presentation follows [Zakharyashev and Alekseev 1995].

1.11 Logics containing $\mathbf{K4.3}$

Each logic in $L \in \mathbf{NExtK4.3}$ is represented in the form

$$L = \mathbf{K4.3} \oplus \{\alpha(\mathfrak{F}_i, \mathfrak{D}_i, \perp) : i \in I\},$$

where all \mathfrak{F}_i are chains of clusters. So our decidability problem reduces to finding an algorithm which, given such a representation with finite I and a canonical formula $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ built on a chain of clusters \mathfrak{F} , could decide whether $\alpha(\mathfrak{F}, \mathfrak{D}, \perp) \in L$. Recall also that, by Fine’s [1974c] Theorem, logics of width 1 are characterized by Kripke frames having the form of Noetherian chains of clusters.

LEMMA 71. *For any Noetherian chain of clusters \mathfrak{G} and any canonical formula $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$, $\mathfrak{G} \not\models \alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ iff there is an injective¹⁰ cofinal subreduction g of \mathfrak{G} to \mathfrak{F} satisfying (CDC) for \mathfrak{D} .*

Proof. If $\mathfrak{G} \not\models \alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ then there is a cofinal subreduction f of \mathfrak{G} to \mathfrak{F} satisfying (CDC) for \mathfrak{D} . Clearly, $f^{-1}(x)$ is a singleton if x is irreflexive.

¹⁰That is $g(x) \neq g(y)$, for every distinct $x, y \in \text{dom}g$.

Suppose now that x is a reflexive point in \mathfrak{F} . Since \mathfrak{G} contains no infinite ascending chains, $f^{-1}(x)$ has a finite cover and so there is a reflexive point $u_x \in f^{-1}(x)$ such that $f^{-1}(x) \subseteq u_x \downarrow$. Fix such a u_x for each reflexive x and define a partial map g by taking

$$g(y) = \begin{cases} f(y) & \text{if either } f(y) \text{ is irreflexive or} \\ & f(y) \text{ is reflexive and } y = u_{f(y)} \\ \text{undefined} & \text{otherwise.} \end{cases}$$

One can readily check that g is the injective cofinal subreduction we need. The converse is trivial. \blacksquare

Roughly, every Noetherian chain of clusters refuting $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ results from \mathfrak{F} by inserting some Noetherian chains of clusters just below clusters $C(x)$ in \mathfrak{F} such that $\{x\} \notin \mathfrak{D}$. We show now that if $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ is not in $L \in \text{NExtK4.3}$ then it can be separated from L by a frame constructed from \mathfrak{F} by inserting in open domains between its adjacent clusters either finite descending chains of irreflexive points possibly ending with a reflexive one or infinite descending chains of irreflexive points.

Let $C(x_0), \dots, C(x_n)$ be all distinct clusters in \mathfrak{F} ordered in such a way that $C(x_0) \subset C(x_1) \downarrow \subset \dots \subset C(x_n) \downarrow$. Say that an n -tuple $t = \langle \xi_1, \dots, \xi_n \rangle$ is a *type* for $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ if either $\xi_i = m$ or $\xi_i = m+$, for some $m < \omega$, or $\xi_i = \omega$, with $\xi_i = 0$ if $\{x_i\} \in \mathfrak{D}$. Given a type $t = \langle \xi_1, \dots, \xi_n \rangle$ for $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$, we define the *t-extension* of \mathfrak{F} to be the frame \mathfrak{G} that is obtained from \mathfrak{F} by inserting between each pair $C(x_{i-1}), C(x_i)$ either a descending chain of m irreflexive points, if $\xi_i = m < \omega$, or a descending chain of $m + 1$ points of which only the last (lowest) one is reflexive, if $\xi_i = m+$, or an infinite descending chain of irreflexive points, if $\xi_i = \omega$. It should be clear that $\mathfrak{G} \not\models \alpha(\mathfrak{F}, \mathfrak{D}, \perp)$.

LEMMA 72. *If $L \in \text{NExtK4.3}$ and $\alpha(\mathfrak{F}, \mathfrak{D}, \perp) \notin L$ then $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ is separated from L by the t -extension of \mathfrak{F} , for some type t for $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$.*

Proof. By Lemma 71, we have a Noetherian chain of clusters \mathfrak{G} for L and an injective cofinal subreduction f of \mathfrak{G} to \mathfrak{F} satisfying (CDC) for \mathfrak{D} . By the Generation Theorem, we may assume that f maps the root of \mathfrak{G} to the root of \mathfrak{F} . Let \mathfrak{G}_0 be the subframe of \mathfrak{G} obtained by removing from \mathfrak{G} all those points that are not in $\text{dom} f$ but belong to clusters containing some points in $\text{dom} f$. The very same map f is an injective cofinal subreduction of \mathfrak{G}_0 to \mathfrak{F} satisfying (CDC) for \mathfrak{D} , and so $\mathfrak{G}_0 \not\models \alpha(\mathfrak{F}, \mathfrak{D}, \perp)$. Since \mathfrak{G}_0 is a reduct of \mathfrak{G} , $\mathfrak{G}_0 \models L$.

Let $C(x_0), \dots, C(x_n)$ be all distinct clusters in \mathfrak{G}_0 such that

$$\text{dom} f = \bigcup_{i=0}^n C(x_i), \quad C(x_0) \subset C(x_1) \downarrow \subset \dots \subset C(x_n) \downarrow.$$

By induction on i we define a sequence of frames $\mathfrak{G}_0 \supseteq \dots \supseteq \mathfrak{G}_n$ such that (a) f is an injective cofinal subreduction of \mathfrak{G}_i to \mathfrak{F} satisfying (CDC) for \mathfrak{D} , (b) between $C(x_{i-1})$ and $C(x_i)$ the frame \mathfrak{G}_i contains either a finite descending chain of irreflexive points possibly ending with a reflexive one or an infinite descending chain of irreflexive points, and (c) $\mathfrak{G}_i \models L$.

Suppose \mathfrak{G}_{i-1} has been already constructed and \mathfrak{C}_i is the chain of clusters located between $C(x_{i-1})$ and $C(x_i)$. Three cases are possible. (1) \mathfrak{C}_i is a finite chain of irreflexive points. Then we put $\mathfrak{G}_i = \mathfrak{G}_{i-1}$. (2) \mathfrak{C}_i contains a non-degenerate cluster $C(x)$ having finitely many distinct successors in \mathfrak{C}_i and all of them are irreflexive. Then \mathfrak{G}_i results from \mathfrak{G}_{i-1} by removing from \mathfrak{C}_i all points save x and those successors. \mathfrak{G}_i is a reduct of \mathfrak{G}_{i-1} and so conditions (a)–(c) are satisfied. (3) Suppose (1) and (2) do not hold. Then \mathfrak{C}_i contains an infinite descending chain Y of irreflexive points accessible from all other points in \mathfrak{C}_i . In this case \mathfrak{G}_i is obtained from \mathfrak{G}_{i-1} by removing all points in \mathfrak{C}_i save those in Y . Clearly, \mathfrak{G}_i satisfies (a) and (b). To prove (c) suppose $\mathfrak{G}_i \not\models \alpha(\mathfrak{H}, \mathfrak{E}, \perp)$ for some $\alpha(\mathfrak{H}, \mathfrak{E}, \perp) \in L$. Then there is an injective cofinal subreduction g of \mathfrak{G}_i to \mathfrak{H} satisfying (CDC) for \mathfrak{E} . Consider g as a cofinal subreduction of \mathfrak{G}_{i-1} to \mathfrak{H} and show that it also satisfies (CDC) for \mathfrak{E} . Indeed, (CDC) could be violated only by a point in $z \in \mathfrak{C}_i - Y$ such that $g(z\uparrow) = w\uparrow$, for some $\{w\} \in \mathfrak{E}$. Since $g^{-1}(w)$ is a singleton and $Y \subseteq z\uparrow$, there is $y \in Y$ such that $g(y\uparrow) = w\uparrow$ and $y \notin \text{dom}g$, contrary to g satisfying (CDC) for \mathfrak{E} as a subreduction of \mathfrak{G}_i to \mathfrak{H} . ■

Thus, a frame separating $\alpha(\mathfrak{F}, \mathfrak{D}, \perp) \notin L$ from $L \in \text{NExt}\mathbf{K4.3}$ can be found in the recursively enumerable class of t -extensions of \mathfrak{F} , t being a type for $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$. Moreover, given a formula $\alpha(\mathfrak{H}, \mathfrak{E}, \perp)$ and a type t for $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$, one can effectively check whether $\alpha(\mathfrak{H}, \mathfrak{E}, \perp)$ is valid in the t -extension of \mathfrak{F} . Indeed, let k be the number of irreflexive points in \mathfrak{H} , $t = \langle \xi_1, \dots, \xi_n \rangle$, and \mathfrak{G} the t -extension of \mathfrak{F} . Construct a cofinal subframe \mathfrak{G}_k of \mathfrak{G} by “cutting off” the infinite descending chains inserted in \mathfrak{F} (if any) just below their $k + 1$ th points, and let X be the set of all these $k + 1$ th points. Clearly, \mathfrak{G}_k is finite. It is now an easy exercise to prove the following

LEMMA 73. $\mathfrak{G} \not\models \alpha(\mathfrak{H}, \mathfrak{E}, \perp)$ iff there is an injective cofinal subreduction f of \mathfrak{G}_k to \mathfrak{H} satisfying (CDC) for \mathfrak{E} and such that $X \cap \text{dom}f = \emptyset$.

As a consequence we obtain

THEOREM 74. All finitely axiomatizable normal extensions of $\mathbf{K4.3}$ are decidable.

1.12 Quasi-normal modal logics

All logics we have considered so far were *normal*, i.e., closed under the rule of necessitation $\varphi/\Box\varphi$. McKinsey and Tarski [1948] noticed, however, that by adding to $\mathbf{S4}$ the McKinsey axiom $\mathbf{ma} = \Box\Diamond p \rightarrow \Diamond\Box p$ and taking

Figure 7.

the closure under modus ponens and substitution we obtain a logic—let us denote it by **S4.1'**—which is not normal in that sense. To understand why this is so, consider the frame \mathfrak{F} shown in Fig. 7. One can easily construct a model on \mathfrak{F} such that $0 \not\models \Box ma$ (0 sees a final proper cluster). On the other hand, ma and all its substitution instances are true at 0 (0 sees a final simple cluster), from which $\mathbf{S4.1}' \subseteq \{\varphi : 0 \models \varphi\}$ and so $\Box ma \notin \mathbf{S4.1}'$.

A set of modal formulas containing **K** and closed under modus ponens and substitution was called by Segerberg [1971] a *quasi-normal logic*. The minimal quasi-normal extension of a logic L with formulas $\varphi_i, i \in I$, will be denoted by $L + \{\varphi_i : i \in I\}$ (i.e., the operation $+$ presupposes taking the closure under modus ponens and substitution only). $\text{Ext}L$ is the class of all quasi-normal logics above L . It is easy to see that a quasi-normal logic is normal iff it is closed under the congruence rule $p \leftrightarrow q / \Box p \leftrightarrow \Box q$.

Quasi-normal logics, introduced originally as some abstract (though natural) generalization of normal ones, attracted modal logicians' attention after Solovay [1976] constructed his provability logics **GL** and **S**. The former one treats \Box as “it is provable in Peano Arithmetic” and describes those properties of Gödel’s provability predicate that are provable in PA; it is normal. The latter characterizes the properties of the provability predicate that are true in the standard arithmetic model, and in view of Gödel’s Incompleteness Theorem it cannot be normal. (For a detailed discussion of provability logic consult *Modal Logic and Self-reference*.) Solovay showed in fact that

$$\mathbf{S} = \mathbf{GL} + \Box p \rightarrow p.$$

At first sight **S** may appear to be inconsistent: Löb’s axiom requires frames to be irreflexive, while $\Box p \rightarrow p$ is refuted in them. And indeed, no Kripke frame validates both these axioms (in particular no consistent extension of **S** is normal).

Having the algebraic semantics for normal modal logics, it is fairly easy to construct an adequate algebraic semantics for a consistent $L \in \text{Ext}\mathbf{K}$. Let M be a normal logic contained in L (for instance the greatest one, which is called the *kernel* of L) and \mathfrak{A}_M its Tarski–Lindenbaum algebra (in Section 11 of *Basic Modal Logic* it was called the canonical modal algebra for M).

The set

$$\nabla = \{[\varphi]_M : \varphi \in L\}$$

is clearly a filter in \mathfrak{A}_M . By the well known properties of the Tarski–Lindenbaum algebras, we then obtain the following completeness result: $\varphi \in L$ iff under every valuation in \mathfrak{A}_M the value of φ belongs to ∇ . Structures of the form $\langle \mathfrak{A}, \nabla \rangle$, where \mathfrak{A} is a modal algebra and ∇ a filter in \mathfrak{A} , are known as *modal matrices*. Thus, every quasi-normal logic is characterized by a suitable class of modal matrices. It is not hard to see that L is normal iff it is characterized by a class of modal matrices with unit filters.

Now, going over to the dual (Stone–Jónsson–Tarski representation) \mathfrak{A}_+ of \mathfrak{A} in a modal matrix $\langle \mathfrak{A}, \nabla \rangle$ and taking ∇_+ to be the set of ultrafilters in \mathfrak{A} containing ∇ , we arrive at the general frame \mathfrak{A}_+ with the set of *distinguished points* (or *actual worlds*) ∇_+ . A formula φ is regarded to be valid in $\langle \mathfrak{A}_+, \nabla_+ \rangle$ iff under any valuation in \mathfrak{A}_+ , φ is true at all points in ∇_+ .

Taking into account the Generation Theorem, we can conclude that every quasi-normal modal logic is characterized by a suitable class of rooted general frames in which the root is regarded to be the only actual world. It follows in particular that, as was first observed by McKinsey and Tarski [1948],

$$\mathbf{K4} + \{\Box\varphi_i : i \in I\} = \mathbf{K4} \oplus \{\Box\varphi_i : i \in I\}.$$

However, one cannot replace here $\mathbf{K4}$ by \mathbf{K} or \mathbf{T} . Note also that as was shown by Segerberg [1971], \mathbf{K} , \mathbf{T} and some other standard normal logics are not finitely axiomatizable with modus ponens and substitution as the only postulated inference rules. Duality theory between modal matrices and frames with distinguished points can be developed along with duality theory for normal logics (for details see [Chagrov and Zakharyashev 1997]). Kripke frames with distinguished points were used for studying quasi-normal logics by Segerberg [1971]. Modal matrices were considered by Blok and Köhler [1983] (under the name of filtered algebras), Chagrov [1985b], and Shum [1985].

EXAMPLE 75. Consider the (transitive) frame $\mathfrak{G} = \langle V, S, Q \rangle$ whose underlying Kripke frame is shown in Fig. 7 and Q consists of \emptyset , V , all finite sets of natural numbers and the complements to them in the space V (so $\omega \in X \in Q$ iff there is $n < \omega$ such that $m \in X$ for all $m \geq n$). Since \mathfrak{G} is irreflexive and Noetherian, it validates \mathbf{GL} . Moreover, we have $\langle \mathfrak{G}, \omega \rangle \models \Box p \rightarrow p$; for if under some valuation $\omega \models \Box p$ then p must be true at every point. It follows that \mathfrak{G} with actual world ω validates \mathbf{S} . (The reader can check that by making ω reflexive we again obtain a frame for \mathbf{S} .)

By inserting the “tail” \mathfrak{G} as in Fig. 7 into finite rooted frames for \mathbf{GL} below their roots and using the fact that \mathbf{GL} has FMP, one can readily

show that, for every formula φ ,

$$\varphi \in \mathbf{S} \text{ iff } \bigwedge_{\Box\psi \in \mathbf{Sub}\varphi} (\Box\psi \rightarrow \psi) \rightarrow \varphi \in \mathbf{GL}.$$

It follows in particular that \mathbf{S} is decidable.

This example shows that the concepts of Kripke completeness and FMP do not play so important role in the quasi-normal case: even simple logics require infinite general frames. One possible way to cope with them at least in the transitive case is to extend the frame-theoretic language of the canonical formulas to the class $\mathbf{ExtK4}$.

Notice first that the canonical formulas, introduced in Section 1.6, cannot axiomatize all logics in $\mathbf{ExtK4}$. Indeed, $\langle \mathfrak{G}, w \rangle \not\models \alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ iff there is a cofinal subreduction f of \mathfrak{G} to \mathfrak{F} satisfying (CDC) for \mathfrak{D} and the following *actual world condition* as well:

(AWC) $f(w)$ is the root of \mathfrak{F} .

Now, consider the frame $\langle \mathfrak{G}, \omega \rangle$ constructed in Example 75. Since each set $X \in Q$ containing ω is infinite and has a dead end, it is impossible to reduce X to \circ or \bullet , and so $\langle \mathfrak{G}, \omega \rangle$ validates all normal canonical formulas. On the other hand, we clearly have $\langle \mathfrak{G}, \omega \rangle \not\models B_n$ for every $n \geq 1$. So the logics $\mathbf{K4BD}_n$ cannot be axiomatized by normal canonical formulas without the postulated necessitation.

To get over this obstacle we have to modify the definition of subreduction so that such sets as X above may be “reduced” at least to irreflexive roots of frames. Given a frame $\mathfrak{G} = \langle V, S, Q \rangle$ with an *irreflexive* root u and a frame $\mathfrak{F} = \langle W, R, P \rangle$, we say a partial map f from W onto V is a *quasi-subreduction* of \mathfrak{F} to \mathfrak{G} if it satisfies (R1) for all $x, y \in \text{dom}f$ such that $f(x) \neq u$ or $f(y) \neq u$, (R2) and (R3).¹¹ Thus, we may map all points in the frame \mathfrak{G} in Fig. 7 to \bullet , and this map will be a quasi-reduction of \mathfrak{G} to \bullet satisfying (AWC). Actually, every frame is quasi-reducible to \bullet .

Now, given a finite frame \mathfrak{F} with an irreflexive root a_0 and a set \mathfrak{D} of antichains in \mathfrak{F} , we define the *quasi-normal canonical formula* $\alpha^\bullet(\mathfrak{F}, \mathfrak{D}, \perp)$ as the result of deleting $\Box p_0$ from φ_0 in $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ (which says that a_0 is not self-accessible); the *quasi-normal negation free canonical formula* $\alpha^\bullet(\mathfrak{F}, \mathfrak{D})$ is defined in exactly the same way, starting from $\alpha(\mathfrak{F}, \mathfrak{D})$. It is not hard to see that $\alpha^\bullet(\mathfrak{F}, \mathfrak{D}, \perp)$ (or $\alpha^\bullet(\mathfrak{F}, \mathfrak{D})$) is refuted in a frame $\langle \mathfrak{G}, w \rangle$ iff there is a cofinal (respectively, plain) quasi-subreduction of \mathfrak{G} to \mathfrak{F} satisfying (CDC) for \mathfrak{D} and (AWC). The following result is obtained by an obvious generalization of the proof of Theorem 44 to frames with distinguished points (for details see [Zakharyashev 1992]).

¹¹Another possibility is to allow “reductions” of X to reflexive points by relaxing (R2); cf. Section 2.6.

THEOREM 76. *There is an algorithm which, given a modal (negation free) formula φ , constructs a finite set Δ of normal and quasi-normal (negation free) canonical formulas such that $\mathbf{K4} + \varphi = \mathbf{K4} + \Delta$.*

For example, $\mathbf{S} = \mathbf{K4} + \alpha(\circ) + \alpha(\bullet)$. Since frames for $\mathbf{S4}$ are reflexive, we have

COROLLARY 77. *There is an algorithm which, given a modal formula φ , constructs a finite set Δ of normal canonical formulas built on reflexive frames such that $\mathbf{S4} + \varphi = \mathbf{S4} + \Delta$.*

As a consequence we obtain

THEOREM 78 (Segerberg 1975). $\text{Ext}\mathbf{S4.3} = \text{NExt}\mathbf{S4.3}$.

Proof. We must show that every logic $L \in \text{Ext}\mathbf{S4.3}$ is normal, i.e., $\varphi \in L$ only if $\Box\varphi \in L$, for every φ . Suppose otherwise. Then by Corollary 77, there exists $\alpha(\mathfrak{F}, \mathfrak{D}, \perp) \in L$ such that $\Box\alpha(\mathfrak{F}, \mathfrak{D}, \perp) \notin L$. Let $\langle \mathfrak{G}, w \rangle$ be a frame validating L and refuting $\Box\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$. Since $\mathfrak{G} \models \mathbf{S4.3}$, \mathfrak{G} is a chain of non-degenerate clusters. And since it refutes $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ there is a cofinal subreduction f of \mathfrak{G} to \mathfrak{F} . It follows, in particular, that \mathfrak{F} is also a chain of non-degenerate clusters and so $\mathfrak{D} = \emptyset$. Let a be the root of \mathfrak{F} . Define a map g by taking

$$g(x) = \begin{cases} f(x) & \text{if } x \in \text{dom } f \\ a & \text{if } x \in f^{-1}(a) \downarrow - \text{dom } f \\ \text{undefined} & \text{otherwise.} \end{cases}$$

It should be clear that g cofinally subreduces \mathfrak{G} to \mathfrak{F} and $g(w) = a$. Consequently, $\langle \mathfrak{G}, w \rangle \not\models \alpha(\mathfrak{F}, \perp)$, which is a contradiction. ■

Let us now briefly consider quasi-normal analogues of subframe and cofinal subframe logics in $\text{NExt}\mathbf{K4}$. Those logics that can be represented in the form

$$(\mathbf{K4} \oplus \{\alpha(\mathfrak{F}_i) : i \in I\}) + \{\alpha(\mathfrak{F}_j) : j \in J\} + \{\alpha^\bullet(\mathfrak{F}_k) : k \in K\}$$

are called (*quasi-normal*) *subframe logics* and those of the form

$$(\mathbf{K4} \oplus \{\alpha(\mathfrak{F}_i, \perp) : i \in I\}) + \{\alpha(\mathfrak{F}_j, \perp) : j \in J\} + \{\alpha^\bullet(\mathfrak{F}_k, \perp) : k \in K\}$$

are called (*quasi-normal*) *cofinal subframe logics*. The classes of quasi-normal subframe and cofinal subframe logics are denoted by $QS\mathcal{F}$ and $QCS\mathcal{F}$, respectively. The example of \mathbf{S} shows that Theorem 52 cannot be extended to $QS\mathcal{F}$ and $QCS\mathcal{F}$. Yet one can show that all finitely axiomatizable logics in $QS\mathcal{F}$ and $QCS\mathcal{F}$ are decidable. We omit almost all proofs and confine ourselves mainly to formulations of relevant results. For details the reader is referred to [Zakharyashev 1996].

Figure 8.

We use the following notation. For a frame $\mathfrak{F} = \langle W, R \rangle$ with irreflexive root u and $0 < \xi < \omega$, \mathfrak{F}_ξ^{ir} and \mathfrak{F}_ξ^r denote the frames obtained from \mathfrak{F} by replacing u with the descending chains $0, \dots, \xi - 1$ of irreflexive and reflexive points, respectively; $\mathfrak{F}_{(\omega+1)^*}^{ir} = \langle W_{(\omega+1)^*}, R_{(\omega+1)^*}^{ir}, P_{(\omega+1)^*} \rangle$ is the frame that results from \mathfrak{F} by replacing u with the infinite descending chain $0, 1, \dots$ of irreflexive points and then adding irreflexive root ω , with $P_{(\omega+1)^*}$ containing all subsets of $W - \{u\}$, all finite subsets of natural numbers $\{0, 1, \dots\}$, all (finite) unions of these sets and all complements to them in the space $W_{(\omega+1)^*}$ (see Fig. 8). Note that \mathfrak{F} is a quasi-reduct of every frame of the form \mathfrak{F}_ξ^{ir} , \mathfrak{F}_ξ^r or $\mathfrak{F}_{(\omega+1)^*}^{ir}$.

The following theorem characterizes the canonical formulas belonging to logics in $QS\mathcal{F}$ and $QCS\mathcal{F}$.

THEOREM 79. *Suppose L is a subframe or cofinal subframe quasi-normal logic. Then*

- rm (i) for every finite frame \mathfrak{F} with root u , $\alpha(\mathfrak{F}, \mathcal{D}, \perp) \in L$ iff $\langle \mathfrak{F}, u \rangle \not\models L$;*
rm (ii) for every finite frame \mathfrak{F} with irreflexive root u , $\alpha^\bullet(\mathfrak{F}, \mathcal{D}, \perp) \in L$ iff $\langle \mathfrak{F}, u \rangle \not\models L$, $\langle \mathfrak{F}_1^r, 0 \rangle \not\models L$ and $\langle \mathfrak{F}_{(\omega+1)^}^{ir}, \omega \rangle \not\models L$.*

Proof. We prove only (\Leftarrow) of (ii). Let $\mathfrak{G} = \langle V, S, Q \rangle$ refute $\alpha^\bullet(\mathfrak{F}, \mathcal{D}, \perp)$ at its root w and show that $\langle \mathfrak{G}, w \rangle \not\models L$. We have a cofinal quasi-subreduction f of \mathfrak{G} to \mathfrak{F} such that $f(w) = u$. Consider the set $U = f^{-1}(u) \in Q$. Without loss of generality we may assume that $U = U \downarrow$. There are three possible cases.

Case 1. The point w is irreflexive and $\{w\} \in Q$. Then the restriction of f to $\text{dom} f - (U - \{w\})$ is a cofinal subreduction of \mathfrak{G} to \mathfrak{F} satisfying (AWC) and so $\langle \mathfrak{G}, w \rangle \not\models L$.

Case 2. There is $X \subseteq U$ such that $w \in X \in Q$ and, for every $x \in X$, there exists $y \in X \cap x \uparrow$. Then the restriction of f to $\text{dom} f - (U - X)$ is a cofinal subreduction of \mathfrak{G} to \mathfrak{F}_1^r satisfying (AWC) and so again $\langle \mathfrak{G}, w \rangle \not\models L$.

Case 3. If neither of the preceding cases holds then, for every $X \subseteq U$ such that $w \in X \in Q$, the set $D_X = X - X \downarrow$ of dead ends in X is a cover for X , i.e., $X \subseteq D_X \downarrow$, and $w \in X - D_X \in Q$. Put

$$X_0 = D_U, \dots, X_{n+1} = D_{U - (X_0 \cup \dots \cup X_n)}, \dots, X_\omega = U - \bigcup_{\xi < \omega} X_\xi.$$

Each of these sets, save possibly X_ω , is an antichain of irreflexive points and belongs to Q . Besides, $X_\zeta \subset X_n \downarrow = \bigcup_{n < \xi \leq \omega} X_\xi$ for every $n < \zeta \leq \omega$. Therefore, the map g defined by

$$g(x) = \begin{cases} f(x) & \text{if } x \in V - U \\ \xi & \text{if } x \in X_\xi, 0 \leq \xi \leq \omega \end{cases}$$

is a cofinal quasi-subreduction of \mathfrak{G} to $\mathfrak{F}_{(\omega+1)^*}^{ir}$ satisfying (AWC).

Now using the fact that $\langle \mathfrak{F}_{(\omega+1)^*}^{ir}, \omega \rangle \not\models L$ and that the composition of (cofinal) (quasi-) subreductions is again a (cofinal) (quasi-) subreduction, it is not hard to see that $\langle \mathfrak{G}, w \rangle \not\models L$. ■

COROLLARY 80. *All subframe and cofinal subframe quasi-normal logics above **S4** have FMP.*

EXAMPLE 81. As an illustration let us use Theorem 79 to characterize those normal and quasi-normal canonical formulas that belong to **S**. Clearly, either $\alpha(\circ)$ or $\alpha(\bullet)$ is refuted at the root of every rooted Kripke frame. So all normal canonical formulas are in **S**. Every quasi-normal formula $\alpha^\bullet(\mathfrak{F}, \mathfrak{D}, \perp)$ associated with \mathfrak{F} containing a reflexive point is also in **S**, since $\Box\alpha(\circ)$ is refuted at the roots of \mathfrak{F} , \mathfrak{F}_1^r and $\mathfrak{F}_{(\omega+1)^*}^{ir}$. But no quasi-normal formula $\alpha^\bullet(\mathfrak{F}, \mathfrak{D}, \perp)$ built on irreflexive \mathfrak{F} belongs to **S**, because $\mathfrak{F}_{(\omega+1)^*}^{ir} \models \alpha(\circ)$ and $\langle \mathfrak{F}_{(\omega+1)^*}^{ir}, \omega \rangle \models \alpha(\bullet)$, since $\{\omega\} \notin P_{(\omega+1)^*}$. Notice that incidentally we have proved the following completeness theorem for **S**.

THEOREM 82. ***S** is characterized by the class*

$$\{\langle \mathfrak{F}_{(\omega+1)^*}^{ir}, \omega \rangle : \mathfrak{F} \text{ is a finite rooted irreflexive frame}\}.$$

Theorem 79 reduces the decision problem for a logic L in QSF or $QCSF$ to the problem of verifying, given a finite frame \mathfrak{F} with root u , whether $\langle \mathfrak{F}, u \rangle$, $\langle \mathfrak{F}_1^r, 0 \rangle$ and $\langle \mathfrak{F}_{(\omega+1)^*}^{ir}, \omega \rangle$ refute an axiom of L . The two former frames present no difficulties: they are finite. As to the latter, it is not hard to see that, for instance, $\langle \mathfrak{F}_{(\omega+1)^*}^{ir}, \omega \rangle \not\models \alpha^\bullet(\mathfrak{G}, \perp)$ iff $\langle \mathfrak{F}_\xi^{ir}, \xi - 1 \rangle$, for some $\xi \leq |\mathfrak{G}|$, is cofinally quasi-subreducible to \mathfrak{G} . Thus we obtain

THEOREM 83. *All finitely axiomatizable subframe and cofinal subframe quasi-normal logics are decidable.*

One can also give a frame-theoretic characterization of the classes QSF and $QCSF$ similar to Theorem 53. Let us say that a frame \mathfrak{F} with actual world u is a (*cofinal*) *subframe* of a frame \mathfrak{G} with actual world w if \mathfrak{F} is a (*cofinal*) subframe of \mathfrak{G} and $u = w$.

THEOREM 84. *L is a (*cofinal*) subframe quasi-normal logic iff L is characterized by a class of frames with actual worlds that is closed under (*cofinal*) subframes.*

1.13 Tabular logics

Every logic L having the finite model property can be represented as the intersection of some *tabular logics*, that is logics characterized by finite frames (or models, algebras, matrices, etc.):

$$L = \bigcap \{ \text{Log} \mathfrak{F} : \mathfrak{F} \text{ is a finite frame for } L \}.$$

(It follows in particular that every fragment of L containing only those formulas whose length does not exceed some fixed $n < \omega$ is determined by a finite frame; for that reason logics with FMP are also called *finitely approximable*.) In many respects tabular logics are very easy to deal with. For instance, the key problem of recognizing whether a formula φ belongs to a tabular L is trivially decided by the direct inspection of all possible valuations of φ 's variables in the finite frame characterizing L . That is why the question “is it tabular?” is one of the first items in the standard “questionnaire” for every new logical system.

First results concerning the tabularity of modal logics were obtained by Gödel [1932] and Dugundji [1940] who showed that intuitionistic propositional logic and all Lewis' modal systems **S1–S5** are not tabular. (Note that using the same method Drabbé [1967] proved that the three non-normal Lewis' systems **S1–S3** cannot be characterized by a matrix with a finite number of distinguished elements). For arbitrary logics in $\text{Ext}\mathbf{K}$ one can easily prove the following syntactical criterion of tabularity, which uses the formulas

$$\begin{aligned} \alpha_n &= \neg(\varphi_1 \wedge \Diamond(\varphi_2 \wedge \Diamond(\varphi_3 \wedge \dots \wedge \Diamond\varphi_n) \dots)), \\ \beta_n &= \bigwedge_{m=0}^{n-1} \neg\Diamond^m(\Diamond\varphi_1 \wedge \dots \wedge \Diamond\varphi_n), \\ \mathbf{tab}_n &= \alpha_n \wedge \beta_n, \end{aligned}$$

where $\varphi_i = p_1 \wedge \dots \wedge p_{i-1} \wedge \neg p_i \wedge p_{i+1} \wedge \dots \wedge p_n$.

THEOREM 85. *$L \in \text{Ext}\mathbf{K}$ is tabular iff $\mathbf{tab}_n \in L$, for some $n < \omega$.*

Proof. A frame $\mathfrak{F} = \langle W, R \rangle$ refutes α_n at a point x_1 iff a chain of length n starts from x_1 , and \mathfrak{F} refutes β_n at x_1 iff there is a chain $x_1 R x_2 R \dots R x_m$

of length $m < n$ such that x_m is of branching n , i.e., $x_m R y_1, \dots, x_m R y_n$ for some distinct y_1, \dots, y_n . It follows that every rooted generated (by an actual world) subframe of the canonical frame for L containing \mathbf{tab}_n has at most $1 + (n-1) + \dots + (n-1)^{n-2}$ points. ■

As a consequence we immediately obtain

COROLLARY 86. *Every tabular modal logic has finitely many extensions and all of them are also tabular.*

The next theorem follows from general algebraic results of [Blok and Köhler 1983]; equally easy it can be proved using the characterization above.

THEOREM 87. *Every tabular logic $L \in \text{Ext}\mathbf{K}$ is finitely axiomatizable.*

Proof. According to Theorem 85, L is an extension of $\mathbf{K} + \mathbf{tab}_n$, for some $n < \omega$. By Corollary 86, we have a chain

$$\mathbf{K} + \mathbf{tab}_n = L_1 \subset L_2 \subset \dots \subset L_{k-1} \subset L_k = L$$

of quasi-normal logics such that $\{L' \in \text{Ext}\mathbf{K} : L_i \subset L' \subset L_{i+1}\} = \emptyset$, for every $i = 1, \dots, k-1$. It remains to notice that if L' is finitely axiomatizable, $L' \subset L''$ and there is no logic located properly between L' and L'' then L'' is also finitely axiomatizable (e.g. $L'' = L' + \varphi$, for any $\varphi \in L'' - L'$). ■

Theorem 12 provides us in fact with an algorithm to decide, given a tabular logic $L \in \text{NExt}\mathbf{K4}$ and an arbitrary formula φ , whether $\mathbf{K4} \oplus \varphi = L$. Indeed, notice first that we have

THEOREM 88. *Each finitely axiomatizable logic $L \in \text{NExt}\mathbf{K4}$ of finite depth is a finite union-splitting, i.e., can be represented in the form*

$$L = \mathbf{K4} \oplus \{\alpha^\sharp(\mathfrak{F}_i, \perp) : i \in I\}$$

with finite I .

Proof. Let $L = \mathbf{K4} \oplus \varphi$ be a logic of depth n and let m be the number of variables in φ . We show that L coincides with the logic

$$L' = \mathbf{K4} \oplus \{\alpha^\sharp(\mathfrak{G}, \perp) : |\mathfrak{G}| \leq \sum_{i=1}^{n+1} 2^m c_m(i), \mathfrak{G} \not\models \varphi\}$$

($c_m(i)$ was defined in Section 1.2). The inclusion $L \supseteq L'$ is obvious. Suppose $\varphi \notin L'$. Then there is a rooted refined m -generated frame \mathfrak{F} for L' refuting φ . Clearly, \mathfrak{F} is of depth $\leq n$, since otherwise $\alpha^\sharp(\mathfrak{G}, \perp)$ is an axiom of L' for every rooted generated subframe \mathfrak{G} of \mathfrak{F} of depth $n+1$ and so $\mathfrak{F} \models L'$, which is a contradiction. But then $\alpha^\sharp(\mathfrak{F}, \perp)$ is an axiom of L' , contrary to our assumption. ■

Thus, all tabular logics in $\text{NExt}\mathbf{K4}$ are finite union-splittings and so, by Theorem 12, we obtain the following

THEOREM 89. *Let L be a tabular logic in $\text{NExt}\mathbf{K4}$.*

- (i) (Blok 1980c) *L has finitely many immediate predecessors and they are also tabular.*
- (ii) *The axiomatizability problem for L above $\mathbf{K4}$ is decidable.*

For logics in $\text{NExt}\mathbf{K}$ this is not the case, witness Theorems 36 and 205.

The tabularity criterion of Theorem 85 is not effective. Moreover, as we shall see in Section 4.4, no effective tabularity criterion exists in general. However, if we restrict attention to sufficiently strong logics, e.g. to the class $\text{NExt}\mathbf{S4}$, the tabularity problem turns out to be decidable. The key idea, proposed by Kuznetsov [1971], is to consider the so called pretabular logics.

A logic $L \in (\text{N})\text{Ext}L_0$ is said to be *pretabular* in the lattice $(\text{N})\text{Ext}L_0$, if L is not tabular but every proper extension of L in $(\text{N})\text{Ext}L_0$ is tabular. In other words, a pretabular logic in $(\text{N})\text{Ext}L_0$ is a maximal non-tabular logic in $(\text{N})\text{Ext}L_0$.

THEOREM 90. *In the lattices $\text{Ext}\mathbf{K}$ and $\text{NExt}\mathbf{K}$ every non-tabular logic is contained in a pretabular one.*

Proof. By Theorem 85, a logic is non-tabular iff it does not contain the formula \mathbf{tab}_n , for any $n < \omega$. It follows that the union of an ascending chain of non-tabular logics is a non-tabular logic as well. The standard use of Zorn's Lemma completes the proof. ■

If there is a simple description of all pretabular logics in a lattice, we obtain an effective (modulo the description) tabularity criterion for the lattice. Indeed, take for definiteness the lattice $\text{NExt}\mathbf{K4}$. How to determine, given a formula φ , whether $\mathbf{K4} \oplus \varphi$ is tabular? We may launch two parallel processes: one of them generates all derivations in $\mathbf{K4} \oplus \varphi$ and stops after finding a derivation of \mathbf{tab}_n , for some $n < \omega$; another process checks if φ belongs to a pretabular logic in $\text{NExt}\mathbf{K4}$ and stops if this is the case. The termination of the first process means that $\mathbf{K4} \oplus \varphi$ is tabular, while that of the second one shows that it is not tabular.

Unfortunately, it is impossible to describe in an effective way all pretabular logics in $(\text{N})\text{Ext}\mathbf{K}$ and even $(\text{N})\text{Ext}\mathbf{K4}$: Blok [1980c] and Chagrov [1989] constructed a continuum of them. However, for smaller lattices like $\text{NExt}\mathbf{S4}$ or $\text{NExt}\mathbf{GL}$ such descriptions were found by Maksimova [1975b], Esakia and Meskhi [1977] and Blok [1980c]. The five pretabular logics in $\text{NExt}\mathbf{S4}$ were presented in Section 17 of *Basic Modal Logic*. In $\text{NExt}\mathbf{GL}$ the picture is much more complicated.

Figure 9.

THEOREM 91 (Blok 1980c, Chagrov 1989). *The set of pretabular logics in NExtGL is denumerable. It consists of the logics $\mathbf{GL.3} = \text{Log}\mathfrak{G}^\omega$ and $\text{Log}\mathfrak{G}_{m,n}^\omega$, for $m \geq 0$, $n \geq 1$, where \mathfrak{G}^ω and $\mathfrak{G}_{m,n}^\omega$ are the frames depicted in Fig. 9. If $\langle m, n \rangle \neq \langle k, l \rangle$ then $\text{Log}\mathfrak{G}_{m,n}^\omega \neq \text{Log}\mathfrak{G}_{k,l}^\omega$.*

Using this semantic description of pretabular logics in NExtGL , it is not hard to find finite sets of formulas axiomatizing them. Moreover, all of them turn out to be decidable. For we have

THEOREM 92. *Every non-tabular logic $L \in \text{NExtK4}$ has a non-tabular extension with FMP, and so every pretabular logic in NExtK4 has FMP.*

Proof. Since L is non-tabular and characterized by the class of its rooted finitely generated refined frames, we have either a sequence \mathfrak{F}_i , $i = 1, 2, \dots$, of rooted finite frames for L of depth i , or a sequence \mathfrak{F}_i of rooted finite frames for L of width $\geq i$. In both cases the logic $\text{Log}\{\mathfrak{F}_i : i < \omega\} \supseteq L$ is non-tabular and has FMP. ■

So we obtain the following result on the decidability of tabularity.

THEOREM 93. *The property of tabularity is decidable in NExtS4 , ExtS4 , NExtGL , ExtGL .*

Since a logic in ExtK4 is locally tabular iff it is determined by a frame of finite depth, the property of local tabularity is decidable in the lattices mentioned in Theorem 93 as well. However, this is not the case for ExtK4 itself.

1.14 Interpolation

One of the fundamental properties of logics is their capability to provide explicit definitions of implicitly definable terms, which is known as the Beth property (Beth [1953] proved it for classical logic). In the modal case we

say a logic L has the *Beth property* if, for any formula $\varphi(p_1, \dots, p_n, p_{n+1})$ and variables p and q different from p_1, \dots, p_n ,

$$\varphi(p_1, \dots, p_n, p) \wedge \varphi(p_1, \dots, p_n, q) \rightarrow (p \leftrightarrow q) \in L$$

only if there is a formula $\psi(p_1, \dots, p_n)$ such that

$$\varphi(p_1, \dots, p_n, p) \rightarrow (p \leftrightarrow \psi(p_1, \dots, p_n)) \in L.$$

The Beth property turns out to be closely related to the interpolation property which was introduced by Craig [1957] for classical logic. Namely, we say that a logic L has the *interpolation property* if, for every implication $\alpha \rightarrow \beta \in L$, there exists a formula γ , called an *interpolant* for $\alpha \rightarrow \beta$ in L , such that $\alpha \rightarrow \gamma \in L$, $\gamma \rightarrow \beta \in L$ and every variable in γ , if any, occurs in both α and β . While in abstract model theory interpolation is weaker than Beth definability, for modal logics we have

THEOREM 94 (Maksimova 1992). *A normal modal logic has interpolation iff it has the Beth property.*

Say also that a normal modal logic L has the *interpolation property for the consequence relation* \vdash_L^* , *\vdash^* -interpolation* for short, if every time when $\alpha \vdash_L^* \beta$, there is a formula γ such that $\alpha \vdash_L^* \gamma$, $\gamma \vdash_L^* \beta$ and $\mathbf{Var}\gamma \subseteq \mathbf{Var}\alpha \cap \mathbf{Var}\beta$. (Here $\mathbf{Var}\varphi$ is the set of all variables in φ .) It should be clear that interpolation implies \vdash^* -interpolation.

By the end of the 1970s interpolation had been established for a good many standard modal systems. The semantical proofs, sometimes rather sophisticated, resemble the Henkin construction of the canonical models. Here are two examples of such proofs (which are due to Maksimova [1982b] and Smoryński [1978]).

THEOREM 95 (Gabbay 1972). *The logics **K**, **K4**, **T**, **S4** have the interpolation property.*

Proof. We consider only **S4**; for the other logics the proofs are similar. Suppose $\alpha \rightarrow \gamma \notin \mathbf{S4}$ and $\gamma \rightarrow \beta \notin \mathbf{S4}$ for any γ whose variables occur in both α and β , and show that in this case $\alpha \rightarrow \beta \notin \mathbf{S4}$.

Let $t = (\Gamma, \Delta)$ be a pair of sets of formulas such that $\mathbf{Var}\varphi \subseteq \mathbf{Var}\alpha$ if $\varphi \in \Gamma$ and $\mathbf{Var}\varphi \subseteq \mathbf{Var}\beta$ if $\varphi \in \Delta$. Say that t is *inseparable* if there are no formulas $\varphi_i \in \Gamma$, $\psi_j \in \Delta$ and γ with $\mathbf{Var}\gamma \subseteq \mathbf{Var}\alpha \cap \mathbf{Var}\beta$ such that $\bigwedge_{i=1}^n \varphi_i \rightarrow \gamma \in \mathbf{S4}$, $\gamma \rightarrow \bigvee_{i=1}^m \psi_i \in \mathbf{S4}$. The pair t is called *complete* if for every φ and ψ with $\mathbf{Var}\varphi \subseteq \mathbf{Var}\alpha$ and $\mathbf{Var}\psi \subseteq \mathbf{Var}\beta$, one of the formulas φ and $\neg\varphi$ is in Γ and one of ψ and $\neg\psi$ is in Δ .

LEMMA 96. *Every inseparable pair $t_0 = (\Gamma_0, \Delta_0)$ can be extended to a complete inseparable pair.*

Proof. Let $\varphi_1, \varphi_2, \dots$ and ψ_1, ψ_2, \dots be enumerations of all formulas whose variables occur in α and β , respectively. Define pairs $t'_n = (\Gamma'_n, \Delta'_n)$ and $t_{n+1} = (\Gamma_{n+1}, \Delta_{n+1})$ inductively by taking

$$t'_n = \begin{cases} (\Gamma_n \cup \{\varphi_n\}, \Delta_n) & \text{if this pair is inseparable} \\ (\Gamma_n \cup \{\neg\varphi_n\}, \Delta_n) & \text{otherwise,} \end{cases}$$

$$t_{n+1} = \begin{cases} (\Gamma'_n, \Delta'_n \cup \{\psi_n\}) & \text{if this pair is inseparable} \\ (\Gamma'_n, \Delta'_n \cup \{\neg\psi_n\}) & \text{otherwise} \end{cases}$$

and put $t^* = (\Gamma^*, \Delta^*)$, where $\Gamma^* = \bigcup_{n < \omega} \Gamma_n$, $\Delta^* = \bigcup_{n < \omega} \Delta_n$. Clearly t^* is complete. Suppose it is separable, i.e., for some $\varphi_1, \dots, \varphi_n \in \Gamma^*$, $\psi_1, \dots, \psi_m \in \Delta^*$ and some γ containing only those variables that occur in both α and β , we have $\bigwedge_{i=1}^n \varphi_i \rightarrow \gamma \in \mathbf{S4}$ and $\gamma \rightarrow \bigvee_{i=1}^m \psi_i \in \mathbf{S4}$. Then there is $k < \omega$ such that $\varphi_1, \dots, \varphi_n \in \Gamma_k$ and $\psi_1, \dots, \psi_m \in \Delta_k$, which means that t_k is separable. So it remains to show that if $t = (\Gamma, \Delta)$ is inseparable, $\mathbf{Var}\varphi \subseteq \mathbf{Var}\alpha$ and $\mathbf{Var}\psi \subseteq \mathbf{Var}\beta$ then

- one of the pairs $(\Gamma \cup \{\varphi\}, \Delta)$ or $(\Gamma \cup \{\neg\varphi\}, \Delta)$ is inseparable and
- one of the pairs $(\Gamma, \Delta \cup \{\psi\})$ or $(\Gamma, \Delta \cup \{\neg\psi\})$ is inseparable.

We prove only the former claim. Suppose, on the contrary, that both pairs are separable, i.e., there are formulas γ_1, γ_2 in variables occurring in both α and β such that, for some $\varphi_1, \dots, \varphi_n \in \Gamma$, $\psi_1, \dots, \psi_m \in \Delta$, we have

$$\varphi_1 \wedge \dots \wedge \varphi_n \wedge \varphi \rightarrow \gamma_1 \in \mathbf{S4}, \quad \gamma_1 \rightarrow \psi_1 \vee \dots \vee \psi_m \in \mathbf{S4},$$

$$\varphi_1 \wedge \dots \wedge \varphi_n \wedge \neg\varphi \rightarrow \gamma_2 \in \mathbf{S4}, \quad \gamma_2 \rightarrow \psi_1 \vee \dots \vee \psi_m \in \mathbf{S4}.$$

Then we obtain $(\varphi_1 \wedge \dots \wedge \varphi_n \wedge \varphi) \vee (\varphi_1 \wedge \dots \wedge \varphi_n \wedge \neg\varphi) \rightarrow \gamma_1 \vee \gamma_2 \in \mathbf{S4}$, $\gamma_1 \vee \gamma_2 \rightarrow \psi_1 \vee \dots \vee \psi_m \in \mathbf{S4}$, from which

$$\varphi_1 \wedge \dots \wedge \varphi_n \rightarrow \gamma_1 \vee \gamma_2 \in \mathbf{S4}, \quad \gamma_1 \vee \gamma_2 \rightarrow \psi_1 \vee \dots \vee \psi_m \in \mathbf{S4},$$

contrary to t being inseparable. ■

Now we define a frame $\mathfrak{F} = \langle W, R \rangle$ by taking W to be the set of all complete and inseparable pairs and, for $t_1 = (\Gamma_1, \Delta_1)$, $t_2 = (\Gamma_2, \Delta_2)$ in W , $t_1 R t_2$ iff $\Box\varphi \in \Gamma_1$ implies $\varphi \in \Gamma_2$. Using the axioms $\Box p \rightarrow p$ and $\Box p \rightarrow \Box\Box p$ of $\mathbf{S4}$, one can readily check that R is a quasi-order on W , i.e., $\mathfrak{F} \models \mathbf{S4}$.

Define a valuation \mathfrak{V} in \mathfrak{F} by taking for every variable $p \in \mathbf{Var}(\alpha \rightarrow \beta)$, $\mathfrak{V}(p) = \{(\Gamma, \Delta) \in W : \text{either } p \in \Gamma \text{ or } p \in \mathbf{Var}\beta \text{ and } p \notin \Delta\}$. Put $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$. By induction on the construction of formulas φ and ψ with $\mathbf{Var}\varphi \subseteq \mathbf{Var}\alpha$, $\mathbf{Var}\psi \subseteq \mathbf{Var}\beta$ one can show that for every $t = (\Gamma, \Delta)$ in \mathfrak{F}

$$(\mathfrak{M}, t) \models \varphi \text{ iff } \varphi \in \Gamma, \quad (\mathfrak{M}, t) \not\models \psi \text{ iff } \psi \in \Delta.$$

Indeed, the basis of induction follows from the definition of \mathfrak{B} and the completeness and inseparability of t . The cases of the Boolean connectives present no difficulty. So suppose $\varphi = \Box\varphi_1$. If $t \models \Box\varphi_1$ then, for every $t' = (\Gamma', \Delta') \in t\uparrow$, we have $t' \models \varphi_1$ and so $\varphi_1 \in \Gamma'$. Suppose $\Box\varphi_1 \notin \Gamma$. Then $\neg\Box\varphi_1 \in \Gamma$. Consider the pair $t_0 = (\Gamma_0, \Delta_0)$, where

$$\Gamma_0 = \{\neg\varphi_1\} \cup \{\chi : \Box\chi \in \Gamma\}, \quad \Delta_0 = \{\neg\chi : \neg\Box\chi \in \Delta\},$$

and show that it is inseparable. Assume otherwise. Then there is γ with $\mathbf{Var}\gamma \subseteq \mathbf{Var}\alpha \cap \mathbf{Var}\beta$ such that, for some formulas $\Box\chi_1, \dots, \Box\chi_n \in \Gamma$, $\neg\Box\chi_{n+1}, \dots, \neg\Box\chi_m \in \Delta$,

$$\neg\varphi_1 \wedge \chi_1 \wedge \dots \wedge \chi_n \rightarrow \gamma \in \mathbf{S4}, \quad \gamma \rightarrow \neg\chi_{n+1} \vee \dots \vee \neg\chi_m \in \mathbf{S4}.$$

It follows that

$$\neg\Box\varphi_1 \wedge \Box\chi_1 \wedge \dots \wedge \Box\chi_n \rightarrow \Diamond\gamma \in \mathbf{S4},$$

$$\Diamond\gamma \rightarrow \neg\Box\chi_{n+1} \vee \dots \vee \neg\Box\chi_m \in \mathbf{S4},$$

contrary to t being inseparable. Let $t' = (\Gamma', \Delta')$ be a complete inseparable extension of t_0 . By the definition of t_0 , we have tRt' and so $\varphi_1 \in \Gamma'$, contrary to $\neg\varphi_1 \in \Gamma_0 \subseteq \Gamma'$ and t' being inseparable.

Suppose now that $\Box\varphi_1 \in \Gamma$. Then for every $t' = (\Gamma', \Delta')$ such that tRt' , we have $\varphi_1 \in \Gamma$ and so $t' \models \varphi_1$. Consequently, $t \models \Box\varphi_1$. The formula ψ is treated in the dual way.

To complete the proof it remains to observe that $\mathfrak{M} \not\models \alpha \rightarrow \beta$. \blacksquare

This proof does not always go through for different kinds of logics. However, sometimes suitable modifications are possible.

THEOREM 97. *\mathbf{GL} has the interpolation property.*

Proof. Suppose $\alpha \rightarrow \beta$ has no interpolant in \mathbf{GL} . Our goal is to construct a finite irreflexive transitive frame refuting $\alpha \rightarrow \beta$.

This time we consider finite pairs $t = (\Gamma, \Delta)$ such that all formulas in Γ and Δ are constructed from variables and their negations using $\wedge, \vee, \Box, \Diamond$. Without loss of generality we will assume α and β to be formulas of that sort. Say that t is *separable* if there is a formula γ with $\mathbf{Var}\gamma \subseteq \mathbf{Var}\alpha \cap \mathbf{Var}\beta$ such that $\bigwedge \Gamma \rightarrow \gamma \in \mathbf{GL}$ and $\gamma \rightarrow \bigvee \Delta \in \mathbf{GL}$. It should be clear that if $t = (\Gamma, \Delta)$ is a finite inseparable pair then in the same way as in the proof of Theorem 95 but taking only subformulas of α and β we can obtain a finite inseparable pair $t^* = (\Gamma^*, \Delta^*)$ satisfying the conditions: for every $\varphi \in \mathbf{Sub}\alpha$ and $\psi \in \mathbf{Sub}\beta$, one of the formulas φ and $\neg\varphi$ (an equivalent formula of the form under consideration, to be more precise) is in Γ^* and one of ψ and $\neg\psi$ is in Δ^* .

Now we construct by induction a finite rooted model for **GL** refuting $\alpha \rightarrow \beta$. As its root we take $(\{\alpha\}^*, \{\beta\}^*)$. If we have already put in our model a pair $t = (\Gamma, \Delta)$ and it has not been considered yet, then for every $\diamond\varphi \in \Gamma$ and every $\Box\psi \in \Delta$, we add to the model the pairs

$$t_1 = (\{\chi, \Box\chi, \Box\neg\varphi, \varphi : \Box\chi \in \Gamma\}^*, \{\chi, \diamond\chi : \diamond\chi \in \Delta\}^*),$$

$$t_2 = \{\chi, \Box\chi : \Box\chi \in \Gamma\}^*, \{\chi, \diamond\chi, \diamond\neg\psi, \psi : \diamond\chi \in \Delta\}^*.$$

One can readily show that if t is inseparable then t_1 and t_2 are also inseparable. Put $tR't_1$ and $tR't_2$. The process of adding new pairs must eventually terminate, since each step reduces the number of formulas of the form $\diamond\varphi$ and $\Box\psi$ in the left and right parts of pairs. Let W be the set of all pairs constructed in this way and R the transitive closure of R' . Clearly, the resulting frame $\mathfrak{F} = \langle W, R \rangle$ validates **GL**. Define a valuation \mathfrak{V} in \mathfrak{F} by taking, for each variable p ,

$$\mathfrak{V}(p) = \{(\Gamma, \Delta) \in W : p \in \Gamma\}.$$

As in the proof of Theorem 95, it is easily shown that $\alpha \rightarrow \beta$ is refuted in \mathfrak{F} under \mathfrak{V} . ■

To clarify the algebraic meaning of interpolation we require the following well known proposition.

PROPOSITION 98. *If ∇ is a normal filter¹² in a modal algebra \mathfrak{A} then the relation \sim_∇ , defined by $a \sim_\nabla b$ iff $a \leftrightarrow b \in \nabla$, is a congruence relation. The map $\nabla \mapsto \sim_\nabla$ is an isomorphism from the lattice of normal filters in \mathfrak{A} onto the lattice of congruences in \mathfrak{A} .*

Denote by \mathfrak{A}/∇ the quotient algebra \mathfrak{A}/\sim_∇ and let $\|a\|_\nabla = \{b : a \sim_\nabla b\}$.

Say that a class \mathcal{C} of algebras is *amalgamable* if for all algebras $\mathfrak{A}_0, \mathfrak{A}_1, \mathfrak{A}_2$ in \mathcal{C} such that \mathfrak{A}_0 is embedded in \mathfrak{A}_1 and \mathfrak{A}_2 by isomorphisms f_1 and f_2 , respectively, there exist $\mathfrak{A} \in \mathcal{C}$ and isomorphisms g_1 and g_2 of \mathfrak{A}_1 and \mathfrak{A}_2 into \mathfrak{A} with $g_1(f_1(x)) = g_2(f_2(x))$, for any x in \mathfrak{A}_0 . If in addition we have

$$g_i(x) \leq g_j(y) \text{ implies } \exists z \in A_0 (x \leq_i f_i(z) \text{ and } f_j(z) \leq_j y)$$

for all $x \in A_i, y \in A_j$ such that $\{i, j\} = \{1, 2\}$, then \mathcal{C} is called *superamalgamable*. Here A_i is the universe of \mathfrak{A}_i and \leq_i its lattice order.

THEOREM 99 (Maksimova 1979). *L has the interpolation property iff the variety $\text{Alg}L$ of modal algebras for L is superamalgamable. L has the \vdash^* -interpolation property iff $\text{Alg}L$ is amalgamable.*

¹²A filter ∇ is *normal* (or open, as in Section 10 of *Basic Modal Logic*) if $\Box a \in \nabla$ whenever $a \in \nabla$.

Proof. We prove only the former claim. (\Rightarrow) Suppose L has the interpolation property and $\mathfrak{A}_0, \mathfrak{A}_1, \mathfrak{A}_2$ are modal algebras for L such that \mathfrak{A}_0 is a subalgebra of both \mathfrak{A}_1 and \mathfrak{A}_2 . With each element $a \in A_i$, $i = 0, 1, 2$, we associate a variable p_a^i in such a way that, for $a \in A_0$, $p_a^0 = p_a^1 = p_a^2$. Denote by \mathcal{L}_i the language with the variables p_a^i , for $a \in A_i$, $i = 0, 1, 2$, and let $\mathcal{L} = \mathcal{L}_1 \cup \mathcal{L}_2$. We will assume that \mathcal{L} is the language of L .

Fix the valuation \mathfrak{V}_i of \mathcal{L}_i in \mathfrak{A}_i , defined by $\mathfrak{V}_i(p_a^i) = a$, and put

$$\Sigma_i = \{\varphi \in \mathbf{For}\mathcal{L}_i : \mathfrak{V}_i(\varphi) = \top\}.$$

Let Σ be the closure of $\Sigma_1 \cup \Sigma_2 \cup L$ under modus ponens. We show that, for every $\varphi \in \mathbf{For}\mathcal{L}_i$, $\psi \in \mathbf{For}\mathcal{L}_j$ such that $\{i, j\} = \{1, 2\}$,

$$(13) \quad \varphi \rightarrow \psi \in \Sigma \text{ iff } \exists \chi \in \mathbf{For}\mathcal{L}_0 \ (\varphi \rightarrow \chi \in \Sigma_i \text{ and } \chi \rightarrow \psi \in \Sigma_j).$$

Suppose $\varphi \rightarrow \psi \in \Sigma$. Then there exist finite sets $\Gamma_i \subseteq \Sigma_i$ and $\Gamma_j \subseteq \Sigma_j$ such that

$$\bigwedge \Gamma_i \wedge \varphi \rightarrow (\bigwedge \Gamma_j \rightarrow \psi) \in L.$$

Since L has interpolation, there is a formula $\chi \in \mathbf{For}\mathcal{L}_0$ such that

$$\bigwedge \Gamma_i \wedge \varphi \rightarrow \chi \in L, \quad \bigwedge \Gamma_j \rightarrow (\chi \rightarrow \psi) \in L,$$

from which $\varphi \rightarrow \chi \in \Sigma_i$ and $\chi \rightarrow \psi \in \Sigma_j$. The converse implication is obvious.

Now construct an algebra \mathfrak{A} by taking the set $\{\|\varphi\| : \varphi \in \Sigma\}$ as its universe, where $\|\varphi\| = \{\psi : \varphi \leftrightarrow \psi \in \Sigma\}$, $\|\varphi\| \wedge \|\psi\| = \|\varphi \wedge \psi\|$ and $\odot\|\varphi\| = \|\odot\varphi\|$, for $\odot \in \{\neg, \Box\}$. One can readily prove that $\mathfrak{A} \in \text{Alg}L$. Define maps g_i from \mathfrak{A}_i into \mathfrak{A} by taking $g_i(a) = \|p_a^i\|$. It is not difficult to show that g_i is an embedding of \mathfrak{A}_i in \mathfrak{A} . And for $a \in A_0$, we have

$$g_1(a) = \|p_a^0\| = g_2(a).$$

It remains to check the condition for superamalgamability: Suppose $a \in A_i$, $b \in A_j$, $\{i, j\} = \{1, 2\}$, and $g_i(a) \leq g_j(b)$. Then $g_i(a) \rightarrow g_j(b) = \top$ and so $\|p_a^i \rightarrow p_b^j\| = \top$, i.e., $p_a^i \rightarrow p_b^j \in \Sigma$. By (13), we have $\chi \in \mathbf{For}\mathcal{L}_0$ with $\mathfrak{V}(\chi) = c$ such that $a \leq_i c \leq_j b$.

(\Leftarrow) Assuming $\text{Alg}L$ to be superamalgamable, we show that L has the interpolation property. To this end we require

LEMMA 100. *Suppose \mathfrak{A}_0 is a subalgebra of modal algebras \mathfrak{A}_1 and \mathfrak{A}_2 , $a \in A_1$, $b \in A_2$ and there is no $c \in A_0$ such that $a \leq_1 c \leq_2 b$. Then there are ultrafilters ∇_1 in \mathfrak{A}_1 and ∇_2 in \mathfrak{A}_2 such that $a \in \nabla_1$, $b \notin \nabla_2$ and $\nabla_1 \cap A_0 = \nabla_2 \cap A_0$.*

Suppose $\varphi(p_1, \dots, p_m, q_1, \dots, q_n)$ and $\psi(q_1, \dots, q_n, r_1, \dots, r_l)$ are formulas for which there is no $\chi(q_1, \dots, q_n)$ such that $\varphi \rightarrow \chi \in L$ and $\chi \rightarrow \psi \in L$. We show that in this case there exists an algebra $\mathfrak{A} \in \text{Var}L$ refuting $\varphi \rightarrow \psi$.

Let \mathfrak{A}'_0 , \mathfrak{A}'_1 and \mathfrak{A}'_2 be the free algebras in $\text{Alg}L$ generated by the sets $\{c_1, \dots, c_n\}$, $\{a_1, \dots, a_m, c_1, \dots, c_n\}$ and $\{c_1, \dots, c_n, b_1, \dots, b_l\}$, respectively. According to this definition, \mathfrak{A}'_0 is a subalgebra of both \mathfrak{A}'_1 and \mathfrak{A}'_2 . By Lemma 100, there are ultrafilters ∇_1 in \mathfrak{A}'_1 and ∇_2 in \mathfrak{A}'_2 such that we have $\varphi(a_1, \dots, a_m, c_1, \dots, c_n) \in \nabla_1$ and $\psi(c_1, \dots, c_n, b_1, \dots, b_l) \notin \nabla_2$. Define normal filters

$$\nabla_i^* = \{a \in A'_i : \forall m < \omega \ \square^m a \in \nabla_i\}$$

and put $\mathfrak{A}_1 = \mathfrak{A}'_1/\nabla_1^*$, $\mathfrak{A}_2 = \mathfrak{A}'_2/\nabla_2^*$. Construct an algebra \mathfrak{A}_0 by taking $A_0 = \{\|a\|_{\nabla_1^*} : a \in A'_0\}$. By the definition, \mathfrak{A}_0 is a subalgebra of \mathfrak{A}_1 , i.e., is embedded in \mathfrak{A}_1 by the map $f_1(x) = x$. One can show that \mathfrak{A}_0 is embedded in \mathfrak{A}_2 by the map $f_2(\|x\|_{\nabla_1^*}) = \|x\|_{\nabla_2^*}$. Then there are an algebra \mathfrak{A} for L and isomorphisms g_1 and g_2 of \mathfrak{A}_1 and \mathfrak{A}_2 into \mathfrak{A} satisfying the conditions of superamalgamability. Define a valuation \mathfrak{V} in \mathfrak{A} by taking $\mathfrak{V}(p_i) = g_1(\|a_i\|_{\nabla_1})$, $\mathfrak{V}(q_j) = g_1(\|c_j\|_{\nabla_1}) = g_2(\|c_j\|_{\nabla_2})$ and $\mathfrak{V}(r_k) = g_2(\|b_k\|_{\nabla_2})$. Then $\mathfrak{V}(\varphi) \not\leq \mathfrak{V}(\psi)$ because otherwise there would exist $\{i, j\} = \{1, 2\}$ and $z \in A_0$ such that $\mathfrak{V}(\varphi) \leq_i f_i(z)$ and $f_j(z) \leq_j \mathfrak{V}(\psi)$. Thus, $\mathfrak{A} \not\models \varphi \rightarrow \psi$ and so $\varphi \rightarrow \psi \notin L$. ■

Using this theorem Maksimova [1979] discovered a surprising fact: there are only finitely many logics in $\text{NExt}\mathbf{S4}$ with the interpolation property (not more than 38, to be more exact) and all of them turned out to be union-splittings. By Theorem 12, we obtain then

THEOREM 101 (Maksimova 1979). *There is an algorithm which, given a modal formula φ , decides whether $\mathbf{S4} \oplus \varphi$ has interpolation.*

We illustrate this result by considering a much simpler class of logics.

THEOREM 102. *Only four logics in $\text{NExt}\mathbf{S5}$ have the interpolation property: $\mathbf{S5}$ itself, the logic of the two-point cluster, \mathbf{Triv} and \mathbf{For} .*

Proof. We have already demonstrated how to prove that a logic has interpolation. So now we show only that no logic L in $\text{NExt}\mathbf{S5}$ different from those mentioned in the formulation has the interpolation property. Suppose on the contrary that L has interpolation. We use the amalgamability of the variety of modal algebras for L to show that an arbitrary big finite cluster is a frame for L , from which it will follow that $L = \mathbf{S5}$.

Figure 10 demonstrates two ways of reducing the three-point cluster to the two-point one. By the amalgamation property, there must exist a cluster reducible to the two depicted copies of the two-point cluster, with the reductions satisfying the amalgamation condition. It should be clear from Fig. 10 that such a cluster contains at least four points. By the same scheme one can prove now that every n -point cluster validates L . ■

It would be naive to expect that such a simple picture can be extended to classes like $\text{NExt}\mathbf{K4}$ or $\text{NExt}\mathbf{K}$. Even in $\text{NExt}\mathbf{GL}$ the situation is quite

Figure 10.

different from that in NExtS4 : Maksimova [1989] discovered that there is a continuum of logics in NExtGL having the interpolation property. This result is based upon the following observation. For $L \in \text{NExtK4}$, we call a formula $\alpha(p)$ *conservative* in $\text{NExt}L$ if

$$\Box^+(\alpha(\perp) \wedge \alpha(p) \wedge \alpha(q)) \rightarrow \alpha(p \rightarrow q) \wedge \alpha(\Box p) \in L.$$

For example, in NExtS4 conservative are $\Box\Diamond p \rightarrow \Diamond\Box p$, $\Box\Diamond p \leftrightarrow \Diamond\Box p$, and $\Box p \leftrightarrow \Diamond p$.

THEOREM 103 (Maksimova 1987). *If $L \in \text{NExtK4}$ has the interpolation property and formulas α_i , for $i \in I$, are conservative in $\text{NExt}L$, then the logic $L \oplus \{\alpha_i : i \in I\}$ also has the interpolation property.*

Proof. Suppose $\varphi \rightarrow \psi \in L \oplus \{\alpha_i : i \in I\}$. Then there is a finite $J \subseteq I$, say $J = \{1, \dots, l\}$, such that $\varphi \rightarrow \psi \in L \oplus \{\alpha_i : i \in J\}$ and so, as follows from the definition of conservative formulas and the Deduction Theorem for $\mathbf{K4}$,

$$\Box^+ \bigwedge_{j=1}^l (\alpha_j(\perp) \wedge \alpha_j(p_1) \wedge \dots \wedge \alpha_j(p_n)) \rightarrow (\varphi \rightarrow \psi) \in L,$$

where $p_1, \dots, p_m, p_{m+1}, \dots, p_k$ and $p_{m+1}, \dots, p_k, p_{k+1}, \dots, p_n$ are all the variables in φ and ψ , respectively. Consequently

$$\begin{aligned} & \Box^+ \bigwedge_{j=1}^l (\alpha_j(\perp) \wedge \alpha_j(p_1) \wedge \dots \wedge \alpha_j(p_k)) \wedge \varphi \rightarrow \\ & (\Box^+ \bigwedge_{j=1}^l (\alpha_j(p_{m+1}) \wedge \dots \wedge \alpha_j(p_n)) \rightarrow \psi) \in L. \end{aligned}$$

Since L has the interpolation property, there is $\chi(p_{m+1}, \dots, p_k)$ such that

$$\begin{aligned} \Box^+ \bigwedge_{j=1}^l (\alpha_j(\perp) \wedge \alpha_j(p_1) \wedge \dots \wedge \alpha_j(p_k)) \wedge \varphi &\rightarrow \chi \in L, \\ \Box^+ \bigwedge_{j=1}^l (\alpha_j(p_{m+1}) \wedge \dots \wedge \alpha_j(p_n)) &\rightarrow (\chi \rightarrow \psi) \in L. \end{aligned}$$

Then we obtain $\varphi \rightarrow \chi \in L \oplus \{\alpha_i : i \in I\}$ and $\chi \rightarrow \psi \in L \oplus \{\alpha_i : i \in I\}$, i.e., χ is an interpolant for $\varphi \rightarrow \psi$ in $L \oplus \{\alpha_i : i \in I\}$. ■

Using the formulas

$$\alpha_i = \Box^+(\Diamond^{i+1}\top \wedge \Box^{i+2}\perp \rightarrow \Box^{i+1}p \vee \Box^{i+1}\neg p)$$

which are conservative in $\text{NExt}\mathbf{GL}$, one can readily construct a continuum of logics in this class with the interpolation property. The set of logics in $\text{NExt}\mathbf{GL}$ without interpolation is also continual.

In general, an interpolant γ for an implication $\alpha \rightarrow \beta \in L$ depends on both α and β . Say that a logic L has *uniform interpolation* if, for any finite set of variables Ξ and any formula α , there exists a formula γ such that $\mathbf{Var}\gamma \subseteq \Xi$ and $\alpha \rightarrow \gamma \in L$, $\gamma \rightarrow \beta \in L$ whenever $\mathbf{Var}\alpha \cap \mathbf{Var}\beta \subseteq \Xi$ and $\alpha \rightarrow \beta \in L$. In this case γ is called a *post-interpolant* for α and Ξ . Roughly speaking, a logic has uniform interpolation if we can choose an interpolant for $\alpha \rightarrow \beta \in L$ independently from the actual shape of β . Uniform interpolation was first investigated by Pitts [1992] who proved that intuitionistic logic enjoys it. It is fairly easy to find multiple examples of modal logics with uniform interpolation by observing that any locally tabular logic with interpolation has uniform interpolation as well. Indeed, for every formula α and every set of variables Ξ , we can define a post-interpolant γ as the conjunction of a maximal set of pairwise non-equivalent in L formulas γ' such that $\mathbf{Var}\gamma' \subseteq \Xi$ and $\alpha \rightarrow \gamma' \in L$ (which is finite in view of the local tabularity of L). It follows, for instance, that $\mathbf{S5}$ has uniform interpolation. In general, however, interpolation does not imply uniform interpolation: [Ghilardi and Zawadowski 1995] showed that $\mathbf{S4}$ does not enjoy the latter, witness the following formula without a post-interpolant for $\{r\}$ in $\mathbf{S4}$

$$p \wedge \Box(p \rightarrow \Diamond q) \wedge \Box(q \rightarrow \Diamond p) \wedge \Box(p \rightarrow r) \wedge \Box(q \rightarrow \neg r).$$

Only a few positive results on the uniform interpolation of modal logics are known: Shavrukov [1993] proved it for \mathbf{GL} , Ghilardi [1995] for \mathbf{K} , and Visser [1996] for \mathbf{Grz} .

A property closely related to interpolation is so called Halldén completeness. A logic L is said to be *Halldén complete* if $\varphi \vee \psi \in L$ and

$\mathbf{Var}\varphi \cap \mathbf{Var}\psi = \emptyset$ imply $\varphi \in L$ or $\psi \in L$. Since every variable free formula is equivalent in \mathbf{D} either to \top or to \perp , $L \in \text{Ext}\mathbf{D}$ is Halldén complete whenever it has interpolation. \mathbf{K} , $\mathbf{K4}$, \mathbf{GL} are examples of Halldén incomplete logics with interpolation: each of them contains $\diamond\top \vee \neg\diamond\top$ but not $\diamond\top$ and $\neg\diamond\top$. On the other hand, $\mathbf{S4.3}$ is a Halldén complete logic (see [van Benthem and Humberstone 1983]) without interpolation (see [Maksimova 1982a]). Actually, there is a continuum of Halldén complete logics in $\text{NExt}\mathbf{S4}$ (see [Chagrova and Zakharyashev 1993]).

Halldén completeness has an interesting lattice-theoretic characterization.

THEOREM 104 (Lemmon 1966c). *A logic $L \in \text{Ext}\mathbf{K}$ is Halldén complete iff it is \cap -irreducible in $\text{Ext}L$.*

Since the lattice $\text{Ext}\mathbf{S5}$ is linearly ordered by inclusion, all logics above $\mathbf{S5}$ are Halldén complete. There are various semantic criteria for Halldén completeness (see e.g. [Maksimova 1995]). Here we note only the following generalization of the result of [van Benthem and Humberstone 1983].

THEOREM 105. *Suppose a logic $L \in \text{Ext}\mathbf{K}$ is characterized by a class \mathcal{C} of descriptive rooted frames with distinguished roots. Then L is Halldén complete iff, for all frames $\langle \mathfrak{F}_1, d_1 \rangle$ and $\langle \mathfrak{F}_2, d_2 \rangle$ in \mathcal{C} , there is a frame $\langle \mathfrak{F}, d \rangle$ for L reducible¹³ to both $\langle \mathfrak{F}_1, d_1 \rangle$ and $\langle \mathfrak{F}_2, d_2 \rangle$.*

For more results and references on Halldén completeness consult [Chagrova and Zakharyashev 1991].

2 POLYMODAL LOGICS

So far we have confined ourselves to considering modal logics with only one necessity operator. From a theoretical point of view this restriction is not such a great loss as it may seem at first sight. In fact, really important concepts of modal logic do not depend on the number of boxes and can be introduced and investigated on the basis of just one. We shall give a precise meaning to this claim in Section 2.3 below where it is shown that polymodal logic is reduced in a natural way to unimodal logic. However, there are at least two reasons for a detailed discussion of polymodal logic in this chapter.

First, a number of interesting phenomena are easily missed in unimodal logic and actually appear in a representative form only in the polymodal case. For example, with the exception of $\text{NExt}\mathbf{K4.3}$ and $QCSF$ all known general decidability results in unimodal logic have been obtained by proving the finite model property. In fact, nearly all natural classes of logics in $\text{NExt}\mathbf{K}$ turned out to be describable by their finite frames. The situation

¹³By reductions that map d to d_i .

drastically changes with the addition of just one more box. Even in the case of linear tense logics or bimodal provability logics one has to start with a thorough investigation of their infinite frames: FMP becomes a rather rare guest. While the result on NExt**K4.3** indicated the need for general methods of establishing decidability without FMP, this need becomes of vital importance only in the context of polymodal logic.

The second reason is that various applications of modal logic require polymodal languages. For example, in tense logic we have two necessity-like operators \Box_1 and \Box_2 . One of them, say the former, is interpreted as “it will always be true” and the other as “it was always true”. Kripke frames for tense logics are structures $\langle W, R_1, R_2 \rangle$ with two binary relations R_1 and R_2 such that R_2 coincides with the converse R_1^{-1} of R_1 (which reflects the fact that a moment x is earlier than y iff y is later than x). The characteristic axioms connecting the two tense operators are

$$p \rightarrow \Box_1 \Diamond_2 p \text{ and } p \rightarrow \Box_2 \Diamond_1 p.$$

For more information about tense systems consult *Basic Tense Logic*.

Another example is basic temporal logic in which we have two necessity-like operators: one of them—usually called Next—is interpreted by the successor relation in ω and the other by its transitive and reflexive closure. Details can be found in [Seegerberg 1989]. Propositional dynamic logic **PDL** and its extensions, like deterministic **PDL**, can also be regarded as polymodal logics (see *Dynamic Logic*).

A number of provability logics use two or more modal operators; see e.g. Boolos [1993]. In **GLB**, for instance, we have one operator \Box_1 understood as provability in PA and another operator \Box_2 interpreted as ω -provability in PA. The unimodal fragments of **GLB** coincide with **GL**. The axioms connecting \Box_1 and \Box_2 are

$$\Box_1 p \rightarrow \Box_2 p \text{ and } \Diamond_1 p \rightarrow \Box_2 \Diamond_1 p.$$

In epistemic logics we need an operator \Box_i for each agent i ; $\Box_i \varphi$ is interpreted as “agent i believes (or knows) φ ”. One possible way to axiomatize the logic of knowledge with m agents is to take the axioms of **S5** for each agent without any principles connecting different \Box_i and \Box_j . We denote the resultant logic by $\bigotimes_{i=1}^m \mathbf{S5}$. Often $\bigotimes_{i=1}^m \mathbf{S5}$ is extended by the common knowledge operator **C** with the intended meaning

$$C\varphi = E\varphi \wedge E^2\varphi \wedge \dots \wedge E^n\varphi \wedge \dots, \text{ where } E\varphi = \bigwedge_{i=1}^m \Box_i \varphi$$

(see e.g. [Halpern and Moses 1992] and [Meyer and van der Hoek 1995]).

The reader will find more items for this list in other chapters of the *Handbook*.

From the semantical point of view, many standard polymodal logics can be obtained by applying Boolean or various natural closure operators to the accessibility relations of Kripke frames. For instance, in frames $\langle W, R_1, \dots, R_n \rangle$ for epistemic logic the common knowledge operator is interpreted by the transitive closure of $R_1 \cup \dots \cup R_n$. Tense frames result from usual $\langle W, R \rangle$ by adding the converse of R . Humberstone [1983] and Goranko [1990a] study the bimodal logic of *inaccessible worlds* determined by frames of the form $\langle W, R, W^2 - R \rangle$. This list of examples can be continued; for a general approach and related topics consult [Goranko 1990b; Gargov *et al.* 1987; Gargov and Passy 1990].

Let us see now how polymodal logics in general fit into the theory developed so far. We begin by demonstrating how the concepts introduced in the unimodal case transfer to polymodal logic and showing that a few general results—like Sahlqvist’s and Blok’s Theorems—have natural analogues in polymodal logic. We hope to convince the reader that up to this point no new difficulties arise when one switches from the unimodal language to the polymodal one. After that, in Section 2.2, we start considering subtler features of polymodal logics.

2.1 From unimodal to polymodal

Let \mathcal{L}_I be the propositional language with a finite number of necessity operators \Box_i , $i \in I$. A *normal polymodal logic* in \mathcal{L}_I is a set of \mathcal{L}_I -formulas containing all classical tautologies, the axioms $\Box_i(p \rightarrow q) \rightarrow (\Box_i p \rightarrow \Box_i q)$ for all $i \in I$, and closed under substitution, modus ponens and the rule of necessitation $\varphi / \Box_i \varphi$ for every $i \in I$. If the language is clear from the context, we call these logics just (*normal*) *modal logics* and denote by $\text{NExt}L$ the family of all normal extensions of L (in the language \mathcal{L}_I). The smallest normal modal logic with n necessity operators is denoted by \mathbf{K}_n ($\mathbf{K} = \mathbf{K}_1$, of course).

Given a logic L_0 in \mathcal{L}_I and a set of \mathcal{L}_I -formulas Γ , we again denote by $L_0 \oplus \Gamma$ the smallest normal logic (in \mathcal{L}_I) containing $L_0 \cup \Gamma$. A number of other notions and results also transfer in a rather straightforward way, e.g. Theorems 4 and 6, Proposition 5 and all concepts involved in their formulations. More care has to be taken to generalize Theorems 1, 2 and 3. Denote by \mathbf{M}_I^* the set of non-empty strings (words) over $\{\Box_i : i \in I\}$ which do not contain any \Box_i twice and put

$$\Box_I \varphi = \bigwedge \{ \mathbf{M} \varphi : \mathbf{M} \in \mathbf{M}_I^* \}, \quad \Box_I^{\leq m} \varphi = \bigwedge \{ \Box_I^n \varphi : n \leq m \}.$$

In the language \mathcal{L}_I the operator \Box_I serves as a sort of surrogate for \Box in \mathbf{K} . For example, the following polymodal version of Theorem 1 holds.

THEOREM 106 (Deduction). *For every modal logic L in \mathcal{L}_I , every set of*

\mathcal{L}_I -formulas Γ , and all \mathcal{L}_I -formulas φ and ψ ,

$$\Gamma, \psi \vdash_L^* \varphi \text{ iff } \exists m \geq 0 \Gamma \vdash_L^* \Box_I^{\leq m} \psi \rightarrow \varphi.$$

Theorems 2 and 3 can be reformulated analogously by replacing \Box with \Box_I (a logic L in \mathcal{L}_I is *n-transitive* if it contains $\Box_I^{\leq n} p \rightarrow \Box_I^{n+1} p$).

Basic semantic concepts are lifted to the polymodal case in a straightforward manner. The algebraic counterpart of $L \in \text{NExt}\mathbf{K}_n$ is the variety of Boolean algebras with n unary operators validating L . A structure $\mathfrak{F} = \langle W, \langle R_i : i \in I \rangle, P \rangle$ is called a (*general polymodal*) *frame* whenever every $\langle W, R_i, P \rangle$, for $i \in I$, is a unimodal frame. We then put

$$\Box_i X = \{x \in W : \forall y (xR_i y \rightarrow y \in X)\}.$$

Differentiated, refined and descriptive frames and the truth-preserving operations can also be defined in the same component-wise way. For instance, a frame $\mathfrak{F} = \langle W, \langle R_i : i \in I \rangle, P \rangle$ is differentiated if all the unimodal frames $\langle W, R_i, P \rangle$, for $i \in I$, are differentiated. $\mathfrak{F} = \langle W, \langle R_i : i \in I \rangle, P \rangle$ is a (*generated*) *subframe* of $\mathfrak{G} = \langle V, \langle S_i : i \in I \rangle, Q \rangle$ if all $\langle W, R_i, P \rangle$ are (generated) subframes of $\langle V, S_i, Q \rangle$, and f is a *reduction* of \mathfrak{F} to \mathfrak{G} if f is a reduction of $\langle W, R_i, P \rangle$ to $\langle V, S_i, Q \rangle$, for every $i \in I$.

There are some exceptions to this rule. A point r is called a root of \mathfrak{F} if it is a root of the unimodal frame $\langle W, \bigcup_{i \in I} R_i \rangle$. This does not mean that r is a root of all unimodal reducts of \mathfrak{F} . Another important exception: as before, a polymodal frame is *\varkappa -generated* if the algebra \mathfrak{F}^+ is \varkappa -generated; however, this does not mean that the unimodal reducts of \mathfrak{F} are \varkappa -generated.

Splittings and the degree of Kripke incompleteness The semantic criterion of splittings by finite frames given in Theorem 15 transfers to polymodal logics by replacing \Box with \Box_I . Again, all finite rooted frames split $\text{NExt}L_0$, if L_0 is an n -transitive logic in \mathcal{L}_I . Notice, however, that n -transitivity is a rather strong condition in the polymodal case. For example, it is easily checked that the fusion $\mathbf{S5} \otimes \mathbf{S5}$ as well as the minimal tense logic $\mathbf{K4.t}$ containing $\mathbf{K4}$ are not n -transitive, for any $n < \omega$ (see Sections 2.2 and 2.4 for precise definitions). In fact, only \circ splits the lattice $\text{NExt}(\mathbf{S5} \otimes \mathbf{S5})$ and only \bullet splits $\text{NExt}\mathbf{K4.t}$ (see [Wolter 1993] and [Kracht 1992], respectively).

Call a frame $\langle W, \langle R_i : i \in I \rangle \rangle$ *cycle free* if the unimodal frame $\langle W, \bigcup_{i \in I} R_i \rangle$ is cycle free. Kracht [1990] showed that precisely the finite cycle free frames split $\text{NExt}\mathbf{K}_n$.

It is not difficult now to extend Blok's result on the degree of Kripke incompleteness to the polymodal case. Note, however, that the degree of incompleteness of \mathbf{For} in $\text{NExt}\mathbf{K}_n$ is 2^{\aleph_0} whenever $n \geq 2$. So, we do not have a polymodal analog of Makinson's Theorem. (An example of an incomplete

maximal consistent logic in $\text{NExt}\mathbf{K}_2$ is the logic determined by the tense frame $\mathfrak{C}(0, \circ)$ introduced in Section 2.5).

THEOREM 107. *Let $n > 1$. If L is a union-splitting of $\text{NExt}\mathbf{K}_n$, then L is strictly Kripke complete. Otherwise L has degree of Kripke incompleteness 2^{\aleph_0} in $\text{NExt}\mathbf{K}_n$.*

Sahlqvist's Theorem and persistence The proof of the following polymodal version of Sahlqvist's Theorem is a straightforward extension of the proof in the unimodal case. Say that φ is a *Sahlqvist formula* (in \mathcal{L}_I) if the result of replacing all \Box_i and \Diamond_i , $i \in I$, in φ with \Box and \Diamond , respectively, is a unimodal Sahlqvist formula.

THEOREM 108. *Suppose that φ is equivalent in $\text{NExt}\mathbf{K}_n$ to a Sahlqvist formula. Then $\mathbf{K}_n \oplus \varphi$ is \mathcal{DF} -persistent, and one can effectively construct a first order formula $\phi(x)$ in R_1, \dots, R_n and $=$ such that, for every descriptive or Kripke frame \mathfrak{F} and every point a in \mathfrak{F} , $(\mathfrak{F}, a) \models \varphi$ iff $\mathfrak{F} \models \phi(x)[a]$.*

Bellissima's result on the \mathcal{DF} -persistence of all logics in $\text{NExt}\mathbf{Alt}_n$ has a polymodal analog as well. Denote by $\bigotimes_{i \in I} \mathbf{Alt}_n$ the smallest polymodal logic in \mathcal{L}_I containing \mathbf{Alt}_n in all its unimodal fragments. It is easy to see that every $L \in \text{NExt} \bigotimes_{i \in I} \mathbf{Alt}_n$ is \mathcal{DF} -persistent and so Kripke complete. However, in contrast to the lattice $\text{NExt}\mathbf{Alt}_1$ —which is countable and all logics in which have FMP (see [Seegerberg 1986] and [Bellissima 1988])—the lattice $\text{NExt}(\mathbf{Alt}_1 \otimes \mathbf{Alt}_1)$ is rather complex: as was shown by Grefe [1994], it contains logics without FMP (even without finite frames at all) and uncountably many maximal consistent logics.

Some FMP results Fine's Theorem on uniform logics can be extended to a suitable class of polymodal logics in \mathcal{L}_I , namely those logics that contain $\Diamond_i \top$, for all $i \in I$, and are axiomatizable by formulas φ in which all maximal sequences of nested modal operators coincide with respect to the distribution of the indices i of \Box_i and \Diamond_i , $i \in I$.

Now consider a result of Lewis [1974] which we have not proved in its unimodal formulation. Call a normal polymodal logic *non-iterative* if it is axiomatizable by formulas without nested modalities. Examples of non-iterative logics are $\mathbf{T} = \mathbf{K} \oplus \Box p \rightarrow p$, $\mathbf{Alt}_m \otimes \mathbf{Alt}_n$ and $\mathbf{K}_2 \oplus \Box_2 p \rightarrow \Box_1 p$.

THEOREM 109 (Lewis 1974). *All non-iterative normal logics have FMP.*

Proof. Suppose the axioms of $L = \mathbf{K}_n \oplus \Gamma$ have no nested modal operators and $\varphi \notin L$. By a φ -description we mean any set of subformulas of φ together with the negations of the remaining formulas in $\mathbf{Sub}\varphi$. For each L -consistent φ -description Θ select a maximal L -consistent set Δ_Θ containing Θ . Denote by W the (finite) set of the selected Δ_Θ and define

$\mathfrak{F} = \langle W, \langle R_i : i \in I \rangle \rangle$ and $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{W} \rangle$ by taking

$$\Delta_\Theta R_i \Delta_\Psi \text{ iff } \diamond_i \bigwedge \Psi \in \Delta_\Theta$$

and $\mathfrak{W}(p) = \{\Delta_\Theta \in W : p \in \Delta_\Theta\}$. It is easily proved that $(\mathfrak{M}, \Delta_\Theta) \models \psi$ iff $\psi \in \Delta_\Theta$, for all subformulas ψ of φ and $\Delta_\Theta \in W$. Hence $\mathfrak{F} \not\models \varphi$. It is also easy to see that for all truth-functional compounds ψ of subformulas in φ ,

$$(14) \quad (\mathfrak{M}, \Delta_\Theta) \models \diamond_i \psi \text{ iff } \diamond_i \psi \in \Delta_\Theta.$$

Consider now a model $\mathfrak{M}' = \langle \mathfrak{F}, \mathfrak{W}' \rangle$ and $\chi \in \Gamma$. For each variable p put

$$\psi_p = \bigvee \left\{ \bigwedge \Theta : \Delta_\Theta \in \mathfrak{W}(p) \right\}$$

and denote by χ' the result of substituting ψ_p for p , for each p in χ . Then $\mathfrak{M}' \models \chi$ iff $\mathfrak{M} \models \chi'$. In view of (14), we have $\mathfrak{M} \models \chi'$ because χ' has no nested modalities. Therefore, $\mathfrak{F} \models \chi$ and so $\mathfrak{F} \models L$. \blacksquare

Tabular Logics Needless to say that all polymodal tabular logics are finitely axiomatizable and have only finitely many extensions. (The proof is the same as in the unimodal case.) A more interesting observation concerns the complexity of polymodal logics whose unimodal fragments are tabular or pretabular. In fact, it is not difficult to construct two tabular unimodal logics L_1 and L_2 such that their fusion $L_1 \otimes L_2$ has uncountably many normal extensions (see e.g. [Grefe 1994]). However, those logics are \mathcal{DF} -persistent and so Kripke complete. Wolter [1994b] showed that the lattice

$\text{NExt}\mathbf{T}$ can be embedded into the lattice $\text{NExt}(\text{Log} \overset{\circ}{\circ} \otimes \mathbf{S5})$ in such a way that properties like FMP, decidability and Kripke completeness are reflected under this embedding. It follows that almost all “negative” phenomena of modal logic are exhibited by bimodal logics one unimodal fragment of which is tabular and the other pretabular.

2.2 Fusions

The simplest way of constructing polymodal logics from unimodal ones is to form the *fusions* (alias *independent joins*) of them. Namely, given two unimodal logics L_1 and L_2 in languages with the same set of variables and distinct modal operators \Box_1 and \Box_2 , respectively, the *fusion* $L_1 \otimes L_2$ of L_1 and L_2 is the smallest bimodal logic to contain $L_1 \cup L_2$. If Γ_1 and Γ_2 axiomatize L_1 and L_2 , then $L_1 \otimes L_2$ is axiomatized by $\Gamma_1 \cup \Gamma_2$, i.e., $L_1 \otimes L_2 = \mathbf{K}_2 \oplus \Gamma_1 \oplus \Gamma_2$. So the fusions are precisely those bimodal logics that are axiomatizable by sets of formulas each of which contains only one of \Box_1, \Box_2 . From the model-theoretic point of view this means that a frame $\langle W, R_1, R_2, P \rangle$ validates $L_1 \otimes L_2$ iff $\langle W, R_i, P \rangle \models L_i$ for $i = 1, 2$.

PROPOSITION 110 (Thomason 1980). *If logics L_1 and L_2 are consistent, then $L_1 \otimes L_2$ is a conservative extension of both L_1 and L_2 .*

Proof. Suppose for definiteness that $\varphi \notin L_1$, for some formula φ in the language of L_1 , and consider the Tarski–Lindenbaum algebras

$$\mathfrak{A}_{L_1}(\omega) = \langle A, \wedge^A, \neg^A, \Box_1 \rangle \text{ and } \mathfrak{A}_{L_2}(\omega) = \langle B, \wedge^B, \neg^B, \Box_2 \rangle.$$

The Boolean reducts of them are countably infinite atomless Boolean algebras which are known to be isomorphic (see e.g. [Koppelberg 1988]). So we may assume that $A = B$, $\wedge^A = \wedge^B$, $\neg^A = \neg^B$. Since the algebra $\mathfrak{A}_{L_1}(\omega)$ refutes φ , $\langle A, \wedge^A, \neg^A, \Box_1, \Box_2 \rangle$ is then an algebra for $L_1 \otimes L_2$ refuting φ . ■

Having constructed the fusion of logics, it is natural to ask which of their properties it inherits. For example, the first order theory of a single equivalence relation has the finite model property and is decidable, but the theory of two equivalence relations is undecidable and so does not have the finite model property (see [Janiczak 1953]). So neither decidability nor the finite model property is preserved under joins of first order theories. On the other hand, as was shown by Pigozzi [1974], decidability is preserved under fusions of equational theories in languages with mutually disjoint sets of operation symbols.

For modal logics we have:

THEOREM 111. *Suppose L_1 and L_2 are normal unimodal consistent logics and \mathcal{P} is one of the following properties: FMP, (strong) Kripke completeness, decidability, Halldén completeness, interpolation, uniform interpolation. Then $L = L_1 \otimes L_2$ has \mathcal{P} iff both L_1 and L_2 have \mathcal{P} .*

Proof. We outline proofs of some claims in this theorem; the reader can consult [Fine and Schurz 1996], [Kracht and Wolter 1991], and [Wolter 1997b] for more details.

The implication (\Rightarrow) presents no difficulties. So let us concentrate on (\Leftarrow) . With each formula φ of the form $\Box_i \psi$ we associate a new variable q_φ which will be called the *surrogate* of φ . For a formula φ containing no surrogate variables, denote by φ^1 the formula that results from φ by replacing all occurrences of formulas $\Box_2 \psi$, which are not within the scope of another \Box_2 , with their surrogate variables $q_{\Box_2 \psi}$. So φ^1 is a unimodal formula containing only \Box_1 . Denote by $\Theta^1(\varphi)$ the set of variables in φ together with all subformulas of $\Box_2 \psi \in \mathbf{Sub}\varphi$. The formula φ^2 and the set $\Theta^2(\varphi)$ are defined symmetrically.

Suppose now that both L_1 and L_2 are Kripke complete and $\varphi \notin L$. To prove the completeness of L we construct a Kripke frame for L refuting φ . Since we know only how to build refutation frames for the unimodal fragments of L , the frame is constructed by steps alternating between \Box_1 and \Box_2 . First, since L_1 is complete, there is a unimodal model \mathfrak{M} based

on a Kripke frame for L_1 and refuting φ^1 at its root r . Our aim now is to ensure that the formulas of the form $\Box_2\psi$ have the same truth-values as their surrogates $q_{\Box_2\psi}$. To do this, with each point x in \mathfrak{M} we can associate the formula

$$\varphi_x = \bigwedge \{ \psi \in \Theta^1(\varphi) : (\mathfrak{M}, x) \models \psi^1 \} \wedge \bigwedge \{ \neg\psi : \psi \in \Theta^1(\varphi), (\mathfrak{M}, x) \not\models \psi^1 \},$$

construct a model \mathfrak{M}_x based on a frame for L_2 and satisfying φ_x^2 at its root y , and then hook \mathfrak{M}_x to \mathfrak{M} by identifying x and y . After that we can switch to \Box_1 and in the same manner ensure that formulas $\Box_1\psi$ have the same truth-values as $q_{\Box_1\psi}$ at all points in every \mathfrak{M}_x . And so forth.

However, to realize this quite obvious scheme we must be sure that φ_x is really satisfiable in a frame for L_2 , which may impose some restrictions on the models we choose. First, one can show that in the construction above it is enough to deal with points x accessible from r by at most $m = md(\varphi)$ steps. Let X be the set of all such points. Now, a sufficient and necessary condition for φ_x to be L - (and so L_2 -) consistent can be formulated as follows. Call a $\Theta^1(\varphi)$ -description the conjunction of formulas in any maximal L -consistent subset of $\Theta^1(\varphi) \cup \{ \neg\psi : \psi \in \Theta^1(\varphi) \}$. It should be clear that φ_x is L -consistent iff it is a $\Theta^1(\varphi)$ -description. Denote by $\Sigma_1(\varphi)$ the set of all $\Theta^1(\varphi)$ -descriptions. It follows that all φ_x , for $x \in X$, are L -consistent iff $(\mathfrak{M}, r) \models \Box_1^{\leq m} (\bigvee \Sigma_1(\varphi))^1$. In other words, we should start with a model \mathfrak{M} satisfying $\varphi^1 \wedge \Box_1^{\leq m} (\bigvee \Sigma_1(\varphi))^1$ at its root r . Of course, the subsequent models \mathfrak{M}_x , for $x \in X$, must satisfy $\varphi_x^2 \wedge \Box_2^{\leq m} (\bigvee \Sigma_2(\varphi_x))^2$, where $\Sigma_2(\varphi_x)$ is the set of all $\Theta^2(\varphi_x)$ -descriptions, etc.

In this way we can prove that Kripke completeness is preserved under fusions. The preservation of strong completeness and FMP can be established in a similar manner. The following lemma plays the key role in the proof of the preservation of the four remaining properties.

LEMMA 112. *The following conditions are equivalent for every φ :*

- (i) $\varphi \in L_1 \otimes L_2$;
- (ii) $\Box_1^{\leq m} (\bigvee \Sigma_1(\varphi))^1 \rightarrow \varphi^1 \in L_1$, where $m = md(\varphi)$;
- (iii) $\Box_2^{\leq m} (\bigvee \Sigma_2(\varphi))^2 \rightarrow \varphi^2 \in L_2$.

For Kripke complete L_1 and L_2 this lemma was first proved by Fine and Schurz [1996] and Kracht and Wolter [1991]; actually, it is an immediate consequence of the consideration above. The proof for the arbitrary case is also based upon a similar construction combined with the algebraic proof of Proposition 110; for details see [Wolter 1997b].

Now we show how one can use this lemma to prove the preservation of the remaining properties. Define $a^1(\varphi)$ to be the length of the longest

sequence $\Box_2, \Box_1, \Box_2, \dots$ of boxes starting with \Box_2 such that a subformula of the form $\Box_2(\dots \Box_1(\dots \Box_2(\dots)))$ occurs in φ . The function $a^2(\varphi)$ is defined analogously by exchanging \Box_1 and \Box_2 , and $a(\varphi) = a^1(\varphi) + a^2(\varphi)$. It is easy to see that

$$a(\varphi) > a(\bigvee \Sigma_1(\varphi)) \text{ or } a(\varphi) > a(\bigvee \Sigma_2(\varphi)).$$

The preservation of decidability, Halldén completeness, interpolation, and uniform interpolation can be proved by induction on $a(\varphi)$ with the help of Lemma 112. We illustrate the method only for Halldén completeness. Notice first that, modulo the Boolean equivalence, we have

$$\bigvee \Sigma_1(\varphi \vee \psi) = \bigvee \Sigma_1(\varphi) \wedge \bigvee \Sigma_1(\psi) \wedge \bigwedge \Delta(\varphi, \psi),$$

where

$$\Delta(\varphi, \psi) = \{\chi_1 \rightarrow \neg\chi_2 : \chi_1 \in \Sigma_1(\varphi), \chi_2 \in \Sigma_1(\psi), \chi_1 \rightarrow \neg\chi_2 \in L\}.$$

Suppose both L_1 and L_2 are Halldén complete. By induction on $n = a(\varphi \vee \psi)$ we prove that $\varphi \vee \psi \in L$ implies $\varphi \in L$ or $\psi \in L$ whenever φ and ψ have no common variables. The basis of induction is trivial. So suppose $a(\varphi \vee \psi) = n > 0$ and $\varphi \vee \psi \in L$. We may also assume that $a(\varphi \vee \psi) > a(\bigvee \Sigma_1(\varphi \vee \psi))$. By the induction hypothesis, it follows that $\Delta(\varphi, \psi) = \emptyset$. Hence, up to the Boolean equivalence, $\bigvee \Sigma_1(\varphi \vee \psi) = \bigvee \Sigma_1(\varphi) \wedge \bigvee \Sigma_1(\psi)$ and, by Lemma 112,

$$\Box_1^{\leq m}(\bigvee \Sigma_1(\varphi))^1 \wedge \Box_1^{\leq m}(\bigvee \Sigma_1(\psi))^1 \rightarrow (\varphi \vee \psi)^1 \in L_1,$$

for $m = md(\varphi \vee \psi)$. Then

$$(\Box_1^{\leq m}(\bigvee \Sigma_1(\varphi))^1 \rightarrow \varphi^1) \vee (\Box_1^{\leq m}(\bigvee \Sigma_1(\psi))^1 \rightarrow \psi^1) \in L_1$$

and, by the Halldén completeness of L_1 , one of the disjuncts in this formula belongs to L_1 . By Lemma 112, this means that $\varphi \in L$ or $\psi \in L$. ■

REMARK. This theorem can be generalized to fusions of polymodal logics with polyadic modalities.

Note that in languages with finitely many variables both **GL.3** and **K** are strongly complete but **GL.3** \otimes **K** is not strongly complete even in the language with one variable (see [Kracht and Wolter 1991]).

It is natural now to ask whether there exist interesting axioms φ containing both \Box_1 and \Box_2 and such that $(L_1 \otimes L_2) \oplus \varphi$ inherits basic properties of $L_1, L_2 \in \text{NExtK}$. Let us start with the observation that even such a simple axiom as $\Box_1 p \leftrightarrow \Box_2 p$ destroys almost all “good” properties because (i) we can identify the logic $(L_1 \otimes L_2) \oplus \Box_1 p \leftrightarrow \Box_2 p$ with the sum of the translation of L_1 and L_2 into a common unimodal language and (ii) such properties as

FMP, decidability, and Kripke completeness are not preserved under sums of unimodal logics (see Example 64 and [ChagroV and Zakharyashev 1997]). Even for the simpler formula $\Box_2 p \rightarrow \Box_1 p$ no general results are available. To demonstrate this we consider the following way of constructing a bimodal logic L_u for a given $L \in \text{NExt}\mathbf{K}$:

$$L_u = (L \otimes \mathbf{S5}) \oplus \Box_2 p \rightarrow \Box_1 p.$$

The modal operator \Box_2 in L_u is called the *universal modality*. Its meaning is explained by the following lemma:

LEMMA 113 (Goranko and Passy 1992). *For every normal unimodal logic L and all unimodal formulas φ and ψ ,*

$$\varphi \vdash_L^* \psi \text{ iff } \vdash_{L_u} \Box_2 \varphi \rightarrow \psi.$$

Proof. Follows immediately from Theorem 19 (ii), since

$$\langle W, R, P \rangle \models L \text{ iff } \langle W, R, W \times W, P \rangle \models L_u,$$

for every frame $\langle W, R, P \rangle$ and every unimodal logic L . ■

The universal modality is used to express those properties of frames $\mathfrak{F} = \langle W, R, W \times W \rangle$ that cannot be expressed in the unimodal language. For example, \mathfrak{F} validates $\Box_2(p \rightarrow \Diamond_1 p) \rightarrow \neg p$ iff it contains no infinite R -chains. Recall that there is no corresponding unimodal axiom, since \mathbf{K} is determined by the class of frames without infinite R -chains. We refer the reader to [Goranko and Passy 1992] for more information on this matter.

THEOREM 114 (Goranko and Passy 1992). *For any $L \in \text{NExt}\mathbf{K}$,*

- (i) L is globally Kripke complete iff L_u is Kripke complete;
- (ii) L has global FMP iff L_u has FMP.

Proof. We prove only (i). Suppose that L_u is Kripke complete and $\varphi \not\vdash_L^* \psi$. Then by Lemma 113, $\Box_2 \varphi \rightarrow \psi \notin L_u$ and so $\Box_2 \varphi \rightarrow \psi$ is refuted in a Kripke frame $\mathfrak{F} = \langle W, R_1, R_2 \rangle$ for L_u . We may assume that $R_2 = W \times W$. But then $\varphi \vdash_L^* \psi$ is refuted in $\langle W, R_1 \rangle$. Conversely, suppose that L is globally Kripke complete and $\varphi \notin L_u$, for a (possibly bimodal) formula φ . Using the properties of $\mathbf{S5}$ it is readily checked that φ is (effectively) equivalent in \mathbf{K}_u to a formula φ' which is a conjunction of formulas ψ of the form

$$\psi = \chi_0 \vee \Diamond_2 \chi_1 \vee \Box_2 \chi_2 \vee \Box_2 \chi_3 \vee \cdots \vee \Box_2 \chi_n$$

such that χ_0, \dots, χ_n are unimodal formulas in the language with \Box_1 . Let ψ be a conjunct of φ' such that $\psi \notin L_u$. Then $\neg \chi_i \not\vdash_L^* \chi_i$, for every $i \in \{0, 2, 3, \dots, n\}$. Since L is globally complete, we have Kripke frames $\langle W_i, R_i \rangle$ for L refuting $\neg \chi_i \vdash_L^* \chi_i$, for $i \in \{0, 2, \dots, n\}$. Denote by $\langle W, R \rangle$ the disjoint union of those frames. Then $\langle W, R, W \times W \rangle$ is a Kripke frame for L_u refuting φ . ■

We have seen in Section 1.5 that there are Kripke complete logics (logics with FMP) which do not enjoy the corresponding global property. In view of Theorem 114, we conclude that neither FMP nor Kripke completeness is preserved under the map $L \mapsto L_u$.

Another interesting way of adding to fusions new axioms mixing the necessity operators is to use the so called *inductive* (or *Seegerberg's*) *axioms*. First, we extend the language \mathcal{L}_I with m necessity operators by introducing the operators \mathbf{E} and \mathbf{C} and then let

$$\mathit{ind} = \{ \mathbf{E}p \leftrightarrow \bigwedge_{i \in I} \Box_i p, \mathbf{C}p \rightarrow \mathbf{E}\mathbf{C}p; \mathbf{C}(p \rightarrow \mathbf{E}p) \rightarrow (p \rightarrow \mathbf{C}p) \}.$$

Now, given $L \in \mathbf{NExtK}_m$, we put

$$\mathbf{LEC}_m = (L \otimes \mathbf{K}_E \otimes \mathbf{S4}_C) \oplus \mathit{ind},$$

where \mathbf{K}_E and $\mathbf{S4}_C$ are just \mathbf{K} and $\mathbf{S4}$ in the languages with \mathbf{E} and \mathbf{C} , respectively. The following proposition explains the meaning of the inductive axioms.

PROPOSITION 115. *A frame $\langle W, R_1, \dots, R_m, R_E, R_C \rangle$ validates \mathbf{LEC}_m iff $\langle W, R_1, \dots, R_m \rangle \models L$, $R_E = R_1 \cup \dots \cup R_m$ and R_C is the transitive reflexive closure of R_E .*

EXAMPLE 116. The logic $(\mathbf{Alt}_1 \oplus \mathbf{D})\mathbf{EC}_1$ is determined by the frame $\langle \omega, S, \leq \rangle$ in which S is the successor relation in ω . (Here we omit writing R_E because $R_E = S$.) For details consult [Seegerberg 1989].¹⁴

No general results are known about the preservation properties of the map $L \mapsto \mathbf{LEC}_m$. In fact, it is easy to extend the counter-examples for the map $L \mapsto L_u$ to the present case (see [Hemaspaandra 1996]). However, at least in some cases—especially those that are of importance for epistemic logic—the logic \mathbf{LEC}_m enjoys a number of desirable properties.

THEOREM 117 (Halpern and Moses 1992). *For every $m \geq 1$, the logics $(\bigotimes_{i=1}^m \mathbf{K})\mathbf{EC}_m$, $(\bigotimes_{i=1}^m \mathbf{S4})\mathbf{EC}_m$ and $(\bigotimes_{i=1}^m \mathbf{S5})\mathbf{EC}_m$ have FMP.*

Proof. We consider only $L = (\bigotimes_{i=1}^m \mathbf{S5})\mathbf{EC}_m$. The proof is by filtration and so the main difficulty is to find a suitable “filter”. Suppose that $\varphi \notin L$ and let $\mathfrak{M} = \langle \langle W, R_1, \dots, R_m, R_E, R_C \rangle, \mathcal{U} \rangle$ be the canonical model for L . Denote by Γ^\neg the closure of a set of formulas Γ under negations and define a filter $\Phi = \Phi_1^\neg \cup \Phi_2^\neg \cup \Phi_3^\neg$, where $\Phi_1 = \mathbf{Sub}\varphi$, $\Phi_2 = \{ \Box_i \psi : \mathbf{E}\psi \in \Phi_1^\neg \}$ and $\Phi_3 = \{ \mathbf{E}\mathbf{C}\psi, \Box_i \mathbf{C}\psi : \mathbf{C}\psi \in \Phi_1^\neg \}$. Certainly, Φ is finite and closed under subformulas. Now, we filter \mathfrak{M} through Φ , i.e., put $W^* = \{ [x] : x \in W \}$,

¹⁴Kristen Seegerberg kindly informed us that this result was independently obtained by D. Scott, H. Kamp, K. Fine and himself.

Figure 11.

where $[x]$ consists of all points that validate the same formulas in Φ as x , and

$$[x]R_i[y] \text{ iff } \forall \Box_i \psi \in \Phi \ ((\mathfrak{M}, x) \models \Box_i \psi \rightarrow (\mathfrak{M}, y) \models \Box_i \psi),$$

$$R_E^* = R_1^* \cup \dots \cup R_m^*,$$

and R_C^* is the transitive and reflexive closure of R_E^* . A rather tedious inductive proof shows that $\langle W^*, R_1^*, \dots, R_m^*, R_E^*, R_C^* \rangle$ refutes φ under the valuation $\mathfrak{U}^*(p) = \{[x] : x \models p\}$, p a variable in φ . For details we refer the reader to [Halpern and Moses 1992] and [Meyer and van der Hoek 1995]. \blacksquare

It would be of interest to look for big classes of logics L for which LEC_m inherits basic properties of L .

2.3 Simulation

In the preceding section we saw how results concerning logics in $NExt\mathbf{K}$ can be extended to a certain class of polymodal logics. More generally, we may ask whether—at least theoretically—polymodal logics are reducible to unimodal ones. The first to attack this problem was Thomason [1974b, 1975c] who proved that each polymodal logic L can be embedded into a unimodal logic L^s in such a way that L inherits almost all interesting properties of L^s . Using this result one can construct unimodal logics with various “negative” properties by presenting first polymodal logics with the corresponding properties, which is often much easier. It was in this way that Thomason [1975c] constructed Kripke incomplete and undecidable unimodal calculi. Kracht [1996] strengthened Thomason’s result by showing that his embedding not only reflects but also (i) preserves almost all important properties and (ii) induces an isomorphism from the lattice $NExt\mathbf{K}_2$ onto the interval $[\mathbf{Sim}, \mathbf{K} \oplus \Box \perp]$, for some normal unimodal logic \mathbf{Sim} . Thus indeed, in many respects polymodal logics turn out to be reducible to unimodal ones.

Below we outline Thomason’s construction following [Kracht 1999] and [Kracht and Wolter 1999]. To define the unimodal “simulation” L^s of a bimodal logic L , let us first transform each bimodal frame into a unimodal one.

So suppose $\mathfrak{F} = \langle W, R_1, R_2, P \rangle$ is a bimodal frame. Construct a unimodal frame $\mathfrak{F}^s = \langle W^s, R^s, P^s \rangle$ —the *simulation* of \mathfrak{F} —by taking

$$\begin{aligned} W^s &= W \times \{1, 2\} \cup \{\infty\}, \\ R^s &= \{ \langle \langle x, 1 \rangle, \langle x, 2 \rangle \rangle : x \in W \} \cup \\ &\quad \{ \langle \langle x, 2 \rangle, \langle x, 1 \rangle \rangle : x \in W \} \cup \\ &\quad \{ \langle \langle x, 1 \rangle, \infty \rangle : x \in W \} \cup \\ &\quad \{ \langle \langle x, 1 \rangle, \langle y, 1 \rangle \rangle : x, y \in W, xR_1y \} \cup \\ &\quad \{ \langle \langle x, 2 \rangle, \langle y, 2 \rangle \rangle : x, y \in W, xR_2y \}, \\ P^s &= \{ (X \times \{2\}) \cup (Y \times \{1\}) \cup Z : X, Y \in P, Z \subseteq \{\infty\} \}. \end{aligned}$$

This construction is illustrated by Fig. 11. One can easily prove that \mathfrak{F}^s is a Kripke (differentiated, refined, descriptive) frame whenever \mathfrak{F} is so. Notice also that if $W = \emptyset$ then $\mathfrak{F}^s \cong \bullet$. Now, given a bimodal logic L , define the *simulation* L^s of L to be the unimodal logic

$$\text{Log}\{\mathfrak{F}^s : \mathfrak{F} \models L\}.$$

To formulate the translation which embeds L into L^s we require the following formulas and notations:

$$\begin{aligned} \gamma &= \Box \perp & \Box_\gamma \varphi &= \Box(\gamma \rightarrow \varphi) \\ \alpha &= \Diamond \Box \perp & \Box_\alpha \varphi &= \Box(\alpha \rightarrow \varphi) \\ \beta &= \neg \gamma \wedge \neg \Diamond \gamma & \Box_\beta \varphi &= \Box(\beta \rightarrow \varphi). \end{aligned}$$

\Diamond_γ , \Diamond_α and \Diamond_β are defined dually. Observe that the formula γ is true in \mathfrak{F}^s only at ∞ , α is true precisely at the points in the set $\{\langle x, 1 \rangle : x \in W\}$, and β is true at the points $\{\langle x, 2 \rangle : x \in W\}$ and only at them. Put

$$\begin{aligned} p^s &= p, \\ (\neg \varphi)^s &= \alpha \wedge \neg \varphi^s, \\ (\varphi \wedge \psi)^s &= \varphi^s \wedge \psi^s, \\ (\Box_1 \varphi)^s &= \Box_\alpha \varphi^s, \\ (\Box_2 \varphi)^s &= \Box_\beta \Box_\beta \Box_\alpha \varphi^s. \end{aligned}$$

By an easy induction on the construction of φ one can prove

LEMMA 118. *Let $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ be a bimodal model, $X = \{x : x \models \alpha\}$ and let $\mathfrak{M}^s = \langle \mathfrak{F}^s, \mathfrak{V}^s \rangle$ be a model such that $\mathfrak{V}^s(p) \cap X = \mathfrak{V}(p) \times \{1\}$, for all variables p . Then for every bimodal formula φ ,*

$$\begin{aligned} (\mathfrak{M}, x) \models \varphi &\text{ iff } (\mathfrak{M}^s, \langle x, 1 \rangle) \models \varphi^s, \\ \mathfrak{M} \models \varphi &\text{ iff } \mathfrak{M}^s \models \alpha \rightarrow \varphi^s, \\ \mathfrak{F} \models \varphi &\text{ iff } \mathfrak{F}^s \models \alpha \rightarrow \varphi^s. \end{aligned}$$

Using this lemma, both consequence relations \vdash_L and \vdash_L^* can be reduced to the corresponding consequence relations for L^s .

PROPOSITION 119. *Let L be a bimodal logic, Δ a set of bimodal formulas and φ a bimodal formula. Then*

$$\begin{aligned} \Delta \vdash_L \varphi & \text{ iff } \alpha \rightarrow \Delta^s \vdash_{L^s} \alpha \rightarrow \varphi^s, \\ \Delta \vdash_L^* \varphi & \text{ iff } \alpha \rightarrow \Delta^s \vdash_{L^s}^* \alpha \rightarrow \varphi^s, \end{aligned}$$

where $\alpha \rightarrow \Delta^s = \{\alpha \rightarrow \delta : \delta \in \Delta^s\}$.

To axiomatize L^s , given an axiomatization of L , we require the following formulas:

- (a) $\alpha \rightarrow (\diamond_\gamma p \leftrightarrow \square_\gamma p), \alpha \wedge \diamond_\gamma p \rightarrow \square_\alpha \diamond_\gamma p,$
- (b) $\alpha \rightarrow (\diamond_\beta p \leftrightarrow \square_\beta p),$
- (c) $\beta \rightarrow (\diamond_\alpha p \leftrightarrow \square_\alpha p),$
- (d) $\alpha \wedge p \rightarrow \square_\beta \square_\alpha p, \beta \wedge p \rightarrow \square_\alpha \square_\beta p,$
- (e) $\alpha \wedge \diamond_\gamma p \rightarrow \square_\beta \square_\beta \square_\alpha \diamond_\gamma p.$

Let $\mathbf{Sim} = \mathbf{K} \oplus \{(a), \dots, (e)\}$. Obviously, \mathfrak{F}^s is a frame for \mathbf{Sim} whenever \mathfrak{F} is a bimodal frame. Consider now a differentiated frame $\mathfrak{F} = \langle W, R, P \rangle$ for \mathbf{Sim} which contains only one point where γ is true. (Actually, every rooted differentiated frame for \mathbf{Sim} satisfies this condition.) Construct a bimodal frame $\mathfrak{F}_s = \langle V, R_1, R_2, Q \rangle$, called the *unsimulation* of \mathfrak{F} , in the following way. Put $V = \{x \in W : x \models \alpha\}$, $V^\bullet = \{x \in W : x \models \beta\}$ and $U = \{x \in W : x \models \gamma\}$. Since $\gamma \vee \alpha \vee \beta \in \mathbf{K}$, we have $W = V \cup V^\bullet \cup U$. It is not hard to verify using (b) and (c) (and the differentiatedness of \mathfrak{F}) that for every $x \in V$ there exists a unique $x^\bullet \in V^\bullet$ such that xRx^\bullet , and for every $y \in V^\bullet$ there exists $y^\circ \in V$ such that yRy° . By (d), $x = x^\circ$. Finally, we put $R_1 = R \cap V^2$, $R_2 = \{\langle x, y \rangle \in V^2 : x^\bullet Ry^\bullet\}$ and $Q = \{X \cap V : X \in P\}$. It is easily proved that \mathfrak{F}_s is a bimodal frame. The name *unsimulation* is justified by the following lemma.

LEMMA 120. *For every differentiated bimodal frame \mathfrak{F} , $(\mathfrak{F}^s)_s \cong \mathfrak{F}$.*

Now we have:

THEOREM 121. *For every bimodal logic $L = \mathbf{K}_2 \oplus \Delta$,*

$$L^s = \mathbf{Sim} \oplus \alpha \rightarrow \Delta^s.$$

Proof. Clearly, $\mathbf{Sim} \oplus \alpha \rightarrow \Delta^s \subseteq L^s$. Assume that the converse inclusion does not hold. Then there exists a rooted differentiated \mathfrak{F} such that $\mathfrak{F} \not\models L^s$ but $\mathfrak{F} \models \mathbf{Sim} \oplus \alpha \rightarrow \Delta^s$. By Lemma 120, $(\mathfrak{F}_s)^s \not\models L^s$. By the definition of L^s , we then conclude that $\mathfrak{F}_s \not\models L$. And by Proposition 119, we have $(\mathfrak{F}_s)^s \not\models \alpha \rightarrow \Delta^s$, from which $\mathfrak{F} \not\models \alpha \rightarrow \Delta^s$. ■

Given $L \in [\mathbf{Sim}, \mathbf{K} \oplus \square\perp]$, the logic $L_s = \{\varphi : \alpha \rightarrow \varphi^s \in L\}$ is called the *unsimulation* of L .

LEMMA 122. *If L is determined by a class \mathcal{C} of frames in which γ is true only at one point then $L_s = \text{Log}\{\mathfrak{F}_s : \mathfrak{F} \in \mathcal{C}\}$.*

We are in a position now to formulate the main result of this section.

THEOREM 123 (Kracht 1999). *The map $L \mapsto L^s$ is an isomorphism from the lattice $\text{NExt}\mathbf{K}_2$ onto the interval $[\mathbf{Sim}, \mathbf{K}_1 \oplus \Box\perp]$. The inverse map is $L \mapsto L_s$. Both these maps preserve tabularity, (global) FMP, (global) Kripke completeness, decidability, interpolation, strong completeness, \mathcal{R} - and \mathcal{D} -persistence, elementarity.*

Proof. To prove the first claim it suffices to show that $(L_s)^s = L$ for every $L \in [\mathbf{Sim}, \mathbf{K} \oplus \Box\perp]$. That $L \subseteq (L_s)^s$ is clear. Consider the set \mathcal{C} of all differentiated frames \mathfrak{F}_s such that $\mathfrak{F} \models L$ and γ is true only at one point in \mathfrak{F} . By Lemma 122, \mathcal{C} characterizes L_s . It is not difficult to show now that the class $\{\mathfrak{F}_s^+ : \mathfrak{F} \in \mathcal{C}\}$ is closed under subalgebras, homomorphic images and direct products; so it is a variety. Consequently, \mathcal{C} is (up to isomorphic copies) the class of all differentiated frames for L_s .

Take a differentiated frame \mathfrak{F} for $(L_s)^s$. Then $\mathfrak{F}_s \models L_s$. So there exists $\mathfrak{G}_s \in \mathcal{C}$ which is isomorphic to \mathfrak{F}_s . Hence $(\mathfrak{F}_s)^s \cong (\mathfrak{G}_s)^s$ and $\mathfrak{F} \models L$, since $\mathfrak{G} \models L$. It follows that L^s is determined by $\{\mathfrak{F}^s : \mathfrak{F} \in \mathcal{C}\}$ whenever L is determined by \mathcal{C} .

The preservation of tabularity, (global) FMP, (global) Kripke completeness, and strong completeness under both maps is proved with the help of Lemma 122 and the observation above. It is also clear that L is decidable whenever L^s is decidable. For the remaining (rather technical) part of the proof the reader is referred to [Kracht 1999] and [Kracht and Wolter 1999]. ■

Besides its theoretical significance, this theorem can be used to transfer rather subtle counter-examples from polymodal logic to unimodal logic. For instance, Kracht [1996] constructs a polymodal logic which has FMP and is globally Kripke incomplete. By Theorem 123, we obtain a unimodal logic with the same properties.

2.4 Minimal tense extensions

Now let us turn to *tense logics* which may be regarded as normal bimodal logics containing the axioms $p \rightarrow \Box_1\Diamond_2p$ and $p \rightarrow \Box_2\Diamond_1p$. Usually studies in Tense Logic concern some special systems representing various models of time, like cyclic time, discrete or dense linear time, branching time, relativistic time, etc. Such systems are discussed in *Basic Tense Logic*, volume 6 of this *Handbook* (see also [Gabbay *et al.* 1994], [Goldblatt 1987] and [van Benthem 1991]). However, as before our concern is general methods which make it possible to obtain results not only for this or that particular system but for wide classes of logics. This direction of studies in Tense Logic is quite

new and actually not so many general results are available. In this and the next section we consider two natural families of tense logics—the minimal tense extensions of unimodal logics and tense logics of linear frames. Our aim is to find out to what extent the theory developed for unimodal logics in $\text{NExt}\mathbf{K}$ and especially $\text{NExt}\mathbf{K4}$ can be “lifted” to these families.

The smallest tense logic $\mathbf{K}.t$ is determined by the class of bimodal Kripke frames $\langle W, R, R^{-1} \rangle$ in which R is the accessibility relation for \Box_1 and R^{-1} for \Box_2 . Frames of this type are known as *tense Kripke frames*; general frames of the form $\langle W, R, R^{-1}, P \rangle$ will be called just *tense frames*. Notice that not all unimodal general frames $\langle W, R, P \rangle$ can be converted into tense frames $\langle W, R, R^{-1}, P \rangle$ because P is not necessarily closed under the operation

$$\Diamond_2 X = \{x \in W : \exists y \in X \ x R^{-1} y\}.$$

For instance, in the frame \mathfrak{F} of Example 7 we have $\Diamond_2\{\omega + 1\} = \{\omega\} \notin P$.

Each normal unimodal logic $L = \mathbf{K} \oplus \Gamma$ in the language with \Box_1 gives rise to its *minimal tense extension* $L.t = \mathbf{K}.t \oplus \Gamma$. From the semantical point of view $L.t$ is the logic determined by the class of tense frames $\langle W, R, R^{-1}, P \rangle$ such that $\langle W, R, P \rangle \models L$. The formation of the minimal tense extensions is the simplest way of constructing tense logics from unimodal ones. Of “natural” tense logics, minimal tense extensions are, for instance, the logics of (converse) transitive trees, (converse) well-founded frames, (converse) transitive directed frames, etc. The main aim of this section is to describe conditions under which various properties of L are inherited by $L.t$.

Notice first that unlike fusions, $L.t$ is not in general a conservative extension of L , witness $L = \text{Log}\mathfrak{F}$ where \mathfrak{F} is again the frame constructed in Example 7: one can easily check that $\mathbf{K4}.t \subseteq L.t$. However, if L is Kripke complete then $L.t$ is a conservative extension of L and so $L'.t = L.t$ implies $L' \subseteq L$. This example may appear to be accidental (as the first examples of Kripke incomplete logics in $\text{NExt}\mathbf{K}$). However, we can repeat (with a slight modification) Blok’s construction of Theorem 35 and prove the following

THEOREM 124. *If L is a union-splitting of $\text{NExt}\mathbf{K}$ or $L = \mathbf{For}$, then $L'.t = L.t$ implies $L' = L$. Otherwise there is a continuum of logics in $\text{NExt}\mathbf{K}$ having the same minimal tense extension as L .*

It is not known whether there exists $L \in \text{NExt}\mathbf{K4}$ such that $L.t$ is not a conservative extension of L .

Theorem 124 leaves us little hope to obtain general positive results for the whole family of minimal tense extensions. As in the case of unimodal logics we can try our luck by considering logics with transitive frames. So in the rest of this section it is assumed that the unimodal and tense logics we deal with contain $\mathbf{K4}$ and $\mathbf{K4}.t$, respectively, and that frames are transitive. But even in this case we do not have general preservation results: Wolter [1996b] constructed a logic $L \in \text{NExt}\mathbf{K4}$ having FMP and such that $L.t$ is not Kripke complete. However, the situation turns out to be not so hopeless

if we restrict attention to the well-behaved classes of logics in $\text{NExt}\mathbf{K4}$, namely logics of finite width, finite depth and cofinal subframe logics. First, we have the following results of [Wolter 1997a].

THEOREM 125. *If $L \in \text{NExt}\mathbf{K4}$ is a logic of finite depth then $L.t$ has FMP. If $L \in \text{NExt}\mathbf{K4}$ is a logic of finite width then $L.t$ is Kripke complete.*

It is to be noted that tense logics of finite depth are much more complex than their unimodal counterparts. For example, there exists an undecidable finitely axiomatizable logic containing $\mathbf{K4.t} \oplus \Box_1 \Box_1 \perp$ (for details see [Kracht and Wolter 1999]).

The minimal tense extensions of cofinal subframe logics were investigated in [Wolter 1995, 1997a].

THEOREM 126. *If $L \in \text{NExt}\mathbf{K4}$ is a cofinal subframe logic then*

- (i) *$L.t$ is Kripke complete;*
- (ii) *$L.t$ has FMP iff L is canonical;*
- (iii) *$L.t$ is decidable whenever L is finitely axiomatizable.*

Before outlining the idea of the proof we note some immediate consequences for a few standard tense logics.

EXAMPLE 127. (i) The logic of the converse well-founded tense frames is $\mathbf{GL.t}$; it does not have FMP but is decidable. (ii) The logic of the converse transitive trees is $\mathbf{K4.3.t}$; it has FMP and is decidable. (iii) The logic of the converse well-founded directed tense frames is $\mathbf{GL.t} \oplus \mathbf{K4.2.t}$; it does not have FMP and is decidable.

Proof. The proof of the negative part, i.e., that $L.t$ does not have FMP if L is not canonical, is rather technical; it is based on the characterization of the canonical cofinal subframe logics of [Zakharyashev 1996]. The reader can get some intuition from the following example: neither $\mathbf{Grz.t}$ nor $\mathbf{GL.t}$ has FMP. Indeed, the Grzegorzcyk axiom

$$\Box_2(\Box_2(p \rightarrow \Box_2 p) \rightarrow p) \rightarrow p$$

is refuted in $\langle \omega, \geq, \leq \rangle$ and so does not belong to $\mathbf{Grz.t}$; however, it is valid in all finite partial orders. The argument for $\mathbf{GL.t}$ is similar: take the Löb axiom in \Box_2 and the frame $\langle \omega, >, < \rangle$.

We sketch now the proof of the positive part. For a tense Kripke frame $\mathfrak{F} = \langle W, R, R^{-1} \rangle$, let rp be a partial function associating with some clusters in \mathfrak{F} one of the frames

$$\langle \omega, >, < \rangle \text{ or } \langle \omega, \geq, \leq \rangle.$$

We call it a *replacement function* for \mathfrak{F} and define \mathfrak{F}^{rp} to be the result of replacing in \mathfrak{F} all clusters C in the domain of rp by (disjoint copies of) $\text{rp}C$. Our first observation is that for each cofinal subframe logic L , $L.t$ is

determined by a set of frames of the form \mathfrak{F}^{rp} such that \mathfrak{F} is of finite depth. Indeed, suppose $\varphi \notin L.t$ and consider a countermodel $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ for φ based on a descriptive finitely generated tense frame $\mathfrak{F} = \langle W, R, R^{-1}, P \rangle$ for $L.t$. Say that a point $x \in W$ is *non-eliminable* (relative to φ) if there are a subformula ψ of φ and $S \in \{R, R^{-1}\}$ such that $x \in \max_S \{y \in W : y \models \psi\}$ or $x \in \max_S \{y \in W : y \models \neg\psi\}$. Denote by W_e the set of non-eliminable points in W and construct a new model \mathfrak{M}_e on the frame $\mathfrak{F}_e = \langle W_e, R \upharpoonright W_e, R^{-1} \upharpoonright W_e \rangle$ by taking $\mathfrak{V}_e(p) = \mathfrak{V}(p) \cap W_e$ for all variables p in φ . Clearly, the Kripke frame \mathfrak{F}_e is of finite depth ($d(\mathfrak{F}_e) \leq 2l(\varphi)$, to be more precise). Besides, using Theorem 23 one can easily show that $(\mathfrak{M}_e, y) \models \psi$ iff $(\mathfrak{M}, y) \models \psi$, for all $\psi \in \mathbf{Sub}\varphi$ and $y \in W_e$. (Note that Theorem 23 is applicable in this case, since $\langle W, R, P \rangle$ is descriptive whenever $\langle W, R, R^{-1}, P \rangle$ is descriptive.) Moreover, the R -reduct $\langle W_e, R \upharpoonright W_e \rangle$ of \mathfrak{F}_e is a cofinal subframe of the R -reduct $\langle W, R \rangle$ of the underlying Kripke frame of \mathfrak{F} . So \mathfrak{F}_e is a frame for $L.t$ whenever L is canonical (= \mathcal{D} -persistent). However, this is not so if L is not canonical.

EXAMPLE 128. Consider the frame $\mathfrak{F} = \langle W, R, R^{-1}, P \rangle$, where $\langle W, R \rangle$ is the reflexive point ∞ followed by the chain $\langle \omega, > \rangle$ and P consists of all cofinite sets containing ∞ and their complements. Then $\mathfrak{F} \models \mathbf{GL}.t$ but (for an arbitrary φ) \mathfrak{F}_e contains ∞ and so $\mathfrak{F}_e \not\models \mathbf{GL}.t$.

A rather tedious proof (see [Wolter 1997a]) shows, however, that there exists a replacement function rp for \mathfrak{F}_e such that \mathfrak{F}_e^{rp} validates $L.t$ and all points in clusters from domrp are eliminable relative to R in \mathfrak{F} . (In the example above we put $\text{rp}\{\infty\} = \langle \omega, >, < \rangle$ and ∞ is eliminable relative to R .) So let us assume that such rp is given and that its domain is empty if L is canonical. Define a model $\mathfrak{M}_e^{rp} = \langle \mathfrak{F}_e^{rp}, \mathfrak{V}^{rp} \rangle$ as follows. First we put $y \in \mathfrak{V}^{rp}(p)$ whenever $y \in \mathfrak{V}_e(p)$ and $y \notin \text{domrp}$. Consider now a cluster $C = \{a_0, \dots, a_{m-1}\}$ in domrp . \mathfrak{V}^{rp} is defined in $\text{rp}C$ by unravelling C into the chain $\text{rp}C$; more precisely, we put

$$\mathfrak{V}^{rp}(p) \cap \text{rp}C = \{mj + i : j < \omega, a_i \in \mathfrak{V}(p)\}.$$

Using the fact that domrp contains only R -eliminable points, one can show by induction that, for every $\psi \in \mathbf{Sub}\varphi$, $(\mathfrak{M}_e, y) \models \psi$ iff $(\mathfrak{M}_e^{rp}, y) \models \psi$, if $C(y)$ does not belong to domrp , and

$$\{n \in \text{rp}C : (\mathfrak{M}_e^{rp}, n) \models \psi\} = \{mj + i : j < \omega, (\mathfrak{M}_e, a_i) \models \psi\},$$

if a cluster $C = \{a_0, \dots, a_{m-1}\}$ is in domrp . Thus \mathfrak{F}_e^{rp} refutes φ , which proves that $L.t$ is Kripke complete.

To show that all canonical logics $L.t$ do have FMP we reduce \mathfrak{F}_e^{rp} once again. Define an equivalence relation \sim on W_e by induction on the R -depth $d_R(x)$ of a point x in \mathfrak{F}_e . Suppose that $d_R(x) = d_R(y)$ and \sim is already defined for all points of R -depth $< d_R(x)$ and put $x \sim y$ if the following

conditions are satisfied: (a) $x \models \psi$ iff $y \models \psi$, for all $\psi \in \mathbf{Sub}\varphi$ ($x \sim_\varphi y$, for short), (b) if z is an R -successor of y and $C(z) \neq C(y)$ then there exists an R -successor z' of x with $C(z') \neq C(x)$ such that $z \sim z'$ and vice versa, (c) the cluster $C(x)$ is degenerate iff $C(y)$ is degenerate, (d) $\mathbf{rp}C(x) = \mathbf{rp}C(y)$, (e) for each $z \in C(x)$ there exists $z' \in C(y)$ such that $z \sim_\varphi z'$ and vice versa.

Let $[x]$ denote the equivalence class generated by x . Define a frame $\mathfrak{G} = \langle V, S, S^{-1} \rangle$ by taking $V = \{[x] : x \in W_e\}$, and $[x]S[y]$ iff there are $x' \in [x]$ and $y' \in [y]$ such that $x'Ry'$. Since \mathfrak{F}_e is of finite depth, V is finite. Moreover, the map $x \mapsto [x]$ is a reduction of the unimodal frame $\langle W_e, R \upharpoonright W_e \rangle$ to $\langle V, S \rangle$. It follows that \mathfrak{G} is a frame for $L.t$ whenever L is canonical. Define a valuation in \mathfrak{G} by putting $[x] \models p$ iff $x \models p$, for all $x \in W_e$ and all variables p in φ . Then one can show that $[x] \models \psi$ iff $x \models \psi$, for all $\psi \in \mathbf{Sub}\varphi$. So $\mathfrak{G} \not\models \varphi$, as required, which means that $L.t$ has FMP.

To prove the decidability of a finitely axiomatizable $L.t$ we first show its completeness with respect to a rather simple class of frames.

Define a replacement function \mathbf{rf} for \mathfrak{G} as follows. For each cluster C in \mathfrak{F}_e the set $[C] = \{[x] : x \in C\}$ is a cluster in \mathfrak{G} , and moreover, every cluster in \mathfrak{G} can be presented in this way. So we put $\mathbf{rf}[C] = \mathbf{rp}C$, for all clusters $[C]$ in \mathfrak{G} . Notice that by (d), \mathbf{rf} is well-defined. It is easily shown now that the R -reduct of \mathfrak{F}_e^{rp} is reducible to the R -reduct of \mathfrak{G}^{rf} and that \mathfrak{G}^{rf} refutes φ . Thus we obtain

LEMMA 129. *For each cofinal subframe logic L ,*

$$L.t = \text{Log}\{\mathfrak{G}^{rp} : \mathfrak{G}^{rp} \models L.t, \mathfrak{G} \text{ finite, rp a replacement function for } \mathfrak{G}\}.$$

So, to establish the decidability of a finitely axiomatizable $L.t$ it is enough now to present an algorithm which is capable of deciding, given an \mathbf{rp} for a finite \mathfrak{G} and φ , whether $\mathfrak{G}^{rp} \models \varphi$. To this end we require the notion of a *cluster assignment* $\mathbf{t} = \langle \mathbf{t}_1, \mathbf{t}_2 \rangle$ in a tense frame \mathfrak{G} , which is any function from the set of clusters in \mathfrak{G} into the set $\{m, j\} \times \{m, j\}$ such that $\mathbf{t}C = (m, m)$ if C is degenerate (here m and j are just two symbols; m stands for “maximal” and j for “joker”). A valuation \mathfrak{V} in \mathfrak{G} is called φ -good for $(\mathfrak{G}, \mathbf{t})$ if the following conditions hold:

- if $\mathbf{t}_1 C = j$ then $C \cap \max_R(\mathfrak{V}(\psi)) = \emptyset$, for all $\psi \in \mathbf{Sub}\varphi$;
- if $\mathbf{t}_2 C = j$ then $C \cap \max_{R^{-1}}(\mathfrak{V}(\psi)) = \emptyset$, for all $\psi \in \mathbf{Sub}\varphi$.

EXAMPLE 130. Let \mathfrak{F} be the frame constructed in Example 128 and suppose that $\mathbf{t}\{\infty\} = (j, m)$. Then each valuation \mathfrak{V} in \mathfrak{F} is φ -good for $(\mathfrak{G}, \mathbf{t})$ no matter what φ is, because ∞ is eliminable relative to R . The point ∞ is not R^{-1} -eliminable, since $\infty \in \max_{R^{-1}}(\top)$.

Given a formula φ , a finite frame \mathfrak{F} and a replacement function \mathbf{rp} for \mathfrak{F} , we construct a finite frame $\mathfrak{G} = \langle V, S, S^{-1} \rangle$ with a cluster assignment

\mathbf{t} as follows. Let k be the number of variables in φ . Then \mathfrak{G} is obtained from \mathfrak{F}^{rp} by replacing every $\text{rp}C = \langle \omega, >, < \rangle$ with a non-degenerate cluster C' of cardinality 2^k , S -followed by a chain of $2l(\varphi)$ irreflexive points, and by replacing every $\text{rp}C = \langle \omega, \geq, \leq \rangle$ with a non-degenerate cluster C' of cardinality 2^k , S -followed by a chain of $2l(\varphi)$ reflexive points. The cluster assignment \mathbf{t} in \mathfrak{G} is defined by putting $\mathbf{t}C' = (j, m)$, for all new clusters C' of cardinality 2^k , and $\mathbf{t}C' = (m, m)$, for all the other clusters. It is not difficult now to prove that $\mathfrak{F}^{rp} \models \varphi$ iff $(\mathfrak{G}, \mathfrak{U}) \models \varphi$, for all φ -good for $(\mathfrak{G}, \mathbf{t})$ valuations \mathfrak{U} in \mathfrak{G} . This equivalence provides an effective procedure for deciding whether $\mathfrak{F}^{rp} \models \varphi$. ■

Note that a similar technique can be used to prove completeness and decidability of various tense logics that are not minimal tense extensions. For instance, all logics of the form $L.t \oplus \diamond_2 \square_2 p \rightarrow \square_2 \diamond_2 p$, where L is a cofinal subframe logic, are complete and decidable if finitely axiomatizable.

2.5 Tense logics of linear frames

One of the most important types of tense logics are logics characterized by linear tense frames, i.e., transitive frames $\langle W, R, R^{-1}, P \rangle$ such that, for all $x, y \in W$, xRy or $xR^{-1}y$ or $x = y$. For example, Bull [1968] and Segerberg [1970] axiomatized the logics of the frames, $\langle \mathbb{Z}, <, > \rangle$, $\langle \mathbb{Q}, <, > \rangle$ and $\langle \mathbb{R}, <, > \rangle$ (\mathbb{Z} , \mathbb{Q} and \mathbb{R} are the sets of integer, rational and real numbers, respectively).

Linear tense logics form the lattice NExtLin , where

$$\mathbf{Lin} = \mathbf{K4}.t \oplus \diamond_1 \diamond_2 p \vee \diamond_2 \diamond_1 p \rightarrow p \vee \diamond_1 p \vee \diamond_2 p$$

is the tense logic determined by the class of all linearly ordered Kripke frames $\langle W, R, R^{-1} \rangle$. As we saw in Section 1.11, even unimodal logics of linear orders are rather non-trivial (for instance, they do not always enjoy FMP). Yet they can be characterized by Kripke frames with a transparent structure, which yields a decision algorithm for those of them that are finitely axiomatizable. Tense logics of linear frames turn out to be even more complicated. In fact, one can find almost all kinds of “monsters” among them: uncountably many logics without Kripke frames, strongly complete logics that are not canonical, canonical logics that are not \mathcal{R} -persistent, incomplete subframe logics, etc. Nevertheless, in this section we show that these logics are quite manageable. Our exposition follows [Wolter 1996b, c], where the reader can find the omitted details. All frames in this section are assumed to be linear.

Given a finite sequence $\overline{\mathfrak{F}} = \langle \mathfrak{F}_i = \langle W_i, R_i, P_i \rangle : 1 \leq i \leq n \rangle$ of disjoint frames, we denote by $[\overline{\mathfrak{F}}] = \mathfrak{F}_1 \triangleleft \cdots \triangleleft \mathfrak{F}_n$ the ordered sum of them, i.e., the

frame $\langle W, R, R^{-1}, P \rangle$ in which

$$W = \bigcup_{i=1}^n W_i, \quad R = \bigcup_{i=1}^n R_i \cup \bigcup_{1 \leq i < j \leq n} (W_i \times W_j)$$

and $P = \{X_1 \cup \dots \cup X_n : X_i \in P_i\}$. Each finite frame can be represented then as the ordered sum $C_1 \triangleleft \dots \triangleleft C_n$ of its clusters.

We begin our study by developing a language of “canonical formulas” for axiomatizing logics in **NExtLin** and characterizing the constitution of their frames. It will play the same role as the language of canonical formulas for **K4**. With every finite frame $\mathfrak{F} = \langle W, R, R^{-1} \rangle = C_1 \triangleleft \dots \triangleleft C_n$ and a cluster assignment $\mathbf{t} = (\mathbf{t}_1, \mathbf{t}_2)$ in it we associate the formula

$$\alpha(\mathfrak{F}, \mathbf{t}) = \delta(\mathfrak{F}, \mathbf{t}) \wedge \Box_1 \delta(\mathfrak{F}, \mathbf{t}) \wedge \Box_2 \delta(\mathfrak{F}, \mathbf{t}) \rightarrow \neg p_r,$$

where r is an arbitrary fixed point in \mathfrak{F} and

$$\begin{aligned} \delta(\mathfrak{F}, \mathbf{t}) = & \bigwedge \{p_x \rightarrow \Diamond_1 p_y : xRy, \neg(yRx)\} \wedge \\ & \bigwedge \{p_x \rightarrow \Diamond_2 p_y : xR^{-1}y, \neg(xRy)\} \wedge \\ & \bigwedge \{p_x \rightarrow \neg p_y : x \neq y\} \wedge \bigwedge \{p_x \rightarrow \neg \Diamond_2 p_y : \neg(xRy)\} \wedge \\ & \bigwedge \{p_x \rightarrow \Diamond_1 p_y : \exists i \leq n (\mathbf{t}_1 C_i = m \wedge x, y \in C_i \wedge xRy)\} \wedge \\ & \bigwedge \{p_x \rightarrow \Diamond_2 p_y : \exists i \leq n (\mathbf{t}_2 C_i = m \wedge x, y \in C_i \wedge xR^{-1}y)\} \wedge \\ & \bigvee \{p_y : y \in W\}. \end{aligned}$$

To explain the semantical meaning of these formulas, notice first that if $\mathbf{t}C = (m, m)$ for all clusters C then $\mathfrak{G} \models \alpha(\mathfrak{F}, \mathbf{t})$ iff \mathfrak{G} is reducible to \mathfrak{F} ; so **Lin** $\oplus \alpha(\mathfrak{F}, \mathbf{t})$ is a splitting of **NExtLin**. Suppose now that $\mathbf{t}_i C = j$ for some $i \in \{1, 2\}$ and some cluster C in \mathfrak{F} . In this case $\mathfrak{G} \models \alpha(\mathfrak{F}, \mathbf{t})$ iff there exist frames \mathfrak{G}_i , for $1 \leq i \leq n$, such that $\mathfrak{G} = \mathfrak{G}_1 \triangleleft \dots \triangleleft \mathfrak{G}_n$ and $\mathfrak{G}_i \models \alpha(C_i, \mathbf{t} \upharpoonright C_i)$ for all $1 \leq i \leq n$. So it suffices to examine the situation when $\mathfrak{G} \models \alpha(C, \mathbf{t})$ for a cluster C . Assume for simplicity that \mathfrak{G} is a Kripke frame. *Case 1:* $\mathbf{t}C = (j, j)$. Then $\mathfrak{G} \models \alpha(C, \mathbf{t})$ iff $|\mathfrak{G}| \geq |C|$. *Case 2:* $\mathbf{t}C = (m, j)$. Then C is non-degenerate and $\mathfrak{G} \models \alpha(C, \mathbf{t})$ iff either \mathfrak{G} contains an R -final cluster of cardinality $\geq |C|$ or it has no R -final point at all. *Case 3:* $\mathbf{t}C = (j, m)$. This is the mirror image of Case 2. *Case 4:* $\mathbf{t}C = (m, m)$. If C is an irreflexive point then \mathfrak{G} is an irreflexive point as well whenever $\mathfrak{G} \models \alpha(C, \mathbf{t})$. If C is non-degenerate and $\mathfrak{G} \models \alpha(C, \mathbf{t})$ then \mathfrak{G} satisfies the conditions of Cases 2 and 3.

EXAMPLE 131. Let $\alpha = \alpha(\overset{a}{\circ} \rightarrow \overset{b}{\circ}, \mathbf{t})$ where $\mathbf{t}a = (m, j)$ and $\mathbf{t}b = (j, m)$. Then $\mathfrak{F} \models \alpha$ iff there exists a non-empty upward closed set $X \in P$ such that $\forall x \in X \exists y \in X yRx$, $W - X \neq \emptyset$ and $\forall x \in W - X \exists y \in W - X xRy$.

Hence $\langle \mathbb{Q}, <, > \rangle \not\models \alpha$ (take $X = \{y \in \mathbb{Q} : \sqrt{2} < y\}$) but $\langle \mathbb{R}, <, > \rangle \models \alpha$, since the real line contains no gaps.

THEOREM 132. *There is an algorithm which, given a formula φ , returns formulas $\alpha(\mathfrak{F}_1, \mathbf{t}_1), \dots, \alpha(\mathfrak{F}_n, \mathbf{t}_n)$ such that*

$$\mathbf{Lin} \oplus \varphi = \mathbf{Lin} \oplus \alpha(\mathfrak{F}_1, \mathbf{t}_1) \oplus \dots \oplus \alpha(\mathfrak{F}_n, \mathbf{t}_n).$$

Proof. Let $(\mathfrak{F}_i, \mathbf{t}_i)$, $1 \leq i \leq n$, be the collection of all finite frames with type assignments such that, for each i , (a) there is a countermodel $\mathfrak{M}_i = \langle \mathfrak{F}_i, \mathfrak{V}_i \rangle$ for φ in which \mathfrak{V}_i is φ -good for $(\mathfrak{F}_i, \mathbf{t}_i)$, (b) the depth of \mathfrak{F}_i does not exceed $4l(\varphi) + 1$, and (c) no cluster in \mathfrak{F}_i contains more than $2^{v(\varphi)}$ points, where $v(\varphi)$ is the number of variables in φ .

Let \mathfrak{F} refute $\alpha(\mathfrak{G}_i, \mathbf{t}_i)$ under a valuation \mathfrak{U} . By the definition of $(\mathfrak{F}_i, \mathbf{t}_i)$, the model \mathfrak{M}_i refutes φ . Define a valuation \mathfrak{U}' in \mathfrak{F} by taking, for all variables p in φ ,

$$\mathfrak{U}'(p) = \bigcup \{ \mathfrak{U}(p_x) : x \in \mathfrak{V}_i(p) \}.$$

It is not hard to show by induction that $\mathfrak{U}'(\psi) = \bigcup \{ \mathfrak{U}(p_x) : x \in \mathfrak{V}_i(\psi) \}$ for all $\psi \in \mathbf{Sub}\varphi$, and so \mathfrak{F} refutes φ under \mathfrak{U}' . Thus $\mathfrak{F} \models \varphi$ implies $\mathfrak{F} \models \alpha(\mathfrak{F}_i, \mathbf{t}_i)$ for every i . The converse direction is rather technical; we refer the reader to [Wolter 1996c]. \blacksquare

“Canonical” axiomatizations of some standard linear tense logics are shown in Table 3, where we use the following abbreviations. Given a finite frame $\mathfrak{F} = C_1 \triangleleft \dots \triangleleft C_n$, we write $\alpha((C_1, \mathbf{t}C_1) \triangleleft \dots \triangleleft (C_n, \mathbf{t}C_n))$ instead of $\alpha(\mathfrak{F}, \mathbf{t})$ and $\alpha(-, (C_1, \mathbf{t}C_1) \triangleleft \dots \triangleleft (C_n, \mathbf{t}C_n))$ instead of

$$\alpha((C_1, \mathbf{t}C_1) \triangleleft \dots \triangleleft (C_n, \mathbf{t}C_n)) \oplus \alpha((\circ, (j, j)) \triangleleft (C_1, \mathbf{t}C_1) \triangleleft \dots \triangleleft (C_n, \mathbf{t}C_n)).$$

$\alpha((C_1, \mathbf{t}C_1) \triangleleft \dots \triangleleft (C_n, \mathbf{t}C_n), -)$ is defined analogously.

Now we exploit the formulas $\alpha(\mathfrak{F}, \mathbf{t})$ to characterize the \bigcap -irreducible logics in $\mathbf{NExtLin}$. Recall that every logic $L \in \mathbf{NExt}L_0$ is represented as

$$L = \bigcap \{ L' \supseteq L : L' \text{ is } \bigcap\text{-irreducible} \}.$$

So such a characterization can open the door to a better understanding of the structure of the lattice $\mathbf{NExtLin}$. The \bigcap -irreducible logics will be described semantically as the logics determined by certain descriptive frames.

DEFINITION 133.

- (1) Denote by \textcircled{k} the non-degenerate cluster with $k > 0$ points.
- (2) Let $\omega^{<}(0)$ be the strictly ascending chain $\langle \omega, <, > \rangle$ of natural numbers, $\omega^{<}(1)$ the chain $\langle \omega, \leq, \geq \rangle$, $\omega^{<}(2)$ the ascending chain of natural numbers in which precisely the even points are reflexive, $\omega^{<}(3)$ the chain in which precisely the multiples of 3 are reflexive, and so on; $\omega^{>}(n)$ is the mirror image of $\omega^{<}(n)$.

Table 3. Axiomatizations of standard tense logics

Ord_t	$= \text{Log}\{\langle \xi, <, > \rangle : \xi \text{ an ordinal}\} =$ $\mathbf{Lin} \oplus \alpha(-, (\circ, (j, m)))$
E_t	$= \mathbf{Lin} \oplus \diamond_1 \top \oplus \diamond_2 \top =$ $\mathbf{Lin} \oplus \alpha(-, (\bullet, (m, m))) \oplus \alpha((\bullet, (m, m)), -)$
O_n	$= \text{Log}\langle \omega n, <, > \rangle =$ $\mathbf{Ord}_t \oplus \alpha(\underbrace{((\circ, (m, j)) \triangleleft \cdots \triangleleft (\circ, (m, j)))}_{n+1}) \oplus \alpha(-, (\bullet, (m, m)))$
RD	$= \text{Log}\{\mathfrak{G} : \forall x(\neg xRx \rightarrow \exists y(xRy \wedge \{z : xRzRy\} = \emptyset))\} =$ $\mathbf{Lin} \oplus \alpha(-, (\bullet, (m, m))) \oplus \alpha(-, (\bullet, (m, m)) \triangleleft (\circ, (m, j)))$
LD	$= \text{the mirror image of RD}$
Z_t	$= \text{Log}\langle \mathbb{Z}, <, > \rangle =$ $\mathbf{RD} \oplus \mathbf{LD} \oplus \alpha((\circ, (j, j)) \triangleleft (\circ, (j, m))) \oplus$ $\alpha((\circ, (m, j)) \triangleleft (\circ, (j, j)))$
Ds_n	$= \mathbf{Lin} \oplus \Box_1^{n+1} p \rightarrow \Box_1^n p =$ $\mathbf{Lin} \oplus \alpha(-, \underbrace{(\bullet, (m, m)) \triangleleft \cdots \triangleleft (\bullet, (m, m))}_{n+1}), -)$
Q_t	$= \text{Log}\langle \mathbb{Q}, <, > \rangle =$ $\mathbf{Ds}_1 \oplus \mathbf{E}_t$
R_t	$= \text{Log}\langle \mathbb{R}, <, > \rangle =$ $\mathbf{Q}_t \oplus \alpha((\circ, (m, j)) \triangleleft (\circ, (j, m)))$
Rd_t	$= \text{Log}\{\langle \xi, \leq, \geq \rangle : \xi \text{ an ordinal}\} =$ $\mathbf{Lin} \oplus \alpha(-, (\circledast, (j, m)))$

- (3) $\mathfrak{C}(0, \textcircled{1})$ is the mirror image of the frame introduced in Example 128, i.e., $\mathfrak{C}(0, \textcircled{1}) = \langle \omega^<(0) \triangleleft \textcircled{1}, P \rangle$, where P consists of all cofinite sets containing $\textcircled{1}$ and their complements. We generalize this construction to chains $\omega^<(n)$ and clusters \textcircled{k} . Namely, for $n < \omega$, $k > 1$ and $\textcircled{k} = \{a_0, \dots, a_{k-1}\}$, we put

$$\mathfrak{C}(n, \textcircled{k}) = \langle \omega^<(n) \triangleleft \textcircled{k}, P \rangle,$$

where P is the set of possible values generated by $\{X_i : 0 \leq i \leq k-1\}$, for $X_i = \{a_i\} \cup \{kj + i : j \in \omega\}$, $0 \leq i \leq k-1$. $\mathfrak{C}(\textcircled{k}, n)$ denotes the mirror image of $\mathfrak{C}(n, \textcircled{k})$.

- (4) $\mathfrak{C}(0, \textcircled{1}, 0) = \langle \omega^<(0) \triangleleft \textcircled{1} \triangleleft \omega^>(0), P \rangle$, where P consists of all cofinite sets containing $\textcircled{1}$ and their complements.

It is easy to check that the frames defined in (3) and (4) are descriptive and a singleton $\{x\}$ is in P iff $x \notin \textcircled{k}$.

For a class of frames \mathcal{C} , we denote by \mathcal{C}^* the class of finite sequences of frames from \mathcal{C} and let $[\mathcal{C}^*] = \{[\mathfrak{F}] : \mathfrak{F} \in \mathcal{C}^*\}$. The class of finite clusters and the frames of the form (3) in Definition 133 is denoted by \mathcal{B}_0 ; put also $\mathcal{B} = \{\mathfrak{C}(0, \textcircled{1}, 0)\} \cup \mathcal{B}_0$.

THEOREM 134. *Each logic $L \in \text{NExtLin}$ is determined by a set $\mathcal{C} \subseteq [\mathcal{B}^*]$. If L is finitely axiomatizable then $L = \text{Log}\mathcal{C}$ for some set $\mathcal{C} \subseteq [\mathcal{B}_0^*]$.*

Proof. We explain the idea of the proof of the first claim. Suppose that $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{A} \rangle$ is a countermodel for $\alpha = \alpha((C_1, \mathfrak{t}C_1) \triangleleft \dots \triangleleft (C_n, \mathfrak{t}C_n))$ based on a descriptive frame $\mathfrak{F} = \langle W, R, R^{-1}, P \rangle$. We must show that there exists $\mathfrak{G} \in [\mathcal{B}^*]$ refuting α and such that $\text{Log}\mathfrak{G} \supseteq \text{Log}\mathfrak{F}$. Consider the sets

$$W_i = \{y \in W : (\mathfrak{M}, y) \models \bigvee \{p_x : x \in C_i\}\}.$$

One can easily show that W_i are intervals in \mathfrak{F} and $\mathfrak{F} = \mathfrak{F}_1 \triangleleft \dots \triangleleft \mathfrak{F}_n$, for the subframes \mathfrak{F}_i of \mathfrak{F} induced by W_i . Moreover, $\mathfrak{G} = [\overline{\mathfrak{G}}]$ is as required if $\overline{\mathfrak{G}} = \langle \mathfrak{G}_1, \dots, \mathfrak{G}_n \rangle$ is a sequence in \mathcal{B}^* such that $\text{Log}\mathfrak{G}_i \supseteq \text{Log}\mathfrak{F}_i$, and $\mathfrak{G}_i \not\models \alpha(C_i, \mathfrak{t}C_i)$, for $1 \leq i \leq n$. Frames \mathfrak{G}_i with those properties are constructed in [Wolter96d]. ■

EXAMPLE 135. The logic \mathbf{Q}_t is determined by the frames $\mathfrak{F} \in [\mathcal{B}^*]$ which contain no pair of adjacent irreflexive points, and \mathbf{R}_t is determined by the frames $\mathfrak{F} \in [\mathcal{B}^*]$ which contain neither a pair of adjacent irreflexive points nor a pair of adjacent non-degenerate clusters.

It is not difficult to show now that the logics $\text{Log}\mathfrak{F}$, for $\mathfrak{F} \in [\mathcal{B}^*]$, coincide with the \bigcap -irreducible logics in NExtLin . Our first aim is achieved, and

in the remaining part of this section we shall draw consequences of this result. Using the same sort of arguments as in the proof of Theorem 126 and Kruskal's [1960] Tree Theorem one can prove

COROLLARY 136. (i) *All finitely axiomatizable logics in $\mathbf{NExtLin}$ are decidable.*

(ii) *A logic L is finitely axiomatizable whenever there exists $n < \omega$ such that $L \in \mathbf{NExtDs}_n$.*

It follows in particular that all logics in \mathbf{NExtQ}_t and all logics of reflexive frames are finitely axiomatizable and decidable.

Now we formulate two corollaries concerning the Kripke completeness of linear tense logics. First, it is not hard to see that every logic in $\mathbf{NExtLin}$ characterized by an infinite frame in $[\mathcal{B}^*]$ is Kripke incomplete. Using this observation one can prove

COROLLARY 137. *Suppose $L \in \mathbf{NExtLin}$ and there is a Kripke frame of infinite depth for L . Then there exists a Kripke incomplete logic in \mathbf{NExtL} .*

This result means in particular that in Tense Logic we do not have analogues of the unimodal completeness results of Bull [1966b] and Fine [1974c]. However, if a logic is complete then it is determined by a simple class of frames. Let \mathcal{K} be the class frames containing finite clusters and frames of the form (2) in Definition 133.

THEOREM 138. *Each Kripke complete logic in $\mathbf{NExtLin}$ is determined by a subset of $[\mathcal{K}^*]$.*

One of the main types of logics considered in conventional Tense Logic are logics determined by strict linear orders, known also as *time-lines*. We call them *t-line logics*. All logics in Table 3, save \mathbf{Rd}_t , are t-line logics. T-line logics were defined semantically, and now we are going to determine a necessary syntactic condition for a linear tense logic to be a t-line logic.

Given a frame \mathfrak{F} , we denote by \mathfrak{F}° the frame that results from \mathfrak{F} by replacing its proper clusters with reflexive points. Call $L \in \mathbf{NExtLin}$ a *t-axiom logic* if L is axiomatizable by a set of formulas of the form $\alpha(\mathfrak{F}, \mathbf{t})$ in which \mathfrak{F} contains no proper clusters.

PROPOSITION 139. *The following conditions are equivalent for all logics $L \in \mathbf{NExtLin}$:*

- (i) *L is a t-axiom logic;*
- (ii) *$\mathfrak{F}^\circ \models L$ implies $\mathfrak{F} \models L$, for every $\mathfrak{F} \in [\mathcal{B}^*]$.*
- (iii) *$\alpha(\mathfrak{G}, \mathbf{t}) \in L$ implies $\alpha(\mathfrak{G}^\circ, \mathbf{t}) \in L$,¹⁵ for every finite \mathfrak{G} .*

¹⁵We assume that $\mathbf{t}C = \mathbf{to}$ whenever \circ replaces C in \mathfrak{G} .

Proof. The implications (i) \Rightarrow (ii) and (iii) \Rightarrow (i) are clear. To prove that (ii) \Rightarrow (iii), suppose $\alpha(\mathfrak{G}^\circ, \mathbf{t}) \notin L$. Then there exists a frame $\mathfrak{F} \in [\mathcal{B}^*]$ for L refuting $\alpha(\mathfrak{G}^\circ, \mathbf{t})$. Without loss of generality we may assume that \mathfrak{F} contains no proper clusters. By enlarging some clusters in \mathfrak{F} we can construct a frame $\mathfrak{H} \in [\mathcal{B}^*]$ such that $\mathfrak{H}^\circ = \mathfrak{F}$ and $\mathfrak{H} \not\models \alpha(\mathfrak{G}, \mathbf{t})$. In view of (ii), $\mathfrak{H} \models L$ and so $\alpha(\mathfrak{G}, \mathbf{t}) \notin L$. \blacksquare

It follows that the t-axiom logics form a complete sublattice of the lattice $\mathbf{NExtLin}$.

THEOREM 140.

- (i) *All finitely axiomatizable t-axiom logics are Kripke complete.*
- (ii) *All t-line logics are t-axiom logics.*

Proof. (i) Suppose that $L = \mathbf{Lin} \oplus \{\alpha(\mathfrak{G}_i^\circ, \mathbf{t}_i) : i \in I\}$, for some finite set I . By Theorem 134, L is determined by a subset of $[\mathcal{B}_0^*]$. For $\mathfrak{F} \in [\mathcal{B}_0^*]$, let $k\mathfrak{F}$ be the Kripke frame that results from \mathfrak{F} by replacing all $\mathfrak{C}(n, \mathbb{k})$ and $\mathfrak{C}(\mathbb{k}, n)$ with $\omega^{<}(n)$ and $\omega^{>}(n)$, respectively. Then we clearly have $\text{Log}k\mathfrak{F} \subseteq \text{Log}\mathfrak{F}$, and $\mathfrak{F} \models \alpha(\mathfrak{G}^\circ, \mathbf{t})$ iff $k\mathfrak{F} \models \alpha(\mathfrak{G}^\circ, \mathbf{t})$. It follows that L is Kripke complete. (ii) Suppose that L is a t-line logic. By Proposition 139 (3), it suffices to observe that $\mathfrak{F} \models \alpha(\mathfrak{G}^\circ, \mathbf{t})$ iff $\mathfrak{F} \models \alpha(\mathfrak{G}, \mathbf{t})$, for all time-lines \mathfrak{F} and all finite \mathfrak{G} . \blacksquare

So the fact that in Table 3 all t-line logics are axiomatized by canonical formulas of the form $\alpha(\mathfrak{G}^\circ, \mathbf{t})$ is no accident. Finding and verifying axiomatizations of t-line logics becomes almost trivial now.

EXAMPLE 141. Let us check the axiomatization of \mathbf{Z}_t in Table 3. Put

$$L = \mathbf{RD} \oplus \mathbf{LD} \oplus \alpha((\circ, (j, j)) \triangleleft (\circ, (j, m))) \oplus \alpha((\circ, (m, j)) \triangleleft (\circ, (j, j))).$$

By Theorem 140, L is complete. By Theorem 138, L is then determined by a subset of $[\mathcal{K}^*]$. Clearly this set contains $\langle \mathbb{Z}, <, > \rangle$, possibly \mathbb{k} for $k > 0$, and nothing else. But the logic of \mathbb{k} contains \mathbf{Z}_t , for all $k > 0$.

We conclude this section by discussing the decidability of properties of logics in $\mathbf{NExtLin}$. In Section 4.4 it will be shown that almost all interesting properties of calculi are undecidable in \mathbf{NExtK} and even in $\mathbf{NExtS4}$. In $\mathbf{NExtLin}$ the situation is different, as was proved in [Wolter 1996c, 1997c].

THEOREM 142. (i) *There are algorithms which, given a formula φ , decide whether $\mathbf{Lin} \oplus \varphi$ has FMP, interpolation, whether it is Kripke complete, strongly complete, canonical, \mathcal{R} -persistent.*

(ii) *A linear tense logic is canonical iff it is \mathcal{D} -persistent iff it is complete and its frames are first order definable.*

(iii) *If a logic in NExtLin has a frame of infinite depth then it does not have interpolation.*

So NExtLin provides an interesting example of a rather complex lattice of modal logics for which almost all important properties of calculi are decidable. We shall not go into details of the proof here but discuss quite natural criteria for canonicity and strong completeness of logics in NExtLin required to prove this theorem. Denote by \mathcal{B}_+ the class of frames containing \mathcal{B} together with frames $\mathfrak{C}(n_1, \mathbb{k}, n_2)$ defined as follows. Suppose $k > 1$, $n_1, n_2 < \omega$ are such that $n_1 + n_2 > 0$ and $\mathbb{k} = \{a_0, \dots, a_{k-1}\}$. Then

$$\mathfrak{C}(n_1, \mathbb{k}, n_2) = \langle \omega^{<}(n_1) \triangleleft \mathbb{k} \triangleleft \omega^{>}(n_2), P \rangle,$$

where P is the set of possible values generated by $\{X_i : 0 \leq i \leq k-1\}$, for

$$X_i = \{a_i\} \cup \{kj + i : j \in \omega\} \cup \{k^*j^* + i^* : j \in \omega\}$$

and $\{0^*, 1^*, \dots, n^*, \dots\}$ being the points in $\omega^{>}(n_2)$.

Let \mathcal{F} be the class of frames of the form

$$\langle \{0, \dots, n_1\}, <, > \rangle \triangleleft \mathbb{1} \triangleleft \langle \{0, \dots, n_2\}, <, > \rangle \text{ or } \langle \{0, \dots, n\}, <, > \rangle.$$

THEOREM 143. (i) *A logic $L \in \text{NExtLin}$ is canonical iff the underlying Kripke frame of each frame $\mathfrak{F} \in [\mathcal{B}_+^*]$ for L validates L as well.*

(ii) *A logic $L \in \text{NExtLin}$ is strongly complete iff for each frame $\mathfrak{F} \in [\mathcal{B}_+^*]$ validating L , there exists a Kripke frame \mathfrak{G} for L which results from \mathfrak{F} by replacing*

- every $\mathfrak{C}(n, \mathbb{k})$ with $\omega^{<}(n)$ or $\omega^{<}(n) \triangleleft \mathfrak{H} \triangleleft \mathbb{k}$, for some $\mathfrak{H} \in \mathcal{F}$, and
- every $\mathfrak{C}(\mathbb{k}, n)$ with $\omega^{>}(n)$ or $\mathbb{k} \triangleleft \mathfrak{H} \triangleleft \omega^{>}(n)$, for some $\mathfrak{H} \in \mathcal{F}$, and
- every $\mathfrak{C}(n_1, \mathbb{k}, n_2)$ with $\omega^{<}(n_1) \triangleleft \mathfrak{H} \triangleleft \omega^{>}(n_2)$, for some $\mathfrak{H} \in \mathcal{F}$.

EXAMPLE 144. The logic \mathbf{R}_t is not canonical because $\mathfrak{C}(2, \mathbb{2}) \models \mathbf{R}_t$ but $\omega^{<}(2) \triangleleft \mathbb{2} \not\models \mathbf{R}_t$. However, \mathbf{R}_t is strongly complete, since $\mathfrak{F} \models \mathbf{R}_t$ whenever $\mathfrak{G} \in [\mathcal{B}_+^*]$ validates \mathbf{R}_t and \mathfrak{F} is obtained from \mathfrak{G} as in the formulation of Theorem 143 with $\mathfrak{H} = \bullet \in \mathcal{F}$.

One can also use Theorem 143 to construct two strongly complete logics $L_1, L_2 \in \text{NExtLin}$ whose sum $L_1 \oplus L_2$ is not strongly complete (see [Wolter 1996b]).

2.6 Bimodal provability logics

Bimodal provability logics emerge when combinations of two different provability predicates are investigated, for example, if \Box_1 is understood as “it

is provable in PA” and \Box_2 as “it is provable in ZF”. In contrast to the situation in unimodal provability logic, where almost all provability predicates behave like the necessity operator \Box in **GL**, there exist quite a lot of different types of bimodal provability logics. Various completeness results extending Solovay’s completeness theorem for **GL** to the bimodal case were established by Smoryński [1985], Montagna [1987], Beklemishev [1994, 1996] and Visser [1995]. Here we will not deal with the interpretation of modal operators as provability predicates but sketch some results on modal logics containing the bimodal provability logic

$$\mathbf{CSM}_0 = (\mathbf{GL} \otimes \mathbf{GL}) \oplus \Box_1 p \rightarrow \Box_2 p \oplus \Box_2 p \rightarrow \Box_1 \Box_2 p$$

(named so by Visser [1995] after Carlson, Smoryński and Montagna). A number of provability logics is included in this class, witness the list below. (As in unimodal provability logic we have quasi-normal logics among them, i.e., sets of formulas containing \mathbf{K}_2 and closed under modus ponens and substitutions (but not necessarily under $\varphi/\Box_i\varphi$). Recall that we denote by $L + \Gamma$ the smallest quasi-normal logic containing L and Γ .)

- $\mathbf{CSM}_1 = \mathbf{CSM}_0 \oplus \Box_2(\Box_1 p \rightarrow p)$. (This is \mathbf{PRL}_{ZF} in [Smoryński 1985] and \mathbf{F} in [Montagna 1987].)
- $\mathbf{NB}_1 = \mathbf{CSM}_0 \oplus (\neg\Box_1 p \wedge \Box_2 p) \rightarrow \Box_2(\Box_1 q \rightarrow q)$.
- $\mathbf{CSM}_2 = \mathbf{CSM}_1 + \Box_1 p \rightarrow p$. (This is $\mathbf{PRL}_{ZF} + \text{Reflection}_{\Box_1}$ in [Smoryński 1985] and \mathbf{F}_1 in [Montagna 1987].)
- $\mathbf{CSM}_3 = \mathbf{CSM}_2 + \Box_2 p \rightarrow p$. (This is $\mathbf{PRL}_{ZF} + \text{Reflection}_{\Box_2}$ in [Smoryński 1985].)
- $\mathbf{NB}_2 = \mathbf{NB}_1 + \Box_2 p \rightarrow p + \Box_2 p \rightarrow \Box_1 p$.

A remarkable feature of \mathbf{CSM}_0 is that—like in **GL**—we have uniquely determined definable fixed points.

THEOREM 145 (Smoryński 1985). *Let $\varphi(p)$ be a formula in which every occurrence of p lies within the scope of some \Box_1 or some \Box_2 . Then*

- (i) *there exists a formula ψ containing only the propositional variables of $\varphi(p)$ different from p such that $\psi \leftrightarrow \varphi(\psi) \in \mathbf{CSM}_0$;*
- (ii) $\Box_1((p \leftrightarrow \varphi(p)) \wedge (q \leftrightarrow \varphi(q))) \rightarrow (p \leftrightarrow q) \in \mathbf{CSM}_0$.

In the remaining part of this section we are concerned with subframe logics containing \mathbf{CSM}_0 , the main result stating that those of them that are finitely axiomatizable are decidable. All the provability logics introduced above turn out to be subframe logics, so we obtain a uniform proof of their decidability. An interesting trait of subframe logics in ExtCSM_0 is that (as a rule) they are Kripke incomplete; in the list above such are \mathbf{CSM}_i ,

$i = 1, 2, 3$, and \mathbf{NB}_i , $i = 1, 2$. The proof extends the techniques introduced by Visser [1995]; for details we refer the reader to [Wolter 1998].

First we develop—as was done for $\mathbf{NExtK4}$ and $\mathbf{NExtLin}$ —a frame theoretic language for axiomatizing subframe logics in the lattice \mathbf{ExtCSM}_0 . A finite frame $\mathfrak{G} = \langle W, R_1, R_2 \rangle$ validates \mathbf{CSM}_0 iff both R_1 and R_2 are transitive, irreflexive, $R_2 \subseteq R_1$ and

$$\forall x, y, z (xR_1y \wedge yR_2z \rightarrow xR_2z).$$

In this section all (not only finite) frames are assumed to satisfy these conditions, *save irreflexivity*.

A finite frame \mathfrak{F} is called a *surrogate frame* if it has precisely one root r and all points different from r are R_2 -irreflexive. Surrogate frames will provide the language to axiomatize subframe logics in \mathbf{ExtCSM}_0 . A *normal surrogate frame* $\langle W, R_1, R_2 \rangle$ is a surrogate frame in which the root r is R_1 -irreflexive. We write $xR_i^p y$ iff $xR_i y$ and $\neg yR_i x$. Given a frame $\mathfrak{G} = \langle V, S_1, S_2, Q \rangle$ for \mathbf{CSM}_0 and a surrogate frame $\mathfrak{F} = \langle W, R_1, R_2 \rangle$, a map h from V onto W is called a *weak reduction* of \mathfrak{G} to \mathfrak{F} if for $i \in \{1, 2\}$ and all $x, y \in V$,

- $xS_i y$ implies $f(x)R_i f(y)$,
- $f(x)R_i^p f(y)$ implies $\exists z \in V (xS_i z \wedge f(z) = f(y))$,
- $f^{-1}(X) \in Q$ for all $X \subseteq W$.

(The standard definition of reduction is relaxed here in the second condition.) Each weak reduction to a \mathbf{CSM}_0 -frames is a usual reduction, since in this case $R_i^p = R_i$. A frame \mathfrak{G} is said to be *weakly subreducible* to a surrogate frame \mathfrak{F} if a subframe of \mathfrak{G} is weakly reducible to \mathfrak{F} . To describe weak subreducibility syntactically, with each surrogate frame $\mathfrak{F} = \langle W, R_1, R_2 \rangle$ we associate the formula

$$\alpha(\mathfrak{F}) = \delta(\mathfrak{F}) \wedge \Box_1 \delta(\mathfrak{F}) \rightarrow \neg p_r,$$

where r is the root of \mathfrak{F} and

$$\begin{aligned} \delta(\mathfrak{F}) = & \bigwedge \{p_x \rightarrow \Diamond_1 p_y : xR_1^p y, x, y \in W\} \wedge \\ & \bigwedge \{p_x \rightarrow \Diamond_2 p_y : xR_2^p y, x, y \in W\} \wedge \\ & \bigwedge \{p_x \rightarrow \neg p_y : x \neq y, x, y \in W\} \wedge \\ & \bigwedge \{p_x \rightarrow \neg \Diamond_1 p_y : \neg(xR_1 y), x, y \in W\} \wedge \\ & \bigwedge \{p_x \rightarrow \neg \Diamond_2 p_y : \neg(xR_2 y), x, y \in W\}. \end{aligned}$$

LEMMA 146. *For every surrogate frame \mathfrak{F} and every \mathbf{CSM}_0 -frame \mathfrak{G} , we have $\mathfrak{G} \models \alpha(\mathfrak{F})$ iff \mathfrak{G} is weakly subreducible to \mathfrak{F} .*

Table 4. Axiomatizations of provability logics

\mathbf{CSM}_1	=	$\mathbf{CSM}_0 \oplus \alpha(\overset{\bullet}{\uparrow})$
$\mathbf{CSM}_0 + \Box_1 p \rightarrow p$	=	$\mathbf{CSM}_0 + \alpha(\bullet)$
$\mathbf{CSM}_0 + \Box_2 p \rightarrow p$	=	$\mathbf{CSM}_0 + \alpha(\overset{1}{\circ})$
$\mathbf{CSM}_0 + \Box_2 p \rightarrow \Box_1 p$	=	$\mathbf{CSM}_0 + \alpha(\overset{\circ 1}{\circ 1})$
\mathbf{NB}_1	=	$\mathbf{CSM}_0 \oplus \alpha(\overset{1}{\rightarrow}) \oplus \alpha(\overset{1}{\leftarrow}) \oplus$ $\alpha(\overset{1}{\rightarrow}) \oplus \alpha(\overset{1}{\leftarrow})$

It follows immediately that $\mathbf{CSM}_0 \oplus \alpha(\mathfrak{F})$ and $\mathbf{CSM}_0 + \alpha(\mathfrak{F})$ are subframe logics. Conversely, we have the following completeness result.

THEOREM 147.

- (i) *There is an algorithm which, given a formula φ such that $\mathbf{CSM}_0 + \varphi$ is a subframe logic, returns surrogate frames $\mathfrak{F}_1, \dots, \mathfrak{F}_n$ for which*

$$\mathbf{CSM}_0 + \varphi = \mathbf{CSM}_0 + \alpha(\mathfrak{F}_1) + \dots + \alpha(\mathfrak{F}_n).$$

- (ii) *There is an algorithm which, given a formula φ such that $\mathbf{CSM}_0 \oplus \varphi$ is a subframe logic, returns normal surrogate frames $\mathfrak{F}_1, \dots, \mathfrak{F}_n$ such that*

$$\mathbf{CSM}_0 \oplus \varphi = \mathbf{CSM}_0 \oplus \alpha(\mathfrak{F}_1) \oplus \dots \oplus \alpha(\mathfrak{F}_n).$$

Table 4 shows axiomatizations of the logics introduced above by means of formulas of the form $\alpha(\mathfrak{F})$. In this section we adopt the convention that in figures we place the number 1 nearby an arrow from x to y if xR_1y and $\neg xR_2y$. An arrow without a number means that xR_2y (and therefore xR_1y as well).

The proof of decidability is based on the completeness of subframe logics in ExtCSM_0 with respect to rather simple descriptive frames. With every surrogate frame \mathfrak{F} we associate a finite set of frames

$$E(\mathfrak{F}) = \{\mathfrak{F}_{\overline{A}} : \overline{A} \in \text{Seq}\mathfrak{F}\}.$$

Loosely, it is defined as follows. Let us first assume that the root r of \mathfrak{F} is R_2 -irreflexive. Then the frames in $E(\mathfrak{F})$ are the results of inserting an infinite strictly descending R_1 -chain, denoted by $C(\omega)$, between each non-degenerate R_1 -cluster C and its R_1 -successors. This defines R_1 uniquely. However, R_2 may be defined in different ways, since a point R_2 -seeing a point in C need not (but may) R_2 -see certain points in the chain $C(\omega)$.

To be more precise, the set $\text{Seq}\mathfrak{F}$ consists of all sequences \bar{A} of the form

$$\bar{A} = \langle A_x : xR_1x, x \in W \rangle.$$

where A_x is a subset of $\{y \in W - C : yR_2x\}$ such that for all y and z , $y \in A_x$ and zR_1y imply $z \in A_x$. For each non-degenerate R_1 -cluster C , denote by $C(\omega)$ the set $\{(n, C) : n \in \omega\}$. Finally, given $\bar{A} \in \text{Seq}\mathfrak{F}$, we construct $\mathfrak{F}_{\bar{A}} = \langle V, S_0, S_1 \rangle$ as the frame satisfying the following conditions:

- $V = W \cup \bigcup \{C(\omega) : C \text{ a non-degenerate } R_1\text{-cluster in } \mathfrak{F}\}$;
- $R_i = S_i \cap (W \times W)$, for $i \in \{1, 2\}$;
- S_1 is defined so that $C(\omega)$ becomes an infinite descending chain between C and its immediate successors;
- for every non-degenerate R_1 -cluster C ,
 - $((C(\omega) \cup C) \times (C(\omega) \cup C)) \cap S_2 = \emptyset$,
 - for all $y \in W - C$ and $x \in C(\omega)$, xS_2y iff CR_2y ,
 - for all $y \in W - C$, $C = \{j : 0 \leq j \leq m - 1\}$ and $x \in C(\omega)$, yS_2x iff $\exists i \in \omega \exists j \leq m - 1 (x = (im + j, C) \wedge y \in A_j)$,
 - for all $x \in C(\omega)$ and $y \in V - C$, xS_2y iff CS_2y .

We illustrate this technical definition by a simple example.

EXAMPLE 148. Construct $E(\mathfrak{F})$ for the frame \mathfrak{F} in Fig. 12 (a). In this case we have two R_1 -reflexive points, namely c and d . So, $\text{Seq}\mathfrak{F}$ consists of pairs $\langle A_c, A_d \rangle$. There are four different pairs and so we have four frames in $E(\mathfrak{F})$: the frame in Fig. 12 (b) is $\mathfrak{F}_{\langle \emptyset, \emptyset \rangle}$ and that in (c) is $\mathfrak{F}_{\langle \{a\}, \{b\} \rangle}$. $\mathfrak{F}_{\langle \emptyset, \{b\} \rangle}$ is obtained from $\mathfrak{F}_{\langle \{a\}, \{b\} \rangle}$ by omitting the R_2 -arrows starting from a , save the arrow to c , and $\mathfrak{F}_{\langle \{a\}, \emptyset \rangle}$ is obtained from $\mathfrak{F}_{\langle \{a\}, \{b\} \rangle}$ by omitting the R_2 -arrows starting from b , save the arrow to d .

Suppose now that the root r of $\mathfrak{F} = \langle W, R_1, R_2 \rangle$ is R_2 -reflexive. We define $\mathfrak{F}_{\bar{A}}$ as in the previous case, but this time we also insert an infinite strictly descending R_2 -chain $C(\omega)$ between r and its R_1 -successors.

We have defined the relational component of our frames and now turn to their sets of possible values. Given $\mathfrak{F}_{\bar{A}} = \langle V, S_1, S_2 \rangle$ and a non-degenerate R_1 -cluster $C = \{j : 0 \leq j \leq m - 1\}$ in \mathfrak{F} , let

$$P_C = \{\{j\}\} \cup \{(im + j, C) : i \in \omega\} : j = 0, \dots, m - 1\}$$

Figure 12.

and denote by P the closure of

$$\{\{x\} : x \in V, \neg xS_1x\} \cup \{P_C : C \text{ is a non-degenerate } R_1\text{-cluster in } \mathfrak{F}\}$$

under intersections and complements in V . The resultant general frame is denoted by $\mathfrak{G}(\overline{\mathfrak{F}}_A) = \langle V, S_1, S_2, P \rangle$. One can check that it is a descriptive frame for \mathbf{CSM}_0 . The following completeness result is proved similarly to that in Section 2.4.

THEOREM 149.

- (i) *Each subframe logic in $\mathbf{NExtCSM}_0$ is determined by a set of frames of the form $\mathfrak{G}(\overline{\mathfrak{F}}_A)$, in which \mathfrak{F} is a normal surrogate frame and $A \in \text{Seq}\mathfrak{F}$.*
- (ii) *Each subframe logic in \mathbf{ExtCSM}_0 is determined by a set of frames with distinguished worlds of the form $\langle \mathfrak{G}(\overline{\mathfrak{F}}_A), r \rangle$ in which \mathfrak{F} is a surrogate frame with root r and $\overline{A} \in \text{Seq}\mathfrak{F}$.*

As a consequence of Theorem 149 and the fact that, for each surrogate frame \mathfrak{F} with root r and each $\overline{A} \in \text{Seq}\mathfrak{F}$, both the logics of $\mathfrak{G}(\overline{\mathfrak{F}}_A)$ and $\langle \mathfrak{G}(\overline{\mathfrak{F}}_A), r \rangle$ are decidable, we obtain

THEOREM 150. *All finitely axiomatizable subframe logics in \mathbf{ExtCSM}_0 are decidable.*

We conjecture that the method above can be extended to logics without the **GL**-axioms, i.e., all finitely axiomatizable subframe logics containing

$$(\mathbf{K4} \otimes \mathbf{K4}) \oplus \Box_1 p \rightarrow \Box_2 p \oplus \Box_2 p \rightarrow \Box_1 \Box_2 p$$

are decidable.

2.7 Cartesian products of modal logics

Polymodal logics can be used for talking about multi-dimensional relational structures such as Cartesian products of Kripke frames. The formation of products is probably the most natural way of introducing a concept of dimension in modal logic in order to reflect interactions between modal operators representing time, space, knowledge, actions, etc. Products of modal logics (i.e., the sets of polymodal formulas that are valid in Cartesian products of Kripke frames for those logics) have been studied in both pure modal logic (see e.g. [Segerberg 1973], [Shehtman 1978a], [Marx and Venema 1997], [Gabbay and Shehtman 1998], [Kurucz 2000], [Wolter 2000]) and applications in computer science and artificial intelligence (see e.g. [Reif and Sistla 1985], [Fagin *et al.* 1995], [Baader and Ohlbach 1995], [Finger and Reynolds 1999], [Wolter and Zakharyashev 1998, 1999b, 1999c, 2000]) since the 1970s. (Products of modal logics are also relevant to finite variable fragments of modal and intermediate predicate logics; see [Gabbay and Shehtman 1993].)

The (*Cartesian*) *product* of two frames $\mathfrak{F}_1 = \langle W_1, R_1 \rangle$ and $\mathfrak{F}_2 = \langle W_2, R_2 \rangle$ is the bimodal frame of the form

$$\mathfrak{F}_1 \times \mathfrak{F}_2 = \langle W_1 \times W_2, R_h, R_v \rangle$$

in which, for all $u_1, u_2 \in W_1$ and $v_1, v_2 \in W_2$,

$$\begin{aligned} \langle u_1, v_1 \rangle R_h \langle u_2, v_2 \rangle &\text{ iff } u_1 R_1 u_2 \text{ and } v_1 = v_2, \\ \langle u_1, v_1 \rangle R_v \langle u_2, v_2 \rangle &\text{ iff } u_1 = u_2 \text{ and } v_1 R_2 v_2. \end{aligned}$$

The subscripts h and v appeal to the geometrical intuition of considering R_h as the “horizontal” accessibility relation in $\mathfrak{F}_1 \times \mathfrak{F}_2$ and R_v as the “vertical” one.

Let \mathcal{L}_2 be the bimodal language with boxes \Box and \square (and their duals \Diamond and \diamond). Frames for this language will be denoted by $\mathfrak{F} = \langle W, R_h, R_v \rangle$, so that \Box and \square are interpreted by the relations R_h and R_v , respectively. Products are just special frames of this form.

Every product $\mathfrak{F} = \mathfrak{F}_1 \times \mathfrak{F}_2$ satisfies the following two important properties: $R_v \circ R_h = R_h \circ R_v$ and $R_v^{-1} \circ R_h \subseteq R_h \circ R_v^{-1}$, known as *commutativity* and the *Church–Rosser property*, respectively. \mathfrak{F} is commutative iff it validates the formula

$$\mathbf{com} = \diamond \Diamond p \leftrightarrow \Diamond \diamond p,$$

and \mathfrak{F} is Church–Rosser iff it validates

$$\mathbf{chr} = \Diamond \square p \rightarrow \square \diamond p.$$

It is to be noted, however, that these properties are not characteristic for products: there are bimodal commutative and Church–Rosser frames that are not (isomorphic to) products of any two frames.

Given two classes of Kripke frames \mathcal{C}_1 and \mathcal{C}_2 , we define their (*Cartesian*) *product* $\mathcal{C}_1 \times \mathcal{C}_2$ by taking

$$\mathcal{C}_1 \times \mathcal{C}_2 = \{\mathfrak{F}_1 \times \mathfrak{F}_2 : \mathfrak{F}_1 \in \mathcal{C}_1, \mathfrak{F}_2 \in \mathcal{C}_2\}.$$

Let \mathcal{C}_1 and \mathcal{C}_2 be the classes of all Kripke frames for complete unimodal logics L_1 and L_2 . Their (*Cartesian*) *product* $L_1 \times L_2$ is defined as the bimodal logic $\text{Log}(\mathcal{C}_1 \times \mathcal{C}_2)$ in the language \mathcal{L}_2 . It is easy to see that $L_1 \times L_2$ is a conservative extension of both L_1 and L_2 , and that

$$L_1 \times L_2 \supseteq (L_1 \otimes L_2) \oplus \mathbf{com} \oplus \mathbf{chr}.$$

In some important cases the converse inclusion also holds:

THEOREM 151 (Gabbay and Shehtman 1998). *Suppose both L_1 and L_2 are axiomatized by variable free formulas and formulas of the form*

$$\diamond^n \Box p \rightarrow \Box^m p.$$

Then

$$L_1 \times L_2 = (L_1 \otimes L_2) \oplus \mathbf{com} \oplus \mathbf{chr}.$$

This theorem yields, for instance, axiomatizations for products of **K**, **D**, **K4**, **T**, **S4**, **S5**. However there are many products of standard logics which cannot be axiomatized in this canonical way, for instance, **Grz** \times **Grz** (see [Gabbay and Shehtman 1998]). Moreover, products of logics of linear frames may be even not recursively enumerable, e.g. **GL.3** \times **GL.3** (see [Reynolds and Zakharyashev 2000]). (On the other hand, as was observed in [Gabbay and Shehtman 1998], if classes $\mathcal{C}_1, \dots, \mathcal{C}_n$ are elementary and recursive then $\text{Log}(\mathcal{C}_1 \times \dots \times \mathcal{C}_n)$ is recursively axiomatizable.)

In contrast to the unimodal case, usually it is rather difficult to prove positive results about products of even simple standard logics. Here we illustrate one of the methods of establishing FMP and decidability developed in [Wolter and Zakharyashev 1998, 1999b] by applying it to **S5** \times **S5**. Other techniques—filtration, finite depth method, and mosaic—can be found in [Gabbay and Shehtman 1998] and [Marx and Venema 1997].

S5 \times **S5** is clearly determined by the class of products of universal frames which will be called **S5-rectangles**. Suppose we are given a formula φ and want to find out whether it is satisfiable in some **S5**-rectangle.

Let us call a *type* for φ any subset t of $\mathbf{Sub}\varphi$ such that

- $\psi \wedge \chi \in t$ iff $\psi \in t$ and $\chi \in t$, for every $\psi \wedge \chi \in \mathbf{Sub}\varphi$,
- $\neg\psi \in t$ iff $\psi \notin t$, for every $\neg\psi \in \mathbf{Sub}\varphi$.

A *type-cluster* for φ is a set T of distinct types for φ such that

$$\forall t \in T \forall \psi \in \mathbf{Sub}\varphi (\psi \in t \leftrightarrow \exists t' \in T \psi \in t').$$

Let Ω be a non-empty set elements a in which are labelled by type-clusters \mathbf{T} for φ . In other words, we can think of Ω as consisting of pairs of the form \mathbf{T}_a with pairwise distinct a .

A *run through* Ω (or a Ω -*run*, for short) is a function \mathbf{r} from Ω to the set of types for φ such that

- $\mathbf{r}(\mathbf{T}_a) \in \mathbf{T}$ for every $\mathbf{T}_a \in \Omega$, and
- $\forall \mathbf{T}_a \in \Omega \forall \diamond\psi \in \mathbf{Sub}\varphi (\diamond\psi \in \mathbf{r}(\mathbf{T}_a) \leftrightarrow \exists sc_b \in \Omega \psi \in \mathbf{r}(sc_b))$.

Say that Ω is a *quasimodel* for φ if, for every $\mathbf{T}_a \in \Omega$ and every $\mathbf{t} \in \mathbf{T}$, there is a Ω -run \mathbf{r} coming through \mathbf{t} , i.e., $\mathbf{r}(\mathbf{T}_a) = \mathbf{t}$. Ω *satisfies* φ if φ belongs to a type occurring in a type-cluster in Ω .

One can readily show that a formula φ is satisfied in an **S5**-rectangle iff φ is satisfied in some quasimodel for φ .

We prove now that every satisfiable formula φ is satisfied in a quasimodel of some bounded size. Let Ω be a quasimodel satisfying φ . Construct a subquasimodel Ω' of Ω in the following way. To begin with, we put in Ω' an element a_0 from Ω labelled by a type-cluster \mathbf{T} containing a type with φ . Then, for every $\mathbf{t} \in \mathbf{T}$ we take a run \mathbf{r} coming through \mathbf{t} , and for each $\diamond\psi \in \mathbf{t}$ select $\mathbf{r}(a)$ containing ψ and put in Ω' the element a together with its copy a' (labelled by the same type-cluster as a). Thus the resulting Ω' contains at most $2^{|\mathbf{Sub}\varphi|} \cdot 2 \cdot |\mathbf{Sub}\varphi|$ elements. It is now easy to see that Ω' is a quasimodel satisfying φ . For suppose we have an element $a \in \Omega'$ labelled by \mathbf{T} and a $\mathbf{t} \in \mathbf{T}$. If $a = a_0$ then, by the construction, we have a Ω' -run coming through \mathbf{t} . Assume now that $a \neq a_0$. We know that there is a Ω -run \mathbf{r}' through \mathbf{t} . Let $\mathbf{r}'(a_0) = \mathbf{t}'$. By the construction we have a Ω' -run \mathbf{r}'' through \mathbf{t}' . But then the function \mathbf{r} defined by

$$\mathbf{r}(b) = \begin{cases} \mathbf{r}'(b) & \text{if } b = a \\ \mathbf{r}''(b) & \text{otherwise,} \end{cases}$$

for $b \in \Omega'$, is a run in Ω' coming through \mathbf{t} . Note that this gives us $2^{2^{|\mathbf{Sub}\varphi|}} \cdot 2 \cdot |\mathbf{Sub}\varphi|$ runs in Ω' coming through all its types. As a consequence we obtain:

THEOREM 152. *Every formula satisfiable in an **S5**-rectangle is satisfied in an **S5**-rectangle containing at most $2^{3^{|\mathbf{Sub}\varphi|}} \cdot 4 \cdot |\mathbf{Sub}\varphi|^2$ points. Thus **S5** \times **S5** has FMP and is decidable.*

Unfortunately, there is no general transfer theorem that could guarantee the preservation of such properties of logics as decidability, axiomatizability, or interpolation under the formation of products. If we consider only products of standard modal logics, then the results obtained so far can roughly be described as follows (for more details consult [Spaan 1993], [Marx and Venema 1997], [Gabbay and Shehtman 1998], [Marx and Areces 1998], [Marx 1999], [Wolter 2000], [Reynolds and Zakharyashev 2000]):

- logics of the form $\mathbf{K} \times L$ and $\mathbf{S5} \times L$ are usually decidable (in particular, for $L \in \{\mathbf{K}, \mathbf{T}, \mathbf{K4}, \mathbf{K4.3}, \mathbf{S4}, \mathbf{S5}\}$);
- products of logics determined by infinite linear orders are undecidable,
- the computational complexity of a decidable product is usually substantially higher than the complexity of its components; for example, the satisfiability problem for $\mathbf{S5} \times \mathbf{S5}$ is *NEXPTIME*-complete.

The decidability and FMP of logics like $\mathbf{K4} \times \mathbf{K4}$, $\mathbf{S4} \times \mathbf{S4}$, $\mathbf{S4} \times \mathbf{S4.3}$ remain challenging open problems of the field.

In higher dimensions—for $n \geq 3$ —the first results related to products of modal logics were obtained in the framework of algebraic logic: as follows from [Maddux 1980] and [Johnson 1969], $\mathbf{S5}^n$ is undecidable and not finitely axiomatizable. However, as we mentioned above, products like $\mathbf{S5}^n$ and \mathbf{K}^n are recursively enumerable. It is worth noting that although \mathbf{K}^n have FMP for all $n < \omega$ [Gabbay and Shehtman 1998], this could imply the decidability of \mathbf{K}^n only if the class of finite frames for \mathbf{K}^n were recursive. We could have such a test if \mathbf{K}^n were finitely axiomatizable; however this is not the case [Kurucz 2000]. To prove the decidability of \mathbf{K}^n , it would also be enough to show that it has the product FMP, i.e., it is characterized by the class of products of n -many finite frames. But this approach does not work either: as has been shown by Hirsch *et al.* [2000], all logics L such that $\mathbf{K}^n \subseteq L \subseteq \mathbf{S5}^n$ are undecidable, non finitely axiomatizable, do not have the product FMP, and it is undecidable whether a finite frame is a frame for L . (The only known example of a decidable higher dimensional product of non-tabular logics is \mathbf{Alt}^n [Gabbay and Shehtman 1998].)

3 SUPERINTUITIONISTIC LOGICS

Although C.I. Lewis constructed his first modal calculus $\mathbf{S3}$ in 1918, it was Gödel's [1933] two page note that attracted serious attention of mathematical logicians to modal systems. While Lewis [1918] used an abstract necessity operator to avoid paradoxes of material implication, Gödel [1933] and earlier Orlov [1928]¹⁶ treated \Box as “it is provable” to give a classical interpretation of intuitionistic propositional logic \mathbf{Int} by means of embedding it into a modal “provability” system which turned out to be equivalent to Lewis' $\mathbf{S4}$.

Approximately at the same time Gödel [1932] observed that there are infinitely many logics located between \mathbf{Int} and classical logic \mathbf{Cl} , which— together with the creation of constructive (proper) extensions of \mathbf{Int} by Kleene [1945] and Rose [1953] (realizability logic), Medvedev [1962] (logic

¹⁶Orlov's paper remained unnoticed till the end of the 1980s. It is remarkable also for constructing the first system of relevant logic.

of finite problems), Kreisel and Putnam [1957]—gave an impetus to studying the class of logics intermediate between **Int** and **Cl**, started by Umezawa [1955, 1959]. Gödel’s embedding of **Int** into **S4**, presented in an algebraic form by McKinsey and Tarski [1948] and extended to all intermediate logics by Dummett and Lemmon [1959], made it possible to develop the theories of modal and intermediate logics in parallel ways. And the structural results of Blok [1976] and Esakia [1979a,b], establishing an isomorphism between the lattices **ExtInt** and **NExtGrz**, along with preservation results of Maksimova and Rybakov [1974] and Zakharyashev [1991], transferring various properties from modal to intermediate logics and back, showed that in many respects the theory of intermediate logics is reducible to the theory of logics in **NExtS4**.

To demonstrate this as well as some features of intermediate logics is the main aim of this part. We will use the same system of notations as in the modal case. In particular, **ExtInt** is the lattice of all logics of the form **Int** + Γ (where Γ is an arbitrary set of formulas in the language of **Int** and + as before means taking the closure under modus ponens and substitution); we call them *superintuitionistic logics* or *si-logics* for short. Basic facts about the syntax and semantics of **Int** and relevant references can be found in *Intuitionistic Logic*, see volume 7 of this *Handbook*. A list of some “standard” si-logics is given in Table 5.

3.1 Intuitionistic frames

As in the case of modal logics, the adequate relational semantics for si-logics can be constructed on the base of the Stone representation of the algebraic “models” for **Int**, known as *Heyting* (or *pseudo-Boolean*) *algebras*. It is hard to trace now who was the first to introduce intuitionistic general frames—the earliest references we know are [Esakia 1974] and [Rautenberg 1979]—but in any case, having at hand [Jónsson and Tarski 1951] and [Goldblatt 1976a], the construction must have been clear.

An *intuitionistic (general) frame* is a triple $\mathfrak{F} = \langle W, R, P \rangle$ in which R is a partial order on $W \neq \emptyset$ and P , the *set of possible values* in \mathfrak{F} , is a collection of upward closed subsets (cones) in W containing \emptyset and closed under the Boolean \cap, \cup , and the operation \supset (for \rightarrow) defined by

$$X \supset Y = \{x \in W : \forall y \in x \uparrow (y \in X \rightarrow y \in Y)\}.$$

If P contains all upward closed subsets in W then we call \mathfrak{F} a *Kripke frame* and denote it by $\mathfrak{F} = \langle W, R \rangle$. An important feature of intuitionistic models $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ (\mathfrak{V} , a *valuation* in \mathfrak{F} , maps propositional variables to sets in P) is that $\mathfrak{V}(\varphi)$, the *truth-value* of a formula φ , is always upward closed.

Every intuitionistic frame $\mathfrak{F} = \langle W, R, P \rangle$ gives rise to the Heyting algebra $\mathfrak{F}^+ = \langle P, \cap, \cup, \supset, \emptyset \rangle$ called the *dual* of \mathfrak{F} . Conversely, given a Heyting algebra

NL_n	= Int + \mathbf{nf}_n , where $\mathbf{nf}_0 = \perp$, $\mathbf{nf}_1 = p$, $\mathbf{nf}_2 = \neg p$, $\mathbf{nf}_\omega = \top$ $\mathbf{nf}_{2m+3} = \mathbf{nf}_{2m+1} \vee \mathbf{nf}_{2m+2}$, $\mathbf{nf}_{2m+4} = \mathbf{nf}_{2m+3} \rightarrow \mathbf{nf}_{2m+1}$

$\mathfrak{A} = \langle A, \wedge, \vee, \rightarrow, \perp \rangle$, we construct its relational representation $\mathfrak{A}_+ = \langle W, R \rangle$ by taking W to be the set of all prime filters in \mathfrak{A} (a filter ∇ is *prime* if it is proper and $a \vee b \in \nabla$ implies $a \in \nabla$ or $b \in \nabla$), R to be the set-theoretic inclusion \subseteq and

$$P = \{ \{ \nabla \in W : a \in \nabla \} : a \in A \}.$$

It is readily checked that \mathfrak{A}_+ , the *dual* of \mathfrak{A} , is an intuitionistic frame, $\mathfrak{A} \cong (\mathfrak{A}_+)^+$ and \mathfrak{A}_+ is differentiated, *tight* in the sense that

$$xRy \text{ iff } \forall X \in P (x \in X \rightarrow y \in X),$$

and *compact*, i.e., for any families $\mathcal{X} \subseteq P$ and $\mathcal{Y} \subseteq \{W - X : X \in P\}$,

$$\bigcap (\mathcal{X} \cup \mathcal{Y}) = \{x \in W : \forall X \in \mathcal{X} \forall Y \in \mathcal{Y} (x \in X \wedge x \in Y)\} \neq \emptyset$$

whenever $\bigcap (\mathcal{X}' \cup \mathcal{Y}') \neq \emptyset$ for every finite subfamilies $\mathcal{X}' \subseteq \mathcal{X}$, $\mathcal{Y}' \subseteq \mathcal{Y}$. Frames with these three properties (actually differentiatedness follows from tightness) are called *descriptive*. In the same way as in the modal case one can prove that \mathfrak{F} is descriptive iff $\mathfrak{F} \cong (\mathfrak{F}^+)_+$. Duality between the

Figure 13.

basic truth-preserving operations on algebras and descriptive frames (the definitions of generated subframes, reductions and disjoint unions do not change) is also established by the same technique.

Since every consistent si-logic L is characterized by its Tarski–Lindenbaum algebra \mathfrak{A}_L , we conclude that L is characterized also by a class of intuitionistic frames, say by the dual of \mathfrak{A}_L .

Refined finitely generated frames for **Int** look similarly to those for **K4**: the only difference is that now all clusters are simple and the truth-sets must be upward closed. Fig. 13 showing (a) the free 1-generated Heyting algebra $\mathfrak{A}_{\text{Int}}(1)$ and (b) its dual $\mathfrak{F}_{\text{Int}}^{\leq \infty}(1)$ will help the reader to restore the details. $\mathfrak{A}_{\text{Int}}(1)$ was first constructed by Rieger [1949] and Nishimura [1960]; it is called the *Rieger–Nishimura lattice*. The formulas nf_n defined in Table 5 and used for the construction are known as *Nishimura formulas* (see also Section 3 of *Intuitionistic Logic*), in volume 7 of this *Handbook*.

At the algebraic level the connection between **Int** and **S4** discovered by Gödel is reflected by the fact, established in [Mckinsey and Tarski 1946], that the algebra of open elements (i.e., elements a such that $\Box a = a$) of every modal algebra for **S4** (known as a *topological Boolean algebra*; see [Rasiowa and Sikorski 1963]) is a Heyting algebra and conversely, every Heyting algebra is isomorphic to the algebra of open elements of a suitable algebra for **S4**. We explain this result in the frame-theoretic language.

Given a frame $\mathfrak{F} = \langle W, R, P \rangle$ for **S4** (which means that R is a quasi-order on W), we denote by ρW the set of clusters in \mathfrak{F} —more generally,

$\rho X = \{C(x) : x \in X\}$ —and put $C(x)\rho C(y)$ iff xRy ,

$$\rho P = \{\rho X : X \in P \wedge X = \Box X\} = \{\rho X : X \in P \wedge X = X\uparrow\}.$$

It is readily checked that the structure $\rho\mathfrak{F} = \langle \rho W, \rho R, \rho P \rangle$ is an intuitionistic frame (for instance, $\rho(X) \supset \rho(Y) = \rho(\Box(-X \cup Y))$); we call it the *skeleton* of \mathfrak{F} . The *skeleton* of a model $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ for **S4** is the intuitionistic model $\rho\mathfrak{M} = \langle \rho\mathfrak{F}, \rho\mathfrak{V} \rangle$, where $\rho\mathfrak{V}(p) = \mathfrak{V}(\Box p)$.

Denote by T the *Gödel translation* prefixing \Box to all subformulas of a given intuitionistic formula.¹⁷ By induction on the construction of φ one can easily prove the following

LEMMA 153 (Skeleton). *For every model \mathfrak{M} for **S4**, every intuitionistic formula φ and every point x in \mathfrak{M} ,*

$$(\rho\mathfrak{M}, C(x)) \models \varphi \text{ iff } (\mathfrak{M}, x) \models T(\varphi).$$

It follows that $\varphi \in \mathbf{Int}$ implies $T(\varphi) \in \mathbf{S4}$. To prove the converse we should be able to convert intuitionistic frames \mathfrak{F} into modal ones with the skeleton (isomorphic to) \mathfrak{F} . This is trivial if \mathfrak{F} is a Kripke frame—we can just regard it to be a frame for **S4**, which in view of the Kripke completeness of both **Int** and **S4**, shows that T really embeds the former into the latter, i.e.,

$$\varphi \in \mathbf{Int} \text{ iff } T(\varphi) \in \mathbf{S4}.$$

In general, the most obvious way of constructing a modal frame from an intuitionistic frame $\mathfrak{F} = \langle W, R, P \rangle$ is to take the closure σP of P under the Boolean operations \cap , \cup and \rightarrow . It is well known in the theory of Boolean algebras (see [Rasiowa and Sikorski 1963]) that for every $X \subseteq W$, X is in σP iff

$$X = (-X_1 \cup Y_1) \cap \cdots \cap (-X_n \cup Y_n)$$

for some $X_1, Y_1, \dots, X_n, Y_n \in P$ and $n \geq 1$. It follows that if $X \in \sigma P$ then

$$\Box X = (X_1 \supset Y_1) \cap \cdots \cap (X_n \supset Y_n) \in P \subseteq \sigma P,$$

and so σP is closed under \Box in $\langle W, R \rangle$ and P coincides with the set of upward closed sets in σP . Thus, $\langle W, R, \sigma P \rangle$ is a partially ordered modal frame; we shall denote it by $\sigma\mathfrak{F}$. Moreover, we clearly have $\mathfrak{F} \cong \rho\sigma\mathfrak{F}$. If $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ is an intuitionistic model then $\sigma\mathfrak{M} = \langle \sigma\mathfrak{F}, \mathfrak{V} \rangle$ is a modal model having \mathfrak{M} as its skeleton. So by the Skeleton Lemma,

$$(\mathfrak{M}, x) \models \varphi \text{ iff } (\sigma\mathfrak{M}, x) \models T(\varphi),$$

¹⁷The translation defined in [Gödel 1933] does not prefix \Box to conjunctions and disjunctions. However this difference is of no importance as far as embeddings into logics in NExt**S4** are concerned.

for every intuitionistic formula φ and every point x in \mathfrak{F} .

It is worth noting that if $\mathfrak{F} = \langle W, R \rangle$ is a finite intuitionistic Kripke frame then $\sigma\mathfrak{F}$ is also a Kripke frame. However, for an infinite \mathfrak{F} , $\sigma\mathfrak{F}$ is not in general a Kripke frame, witness $\langle \omega, \leq \rangle$.

The operator σ is not the only one which, given an intuitionistic frame \mathfrak{F} , returns a modal frame whose skeleton is isomorphic to \mathfrak{F} . As an example, we define now an infinite class of such operators. For Kripke frames $\mathfrak{F} = \langle W, R \rangle$ and $\mathfrak{G} = \langle V, S \rangle$, denote by $\mathfrak{F} \times \mathfrak{G}$ the *direct product* of \mathfrak{F} and \mathfrak{G} , i.e., the frame $\langle W \times V, R \times S \rangle$ in which the relation $R \times S$ is defined component-wise:

$$\langle x_1, y_1 \rangle (R \times S) \langle x_2, y_2 \rangle \text{ iff } x_1 R x_2 \text{ and } y_1 S y_2.$$

Let $0 < k \leq \omega$. We will regard k to be the set $\{0, \dots, k-1\}$ if $k < \omega$ and $\{0, 1, \dots\}$ if $k = \omega$. Denote by τ_k an operator which, given an intuitionistic frame $\mathfrak{F} = \langle W, R, P \rangle$, returns a modal frame $\tau_k\mathfrak{F} = \langle kW, kR, kP \rangle$ such that

(i) $\langle kW, kR \rangle$ is the direct product of the k -point cluster $\langle k, k^2 \rangle$ and $\langle W, R \rangle$ (in other words, $\langle kW, kR \rangle$ is obtained from $\langle W, R \rangle$ by replacing its every point with a k -point cluster);

(ii) $\rho\tau_k\mathfrak{F} \cong \mathfrak{F}$;

(iii) $I \times X \in kP$, for every $I \subseteq k$ and $X \in \sigma P$.

For instance, we can take kP to be the Boolean closure of the set

$$\{I \times X : I \subseteq k, X \in \sigma P\}.$$

For a Kripke frame $\mathfrak{F} = \langle W, R, \text{Up}W \rangle$ we can, of course, take $kP = 2^{kW}$ and then $\tau_k\mathfrak{F} = \langle kW, kR, 2^{kW} \rangle$.

3.2 Canonical formulas

The language of canonical formulas, axiomatizing all si-logics and characterizing the structure of their frames, can be easily developed following the scheme of constructing the canonical formulas for **K4** outlined in Section 1.6 and using the connection between modal and intuitionistic frames established above. We confine ourselves here only to pointing out the differences from the modal case and some interesting peculiarities; details can be found in [Zakharyashev 1983, 1989] and [Chagrov and Zakharyashev 1997].

Actually, there are two important differences. First, in the definition of subreduction of $\mathfrak{F} = \langle W, R, P \rangle$ to \mathfrak{G} the condition (R3) does not correspond to the fact that all sets in P are upward closed. We replace it by the following condition

$$(R3') \quad \forall X \in \overline{Q} \ f^{-1}(X) \downarrow \in \overline{P},$$

where $\overline{Q} = \{V - X : X \in Q\}$ and $\overline{P} = \{W - X : X \in P\}$. For a completely defined f satisfying (R1) and (R2) the condition (R3') is clearly

Figure 14.

equivalent to (R3) and so every reduction is also a subreduction. If \mathfrak{G} is a finite Kripke frame then (R3') is equivalent to $\forall z \in V \ f^{-1}(z) \downarrow \in \overline{P}$. \mathfrak{G} is a *subframe* of \mathfrak{F} if $\kappa\mathfrak{G}$ is a subframe of $\kappa\mathfrak{F}$ and the identity map on V is a subreduction of \mathfrak{F} to \mathfrak{G} . It is of interest to note that in the intuitionistic case (cofinal) subreductions are dual to IC(N)-subalgebras of Heyting algebras which preserve only implication, conjunction (and negation or \perp) but do not necessarily preserve disjunction.

Second, we have to change the definition of open domains. Now we say an antichain \mathfrak{a} (of at least two points) is an *open domain* in an intuitionistic model \mathfrak{M} relative to a formula φ if there is a pair $t_{\mathfrak{a}} = (\Gamma_{\mathfrak{a}}, \Delta_{\mathfrak{a}})$ such that $\Gamma_{\mathfrak{a}} \cup \Delta_{\mathfrak{a}} = \mathbf{Sub}\varphi$, $\bigwedge \Gamma_{\mathfrak{a}} \rightarrow \bigvee \Delta_{\mathfrak{a}} \notin \mathbf{Int}$ and

- $\psi \in \Gamma_{\mathfrak{a}}$ iff $a \models \psi$ for all $a \in \mathfrak{a}$.

It is worth noting that in any intuitionistic model every antichain \mathfrak{a} is open relative to every disjunction free formula φ . Indeed, let $\Gamma_{\mathfrak{a}}$ be defined by condition above and $\Delta_{\mathfrak{a}} = \mathbf{Sub}\varphi - \Gamma_{\mathfrak{a}}$. It should be clear that $\psi \wedge \chi \in \Gamma_{\mathfrak{a}}$ iff $\psi \in \Gamma_{\mathfrak{a}}$ and $\chi \in \Gamma_{\mathfrak{a}}$. And if $\psi \rightarrow \chi \in \Gamma_{\mathfrak{a}}$, $\psi \in \Gamma_{\mathfrak{a}}$ but $\chi \in \Delta_{\mathfrak{a}}$ then $a \models \psi$ for every $a \in \mathfrak{a}$ and $b \not\models \chi$ for some $b \in \mathfrak{a}$, whence $b \not\models \psi \rightarrow \chi$, which is a contradiction. It follows that $\bigwedge \Gamma_{\mathfrak{a}} \rightarrow \bigvee \Delta_{\mathfrak{a}} \notin \mathbf{Int}$.

EXAMPLE 154. Let us try to characterize the class of intuitionistic refutation frames for the *Weak Kreisel–Putnam Formula*

$$\mathbf{wkp} = (\neg p \rightarrow \neg q \vee \neg r) \rightarrow (\neg p \rightarrow \neg q) \vee (\neg p \rightarrow \neg r).$$

First we construct its simplest countermodel; it is depicted in Fig. 14, where by putting a formula to the left (right) of a point we mean that it is true (not true) at the point. Then we observe that every frame \mathfrak{F} refuting \mathbf{wkp} is cofinally subreducible to the frame \mathfrak{G} underlying this countermodel by

the map f defined as follows:

$$f(x) = \begin{cases} 0 & \text{if } x \models \neg p \rightarrow \neg q \vee \neg r, x \not\models (\neg p \rightarrow \neg q) \vee (\neg p \rightarrow \neg r) \\ 1 & \text{if } x \models \neg p \rightarrow \neg q \vee \neg r, x \models \neg p \text{ and } x \models q \\ 2 & \text{if } x \models \neg p \rightarrow \neg q \vee \neg r, x \models \neg p \text{ and } x \models r \\ 3 & \text{if } x \models p \text{ or } x \models \neg p \wedge \neg q \wedge \neg r \\ \text{undefined} & \text{otherwise.} \end{cases}$$

However, the cofinal subreducibility to \mathfrak{G} is only a necessary condition for $\mathfrak{F} \not\models \mathbf{wkp}$, witness the frame having the form of the three-dimensional Boolean cube with the top point deleted. The reason for this is that the antichain $\{1, 2\}$ is a closed domain in \mathfrak{N} : it is impossible to insert a point a between 0 and $\{1, 2\}$ and extend to it consistently the truth-sets for the depicted formulas. Indeed, otherwise we would have $a \models \neg p \rightarrow \neg q \vee \neg r$, $a \not\models \neg q \vee \neg r$ and so $a \not\models \neg p$, i.e., there must be a point $x \in a\uparrow$ such that $x \models p$, but such a point does not exist. In fact, $\mathfrak{F} \not\models \mathbf{wkp}$ iff there is a cofinal subreduction of \mathfrak{F} to \mathfrak{G} satisfying (CDC) for $\{\{1, 2\}\}$.

Now, as in the modal case, with every finite rooted intuitionistic frame $\mathfrak{F} = \langle W, R \rangle$ and a set \mathfrak{D} of antichains in it we can associate two formulas $\beta(\mathfrak{F}, \mathfrak{D}, \perp)$ and $\beta(\mathfrak{F}, \mathfrak{D})$, called the *canonical* and *negation free canonical formulas*, respectively, so that $\mathfrak{G} \not\models \beta(\mathfrak{F}, \mathfrak{D}, \perp)$ ($\mathfrak{G} \not\models \beta(\mathfrak{F}, \mathfrak{D})$) iff there is a (cofinal) subreduction of \mathfrak{G} to \mathfrak{F} satisfying (CDC) for \mathfrak{D} . For instance, if a_0, \dots, a_n are all points in \mathfrak{F} and a_0 is its root, then one can take

$$\beta(\mathfrak{F}, \mathfrak{D}, \perp) = \bigwedge_{a_i R a_j} \psi_{ij} \wedge \bigwedge_{\mathfrak{d} \in \mathfrak{D}} \psi_{\mathfrak{d}} \wedge \psi_{\perp} \rightarrow p_0,$$

where

$$\begin{aligned} \psi_{ij} &= \left(\bigwedge_{\neg a_j R a_k} p_k \rightarrow p_j \right) \rightarrow p_i, \\ \psi_{\mathfrak{d}} &= \bigwedge_{a_i \in W - \mathfrak{d}\uparrow} \left(\bigwedge_{\neg a_i R a_k} p_k \rightarrow p_i \right) \rightarrow \bigvee_{a_j \in \mathfrak{d}} p_j, \\ \psi_{\perp} &= \bigwedge_{i=0}^n \left(\bigwedge_{\neg a_i R a_k} p_k \rightarrow p_i \right) \rightarrow \perp. \end{aligned}$$

$\beta(\mathfrak{F}, \mathfrak{D})$ is obtained from $\beta(\mathfrak{F}, \mathfrak{D}, \perp)$ by deleting the conjunct ψ_{\perp} .

THEOREM 155. *There is an algorithm which, given an intuitionistic φ , returns canonical formulas $\beta(\mathfrak{F}_1, \mathfrak{D}_1, \perp), \dots, \beta(\mathfrak{F}_n, \mathfrak{D}_n, \perp)$ such that*

$$\mathbf{Int} + \varphi = \mathbf{Int} + \beta(\mathfrak{F}_1, \mathfrak{D}_1, \perp) + \dots + \beta(\mathfrak{F}_n, \mathfrak{D}_n, \perp).$$

So the set of intuitionistic canonical formulas is complete for \mathbf{ExtInt} . If φ is negation free then one can use only negation free canonical formulas. And if φ is disjunction free then all \mathfrak{D}_i are empty.

Table 6 and Theorem 156 show canonical axiomatizations of the si-logics in Table 5. Using this “geometrical” representation it is not hard to see, for instance, that **SmL**, known as the *Smetanich logic*, is the greatest consistent extension of **Int** different from **Cl**; it is the logic of the two-point rooted frame. **KC**, the logic of the *Weak Law of the Excluded Middle*, is characterized by the class of directed frames. It is the greatest si-logic containing the same negation free formulas as **Int** (see [Jankov 1968a]). **LC**, the *Dummett* or *chain logic*, is characterized by the class of linear frames (see [Dummett 1959]). **BD_n** and **BW_n** are the minimal logics of depth n and width n , respectively (see [Hosoi 1967] and [Smoryński 1973]). Finite frames for **BTW_n** contain $\leq n$ top points [Smoryński 1973] and finite frames for **T_n** are of branching $\leq n$, i.e., no point has more than n immediate successors.

THEOREM 156 (Nishimura 1960, Anderson 1972). *Every extension L of **Int** by formulas in one variable can be represented either as*

$$L = \mathbf{Int} + \mathbf{nf}_{2n} = \mathbf{Int} + \beta^\sharp(\mathfrak{H}_n, \perp)$$

or as

$$L = \mathbf{Int} + \mathbf{nf}_{2n-1} = \mathbf{Int} + \beta^\sharp(\mathfrak{H}_{n+1}, \perp) + \beta^\sharp(\mathfrak{H}_{n+2}, \perp),$$

where $\mathfrak{H}_n, \mathfrak{H}_{n+1}, \mathfrak{H}_{n+2}$ are the subframes of the frame in Fig. 13 generated by the points $n, n+1$ and $n+2$, respectively, and $\beta^\sharp(\mathfrak{F}, \perp)$ is an abbreviation for $\beta(\mathfrak{F}, \mathfrak{D}^\sharp, \perp)$, \mathfrak{D}^\sharp the set of all antichains in \mathfrak{F} .

Jankov [1969] proved in fact that logics of the form $\mathbf{Int} + \beta^\sharp(\mathfrak{F}, \perp)$ and only them are splittings of **ExtInt**. However, not every si-logic is a union-splitting of **ExtInt** which means that this class has no axiomatic basis.

3.3 Modal companions and preservation theorems

The fact that the Gödel translation T embeds **Int** into **S4** and the relationship between intuitionistic and modal frames established in Section 3.1 can be used to reduce various problems concerning **Int** (e.g. proving completeness or FMP) to those for **S4** and vice versa. Moreover, it turns out that each logic in **ExtInt** is embedded by T into some logics in **NExtS4**, and for each logic in **NExtS4** there is one in **ExtInt** embeddable in it.

We say a modal logic $M \in \mathbf{NExtS4}$ is a *modal companion* of a si-logic L if L is embedded in M by T , i.e., if for every intuitionistic formula φ ,

$$\varphi \in L \text{ iff } T(\varphi) \in M.$$

If M is a modal companion of L then L is called the *si-fragment* of M and denoted by ρM . The reason for denoting the operator “modal logic \mapsto its si-fragment” by the same symbol we used for the skeleton operator is explained by the following

Table 6. Canonical axioms of standard superintuitionistic logics

For	=	Int	+	$\beta(\circ)$		
Cl	=	Int	+	$\beta(\begin{array}{c} \circ \\ \\ \circ \end{array})$		
SmL	=	Int	+	$\beta(\begin{array}{c} \circ & \circ \\ \diagdown & / \\ \circ \end{array})$	+	$\beta(\begin{array}{c} \circ \\ \\ \circ \\ \\ \circ \end{array})$
KC	=	Int	+	$\beta(\begin{array}{c} \circ & \circ \\ \diagdown & / \\ \circ \end{array}, \perp)$		
LC	=	Int	+	$\beta(\begin{array}{c} \circ & \circ \\ \diagdown & / \\ \circ \end{array})$		
SL	=	Int	+	$\beta^\sharp(\begin{array}{c} \circ & \circ \\ \diagdown & / \\ \circ \end{array}, \perp)$		
KP	=	Int	+	$\beta(\begin{array}{c} \circ 1 & \circ 2 & \circ \\ \diagdown & & / \\ \circ \end{array}, \{\{1, 2\}\}, \perp)$	+	$\beta(\begin{array}{c} \circ \\ \diagup & \diagdown \\ \circ 1 & \circ 2 & \circ \end{array}, \{\{1, 2\}\}, \perp)$
BD_n	=	Int	+	$\beta(\begin{array}{c} \circ n \\ \vdots \\ \circ 1 \\ \\ \circ 0 \end{array})$		
BW_n	=	Int	+	$\beta(\begin{array}{c} \overbrace{\circ \dots \circ}^{n+1} \\ \diagdown & / \\ \circ \end{array})$		
BTW_n	=	Int	+	$\beta(\begin{array}{c} \overbrace{\circ \dots \circ}^{n+1} \\ \diagdown & / \\ \circ \end{array}, \perp)$		
T_n	=	Int	+	$\beta^\sharp(\begin{array}{c} \overbrace{\circ \dots \circ}^{n+1} \\ \diagdown & / \\ \circ \end{array})$		
B_n	=	Int	+	$\beta^\sharp(\begin{array}{c} \overbrace{\circ \dots \circ}^{n+1} \\ \diagdown & / \\ \circ \end{array}, \perp)$		

THEOREM 157. *For every $M \in \text{NExtS4}$, $\rho M = \{\varphi : T(\varphi) \in M\}$. Moreover, if M is characterized by a class \mathcal{C} of modal frames then ρM is characterized by the class $\rho\mathcal{C} = \{\rho\mathfrak{F} : \mathfrak{F} \in \mathcal{C}\}$ of intuitionistic frames.*

Proof. It suffices to show that $\{\varphi : T(\varphi) \in M\} = \text{Log}\rho\mathcal{C}$. Suppose that $T(\varphi) \in M$. Then $\mathfrak{F} \models T(\varphi)$ and so, by the Skeleton Lemma, $\rho\mathfrak{F} \models \varphi$ for every $\mathfrak{F} \in \mathcal{C}$, i.e., $\varphi \in \text{Log}\rho\mathcal{C}$. Conversely, if $\rho\mathfrak{F} \models \varphi$ for all $\mathfrak{F} \in \mathcal{C}$ then, by the same lemma, $T(\varphi)$ is valid in all frames in \mathcal{C} and so $T(\varphi) \in M$. ■

Thus, ρ maps NExtS4 into ExtInt . The following simple observation shows that actually ρ is a surjection. Given a logic $L \in \text{ExtInt}$, we put

$$\tau L = \mathbf{S4} \oplus \{T(\varphi) : \varphi \in L\}.$$

THEOREM 158 (Dummett and Lemmon 1959). *For every si-logic L , τL is a modal companion of L .*

Proof. Clearly, $L \subseteq \rho\tau L$. To prove the converse inclusion, suppose $\varphi \notin L$, i.e., there is a frame \mathfrak{F} for L refuting φ . Since $\mathfrak{F} \cong \rho\sigma\mathfrak{F}$, by the Skeleton Lemma we have $\sigma\mathfrak{F} \models \tau L$ and $\sigma\mathfrak{F} \not\models T(\varphi)$. Therefore, $T(\varphi) \notin \tau L$ and so $\varphi \notin \rho\tau L$. ■

Now we use the language of canonical formulas to obtain a general characterization of all modal companions of a given si-logic L . Our presentation follows [Zakharyashev 1989, 1991]. Notice first that for every modal frame \mathfrak{G} and every intuitionistic canonical formula $\beta(\mathfrak{F}, \mathfrak{D}, \perp)$, $\mathfrak{G} \models \alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ iff $\rho\mathfrak{G} \models \beta(\mathfrak{F}, \mathfrak{D}, \perp)$ and so $\mathbf{S4} \oplus T(\beta(\mathfrak{F}, \mathfrak{D}, \perp)) = \mathbf{S4} \oplus \alpha(\mathfrak{F}, \mathfrak{D}, \perp)$. The same concern, of course, the negation free canonical formulas.

THEOREM 159. *A logic $M \in \text{NExtS4}$ is a modal companion of a si-logic $L = \text{Int} + \{\beta(\mathfrak{F}_i, \mathfrak{D}_i, \perp) : i \in I\}$ iff M can be represented in the form*

$$M = \mathbf{S4} \oplus \{\alpha(\mathfrak{F}_i, \mathfrak{D}_i, \perp) : i \in I\} \oplus \{\alpha(\mathfrak{F}_j, \mathfrak{D}_j, \perp) : j \in J\},$$

where every frame \mathfrak{F}_j , for $j \in J$, contains a proper cluster.

Proof. (\Leftarrow) We must show that for every intuitionistic formula φ , $\varphi \in L$ iff $T(\varphi) \in M$. Suppose that $\varphi \notin L$ and $\mathfrak{F} = \langle W, R, P \rangle$ is a frame separating φ from L . We prove that $\sigma\mathfrak{F}$ separates $T(\varphi)$ from M . As was observed above, $\sigma\mathfrak{F} \not\models T(\varphi)$ and $\sigma\mathfrak{F} \models \alpha(\mathfrak{F}_i, \mathfrak{D}_i, \perp)$ for any $i \in I$. So it remains to show that $\sigma\mathfrak{F} \models \alpha(\mathfrak{F}_j, \mathfrak{D}_j, \perp)$ for every $j \in J$.

Suppose otherwise. Then, for some $j \in J$, we have a subreduction f of $\sigma\mathfrak{F}$ to \mathfrak{F}_j . Let a_1 and a_2 be distinct points belonging to the same proper cluster in \mathfrak{F}_j . By the definition of subreduction, $f^{-1}(a_1) \subseteq f^{-1}(a_2) \downarrow$ and $f^{-1}(a_2) \subseteq f^{-1}(a_1) \downarrow$, and so there is an infinite chain $x_1 R y_1 R x_2 R y_2 R \dots$

in $\sigma\mathfrak{F}$ such that $\{x_1, x_2, \dots\} \subseteq f^{-1}(a_1)$ and $\{y_1, y_2, \dots\} \subseteq f^{-1}(a_2)$. And since R is a partial order, all the points x_i and y_i are distinct.

Since $f^{-1}(a_1) \in \sigma P$, there are $X_i, Y_i \in P$ such that

$$f^{-1}(a_1) = (-X_1 \cup Y_1) \cap \dots \cap (-X_n \cup Y_n).$$

And since $f^{-1}(a_1) \cap f^{-1}(a_2) = \emptyset$, for every point y_i there is some number n_i such that $y_i \in X_{n_i}$ and $y_i \notin Y_{n_i}$. But then, for some distinct l and m , the numbers n_l and n_m must coincide, and so if, say, $y_l R y_m$ then $x_m \notin Y_{n_m}$ and $x_m \in X_{n_l}$ (for $y_l R x_m R y_m$, $X_i = X_i \uparrow$, $Y_i = Y_i \uparrow$). Therefore, $x_m \notin f^{-1}(a_1)$, which is a contradiction.

The rest of the proof presents no difficulties. ■

This proof does not touch upon the cofinality condition. So along with canonical formulas in Theorem 159 we can use negation free canonical formulas. Thus, we have:

$$\begin{aligned} \rho\mathbf{S4} &= \rho\mathbf{S4.1} = \rho\mathbf{Dum} = \rho\mathbf{Grz} = \mathbf{Int}, \\ \rho\mathbf{S4.2} &= \rho(\mathbf{S4.2} \oplus \mathbf{Grz}) = \mathbf{KC}, \\ \rho\mathbf{S4.3} &= \rho(\mathbf{S4.3} \oplus \mathbf{Grz}) = \mathbf{LC}, \\ \rho\mathbf{S5} &= \rho(\mathbf{S5} \oplus \mathbf{Grz}) = \mathbf{Cl}. \end{aligned}$$

COROLLARY 160. *The set of modal companions of every consistent si-logic L forms the interval*

$$\rho^{-1}(L) = [\tau L, \tau L \oplus \alpha(\overline{\circ\circ})] = \{M \in \mathbf{NExtS4} : \tau L \subseteq M \subseteq \tau L \oplus \mathbf{Grz}\}$$

and contains an infinite descending chain of logics.

Proof. Notice first that $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ and $\alpha(\mathfrak{F}, \mathfrak{D})$ are in \mathbf{Grz} iff \mathfrak{F} contains a proper cluster. So $\rho^{-1}(L) \subseteq [\tau L, \tau L \oplus \alpha(\overline{\circ\circ})]$. On the other hand, the si-fragments of all logics in the interval are the same, namely L . Therefore, $\rho^{-1}(L) = [\tau L, \tau L \oplus \alpha(\overline{\circ\circ})]$. Now, if L is consistent then $\beta(\circ) \notin L$ and so we have

$$\tau L \subset \dots \subset \tau L \oplus \alpha(\mathfrak{C}_n) \subset \dots \subset \tau L \oplus \alpha(\mathfrak{C}_2) \subset \tau L \oplus \alpha(\mathfrak{C}_1) = \mathbf{For},$$

where \mathfrak{C}_i is the non-degenerate cluster with i points. ■

This result is due to Maksimova and Rybakov [1974], Blok [1976] and Esakia [1979b].

Thus, all modal companions of every si-logic L are contained between the least companion τL and the greatest one, viz., $\tau L \oplus \alpha(\overline{\circ\circ})$, which will be denoted by σL . Using Theorems 159 and 44, we obtain

COROLLARY 161. *There is an algorithm which, given a modal formula φ , returns an intuitionistic formula ψ such that $\rho(\mathbf{S4} \oplus \varphi) = \mathbf{Int} + \psi$.*

The following theorem, which is also a consequence of Theorem 159, describes lattice-theoretic properties of the maps ρ , τ and σ . Items (i), (ii) and (iv) in it were first proved by Maksimova and Rybakov [1974], and (iii) is due to Blok [1976] and Esakia [1979b] and known as the Blok–Esakia Theorem.

THEOREM 162.

- (i) *The map ρ is a homomorphism of the lattice $\mathbf{NExtS4}$ onto the lattice \mathbf{ExtInt} .*
- (ii) *The map τ is an isomorphism of \mathbf{ExtInt} into $\mathbf{NExtS4}$.*
- (iii) *The map σ is an isomorphism of \mathbf{ExtInt} onto $\mathbf{NExtGrz}$.*
- (iv) *All these maps preserve infinite sums and intersections of logics.*

Now we give frame-theoretic characterizations of the operators τ and σ . Note first that the following evident relations between frames for si-logics and their modal companions hold:

$$\mathfrak{F} \models \rho M \text{ iff } \sigma \mathfrak{F} \models M, \quad \mathfrak{F} \models L \text{ iff } \sigma \mathfrak{F} \models \sigma L,$$

$$\rho \mathfrak{F} \models L \text{ iff } \mathfrak{F} \models \tau L, \quad \mathfrak{F} \models L \text{ iff } \tau_k \mathfrak{F} \models \tau L.$$

THEOREM 163 (Maksimova and Rybakov 1974). *A si-logic L is characterized by a class \mathcal{C} of intuitionistic frames iff σL is characterized by the class $\sigma \mathcal{C} = \{\sigma \mathfrak{F} : \mathfrak{F} \in \mathcal{C}\}$.*

Proof. (\Rightarrow) It suffices to show that any canonical formula $\alpha(\mathfrak{F}, \mathcal{D}, \perp) \notin \sigma L$ is refuted by some frame in $\sigma \mathcal{C}$. Since \mathfrak{F} is partially ordered, $\beta(\mathfrak{F}, \mathcal{D}, \perp) \notin L$, i.e., there is $\mathfrak{F} \in \mathcal{C}$ refuting $\beta(\mathfrak{F}, \mathcal{D}, \perp)$ and so $\sigma \mathfrak{F} \not\models \alpha(\mathfrak{F}, \mathcal{D}, \perp)$. (\Leftarrow) is straightforward. ■

To characterize τ we require

LEMMA 164. *For any canonical formula $\alpha(\mathfrak{F}, \mathcal{D}, \perp)$ built on a quasi-ordered frame \mathfrak{F} , $\alpha(\mathfrak{F}, \mathcal{D}, \perp) \in \mathbf{S4} \oplus \alpha(\rho \mathfrak{F}, \rho \mathcal{D}, \perp)$, where $\rho \mathcal{D} = \{\rho \mathfrak{d} : \mathfrak{d} \in \mathcal{D}\}$ and $\rho \mathfrak{d} = \{C(x) : x \in \mathfrak{d}\}$.*

Proof. Let \mathfrak{G} be a quasi-ordered frame refuting $\alpha(\mathfrak{F}, \mathcal{D}, \perp)$. Then there is a cofinal subreduction f of \mathfrak{G} to \mathfrak{F} satisfying (CDC) for \mathcal{D} . The map h from \mathfrak{F} onto $\rho \mathfrak{F}$ defined by $h(x) = C(x)$, for every x in \mathfrak{F} , is clearly a reduction of \mathfrak{F} to $\rho \mathfrak{F}$. So the composition hf is a cofinal subreduction of \mathfrak{G} to $\rho \mathfrak{F}$, and it is easy to verify that it satisfies (CDC) for $\rho \mathcal{D}$. ■

THEOREM 165. *A si-logic L is characterized by a class \mathcal{C} of frames iff τL is characterized by the class $\bigcup_{0 < k < \omega} \tau_k \mathcal{C}$, where $\tau_k \mathcal{C} = \{\tau_k \mathfrak{F} : \mathfrak{F} \in \mathcal{C}\}$.*

Proof. (\Rightarrow) As was noted above, if \mathfrak{F} is a frame for L then $\tau_k \mathfrak{F}$ is a frame for τL . So suppose that a formula $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$, built on a quasi-ordered frame $\mathfrak{F} = \langle W, R \rangle$, does not belong to τL and show that it is refuted by some frame in $\bigcup_{0 < k < \omega} \tau_k \mathcal{C}$. By Lemma 164, $\alpha(\rho \mathfrak{F}, \rho \mathfrak{D}, \perp) \notin \tau L$ and so $\beta(\rho \mathfrak{F}, \rho \mathfrak{D}, \perp) \notin L$. Hence there is a frame $\mathfrak{G} = \langle V, S, Q \rangle$ in \mathcal{C} which refutes $\beta(\rho \mathfrak{F}, \rho \mathfrak{D}, \perp)$. But then $\sigma \mathfrak{G} \models \tau L$ and $\sigma \mathfrak{G} \not\models \alpha(\rho \mathfrak{F}, \rho \mathfrak{D}, \perp)$. Let f be a subreduction of $\sigma \mathfrak{G}$ to $\rho \mathfrak{F}$ satisfying (CDC) for $\rho \mathfrak{D}$ and let $k = \max\{|C(x)| : x \in W\}$. Define a partial map h from $\tau_k \mathfrak{G} = \langle kV, kS, kQ \rangle$ onto \mathfrak{F} as follows: if $x \in V$, $y_0 \in W$, $f(x) = C(y_0)$ and $C(y_0) = \{y_0, \dots, y_n\}$ then we put $h(\langle i, x \rangle) = y_i$, for $i = 0, \dots, n$. By the definition of τ_k , for any $i \in \{0, \dots, n\}$ we have

$$h^{-1}(y_i) = \{\langle i, x \rangle : x \in f^{-1}(C(y_0))\} = \{i\} \times f^{-1}(C(y_0)) \in kQ.$$

Now, one can readily prove that h is a cofinal subreduction of $\tau_k \mathfrak{G}$ to \mathfrak{F} satisfying (CDC) for \mathfrak{D} . So $\tau_k \mathfrak{G} \not\models \alpha(\mathfrak{F}, \mathfrak{D}, \perp)$. (\Leftarrow) is obvious. ■

It is worth noting that this proof will not change if we put in it $k = \omega$.

COROLLARY 166. *A logic $L \in \text{ExtInt}$ is characterized by a class \mathcal{C} of frames iff τL is characterized by the class $\tau_\omega \mathcal{C}$.*

The following theorem provides a deductive characterization of the maps τ and σ .

THEOREM 167. *For every si-logic L and every modal canonical formula $\alpha(\mathfrak{F}, \mathfrak{D}, \perp)$ built on a quasi-ordered frame \mathfrak{F} ,*

- (i) $\alpha(\mathfrak{F}, \mathfrak{D}, \perp) \in \tau L$ iff $\beta(\rho \mathfrak{F}, \rho \mathfrak{D}, \perp) \in L$;
- (ii) $\alpha(\mathfrak{F}, \mathfrak{D}, \perp) \in \sigma L$ iff either \mathfrak{F} is partially ordered and $\beta(\mathfrak{F}, \mathfrak{D}, \perp) \in L$ or \mathfrak{F} contains a proper cluster.

Proof. (i) The implication (\Rightarrow) was actually established in the proof of Theorem 165, and the converse one follows from Lemma 164.

(ii) Suppose $\alpha(\mathfrak{F}, \mathfrak{D}, \perp) \in \sigma L$. Then either \mathfrak{F} is partially ordered, and so $\beta(\mathfrak{F}, \mathfrak{D}, \perp) \in L$, or \mathfrak{F} contains a proper cluster. The converse implication follows from (i) and the fact that $\alpha(\mathfrak{F}, \mathfrak{D}, \perp) \in \mathbf{Grz}$ for every frame \mathfrak{F} with a proper cluster. ■

The results obtained in this section not only establish some structural correspondences between logics in ExtInt and NExtS4 and their frames, but may be also used for transferring various properties of modal logics to their si-fragments and back. A few results of that sort are collected in

Table 7. Preservation Theorem

Property of logics	Preserved under		
	ρ	τ	σ
Decidability	Yes	Yes	Yes
Kripke completeness	Yes	Yes	No
Strong completeness	Yes	Yes	No
Finite model property	Yes	Yes	Yes
Tabularity	Yes	No	Yes
Pretabularity	Yes	No	Yes
\mathcal{D} -persistence	Yes	Yes	No
Local tabularity	Yes	No	No
Disjunction property	Yes	Yes	Yes
Halldén completeness	Yes	No	No
Interpolation property	Yes	No	No
Elementarity	Yes	Yes	No
Independent axiomatizability	No	Yes	Yes

Table 7; we shall cite them as the Preservation Theorem. The preservation of decidability follows from the definition of ρ and Theorem 167. That ρ preserves Kripke completeness, FMP and tabularity is a consequence of Theorem 157. The map τ preserves Kripke completeness and FMP, since we can define τ_k in Theorem 165 so that $\tau_k \langle W, R \rangle = \langle kW, kR \rangle$; however, τ does not in general preserve the tabularity, because $\tau \mathbf{CI} = \mathbf{S5}$ is not tabular. The preservation of FMP and tabularity under σ follows from Theorem 163. On the other hand, Shehtman [1980] proved that σ does not preserve Kripke completeness (since τ preserves it and \mathbf{Grz} is complete, this means in particular that Kripke completeness is not preserved under sums of logics in $\mathbf{NExtS4}$). Some other preservation results in Table 7 will be discussed later. For references see [Chagrov and Zakharyashev 1992, 1997].

3.4 Completeness

In this section we briefly discuss the most important results concerning completeness of si-logics with respect to various classes of Kripke frames.

Kripke completeness That not all si-logics are complete with respect to Kripke frames was discovered by Shehtman [1977], who found a way

to adjust Fine’s [1974b] idea to the intuitionistic case (which was not so easy because intuitionistic formulas do not “feel” infinite ascending chains essential in Fine’s construction; see Section 20 of *Basic Modal Logic*). Note however that Kuznetsov’s [1975] question whether all si-logics are complete with respect to the topological semantics (see *Intuitionistic Logic*, volume 7 of this *Handbook*) is still open.

As to general positive results, notice first that the Preservation Theorem yields the following translation of Fine’s [1974c] Theorem on finite width logics (si-logics of finite width were studied by Sobolev [1977a]).

THEOREM 168. *Every si-logic of width n (i.e., a logic in ExtBW_n ; see Table 5) is characterized by a class of Noetherian Kripke frames of width $\leq n$.*

The translation of Sahlqvist’s Theorem gives nothing interesting for si-logics. A sort of intuitionistic analog of this theorem has been recently proved by Ghilardi and Meloni [1997]. Here is a somewhat simplified variant of their result in which $\bar{p}, \bar{q}, \bar{r}, \bar{s}$ denote tuples of propositional variables and $\bar{\psi}, \bar{\chi}$ tuples of formulas of the same length as \bar{r} and \bar{s} , respectively.

THEOREM 169 (Ghilardi and Meloni 1997). *Suppose $\varphi(\bar{p}, \bar{q}, \bar{r}, \bar{s})$ is an intuitionistic formula in which the variables \bar{r} occur positively and the variables \bar{s} occur negatively, and which does not contain any \rightarrow , except for negations and double negations of atoms, in the premise of a subformula of the form $\varphi' \rightarrow \varphi''$. Assume also that $\bar{\psi}(\bar{p}, \bar{q})$ and $\bar{\chi}(\bar{p}, \bar{q})$ are formulas such that \bar{p} occur positively in $\bar{\psi}$ and negatively in $\bar{\chi}$, while \bar{q} occur negatively in $\bar{\psi}$ and positively in $\bar{\chi}$. Then the logic*

$$\mathbf{Int} + \varphi(\bar{p}, \bar{q}, \bar{\psi}(\bar{p}, \bar{q}), \bar{\chi}(\bar{p}, \bar{q}))$$

is canonical.

The preservation of \mathcal{D} -persistence under ρ (see [Zakharyashev 1996]) and the fact (discovered by Chagrova [1990]) that τL is characterized by an elementary class of Kripke frames whenever L is determined by such a class provide us with an intuitionistic variant of the Fine–van Benthem Theorem.

THEOREM 170. *If a si-logic is characterized by an elementary class of Kripke frames then it is \mathcal{D} -persistent.*

As in the modal case, it is unknown whether the converse of this theorem holds. All known non-elementary si-logics, for instance the Scott logic **SL** and the logics **T_n** of finite n -ary trees (see [Rodenburg 1986]) are not canonical and even strongly complete either, as was shown by Shimura [1995]. (Actually he proved that no logic in the intervals [**SL**, **SL** + **bd**₃] and [**Int**, **T**₂], save of course **Int**, is strongly complete.)

As far as we know, there are no examples of si-logics separating canonicity, \mathcal{D} -persistence and strong completeness. (Ghilardi, Meloni and Miglioli have

recently showed that **SL** in any language with finitely many variables is canonical). Theorem 40 which holds in the intuitionistic case as well gives an algebraic counterpart of strong Kripke completeness.

The finite model property. The first example of an infinitely axiomatizable si-logic without FMP was constructed by Jankov [1968b]—that was in fact the starting point of a long series of “negative” results in modal logic. A finitely axiomatizable logic without FMP appeared two years later in [Kuznetsov and Gerchiu 1970]. The reader can get some impression about this and other examples of that sort by proving (it is really not hard) that

$$\varphi = \beta(\begin{array}{c} \circ \\ \swarrow \quad \downarrow \quad \searrow \\ \circ \quad \circ \quad \circ \\ \uparrow \quad \uparrow \quad \uparrow \\ 1 \quad 2 \quad \circ \end{array}) \notin L = \mathbf{Int} + \mathbf{bw}_4 + \beta(\begin{array}{c} \circ \\ \swarrow \quad \downarrow \quad \searrow \\ \circ \quad \circ \quad \circ \\ \uparrow \quad \uparrow \quad \uparrow \\ 1 \quad 2 \quad \circ \end{array}, \{\{1, 2\}\})$$

but no finite frame can separate φ from L . (Notice by the way that τL is axiomatizable by Sahlqvist formulas; see [Chagrov and Zakharyashev 1995b].)

FMP of a good many si-logics was proved using various forms of filtration; see e.g. [Gabbay 1970], [Ono 1972], [Smoryński 1973], [Ferrari and Miglioli 1993]. As an illustration of a rather sophisticated selective filtration we present here the following

THEOREM 171 (Gabbay and de Jongh 1974). *The logic \mathbf{T}_n (see Table 5) is characterized by the class of finite n -ary trees.*

Proof. First we prove that \mathbf{T}_n is characterized by the class of finite frames of branching $\leq n$. Suppose $\varphi \notin \mathbf{T}_n$ and $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ is a model for \mathbf{T}_n refuting φ . Without loss of generality we may assume that $\mathfrak{F} = \langle W, R \rangle$ is a tree. Let $\Sigma = \mathbf{Sub}\varphi$ and $\Gamma_x = \{\psi \in \Sigma : x \models \psi\}$, for every point x in \mathfrak{F} .

Given x in \mathfrak{F} , put $rg(x) = \{[y] : y \in x\uparrow\}$ and say that x is of *minimal range* if $rg(x) = rg(y)$ for every $y \in [x] \cap x\uparrow$. Since there are only finitely many distinct Σ -equivalence classes in \mathfrak{M} , every $y \in [x]$ sees a point $z \in [x]$ of minimal range. Now we extract from \mathfrak{M} a finite refutation frame $\mathfrak{G} = \langle V, S \rangle$ for φ of branching $\leq n$. To begin with, we select some point x of minimal range at which φ is refuted and put $V_0 = \{x\}$.

Suppose V_k has already been defined. If $|rg(x)| = 1$ for every $x \in V_k$, then we put $\mathfrak{G} = \langle V, S \rangle$, where $V = \bigcup_{i=0}^k V_i$ and S is the restriction of R to V . Otherwise, for each $x \in V_k$ with $|rg(x)| > 1$ and each $[y] \in rg(x)$ different from $[x]$ and such that $\Gamma_z \subset \Gamma_y$ for no $[z] \in rg(x) - \{[x]\}$, we select a point $u \in [y] \cap x\uparrow$ of minimal range. Let U_x be the set of all selected points for x and $V_{k+1} = \bigcup_x U_x$. It should be clear that $\Gamma_x \subset \Gamma_u$ (and $rg(x) \supset rg(u)$), for every $u \in U_x$, and so the inductive process must terminate. Consequently $\mathfrak{G} \not\models \varphi$.

It remains to establish that $\mathfrak{G} \models \mathbf{T}_n$, i.e., \mathfrak{G} is of branching $\leq n$. Suppose otherwise. Then there is a point x in \mathfrak{G} with $m \geq n+1$ immediate successors x_0, \dots, x_m , which are evidently in U_x because \mathfrak{F} is a tree. We are going to construct a substitution instance of \mathbf{T}_n 's axiom \mathbf{bb}_n which is refuted at x in \mathfrak{M} .

Denote by δ_i the conjunction of the formulas in Γ_{x_i} . Since all of them are true at x_i in \mathfrak{M} , we have $x_i \models \delta_i$; and since $\Gamma_i \subseteq \Gamma_j$ for no distinct i and j , we have $x_j \not\models \delta_i$ if $i \neq j$. Put $\chi_i = \delta_i$, for $0 \leq i < n$, $\chi_n = \delta_n \vee \dots \vee \delta_m$ and consider the truth-value of the formula $\psi = \mathbf{bb}_n\{\chi_0/p_0, \dots, \chi_n/p_n\}$ at x in \mathfrak{M} .

Since xRx_i for every $i = 0, \dots, m$, we have $x \not\models \bigvee_{i=0}^n \chi_i$. Suppose that $x \not\models \bigwedge_{i=0}^n ((\chi_i \rightarrow \bigvee_{i \neq j} \chi_j) \rightarrow \bigvee_{i \neq j} \chi_j)$. Then $y \models \chi_i \rightarrow \bigvee_{i \neq j} \chi_j$ and $y \not\models \bigvee_{i \neq j} \chi_j$, for some $y \in x\uparrow$ and some $i \in \{0, \dots, n\}$, and hence $y \not\models \chi_i$. Since $x_i \models \chi_i$ and $x_i \not\models \bigvee_{i \neq j} \chi_j$, y sees no point in $[x_i]$ and so $y \not\sim_{\Sigma} x$ (for otherwise x would not be of minimal range). Therefore, $\Gamma_{x_j} \subseteq \Gamma_y$ for some $j \in \{0, \dots, m\}$, and then $y \models \chi_j$ if $j < n$ and $y \models \chi_n$ if $j \geq n$, which is a contradiction.

It follows that $x \models \bigwedge_{i=0}^n ((\chi_i \rightarrow \bigvee_{i \neq j} \chi_j) \rightarrow \bigvee_{i \neq j} \chi_j)$, from which $x \models \psi$, contrary to \mathfrak{M} being a model for \mathbf{bb}_n . It remains to notice that every finite frame of branching $\leq n$ is a reduct of a finite n -ary tree, which clearly validates \mathbf{T}_n . ■

Another way of obtaining general results on FMP of si-logics is to translate the corresponding results in modal logic with the help of the Preservation Theorem.

THEOREM 172. *Every si-logic of finite depth (i.e., every logic in $\text{Ext}\mathbf{BD}_n$, for $n < \omega$) is locally tabular.*

Note, however, that unlike $\text{NExt}\mathbf{K4}$, the converse does not hold: the Dummett logic \mathbf{LC} , characterized by the class of finite chains (or by the infinite ascending chain), is locally tabular. As we saw in Section 1.7, every non-locally tabular in $\text{NExt}\mathbf{S4}$ logic is contained in $\mathbf{Grz.3}$, the only *pre-locally tabular logic* in $\text{NExt}\mathbf{S4}$. But in $\text{Ext}\mathbf{Int}$ this way of determining local tabularity does not work:

THEOREM 173 (Mardaev 1984). *There is a continuum of pre-locally tabular logics in $\text{Ext}\mathbf{Int}$.*

Besides, it is not clear whether every locally tabular logic in $\text{Ext}\mathbf{Int}$ (or $\text{NExt}\mathbf{K4}$) is contained in a pre-locally tabular one.

An intuitionistic formula is said to be *essentially negative* if every occurrence of a variable in it is in the scope of some \neg . If φ is essentially negative then $T(\varphi)$ is a $\Box\Diamond$ -formula, which yields

THEOREM 174 (McKay 1971, Rybakov 1978). *If a si-logic L is decidable (or has FMP) and φ is an essentially negative formula then $L+\varphi$ is decidable (has FMP).*

Originally this result was proved with the help of Glivenko's Theorem (see Section 7 in *Intuitionistic Logic*). Say that an occurrence of a variable in a formula is *essential* if it is not in the scope of any \neg . A formula φ is *mild* if every two essential occurrences of the same variable in φ are either both positive or both negative. Kuznetsov [1972] claimed (we have not seen the proof) that all si-logics whose extra axioms do not contain negative occurrences of essential variables have FMP. And Wroński [1989] announced that if L is a decidable si-logic and φ a mild formula then $L + \varphi$ is also decidable.

Subframe and cofinal subframe si-logics—that is logics axiomatizable by canonical formulas of the form $\beta(\mathfrak{F})$ and $\beta(\mathfrak{F}, \perp)$, respectively—can be characterized both syntactically and semantically (see [Zakharyashev 1996]).

THEOREM 175. *The following conditions are equivalent for every si-logic L :*

- (i) *L is a (cofinal) subframe logic;*
- (ii) *L is axiomatizable by implicative (respectively, disjunction free) formulas;*
- (iii) *L is characterized by a class of finite frames closed under the formation of (cofinal) subframes.*

That all si-logics with disjunction free axioms have FMP was first proved by McKay [1968] with the help of Diego's [1966] Theorem according to which there are only finitely many pairwise non-equivalent in **Int** disjunction free formulas in variables p_1, \dots, p_n (see also [Urquhart 1974]).

Since frames for **Int** contain no clusters, Theorem 58 and its analog for cofinal subframe logics reduce in the intuitionistic case to the following result which is due to Chagrova [1986], Rodenburg [1986], Shimura [1993] and Zakharyashev [1996].

THEOREM 176. *All si-logics with disjunction free axioms are elementary (definable by $\forall\exists$ -sentences) and \mathcal{D} -persistent.*

Theorem 68 is translated into the intuitionistic case simply by replacing **K4** with **Int**, \oplus with $+$ and α with β . As a consequence we obtain, for instance, that Ono's [1972] \mathbf{B}_n and all other logics whose canonical axioms are built on trees have FMP. Moreover, we also have

THEOREM 177 (Sobolev 1977b, Nishimura 1960). *All si-logics with extra axioms in one variable have FMP and are decidable.*

In fact Sobolev [1977b] proved a more general (but rather complicated) syntactical sufficient condition of FMP and constructed a formula in two variables axiomatizing a si-logic without FMP (Shehtman's [1977] incomplete si-logic has also axioms in two variables).

Tabularity By the Blok–Esakia and Preservation Theorems, the situation with tabular logics in ExtInt is the same as in NExtGrz . In particular, $L \in \text{ExtInt}$ is tabular iff $\mathbf{BD}_n + \mathbf{BW}_n \subseteq L$ for some $n < \omega$ iff L is not a sublogic of one of the three pretabular logics in ExtInt , namely \mathbf{LC} , \mathbf{BD}_2 and $\mathbf{KC} + \mathbf{bd}_3$. (The pretabular si-logics were described by Maksimova [1972].) The tabularity problem is decidable in ExtInt .

3.5 Disjunction property

One of the aims of studying extensions of \mathbf{Int} , which may be of interest for applications in computer science, is to describe the class of constructive si-logics. At the propositional level a consistent logic $L \in \text{ExtInt}$ is regarded to be constructive if it has the *disjunction property* (DP, for short) which means that for all formulas φ and ψ ,

$$\varphi \vee \psi \in L \text{ implies } \varphi \in L \text{ or } \psi \in L.$$

That intuitionistic logic itself is constructive in this sense was proved in a syntactic way by Gentzen [1934–1935]. However, Łukasiewicz (1952) conjectured that no proper consistent extension of \mathbf{Int} has DP.

A similar property was introduced for modal logics (see e.g. [Lemmon and Scott 1977]): $L \in \text{NExtK}$ has the (*modal*) *disjunction property* if, for every $n \geq 1$ and all formulas $\varphi_1, \dots, \varphi_n$,

$$\Box\varphi_1 \vee \dots \vee \Box\varphi_n \in L \text{ implies } \varphi_i \in L, \text{ for some } i \in \{1, \dots, n\}.$$

The following theorem (in a somewhat different form it was proved in [Hughes and Cresswell 1984] and [Maksimova 1986]) provides a semantic criterion of DP.

THEOREM 178. *Suppose a modal or si-logic L is characterized by a class \mathcal{C} of descriptive rooted frames closed under the formation of rooted generated subframes. Then L has DP iff, for every $n \geq 1$ and all $\mathfrak{F}_1, \dots, \mathfrak{F}_n \in \mathcal{C}$ with roots x_1, \dots, x_n , there is a frame \mathfrak{F} for L with root x such that the disjoint union $\mathfrak{F}_1 + \dots + \mathfrak{F}_n$ is a generated subframe of \mathfrak{F} with $\{x_1, \dots, x_n\} \subseteq x\uparrow$.*

Proof. We consider only the modal case. (\Rightarrow) Let $\mathfrak{F}_L = \langle W_L, R_L, P_L \rangle$ be a universal frame for L , big enough to contain $\mathfrak{F}_1 + \dots + \mathfrak{F}_n$ as its generated subframe. Assuming that \mathfrak{F}_L is associated with a suitable canonical model for L , we show that there is a point x in \mathfrak{F}_L such that $x\uparrow = W_L$. The set

$$\Delta' = \{\neg\Box\varphi : \exists y \in W_L y \not\models \varphi\}$$

is L -consistent (for otherwise $\Box\varphi_1 \vee \dots \vee \Box\varphi_n \in L$ for some $\varphi_1, \dots, \varphi_n \notin L$). Let Δ be a maximal L -consistent extension of Δ' and x the point in \mathfrak{F}_L where Δ is true. Then $xR_L y$, for every $y \in W_L$.

(\Leftarrow) Suppose otherwise. Then there are formulas $\varphi_1, \dots, \varphi_n \notin L$ such that $\Box\varphi_1 \vee \dots \vee \Box\varphi_n \in L$. Take frames $\mathfrak{F}_1, \dots, \mathfrak{F}_n \in \mathcal{C}$ refuting $\varphi_1, \dots, \varphi_n$ at their roots, respectively, and let \mathfrak{F} be a rooted frame for L containing $\mathfrak{F}_1 + \dots + \mathfrak{F}_n$ as a generated subframe and such that its root x sees the roots of $\mathfrak{F}_1, \dots, \mathfrak{F}_n$. Then all the formulas $\Box\varphi_1, \dots, \Box\varphi_n$ are refuted at x and so $\Box\varphi_1 \vee \dots \vee \Box\varphi_n \notin L$, which is a contradiction. \blacksquare

It should be clear that if we use only the sufficient condition of Theorem 178, the requirement that frames in \mathcal{C} are descriptive is redundant. Furthermore, it is easy to see that for $L \in \text{NExt}\mathbf{K4}$ we may assume $n \leq 2$. And clearly a logic $L \in \text{NExt}\mathbf{S4}$ has DP iff, for all φ and ψ , $\Box\varphi \vee \Box\psi \in L$ implies $\Box\varphi \in L$ or $\Box\psi \in L$.

As a direct consequence of the proof above we obtain

COROLLARY 179. *A modal or si-logic L has DP iff the canonical frame $\mathfrak{F}_L = \langle W_L, R_L \rangle$ contains a point x such that $x\uparrow = W_L$.*

Using the semantic criterion above it is not hard to show that DP is preserved under ρ , τ and σ . It is also a good tool for proving and disproving DP of logics with transparent semantics.

EXAMPLE 180.

- (i) Let $\mathfrak{F}_1, \dots, \mathfrak{F}_n$ be serial rooted Kripke frames. Then the frame obtained by adding a root to $\mathfrak{F}_1 + \dots + \mathfrak{F}_n$ is also serial. Therefore, \mathbf{D} has DP. In the same way one can show that \mathbf{K} , $\mathbf{K4}$, \mathbf{T} , $\mathbf{S4}$, \mathbf{Grz} , \mathbf{GL} and many other modal logics have DP.
- (ii) Since no rooted symmetrical frame can contain a proper generated subframe, no consistent logic in $\text{NExt}\mathbf{KB}$ has DP.

The first proper extensions of \mathbf{Int} with DP were constructed by Kreisel and Putnam [1957]: these were \mathbf{KP} (now called the *Kreisel–Putnam logic*) and \mathbf{SL} (known as the *Scott logic*). We present here Gabbay's [1970] proof that \mathbf{KP} has DP.

THEOREM 181 (Kreisel and Putnam 1957). *\mathbf{KP} has DP.*

Proof. Using filtration one can show that \mathbf{KP} is characterized by the class of finite rooted frames $\mathfrak{F} = \langle W, R \rangle$ satisfying the condition

$$(15) \quad \forall x, y, z (xRy \wedge xRz \wedge \neg yRz \wedge \neg zRy \rightarrow \exists u (xRu \wedge uRy \wedge uRz \wedge \forall v (uRv \rightarrow \exists w (vRw \wedge (yRw \vee zRw))))).$$

If \mathfrak{F} is such a frame then for each non-empty $X \subseteq W^{\leq 1}$, the generated subframe of \mathfrak{F} based on the set $W - (W^{\leq 1} - X)\downarrow$ is rooted; we denote its root by $r(X)$.

Let $\mathfrak{F}_1 = \langle W_1, R_1 \rangle$ and $\mathfrak{F}_2 = \langle W_2, R_2 \rangle$ be finite rooted frames satisfying (15). We construct from them a frame $\mathfrak{F} = \langle W, R \rangle$ by taking

$$W = W_1 \cup W_2 \cup U,$$

where $U = \{X_1 \cup X_2 : X_1 \subseteq W_1^{\leq 1}, X_2 \subseteq W_2^{\leq 1}, X_1, X_2 \neq \emptyset\}$, and

$$\begin{aligned} xRy \quad \text{iff} \quad & (x, y \in W_i \wedge xR_i y) \vee (x, y \in U \wedge x \supseteq y) \vee \\ & (x = X_1 \cup X_2 \in U \wedge y \in W_i \wedge r(X_i)R_i y). \end{aligned}$$

It follows from the given definition that $\mathfrak{F}_1 + \mathfrak{F}_2$ is a generated subframe of \mathfrak{F} , $W_1 \cup W_2$ is a cover for \mathfrak{F} and $W_1^{\leq 1} \cup W_2^{\leq 1}$ is its root. So our theorem will be proved if we show that (15) holds.

Suppose $x, y, z \in W$ satisfy the premise of (15). Since (15) holds for \mathfrak{F}_1 and \mathfrak{F}_2 , we can assume that $x = X_1 \cup X_2 \in U$. Let $Y_1 \cup Y_2$ and $Z_1 \cup Z_2$ be the sets of final points in $y\uparrow$ and $z\uparrow$, respectively, with $Y_i, Z_i \subseteq W_i$. By the definition of R , we have $Y_i, Z_i \subseteq X_i$. Consider $u = (Y_1 \cup Z_1) \cup (Y_2 \cup Z_2)$. Clearly, xRu, uRy and uRz . Suppose now that $v \in u\uparrow$. Let w be any final point in $v\uparrow$. Then $v \in (Y_1 \cup Z_1) \cup (Y_2 \cup Z_2)$ and so either yRw or zRw . ■

Other examples of constructive si-logics were constructed by Ono [1972] and Gabbay and de Jongh [1974], namely, \mathbf{B}_n and \mathbf{T}_n . Anderson [1972] proved that among the consistent si-logics with extra axioms in one variable only those of the form $\mathbf{Int} + n\mathbf{f}_{2n+2}$, for $n \geq 5$, have DP (for $n = 6$ the proof was found by Wroński [1974]; see also [Sasaki 1992]). Finally, Wroński [1973] showed that there is a continuum of si-logics with DP.

The additional axioms of logics in all these examples contained occurrences of \vee ; on the other hand, known examples of si-logics with disjunction free extra axioms, say \mathbf{LC} , \mathbf{KC} , \mathbf{Cl} , \mathbf{BW}_n or \mathbf{BD}_n , were not constructive. This observation led Hosoi and Ono [1973] to the conjecture that the disjunction free fragment of every consistent si-logic with DP coincides with that of \mathbf{Int} . We present a proof of this conjecture following [Zakharyashev 1987].

First we describe the cofinal subframe logics in $\mathbf{NExtS4}$ with DP, assuming that every such logic L is represented by its independent canonical axiomatization

$$(16) \quad L = \mathbf{S4} \oplus \{\alpha(\mathfrak{F}_i, \perp) : i \in I\}.$$

All frames in the rest of this section are assumed to be quasi-ordered.

Say that a finite rooted frame \mathfrak{F} with ≥ 2 points is *simple* if its root cluster and at least one of the final clusters are simple. Suppose $\mathfrak{F} = \langle W, R \rangle$ is a

simple frame, $a_0, a_1, \dots, a_m, a_{m+1}, \dots, a_n$ are all its points, with a_0 being the root, $C(a_1), \dots, C(a_m)$ all the distinct immediate cluster-successors of a_0 , and a_n a final point with simple $C(a_n)$. For every $k = 1, \dots, n$, define a formula ψ_k by taking

$$\psi_k = \bigwedge_{a_i R a_j, i \neq 0} \varphi_{ij} \wedge \bigwedge_{i=1}^n \varphi_i \wedge \varphi'_\perp \rightarrow p_k$$

where φ_{ij} , φ_i were defined in Section 3.2 and $\varphi'_\perp = \Box(\bigwedge_{i=1}^n \Box p_i \rightarrow \perp)$. Now we associate with \mathfrak{F} the formula $\gamma(\mathfrak{F}) = \Box p_0 \vee \Box \psi_1$ if $m = 1$, and the formula $\gamma(\mathfrak{F}) = \Box \psi_1 \vee \dots \vee \Box \psi_m$ if $m > 1$.

LEMMA 182. *For every simple frame \mathfrak{F} , $\gamma(\mathfrak{F}) \in \mathbf{S4} \oplus \alpha(\mathfrak{F}, \perp)$.*

Proof. It is enough to show that $\mathfrak{G} \not\models \gamma(\mathfrak{F})$ implies $\mathfrak{G} \not\models \alpha(\mathfrak{F}, \perp)$, for any finite \mathfrak{G} . So suppose $\gamma(\mathfrak{F})$ is refuted in a finite frame \mathfrak{G} under some valuation. Define a partial map f from \mathfrak{G} onto \mathfrak{F} by taking

$$f(x) = \begin{cases} a_0 & \text{if } x \not\models \gamma(\mathfrak{F}) \\ a_i & \text{if } x \not\models \psi_i, 1 \leq i \leq n \\ \text{undefined} & \text{otherwise.} \end{cases}$$

One can readily check that f is a subreduction of \mathfrak{G} to \mathfrak{F} . However it is not necessarily cofinal. So we extend f by putting $f(x) = a_n$, for every x of depth 1 in \mathfrak{G} such that $f(x \downarrow) = \{a_0\}$. Clearly, the improved map is still a subreduction of \mathfrak{G} to \mathfrak{F} , and φ'_\perp ensures its cofinality. ■

Using the semantical properties of the canonical formulas it is a matter of routine to prove the following

LEMMA 183. *Suppose $i \in \{1, \dots, m\}$ and \mathfrak{G} is the subframe of \mathfrak{F} generated by a_i . Then $\alpha(\mathfrak{G}, \perp) \in \mathbf{S4} \oplus \psi_i$.*

We are in a position now to prove a criterion of DP for the cofinal subframe logics in $\mathbf{NExtS4}$.

THEOREM 184. *A consistent cofinal subframe logic $L \in \mathbf{NExtS4}$ has the disjunction property iff no frame \mathfrak{F}_i in its independent axiomatization (16) is simple, for $i \in I$.*

Proof. (\Rightarrow) Suppose, on the contrary, that \mathfrak{F}_i is simple, for some $i \in I$. Since the axiomatization (16) is independent, every proper generated subframe of \mathfrak{F}_i validates L . By Lemma 182, $\gamma(\mathfrak{F}_i) \in L$ and so either $p_0 \in L$ or $\psi_j \in L$. However, both alternatives are impossible: the former means that L is inconsistent, while the latter, by Lemma 183, implies $\alpha(\mathfrak{G}, \perp) \in L$, where \mathfrak{G} is the subframe of \mathfrak{F}_i generated by an immediate successor of \mathfrak{F}_i 's root.

Figure 15.

(\Leftarrow) Given two finite rooted frames \mathfrak{G}_1 and \mathfrak{G}_2 for L , we construct the frame \mathfrak{F} as shown in Fig. 15 and prove that $\mathfrak{F} \models L$. Suppose otherwise, i.e., there exists a cofinal subreduction f of \mathfrak{F} to \mathfrak{F}_i , for some $i \in I$. Let x_i be the root of \mathfrak{F}_i . Since \mathfrak{G}_1 and \mathfrak{G}_2 are not cofinally subreducible to \mathfrak{F}_i and since L is consistent, $f^{-1}(x_i) = \{x\}$. By the cofinality condition, it follows in particular that $y \in \text{dom} f$. But then \mathfrak{F}_i is simple, which is a contradiction. Thus, by Theorem 178, L has DP. \blacksquare

Note that in fact the proof of (\Rightarrow) shows that if $L \in \text{NExtS4}$, \mathfrak{F} is a simple frame, $\alpha(\mathfrak{F}, \perp) \in L$ and $\alpha(\mathfrak{G}, \perp) \notin L$ for any proper generated subframe \mathfrak{G} of \mathfrak{F} then L does not have DP. Transferring this observation to the intuitionistic case, we obtain

THEOREM 185 (Minari 1986, Zakharyashev 1987). *If a si-logic is consistent and has DP then the disjunction free fragments of L and **Int** are the same.*

Sufficient conditions of DP in terms of canonical formulas can be found in [Chagro and Zakharyashev 1993, 1997].

Since classical logic is not constructive, it is of interest to find maximal consistent si-logics with DP. That they exist follows from Zorn's Lemma. Here is a concrete example of such a logic.

Trying to formalize the proof interpretation of intuitionistic logic, Medvedev [1962] proposed to treat intuitionistic formulas as finite problems. Formally, a *finite problem* is a pair $\langle X, Y \rangle$ of finite sets such that $Y \subseteq X$ and $X \neq \emptyset$; elements in X are called *possible solutions* and elements in Y *solutions* to the problem. The operations on finite problems, corresponding to the logical connectives, are defined as follows:

$$\begin{aligned} \langle X_1, Y_1 \rangle \wedge \langle X_2, Y_2 \rangle &= \langle X_1 \times X_2, Y_1 \times Y_2 \rangle, \\ \langle X_1, Y_1 \rangle \vee \langle X_2, Y_2 \rangle &= \langle X_1 \sqcup X_2, Y_1 \sqcup Y_2 \rangle, \\ \langle X_1, Y_1 \rangle \rightarrow \langle X_2, Y_2 \rangle &= \langle X_2^{X_1}, \{f \in X_2^{X_1} : f(Y_1) \subseteq Y_2\} \rangle, \end{aligned}$$

Figure 16.

$$\perp = \langle X, \emptyset \rangle.$$

Here $X \sqcup Y = (X \times \{1\}) \cup (Y \times \{2\})$ and X^Y is the set of all functions from X into Y . Note that in the definition of \perp the set X is fixed, but arbitrary; for definiteness one can take $X = \{\emptyset\}$.

Now we can interpret formulas by finite problems. Namely, given a formula φ , we replace its variables by arbitrary finite problems and perform the operations corresponding to the connectives in φ . If the result is a problem with a non-empty set of solutions no matter what finite problems are substituted for the variables in φ , then φ is called *finitely valid*. One can show that the set of all finitely valid formulas is a si-logic; it is called *Medvedev's logic* and denoted by **ML**.

In fact, **ML** can be defined semantically. Medvedev [1966] showed that **ML** coincides with the set of formulas that are valid in all frames \mathfrak{B}_n having the form of the n -ary Boolean cubes with the topmost point deleted; for $n = 1, 2, 3, 4$, the Medvedev frames are shown in Fig. 16. Since $\mathfrak{B}_n + \mathfrak{B}_m$ is a generated subframe of \mathfrak{B}_{n+m} , **ML** has DP. Moreover, Levin [1969] proved that it has no proper consistent extension with DP. The following proof of this result is due to Maksimova [1986].

THEOREM 186 (Levin 1969). **ML** is a maximal si-logic with DP.

Proof. Suppose, on the contrary, that there exists a proper consistent extension L of **ML** having DP. Then we have a formula $\varphi \in L - \mathbf{ML}$. We show first that there is an essentially negative substitution instance φ^* of φ such that $\varphi^* \notin \mathbf{ML}$. Since $\varphi(p_1, \dots, p_n) \notin \mathbf{ML}$, there is a Medvedev frame \mathfrak{B}_m refuting φ under some valuation \mathfrak{V} . With every point x in \mathfrak{B}_m we associate a new variable q_x and extend \mathfrak{V} to these variables by taking $\mathfrak{V}(q_x)$ to be the set of final points in \mathfrak{B}_m that are not accessible from x . By the construction of \mathfrak{B}_m , we have $y \models \neg q_x$ iff $y \in x\uparrow$, from which

$$\mathfrak{V}\left(\bigvee_{x \in \mathfrak{V}(p_i)} \neg q_x\right) = \mathfrak{V}(p_i).$$

Let $\varphi^* = \varphi(\bigvee_{x \in \mathfrak{B}(p_1)} \neg q_x, \dots, \bigvee_{x \in \mathfrak{B}(p_n)} \neg q_x)$. It follows that $\mathfrak{B}(\varphi^*) = \mathfrak{B}(\varphi)$ and so $\varphi^* \notin \mathbf{ML}$.

Thus, we may assume that φ is an essentially negative formula. Since $\mathbf{KP} \subseteq \mathbf{ML}$, \mathbf{ML} contains the formulas

$$\mathbf{nd}_k = (\neg p \rightarrow \neg q_1 \vee \dots \vee \neg q_k) \rightarrow (\neg p \rightarrow \neg q_1) \vee \dots \vee (\neg p \rightarrow \neg q_k)$$

which, as is easy to see, belong to \mathbf{KP} . Let us consider the logic

$$\mathbf{ND} = \mathbf{Int} + \{\mathbf{nd}_k : k \geq 1\}.$$

Using the fact that the outermost \rightarrow in \mathbf{nd}_k can be replaced with \leftrightarrow and that $(\neg p \rightarrow \neg q) \leftrightarrow \neg(\neg p \wedge q) \in \mathbf{Int}$, one can readily show that every essentially negative formula is equivalent in \mathbf{ND} to the conjunction of formulas of the form $\neg\chi_1 \vee \dots \vee \neg\chi_l$. So $L\text{-}\mathbf{ML}$ contains a formula of the form $\neg\chi_1 \vee \dots \vee \neg\chi_l$. Since L has DP, $\neg\chi_i \in L$ for some i . But then, by Glivenko's Theorem, $\neg\chi_i \in \mathbf{ML}$, which is a contradiction. ■

REMARK. \mathbf{ML} is not finitely axiomatizable, as was shown by Maksimova *et al.* [1979]. Nobody knows whether it is decidable.

It turns out, however, that \mathbf{ML} is not the unique maximal logic with DP in \mathbf{ExtInt} . Kirk [1982] noted that there is no greatest consistent si-logic with DP. Maksimova [1984] showed that there are infinitely many maximal constructive si-logics, and Chagrov [1992a] proved that in fact there are a continuum of them; see also Ferrari and Miglioli [1993, 1995a, 1995b]. Galanter [1990] claims that each si-logic characterized by the class of frames of the form

$$\langle \{W : W \subseteq \{1, \dots, n\}, W \neq \emptyset, |W| \notin N\}, \supseteq \rangle,$$

where $n = 1, 2, \dots$ and N is some fixed infinite set of natural numbers, is a maximal si-logic with DP.

3.6 Intuitionistic Modal Logics

All modal logics we have dealt with so far were constructed on the classical non-modal basis. It can be replaced by logics of other types. For instance, one can consider modal logics based on relevant logic (see e.g. [Fuhrmann 1989]) or many-valued logics (see e.g. [Seegerberg 1967], [Morikawa 1989], [Ostermann 1988]), and many others. In this section we briefly discuss modal logics with the intuitionistic basis.

Unlike the classical case, the intuitionistic \Box and \Diamond are not supposed to be dual, which provides more possibilities for defining intuitionistic modal logics. For a non-empty set M of modal operators, let \mathcal{L}_M be the standard propositional language augmented by the connectives in M . By an

intuitionistic modal logic in the language \mathcal{L}_M we understand any subset of \mathcal{L}_M containing **Int** and closed under modus ponens, substitution and the regularity rule $\varphi \rightarrow \psi / \bigcirc \varphi \rightarrow \bigcirc \psi$, for every $\bigcirc \in M$.

There are three ways of defining intuitionistic analogues of (classical) normal modal logics. First, one can take the family of logics extending the basic system **IntK** $_{\square}$ in the language \mathcal{L}_{\square} which is axiomatized by adding to **Int** the standard axioms of **K**

$$\square(p \wedge q) \leftrightarrow \square p \wedge \square q \text{ and } \square \top.$$

An example of a logic in this family is Kuznetsov's [1985] intuitionistic provability logic **I** $^{\Delta}$ (Kuznetsov used Δ instead of \square), the intuitionistic analog of the provability logic **GL**. It can be obtained by adding to **IntK** $_{\square}$ (and even to **Int**) the axioms

$$p \rightarrow \square p, (\square p \rightarrow p) \rightarrow p, ((p \rightarrow q) \rightarrow p) \rightarrow (\square q \rightarrow p).$$

A model theory for logics in **NExtIntK** $_{\square}$ was developed by Ono [1977], Božić and Došen [1984], Došen [1985a], Sotirov [1984] and Wolter and Zakharyashev [1997, 1999a]; we discuss it below. Font [1984, 1986] considered these logics from the algebraic point of view, and Luppi [1996] investigated their interpolation property by proving, in particular, that the superamalgamability of the corresponding varieties of algebras is equivalent to interpolation.

A possibility operator \diamond in logics of this sort can be defined in the classical way by taking $\diamond \varphi = \neg \square \neg \varphi$. Note, however, that in general this \diamond does not distribute over disjunction and that the connection via negation between \square and \diamond is too strong from the intuitionistic standpoint (actually, the situation here is similar to that in intuitionistic predicate logic where \exists and \forall are not dual.)

Another family of "normal" intuitionistic modal logics can be defined in the language \mathcal{L}_{\diamond} by taking as the basic system the smallest logic in \mathcal{L}_{\diamond} to contain the axioms

$$\diamond(p \vee q) \leftrightarrow \diamond p \vee \diamond q \text{ and } \neg \diamond \perp;$$

it will be denoted by **IntK** $_{\diamond}$. Logics in **NExtIntK** $_{\diamond}$ were studied by Božić and Došen [1984], Došen [1985a], Sotirov [1984] and Wolter [1997e].

Finally, we can define intuitionistic modal logics with independent \square and \diamond . These are extensions of **IntK** $_{\square \diamond}$, the smallest logic in the language $\mathcal{L}_{\square \diamond}$ containing both **IntK** $_{\square}$ and **IntK** $_{\diamond}$. Fischer Servi [1980, 1984] constructed a logic in **NExtIntK** $_{\square \diamond}$ by imposing a weak connection between the necessity and possibility operators:

$$\mathbf{FS} = \mathbf{IntK}_{\square \diamond} \oplus \diamond(p \rightarrow q) \rightarrow (\square p \rightarrow \diamond q) \oplus (\diamond p \rightarrow \square q) \rightarrow \square(p \rightarrow q).$$

A remarkable feature of **FS** is that the standard translation ST of modal formulas into first order ones (see *Correspondence Theory*) not only embeds **K** into classical predicate logic but also **FS** into intuitionistic first order logic: φ belongs to the former iff $ST(\varphi)$ is a theorem of the latter. According to Simpson [1994], this result was proved by C. Stirling; see also Grefe [1997].

Various extensions of **FS** were studied by Bull [1966a], Ono [1977], Fischer Servi [1977, 1980, 1984], Amati and Pirri [1994], Ewald [1986], Wolter and Zakharyashev [1997], Wolter [1997e]. The best known one is probably the logic

$$\begin{aligned} \mathbf{MIPC} = \mathbf{FS} \oplus \Box p \rightarrow p \oplus \Box p \rightarrow \Box \Box p \oplus \Diamond p \rightarrow \Box \Diamond p \oplus \\ p \rightarrow \Diamond p \oplus \Diamond \Diamond p \rightarrow \Diamond p \oplus \Diamond \Box p \rightarrow \Box p \end{aligned}$$

introduced by Prior [1957]. Bull [1966a] noticed that the translation $*$ defined by

$$\begin{aligned} (p_i)^* &= P_i(x), \quad \perp^* = \perp, \\ (\psi \odot \chi)^* &= \psi^* \odot \chi^*, \text{ for } \odot \in \{\wedge, \vee, \rightarrow\}, \\ (\Box \psi)^* &= \forall x \psi^*, \quad (\Diamond \psi)^* = \exists x \psi^* \end{aligned}$$

is an embedding of **MIPC** into the monadic fragment of intuitionistic predicate logic. Ono [1977], Ono and Suzuki [1988], Suzuki [1990], and Bezhanishvili [1998] investigated the relations between logics in **NExtMIPC** and superintuitionistic predicate logics induced by that translation.

In what follows we restrict attention only to the classes of intuitionistic modal logics introduced above. An interesting example of a system not covered here was constructed by Wijesekera [1990]. A general model theory for such logics is developed by Sotirov [1984] and Wolter and Zakharyashev [1997].

Let us consider first the algebraic and relational semantics for the logics introduced above. All the semantical concepts to be defined below turn out to be natural combinations of the corresponding notions developed for classical modal and si-logics. For details and proofs we refer the reader to Wolter and Zakharyashev [1997, 1999a].

From the algebraic point of view, every logic $L \in \mathbf{NExtIntK}_M$, for $M \subseteq \{\Box, \Diamond\}$, corresponds to the variety of Heyting algebras with one or two operators validating L . The variety of algebras for **IntK_M** will be called the *variety of M-algebras*.

To construct the relational representations of M -algebras, we define a \Box -*frame* to be a structure of the form $\langle W, R, R_\Box, P \rangle$ in which $\langle W, R, P \rangle$ is an intuitionistic frame, R_\Box a binary relation on W such that

$$R \circ R_\Box \circ R = R_\Box$$

and P is closed under the operation

$$\Box X = \{x \in W : \forall y \in W (xR_\Box y \rightarrow y \in X)\}.$$

A \diamond -frame has the form $\langle W, R, R_\diamond, P \rangle$, where $\langle W, R, P \rangle$ is again an intuitionistic frame, R_\diamond a binary relation on W satisfying the condition

$$R^{-1} \circ R_\diamond \circ R^{-1} = R_\diamond$$

and P is closed under

$$\diamond X = \{x \in W : \exists y \in X \ x R_\diamond y\}.$$

Finally, a $\Box\diamond$ -frame is a structure $\langle W, R, R_\Box, R_\diamond, P \rangle$ the unimodal reducts $\langle W, R, R_\Box, P \rangle$ and $\langle W, R, R_\diamond, P \rangle$ of which are \Box - and \diamond -frames, respectively. (To see why the intuitionistic and modal accessibility relations are connected by the conditions above the reader can construct in the standard way the canonical models for the logics under consideration. The important point here is that we take the Leibnizean definition of the truth-relation for the modal operators. Other definitions may impose different connecting conditions; see below.)

Given a $\Box\diamond$ -frame $\mathfrak{F} = \langle W, R, R_\Box, R_\diamond, P \rangle$, it is easy to check that its *dual*

$$\mathfrak{F}^+ = \langle P, \cap, \cup, \rightarrow, \emptyset, \Box, \diamond \rangle$$

is a $\Box\diamond$ -algebra. Conversely, for each $\Box\diamond$ -algebra $\mathfrak{A} = \langle A, \wedge, \vee, \rightarrow, \perp, \Box, \diamond \rangle$ we can define the *dual frame*

$$\mathfrak{A}_+ = \langle W, R, R_\Box, R_\diamond, P \rangle$$

by taking $\langle W, R, P \rangle$ to be the dual of the Heyting algebra $\langle A, \wedge, \vee, \rightarrow, \perp \rangle$ and putting

$$\nabla_1 R_\Box \nabla_2 \text{ iff } \forall a \in A \ (\Box a \in \nabla_1 \rightarrow a \in \nabla_2),$$

$$\nabla_1 R_\diamond \nabla_2 \text{ iff } \forall a \in A \ (a \in \nabla_2 \rightarrow \diamond a \in \nabla_1).$$

\mathfrak{A}_+ is a $\Box\diamond$ -frame and, moreover, $\mathfrak{A} \cong (\mathfrak{A}_+)^+$. Using the standard technique of the model theory for classical modal and si-logics, one can show that a $\Box\diamond$ -frame \mathfrak{F} is isomorphic to its bidual $(\mathfrak{F}^+)_+$ iff $\mathfrak{F} = \langle W, R, R_\Box, R_\diamond, P \rangle$ is *descriptive*, i.e., $\langle W, R, P \rangle$ is a descriptive intuitionistic frame and, for all $x, y \in W$,

$$x R_\Box y \text{ iff } \forall X \in P \ (x \in \Box X \rightarrow y \in X),$$

$$x R_\diamond y \text{ iff } \forall X \in P \ (y \in X \rightarrow x \in \diamond X).$$

Thus we get the following completeness theorem.

THEOREM 187. *Every logic $L \in \text{NExtIntK}_{\Box\diamond}$ is characterized by a suitable class of (descriptive) $\Box\diamond$ -frames, e.g. by the class $\{\mathfrak{A}_+ : \mathfrak{A} \models L\}$.*

Similar results hold for logics in NExtIntK_\Box and NExtIntK_\diamond .

As usual, by a *Kripke frame* we understand a frame $\langle W, R, R_\square, R_\diamond, P \rangle$ in which P consists of all R -cones; in this case we omit P . An intuitionistic modal logic L is \mathcal{D} -persistent if the underlying Kripke frame of each descriptive frame for L validates L . For example, **FS** as well as the logics

$$\mathbf{L}(k, l, m, n) = \mathbf{IntK}_{\square\Diamond} \oplus \Diamond^k \square^l p \rightarrow \square^m \Diamond^n p, \text{ for } k, l, m, n \geq 0$$

are \mathcal{D} -persistent and so Kripke complete (see Wolter and Zakharyashev [1997]). Descriptive frames validating **FS** satisfy the conditions

$$xR_\diamond y \rightarrow \exists z (yRz \wedge xR_\square z \wedge xR_\diamond z),$$

$$xR_\square y \rightarrow \exists z (xRz \wedge zR_\square y \wedge zR_\diamond y),$$

and those for $\mathbf{L}(k, l, m, n)$ satisfy

$$xR_\diamond^k y \wedge xR_\square^m y \rightarrow \exists u (yR_\square^l u \wedge zR_\diamond^n u).$$

It follows, in particular, that **MIPC** is \mathcal{D} -persistent; its Kripke frames have the properties: R_\square is a quasi-order, $R_\diamond = R_\square^{-1}$ and $R_\square = R \circ (R_\square \cap R_\diamond)$. On the contrary, \mathbf{I}^Δ is not \mathcal{D} -persistent, although it is complete with respect to the class of Kripke frames $\langle W, R, R_\square \rangle$ such that $\langle W, R_\square \rangle$ is a frame for **GL** and R the reflexive closure of R_\square .

The next step in constructing duality theory of M-algebras and M-frames is to find relational counterparts of the algebraic operations of forming homomorphisms, subalgebras and direct products. Let $\mathfrak{F} = \langle W, R, R_\square, R_\diamond, P \rangle$ be a $\square\Diamond$ -frame and V a non-empty subset of W such that

$$\forall x \in V \forall y \in W (xR_\square y \vee xRy \rightarrow y \in V),$$

$$\forall x \in V \forall y \in W (xR_\diamond y \rightarrow \exists z \in V (xR_\diamond z \wedge yRz)).$$

Then $\mathfrak{G} = \langle V, R \upharpoonright V, R_\square \upharpoonright V, R_\diamond \upharpoonright V, \{X \cap V : X \in P\} \rangle$ is also a $\square\Diamond$ -frame which is called the *subframe of \mathfrak{F} generated by V* . The former of the two conditions above is standard: it requires V to be upward closed with respect to both R and R_\square . However, the latter one does not imply that V is upward closed with respect to R_\diamond : the frame \mathfrak{G} in Fig. 17 is a generated subframe of \mathfrak{F} , although the set $\{x, z\}$ is not an R_\diamond -cone in \mathfrak{F} . This is one difference from the standard (classical modal or intuitionistic) case. Another one arises when we define the relational analog of subalgebras.

Given $\square\Diamond$ -frames $\mathfrak{F} = \langle W, R, R_\square, R_\diamond, P \rangle$ and $\mathfrak{G} = \langle V, S, S_\square, S_\diamond, Q \rangle$, we say a map f from W onto V is a *reduction* of \mathfrak{F} to \mathfrak{G} if $f^{-1}(X) \in P$ for every $X \in Q$ and, for all $x, y \in W$ and $u \in V$,

$$xRy \text{ implies } f(x)Sf(y),$$

$$xR_\circ y \text{ implies } f(x)S_\circ f(y), \text{ for } \circ \in \{\square, \diamond\},$$

$$f(x)Su \text{ implies } \exists z \in f^{-1}(u) xRz,$$

Figure 17.

Figure 18.

$f(x)S_{\square}u$ implies $\exists z \in f^{-1}(u) \ xR_{\square}z$,
 $f(x)S_{\diamond}u$ implies $\exists z \in W \ (xR_{\diamond}z \wedge uSf(z))$.

Again, the last condition differs from the standard one: given $f(x)S_{\diamond}f(y)$, in general we do not have a point z such that $xR_{\diamond}z$ and $f(y) = f(z)$, witness the map gluing 0 and 1 in the frame \mathfrak{F} in Fig. 18 and reducing it to \mathfrak{G} .

Note that both these concepts coincide with the standard ones in classical modal frames, where R and S are the diagonals. The relational counterpart of direct products—disjoint unions of frames—is defined as usual.

THEOREM 188.

- (i) *If \mathfrak{G} is the subframe of a $\square\diamond$ -frame \mathfrak{F} generated by V then the map h defined by $h(X) = X \cap V$, for X an element in \mathfrak{F}^+ , is a homomorphism from \mathfrak{F}^+ onto \mathfrak{G}^+ .*
- (ii) *If h is a homomorphism from a $\square\diamond$ -algebra \mathfrak{A} onto a $\square\diamond$ -algebra \mathfrak{B} then the map h_+ defined by $h_+(\nabla) = h^{-1}(\nabla)$, ∇ a prime filter in \mathfrak{B} , is an isomorphism from \mathfrak{B}_+ onto a generated subframe of \mathfrak{A}_+ .*
- (iii) *If f is a reduction of a $\square\diamond$ -frame \mathfrak{F} to a $\square\diamond$ -frame \mathfrak{G} then the map f^+ defined by $f^+(X) = f^{-1}(X)$, X an element in \mathfrak{G}^+ , is an embedding of \mathfrak{G}^+ into \mathfrak{F}^+ .*
- (iv) *If \mathfrak{B} is a subalgebra of a $\square\diamond$ -algebra \mathfrak{A} then the map f defined by $f(\nabla) = \nabla \cap B$, ∇ a prime filter in \mathfrak{A} and B the universe of \mathfrak{B} , is a reduction of \mathfrak{A}_+ to \mathfrak{B}_+ .*

This duality can be used for proving various results on modal definability. For instance, a class \mathcal{C} of $\square\diamond$ -frames is of the form $\mathcal{C} = \{\mathfrak{F} : \mathfrak{F} \models \Gamma\}$, for

some set Γ of $\mathcal{L}_{\Box\Diamond}$ -formulas, iff \mathcal{C} is closed under the formation of generated subframes, reducts, disjoint unions, and both \mathcal{C} and its complement are closed under the operation $\mathfrak{F} \mapsto (\mathfrak{F}^+)_+$ (see Wolter and Zakharyashev [1997]). Moreover, one can extend Fine's Theorem connecting the first order definability and \mathcal{D} -persistence of classical modal logics to the intuitionistic modal case:

THEOREM 189. *If a logic $L \in \text{NExtIntK}_{\Box\Diamond}$ is characterized by an elementary class of Kripke frames then L is \mathcal{D} -persistent.*

These results may be regarded as a justification for the relational semantics introduced in this section. However, it is not the only possible one. For example, Božić and Došen [1984] impose a weaker condition on the connection between R and R_{\Box} in \Box -frames. Fisher Servi [1980] interprets **FS** in birelational Kripke frames of the form $\langle W, R, S \rangle$ in which R is a partial order, $R \circ S \subseteq S \circ R$, and

$$xRy \wedge xSz \rightarrow \exists u (ySu \wedge zRu).$$

The intuitionistic connectives are interpreted by R and the truth-conditions for \Box and \Diamond are defined as follows

$$\Box X = \{x \in W : \forall y, z (xRySz \rightarrow z \in X)\},$$

$$\Diamond X = \{x \in W : \exists y \in X xSy\}.$$

In birelational frames for **MIPC** S is an equivalence relation and

$$xSyRz \rightarrow \exists u xRuSz.$$

These frames were independently introduced by L. Esakia who also established duality between them and “monadic Heyting algebras”.

There are two ways of investigating various properties of intuitionistic modal logics. One is to continue extending the classical methods to logics in NExtIntK_M . Another one uses those methods indirectly via embeddings of intuitionistic modal logics into classical ones. That such embeddings are possible was noticed by Shehtman [1979], Fischer Servi [1980, 1984], and Sotirov [1984]. Our exposition here follows Wolter and Zakharyashev [1997, 1999a]. For simplicity we confine ourselves only to considering the class NExtIntK_{\Box} and refer the reader to the cited papers for information about more general embeddings.

Let T be the translation of \mathcal{L}_{\Box} into $\mathcal{L}_{\Box_I\Box}$ prefixing \Box_I to every subformula of a given \mathcal{L}_{\Box} -formula. Thus, we are trying to embed intuitionistic modal logics in NExtIntK_{\Box} into classical bimodal logics with the necessity operators \Box_I (of **S4**) and \Box . Say that T embeds $L \in \text{NExtIntK}_{\Box}$ into $M \in \text{NExt}(\mathbf{S4} \otimes \mathbf{K})$ (**S4** in \mathcal{L}_{\Box_I} and **K** in \mathcal{L}_{\Box}) if, for every $\varphi \in \mathcal{L}_{\Box}$,

$$\varphi \in L \text{ iff } T(\varphi) \in M.$$

In this case M is called a *bimodal* (or **BM**-) *companion* of L .

For every logic $M \in \text{NExt}(\mathbf{S4} \otimes \mathbf{K})$ put

$$\rho M = \{\varphi \in \mathcal{L}_\square : T(\varphi) \in M\},$$

and let σ be the map from NExtIntK_\square into $\text{NExt}(\mathbf{S4} \otimes \mathbf{K})$ defined by

$$\sigma(\text{IntK}_\square \oplus \Gamma) = (\mathbf{Grz} \otimes \mathbf{K}) \oplus \mathbf{mix} \oplus T(\Gamma),$$

where $\Gamma \subseteq \mathcal{L}_\square$ and $\mathbf{mix} = \square_I \square \square_I p \leftrightarrow \square p$. (The axiom \mathbf{mix} reflects the condition $R \circ R_\square \circ R = R_\square$ of \square -frames.) Then we have the following extension of the embedding results of Maksimova and Rybakov [1974], Blok [1976] and Esakia [1979a,b]:

THEOREM 190.

- (i) *The map ρ is a lattice homomorphism from the lattice $\text{NExt}(\mathbf{S4} \otimes \mathbf{K})$ onto NExtIntK_\square preserving decidability, Kripke completeness, tabularity and the finite model property.*
- (ii) *Each logic $\text{IntK}_\square \oplus \Gamma$ is embedded by T into any logic M in the interval*

$$(\mathbf{S4} \otimes \mathbf{K}) \oplus T(\Gamma) \subseteq M \subseteq (\mathbf{Grz} \otimes \mathbf{K}) \oplus \mathbf{mix} \oplus T(\Gamma).$$

- (iii) *The map σ is an isomorphism from the lattice NExtIntK_\square onto the lattice $\text{NExt}(\mathbf{Grz} \otimes \mathbf{K}) \oplus \mathbf{mix}$ preserving FMP and tabularity.*

Note that Fischer Servi [1980] used another generalization of the Gödel translation. She defined

$$\begin{aligned} T(\diamond\varphi) &= \diamond T(\varphi), \\ T(\square\varphi) &= \square_I \square T(\varphi) \end{aligned}$$

and showed that this translation embeds \mathbf{FS} into the logic

$$(\mathbf{S4} \otimes \mathbf{K}) \oplus \diamond \square_I p \rightarrow \square_I \diamond p \oplus \diamond \diamond_I p \rightarrow \diamond_I \diamond p.$$

It is not clear, however, whether all extensions of \mathbf{FS} can be embedded into classical bimodal logics via this translation.

Let us turn now to completeness theory of intuitionistic modal logics. As to the standard systems \mathbf{I}^Δ , \mathbf{FS} , and \mathbf{MIPC} , their FMP can be proved by using (sometimes rather involved) filtration arguments; see Muravitskij [1981], Simpson [1994] and Grefe [1997], and Ono [1977], respectively. Further results based on the filtration method were obtained by Sotirov [1984] and Ono [1977]. However, in contrast to classical modal logic, only a few general completeness results covering interesting classes of intuitionistic modal logics are known. The proofs of the following two theorems are based on the translation into classical bimodal logics discussed above.

THEOREM 191. *Suppose that a si-logic $\mathbf{Int} + \Gamma$ has one of the properties: decidability, Kripke completeness, FMP. Then the logics $\mathbf{IntK}_\square \oplus \Gamma$ and $\mathbf{IntK}_\square \oplus \Gamma \oplus \square p \rightarrow p$ also have the same property.*

Proof. It suffices to show that there is a BM-companion of each of these systems satisfying the corresponding property. Notice that

$$\rho((\mathbf{S4} \oplus T(\Gamma)) \otimes \mathbf{K}) = \mathbf{IntK}_\square \oplus \Gamma,$$

$$\rho((\mathbf{S4} \oplus T(\Gamma)) \otimes (\mathbf{K} \oplus \square p \rightarrow p)) = \mathbf{IntK}_\square \oplus \Gamma \oplus \square p \rightarrow p.$$

So it remains to use the fact that if $\mathbf{Int} + \Gamma$ has one of the properties under consideration then its smallest modal companion $\mathbf{S4} \oplus T(\Gamma)$ has this property as well (Table 7), and if L_1, L_2 are unimodal logics having one of those properties then the fusion $L_1 \otimes L_2$ also enjoys the same property (Theorem 111). ■

Such a simple reduction to known results in classical modal logic is not available for logics containing $\mathbf{IntK4}_\square = \mathbf{IntK}_\square \oplus \square p \rightarrow \square \square p$. However, by extending Fine's [1974] method of maximal points to bimodal companions of extensions of $\mathbf{IntK4}_\square$ Wolter and Zakharyashev [1999a] proved the following:

THEOREM 192. *Suppose $L \supseteq \mathbf{IntK4}_\square$ has a \mathcal{D} -persistent BM-companion $M \supseteq (\mathbf{S4} \otimes \mathbf{K4}) \oplus \mathbf{mix}$ whose Kripke frames are closed under the formation of substructures. Then*

- (i) *for every set Γ of intuitionistic negation and disjunction free formulas, $L \oplus \Gamma$ has FMP;*
- (ii) *for every set Γ of intuitionistic disjunction free formulas and every $n \geq 1$,*

$$L \oplus \Gamma \oplus \bigvee_{i=0}^n (p_i \rightarrow \bigvee_{j \neq i} p_j)$$

has the finite model property.

One can use this result to show that the following (and many other) intuitionistic modal logics enjoy FMP:

- (1) $\mathbf{IntK4}_\square$;
- (2) $\mathbf{IntS4}_\square = \mathbf{IntK4}_\square \oplus \square p \rightarrow p$ (R_\square is reflexive);
- (3) $\mathbf{IntS4.3}_\square = \mathbf{IntS4}_\square \oplus \square(\square p \rightarrow q) \vee \square(\square q \rightarrow p)$ (R_\square is reflexive and connected);
- (4) $\mathbf{IntK4}_\square \oplus p \vee \square \neg \square p$ (R_\square is symmetrical);

- (5) $\mathbf{IntK4}_\Box \oplus \Box p \vee \Box \neg \Box p$ (R_\Box is Euclidean);
- (6) $\mathbf{IntK4}_\Box \oplus \Box p \vee \neg \Box p$ ($xRy \wedge xR_\Box z \rightarrow yR_\Box z$).

We conclude this section with some remarks on lattices of intuitionistic modal logics. Wolter [1997e] uses duality theory to study splittings of lattices of intuitionistic modal logics. For example, he showed that each finite rooted frame splits $\mathbf{NExt}(L \oplus \Box^{\leq n} p \rightarrow \Box^{n+1} p)$, for $L = \mathbf{IntK}_\Box$ and $L = \mathbf{FS}$, and each R_\Box -cycle free finite rooted frame splits the lattices of extensions of \mathbf{IntK}_\Box and \mathbf{FS} . No positive results are known, however, for the lattice $\mathbf{NExtIntK}_\Diamond$. In fact, the behavior of \Diamond -frames is quite different from that of frames for \mathbf{FS} . For instance, in classical modal logic we have $\mathbf{RG}\mathcal{F} = \mathbf{GR}\mathcal{F}$, for each class of frames (or even \Box -frames) \mathcal{F} , where \mathbf{G} and \mathbf{R} are the operations of forming generated subframes and reducts, respectively. But this does not hold for \Diamond -frames. More precisely, there exists a finite \Diamond -frame \mathfrak{G} such that $\mathbf{RG}\{\mathfrak{G}\} \not\cong \mathbf{GR}\{\mathfrak{G}\}$. In other terms, the variety of modal algebras for \mathbf{K} has the *congruence extension property* (i.e., each congruence of a subalgebra of a modal algebra can be extended to a congruence of the algebra itself) but this is not the case for the variety of \Diamond -algebras.

Vakarelov [1981, 1985] and Wolter [1997e] investigate how logics having \mathbf{Int} as their non-modal fragment are located in the lattices of intuitionistic modal logics. It turns out, for instance, that in $\mathbf{NExtIntK}_\Diamond$ the inconsistent logic has a continuum of immediate predecessors all of which have \mathbf{Int} as their non-modal fragment, but no such logic exists in the lattice of extensions of \mathbf{IntK}_\Box .

For a recent methodological approach to combining logics, see [Gabbay, 1988].

4 ALGORITHMIC PROBLEMS

All algorithmic results considered in the previous sections were positive: we presented concrete procedures for deciding whether an arbitrary given formula belongs to a given logic in some class or whether it axiomatizes a logic with a certain property. What is the complexity of those decision algorithms? Do there exist undecidable calculi¹⁸ and properties? These are the main questions we address in this chapter.

4.1 Undecidable calculi

The first undecidable modal and si-calculi were constructed by Thomason [1975c] (polymodal and unimodal), Isard [1977] (unimodal) and Shehtman

¹⁸By a calculus we mean a logic with finitely many axioms (inference rules in our case are fixed).

[1978c] (superintuitionistic). However, we begin with the very simple example of [Shehtman 1982] which is a modal reformulation of the undecidable associative calculus T of [Tseitin 1958]. The axioms of T are

$$\begin{aligned} ac = ca, & & ad = da, \\ bc = cb, & & bd = db, \\ edb = be, & & eca = ae, \\ abac = abacc. \end{aligned}$$

The reader will notice immediately an analogy between them and the axioms of the following modal calculus with five necessity operators:

$$\begin{aligned} L = \mathbf{K}_5 \oplus & \square_1 \square_3 p \leftrightarrow \square_3 \square_1 p \oplus \square_1 \square_4 p \leftrightarrow \square_4 \square_1 p \oplus \\ & \square_2 \square_3 p \leftrightarrow \square_3 \square_2 p \oplus \square_2 \square_4 p \leftrightarrow \square_4 \square_2 p \oplus \\ & \square_5 \square_4 \square_2 p \leftrightarrow \square_2 \square_5 p \oplus \square_5 \square_3 \square_1 p \leftrightarrow \square_1 \square_5 p \oplus \\ & \square_1 \square_2 \square_1 \square_3 p \leftrightarrow \square_1 \square_2 \square_1 \square_3 \square_3 p. \end{aligned}$$

Moreover, it is not hard to see that words x, y in the alphabet $\{a, b, c, d, e\}$ are equivalent in T^{19} iff $f(x)p \leftrightarrow f(y)p \in \mathbf{K}_5$, where f is the natural one-to-one correspondence between such words and modalities in language $\{\square_1, \dots, \square_5\}$ under which, for instance, $f(cadedb) = \square_3 \square_1 \square_4 \square_5 \square_4 \square_2$. It follows immediately that L is undecidable. Using the undecidable associative calculus of Matiyasevich [1967], one can construct in the same way an undecidable bimodal calculus having three reductions of modalities as its axioms. It is unknown whether there is an undecidable unimodal calculus axiomatizable by reductions of modalities.

Another simple way of proving undecidability, known as the *domino* or *tiling technique*, was suggested by Harel [1983]. It is particularly useful in the case of multi-dimensional modal logics, say Cartesian products.

Tiles can be thought of as 4-tuples of colours

$$t = \langle left(t), right(t), up(t), down(t) \rangle.$$

A finite set T of tiles is said to *tile* $\mathbb{N} \times \mathbb{N}$ if there is a map $\tau : \mathbb{N} \times \mathbb{N} \mapsto T$ such that for all $i, j \in \mathbb{N}$,

- $up(\tau(i, j)) = down(\tau(i, j + 1))$ and
- $right(\tau(i, j)) = left(\tau(i + 1, j))$.

If we think of a tile as a physical 1×1 -square with colours along its four edges, then a tiling of $\mathbb{N} \times \mathbb{N}$ is just a way of placing an infinite number of

¹⁹I.e., they can be obtained from each other by a finite number of transformations of the form $w_1 w w_2 \rightarrow w_1 v w_2$, where $w = v$ or $v = w$ is an axiom of T .

tiles, each of a type from T , together to cover the first quarter of the infinite plane, with no rotation of the tiles allowed and the colours on adjacent edges of adjacent tiles matching.

The *tiling problem* for $\mathbb{N} \times \mathbb{N}$ is formulated as follows: “given a finite set T of tiles, does T tile $\mathbb{N} \times \mathbb{N}$?” Robinson [1971] proved that this problem is undecidable (in fact, co-r.e.-complete).

We will demonstrate the use of tiling to show the undecidability of the logic $(\mathbf{K} \times \mathbf{K})_u$, i.e., the square of \mathbf{K} (with boxes \boxplus and \boxminus) extended with the universal modality \square (see Section 2.2); this result is due to Spaan [1993].

Given a finite set T of tiles, construct a formula φ_T as the conjunction of the following formulas:

$$\begin{aligned} & \square \bigvee_{t \in T} p_t, \\ & \square \bigwedge_{t \neq t'} \neg(p_t \wedge p_{t'}), \\ & \square \bigwedge_{t \in T} (p_t \rightarrow \bigvee_{up(t)=down(t')} \boxplus p_{t'}), \\ & \square \bigwedge_{t \in T} (p_t \rightarrow \bigvee_{right(t)=left(t')} \boxminus p_{t'}), \\ & \square(\diamond \top \wedge \diamond \top). \end{aligned}$$

It is easily seen (see e.g. [Spaan 1993] or [Marx 1999]) that φ_T is satisfiable in the product of two frames iff T tiles $\mathbb{N} \times \mathbb{N}$. It follows that $(\mathbf{K} \times \mathbf{K})_u$ is undecidable.

Thomason’s simulation and the undecidable polymodal calculi mentioned above provide us with examples of undecidable calculi in $\text{NExt}\mathbf{K}$. However, to find axioms of undecidable unimodal calculi with transitive frames, as well as undecidable si-calculi, a more sophisticated construction is required.

Instead of associative calculi, let us use now Minsky machines with two tapes (or register machines with two registers). A *Minsky machine* is a finite set (program) of instructions for transforming triples $\langle s, m, n \rangle$ of natural numbers, called *configurations*. The intended meaning of the current configuration $\langle s, m, n \rangle$ is as follows: s is the number (label) of the current machine state and m, n represent the current state of information. Each instruction has one of the four possible forms:

$$\begin{aligned} & s \rightarrow \langle t, 1, 0 \rangle, \quad s \rightarrow \langle t, 0, 1 \rangle, \\ & s \rightarrow \langle t, -1, 0 \rangle (\langle t', 0, 0 \rangle), \quad s \rightarrow \langle t, 0, -1 \rangle (\langle t', 0, 0 \rangle). \end{aligned}$$

The last of them, for instance, means: transform $\langle s, m, n \rangle$ into $\langle t, m, n - 1 \rangle$ if $n > 0$ and into $\langle t', m, n \rangle$ if $n = 0$. For a Minsky machine \mathbf{P} , we shall write $\mathbf{P} : \langle s, m, n \rangle \rightarrow \langle t, k, l \rangle$ if starting with $\langle s, m, n \rangle$ and applying the instructions in \mathbf{P} , in finitely many steps (possibly, in 0 steps) we can reach $\langle t, k, l \rangle$.

We shall use the well known fact (see e.g. [Mal’cev 1970]) that the following *configuration problem* is undecidable: given a program \mathbf{P} and configurations $\langle s, m, n \rangle, \langle t, k, l \rangle$, determine whether $\mathbf{P} : \langle s, m, n \rangle \rightarrow \langle t, k, l \rangle$.

Figure 19.

With every program \mathbf{P} and configuration $\langle s, m, n \rangle$ we associate the transitive frame \mathfrak{F} depicted in Fig. 19. Its points $e(t, k, l)$ represent configurations $\langle t, k, l \rangle$ such that $\mathbf{P} : \langle s, m, n \rangle \rightarrow \langle t, k, l \rangle$; $e(t, k, l)$ sees the points a_t^0, a_k^1, a_l^2 representing the components of $\langle t, k, l \rangle$. The following variable free formulas characterize points in \mathfrak{F} in the sense that each of these formulas, denoted by Greek letters with subscripts and/or superscripts, is true in \mathfrak{F} only at the point denoted by the corresponding Roman letter with the same subscript and/or superscript:

$$\begin{aligned} \alpha &= \diamond \top \wedge \square \diamond \top, \quad \beta = \square \perp, \quad \gamma = \diamond \alpha \wedge \diamond \beta \wedge \neg \diamond^2 \beta, \\ \delta &= \neg \gamma \wedge \diamond \beta \wedge \neg \diamond^2 \beta, \quad \delta_1 = \diamond \delta \wedge \neg \diamond^2 \delta, \quad \delta_2 = \diamond \delta_1 \wedge \neg \diamond^2 \delta_1, \\ \gamma_1 &= \diamond \gamma \wedge \neg \diamond^2 \gamma \wedge \neg \diamond \delta, \quad \gamma_2 = \diamond \gamma_1 \wedge \neg \diamond^2 \gamma_1 \wedge \neg \diamond \delta, \\ \alpha_0^0 &= \diamond \gamma \wedge \diamond \delta \wedge \neg \diamond^2 \gamma \wedge \neg \diamond^2 \delta, \\ \alpha_0^1 &= \diamond \gamma_1 \wedge \diamond \delta_1 \wedge \neg \diamond^2 \gamma_1 \wedge \neg \diamond^2 \delta_1, \\ \alpha_0^2 &= \diamond \gamma_2 \wedge \diamond \delta_2 \wedge \neg \diamond^2 \gamma_2 \wedge \neg \diamond^2 \delta_2, \\ \alpha_{j+1}^i &= \diamond \alpha_j^i \wedge \neg \diamond^2 \alpha_j^i \wedge \bigwedge_{i \neq k} \neg \diamond \alpha_0^k, \end{aligned}$$

where $i \in \{0, 1, 2\}$, $j \geq 0$. The formulas characterizing $e(t, k, l)$ are denoted by $\epsilon(t, \alpha_k^1, \alpha_l^2)$, where

$$\epsilon(t, \varphi, \psi) = \bigwedge_{i=0}^t \diamond \alpha_i^0 \wedge \neg \diamond \alpha_{i+1}^0 \wedge \diamond \varphi \wedge \neg \diamond^2 \varphi \wedge \diamond \psi \wedge \neg \diamond^2 \psi.$$

We require also formulas characterizing not only fixed but arbitrary configurations:

$$\begin{aligned}\pi_1 &= (\Diamond\alpha_0^1 \vee \alpha_0^1) \wedge \neg\Diamond\alpha_0^0 \wedge \neg\Diamond\alpha_0^2 \wedge p_1 \wedge \neg\Diamond p_1, \\ \pi_2 &= \Diamond\alpha_0^1 \wedge \neg\Diamond\alpha_0^0 \wedge \neg\Diamond\alpha_0^2 \wedge \Diamond p_1 \wedge \neg\Diamond^2 p_1, \\ \tau_1 &= (\Diamond\alpha_0^2 \vee \alpha_0^2) \wedge \neg\Diamond\alpha_0^0 \wedge \neg\Diamond\alpha_0^1 \wedge p_2 \wedge \neg\Diamond p_2, \\ \tau_2 &= \Diamond\alpha_0^2 \wedge \neg\Diamond\alpha_0^0 \wedge \neg\Diamond\alpha_0^1 \wedge \Diamond p_2 \wedge \neg\Diamond^2 p_2.\end{aligned}$$

Now we are fully equipped to simulate the behavior of Minsky machines by means of modal formulas. Let us consider for simplicity only tense logics and observe that \mathfrak{F} satisfies the condition

$$\forall x \forall y \exists z (xRzR^{-1}y \vee xR^{-1}zRy \vee xRy \vee xR^{-1}y \vee x = y).$$

So, for every valuation in \mathfrak{F} , a formula φ is true at some point in \mathfrak{F} iff the formula

$$\bigcirc\varphi = \Diamond\Diamond^{-1}\varphi \vee \Diamond^{-1}\Diamond\varphi \vee \Diamond\varphi \vee \Diamond^{-1}\varphi \vee \varphi$$

is true at all points in \mathfrak{F} , i.e., the modal operator \bigcirc can be understood as ‘‘omniscience’’. Let χ be a formula which is refuted in \mathfrak{F} and does not contain p_1 and p_2 . With each instruction I in \mathbf{P} we associate a formula AxI by taking:

$$AxI = \neg\chi \wedge \bigcirc\epsilon(t, \pi_1, \tau_1) \rightarrow \neg\chi \wedge \bigcirc\epsilon(t', \pi_2, \tau_1)$$

if I has the form $t \rightarrow \langle t', 1, 0 \rangle$,

$$AxI = \neg\chi \wedge \bigcirc\epsilon(t, \pi_1, \tau_1) \rightarrow \neg\chi \wedge \bigcirc\epsilon(t', \pi_1, \tau_2)$$

if I is $t \rightarrow \langle t', 0, 1 \rangle$,

$$\begin{aligned}AxI = & (\neg\chi \wedge \bigcirc\epsilon(t, \pi_2, \tau_1) \rightarrow \neg\chi \wedge \bigcirc\epsilon(t', \pi_1, \tau_1)) \wedge \\ & (\neg\chi \wedge \bigcirc\Diamond\epsilon(t, \alpha_0^1, \tau_1) \rightarrow \neg\chi \wedge \bigcirc\epsilon(t'', \alpha_0^1, \tau_1))\end{aligned}$$

if I is $t \rightarrow \langle t', -1, 0 \rangle (\langle t'', 0, 0 \rangle)$,

$$\begin{aligned}AxI = & (\neg\chi \wedge \bigcirc\epsilon(t, \pi_1, \tau_2) \rightarrow \neg\chi \wedge \bigcirc\epsilon(t', \pi_1, \tau_1)) \wedge \\ & (\neg\chi \wedge \bigcirc\epsilon(t, \pi_1, \alpha_0^2) \rightarrow \neg\chi \wedge \bigcirc\epsilon(t'', \pi_1, \alpha_0^2))\end{aligned}$$

if I is $t \rightarrow \langle t', 0, -1 \rangle (\langle t'', 0, 0 \rangle)$. The formula simulating \mathbf{P} as a whole is

$$AxP = \bigwedge_{I \in \mathbf{P}} AxI.$$

Now, by induction on the length of computations and using the frame \mathfrak{F} in Fig. 19 one can show that for every program \mathbf{P} and configurations $\langle s, m, n \rangle$, $\langle t, k, l \rangle$, we have $\mathbf{P} : \langle s, m, n \rangle \rightarrow \langle t, k, l \rangle$ iff

$$\neg\chi \wedge \bigcirc\epsilon(s, \alpha_m^1, \alpha_n^2) \rightarrow \neg\chi \wedge \bigcirc\epsilon(t, \alpha_k^1, \alpha_l^2) \in \mathbf{K4}.t \oplus AxP.$$

Thus, if the configuration problem is undecidable for \mathbf{P} then the tense calculus $\mathbf{K4.t} \oplus AxP$ is undecidable too. In the same manner (but using somewhat more complicated frames and formulas) one can construct undecidable calculi in $\mathbf{NExtK4}$ and even \mathbf{ExtInt} ; for details consult [Chagrova, 1991] and [Chagrov and Zakharyashev, 1997]. The following table presents some "quantitative characteristics" of known undecidable calculi in various classes of logics. Its first line, for instance, means that there is an undecidable si-calculus with axioms in 4 variables and the derivability problem in it is undecidable in the class of formulas in 2 variables; = means that the number of variables is optimal, and \leq indicates that the optimal number is still unknown.

Class of logics	The number of variables in	
	undecidable calculi	separated formulas
\mathbf{ExtInt}	$\leq 4, \geq 2$	$= 2$
$\mathbf{NExtS4}$	$\leq 3, \geq 2$	$= 1$
$\mathbf{ExtS4}$	≤ 3	$= 1$
\mathbf{NExtGL}	$= 1$	$= 1$
\mathbf{ExtGL}	$= 1$	$= 1$
\mathbf{ExtS}	$= 1$	$= 1$
$\mathbf{NExtK4}$	$= 1$	$= 0$
$\mathbf{ExtK4}$	$= 1$	$= 0$

These observations follow from [Anderson, 1972; Chagrov, 1994; Sobolev, 1977a] and [Zakharyashev, 1997a]. Say that a formula ψ is *undecidable* in $(\mathbf{N})\mathbf{ExtL}$ if no algorithm can determine for an arbitrary given φ whether $\psi \in L + \varphi$ (respectively, $\psi \in L \oplus \varphi$). For example, formulas in one variable, the axioms of \mathbf{BW}_n and \mathbf{BD}_n are decidable in \mathbf{ExtInt} . On the other hand, there are purely implicative undecidable formulas in \mathbf{ExtInt} , and

$$\neg(p \wedge q) \vee \neg(\neg p \wedge q) \vee \neg(p \wedge \neg q) \vee \neg(\neg p \wedge \neg q)$$

is the shortest known undecidable formula in this class. Here are some modal examples: the formula $\Box(\Box^2 \perp \rightarrow \Box p \vee \Box \neg p)$ is undecidable in \mathbf{NExtGL} , $\Box^+ \neg \Box^+ p \vee \Box^+ \neg \Box^+ \neg \Box^+ p$ in \mathbf{ExtS} , \perp in $\mathbf{ExtK4}$ and $\mathbf{NExtK4.t}$; in \mathbf{NExtK} and $\mathbf{NExtK4.t}$ undecidable is the conjunction of axioms of any consistent tabular logic in these classes. However, no non-trivial criteria are known for a formula to be decidable; it is unclear also whether one can effectively recognize the decidability of formulas in the classes \mathbf{ExtInt} , $(\mathbf{N})\mathbf{ExtS4}$, $(\mathbf{N})\mathbf{ExtGL}$, \mathbf{ExtS} , $(\mathbf{N})\mathbf{ExtK4}$.

4.2 Admissibility and derivability of inference rules

Another interesting algorithmic problem for a logic L is to determine whether an arbitrary given inference rule $\varphi_1, \dots, \varphi_n / \varphi$ is *derivable* in L , i.e., φ is

derivable in L from the assumptions $\varphi_1, \dots, \varphi_n$, and whether it is *admissible* in L , i.e., for every substitution \mathbf{s} , $\varphi \mathbf{s} \in L$ whenever $\varphi_1 \mathbf{s}, \dots, \varphi_n \mathbf{s} \in L$. (Note that derivability depends on the postulated inference rules in L , while admissibility depends only on the set of formulas in L .) Admissible and derivable rules are used for simplifying the construction of derivations. Derivable rules, like the well known rule of syllogism

$$\frac{\varphi \rightarrow \psi, \psi \rightarrow \chi}{\varphi \rightarrow \chi},$$

may replace some fragments of fixed length in derivations, thereby shortening them linearly. Admissible rules in principle may reduce derivations more drastically. Since $\varphi \in L$ iff the rule \top/φ is derivable (or admissible) in L , the derivability and admissibility problems for inference rules may be regarded as generalizations of the decidability problem.

If the only postulated rules in L are substitution and modus ponens, the Deduction Theorem reduces the derivability problem for inference rules in L to its decidability:

$$\frac{\varphi_1, \dots, \varphi_n}{\psi} \text{ is derivable in } L \text{ iff } \varphi_1 \wedge \dots \wedge \varphi_n \rightarrow \psi \in L.$$

However, if the rule of necessitation $\varphi/\Box\varphi$ is also postulated in L , we have only

$$\frac{\varphi_1, \dots, \varphi_n}{\psi} \text{ is derivable in } L \text{ iff } \varphi_1, \dots, \varphi_n \vdash_L^* \psi.$$

For n -transitive L this is equivalent to $\Box^{\leq n}(\varphi_1 \wedge \dots \wedge \varphi_n) \rightarrow \psi \in L$, and so the derivability problem for inference rules in n -transitive logics is decidable iff the logics themselves are decidable. In general, in view of the existential quantifier in Theorem 1, the situation is much more complicated.

Notice first that similarly to Harrop's Theorem, a sufficient condition for the derivability problem to be decidable in a calculus is its global FMP (see Section 1.5). Thus we have

THEOREM 193. *The derivability problem for inference rules in \mathbf{K} , \mathbf{T} , \mathbf{D} , \mathbf{KB} is decidable.*

Moreover, sometimes we can obtain an upper bound for the parameter m in the Deduction Theorem, which also ensures the decidability of the derivability problem for inference rules. One can prove, for instance, that for \mathbf{K} it is enough to take $m = 2^{|\mathbf{Sub}\varphi \cup \mathbf{Sub}\psi|}$. In general, however, the derivability problem for inference rules in a logic L turns out to be more complex than the decidability problem for L . (Recall, by the way, that there are logics with FMP but not global FMP.)

THEOREM 194 (Spaan 1993). *There is a decidable calculus in \mathbf{NExtK} the derivability problem for inference rules in which is undecidable.*

Spaan proves this result by simulating in \vdash_L^* , L the decidable logic defined below, the tiling problem for $\mathbb{N} \times \mathbb{N}$. The logic L is surprisingly simple:

$$L = \mathbf{Alt}_2 \oplus \bigwedge_{1 \leq i \leq 4} \diamond \diamond p_i \rightarrow \bigvee_{1 \leq i < j \leq 4} \diamond \diamond (p_i \wedge p_j).$$

It is a subframe logic, so it is \mathcal{D} -persistent and has FMP (because $\mathbf{Alt}_2 \subseteq L$; see Theorem 22 and Proposition 59). Note also that the bimodal logic L_u (see Section 2.2) is a complete and elementary subframe logic which is undecidable because \vdash_L^* is undecidable. Using this observation one can construct a unimodal subframe logic in \mathbf{NExtK} with the same properties.

Let us turn now to the admissibility problem. It is not hard to see that the rules

$$\frac{(\neg \neg p \rightarrow p) \rightarrow p \vee \neg p}{\neg p \vee \neg \neg p} \quad \text{and} \quad \frac{\neg p \rightarrow q \vee r}{(\neg p \rightarrow q) \vee (\neg p \rightarrow r)}$$

are admissible but not derivable in \mathbf{Int} and $\diamond p \wedge \diamond \neg p / \perp$ is admissible but not derivable in any extension of **S4.3** save those containing $\Box \diamond p \rightarrow \diamond \Box p$, in which it is derivable. (Recall that a logic L is said to be *structurally complete* if every admissible inference rule in L is derivable in L . We have just seen that \mathbf{Int} as well as **S4.3** are not structurally complete. For more information on structural completeness see e.g. [Tsytkin 1978, 1987] and [Rybakov 1995].) The following result strengthens Fine's [1971] Theorem according to which all logics in $\mathbf{ExtS4.3}$ are decidable.

THEOREM 195 (Rybakov 1984a). *The admissibility problem for inference rules is decidable in every logic containing **S4.3**.*

An impetus for investigations of admissible inference rules in various logics was given by Friedman's [1975] problem 40 asking whether one can effectively recognize admissible rules in \mathbf{Int} . This problem turned out to be closely connected to the admissibility problem in suitable modal logics. We demonstrate this below for the logic **GL** following [Rybakov 1987, 1989].

First we show that dealing with logics in \mathbf{NExtK} , it is sufficient to consider inference rules of a rather special form. Let $\varphi(q_1, \dots, q_{2n+2})$ be a formula containing no \Box and \diamond and represented in the full disjunctive normal form. Say that an inference rule is *reduced* if it has the form

$$\varphi(p_0, \dots, p_n, \diamond p_0, \dots, \diamond p_n) / p_0.$$

THEOREM 196. *For every rule φ/ψ one can effectively construct a reduced rule φ'/ψ' such that φ/ψ is admissible in a logic $L \in \mathbf{NExtK}$ iff φ'/ψ' is admissible in L .*

Proof. Observe first that if φ and ψ do not contain p then φ/ψ is admissible in L iff $\varphi \wedge (\psi \leftrightarrow p) / p$ is admissible in L . So we can consider only rules of

the form φ/p_0 . Besides, without loss of generality we may assume that φ does not contain \Box . With every non-atomic subformula χ of φ we associate the new variable p_χ . For convenience we also put $p_\chi = p_i$ if $\chi = p_i$ and $p_\chi = \perp$ if $\chi = \perp$. We show now that the rule

$$p_\varphi \wedge \bigwedge \{p_\chi \leftrightarrow p_{\chi_1} \odot p_{\chi_2} : \chi = \chi_1 \odot \chi_2 \in \mathbf{Sub}\varphi, \odot \in \{\wedge, \vee, \rightarrow\}\} \wedge \\ \bigwedge \{p_\chi \leftrightarrow \Diamond p_{\chi_1} : \chi = \Diamond \chi_1 \in \mathbf{Sub}\varphi\} / p_0$$

is admissible in L iff φ/p_0 is admissible in L . For brevity we denote the antecedent of that rule by φ'' .

(\Rightarrow) Since every substitution instance of φ''/p_0 is admissible in L , the rule $\varphi \wedge \bigwedge_{\chi \in \mathbf{Sub}\varphi} (\chi \leftrightarrow \chi) / p_0$ and so φ/p_0 are also admissible in L .

(\Leftarrow) Suppose φ/p_0 is admissible in L and $\varphi''s$ is in L , for some substitution $s = \{\alpha_\chi/p_\chi : \chi \in \mathbf{Sub}\varphi\}$. By induction on the construction of χ one can readily show that $\alpha_\chi \leftrightarrow \chi s \in L$. Therefore, $\alpha_\varphi \leftrightarrow \varphi s \in L$. Since $\varphi''s \in L$, we must have $p_\varphi s = \alpha_\varphi \in L$, from which $\varphi s \in L$ and so $p_0 s \in L$. Thus φ''/p_0 is admissible in L .

The rule φ''/p_0 is not reduced, but it is easy to make it so simply by representing φ'' in its full disjunctive normal form φ' , treating subformulas $\Diamond p_i$ as variables. \blacksquare

From now on we will deal with only reduced rules different from \perp/p_0 (which is clearly admissible in any logic). Let $\bigvee_j \varphi_j/p_0$ be a reduced rule in which every disjunct φ_j is the conjunction of the form

$$(17) \quad \neg_0 p_0 \wedge \cdots \wedge \neg_m p_m \wedge \neg^0 \Diamond p_0 \wedge \cdots \wedge \neg^m \Diamond p_m,$$

where each \neg_i and \neg^j is either blank or \neg . We will identify such conjunctions with the sets of their conjuncts. Now, given a non-empty set W of conjunctions of the form (17), we define a frame $\mathfrak{F} = \langle W, R \rangle$ and a model $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ by taking

$$\varphi_i R \varphi_j \quad \text{iff} \quad \forall k \in \{0, \dots, m\} (\neg \Diamond p_k \in \varphi_i \rightarrow \neg \Diamond p_k \in \varphi_j \wedge \neg p_k \in \varphi_j) \wedge \\ \exists k \in \{0, \dots, m\} (\neg \Diamond p_k \in \varphi_j \wedge \Diamond p_k \in \varphi_i), \\ \mathfrak{V}(p_k) = \{\varphi_i \in W : p_k \in \varphi_i\}.$$

It should be clear that \mathfrak{F} is finite, transitive and irreflexive.

THEOREM 197. *A reduced rule $\bigvee_j \varphi_j/p_0$ is not admissible in \mathbf{GL} iff there is a model $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ defined as above on a set W of conjunctions of the form (17) and such that*

- (i) $\neg p_0 \in \varphi_i$ for some $\varphi_i \in W$;
- (ii) $\varphi_i \models \varphi_i$ for every $\varphi_i \in W$;

- (iii) for every antichain \mathfrak{a} in \mathfrak{F} there is $\varphi_j \in W$ such that, for every $k \in \{0, \dots, m\}$, $\varphi_j \models \Diamond p_k$ iff $\varphi_i \models \Diamond^+ p_k$ for some $\varphi_i \in \mathfrak{a}$.

Proof. (\Rightarrow) We are given that there are formulas ψ_0, \dots, ψ_m in variables q_1, \dots, q_n such that $\bigvee_j \varphi_j^* \in \mathbf{GL}$ and $p_0^* \notin \mathbf{GL}$, where by χ^* we denote $\chi\{\psi_0/p_0, \dots, \psi_m/p_m\}$. This is equivalent to $\mathfrak{M}_{\mathbf{GL}}(n) \models \bigvee_j \varphi_j^*$ and $\mathfrak{M}_{\mathbf{GL}}(n) \not\models p_0^*$. Define W to be the set of those disjuncts φ_j in $\bigvee_j \varphi_j^*$ whose substitution instances φ_j^* are satisfied in $\mathfrak{M}_{\mathbf{GL}}(n)$. Clearly $W \neq \emptyset$. Let us check (i) – (iii).

- (i) Take a point x in $\mathfrak{M}_{\mathbf{GL}}(n)$ at which p_0^* is false. As $\mathfrak{M}_{\mathbf{GL}}(n) \models \bigvee_j \varphi_j^*$, we must have $x \models \varphi_i^*$ for some i . One of the formulas p_0^* or $\neg p_0^*$ is a conjunct of φ_i^* . Clearly it is not p_0^* . Therefore, $\neg p_0 \in \varphi_i$.
- (ii) It suffices to show that, for all $\varphi_i \in W$ and $k \in \{0, \dots, m\}$, $\varphi_i \models \Diamond p_k$ iff $\Diamond p_k \in \varphi_i$. Suppose $\varphi_i \models \Diamond p_k$. Then there is $\varphi_j \in W$ such that $\varphi_i R \varphi_j$ and $\varphi_j \models p_k$. By the definition of \mathfrak{R} and R , this means that $p_k \in \varphi_j$ and $\Diamond p_k \in \varphi_i$. Conversely, suppose $\Diamond p_k \in \varphi_i$. Then $x \models \varphi_i^*$ and in particular $x \models \Diamond p_k^*$ for some x in $\mathfrak{M}_{\mathbf{GL}}(n)$. Let y be a final point in the set $\{z \in x\uparrow : z \models p_k^*\}$. Since $\mathfrak{M}_{\mathbf{GL}}(n)$ is irreflexive, we have $y \models p_k^*$, $y \not\models \Diamond p_k^*$ and $y \models \varphi_j^*$ for some $\varphi_j \in W$. It follows that $\varphi_i R \varphi_j$ and $\varphi_j \models p_k$, from which $\varphi_i \models \Diamond p_k$.
- (iii) Let \mathfrak{a} be an antichain in \mathfrak{F} . For every $\varphi_i \in \mathfrak{a}$, let x_i be a final point in the set $\{y \in W_{\mathbf{GL}}(n) : y \models \varphi_i^*\}$. It should be clear that the points $\{x_i : \varphi_i \in \mathfrak{a}\}$ form an antichain \mathfrak{b} in $\mathfrak{F}_{\mathbf{GL}}(n)$ and so, by the construction of $\mathfrak{F}_{\mathbf{GL}}(n)$, there is a point y in $\mathfrak{F}_{\mathbf{GL}}(n)$ such that $y\uparrow = \mathfrak{b}\uparrow$. Then the formula $\varphi_j \in W$ we are looking for is any one satisfying the condition $y \models \varphi_j^*$, as can be easily checked by a straightforward inspection.

(\Leftarrow) The proof in this direction is rather technical; we confine ourselves to just a few remarks. Let \mathfrak{M} be a model satisfying (i)–(iii). To prove that $\bigvee_j \varphi_j/p_0$ is not admissible in \mathbf{GL} we require once again the n -universal model $\mathfrak{M}_{\mathbf{GL}}(n)$, but this time we take n to be the number of symbols in the rule. By induction on the depth of points in \mathfrak{M} one can show that \mathfrak{M} is a generated submodel of $\mathfrak{M}_{\mathbf{GL}}(n)$.

Our aim is to find formulas ψ_0, \dots, ψ_m such that $\mathfrak{M}_{\mathbf{GL}}(n) \models \bigvee_j \varphi_j^*$ and $\mathfrak{M}_{\mathbf{GL}}(n) \not\models p_0^*$ (here again $\chi^* = \chi\{\psi_0/p_0, \dots, \psi_m/p_m\}$). Loosely, we need to extend the properties of \mathfrak{M} to the whole model $\mathfrak{M}_{\mathbf{GL}}(n)$. To this end we can take the sets $\{\varphi_i\}$ in $\mathfrak{F}_{\mathbf{GL}}(n)$ and augment them inductively in such a way that we could embrace all points in $\mathfrak{F}_{\mathbf{GL}}(n)$. At the induction step we use the condition (iii), and the required ψ_0, \dots, ψ_m are constructed with the help of (i) and (ii); roughly, they describe in $\mathfrak{M}_{\mathbf{GL}}(n)$ the analogues of the truth-sets in \mathfrak{M} of the variables in our rule. ■

A remarkable feature of this criterion is that it can be effectively checked. Thus we have

THEOREM 198. *There is an algorithm which, given an inference rule, can decide whether it is admissible in **GL**.*

In a similar way one can prove

THEOREM 199 (Rybakov 1987). *The admissibility problem in **Grz** is decidable.*

We show now that the admissibility problem in **Int** can be reduced to the same problem in **Grz** and so is also decidable. To this end we require the following

THEOREM 200 (Rybakov 1984b). *A rule φ/ψ is admissible in **Int** iff the rule $T(\varphi)/T(\psi)$ is admissible in **Grz**.*

As a consequence of Theorems 199 and 200 we obtain

THEOREM 201 (Rybakov 1984b). *The admissibility problem in **Int** is decidable.*

Although there are many other examples of logics in which the admissibility problem is decidable and the scheme of establishing decidability is quite similar to the argument presented above,²⁰ proofs are rather difficult and only in few cases they work for big families of logics as in [Rybakov 1994]. Besides, all these results hold only for extensions of **K4** and **Int**. For logics with non-transitive frames, even for **K**, the admissibility problem is still waiting for a solution. The same concerns polymodal, in particular tense logics. Chagrov [1992b] constructed a decidable infinitely axiomatizable logic in **NExtK4** for which the admissibility problem is undecidable. It would be of interest to find modal and si-calculi of that sort.

A close algorithmic problem for a logic L is to determine, given an arbitrary formula $\varphi(p_1, \dots, p_n)$, whether there exist formulas ψ_1, \dots, ψ_n such that $\varphi(\psi_1, \dots, \psi_n) \in L$. Note that an “equation” $\varphi(p_1, \dots, p_n)$ has a solution in L iff the rule $\varphi(p_1, \dots, p_n)/\perp$ is not admissible in L . This observation and Theorem 195 provide us with examples of logics in which the substitution problem is decidable (see e.g. [Rybakov 1993]). We do not know, however, if there is a logic such that the substitution problem in it is decidable, while the admissibility one is not.

The inference rules we have dealt with so far were *structural* in the sense that they were “closed” under substitution. An interesting example of a

²⁰Quite recently S. Ghilardi [1999a,b] has found another way of recognizing admissibility of inference rules. He showed that certain si- and modal logics L (in particular, **Int**, **K4**, **S4**, **GL**, **Grz**) have the following property. Given an L -consistent formula φ , one can effectively compute substitutions $\sigma_1, \dots, \sigma_n$ such that $\sigma_i \varphi \in L$ for every $i = 1, \dots, n$, and if $\sigma \varphi \in L$ for some substitution σ , then σ is, up to provable equivalence, an instantiation of some of the σ_i . A rule φ/ψ is then admissible in L iff $\sigma_i \psi \in L$ for all $i = 1, \dots, n$.

nonstructural rule was considered by Gabbay [1981a]:

$$\frac{\varphi \vee (\Box p \rightarrow p), \text{ where } p \notin \mathbf{Sub}\varphi}{\varphi}$$

It is readily seen that this rule holds in a frame \mathfrak{F} (in the sense that for every formula φ and every variable p not occurring in φ , φ is valid in \mathfrak{F} whenever $(\Box p \rightarrow p) \vee \varphi$ is valid in \mathfrak{F}) iff \mathfrak{F} is irreflexive and that \mathbf{K} is closed under it (since \mathbf{K} is characterized by the class of irreflexive frames). We refer the reader to [Venema 1991] and [Marx and Venema 1997] for more information about rules of this type.

4.3 Properties of recursively axiomatizable logics

Dealing with infinite classes of logics, we can regard questions like “Is a logic L decidable?”, “Does L have FMP?”, etc., as mass algorithmic problems. But to formulate such problems properly we should decide first how to represent the input data of algorithms recognizing properties of logics. One can, for instance, consider the class of recursively axiomatizable logics (which, by Craig’s [1953] Theorem, coincides with that of recursively enumerable ones) and represent them as programs generating their axioms. However, this approach turns out to be too general because the following analog of the Rice–Uspenskij Theorem holds.

THEOREM 202 (Kuznetsov). *No nontrivial property of recursively axiomatizable si-logics is decidable.*

Of course, nothing will change if we take some other family of logics, say $\mathbf{NExtK4}$. The proof of this theorem (Kuznetsov left it unpublished) is very simple; we give it even in a more general form than required.

PROPOSITION 203. *Suppose L_1 and L_2 are logics in some family \mathcal{L} , L_1 is recursively axiomatizable, $L_1 \subset L_2$, L_2 is finitely axiomatizable (say, by a formula γ), and a property \mathcal{P} holds for only one of L_1, L_2 . Then no algorithm can recognize \mathcal{P} , given a program enumerating axioms of a logic in \mathcal{L} .*

Proof. Let $\alpha_0, \alpha_1, \dots$ be a recursive sequence of axioms for L_1 . Given an arbitrary (Turing, Minsky, Pascal, etc.) program \mathbf{P} having natural numbers as its input, we define the following recursive sequence of formulas (where $(n)_1$ and $(n)_2$ are the first and second components of the pair of natural numbers with code n under some fixed effective encoding):

$$\beta_n = \begin{cases} \alpha_n & \text{if } \mathbf{P} \text{ does not come to a stop on input } (n)_1 \text{ in } (n)_2 \text{ steps} \\ \gamma & \text{otherwise.} \end{cases}$$

This sequence axiomatizes L_1 if \mathbf{P} does not come to a stop on any input and L_2 otherwise. It is well known in recursion theory that the halting problem is undecidable, and so the property \mathcal{P} is undecidable in \mathcal{L} as well. ■

The reader must have already noticed that this proof has nothing to do with modal and si-logics; it is rather about effective computations. To avoid this unpleasant situation let us confine ourselves to the smaller class of *finitely axiomatizable* modal and si-logics and try to find algorithms recognizing properties of the corresponding calculi. However, even in this case we should be very careful. If arbitrary finite axiomatizations are allowed then we come across the following

THEOREM 204 (Kuznetsov 1963). *For every finitely axiomatizable si-logic L (in particular, **Int**, **Cl**, inconsistent logic), there is no algorithm which, given an arbitrary finite list of formulas, can determine whether its closure under substitution and modus ponens coincides with L .*

Needless to say that the same holds for (normal) modal logics as well. Fortunately, the situation is not so hopeless if we consider finite axiomatizations over some basic logics. For instance, by Makinson's Theorem, one can effectively recognize, given a formula φ , whether the logic $\mathbf{K} \oplus \varphi$ is consistent. Other examples of decidable properties in various lattices of modal logics were presented in Theorems 89, 93, 101, and 142. In the next section we consider those properties that turn out to be undecidable in various classes of modal and si-calculi.

4.4 Undecidable properties of calculi

The first "negative" algorithmic results concerning properties of modal calculi were obtained by Thomason [1982] who showed that FMP and Kripke completeness are undecidable in $\text{NExt}\mathbf{K}$, and consistency is undecidable in $\text{NExt}\mathbf{K}.t$. Later Thomason's discovery has been extended to other properties and narrower classes of logics. In fact, a good many standard properties of modal and si-calculi (in reasonably big classes) proved to be undecidable; decidable ones are rather exceptional.

In this section we present three known schemes of proving such kind of undecidability results. Each of them has its advantages (as well as disadvantages) and can be adjusted for various applications. The first one is due to Thomason [1982].

Let $L(n)$ be a recursive sequence of normal bimodal calculi such that no algorithm can decide, given n , whether $L(n)$ is consistent. Such sequences, as we shall see a bit later, exist even in $\text{NExt}\mathbf{K}.t$. Suppose also that L^* is a normal unimodal calculus which does not have some property, say, FMP, decidability or Kripke completeness. Consider now the recursive sequence of logics $L(n) \otimes L^*$ with three necessity operators. If $L(n)$ is inconsistent then the fusion $L(n) \otimes L^*$ is inconsistent too and so has the properties mentioned above. And if $L(n)$ is consistent then, in accordance with Proposition 110, $L(n) \otimes L^*$ is a conservative extension of both $L(n)$ and L^* , which means that it is Kripke incomplete, undecidable and does not have FMP whenever

L^* is so. Consequently, the three properties under consideration cannot be decidable in the class $\text{NExt}\mathbf{K}_3$, for otherwise the consistency of $L(n)$ would be decidable. By Theorem 123, these properties are undecidable in $\text{NExt}\mathbf{K}$ as well. Note however that, since Thomason’s simulation embeds polymodal logics only into “non-transitive” unimodal ones, this very simple scheme does not work if we want to investigate algorithmic aspects of properties of calculi in $\text{NExt}\mathbf{K4}$ and ExtInt .

To illustrate the second scheme let us recall the construction of the undecidable calculus in $\text{NExt}\mathbf{K4.t}$ discussed in Section 4.1. First, we choose a Minsky program \mathbf{P} and a configuration $\mathbf{a} = \langle s, m, n \rangle$ so that no algorithm can decide, given a configuration \mathbf{b} , whether $\mathbf{P} : \mathbf{a} \rightarrow \mathbf{b}$. (That they exist is shown in [Chagrov 1990b].) Then we put $\chi = \perp$ and add to $\mathbf{K4.t} \oplus AxP$ one more axiom

$$(\neg\chi \wedge \bigcirc\epsilon(s, \alpha_m^1, \alpha_n^2) \rightarrow \neg\chi \wedge \bigcirc\epsilon(t, \alpha_k^1, \alpha_l^2)) \rightarrow \chi,$$

where $\mathbf{c} = \langle t, k, l \rangle$ is an arbitrary fixed configuration. The resulting calculus is denoted by $L(\mathbf{c})$. Suppose that $\mathbf{P} : \mathbf{a} \not\rightarrow \mathbf{c}$. Then one can readily check that the new axiom is valid in the frame \mathfrak{F} shown in Fig. 19 and prove that $\mathbf{P} : \langle s, m, n \rangle \rightarrow \langle t', k', l' \rangle$ iff

$$\neg\chi \wedge \bigcirc\epsilon(s, \alpha_m^1, \alpha_n^2) \rightarrow \neg\chi \wedge \bigcirc\epsilon(t', \alpha_k^1, \alpha_l^2) \in L(\mathbf{c}).$$

Therefore, $L(\mathbf{c})$ is undecidable, consistent and does not have FMP. And if $\mathbf{P} : \mathbf{a} \rightarrow \mathbf{c}$ then $L(\mathbf{c})$ is clearly inconsistent. It follows by the choice of \mathbf{P} and \mathbf{a} that consistency, decidability and FMP are undecidable in $\text{NExt}\mathbf{K4.t}$. In fact, the argument will change very little if we take as χ the axiom of some tabular logic in $\text{NExt}\mathbf{K4.t}$. So we obtain

THEOREM 205. *The properties of tabularity and coincidence with an arbitrary fixed tabular logic (in particular, inconsistent) are undecidable in $\text{NExt}\mathbf{K4.t}$*

Moreover, these results (except the consistency problem, of course) can be transferred to logics in $\text{NExt}\mathbf{K}$. We demonstrate this by an example; complete proofs can be found in [Chagrov 1996].

We require the frame which results from that in Fig. 19 by adding to it a reflexive point c_0 and an irreflexive one c_1 so that c_1 sees all other points save a and b and is seen itself only from a and b . As before, we denote the frame by \mathfrak{F} .

PROPOSITION 206. *Let χ be a formula refutable at some point in \mathfrak{F} different from c_0 and $\diamond\top \in \mathbf{K} \oplus \chi$. Then the problem of deciding, for an arbitrary formula φ , whether $\mathbf{K} \oplus \varphi = \mathbf{K} \oplus \chi$ is undecidable.*

Proof. It should be clear that χ contains at least one variable, say r , and there are points in \mathfrak{F} at which r has distinct truth-values (under the

valuation refuting χ); c_0 and c_1 are then the only points in \mathfrak{F} where the formulas $\sigma_0 = \Box^3 r \vee \Box^3 \neg r$ and

$$\sigma_1 = \Diamond \sigma_0 \wedge (r \vee \Diamond r \vee \Diamond^2 r) \wedge (\neg r \vee \Diamond \neg r \vee \Diamond^2 \neg r)$$

are true, respectively. Observe that from every point in \mathfrak{F} save c_0 we can reach all points in \mathfrak{F} by ≤ 3 steps. So we can take $\bigcirc = \Diamond^{\leq 3}$. The formulas α and β should be replaced with $\alpha = \Diamond \sigma_1 \wedge \Diamond^2 \sigma_1$, $\beta = \Diamond \sigma_1 \wedge \neg \Diamond^2 \sigma_1$ which (under the valuation refuting χ) are true only at a and b , respectively. Now consider the logic

$$L(\mathfrak{c}) = \mathbf{K} \oplus AxP \oplus (\neg \chi \wedge \bigcirc \epsilon(s, \alpha_m^1, \alpha_n^2) \rightarrow \neg \chi \wedge \bigcirc \epsilon(t, \alpha_k^1, \alpha_l^2)) \rightarrow \chi.$$

If $\mathbf{P} : \mathfrak{a} \rightarrow \mathfrak{c}$ then $L(\mathfrak{c}) = \mathbf{K} \oplus \chi$. And if $\mathbf{P} : \mathfrak{a} \not\rightarrow \mathfrak{c}$ then, using the fact that the set of points in \mathfrak{F} where χ is refutable coincides with the set of points from which every point of the form $e(x, y, z)$ is accessible by three steps, one can show that $\mathfrak{F} \models L(\mathfrak{c})$ and so $L(\mathfrak{c}) \neq \mathbf{K} \oplus \chi$. ■

Putting, for instance, $\chi = \Box p \leftrightarrow p$, we obtain then that the problem of coincidence with Logo is undecidable in $\text{NExt}\mathbf{K}$. Likewise one can prove the following

THEOREM 207.

- (i) *If a consistent finitely axiomatizable logic L is not a union-splitting of $\text{NExt}\mathbf{K}$ then the axiomatization problem for L above \mathbf{K} is undecidable.*
- (ii) *The properties of tabularity and coincidence with an arbitrary fixed consistent tabular logic are undecidable in $\text{NExt}\mathbf{K}$.*
- (iii) *The problem of coincidence with an arbitrary fixed consistent calculus in $\text{NExt}\mathbf{D4}$ or in $\text{NExt}\mathbf{GL}$ is undecidable in $\text{NExt}\mathbf{K}$.*
- (iv) *The properties of tabularity and coincidence with an arbitrary fixed tabular (in particular, inconsistent) logic are undecidable in $\text{Ext}\mathbf{K4}$.*

Of the algorithmic problems concerning tabularity that remain open the most intriguing are undoubtedly the tabularity and local tabularity problems in $\text{NExt}\mathbf{K4}$. Note that a positive solution to the former implies a positive solution to the latter.

Now we present the second scheme in a more general form used in [Chagrova 1990b] and [Chagrova and Zakharyashev 1993]. Assume again that the second configuration problem is undecidable for \mathbf{P} and \mathfrak{a} , and let χ be a formula such that $L_0 \oplus \chi$ has some property \mathcal{P} , where L_0 is the minimal logic in the class under consideration. Associate with \mathbf{P} , \mathfrak{a} and a configuration \mathfrak{b} formulas AxP and $\psi(\mathfrak{a}, \mathfrak{b})$ such that $\psi(\mathfrak{a}, \mathfrak{b}) \in L_0 \oplus AxP$ iff $\mathbf{P} : \mathfrak{a} \rightarrow \mathfrak{b}$.

Besides, χ and AxP are chosen so that $AxP \in L_0 \oplus \chi$. Now consider the calculus

$$L(\mathfrak{b}) = L_0 \oplus AxP \oplus \psi(\mathfrak{a}, \mathfrak{b}) \rightarrow \chi \oplus \gamma,$$

where γ is some formula such that $\gamma \in L_0 \oplus \chi$. If $\mathbf{P} : \mathfrak{a} \rightarrow \mathfrak{b}$ then we clearly have $L(\mathfrak{b}) = L_0 \oplus \chi$ and so $L(\mathfrak{b})$ has \mathcal{P} ; but if $\mathbf{P} : \mathfrak{a} \not\rightarrow \mathfrak{b}$ then the fact that $L(\mathfrak{b})$ does not have \mathcal{P} must be ensured by an appropriate choice of γ . (In the considerations above we did not need γ , i.e., it was sufficient to put $\gamma = \top$). With the help of this scheme one can prove the following

THEOREM 208.

- (i) *The properties of decidability, Kripke completeness as well as FMP are undecidable in the classes ExtInt, (N)ExtGrz, (N)ExtGL.*
- (ii) *The interpolation property is undecidable in (N)ExtGL.*
- (iii) *Halldén completeness is undecidable in ExtInt, (N)ExtGrz, ExtS.*

These and some other results of that sort can be found in [Chagrov 1990b,c, 1994, 1996], [Chagrova 1991], [Chagrov and Zakharyashev 1993, 1995b].

The third scheme was developed in [Chagrova 1989, 1991] and [Chagrov and Chagrova 1995] for establishing the undecidability of certain first order properties of modal calculi (or formulas). The difference of this scheme from the previous one is that now we use calculi of the form

$$L(\mathfrak{b}) = L_0 \oplus AxP \oplus \psi(\mathfrak{a}, \mathfrak{b}) \vee \gamma,$$

where AxP satisfies one more condition besides those mentioned above: it must be first order definable on Kripke frames for L_0 . If $P : \mathfrak{a} \rightarrow \mathfrak{b}$ then the formula $AxP \wedge (\psi(\mathfrak{a}, \mathfrak{b}) \vee \gamma)$ is equivalent to AxP in the class of Kripke frames for L_0 and so is first order definable on that class or its any subclass. And if $P : \mathfrak{a} \not\rightarrow \mathfrak{b}$ then by choosing an appropriate γ one can show that $AxP \wedge (\psi(\mathfrak{a}, \mathfrak{b}) \vee \gamma)$ is not first order definable on, say, countable Kripke frames for L_0 , as in [Chagrova 1989], or on finite frames for L_0 , as in [Chagrov and Chagrova 1995]. In this way the following theorem is proved:

THEOREM 209.

- (i) *No algorithm is able to recognize the first order definability of modal formulas on the class of Kripke frames for **S4** and even the first order definability on countable (finite) Kripke frames for **S4**. The properties of first order definability and definability on countable (finite) Kripke frames of intuitionistic formulas are undecidable as well.*
- (ii) *The set of modal or intuitionistic formulas that are first order definable on countable (finite) frames but are not first order definable on the*

class of all (respectively, countable) Kripke frames mentioned in (i) is undecidable.

We conclude this section with two remarks. First, all undecidability results above can be formulated in the stronger form of recursive inseparability. For instance, the set of inconsistent calculi in NExtK4.t and the set of calculi without FMP are recursively inseparable. And second, some properties are not only undecidable but the families of calculi having them are not recursively enumerable; for example, the set of consistent calculi in NExtK4.t is not enumerable. However, for the majority of other properties the problem of enumerability of the corresponding calculi is open.

4.5 Semantical consequence

So far we have dealt with only syntactical formalizations of logical entailment. However, sometimes a semantical approach is preferable. Say that a formula φ is a *semantical consequence* of a formula ψ in a class of frames \mathcal{C} if φ is valid in all frames in \mathcal{C} validating ψ . (One can consider also the local, i.e., point-wise variant of this relation.) Note that φ is a consequence of ψ in the class of, say, Kripke frames for **S4** iff φ is a consequence of $(\Box p \rightarrow \Box^2 p) \wedge (\Box p \rightarrow p) \wedge \psi$ in the class of all Kripke frames. But the consequence relation on finite frames is not expressible by modal formulas (as was shown in [Chagrov 1995], if $(\Box p \rightarrow \Box^2 p) \wedge \varphi$ is valid in arbitrarily large finite rooted frames then it is valid in some infinite rooted frame as well).

In parallel with constructing and proving the undecidability of modal and si-calculi we can obtain the following

THEOREM 210. *The semantical consequence relation in the class of all (**K4**-, **S4**-, **Int**-) Kripke frames is undecidable. Moreover, if \models denotes one of these relations then there is a formula ψ (a formula φ) such that the set $\{\varphi : \psi \models \varphi\}$ is undecidable.*

In a sense, formulas ψ and φ , for which $\{\varphi : \psi \models \varphi\}$ is undecidable are analogous to undecidable calculi and formulas, respectively. However, this analogy is far from being perfect: for every formula ψ , the sets $\{\varphi : \psi \vdash \varphi\}$ and $\{\varphi : \psi \vdash^* \varphi\}$ are recursively enumerable, which contrasts with

THEOREM 211 (Thomason 1975a). *There exists a formula ψ such that $\{\varphi : \psi \models \varphi\}$ is a Π_1^1 -complete set.*

Unfortunately, Thomason's [1974b, 1975b, 1975c] results have not been transferred so far to transitive frames, although this does not seem to be absolutely impossible.

Chagrov [1990a] (see also [Chagrov and Chagrova 1995]) developed a technique for proving the analog of Theorem 210 for the consequence relation

on all (**K4**-, **S4**-, **GL**-, **Int**-) finite frames. Moreover, since this relation is clearly enumerable, instead of “undecidable” one can use “not enumerable”.

4.6 Complexity problems

Having proved that a given logic is decidable, we are facing the problem of finding an optimal (in one sense or another) decision algorithm for it. The complexity of decision algorithms for many standard modal and si-logics is determined by the size of minimal frames separating formulas from those logics. For instance, as was shown by Jaśkowski (1936) and McKinsey (1941), for every $\varphi \notin \mathbf{S4}$ (or $\varphi \notin \mathbf{Int}$) there is a frame $\mathfrak{F} \models \mathbf{S4}$ with $\leq 2^{|\text{Sub}\varphi|}$ points such that $\mathfrak{F} \not\models \varphi$. The same upper bound is usually obtained by the standard filtration. Is it possible to reduce the exponential upper bound to the polynomial one? This question was raised by Kuznetsov [1975] for **Int**. It turned out, however, that it concerns not only **Int**. First, Kuznetsov observed (for the proof see [Kuznetsov 1979]) that if the answer to his question is positive, i.e., **Int** has polynomial FMP, then the problem “Are **Int** and **Cl** polynomially equivalent?” has a positive solution as well. (Logics L_1 and L_2 are *polynomially equivalent* if there are polynomial time transformations f and g of formulas such that $\varphi \in L_1$ iff $f(\varphi) \in L_2$ and $\varphi \in L_2$ iff $g(\varphi) \in L_1$.) Then Statman [1979] showed that the problem “ $\varphi \in \mathbf{Int}$?” is *PSPACE*-complete and so Kuznetsov’s problem is equivalent to one of the “hopeless” complexity problems, namely “ $\mathbf{NP} = \mathbf{PSPACE}$?”.

Complexity function

For a logic L with FMP, we introduce the *complexity function*

$$f_L(n) = \max_{\substack{l(\varphi) \leq n \\ \varphi \notin L}} \min_{\substack{\mathfrak{F} \models L \\ \mathfrak{F} \not\models \varphi}} |\mathfrak{F}|,$$

where $l(\varphi)$, the *length* of φ , is the number of subformulas in φ and $|\mathfrak{F}|$ the number of points in \mathfrak{F} . If there is a constant c such that

$$f_L(n) \leq 2^{c \cdot n} \text{ (or } f_L(n) \leq n^c \text{ or } f_L(n) \leq c \cdot n),$$

L is said to have the *exponential* (respectively, *polynomial* or *linear*) *finite model property*. The following result shows that **Int** does not have polynomial FMP.

THEOREM 212 (Zakharyashev and Popov 1979). $\log_2 f_{\mathbf{Int}}(n) \asymp n$.

Proof. The exponential upper bound is well known and to establish the lower one it is sufficient to use the formulas

$$\beta_n = \bigwedge_{i=1}^{n-1} ((\neg p_{i+1} \rightarrow q_{i+1}) \vee (p_{i+1} \rightarrow q_{i+1}) \rightarrow q_i) \rightarrow (\neg p_1 \rightarrow q_1) \vee (p_1 \rightarrow q_1).$$

It is not hard to see that $\beta_n \notin \mathbf{Int}$ and every refutation frame for β_n contains the full binary tree of depth n as a subframe. \blacksquare

Likewise the same result can be proved for many other standard super-intuitionistic and modal logics whose FMP is established by the usual filtration and whose frames contain full binary trees of arbitrary finite depth. Such are, for instance, **KC**, **SL**, **K4**, **S4**, **GL**. In the case of **K** the length of formulas that play the role of β_n is not a linear but a square function of n , which means that $f_{\mathbf{K}}(n) \geq 2^{\sqrt{c \cdot n}}$, for some constant $c > 0$, and so **K** does not have polynomial FMP either. As was shown in [Zakharyashev 1996], all cofinal subframe modal and si-logics have exponential FMP. It seems plausible that $\log_2 f_L(n) \asymp n$ for every consistent si-logic L different from **CI** and axiomatizable by formulas in one variable.

The construction of Theorem 212 does not work for logics whose frames do not contain arbitrarily large full binary trees. Such are, for instance, logics of finite width or of finite depth, and the following was proved in [Chagrov 1983].

THEOREM 213.

- (i) *The minimal logics of width $n < \omega$ in the classes **NExtK4**, **NExtS4**, **NExtGrz**, **NExtGL**, **ExtInt** have polynomial FMP.*
- (ii) **Lin** and all logics containing **S4.3** have linear FMP.
- (iii) *The minimal logics of depth n in **NExtGrz**, **NExtGL**, **ExtInt** have polynomial FMP, with the power of the corresponding polynomial $\leq n - 1$.*
- (iv) *The minimal logics of depth n in **NExtK4**, **NExtS4** have polynomial FMP, with the power of the corresponding polynomial $\leq n$.*

Proof. (i) is proved by two filtrations. First, with the help of the standard filtration one constructs a finite frame separating a formula φ from the given logic L and then, using the selective filtration, extracts from it a polynomial separation frame: it suffices to take a point refuting φ and all maximal points at which ψ is false, for some $\Box\psi \in \mathbf{Sub}\varphi$ (in the intuitionistic case $\psi \rightarrow \chi \in \mathbf{Sub}\varphi$ should be considered). (ii) is proved analogously.

To illustrate the proof of (iii) and (iv), we consider the minimal logic L of depth 3 in **NExtGL**. Suppose $\varphi \notin L$. Then there is a transitive irreflexive model \mathfrak{M} of depth ≤ 3 refuting φ at its root r . Let $\Box\psi_i$, for $1 \leq i \leq m$, be all “boxed” subformulas of φ . For every $i \in \{1, \dots, m\}$, we choose a point refuting ψ_i , if it exists. And then we do the same in the set $x\uparrow$, for every chosen point x . Let \mathfrak{M}' be the submodel formed by the selected points and r . Clearly, it contains at most $1 + m + m^2$ points. And by induction on the

Figure 20.

construction of formulas in **Sub** φ one can easily show that \mathfrak{M}' refutes φ at r .

To prove the lower bound one can use the formulas

$$\alpha_n = \neg \left(\bigwedge_{i=1}^n \Box(p_{i+1} \rightarrow p_i) \wedge \bigwedge_{i=1}^n \Box(q_{i+1} \rightarrow q_i) \wedge \bigwedge_{i=1}^n \Diamond(\Diamond \top \wedge \Box^+(\neg p_{i+1} \wedge p_i)) \wedge \Box(\Diamond \perp \rightarrow \bigwedge_{i=1}^n \Diamond(\neg q_{i+1} \wedge q_i)) \right)$$

which are not in L and every separation frame for which contains the full n -ary tree of depth 3, i.e., at least $1 + n + n^2$ points. ■

However, even if frames for a logic with FMP do not contain full finite binary trees its complexity function can grow very fast, witness the following result of [Chagrov 1985a].

THEOREM 214. *For every arithmetic function $f(n)$, there are logics L of width 1 in **NExtK4** and of width 2 in **ExtInt**, **NExtGrz**, **NExtGL** having FMP and such that $f_L(n) \geq f(n)$.*

Proof. We construct a logic $L \in \mathbf{NExtK4.3}$ whose complexity function grows faster than a given increasing arithmetic function $f(n)$. Define L to be the logic of all frames of the form shown in Fig. 20. To see that L satisfies the property we need, consider the sequence of formulas

$$\beta_1 = p_1 \vee \Box(\Box p_1 \rightarrow (\Box(\Box p \rightarrow p) \rightarrow p)),$$

$$\beta_{i+1} = p_{i+1} \vee \Box(\Box p_{i+1} \rightarrow \beta_i).$$

Since these formulas are refuted at points of the form a_j in sufficiently large frames depicted in Fig. 20, they are not in L . And since L contains the formulas

$$\neg \beta_n \rightarrow \Diamond(\Diamond^{f(n)-1} \top \wedge \Box^{f(n)} \perp),$$

β_n cannot be separated from L by a frame with $\leq f(n)$ points. ■

For logics of finite depth this theorem does not hold, since according to the description of finitely generated universal frames in Section 1.2, for every $L \in \mathbf{NExtK4BD}_k$ ($k \geq 3$), we have

$$f_L(n) \leq 2^{\left. \begin{matrix} 2^{\dots 2^c \cdot n} \\ \dots \end{matrix} \right\} k-2}$$

for some constant $c > 0$. And as was shown in [Chagrov 1985a], one cannot in general reduce this upper bound.

THEOREM 215. *For every $k \geq 3$, there are logics L of depth k in NExtGrz , NExtGL , ExtInt such that*

$$f_L(n) \geq 2^{2^{\dots^{2^n}}} \Big\}^{k-2} .$$

Proof. We illustrate the proof for $k = 3$ in NExtGL . Let L be the logic characterized by the class of rooted frames \mathfrak{F}_m for GL of depth 3 defined as follows. \mathfrak{F}_m contains m dead ends, every non-empty set of them has a focus, i.e., a point that sees precisely the dead ends in this set, and besides the root there are no other points in \mathfrak{F}_m . It should be clear that L does not contain the formulas

$$\gamma_m = \bigwedge_{i=1}^n \Box(p_{i+1} \rightarrow p_i) \rightarrow \bigwedge_{i=1}^n \Box\Box(p_i \rightarrow p_{i+1}).$$

On the other hand γ_n is not refutable in a frame for L with $< 2^m$ points because the following formulas are in L :

$$\neg\gamma_m \rightarrow \bigwedge_{X \subseteq \{1, \dots, m\}, X \neq \emptyset} \Diamond \left(\bigwedge_{i \in X} \Diamond \delta_i \wedge \bigwedge_{i \notin X, 1 \leq i \leq m} \neg \Diamond \delta_i \right),$$

where $\delta_i = p_1 \wedge \dots \wedge p_i \wedge \neg p_{i+1} \wedge \dots \wedge \neg p_{m+1}$. ■

Note, however, that the logics constructed in the proofs of the last two theorems are not finitely axiomatizable. We know of only one “very complex” calculus with FMP.

THEOREM 216. $\log_2 \log_2 f_{\text{KP}}(n) \asymp n$.

For the proof see [Chagrov and Zakharyashev 1997], where the reader can find also some other results in this direction.

Relation to complexity classes

Let us return to the original problem of optimizing decision algorithms for the logics under consideration. First of all, it is to be noted that there is a natural lower bound for decision algorithms which cannot be reduced—we mean the complexity of decision procedures for **CI**. This is clear for (consistent) modal logics on the classical base; and by Glivenko’s Theorem, every si-logic “contains” **CI** in the form of the negated formulas. Thus, if we manage to construct an effective decision procedure for some of our logics then **CI** can be decided by an equally effective algorithm. (We remind the reader that all existing decision algorithms for **CI** require exponential

time (of the number of variables in the tested formulas). On the other hand, only polynomial time algorithms are regarded to be acceptable in complexity theory.)

So, when analyzing the complexity of decision algorithms for modal and si-logics, it is reasonable to compare them with decision algorithms for **CI**. For example, if a logic L is polynomially equivalent to **CI** then we can regard these two logics to be of the same complexity. Moreover, provided that somebody finds a polynomial time decision procedure for **CI**, a polynomial time decision algorithm can be constructed for L as well. The following theorem lists results obtained by [Ladner 1977], [Ono and Nakamura 1980], [Chagrova 1983], and [Spaan 1993].

THEOREM 217. *All logics mentioned in the formulation of Theorem 213 are polynomially equivalent to **CI**.*

Proof. We illustrate the proof only for the minimal logic L of depth 3 in **NExtGL** using the method of [Kuznetsov 1979]. Suppose φ is a formula of length n . By Theorem 213, the condition $\varphi \notin L$ means that $\mathfrak{M} \not\models \varphi$, for some model $\mathfrak{M} = \langle \mathfrak{F}, \mathfrak{V} \rangle$ based on a frame \mathfrak{F} for **GL** of depth ≤ 3 and cardinality $\leq c \cdot n^2$. We describe this observation by means of classical formulas, understanding their variables as follows. Let x, y, z be names (numbers) of points in \mathfrak{F} , for $1 \leq x, y, z \leq c \cdot n^2$. With every pair $\langle x, y \rangle$ of points in \mathfrak{F} we associate a variable p_{xy} whose meaning is “ x sees y ”. And with every $\psi \in \mathbf{Sub}\varphi$ and every x we associate a variable q_x^ψ which means “ ψ is true at x ”. Denote by α the conjunction

$$q_1^\varphi \wedge q_2^\varphi \wedge \cdots \wedge q_{c \cdot n^2}^\varphi.$$

It means that φ is true in \mathfrak{M} . And let β be the conjunction of the following formulas under all possible values of their subscripts:

$$\begin{aligned} & \neg p_{xx}, \quad p_{xy} \wedge p_{yz} \rightarrow p_{xz}, \quad q_x^{\neg\psi} \leftrightarrow \neg q_x^\psi, \\ & q_x^{\psi \wedge \chi} \leftrightarrow q_x^\psi \wedge q_x^\chi, \quad q_x^{\psi \vee \chi} \leftrightarrow q_x^\psi \vee q_x^\chi, \quad q_x^{\Box\psi} \leftrightarrow \bigwedge_{y=1}^{c \cdot n^2} (p_{xy} \rightarrow q_y^\psi). \end{aligned}$$

(The first two formulas say that R is irreflexive and transitive and the rest simulate the truth-relation in \mathfrak{M} .) Finally, we define a formula saying that our frame is of depth ≤ 3 :

$$\gamma = \bigwedge_{1 \leq x, y, z, u \leq c \cdot n^2} \neg(p_{xy} \wedge p_{yz} \wedge p_{zu}).$$

The formula $\beta \wedge \gamma \wedge \neg\alpha$ is of length $\leq 50(c \cdot n^2)^5$ and can be clearly constructed by an algorithm working at most polynomial time in the length of φ . It is readily seen that $\varphi \notin L$ iff $\beta \wedge \gamma \wedge \neg\alpha$ is satisfiable in **CI**. Thus we have

polynomially reduced the derivability problem in L to that in \mathbf{Cl} . Since the converse reduction is trivial, L and \mathbf{Cl} are polynomially equivalent. ■

The reader must have noticed that Theorem 217 lists almost all logics known to have polynomial FMP. Kuznetsov [1975] conjectured that every calculus having polynomial FMP is polynomially equivalent to \mathbf{Cl} . This conjecture is closely related to some problems in the complexity theory of algorithms. We remind the reader that \mathbf{NP} is the class of problems that can be solved by polynomial time algorithms on nondeterministic (Turing) machines. An \mathbf{NP} -complete problem is a problem in \mathbf{NP} to which all other problems in \mathbf{NP} are polynomially reducible. (For more detailed definitions consult [Garey and Johnson 1979].) The most popular \mathbf{NP} -complete problem is the satisfiability problem for Boolean formulas, i.e., the nonderivability problem for \mathbf{Cl} . So the nonderivability problem for all logics listed Theorem 217 is \mathbf{NP} -complete and Kuznetsov's conjecture is equivalent to a positive solution to the problem whether the nonderivability problem for every calculus with polynomial FMP is \mathbf{NP} -complete.

Note that if $\mathbf{coNP} = \mathbf{NP}$ (for the definition of the class \mathbf{coNP} see [Garey and Johnson 1979]; we just mention that the derivability problem in \mathbf{Cl} is \mathbf{coNP} -complete) then Kuznetsov's conjecture does hold. But since “ $\mathbf{coNP} = \mathbf{NP}$?” belongs to the list of “unsolvable” problems under the current state of knowledge, it may be of interest to find out whether Kuznetsov's conjecture implies $\mathbf{coNP} = \mathbf{NP}$.

Another complexity class we consider here is the class \mathbf{PSPACE} of problems that can be solved by polynomial space algorithms. A typical example of a \mathbf{PSPACE} -complete problem is the truth problem for quantified Boolean formulas. The following theorem (which summarizes results obtained by Ladner [1977], Statman [1979], Chagrov [1985a], Halpern and Moses [1992] and Spaan [1993]) lists some \mathbf{PSPACE} -complete logics.

THEOREM 218. *The nonderivability problem (and so the derivability problem) in the following logics is \mathbf{PSPACE} -complete: \mathbf{Int} , \mathbf{KC} , \mathbf{K} , $\mathbf{K} \otimes \mathbf{K}$, $\mathbf{S4}$, $\mathbf{S4} \otimes \mathbf{S4}$, $\mathbf{S5} \otimes \mathbf{S5}$, \mathbf{GL} , \mathbf{Grz} , $\mathbf{K.t}$ and $\mathbf{K4.t}$.*

It follows in particular that complexity is not preserved under the formation of fusions of logics (under the assumption $\mathbf{NP} \neq \mathbf{PSPACE}$), since nonderivability in $\mathbf{S5}$ is \mathbf{NP} -complete. For more information on the preservation of complexity under fusions consult [Spaan 1993].

Finally we note that the nonderivability problem in logics with the universal modality or common knowledge operator is mostly even $\mathbf{EXPTIME}$ -complete, witness \mathbf{K}_u [Spaan 1993] and $\mathbf{S4EC}_2$ [Halpern and Moses 1992]. The complexity of the nonderivability problem for Cartesian products of many standard modal logics is $\mathbf{NEXPTIME}$ -hard; $\mathbf{S5} \times \mathbf{S5}$ and $\mathbf{K} \times \mathbf{S5}$ are examples of $\mathbf{NEXPTIME}$ -complete logics (see [Marx 1999]). (Note, by the way, that the known upper bound for $\mathbf{K} \times \mathbf{K}$ is non-elementary.)

5 APPENDIX

We conclude this chapter with a (by no means complete) list of references for those directions of research in modal logic that were not considered above:

- *Congruential logics.* These are modal logics that do not necessarily contain the distribution axiom $\Box(p \rightarrow q) \rightarrow (\Box p \rightarrow \Box q)$ but are closed under modus ponens and the congruence rule $p \leftrightarrow q / \Box p \leftrightarrow \Box q$. Segerberg [1971] and Chellas [1980] define a semantics for these logics; Lewis [1974] proves FMP of all congruential non-iterative logics and Surendonk [1996] shows that they are canonical. Došen [1988] considers duality between algebras and neighbourhood frames and Kracht and Wolter [1999] study embeddings into normal bimodal logics.
- *Modal logics with graded modalities.* The truth-relation for their possibility operators \Diamond_n is defined as follows: $x \models \Diamond_n p$ iff there exist at least n points accessible from x at which p holds. An early reference is [Fine 1972]; more recent are [van der Hoek 1992] (applications to epistemic logic) and [Cerrato 1994] (FMP and decidability).
- *Modal logics with the difference operator* or with *nominals* (or *names*). The semantics of nominals is similar to that of propositional variables; the difference is that a nominal is true at exactly one point in a frame. For the difference operator $[\neq]$, we have $x \models [\neq]p$ iff p is true everywhere except x . De Rijke [1993], Blackburn [1993] and Goranko and Gargov [1993] study the completeness and expressive power of systems of that sort. Closely related to the difference operator is the modal operator $[i]$ for inaccessible worlds: $x \models [i]p$ iff p is true in all worlds which are not accessible from x , see [Humberstone 1983] and [Goranko 1990a].
- *Modal logics with dyadic* or even *polyadic operators.* For duality theory in this case see [Goldblatt 1989]. An extensive study of Sahlqvist-type theorems with applications to polyadic logics is [Venema 1991]. For connections with the theory of relational algebras see [Mikulas 1995] and [Marx 1995]. In those dissertations the reader can find also recent results on arrow logic, i.e., a certain type of polyadic logic which is interpreted in Kripke frames built from arrows. An embedding of polyadic logics into polymodal logics is discussed in [Kracht and Wolter 1997].
- *Bisimulations.* Bisimulations were introduced in modal logic by van Benthem [1983] to characterize its expressive power; see also [de Rijke 1996]. Visser [1996] used bisimulations to prove uniform interpolation. Recently, bisimulations have attracted attention because they form a

common tool in modal logic and process theory. We refer the reader to collection [Ponse *et al.* 1996] for information on this subject.

- *Modal logics with fixed point operators*, i.e., modal logics enriched by operators forming the least and greatest fixed points of monotone formulas. These systems are also called *modal μ -calculi*. Under this name they were introduced and studied by Kozen [1983, 1988]; see also [Walukiewicz 1993, 1996] and [Bosangue and Kwiatkowska 1996].
- *Proof theory*. Early references to studies of sequent calculi and natural deduction systems for a few modal logics can be found in *Basic Modal Logic*. More recently, (non-standard) sequent calculi for modal logics have been considered by Došen [1985b], Masini [1992] and Avron [1996]; see also collection [Wansing 1996] and the chapter *Sequent systems for modal logics* later in this *Handbook*. For natural deduction systems see Borghuis [1993]; tableau systems for modal and tense logics were constructed in [Fitting 1983], [Rautenberg 1983], [Gore 1994] and [Kashima 1994]. Orłowska [1996] develops *relational proof systems*. Display calculi for modal logics were introduced by Belnap [1982]; see also [Wansing 1994] and collection [Wansing 1996].
- *Description logic*, a formalism closely related to modal logic, was designed in artificial intelligence by Brachman and Schmolze [1985] as a means for knowledge representation and reasoning (for a survey see [Donini *et al.* 1996]). Schild [1991] was the first to observe that the basic description logic \mathcal{ALC} is just a terminological variant of the polymodal \mathbf{K} . Recently, in order to represent dynamic and intensional knowledge, combinations of description and modal logics have been introduced, see e.g. Baader and Ohlbach [1995], Baader and Laux [1995], and Wolter and Zakharyashev [1998, 1999b,c].

ACKNOWLEDGMENTS

First of all, we are indebted to our friend and colleague Marcus Kracht who not only helped us with numerous advices but also supplied us with some material for this chapter. We are grateful to Hiroakira Ono and the members of his Logic Group in Japan Advanced Institute of Science and Technology for the creative and stimulating atmosphere that surrounded the first two authors during their stay in JAIST in 1996–97, where the bulk of this chapter was written. Thanks are also due to Johan van Benthem, Wim Blok, Dov Gabbay, Silvio Ghilardi, Agnes Kurucz, Krister Segerberg, Valentin Shehtman, Dimitar Vakarelov, and Heinrich Wansing for their helpful comments and stimulating discussions. And certainly our work would be impossible without constant support and love of our wives: Olga, Imke and Lilia.

The work of the first author was partly financed by the Alexander von Humboldt Foundation.

JAMES W. GARSON

QUANTIFICATION IN MODAL LOGIC

0 INTRODUCTION

0.1 An Outline of this Chapter

The novice may wonder why quantified modal logic (QML) is considered difficult. QML would seem to be easy: simply add the principles of first-order logic to propositional modal logic. Unfortunately, this choice does not correspond to an intuitively satisfying semantics. From the semantical point of view, we are confronted with a number of decisions concerning the quantifiers, and these in turn prompt new questions about the semantics of identity, terms, and predicates. Since most of the choices can be made independently, the number of interesting quantified modal logics seems bewilderingly large.

The main purpose of this chapter is to try to make sense of this seemingly chaotic terrain. Section 1 provides a review of the major systems. Section 2 explains the difficulties in completeness proofs for QMLs, and presents strategies for overcoming them. Section 3 shows that some systems of QML behave like second-order logics; they have strong expressive powers and so are incomplete. The Appendix lists rules, systems, and semantical conditions covered in this chapter.

Free logic serves, in one way or another, as the foundation for most of the systems we will study. We will argue in Section 1.2.1.2 that allegiance to first-order logic is a source of *ad hoc* stipulations in semantics for QML. However, when the principles of free logic are adopted, complications can be avoided. Since free logic is such a crucial foundation for QML, we will give a brief description of it here. The reader who knows about free logic, or who wants to read Bencivena's chapter (in Volume 7 of this *Handbook*) on the topic, may skip section 0.2. Since free logics are usually formulated using = in QML in any case, we will briefly discuss identity in intensional logics in Section 0.3.

0.2 A Short Review of Free Logic

One oddity of first-order logic with identity is that it seems to provide an argument for the existence of God. From the provable identity $g = g$ we may derive, $\exists x x = g$ by Existential Generalisation. If g abbreviates 'God', then $\exists x x = g$ reads 'God exists'. This anomaly is connected with the basic assumption made in the semantics for quantificational logic that every constant (such as g) refers to an object in the domain of quantification.

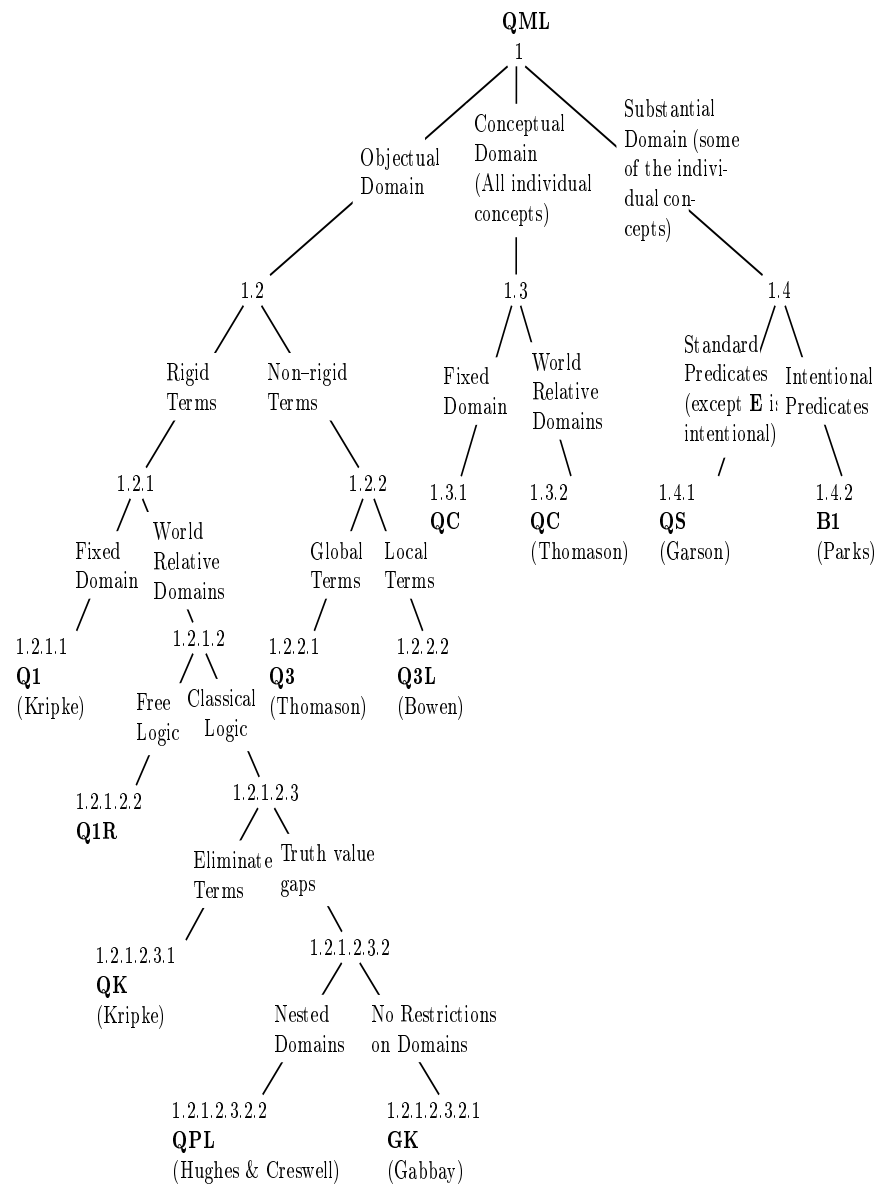

Figure 1. ROADMAP

Explanation of the quantified Modal Logic Roadmap

This tree represents the structure of the discussion of quantified modal logic in this chapter. Each node contains a number indicating the section of this chapter where a topic is discussed. Branches from each node are labelled with the main options which one can choose at that point. The 'leaves' of the tree are labelled with the name used in this chapter of the system which results from choosing the options on all branches leading to it. Beneath the name of each system is the name of an author associated with the system. The references in the bibliography associated with his name contain a description of the system in question.

There are a number of ways for a believer in the principles of first-order logic to handle this problem. One popular tactic is to count ‘God’ as a definite description $IxGx$, where Gx is interpreted to be true only of God. Then ‘God exists’ translates to $\exists yy = IxGx$. By Russell’s theory of descriptions, this amounts to $\exists z(\exists yy = z \wedge Gz \wedge \forall x(Gx \rightarrow x = z))$, which is not a theorem. However, this reply depends on a debatable assumption, namely that for every name which may fail to refer, we can find a predicate (or open sentence) which picks out that referent uniquely. Kripke [1972] presents strong evidence that we cannot find such uniquely identifying predicates. Even if we could solve this problem, the use of Russell’s theory causes another problem. We want to be able to say that ‘Pegasus has wings’ is true, but that ‘Pegasus is a hippopotamus’ is false. If we translated ‘Pegasus’ away in these two sentences according to Russell’s theory of descriptions, we obtain sentences of the shapes $W(IxPx)$ and $H(IxPx)$, which are both false since Pegasus does not exist. We do no better translating these sentences by $\forall x(Px \rightarrow Wx)$ and $\forall x(Px \rightarrow Hx)$, because in this case both are vacuously true, since nothing satisfies the predicate P .

Free logic avoids these difficulties by dropping the assumption that every name must refer to an object in the domain of quantification. As a result, the principles for the quantifiers are somewhat weaker. Let us assume that we have a primitive predicate E , whose extension is the domain of quantification. The revised axiom of Existential Generalisation becomes:

$$(FEG) \quad (Pt \wedge Et) \rightarrow \exists xPx.$$

The proof we gave for $\exists xx = g$ in first-order logic is now blocked. Using (FEG), we may obtain $\exists xx = g$ from $g = g$ only if we have already proven Eg , and Eg expresses what we are trying to prove.

A complete system **MFL** of minimal free logic with identity can be constructed by defining $\exists x$ and $\neg\forall x\neg$ and adding the following rules to propositional logic plus identity theory:

$$(FUI) \quad \frac{\forall xPx}{Et \rightarrow Pt} \quad \text{for any term } t$$

$$(FUG) \quad \frac{\vdash A \rightarrow (Et \rightarrow Pt)}{\vdash A \rightarrow \forall xPx} \quad t \text{ is a term that does not appear in } A \rightarrow \forall xPx.$$

In these rules, and throughout this chapter, A and Px are wffs, x is any variable, and Pt is the result of substituting the term t properly for all occurrences of x in Px . It is an easy exercise to show that Et is equivalent in **MFL** to $\exists xx = t$ (where x is not t). So we could have defined Et as $\exists xx = t$, and avoided the introduction of a special predicate letter E . However, in some intensional logics, there is no way to define Et in terms of the rest of the primitive vocabulary, and so we have prepared for this by assuming that E is primitive.

0.3 Identity in Intensional Logics

The failure of the substitution of identical terms is a familiar criterion for identifying intensional expressions. For example, the invalidity of the famous argument:

Scott is the author of Waverley	
King George wonders whether Scott is Scott	
King George wonders whether Scott is the author of Waverley	

serves as evidence that ‘King George wonders whether’ is intensional. It should not surprise us, then, if we need to limit the rule of substitution of identities in intensional logics. One simple way to enforce the desired restriction is to allow substitution in atomic sentences only, as in the following system **ID** for identity:

$$(= \text{In}) \quad t = t \qquad (= \text{Out}) \quad \frac{t = t'}{Pt \rightarrow Pt'} \quad \text{where } Pt \text{ is an atom.}$$

Although the restriction to atomic sentences may seem strong, it has no effect whatsoever in first-order logic, because (= Out) insures the substitution of identities in all extensional sentences. However, in intensional logics, it does not guarantee substitution of identical terms which lie in the scope of intensional operators.

Some may object to the view that the substitution of identicals fails. Russell, for example, gave an explanation of the invalidity of the argument about the author of Waverley which did not require any restrictions on the rule of substitution. Russell claimed that the description ‘the author of Waverley’, does not count as a term. When the description is eliminated according to his theory, the first premise of the argument no longer has the form of an identity. This tactic does not work, however, for arguments such as the following where there are no descriptions to eliminate:

Cicero is Tully.	
King George knows that Cicero is Cicero.	
King George knows that Cicero is Tully.	

One reaction to this sort of example is to argue that the failure of the rule of substitution is a sign that the expression being substituted is not really a term. So the invalidity of the last argument shows that ‘Cicero’ and ‘Tully’ are not terms, and must be translated using corresponding descriptions: $IxCx$ and $IxTx$. When this is done, the first premise of the argument no longer has the form of an identity, and so does not count as a case of substitution.

Notice, however, that adherence to the principle of unrestricted substitution leads us to a position similar to the one which resulted from adherence

to the classical rules for quantifiers, we conclude that many of the expressions which we would ordinarily count as terms, must be treated instead as descriptions. We were forced before to deny the termhood of expressions which might fail to denote, and now we are compelled to deny it of expressions which might have synonyms. Since we have little guarantee that a given expression avoids either defect, we feel pressure, as Quine did, to claim that no expression of English should be rendered as a constant in first-order logic.

Given the simplicity of the alternative rules, the insistence on the classical rules for quantifiers and the unrestricted substitution of identities is, in our opinion, a prejudice, and one which blocks a natural exposition of an adequate foundation for quantified modal logics.

1 A TAXONOMY OF QUANTIFIED INTENSIONAL LOGIC

One of the most significant points of difference between semantical treatments of QML concerns the domain of quantification. Some systems quantify over objects, while others quantify over what Carnap [1947] called individual concepts. The second approach is more general, but it is also more abstract, and more difficult to motivate. So we will open this account of QML with systems that use the objectual interpretation.

1.1 *Some Semantical Preliminaries*

Before we begin, it will be helpful to define a few semantical ideas which we will use throughout this chapter. We assume that a quantified modal language is constructed from predicate letters, the primitive predicate constant E , terms (which include infinitely many variables) the logical constants \neg , \rightarrow , \Box , $=$, and a quantifier $\forall x$ for each of the variables x . The predicate letters come equipped with integers indicating their arity. The propositional variables are taken to be 0-ary predicate letters, and well-formed formulas are defined in the usual way. Given a set D , the extensions of terms and predicate letters are defined just as they are in first-order logic. The *extension of a term* is some member of D , and the *extension of an i -ary predicate letter* is a set of i -length sequences of members of D . Given a set W of indices (typically, possible worlds), the *intension of an expression* is simply a function which takes each member of W into an appropriate extension for that expression. Carnap's *individual concepts* are simply term intensions, that is, functions from the set of possible worlds into the domain of objects.

Throughout this chapter, a Q -model $\langle W, R, D, Q, a \rangle$ will contain a set W of possible worlds, a binary relation R on W , a nonempty set D of possible objects, some item Q which determines the domain of quantification, and an assignment function a , which interprets the terms (including variables)

and predicate letters by assigning them the corresponding kind of intensions with respect to W and D . If the quantifier rules of a system are based on free logic, then there will be a predicate letter E in the language. To ensure that E receives the proper interpretation as picking out the quantifier domain, we will assume that a Q -model for a language that contains E always meets the condition that $a(E)$ is Q .

In some semantics, the terms are *rigid designators*, that is, their extensions are the same in all possible worlds. Usually such terms are assigned no intensions, but given extensions directly. However, in order to keep the description of a model as consistent as possible, we will assume that terms always have intensions, and that terms which are rigid designators simply meet the added condition that their intensions are constant functions.

The symbol $=$ will always be interpreted as contingent identity. This means that $t = t'$ is ruled true in a world just in case t and t' have the same extension in that world. The truth value of a sentence A on a model $\langle W, R, D, Q, a \rangle$ at world w of W (written $a(A)(w)$) will be defined by induction on the shape of A using the standard clauses for atomic sentences, \neg , \rightarrow and \Box . When we present a given approach to the quantifiers, we usually will need only to say what Q is like, and to give the truth clause for the quantifier.

The quantified modal logics we are going to discuss are all extensions of propositional modal logics which are adequate with respect to some class of Kripke frames. For example, we will consider extensions of **S4**, which are adequate (semantically consistent and complete) with respect to the class **R(S4)** of Kripke frames $\langle W, R \rangle$ that are reflexive and transitive. Usually we will not care which propositional modal logic is chosen as the foundation for our quantified logic. We will assume that some propositional modal logic has already been chosen, and that the frame of any Q -model is in $R(S)$. When we need to be explicit, we will talk of S -models, and mean models whose Kripke frames are in the set $R(S)$. The notions of Q -satisfiability and Q -validity are determined by the concept of a Q -model exactly as in propositional modal logic.

1.2 The Objectual Interpretation

1.2.1 *Rigid Terms.* Kripke's historic paper [1963] serves as an excellent starting point for a discussion of logics with the objectual interpretation. One reason is that he made the important simplifying assumption that all terms of the language are rigid designators. Systems that allow nonrigid terms are, as we shall see, rather complicated, and so we will begin, as Kripke did, by assuming that the intension of every term is a constant function. This assumption validates the following two rules which we refer

to together as (RT) (for rigid terms).

$$(RT) \quad \frac{t = t'}{\Box t = t'} \quad \frac{\neg t = t'}{\Box \neg t = t'}$$

The rigidity condition reflects the view that proper names have extensions, but no intensions. Since (RT) guarantees the substitution of identity in all contexts, it sits well with those who object to restrictions on substitution of identities.

Kripke's paper also lays out two important options concerning the quantifier domains. The simplest of the two, the fixed domain approach, assumes a single domain of quantification which contains, presumably, all the possible objects. The world-relative interpretation, on the other hand, assumes that the domain of quantification contains only the objects that exist in a given world, and so the domain varies from one world to another.

1.2.1.1 *Fixed Domains: The System Q1.* Although the fixed domain approach is less general, it is attractive from the semantical point of view because we need only add the familiar machinery for $\forall x$ to the semantics of a modal logic in the following way. A *fixed domain objectual model with rigid terms* (or **Q1-model**) is a sequence $\langle W, R, D, \mathbf{Q1}, a \rangle$, where the domain of quantification **Q1** is D , the set of possible objects, and where a meets the condition (aRT), which guarantees that the term intensions are constant functions.

$$(aRT) \quad a(t)(w) \text{ is } a(t)(w') \text{ for all } w, w' \text{ in } W.$$

The truth value of a sentence on a model is then defined using the following clause for the quantifier:

$$(Q1) \quad a(\forall x A)(w) \text{ is } T \text{ iff for all } d \text{ in } \mathbf{Q1}, a(d/x)(A)(w) \text{ is } T.$$

(Here $a(d/x)$ is the assignment like a save that $a(x) = d$.)

For each propositional modal logic S , let the formal system **Q1-S** consist of the principles of S , rules for first-order logic (ID), (RT), and the Barcan formula (BF):

$$(BF) \quad \forall x \Box A \rightarrow \Box \forall x A.$$

One satisfying feature of the fixed domain account is that most propositional modal logics S for which we can show completeness with respect to a set $R(S)$ of Kripke frames, have the feature that the system **Q1-S** is semantically consistent and complete with respect to **Q1-S**-validity. There are exceptions, however. For example, Cresswell [1995] explains that when $R(S)$ is convergent, completeness of **Q1-S** may fail.

1.2.1.2 *World-Relative Domains.*

1.2.1.2.1 *The Motivation for World-relative Domains.* The fixed domain interpretation is satisfying from the formal point of view, but it is not an accurate account of the semantics of quantifier expressions of natural language. We do not think that ‘There is a man who signed the Declaration of Independence’ is true, at least not if we read ‘there is’ in the present tense. Nevertheless, this sentence was true in 1777, which shows that the domains of the present tense quantifiers changes to reflect which objects exist at different times. The domain varies along other dimensions as well. For example, when I announce to my class that everyone did well on the midterm, it is understood that I am not praising the whole human race. Time, place, speaker, and even topic of discussion play a role in determining the domain in ordinary communication. There are also strong reasons for rejecting fixed domains in modal languages. On the fixed domain interpretation, the sentence $\forall x \Box \exists y (y = x)$ (which reads ‘everything exists necessarily’) is valid, but we would not ordinarily count this as a logical truth because we assume that different things exist in the different possible worlds.

The defender of the fixed domain interpretation can respond to these objections by insisting that the domain of $\forall x$ contains merely possible objects. Expressions whose domain depends on the context, can then be defined using $\forall x$ and predicate letters. For example, the present tense quantifier can be defined using $\forall x$ and a predicate letter that reads ‘presently exists’.

One difficulty with this proposal is that it requires the invention of predicates for all the different subdomains which we may ever intend for quantifier expressions, and it forces us to represent simple expressions of natural language differently in different contexts of their use. It would be more satisfying if we could specify semantics for intensional logic which admits the context dependence of the domain.

1.2.1.2.2 *World-Relative Models: Q1R-Semantics.* Let us define a *world-relative objectual model with rigid terms* (or **Q1R-model**) as a sequence $\langle W, R, D, \mathbf{Q1R}, a \rangle$, where **Q1R** is a function that assigns a subset $D(w)$ to D to each possible world w , and where a meets condition (*aRT*). The truth clause for the quantifier reads as follows:

$$(\mathbf{Q1R}) \quad a(\forall x A)(w) \text{ is } T \text{ iff for every } d \text{ in } D(w), a(d/x)(A)(w) \text{ is } T.$$

An adequate logic **Q1R** for **Q1R**-validity can generally be formulated by adding the principles **MFL** of free logic, rules **ID** for (intensional) identity, and (**RT**) to the underling modal logic.

1.2.1.2.3 *Methods for Preserving Classical Quantifier Rules.* The world-relative interpretation of the quantifiers virtually demands the adoption of free logic. I say ‘virtually’ because there are systems which use first-order rules with the world-relative interpretation; however, they have serious

limitations. To appreciate the difficulties in trying to maintain the standard rules, notice first that the sentence $\exists x(x = t)$ is true at a world on a model just in case the extension of t is in the domain of that world. However, $\exists x(x = t)$ is a theorem of first-order logic, and so it follows that every term t of the language must refer to an object that exists in every possible world. This leads to two difficulties. First, there may not be any one object that exists in all the worlds. Second, the whole motivation for the world relative approach was to reflect the idea that objects in one world may not exist in another; but if standard rules are used, no terms may refer to such objects.

1.2.1.2.3.1 *Eliminate terms: the system QK*. Kripke [1963] gives an example of a system for the world-relative interpretation which keeps the classical rules. The system **QK** has no terms other than variables. On a semantics where variables are given extensions in the domain, the validity of $\exists x x = y$ would demand that the extension of y be a member of every possible world. Kripke avoids this difficulty by giving sentences with free variables the closure interpretation. So $\exists x x = y$ has the semantical effect of $\forall y \exists x x = y$, which is valid in free logic. From the semantical point of view, then, Kripke's system, has no terms at all, because the variables are really disguised universal quantifiers. Although Kripke has shown that modal extensions of first-order logic with the world-relative interpretation are possible, his system underscores a theme which we have been developing throughout this chapter, namely that adoption of the classical rules forces us into an inadequate account of terms. Another oddity of Kripke's system is that he must weaken the necessitation rule: 'if A is a theorem, then so is $\Box A$ '. Otherwise we would be able to derive $\Box \exists x x = y$ which, since it is given the closure interpretation, says that any object of one domain exists in all the others. The rule is repaired by restricting it to closed sentences.

1.2.1.2.3.2 *Nested domains and truth value gaps*. There is a second problem with using classical logic with the world- relative interpretation which has exerted pressure on the way semantics for quantified modal logics is formulated. The principles of classical logic, along with the (unrestricted) rule of necessitation entail (CBF), the converse of the Barcan Formula.

$$(CBF) \quad \Box \forall x A \rightarrow \forall x \Box A.$$

It is not difficult to show that every world-relative model of (CBF) must meet condition (ND) (for 'nested domains').

$$(ND) \quad \text{If } wRw' \text{ then } D(w) \text{ is a subset of } D(w').$$

To see this, notice that $\Box \forall x \exists y y = x$ is **Q1R**-relative valid, and entails $\forall x \Box \exists y y = x$ by (CBF). Our desire to avoid $\forall x \Box \exists y y = x$ was one of the things which prompted the world-relative interpretation, for $\forall x \Box \exists y y = x$ claims that any object which exists in the real world must also exist in all

worlds which are possible relative to ours. Certainly, we want to allow that there are possible worlds where at least one of the things of our world fails to exist.

If R is symmetric, then it follows from (ND) that all worlds accessible from ours have exactly the same domains. This result is reflected in the fact that the Barcan Formula (BF) is provable in systems as strong as **B** which use the standard quantifier rules. In models of **S5** where all worlds are accessible from each other, (ND) demands that all domains be the same, in direct conflict with our intention to distinguish the domains.

Despite these difficulties in using classical principles with an unrestricted necessitation rule, several authors have defined systems which preserve the classical rules. Typically, their systems simply adopt (ND). Yet other adjustments must be made, however, to preserve classical logic. The sentence $\forall xPx \rightarrow Pt$, for example, is not valid on a model where the extension of t at a world w is outside $D(w)$, and the extension of P at w is $D(w)$. One simple way to restore validity to the rule of Universal Instantiation is to stipulate that the terms are local, that is, the extension of a term at a world must be in the domain $D(w)$ of that world. However, there are serious problems with this. According to this view, ‘Pegasus’ and possibly ‘God’ cannot count as terms since their extensions are not in the real world. As we have argued in Section 0.2, there are good reasons for wanting to count these as terms. Furthermore, we have been assuming that terms are rigid, so terms must have the same referent in all worlds. So the demand that terms be local entails that any term must have an extension which exists in all the worlds. In fact, the only objects at which the domains might vary are ones which are never named in any world. This undercuts the whole point of introducing world-relative domains, namely to accommodate terms that refer to things that may not exist in other possible worlds.

The consequences of having terms that are both local and rigid are disastrous. There is another related idea, however, that looks as though it might work. If we assume that *predicate letters* are local, i.e. that their extensions at a world must contain only objects that exist at that world, then we will ensure that the classical sentence $Ft \rightarrow \exists xFx$ (hence $\forall xPx \rightarrow Pt$) is valid. The reason is that from the truth of Ft , it follows that t refers to an existing object, and from this it follows that $\exists xFx$ is true. Nevertheless, local predicates set up other anomalies, and they do not lead to the validation of the classical rules. To see why, consider $\neg Ft \rightarrow \exists x\neg Ft$. From the truth of $\neg Ft$, it does not follow that the extension of t is an existing object, and so it does not follow that $\exists x\neg Ft$ is true. Not only do we fail to validate the rule of Existential Generalisation, but the valid principles cannot be expressed as axiom schemata. (We cannot write $Pt \rightarrow \exists xPx$ for arbitrary sentences Pt , because some of these instances are valid, and others are not.) In case we are using axioms and a rule of substitution of formulas for atoms, the problem re-emerges in the failure of the rule of substitution. Either way,

the use of local predicates leads to serious formal difficulties.

There is a somewhat more plausible way to ensure the classical principles. A Strawsonian treatment would rule that a sentence has no truth value when it contains a term that does not refer to an existing object. Following this idea, we allow terms to refer to objects outside of the domain of a given world, but rule that sentences which contain such terms lack truth values. Valid sentences are then defined as ones which are never false. As a result, $\forall xPx \rightarrow Pt$ is valid, since any assignment that gives t an extension outside the domain for a world leaves the whole conditional without a value, and assignments that give t an extension inside the domain will make Pt true if $\forall xPx$ is true.

1.2.1.2.3.2.1 *The systems **GKc** and **GKs**.* When truth value gaps are introduced, we are faced with a number of options concerning the truth clause for \Box . On at least one of these options we may drop the nesting condition (ND) if we like and still obtain the classical rules. However, there are pressures that make us want to keep it. Suppose we are evaluating $\Box Ft$ at w and the referent of t is in the domain $D(w)$ of w . Then we expect to give $\Box Ft$ a truth value on the basis of the values Ft has in the worlds accessible from w . Unless we adopt (ND), there is no guarantee that t refers to an existing object in all accessible worlds, and so Ft may be undefined in some of them. Adopting the nesting condition ensures that we will always determine a value for $\Box Ft$ at w on the basis of the values which Ft is bound to have in all accessible worlds. If we drop (ND), however, there are two ways to determine the value of $\Box Ft$ at w depending on whether the failure of Ft to be defined in an accessible world should make $\Box Ft$ false or not. On the first option, Gabbay's **GKc** [Gabbay, 1976, pp. 75 ff.], the necessitation rule must be restricted so that we can no longer derive (CBF). On the second option, **GKs**, (CBF) is derivable, but the truth of (CBF) in a model no longer entails (ND). Either way, the rules of the underlying modal logic must be changed.

1.2.1.2.3.2.2 *The system **QPL**.* For these reasons, the more popular choice [Hughes and Cresswell, 1968] has been to assume (ND) and to define satisfiability as follows. A **QPL-satisfiable set** is one where none of its sentences is false in any world on some **Q1R**-model that meets (ND), and where any sentence which contains a term t with extension $a(t)(w) \notin D(w)$ has no truth value at w .

QPL-semantics is attractive from a purely formal point of view because we have relatively simple completeness proofs for systems that result from adding the principles of (classical) predicate logic to certain propositional modal logics, provided, that is, that the language omits $=$. Proofs are available, for example, for **M** and **S4**. In case the modality is as strong as **B**, the domains become rigid, and the completeness proof is carried out using methods developed for systems that validate the Barcan Formula.

1.2.1.2.4 *Conclusion: We Should Adopt Free Logic.* The appeal of simple completeness proofs should not blind us to the fact that the stipulations required in order to preserve the classical principles do not always sit well with our intuitions. Our conclusion, then, is that there is little reason to attempt to preserve the classical rules in formulating systems with the objectual interpretation and world-relative domains. The principles of free logic are much better suited to the task. As we will see in Section 2, results for systems based on free logic are actually not that difficult, especially when identity is not present.

1.2.2 *Non-rigid terms and world-relative domains*

1.2.2.1 *The System Q3.* There are two important reasons why the assumption that all terms are rigid designators should be rejected. First, expressions like ‘the tallest man’ clearly refer to different objects in different worlds. If we want to count descriptions among our terms, as we do on a Strawsonian account, we cannot accept the rigidity condition. Second, David Lewis [1968] contends that it makes no sense to talk of identity of objects across possible worlds. Objects from two different worlds are never identical, although it may make sense to talk of the counterpart of an object in another world. On counterpart theory, then, it is impossible for the intension of any term to be a constant function. Since it is important that a logical theory not rule out reasonable positions, we would like to relax the restriction that terms are rigid. Let us define a **Q3-model**, then, as a **Q1R-model** which (possibly) fails to meet condition (*aRT*).

Something unexpected happens when we relax the assumption that terms are rigid. The rule (FUI) of instantiation for free logic is no longer **Q3**-valid. In order to see why, notice that the sentence $(\Box t = t \wedge Et) \rightarrow \exists x \Box x = t$ is a consequence of (FUI). Since $\Box t = t$ is also provable there, we obtain (*E□*).

$$(E\Box) \quad Et \rightarrow \exists x \Box x = t.$$

If t reads ‘the author of “Counterpart Theory”’, then (*E□*) says that if the author of ‘Counterpart Theory’ exists, then there is someone who is necessarily the author of ‘Counterpart Theory’. Intuitively, (*E□*) is unacceptable, and it is not difficult to back up this insight with a formal counter-example. Let us imagine a model with two worlds, r (real) and u (unreal) whose domains both contain two objects, namely David Lewis and Saul Kripke. Assume that both worlds are accessible from themselves and each other. Imagine that the extension of t at the real world r is Lewis, but that it is Kripke in the unreal world u . On this model, $\exists x \Box x = t$ is false in r because neither Lewis nor Kripke is the extension of t in both worlds. Nevertheless, Et is true in r since the extension of t in the real world, namely David Lewis, is in the domain of r .

This counterexample helps us appreciate the subtle reason why (FUI) has been broken down. There is no question that David Lewis exists, and there is no

question that the author of ‘Counterpart Theory’ is identical to the author of ‘Counterpart Theory’ in any world we choose. However, the claim that any *one* person counts as the author of ‘Counterpart Theory’ in all worlds seems false. One way to help diagnose this situation is to reformulate **Q3** semantics in an equivalent, but more complex way. Replace each object with the constant function which takes any world to that object. Seen this way, the items in our domain(s) are all intensions of rigid terms. The rule of instantiation is no longer valid because the domain of quantification includes only constant term intensions, whereas terms may have nonconstant intensions.

The rules of free logic would be **Q3**-valid if we were to interpret the primitive predicate E so that Et is true in world w iff the extension $a(t)(w)$ of $t \in D(w)$ and $a(t)$ is a constant function. Notice, however, that the extension of E must contain term intensions, and not objects, if it is to do this job. As a result, E is an *intensional predicate*, which means that substitution of identity does not hold for its term position. Substitution fails because E ‘David Lewis’ is presumably true, while E ‘the author of “Counterpart Theory” ’ is not, even though ‘David Lewis’ and ‘the author of “Counterpart Theory” ’ refer to the same thing in the real world.

Aldo Bressan [1973] has championed the view that even scientific language requires intensional predicates. His more general semantics defines the *extension* of a one-place predicate at a possible world as a set of individual concepts (i.e. term intensions) not a set of objects. As a result, he has no difficulty accommodating a primitive predicate which expresses rigidity.

Hintikka [1970] chose more modest methods. He showed how to formulate a correct rule of instantiation for **Q3** that does not require an intensional existence predicate. Notice that the sentence $\exists x \Box x = t$ is true in a model at world w iff the intension of t has the same value in all worlds accessible from w . Similarly, $\exists x \Box \Box x = t$ is true at w just in case the intension of t is constant in all worlds accessible from those worlds. While there is no one sentence that expresses that a term is rigid, a sentence of the shape $\exists x \boxed{i}x = t$, where \boxed{i} is a string of i boxes, guarantees that the intension of t is constant across enough worlds so that $\boxed{i}Ft$ follows from $\forall x \boxed{i}Fx$ when Ft is atomic. This idea is generalised in Hintikka’s formulation (HUI) of a valid rule of universal instantiation for nonrigid terms.

$$(HUI) \frac{\forall x Px}{(\exists x \boxed{i}x = t \wedge \dots \wedge \exists x \boxed{k}x = t) \rightarrow Pt}$$

where i, \dots, k is a list of integers which records for each occurrence of x in Px , the number of boxes whose scope includes that occurrence.

In modal logic as strong as **S4**, this rule can be simplified considerably because there $\exists x \boxed{i}x = t$ is equivalent to $\exists x \Box x = t$. Thomason [1970] demonstrates the adequacy of **Q3–S4**, using (TUI) as the instantiation rule.

$$(TUI) \frac{\forall xPx}{\exists x\Box x = t \rightarrow Pt}$$

Completeness proofs for the weaker modalities have never been published as far as I know. Perhaps researchers have been daunted by the complexity of Hintikka's rule. It is interesting to note that even in the context of **S4**, Thomason was forced to adopt other complex rules for identity and the quantifier. Parsons [1975] has given a weak completeness result for a system that uses more standard rules, but he also shows that, in general, Thomason's rules cannot be simplified in the obvious way.

1.2.2.2 *A Classical Logic with Local Terms: The System Q3L*. There is a simple way to avoid the complicated instantiation rule needed in **Q3**. If we add the assumption that terms are local, that is, that the extension of a term at a world w is always in that world's domain, then we restore the classical quantifier rules. A **Q3** model with local terms (**Q3L-model**) is a **Q3**-model which meets condition (L)

$$(L) \quad a(t)(w) \in D(w) \quad \text{for all } w \text{ in } W, \text{ and all terms } t.$$

This condition could not be sensibly imposed for systems with rigid terms because then, any object referred to by a term would have to exist in all the domains. However, when terms are nonrigid, the domains can change as long as the extension of the terms change in corresponding ways.

There is an important application of **Q3L** which Cocchiarella discusses in his chapter in Volume 3.4. If \Box is to capture logical necessity, then we may think of possible worlds w as predicate logic models $\langle Dw, aw \rangle$, each equipped with its own domain Dw , and assignment function aw . We expect an assignment function aw of a model $\langle Dw, aw \rangle$ to give extensions to the terms (and predicate letters) in the corresponding domain Dw . So it is only natural in this case to adopt nonrigid terms, world-relative domains, the objectual interpretation, and local terms.

If we interpret $\Box A$ to mean that A is true in all models, then **Q3L**-semantics cannot be axiomatised. However, if we give $\Box A$ the generalised interpretation where $\Box A$ is true iff it is true on all models in an arbitrarily selected set of models, then **Q3L** is axiomatised by adding the principles of predicate logic to **S5**.

A more general account stipulates that $\Box A$ is true on a model U just in case A is true in all models U' suitably related to U . In this case the underlying modality depends on the conditions we adopt on the accessibility relation between models. If we take this option, however, and the accessibility relation is not symmetric, then we are forced to assume nested domains (ND), in order to preserve the classical quantifier rules. Bowen [1979] investigates systems of this kind. Even if we are willing to give up the nesting condition, problems arise. Suppose we are evaluating $\forall x\Box Fx$ in a world w where object o exists, and w' is an accessible world where o

does not exist. To determine the value of $\forall x \Box Fx$, we need to find the value of $\Box Fx$ when x refers to o . This requires that we find the value of Fx in world w' where o does not exist. At this point we are faced with the same options we described in Section 1.2.1.2.3.2. We may use truth value gaps, or we may rule that Fx in this case is false. As we pointed out, both choices have disadvantages.

Despite its application to certain notions of logical necessity, the local term condition (L) is not usually acceptable. In ordinary reasoning, we would find the assumption that anything that exists in the real world exists in all worlds possible relative to our is quite implausible. For this reason, we are still interested in **Q3** without local terms, even though the rules may be difficult.

1.3 *The Conceptual Interpretation*

The systems we have discussed so far are not especially satisfying. We have good reasons for wanting to allow nonrigid terms in our language, and yet the rules we need for **Q3** are quite complex, unless we move to a language with a primitive intensional predicate that expresses rigidity. On the other hand, systems with local variables, like **Q3L**, have limited applications. One account of our difficulties, as we explained earlier, is that our terms can be assigned any intension, while the domain(s) of quantification contain only constant intensions. Perhaps allowing nonrigid intensions in our *domain* might result in a better match between the quantifiers and the terms, and so yield simpler rules.

Though it may seem philosophically dangerous to quantify over individual concepts, there are intuitions concerning tense and modality that support this choice. For example, imagine that our possible worlds are now states of the universe at a given time. The extension of a term at a given time will turn out to be a temporal slice of some thing, ‘frozen’ as it is at that instant. Notice that things, since they change, cannot be identified with term extensions. Instead, things are world-lines, or functions from times into time slices, and so they correspond to term intensions or individual concepts. Since our ontology takes things, not their slices as ontologically basic, it is only natural to quantify over term intensions in temporal logic. Our reluctance to quantify over individual concepts may be an accident of nomenclature. The so called ‘objects’ of a temporal semantics are not the familiar things of our world, while the formal entities that do correspond to things are misleadingly called ‘individual concepts’.

1.3.1. *Fixed Domains: The System QC.*

Let us now formulate what we will call the conceptual interpretation of the quantifier. A *conceptual model* (or **QC-model**) is a sequence $\langle W, R, D, \mathbf{QC}, a \rangle$

where \mathbf{QC} is the set of functions from W into D . The truth clause for the quantifier reads as follows:

(\mathbf{QC}) $a(\forall xA)(w)$ is T iff for every f in \mathbf{QC} , $a(f/x)(A)(w)$ is T .

Here ' $a(f/x)$ ' represents the assignment function identical to a except that the intension of x on $a(f/x)$ is function f .

Although the conceptual interpretation is designed to satisfy reasonable intuitions, there are a number of problems with it. One formal difficulty is that no (consistent) system is complete for this semantics. Whenever we interpret the domain of any quantifier as a set of all functions, we run the risk that the language will have the expressive power of second-order arithmetic, with the result that Gödel's Theorem applies. As we will show in Section 3, that is exactly what happens with \mathbf{QC} .

There are also intuitive difficulties. First, notice that $\exists x \Box x = t$ is \mathbf{QC} -valid, and yet we have given an intuitive counterexample to it in Section 1.2.2.1. We do now want to say that there is something which is necessarily the author of 'Counterpart Theory', because no one thing is the author of that paper in all possible worlds. However, on the conceptual interpretation, $\exists x \Box x = t$ is true as long as we can find some term intension which matches that of t in all possible worlds, and the term intension of t so qualifies. This shows that the conceptual interpretation differs from our ordinary reading of the quantifier. Another \mathbf{QC} -valid sentence which may tantalise some readers is $\exists x \Box \exists yy = x$, which claims that there is something (God?) which necessarily exists. However the \mathbf{QC} -validity of this sentence will do little to satisfy those who still search for an ontological argument for the existence of God. Any term intension will do to satisfy $\Box \exists yy = x$, simply because any term intension has the property that there is a term intension (namely itself) which agrees with it in accessible worlds.

1.3.2. *World-relative Domains: The System $\mathbf{Q2}$.*

The reader may think that we can repair these problems by introducing world-relative domains. Let us investigate the situation, then, when a $\mathbf{Q2}$ -model is a sequence $\langle W, R, D, \mathbf{Q2}, a \rangle$, where $\mathbf{Q2}$ is a function that assigns a domain $D(w)$ to each world w . The quantifier truth clause now reads as follows.

($\mathbf{Q2}$) $a(\forall xA)(w)$ is T iff for every function $f : W \rightarrow D$,
if $f(w) \in D(w)$, $a(f/x)(A)(w)$ is T .

Unfortunately, the problems we mentioned still remain. First, the incompleteness result still applies to the new semantics. Second, although both $\exists x \Box x = t$ and $\exists x \Box \exists yy = x$ are no longer valid, they still do not receive their intuitive interpretations. For example, $\exists x \Box \exists yy = x$ will turn out to be true on every model where the domains of the worlds all contain at least

one object. In that case, any function that picks a member of $D(w)$ for each world w will satisfy $\Box\exists yy = x$, and so verify $\exists x\Box\exists yy = x$.

1.4 *The Substantial Interpretation*

As we showed in the last section, the conceptual interpretation of the quantifiers does not match the interpretation which we give to quantifier expressions in ordinary language. The sentence $\exists x\Box\exists yy = x$, which we interpret as making the very strong claim that some thing must exist in every possible world, is valid on the conceptual interpretation as long as no possible world has an empty domain. The difference between our intuitive understanding of $\exists x\Box\exists yy = x$, and the conceptual interpretation is that the existence of a term intension that (say) picks out David Lewis in this world, a rock in another, a blade of grass in another, and so on, counts to verify $\exists x\Box\exists yy = x$. On the other hand, our intuitions demand that any term intension that verifies $\exists x\Box\exists yy = x$ must be coherent in some sense; our concept of a thing brings with it some notion of what it would be like in other worlds. Only certain collections of objects, (and certainly not a collection consisting of David Lewis, a rock, a blade of grass, etc.) could count as the manifestations of a thing, and so only these collections should count to verify $\exists x\Box\exists yy = x$.

In order to do justice to these intuitions, we must restrict the domain of quantification to the term intensions that reflect ‘the way things are’ across possible worlds. Thomason [1969] suggests that the domain should contain only constant functions. The idea is that for $\exists x\Box\exists yy = x$ to be true there must be one thing, identical across possible worlds, which exists in each one. This proposal is simply **Q3**, the objectual interpretation with non-rigid terms. We have already discussed some of the formal difficulties with this option in Section 1.2.2. There are also intuitive objections similar to the ones which we used in arguing against systems with rigid terms. First, Thomason’s account of substances is incompatible with counterpart theory, for on that view, the domains of the possible worlds are disjoint, and so there cannot be any constant term intensions to fill the domain of the quantifier. Second, in temporal logic, where objects are time slices, we do not want a thing to consist of the same time slice across different times. The slices of a thing picked out at different times may be quite different, but the world line composed of the slices still represents one unified thing.

1.4.1. The System **QS**.

If we are to accommodate a variety of conceptions about what things are like, we should not assume that they are the constant term intensions (**Q3**), nor that they are all the term intensions (**Q2**). To be completely general, we introduce a set of term intensions for each world, to serve as its domain

of quantification, and we will make no stipulations about what these sets contain. Let us now give a formal account of this approach.

A *world-relative substantial model* (or **QS-model**) is a sequence $\langle W, R, D, \mathbf{QS}, a \rangle$, where **QS** is a function that assigns to each world w a set $S(w)$ of functions from W into D . (We call $S(w)$ the set of substances for world w .) The truth clause for the quantifier reads as follows:

$$(\mathbf{QS}) \quad a(\forall xA)(w) \text{ is } T \quad \text{iff} \quad \text{for every member } f \text{ of } S(w), \\ a(f/x)(A)(w) \text{ is } T.$$

It is not difficult to see that $\exists x \Box \exists y y = x$ is not valid on this semantics, for it would only be true in world w if there were a substance f in $S(w')$ in every world w' accessible from w .

Complete systems for **QS** can be constructed as long as we are willing to introduce the intensional predicate constant E to represent which functions count as substances in each possible world. An adequate system for this semantics very often results from adding the rules of **MFL**, and the rules **ID** for (intensional) identity to the underlying modal logic. As we will explain in Section 2.2.4, more general quantifier rules may be needed for weaker modal logics.

We should note an important restriction on the rule of substitution of identities in **QS**. The constant E is an intensional predicate, and this means that substitution of term identities does not hold in its term position. When we formulate the rule of substitution for identities, we must make it clear that we do not consider Et to be an atomic sentence, for otherwise we would be able to deduce Et' from $t = t'$ and Et .

1.4.2. Fully Intensional Predicates: The System **B1**.

During our discussion of **Q3**, we pointed out that one way to simplify the instantiation rule is to introduce an intensional predicate E to the language. A *predicate is intensional* when its extension at a world w contains term intensions, and not objects as we ordinarily expect. To be more careful, the *extension of an n -ary intensional predicate letter* at a world is a set of n -length sequences of term intensions.

Bressan [1973] presents a beautifully general modal logic, with descriptions and quantifiers for all types, which assumes that predicate letters are intensional in this sense. Clearly, such a strong language cannot be axiomatised. However, Parks [1976] has axiomatised the first-order fragment **B1** of Bressan's system, using the substantial interpretation of the quantifier. **B1** uses **S5** as its modal foundation, and a fixed domain of substances. For this reason **B1** validates classical quantifier rules and the Barcan Formula. However, more general languages with weaker modalities and world-relative domains of substances can be constructed using Bressan's more general treatment of predicates. In fact, we can add such predicate letters to **QS** without causing any major complications. All we need to do is adjust the

rule of substitution of identities for those predicate letters so that substitution of one term for another is not allowed unless we already have a sentence which informs us that their intensions (not just their extensions at a given world) are the same. In weaker modal logics, this requires that we introduce a symbol for strong identity, interpreted so that a strong identity is true just in case the flanking terms have the same intensions. Once this symbol is available, we simply adopt a rule of substitution of strong identities for term positions of the intensional predicate letters.

2 COMPLETENESS IN QUANTIFIED INTENSIONAL LOGIC

2.1 *Why Completeness is Hard to Prove in Quantified Modal Logic*

Completeness proofs in QML are quite a bit harder than completeness proofs for propositional modal logic or first-order logic. One reason that proofs are difficult is that sometimes there are none to find, as is the case of the conceptual interpretation **Q2**. Even when a system is complete, the proof may be elusive, and difficult to formulate in a simple way. Another problem is lack of generality: a proof strategy may only work when the underlying modal logic is fairly strong (for example, as strong as **S4**), or when *ad hoc* conditions are placed on the models.

One of the best ways to understand the methods used in completeness proofs for QML is to locate the main difficulty which arises if we simply try to ‘paste together’ proofs for quantificational logic and propositional modal logic. In order to uncover the problem, let us review the crucial steps in the completeness proofs in each kind of logic.

2.1.1. *Completeness Proofs for Propositional Modal Logics*

The most powerful method for proving completeness of a propositional modal logic S is to use maximally consistent sets. Completeness follows if we can show that any S -consistent set is S -satisfiable. (A set is S -consistent iff there is no proof of a contradiction from the sentences in that set.) We begin by extending a given S -consistent set H to a maximally consistent set r (for real world) by Lindenbaum’s Lemma. Then we build what we will call the *standard model* $\langle W, R, a \rangle$ for S . The set W of possible world of the model is taken to be the set of all maximally consistent sets of S , (on occasion, W contains just some of the maximally consistent sets related in some way to r). The relation R (of accessibility) is usually defined so that wRw' iff if $\Box A \in w$, then $A \in w'$. Finally, the assignment function a is defined for propositional variables p so that $a(p)(w)$ is T iff $p \in w$. The central lemma (TL) (for Truth Lemma) in the proof shows that membership in w and truth in w on the standard model amount to the same thing.

(TL) $a(A)(w)$ is T iff $A \in w$.

Once (TL) is shown, it follows that all members of H are true at r on the standard model. We can also prove that $\langle W, R \rangle \in R(S)$ (the set of Kripke frames that corresponds to S), and so the standard model S -satisfies H .

The proof of (TL) is an induction on the construction of A , and the only really interesting case is when A has the shape $\Box B$. (The case for propositional variables is trivial given the definition of the standard model, and cases for \neg and \rightarrow simply depend on corresponding properties of maximally consistent sets w : $\neg B \in w$ iff $B \notin w$, and $B \rightarrow C \in w$ iff either $B \notin w$ or $C \in w$.) The proof of the case for \Box takes the following form.

$$\begin{aligned} a(\Box A)(w) \text{ is } T & \text{ iff } \text{if } wRw' \text{ then } a(A)(w') \text{ is } T \\ (1) & \text{ iff } \text{if } wRw' \text{ then } A \in w' \\ (2) & \text{ iff } \Box A \in w. \end{aligned}$$

The only difficult part is to show the equivalence of (1) and (2). The inference from (2) to (1) is a simple consequence of the way we defined R . In order to show that (1) implies (2), we show $(\neg\Box)$ instead.

$(\neg\Box)$ if $\Box B \notin w$, then there is a maximally consistent set w' such that wRw' and $B \notin w'$.

The proof of $(\neg\Box)$ makes a second use of the Lindenbaum Lemma. Given that $\Box B \notin w$, we show the consistency of the set $w^* = \{A : \Box A \in w\} \cup \{\neg B\}$. Then we use the Lindenbaum Lemma to extend w^* to a maximally consistent set w' . The set w' is such that wRw' because for each sentence $\Box A$ in w , $A \in w'$; it does not contain B since it is consistent and contains $\neg B$.

2.1.2. Completeness of First-order Logic

In this section we will give a quick review of a completeness proof for PL, first-order logic with identity. Again we show that any PL-consistent set is PL-satisfiable by first extending H to a maximally consistent set r , written in language L . We then construct a model $\langle D, a \rangle$ from r as follows. The assignment function a is defined so that the extension $a(t)$ of t is $\{t' : t = t' \in r\}$, the equivalence class of terms ruled identical in r . The domain D contains $a(t)$ for each term t . The assignment function a is defined for i -ary predicate letters F so that $\langle d_1, \dots, d_i \rangle$ is a member of $a(F)$ just in case $Ft_1, \dots, t_i \in r$ and $a(t_j)$ is d_j for each of the t_j of t_1, \dots, t_i .

Given the presence of principles of identity, it is not difficult to show that (TL) holds for atomic sentences on this model. In order to establish (TL) for all sentences, we must be sure that the set r meets one further condition concerning the quantifier, namely $(\forall x)$.

$(\forall x)$ $a(\forall xPx)$ is T iff $\forall xPx \in r$.

The proof of $(\forall x)$ will be ensured if we can show that r is omega-complete (OC).

- (OC) If $r \vdash Pt$, for every term t of L , then
 $r \vdash \forall xPx$, for any variable x .

(Here we write ' $r \vdash A$ ' for ' A is provable from the set of hypotheses r '.) Notice that (OC) is equivalent to (OC').

- (OC') If $r \cup \{\neg \forall xPx\}$ is consistent, then
 for some term t of L , $r \cup \{\neg Pt\}$ is consistent.

There are maximally consistent sets that are not omega-complete, so when we extend H to r using the Lindenbaum procedure, we must take special steps to guarantee (OC). Remember that the Lindenbaum method for extending a consistent set to a maximally consistent one begins by ordering the wffs. A series of sets $M_0 = H, M_1, \dots$, is then formed by letting M_{i+1} be the result of adding the $i + 1$ th wff to M_i , iff doing so would leave M_{i+1} consistent. (Otherwise M_{i+1} is M_i .) The maximally consistent set desired is the union of all the M_i . To ensure a set is omega-complete during this construction, we do the following. If M_i is the i th set formed in that construction, and $\neg \forall xPx$ is the $i + 1$ th sentence in our ordering of all the well-formed formulas, and if adding $\neg \forall xPx$ to M_i would yield a consistent set, then we form M_{i+1} from M_i by adding both $\neg \forall xPx$, and a sentence of the form $\neg Pt$, where t is a term that is new to $\neg \forall xPx$ and M_i . It is not too hard to see that adding this second sentence to M_{i+1} cannot cause M_{i+1} to become inconsistent, as long as M_i plus $\neg \forall xPx$ was already consistent as we have assumed. (The reason is that if $M_{i+1} = M_i \cup \{\neg \forall xPx, \neg Pt\}$ were inconsistent, then $M_i \cup \{\neg \forall xPx\} \vdash Pt$. Since t is foreign to both M_i and $\neg \forall xPx$, it follows by the rule of Universal Generalisation that $M_i \cup \{\neg \forall xPx\} \vdash \forall xPx$, which entails that $M_i \cup \{\neg \forall xPx\}$ is inconsistent, contrary to our assumption.) We can also see from the second formulation (OC') of omega-completeness that the result of the construction is omega-complete, and so a saturated set. (A saturated set is a maximally consistent set that is omega-complete.)

Now suppose we use this construction to produce a saturated extension r of H . As a result, we can show that $(\forall x)$ holds in the model constructed from r by the following reasoning.

- | | | | |
|-----|-------------------------|-----|--|
| | $a(\forall xPx)$ is T | iff | for all d in D , $a(d/x)(Px)$ is T |
| (1) | | iff | for all terms t , $a(a(t)/x)(Px)$ is T |
| (2) | | iff | for all terms t , $a(Pt)$ is T |
| (3) | | iff | for all terms t , $Pt \in w$ |
| (4) | | iff | $\forall xPx \in w$. |

The equivalence between (1) and (2) is proven by a straightforward induction on the length of Px . The equivalence of (2) and (3) is the result of the hypothesis of the induction; (3) entails (4) because r is omega-complete; and (4) entails (3) because of the rule of Universal Instantiation.

Now that we have finished the proof of the case for $\forall x$, we have a proof of (TL). It follows that the PL-model we have defined satisfies all the sentences

of r and, hence, all sentences of our original set H . We conclude that any PL-consistent set is PL-satisfiable.

2.1.3. *The Difficulties in Quantified Modal Logics*

Notice that the method we described for constructing a saturated set for first-order logic requires that we have an infinite set of terms of L which are foreign to H . Since we may have infinitely many sentences $\neg\forall xPx$ to add, we need infinitely many ‘instances’ $\neg Pt$ where t is new to the construction. As a result, the set w which we constructed using this method, contains an infinite set of terms of L which did not appear in H .

Now let us imagine that we hope to prove completeness of a modal logic Q , which adds principles of first-order logic to the propositional modal logic S . We begin with an Q -consistent set H which we hope to show is Q -satisfiable by extending H to a saturated set r written in language L . We then hope to construct the standard model, which will make all sentences of H true at r . Difficulties arise when we try to prove (TL), for there is a conflict between what we need to ensure $(\forall x)$ and (\Box) together. Condition $(\forall x)$ demands that the set W of possible worlds be the set of saturated sets in language L , for the terms of L (actually their equivalence classes) determine the domain of the quantification of our model. On the other hand, the proof of condition (\Box) requires the following. From a given possible world w which contains $\neg\Box B$, we must be able to construct a saturated set in language L which is an extension of $w^* = \{A : \Box A \in w\} \cup \{\neg B\}$. The problem is that in order to extend w^* to a saturated set in L , we must find an infinite set of terms of L that do not appear in w^* . However, the world w contains $\Box(Pt \rightarrow Pt)$ for each term t of L , with the result that all formulas $Pt \rightarrow Pt$ appear in w^* . So there are no terms of L foreign to w^* . If we attempt to remedy the problem at this point by constructing a world w' from W^* in a larger language L' , then we find ourselves in a vicious circle. Now we must prove property $(\forall x)$ for L' instead of L . This forces us to define W as the set of all saturated sets in language L' , so that when we want to extend w^* to a saturated set, we must find infinitely many terms of L' foreign to w^* . However, w is now a saturated set in language L' , and contains $\Box(Pt \rightarrow Pt)$ for all terms t of L' . Again, we have no guarantee that there are any terms of L' which do not appear in w^* .

2.2 *Strategies for Quantified Modal Logic Completeness Proofs*

In this section, we will illustrate four different strategies for obtaining completeness proofs in QML. Each of them has its strengths and weaknesses. Ideally, we would like to find a completely general completeness proof. The proof would demonstrate completeness of the most general semantics we have considered, namely **QS**. The proofs for all less general systems would

then fall out of the general proof just as proofs for the stronger propositional modal logics result from the completeness proof for **K**. This would help clarify and unify quantified modal logic. The strategy we present in Section 2.2.4 comes closest to providing such a general proof. However any such method will face some limitations for the reasons discussed at the end of Section 2.2.1.

2.2.1. Strategy 1: Extend w^ to a saturated set without using any new terms (completeness of **Q1**)*

The completeness proof for **Q1** given by Thomason [1970] is worth reviewing because it illustrates an important strategy for overcoming the problem which we outlined in Section 2.1.3. Remember our difficulty was that we needed a way to extend a consistent set w^* to a saturated one, but we did not have an infinite set of terms missing from w^* in order to carry out the construction. The system **Q1** uses fixed domains, the objectual interpretation, and rigid terms. It verifies classical quantifier principles and the Barcan Formula. When these are present, it turns out that w^* is already omega-complete in the case of most modal logics. Since any consistent omega-complete set can be extended to a saturated set in the same language [Henkin, 1949], we can extend w^* to a saturated set without needing any extra terms.

The details of this reasoning are given in the following lemmas.

LEMMA 1. *If w is omega-complete, then so is $w \cup f$, provided f is finite.*

Proof. Suppose that w is omega-complete. To show that $w \cup f$ is also omega-complete, let us assume that $w \cup f \vdash Pt$ for all terms t . It follows that $w \vdash \wedge f \rightarrow Pt$ for all terms t , where $\wedge f$ is the conjunction of the members of f . Since w is omega-complete, it follows that $w \vdash \forall x(\wedge f \rightarrow Px)$ for any choice of variable x we like. If we choose a variable x foreign to $\wedge f$, it follows that $w \vdash \wedge f \rightarrow \forall xPx$, and so $w \cup f \vdash \forall xPx$. By principles of quantificational logic, we can replace the variable x of $\forall xPx$ for any other variable. It follows, then, that whenever $w \cup f \vdash Pt$ for all terms t , then $w \cup f \vdash \forall xPx$, and so $w \cup f$ is omega-complete. ■

LEMMA 2. *Any consistent omega-complete set w can be extended to a saturated set written in the same language.*

Proof. We construct a saturated extension of w using a variant of the method described in Section 2.1.2. Suppose that the set M_i plus $\neg\forall xPx$ is consistent, so that we are to form M_{i+1} by adding $\neg\forall xPx$ and an instance $\neg Pt$ to M_i . Ordinarily, we would choose a term t foreign to both M_i and $\neg\forall xPx$ in order to ensure that adding $\neg Pt$ will not cause M_{i+1} to become

inconsistent. In this case, however, we must use a term t which may already appear in w . When w is omega-complete as we have assumed, it follows by Lemma 1 that M_i is omega-complete as well. (M_i is formed by adding only finitely many sentences to w .) Since $M_i \cup \{\neg\forall xPx\}$ is consistent, it follows by formulation (OC') of omega-completeness that $M_i \cup \{\neg Pt\}$ is consistent for some term t of L . So $\neg Pt$ can be consistently added to M_i for this choice of t , and since $\neg Pt$ entails $\neg\forall xPx$, the result of adding both these sentences to M_i remains consistent. Once we ensure that instances $\neg Pt$ are consistently added in this way, it is a simple matter to verify that the union of the M_i is a saturated extension of w . ■

LEMMA 3. *If w is a saturated set which contains $\neg\Box B$, then $w^* = \{A : \Box A \in w\} \cup \{\neg B\}$ is consistent and omega-complete.*

Proof. We can show that w^* is consistent just as we do in propositional modal logic. By Lemma 1, w^* is omega-complete if $\{A : \Box A \in w\}$ is. Assume now that $\{A : \Box A \in w\} \vdash Pt$ for every term t . By principles of the modal logic K , $w \vdash \Box Pt$ for each term t , and since w is omega-complete, it follows that $w \vdash \forall x\Box Px$. By the Barcan Formula, it follows that $w \vdash \Box\forall xPx$. Since w is maximal, $\Box\forall xPx \in w$, and so $\forall xPx \in \{A : \Box A \in w\}$. It follows that $\{A : \Box A \in w\} \vdash \forall xPx$. ■

LEMMA 4. *If w is a saturated set that contains $\neg\Box B$ then $w^* = \{A : \Box A \in w\} \cup \{\neg B\}$ can be extended to a saturated set written in the same language.*

Proof. By Lemma 3, w^* is consistent and omega-complete. By Lemma 2, it can be extended to a saturated set in the same language. ■

Now let us assume that the system **Q1** results from adding rules of classical logic, rules (**ID**) for identity, and (**RT**) for rigid terms to propositional modal logic S . To show completeness, we prove, as usual, that every **Q1**-consistent set is **Q1**-satisfiable. Given a consistent set, we extend it to a saturated set r written in language L in the usual way. We then construct the standard **Q1**-model $\langle W, R, D, \mathbf{Q1}, a \rangle$ as follows. W is the set of all saturated sets that contain $t = t'$ just in case $t = t' \in r$. R is defined in the usual way. The extension $a(t)(w)$ of term t is $\{t' : t = t' \in r\}$. D is the set of all term extensions. Sequence $\langle d_1, \dots, d_i \rangle \in a(F)(w)$ iff $Ft_1, \dots, t_i \in w$ and $a(t_j)(w)$ is d_j for the d_j of d_1, \dots, d_i . For most modal logics, we may show that $\langle W, R \rangle \in R(S)$ just as we did in the completeness proof for S , and so once we prove the truth lemma (TL), we will know that the sentences of H are all true at r on this model. It will follow that H is **Q1**-satisfiable.

The interesting cases in the proof of (TL), concern \Box and $\forall x$. The proof of $(\forall x)$ can be carried out along the lines we specified in Section 2.1.2. To establish (\Box) , it is crucial to show $(\neg\Box)$.

($\neg\Box$) if $\neg\Box B \in w$, then there is a member w' of W such that wRw' and $\neg B \in w'$.

By Lemma 4, we know that we can construct a saturated extension w' of $\{A : \Box A \in w\} \cup \{\neg B\}$. We can show that this w' is a member of W if we can show that $t = t' \in w'$ iff $t = t' \in r$. Since w is a member of W , we already know that $t = t' \in w$ iff $t = t' \in r$. Notice that if $t = t' \in w$, then by (RT), $\Box(t = t') \in w$, and $t = t' \in w'$. If $t = t' \notin w$, then $\neg t = t'$ is, and so by (RT) $\Box\neg t = t' \in w$, and $\neg t = t' \in w'$. It follows that w' contains exactly the identities of r and so is a member of W . Since $\{A : \Box A \in w\}$ is a subset of w' , we know that wRw' , and so we have completed the proof of ($\neg\Box$).

Strategy 1 has important limitations. First, the method depends on using first-order logic and the Barcan Formulas, so it is not applicable to systems that give a more general account of the quantifiers. Second, the completeness result is blocked for certain underlying modal logics S . We illustrate the problem with modal logics where R is convergent.

In proving that the standard model is convergent for propositional modal logics, one assumes wRw' and wRw'' , establishes the consistency of $\{A : \Box A \in w'\} \cup \{A : \Box A \in w''\}$, and then employs the Lindenbaum Lemma to extend this set to a maximally consistent set w''' such that $w'Rw'''$ and $w''Rw'''$. In the case of a quantified modal logic, we must know that $\{A : \Box A \in w'\} \cup \{A : \Box A \in w''\}$ is omega-complete as well as consistent before Lemma 2 can be used to extend it to a saturated set. However, there is no guarantee that $\{A : \Box A \in w'\} \cup \{A : \Box A \in w''\}$ will be omega-complete. It will not be, for example, if $\{A : \Box A \in w'\}$ contains each of Pt_1, Pt_3, \dots , and $\{A : \Box A \in w''\}$ contains $\sim \forall xPx, Pt_2, Pt_4, \dots$, and t_1, t_2, \dots is a list of all terms of L. Under these circumstances $\{A : \Box A \in w'\} \cup \{A : \Box A \in w''\}$ contains $\{\sim \forall xPx, Pt_1, Pt_2, Pt_3, \dots\}$ and so is not omega-complete.

Difficulties of this kind can be expected whenever the proof that $\langle W, R \rangle \in R(S)$ for the propositional modal logic S rests on proving the existence of a consistent set, and then extending it to a maximally consistent set by the Lindenbaum Lemma. (Convergence and density are two conditions where this technique is typically used.) In this kind of case, the proof that $\langle W, R \rangle \in (S)$ may fail for the quantificational logic when a consistent set formed fails to be omega-complete.

The problem does not arise for most modal logics. Strategy 1 works to show completeness, for example, for systems whose corresponding conditions on R are preserved under subsets. (Conditions are preserved under subsets iff when the conditions hold for $\langle W, R \rangle$ they also hold for $\langle W', R' \rangle$, where W' is a subset of W and R' is R restricted to W' .) Conditions preserved under subsets include the universal conditions, i.e. conditions on R that can be expressed with universal quantifiers alone. However, for systems whose conditions are not preserved under subsets, strategy 1 does not necessarily

yield a completeness result. This failure is directly related to the fact that system **Q1-S** is not complete for a semantics with convergent R [Cresswell, 1995].

*2.2.2. Strategy 2: Build the set of possible worlds all in one construction (completeness for **Q1-S5**)*

Gallin [1975, p. 25 ff.] offers another strategy for proving completeness of **S5** systems that contain classical principles and the Barcan Formula. It is a clever technique which has applications to systems with weaker rules. Gallin avoids the complication we encountered in extending w^* to a saturated set by defining the set of worlds of his standard model so that all the worlds w are saturated and already satisfying condition $(\neg\Box\mathbf{S5})$.

$(\neg\Box\mathbf{S5})$ If $\neg\Box A \in w$, then there is a world w' such that $\neg A \in w'$.

In **S5**, this condition is sufficient for demonstrating the case of (TL) for formulas that begin with \Box .

Gallin shows how to build a whole collection W of saturated sets from a consistent set H , using a variation of the Lindenbaum construction. The sets in W are the possible worlds of the standard model. In order to coordinate the construction properly, let W be a sequence w_0, w_1, w_2, \dots of possible worlds. W is constructed from a consistent set H , using a series W_0, W_1, W_2, \dots . Each of the W_i contains a sequence w_0, w_1, w_2, \dots of consistent sets, each of which is on its way to becoming saturated as we move to larger W_j . The W_i are also arranged so that eventually, $(\neg\Box\mathbf{S5})$ is met for each formula A .

To define the W_i , we need a generalisation of the notion of consistency. We say that a sequence W of sets is consistent just in case no finite subset f of any of the sets w in W is such that $\Diamond \wedge f \vdash p \wedge \neg p$. A formula A can be consistently added to world w of sequence W just in case doing so would leave the sequence W consistent. This definition of consistency ensures not only that adding A to a world w leaves w consistent, but that adding A is also consistent with all the facts about all the other worlds.

Now we are ready to define the series W_0, W_1, W_2, \dots . We let W_0 be the sequence such that its first world w_0 is H , and all the other worlds w_1, w_2, \dots are empty. We then order the pairs $\langle i, A \rangle$ consisting of integers i and formulas A , and for each pair $\langle i, A \rangle$, we pick a term $t(i, A)$, which is foreign to H , and all sentences of previous pairs in the ordering. For each W_j , we define W_{j+1} as follows. We consider the $j+1$ th pair $\langle i, A \rangle$ in the ordering and we add A to world w_i of W_j iff H can be consistently added to w_i of W_j . (Otherwise we set W_{j+1} equal to W_j .) In case A has the shape $\neg\forall xPx$, we also add $\neg Pt$, where t is $t(i, A)$. In case A has the shape $\neg\Box A$, we also find the first empty set in the sequence W_{j+1} , and we add $\neg A$ to it. There is such an empty set in W_{j+1} , because we have only added

finitely many formulas to this point, and W_0 contained an infinite sequence of empty sets. It is also clear that adding this formula could not cause W_{j+1} to become inconsistent.

Once the W_j have been defined this way, we let W be the sequence we get by letting the i th world of W_j be the union over all the sets w_0, w_1, w_2, \dots , which were the i th worlds of W_0, W_1, W_2, \dots . It is not difficult to prove that each of the worlds of W is a saturated set that meets property $(\neg \Box \mathbf{S5})$. Notice, however, that because of the special definition Gallin uses for consistency, the demonstration that these sets are saturated requires the Barcan Formula and classical principles for the quantifiers.

Gallin claims that this proof is significantly easier than the method we presented as strategy 1. We do not agree with Gallin's taste in simplicity. However, this strategy is quite interesting, and it can be modified for use with weaker rules as [Menzel, 1991] shows.

2.2.3. Strategy 3: Allow the language to vary across possible worlds

The second strategy we are going to discuss is illustrated by a completeness proof [Garson, 1978] for **QS**, the most general semantics we have described. The same idea will be used to sketch the proof of the completeness for **QPL** along the lines of Hughes and Cresswell [1968, p. 147 ff.] and Gabbay [1976, p. 46 ff.].

2.2.3.1 Completeness of QS. In systems with world-relative domains, the Barcan Formula is not valid, and so we no longer know that $\{A : \Box A \in w\}$ is omega-complete. Notice, however, that since the domain of quantification varies from one possible world to the next, we are free to select a different language for each of the saturated sets which are in W in the standard model. When it comes time to construct a saturated set from w^* , we simply build a saturated set in a language larger than the one in which w is written.

Since **QS** is based on free logic, we have to readjust our definition of omega-completeness and, hence, our definition of saturation. An omega-complete set for free logic in language L is any set that meets condition (FOC).

(FOC) If $w \vdash Et \rightarrow Pt$ for every term t of L , then $w \vdash \forall xPx$ for any variable x .

A *free logic saturated set* for L is simply any maximally consistent set w for which (FOC) holds. It is easy to prove that a consistent set written in language L can be extended to a set which is free logic saturated for a language with infinitely many more terms than L . To provide the proof simply replace ' $Et \rightarrow Pt$ ' for ' Pt ' in the corresponding proof for first-order logic (see Section 2.1.2).

Let **QS** be the logic that results from adding the principles of **MFL** and **ID** to certain propositional modal logics S . We will explain more about which logics these are later. We will demonstrate the completeness of **QS** with respect to the set of all **QS**-models (world relative substantial models for S). See Section 1.4.1 for the definition of a **QS**-model.

As usual we assume that set H is consistent in **QS**, and we extend H to a free logic saturated set r written in a language L . At this point, however, we consider a larger language L^+ , which contains infinitely many terms which are not in L . We then define the set W of possible worlds for our *standard QS-model* $\langle W, R, D, S, a \rangle$ as the set of all free logic saturated sets written in some language L' such that there are infinitely many terms of L^+ that do not appear in L' . The idea behind this is to guarantee that whenever $w \in W$, there will be infinitely many terms foreign to $w^* = \{A : \Box A \in w\} \cup \{\neg B\}$ so that w^* can be extended to a saturated set in language L^+ . The other parts of the definition of the standard **QS**-model are straightforward. R is defined in the usual way: wRw' iff if $\Box A \in w$, then $A \in w'$. The intension $a(t)$ of a term t given by a is defined so that $a(t)(w)$ is $\{t : t = t' \in w\}$, the equivalence class of terms ruled identical in w . S is defined so that $s \in S(w)$ iff s is $a(t)$ for some term t such that $Et \in w$. The domain of possible objects D is simply the set of all term extensions in all the possible worlds. The intension $a(F)$ of an i -ary predicate letter F is given as one would expect: $\langle d_1, \dots, d_i \rangle \in a(F)(w)$ iff $Ft_1, \dots, t_i \in w$ and each of the $a(t_j)(w)$ is d_j . The intension $a(E)$ is S .

Because the members of w are free logic saturated sets written in different languages, we cannot prove the Truth Lemma (TL) for this standard model. If t does not appear in Lw , the language in which the saturated set w is written, then $a(\neg Ft)(w)$ is T , but $\neg Ft \notin w$. However, there is a weaker formulation (w TL) which will still serve our purposes.

(w TL) If A is a sentence of Lw , then $a(A)(w)$ is T iff $A \in w$.

The proof of (w TL) for cases other than \Box and $\forall x$ is straightforward. The crucial step in the case for \Box is to demonstrate $(\neg\Box)$.

($\neg\Box$) If $\Box B$ is a sentence of Lw , then if $\neg\Box B \in w$ then there is a w' in W such that wRw' and $\neg B \in w'$.

We begin the proof by assuming that $\Box B$ is a sentence of Lw , and that $\neg\Box B \in w$. We construct $w^* = \{A : \Box A \in w\} \cup \{\neg B\}$ which we show to be consistent in the usual way. Since w is a member of W , there must be an infinite set N of terms of L^+ that do not appear in w . By the definition of w^* , it is clear that none of these terms appear in w^* either. We could construct a free logic saturated set w' from w^* using these terms. However, if w' is to be a member of W , there must be an infinite set of terms of L^+ foreign to w' . In order to ensure that we do not 'use up' all the terms in our

construction of w' , we divide N into two infinite sets N_1 and N_2 . We use N_1 to extend w^* to a free logic saturated set w' , and we leave N_2 in reserve to ensure that $w' \in W$. When w' is constructed in this way, we can easily prove that wRw' , and that $\neg B \in w'$, and so we have finished the proof of $(\neg\Box)$.

We would have skipped the case for $\forall x$ if it were not for one ticklish point. Along the way, we need to show (ES).

$$(ES) \quad a(t') \in S(w) \text{ iff } Et' \in w.$$

((ES) is also needed to show the case of formulas with the shape Et .)

The proof of (ES) would seem to be trivial given our definition of $S(w)$, but it is not. The trouble comes in showing (ES) from left to right. Suppose that $a(t') \in S(w)$. Then by the definition of $S(w)$, there is a term t such that $a(t')$ is at $a(t)$ and $Et \in w$. For ordinary predicates, this would be enough to ensure that $Et' \in w$, for when $a(t)(w)$ is $a(t')(w)$, we have that $t = t' \in w$, and so can substitute t' for t . Remember, however, that E is an intensional predicate for which the rule of substitution of identities does not hold, so this reasoning will not work. We must find some other way to ensure that $Et' \in w$. Things look bad when we realise that t' may not even be in the language Lw , in which case $Et' \notin w$. Luckily, our definition of the standard model ensures that whenever $a(t)$ is $a(t')$ then t and t' are the same term. The reason is that when $t \notin Lw$, it follows that $a(t)(w) = \{t' : t = t' \in w\}$ is empty. For any pair of distinct terms t, t' we choose, we can always find a language Lw such that t is in Lw and t' is not. It follows that the only way that $a(t)$ and $a(t')$ can be identical is if t is identical to t' . We have that $Et \in w$, so we conclude that $Et' \in w$ and our proof of (ES) is finished.

Once Lemma (wTL) is established in this way, the completeness of **QS** is shown fairly easily. We have already extended the **QS**-consistent set H to a free logic saturated set r , and since there were infinitely many terms foreign to r in L^+ , it turns out that $r \in W$. By (wTL), it follows that all members of r (and so all members of H) are true at r on the standard model, and so H is **QS**-satisfiable.

Although this proof is satisfying because it shows completeness for a system with a very general treatment of the quantifiers, it does not count as the general sort of completeness proof which we desire. The reason is that the strategy does not work to establish completeness of systems that use less general treatments of the quantifiers. For example, we might hope to show the completeness of the objectual interpretation with world relative domains and rigid terms by considering the system which results from adding (RT) to **QS**. We would hope that (RT) would ensure that terms are rigid on our standard model, with the result that all members of $S(w)$ are constant functions.

However, these hopes cannot be realised using the present definition of the standard model. In order to ensure that (wTL) holds for sentences

$t = t'$, we are virtually forced into defining $a(t)(w)$ as $\{t : t = t' \in w\}$. If any term t is rigid on this model, it would follow that $a(t)(w)$ is $a(t)(w')$, and so that w and w' share exactly the same identities. Because every saturated set for L contains $t = t$ for every term t of L , it follows that w and w' must be written in languages with the same terms. However, the strategy of this completeness proof depends on allowing our languages to shift from one saturated set to the next. Using similar reasoning, we can see that it is pointless to hope for a completeness proof for systems with fixed domains using the standard model of this section.

There is another respect in which the variable language strategy lacks generality. The method does not work for all propositional modal logics S . (Garson's [1978] claim to the contrary is an error.) The reason is that when possible worlds are written in different languages, we lose an important property (\diamond) which is needed in showing that $\langle W, R \rangle$ on the standard model is in $R(S)$.

(\diamond) If wRw' and $A \in w'$, then $\diamond A \in w$.

This property fails if term t is in the language of w' , but not the language of w , and A is (say) Ft . The sentence $\diamond Ft$ cannot be in w because it is not in the language of w .

For many modal logics (for example, **D**, **M**, and **S4**), we do not need (\diamond) in order to show that $\langle W, R \rangle \in R(S)$. However, for systems like **B**, the property seems indispensable. There are tricks one can use to overcome the difficulty for individual systems, but the changing language strategy does not provide a proof that is general with respect to the underlying modal logic.

2.2.3.2 Completeness of QPL without identity. When $=$ is absent from our language, the problems we described in extending the completeness proof of **QS** to systems that use the objectual interpretation can be overcome, at least for some of the propositional modal logics. We will illustrate this by sketching the proof for **QPL** with respect to a **QPL**-semantics, where we use the objectual interpretation, world-relative domains, the nesting condition (ND), and truth value gaps. (See Section 1.2.1.2.3.2). We will be assuming that the underlying modal logic S does not require property (\diamond) for its completeness proof. Remember that the system **QPL** simply results from adding the rules of first-order logic to S . Since we are using classical principles, we define the standard model using the ordinary definition of saturation. Since identity is absent, we may simply let the extension of a term (at any world) be itself. This ensures the rigidity of the terms, and so the objectual interpretation for the domains. It is easy to arrange that domains are nested in the standard model by defining R so that wRw' iff w' contains the terms of w , and if $\Box A \in w$, then $A \in w'$. This calls for no changes in the proof of the case for \Box .

It is particularly convenient that we are allowed truth value gaps in this semantics, since we may consider each world w as defining the class of sentences defined at w . The formal neatness of truth value gaps at this point suggests that their introduction was not designed to meet philosophical intuitions, but rather to avoid formal complications in the completeness proof.

2.2.4. *Strategy 4: Redefine Saturation*

Thomason’s [1970] proof of the completeness of **Q3** is the inspiration for the next strategy we are going to present. At the risk of repetition, we will give a second completeness proof for **QS**. Once we have presented the details, we will show how to modify the proof to obtain completeness results for **Q3**, and several other systems.

Strategy 4 follows the outlines of strategy 1; however, the concept of omega-completeness is adjusted to reflect the fact that the Barcan Formula and classical principles of quantification are no longer available. As we have already pointed out, w^* is not omega-complete in logics that lack the Barcan Formula. However, w^* has a weaker property which ensures that w^* can be extended to a set that has a correspondingly weaker form of saturation, a form which nevertheless ensures a proof of the quantifier case of the Truth Lemma.

Although this strategy turns out to be quite powerful, it has the disadvantage that we must reformulate the quantificational principles in a more general, and more complex way. In order to help simplify our presentation, we will adopt a few abbreviations. We use ‘ \rightarrow ’ for strict implication, so that ‘ $A \rightarrow B$ ’ abbreviates ‘ $\Box(A \rightarrow B)$ ’. We will be working constantly with formulas that have the shape (GF), where parentheses are to be restored from right to left.

$$(GF) \quad A_1 \rightarrow A_2 \rightarrow \dots \rightarrow A_i \rightarrow B.$$

(For example, $A \rightarrow B \rightarrow C \rightarrow D$ amounts to $A \rightarrow (B \rightarrow (C \rightarrow D))$, or $A \rightarrow \Box(B \rightarrow \Box(C \rightarrow D))$.) We will use ‘ $G(B)$ ’ to represent any sentence with shape (GF), and $G(C)$ will be the sentence that results from replacing C for B in $G(B)$. Using this notation, we may now present two general rules for the quantifiers.

$$(GUI) \quad \frac{G(\forall xPx)}{G(Ex \rightarrow Pt)}$$

$$(GUG) \quad \frac{\vdash G(Ex \rightarrow Pt)}{\vdash G(\forall xPx)} \text{ where } t \text{ does not appear in } G(\forall xPx).$$

We should make clear that $G(A)$ may represent a sentence where any of the arrows (whether \rightarrow or $\rightarrow\!\!\rightarrow$) is missing in the pattern (GF). So all of the following, for example, are instances of the rule (GUI).

$$\frac{\forall xPx}{Et \rightarrow Pt} \quad \frac{A \rightarrow \forall xPx}{A \rightarrow Et \rightarrow Pt} \quad \frac{A \rightarrow\!\!\rightarrow \forall xPx}{A \rightarrow\!\!\rightarrow Et \rightarrow Pt} \quad \frac{A \rightarrow\!\!\rightarrow B \rightarrow\!\!\rightarrow \forall xPx}{A \rightarrow\!\!\rightarrow B \rightarrow\!\!\rightarrow Et \rightarrow Pt}$$

The reader can verify that (GUI) and (GUG) are **QS**-valid.

The system (GS) consists of (GUI), (GUG), (=In), (=Out), and principles for propositional modal logics S . The quantifier rules (GUI) and (GUG) appear to be very odd and cumbersome. However, GS has a simple and natural reformulation in natural deduction format. The propositional modal logic K may be formulated by introducing boxed subproofs:

Together with introduction and elimination rules for $\boxed{\quad}$:

($\boxed{\text{In}}$)

$$\frac{\boxed{\quad} \Big| \begin{array}{c} \vdots \\ A \end{array}}{\boxed{A}}$$

($\boxed{\text{Elim}}$)

$$\frac{\boxed{A} \quad \boxed{\quad} \Big| \begin{array}{c} \vdots \\ A \end{array}}{\quad}$$

(See [Konyndyk, 1986, p. 34 ff].)

When natural deduction rules are employed, GS may be reformulated using the standard free logic rules (FUI) and (FUG), with the understanding that these apply within any subproof. It is a straightforward matter to show that this natural deduction formulation is equivalent to GS.

Another feature of GS is evidence for its naturalness. One would hope to construct a quantified modal logic with *fixed* domains by adding Et as an axiom, thus ensuring that the free logic rules collapse to their classical counterparts. In QS, the addition of Et entails (CBF), but (BF) is independent, and must be added as a separate axiom. However, when Et is added to GS, both the Barcan Formula (BF) and its converse (CBF) are provable. It is pleasing that the generalised rules are symmetrical with respect to the adoption of the Barcan Formula and its converse.

The concept of omega-completeness which corresponds to the rules of GS is (GOC) (for *general omega-completeness*).

(GOC) If $w \vdash G(Et \rightarrow Pt)$ for every term t of L ,
then $w \vdash G(\forall xPx)$, for any variable x .

A *GOC set* is just a set with property (GOC), and a *set is generally saturated* (for language L) just in case it is a maximally consistent GOC set.

Our next task is to state and prove analogues of Lemmas 1–4 of Section 2.2.1 for general omega-completeness and general saturation.

LEMMA G1. *If w is GOC, then so is $w \cup f$, provided that f is finite.*

Proof. Suppose that w is GOC, and assume that for all terms t , $w \cup f \vdash G(Pt)$. It follows that $w \vdash \wedge f \rightarrow G(Pt)$. By propositional logic, this sentence is equivalent to one with the shape (GF), so we know that $w \vdash \wedge f \rightarrow G(\forall xPx)$, and hence that $w \cup f \vdash G(\forall xPx)$. ■

LEMMA G2. *Any consistent set w with property (GOC) can be extended to a generally saturated set written in the same language.*

Proof. If $\neg G(\forall xPx)$ is the candidate for addition to M_i in the Lindenbaum construction, and if $M_i \cup \{\neg G(\forall xPx)\}$ is consistent, then we add both $\neg G(\forall xPx)$ and $\neg G(Et \rightarrow Pt)$ to M_i to form M_{i+1} , for some term t which leaves M_{i+1} consistent. There is such a term because w is GOC and so, by Lemma G1, M_{i+1} is GOC. This construction preserves consistency, and results in a GOC set, and so it yields a generally saturated set. ■

LEMMA G3. *If w is a generally saturated set that contains $\neg \Box B$, then $w^* = \{A : \Box A \in w\} \cup \{\neg B\}$ is consistent and GOC.*

Proof. The consistency of w^* is proven in the standard way. To show that w^* is GOC, assume that $w^* \vdash G(Et \rightarrow Pt)$ for any term t of L . It follows that $\{A : \Box A \in w\} \vdash \neg B \rightarrow G(Et \rightarrow Pt)$. By principles of propositional modal logic **K**, $w \vdash \Box(\neg B \rightarrow G(Et \rightarrow Pt))$, and so $w \vdash \neg B \rightarrow \Box G(Et \rightarrow Pt)$ for every term t of L . Since w is GOC, $w \vdash \neg B \rightarrow \Box G(\forall xPx)$, and since w is maximal, $\neg B \rightarrow \Box G(\forall xPx) \in w$. As a result, $\neg B \rightarrow G(\forall xPx) \in \{A : \Box A \in w\}$, and so $w^* \vdash G(\forall xPx)$. ■

LEMMA G4. *If w is generally saturated and contains $\neg \Box B$, then $w^* = \{A : \Box A \in w\} \cup \{\neg B\}$ can be extended to a generally saturated set written in the same language.*

Proof. By Lemmas G2 and G3. ■

2.2.4.1 *Completeness of GS*. Now that we have proven Lemmas G1–G4, only a few details need to be mentioned to finish a completeness proof for **GS**. We begin with a **GS**-consistent set, and we extend it to a generally saturated set r written in language L . (To do so, we merely generalise the standard construction so that when $\neg G(\forall xPx)$ is added, then so is $\neg G(Et \rightarrow Pt)$, where t is new to the construction.) We define the standard **GS**-model so that W is the set of all generally saturated sets for L . Items R, D, S and a are defined in exactly the way as they were in Section 2.2.1. We may also prove the stronger truth lemma (TL) in a straightforward way. The case for \Box requires that we show that if $\neg\Box A \in w$, then there is a w' in W such that wRw' and $\neg A \in w'$, but this is easily established using Lemma G4.

To prove the case for $\forall x$ we notice first that all generally saturated sets are free logic saturated, because free logic omega-completeness (FOC) is a special case of (GOC) when $G(Et \rightarrow Pt)$ is $Et \rightarrow Pt$. So we will have no difficulty proving that $a(\forall xPx)(w)$ is T iff $\forall xPx \in w$ as long as we can show (ES).

(ES) $a(t) \in S(w)$ iff $Et \in w$.

In order to show (ES) in Section 2.2.3.1, we proved that if t and t' are distinct, then so are their intensions $a(t)$ and $a(t')$. We can show this is true of the standard **GS**-model as follows. In all the systems we are considering, the sentence $\neg t = t'$ is consistent if t and t' are distinct. So there is a generally saturated set in W that contains $\neg t = t'$, and the extensions of t and t' differ there.

This method of proving completeness has a number of advantages. Since all our sets are generally saturated in the same language, we no longer face the difficulties noted in Section 2.2.3 in showing that $\langle W, R \rangle \in R(S)$. Property (\diamond) now holds, and so the proof proceeds exactly the way it does in propositional modal logics. However, there are still modal logics for which the method does not apply. The proof is still blocked, for example, when R is convergent for reasons similar to the ones we explained at the end of Section 2.2.1. Sets we can show to be consistent which we would hope to extend to a generally saturated set by Lemma G2 need not be GOC.

Although strategy 4 does not solve the completeness problem for all underlying propositional modal logics, it can be generalised in another way. Once a completeness proof is available for **GS**, the method may be modified to obtain completeness results for extensions of **GS** that correspond to less general treatments of the terms and the quantifiers. A number of variations on this theme will be explored in the next sections.

Despite its generality, there is another problem with this method. The systems we have proven complete use the generalised quantifier rules (GUI) and (GUG). We would like to be able to show completeness for logics which use the more modest principles (FUI) and (FUG) of free logic. However, this is not always possible. Parsons [1975] has shown that (GUI) is independent

from the free logic rules in **Q3**. One reason for the sporadic nature of published completeness results is that certain systems are complete only when the generalised quantifier rules are chosen. Determining the conditions under which the generalised rules are necessary is an interesting topic for future research.

2.2.4.2 *Rigid Terms: Completeness of GQ1R*. One advantage of strategy 4 is that it can be used to obtain completeness proofs for a variety of logics that use the objectual interpretation, even if they contain identity. A simple formulation of a system **GQ1R** which is complete for the objectual interpretation results from adding the rules (RT) and (=E) to **GS** to ensure that all the terms are rigid.

$$(=E) \quad \frac{t = t'}{Et \rightarrow Et'}$$

Remember that E is an intensional predicate in **GS**, and so the rule of substitution does not apply to it. However, once the terms are rigid, substitution of identicals is valid in all contexts, and so (=E) is valid.

It is not difficult to show the completeness of **GQ1R** for the objectual interpretation with rigid terms and world relative domains. Only one change in the definition of the standard model is required, along with a simple adjustment to the proof of (TL). We begin with a consistent set H , which we extend to r , a generally saturated set in L . We then define the standard model as before, except we ensure the rigidity of all the terms by restricting W to sets that contain exactly the identities of r . We must adjust the proof of the case for \Box because we will need to know that w^* can be extended to a set that contains the same identities as r . However, this can be shown using virtually the same argument we gave in Section 2.2.1, using the fact that (RT) is provable in **GQ1R**. Because our terms are rigid, the proof of (ES) is simplified. Since substitution now holds in the term slot of E , the proof that $Et \in w$ iff $a(t) \in S(w)$ no longer requires a demonstration that the intensions of t and t' are identical only if t and t' are identical.

Since all term intensions are rigid on this standard model, and since our domains contain only term intension, we can modify the model by replacing each constant term intension in a domain $D(w)$ with its value. The result is a **Q1R**-model which satisfies r and hence, H .

2.2.4.3 *Fixed Domains: Completeness of GQ1*. It is a simple matter to verify that adding (CBF) (the converse of the Barcan Formula) to **GS** ensures that the standard model meets the nesting condition (ND).

$$(CBF) \quad \Box \forall x Px \rightarrow \forall x \Box Px.$$

$$(ND) \quad \text{If } wRw' \text{ then } D(w) \text{ is a subset of } D(w').$$

The relationship between (CBF) and (ND) can be appreciated better when it is pointed out that (BF) is equivalent (in free logic plus modal logic **K**) to $(\Box E)$.

$$(\Box E) \quad \forall x \Box Ex.$$

Objection to $(\Box E)$ prompted our interest in logics with world relative domains. It is not hard to see that any model that satisfies $(\Box E)$ meets the nesting condition.

Presence of the Barcan Formula (BF) forces the ‘converse’ condition (CND) on the standard model.

$$(\text{BF}) \quad \forall x \Box Px \rightarrow \Box \forall x Px$$

$$(\text{CND}) \quad \text{If } wRw' \text{ then } D(w') \text{ is a subset of } D(w).$$

Let us restrict the domain W of the standard model so that it contains only worlds such that $rR^i w$, where R^i is the result of composing R with itself i times, and R^0 is the identity relation. It follows from the presence of both (BF) and (CBF) that the domains of the standard model are all identical, and so can be collapsed into one. So we may use strategy 4 to give a completeness proof for a semantics with a fixed domain of the quantifier, but with a possibly wider domain for the terms.

In order to prove completeness for **GQ1**, we need only ensure that the terms are all given extensions in the domain of quantification. The standard model meets this condition when (E) is added to **GS**, and so we have an easy completeness proof of **GQ1** = **GQ1R** + (E).

$$(E) \quad Et$$

It is interesting to note that both (BF) and (CBF) are derivable as soon as (E) is added to **GS**. In free logic, the addition of Et would restore the classical quantifier rules, and so allow us to prove (CBF); but (BF) is still independent. It is pleasing that the generalised rules are symmetrical with respect to the adoption of the Barcan Formula and its converse.

2.2.4.4 Nonrigid Terms: Completeness of Q3. Something like strategy 4 was invented by Thomason to prove completeness of **Q3–S4**. The system he showed complete is necessarily based on the generalised quantifier rules. We will use strategy 4 here to prove completeness of several kinds of **Q3** logics. In our discussion of systems with the objectual interpretation and non-rigid terms (Section 1.2.2), we pointed out that quantifier rules are quite complicated unless we introduce a primitive predicate that expresses that a term intension is a constant function. We have been presuming all along that there is a primitive predicate E in our language which is interpreted so that $a(E)$ is S , the set of ‘real’ substances. So we will begin with proofs for systems with arbitrarily strong modal logic and a primitive

existence predicate. Later we will show how to modify the proof for systems as strong as **S4**, so that the inclusion of a primitive predicate is not needed.

There is a problem which arises when we allow non-rigid terms with the objectual interpretation which draws our attention to a step in the proof of (TL) which we have so far ignored. Let us look at the reasoning we will need to carry out the proof of the case for the quantifier.

- $$\begin{array}{ll}
 (1) & a(\forall xPx)(w) \text{ is } T \quad \text{iff} \quad \text{for all } d \text{ in } D(w), a(d/x)(Px)(w) \text{ is } T \\
 & \quad \text{iff} \quad \text{for all } t, \text{ if } a(t)(w) \in D(w), \\
 & \quad \quad \text{then } a(a(t)(w)/x)(Px)(w) \text{ is } T \\
 (2) & \quad \text{iff} \quad \text{for all } t, \text{ if } a(t)(w) \in D(w), \\
 & \quad \quad \text{then } a(Pt)(w) \text{ is } T \\
 & \quad \text{iff} \quad \text{for all } t, (Et \rightarrow Pt) \in w \\
 & \quad \text{iff} \quad \forall xPx \in w.
 \end{array}$$

The proof that (1) and (2) are equivalent requires the proof of (SL) (for Substitution Lemma).

$$(SL) \quad a(a(t)(w)/x)(Px)(w) \text{ is } a(Pt)(w).$$

Unfortunately, (SL) is not always true if t is non-rigid. It is false, for example, for $Pt = \Box Ft$ on the following model. The set of worlds W contains (the real) world r , and (an unreal) world u , and they are both accessible from themselves and each other. The domain D contains two objects d , for (David Lewis) and s (for Saul Kripke). The term t (read ‘the author of “Counterpart Theory” ’) has d as its extension in the real world, and s as its extension in the unreal world u . The extension of F (read ‘is author of “Counterpart Theory” ’) contains d in r , and s in u . Notice now that $a(a(t)(u)/x)(\Box Fx)(u)$ is $a(s/x)(\Box Fx)(u)$, which is false, since s is not in the extension of F in both worlds. However $a(\Box Ft)(u)$ is true because the extension of t is in the extension of F in each world. We see that (SL) fails for reasons closely related to the fact that substitution of identities fails for non-rigid terms.

We did not face this problem for systems with rigid terms, because (SL) is true when $a(t)$ is a constant function. The problem did not arise with the substantial interpretation because there the lemma we need (SSL) concerns substitution of intensions and is readily proven.

$$(SSL) \quad a(a(t)/x)(Px)(w) \text{ is } a(Pt)(w).$$

Thomason tackles the problem posed by the failure of (SL) in a direct way. He stipulates that variables are rigid designators and uses variables, not terms, to fix the domains of his standard model. The extension $a(t)(w)$ is set to $\{x : x = t \in w\}$, and the domain $D(w)$ contains the extensions of all terms t such that $Et \in w$. By adding the rules (RV), to the system, he can ensure that the standard model has rigid variables, using the methods we outlined in Section 2.2.4.2.

$$(RV) \quad \frac{x = y}{\Box x = y} \quad \frac{\neg x = y}{\Box \neg x = y} \quad \frac{x = y}{Ex \rightarrow Ey}$$

However, the use of rigid variables leads to further complications. In order to establish the case for identity in (TL), we need to know that if $a(t)(w)$ is $a(t')(w)$ then $t = t' \in w$. The identity of $a(t)(w)$ only establishes that $x = t \in w$ iff $x = t' \in w$, for all variables x . To show that $t = t' \in w$, we need to know that there is some variable y such that $y = t \in w$. This requires us to restrict the set W of possible worlds of our model to those that meet condition (V).

(V) For all w in W , and all terms t of L , there is a y such that $y = t \in w$.

In order to meet condition (V) when it comes time to extend w^* to a set in W , Thomason added the following rule to this system.

$$(G=) \quad \frac{\vdash G(\neg y = t)}{\vdash G(p \wedge \neg p)}$$

The rule (G=) ensures that we can consistently add a sentence of the form $y = t$ for each of the terms t during the construction of a saturated set, and to do so without extending the language.

The system **Q3** which we can show to be complete using this method is composed of **GS**, (RV), and (G=).

The system Thomason [1970] showed to be complete lacked the primitive existence predicate E , and was built on **S4**. In **S4**, the sentence $\exists x \Box x = t$ is true in the standard model just in case the intension of t is rigid. Also, the replacement of Et with $\exists x \Box x = t$ in the rules of free logic results in valid quantifier rules. It follows that if **S** is **S4** or stronger, we can formulate a complete system for **Q3-S** without a primitive existence predicate by replacing Et with $\exists x \Box x = t$ in the rules of **Q3-S**.

3 UNAXIOMATISABILITY OF SOME QUANTIFIED INTENSIONAL LOGICS

3.1 Introduction

Certain quantified modal languages are capable of expressing statements of arithmetic. These systems cannot be axiomatised, for if they were, they would be adequate for arithmetic, which is impossible by Gödel's Theorem. In this section we will give examples of three quantified modal logics which are incomplete for this reason. First, we review Scott's result (reported in [Kamp, 1977]) that predicate tense logic is incomplete if time is described by the reals. Next we will discuss unaxiomatisability results [Fine, 1970] for propositional modal logics with quantifiers over propositional variables.

Finally, we will show that **Q2** cannot be formalised, at least not if the underlying modal logic is **S4.3** or weaker. (This is Kripke's result reported in [Kamp, 1977].) The rest of this section contains preliminary material which we need later. A reader with a background in mathematical logic will probably want to skip to Section 3.2.

3.1.1 Languages that express arithmetic

The language **PA** (for Peano Arithmetic) contains quantifiers, =, a constant 0, and function symbols ', +, ·. A model $\langle D, a \rangle$ of **PA** consists of a non-empty domain D (of quantification), and an assignment function a that assigns to ' a unary function $a(')$ from D to D , and to both + and ·, binary functions $a(+)$ and $a(\cdot)$ from $D \times D$ to D . A model is the standard model of arithmetic iff D is the set of integers $0, 1, 2, \dots$, $a(')$ is the function that takes each integer into its successor, $a(+)$ is the addition function, and $a(\cdot)$ is multiplication.

Now suppose we have a language L which includes the symbols of **PA** and which contains a sentence SMA which is true on a model just in case it is the standard model of arithmetic. It follows that the valid sentences of L cannot be formalised. The reason is that the sentence A of arithmetic is true on the standard model just in case $SMA \rightarrow A$ is a valid sentence of L . So any axiomatisation of L would provide a way to formalise the true sentences of arithmetic, and this, Gödel showed, cannot be done.

There is no need for SMA to pick out the standard model exactly. (In fact, it cannot.) It is easy to see that the same sentences are true on any pair of isomorphic models. So L will be unaxiomatisable as long as it contains a sentence SMA which is true only on models of PA that are isomorphic to the standard model. (To avoid talking all the time of isomorphic models, we will mean by a 'standard model' any model isomorphic to the standard one.)

We do not need 0, ', + and · in the language in order to obtain this kind of incompleteness result. It is well known that constants and function symbols are eliminable in favour of corresponding predicate letters. For example, we may introduce the predicate Z for zero, and the sentence $\exists!xZx$ which ensures that the extension of Z is a singleton. (We use $\exists!xPx$ to abbreviate $\exists x(Px \wedge \forall y(Py \rightarrow x = y))$, where y is chosen new to Px .) We may then conjoin $\exists!xZx$ to SMA , and replace each sentence $P0$ of SMA involving 0, with $\forall x(Zx \rightarrow Px)$, which says the same thing. To eliminate ', we introduce a binary predicate letter N , and we add $\exists!yNxy$ to ensure that the extension of N is a unary function. We then replace axioms Px' involving ', with $\forall y(Nxy \rightarrow Py)$. By introducing ternary predicates, for + and ·, and performing the same manoeuvre, we can complete the elimination of function symbols. It follows that any language which contains first-order logic with identity and contains a sentence SMA which is true only on a

standard model is incomplete, (if it is consistent). (In the case of a language that uses predicate letters, Z, N, T, P for arithmetic, $\langle D, a \rangle$ counts as a standard model iff a is a function over these predicate letters which assigns them extensions, and $\langle D, a \rangle$ is isomorphic to another model of the same kind whose domain is the integers and which gives Z, N, T, P the extension zero, the successor function, plus, and times.)

3.2 Incompleteness of Predicate Tense Logic with Real Time

It is crucial in physics that we represent moments of time using numbers. If time is atomic, and there is a first moment, then the set of times looks like the integers of the standard model of arithmetic. We are more likely to think of time as dense, and so represent it using the rationals, or the reals.

Scott showed that if time is mathematical in any of these senses, then predicate tense logic is incomplete. (The result is reported in [Kamp, 1977].) When we assume that the Kripke frame $\langle W, R \rangle$ of any tense logic model $\langle W, R, D, a \rangle$ is such that W is the set of integers, and R the relation ‘less than’, then we can find a sentence SMA which is true only on standard models. Even when we consider frames $\langle W, R \rangle$ where W is the set of rationals or reals, the same argument can be constructed.

3.2.1 Syntax and Semantics of Predicate Tense Logic

Let us define **T1** (tense predicate logic like **Q1**) in the following way. *The syntax of T1* involves an alphabet which includes symbols of first-order logic, and two sentential operators G and H (read ‘it will always be that’ and ‘it was always the case that’). The more familiar operators F and P (read ‘it will be that’ and ‘it was the case that’) are defined by $F =_{df} \neg G \neg$, and $P =_{df} \neg H \neg$.

To formulate the semantics of **T1** let us define a **T1-model** as a sequence $\langle W, R, D, a \rangle$, where $\langle W, R \rangle$ is like the integers in that sense that W is the set consisting of $0, 1, 2, \dots$, and R is ‘less than’. The quantifier of **T1** is interpreted with a fixed domain D , so its truth clause is (**Q1**).

(**Q1**) $a(\forall x Px)(w)$ is T iff for all d in D , $a(d/x)(Px)(w)$ is T .

The truth clauses for G and H read as follows.

(G) $a(GA)(w)$ is T iff if wRw' , then $a(A)(w')$ is T .

(H) $a(HA)(w)$ is T iff if $w'Rw$, then $a(A)(w')$ is T .

For the moment, we will assume that terms are all rigid designators, so $a(t)(w)$ is $a(t)(w')$ for all w, w' in W . This restriction can be relaxed without changing the essentials of the incompleteness proof. Notice, then, that semantics for **T1** is exactly like **Q1**, except that in **T1** we have two intensional operators.

3.2.2 The Expressive Capabilities of **T1**

If we had quantifiers and predicate letters in **T1** whose domain were the set W of times, then the unaxiomatisability of **T1** would be easy to show. In that case, sentences valid in **T1** would be those that are valid on all frames $\langle W, R \rangle$ where W is the integers. We could then construct the sentence Q consisting of the axioms of (first-order) arithmetic using predicate letters Z, N, P, T . (See [Boolos and Jeffrey, 1989, p. 161] for these axioms.) Sentence Q would serve as the sentence which expresses that a model is standard.

Our problem is, however, that W is not the domain of quantification in **T1**. The quantifiers range instead, over the domain D of objects. Nevertheless, it is possible to find a sentence of **T1** that sets up a correspondence between members of W and members of D so that sentences that express properties of the domain D reflect corresponding properties in the set of worlds W . In order to show how this correspondence is brought about, let us first give a few definitions and facts concerning the things that **T1** can express.

First, we will define two operators A , and S (read ‘it is always the case that’ and ‘it is sometimes the case that’) as follows.

$$AA = A \wedge GA \wedge HA, \quad SA = A \vee FA \vee PA.$$

Since W in every model of **T1** is the set of integers, it is easy to verify the following facts about all models of **T1**.

FACT 1. AA is true at w iff A is true at every time w' in W .

FACT 2. SA is true at w iff A is true at some time w' in W .

Now let us introduce the predicate letter E (read ‘exists’). We will use the following two sentences to ensure that every member of D is in the extension of E at some time, and that the extension of E is always either a singleton or empty.

(F1) $\forall xS(Ex \wedge H\neg Ex \wedge G\neg Ex)$
(Everything exists at exactly one time.)

(F2) $A\forall x\forall y((Ex \wedge Ey) \rightarrow x = y)$
(No two things exist at the same time.)

Any model that makes both of these sentences true sets up a function from D into W , because for each member d of D , we know there is exactly one integer t_d of W at which d exists.

Now let us introduce the following abbreviation.

($<$) $x < y =_{df} S(Ex \wedge FEy)$.

The sentence $S(Ex \wedge FEy)$ is true at t for a just in case there is some time where $a(x)$ exists, and a later time where $a(y)$ exists. Since (F1) guarantees that an object exists at only one time, it follows that the pair d, d' satisfies the extension of $<$ at any time just in case the integer t_d where d exists is less than the integer $t_{d'}$ where d' exists. So $<$ sets up an ordering on D that corresponds to the relation 'less than' on the integers. Actually, $<$ does not express all the facts about 'less than' on the integers, because (F1) and (F2) do not guarantee that something exists at every time. The extension of $<$ corresponds to 'less than' restricted to WD the set of those times when objects exist. We could set up a one-one correspondence between W and D by adding the sentence $A\exists xEx$, but this will block the proof for the case of the rationals and the reals, as we will see.

3.2.3 Unaxiomatisability of **T1**

Now let us introduce an equivalence that fixes the extension of predicate N as the successor function, and guarantees that every object in the ordering set up by $<$ has a successor.

$$(F3) \quad xNy \leftrightarrow x < y \wedge \forall z((\neg z = y \wedge x < z) \rightarrow y < z),$$

$$(F4) \quad \exists y(Ey \wedge xNy).$$

If (F3) and (F4) are both true at any time t of W , then the pair $\langle d, d' \rangle$ is in the extension of N at t just in case the corresponding times $t_d, t_{d'}$ are such that $t_{d'}$ is the successor of t_d in WD (the set of times where objects exist).

We may also define Z (read 'is zero'), and guarantee that zero exists as follows.

$$(F5) \quad Zx \leftrightarrow \forall y \neg y < x$$

$$(F6) \quad \exists x(Ex \wedge Zx).$$

These two sentences ensure that there is a least member t_0 in the set WD of times at which objects exist.

Let SMA be the conjunction of (F1)–(F6) and Q^* , the result of eliminating $0, ', +$ and \cdot in favour of predicate letters Z, N, P and T in the axioms Q of first-order arithmetic. We claim that SMA expresses that a model is standard in the following sense.

LEMMA 5. *For any model $\langle W, R, D, a \rangle$ of **T1**, and any w in W , $a(SMA)(w)$ is T only if $\langle D, a(w) \rangle$ is standard.*

Here $a(w)$ is the function that gives to each predicate letter F , the extension $a(F)(w)$, that F receives on a at world w .

Proof. Let us imagine a model $\langle W, R, D, a \rangle$ that satisfies *SMA* at w . As we said, the truth of (F1) and (F2) sets up a correspondence between objects of D and a subset WD of W . (F3) ensures that a pair of objects $\langle d, d' \rangle$ is in the extension of $<$ just in case the corresponding numbers $t_d, t_{d'}$ bear the relation ‘less than’. (F4) and (F5) ensure that there is a successor for any number t_i of the series, and (F6) ensures that there is a least member t_0 in the series. It follows from this that the objects of D correspond to a sequence $w_0, w_1, w_2, w_3, \dots$ of numbers of W ordered by ‘less than’, with a first member w_0 . Furthermore, the extension of N picks out the successor function on this ordering. Given that the sentence Q is satisfied, we also know the extensions of P and T at w must be plus and times. It follows then that $\langle D, a(w) \rangle$ is a standard model of arithmetic. ■

Let us suppose that A is any sentence of arithmetic, and that A^* is the result of eliminating $0, ', +, \cdot$ in favour of predicate letters Z, N, P, T in the usual way. We may now show that **T1** is incomplete on the basis of the following theorem.

THEOREM 1. *SMA* $\rightarrow A^*$ is **T1**-valid iff A is true on the standard model of arithmetic.

Proof. (left to right) Let $\langle W, R, D, a \rangle$ be a **T1**-model such that W is the integers (rationals, reals), R is the ordering ‘less than’ on W , D is the integers, and $d \in a(E)(w)$ iff $d = w$, and $a(E)(w)$ is the empty set if w is not an integer. On this model $a(SMA)(w)$ is T , for any w in W . By the **T1**-validity of *SMA* $\rightarrow A^*$, it follows that $a(A^*)(w)$ is T . Notice that A^* contains no intensional operators, and so its value is determined by the extensions of Z, N, P, T exactly as it would be on the extensional model $\langle D, a(w) \rangle$. Since this is a standard model, A must be true on the standard model of arithmetic.

(right to left) Suppose that A is true on the standard model for arithmetic and suppose that $a(SMA)(w)$ is T at any w in W , on a model of **T1**. By Lemma 5, $\langle D, a(w) \rangle$ is standard, and so $a(A^*)(w)$ is T . We conclude that *SMA* $\rightarrow A^*$ is **T1**-valid. ■

Notice that Theorem 1 can be proved as long as we begin with any frame $\langle W, R \rangle$ which contains a substructure which is isomorphic to the integers ordered by ‘less than’. It follows that **T1** is incomplete with respect to the integers, the rationals, the reals, and virtually any other conceivable numerical account of time. It is also clear that the same argument works for logics that have world-relative domains. In this case, we are already supplied with a primitive predicate E which picks out things that exist at a given time, and the same argument can be carried out for this E .

3.3 *Incompleteness of Second-Order Propositional Modal Logics*

Fine [1970] shows that second-order propositional modal logic (**SOPML**) is incomplete when the modality is **S4.2** or less. **SOPML** is ordinary propositional modal logic, except we introduce quantifiers which bind the propositional variables. Here, we will give an incompleteness result for a somewhat different system called **SOMA** (for Second-Order Modal Arithmetic), assuming that the modality is **S4.3** or less. **SOMA** is **SOPML** supplemented with a propositional constant 0 , and connectives $'$, $+$, and \cdot , of arities 1, 2, 2 respectively. The unaxiomatisability of **SOMA** is easier to prove than it is for **SOPML**, because **SOMA** already contains the notation for arithmetic. In the case of **SOPML**, we need to show how to get the effect of the binary function symbols $+$ and \cdot . The proof of **SOMA** allows us to display the main strategy used in the proof for **SOPML**, without having to cover this less central detail. Another reason for concentrating on **SOMA** is that its relatively easy incompleteness result provides a quick proof of the incompleteness of **Q2**, which we give in Section 3.4.

3.3.1 *The Intuitions behind the Proof*

We know that a system is incomplete as long as it contains a sentence that expresses that its models contain a standard model of arithmetic. It is well known that any model of both the axioms of first-order arithmetic **Q**, and (MI) (the second-order axiom of mathematical induction) is a standard model. (See, for example [Boolos and Jeffrey, 1989, Ch. 18].)

$$(MI) \quad \forall P((P0 \wedge \forall x(Px \rightarrow Px')) \rightarrow \forall xPx).$$

Q can be expressed in first-order logic; however, (MI) requires quantification over a monadic predicate letter. So any extension of first-order logic that can achieve the effect of quantification over monadic predicates will express arithmetic, and so be incomplete.

The idea behind the incompleteness proof for **SOMA**, then, is to show that quantification over propositional variables in modal logic can be used to get the effect of both quantification over worlds and quantification over predicates of worlds. To see how this is done, think of the intensions of propositional variables as truth sets. (The truth set of a propositional variable is just the set of worlds where it is true.) So quantification over propositional variables amounts to quantification over truth sets, that is, over properties of worlds. We also need to be able to quantify over objects of W if we are to express the axioms of arithmetic. This is done in **SOMA** by finding a way to say that an intension contains a single world. Then quantification over all singleton sets of worlds amounts to quantification over the individual worlds themselves.

3.3.2 *The Expressive Resources of SOMA*

We turn now to the details involved in showing that **SOMA** can express arithmetic. To fix our later discussion, we will give the semantics for **SOMA** here. A model $\langle W, R, a \rangle$ of **SOMA** assigns to each propositional variable p a subset $a(p)$ of W , called the truth set of p . It also assigns to $'$, $+$, and \cdot , functions that take us from subsets of W into new subsets of W in the case of $'$ and from subsets of $W \times W$ to W in the case of $+$ and \cdot . Since we are proving incompleteness for **SOMA-S4.3**, we will assume that $\langle D, R \rangle$ is reflexive, transitive and connected.

The clauses for sentences with shapes A' , $A + B$, and $A \cdot B$ are as follows

$$\begin{aligned} a(A') &= a(')(a(A)) \\ a(A + B) &= a(+)(a(A), a(B)) \\ a(A \cdot B) &= a(\cdot)(a(A), a(B)) \end{aligned}$$

and the clauses for \neg , \rightarrow , and \Box are given in the usual way.

For the quantifier we have the following.

$$(\forall p) \quad w \in a(\forall p P p) \text{ iff for every subset } s \text{ of } W, w \in a(s/p)(P p)$$

Here $a(s/p)$ is the assignment just like a save that $a(s/p)(p)$ is s .

Most of the properties we can express in **SOMA** only apply to a portion of the model $\langle W, R, a \rangle$. It will turn out, however, that this is enough for our purposes. We define the future of model $\langle W, R, a \rangle$ at w , as the model $\langle Wf, Rf, af \rangle$, where Wf is $\{w' : wRw'\}$ and Rf and af are R and a restricted to Wf . The future at w , then, contains just those worlds accessible from w , and the portions of R and a which concern these worlds. For convenience, we will also call $\langle Wf, af \rangle$ the future of $\langle W, R, a \rangle$ at w , where in this case, $af(')$, $af(+)$ and $af(\cdot)$ are restricted to singleton sets of Wf . We are going to show how to construct a sentence which is true at w just in case the future $\langle Wf, af \rangle$ at w is a standard model of arithmetic.

In order to get the effect of quantification over objects of W , let us present a sentence I_p of **SOMA** whose truth at w ensures that the intension of p is a singleton in the future at w .

$$(I) \quad I_p =_{af} \Diamond p \wedge \forall q (\Box(p \rightarrow q) \vee \Box(p \rightarrow \neg q)).$$

There is an interesting intuition behind this definition. I_p says that the sentences entailed by p form a maximally consistent set, for the first conjunct says that p is consistent, and the second, that p entails any sentence or its negation. Given that worlds are maximally consistent sets, it follows that p could only be true at one world.

Let us show now that I_p actually has this intended effect. The first conjunct ensures that there is a world accessible from w where p is true, so we know that $af(p)$ contains at least one member of Wf . Notice next that

$\Box(p \rightarrow q)$ ensures that every world accessible from $w \in af(p)$ only if it is in $af(q)$, and so that $af(p)$ is a subset of $af(q)$. The effect of the second conjunct of I_p , then, is to ensure that for any subset of Wf we choose, $af(p)$ will be a subset of either it or its complement. It follows that $af(p)$ must be a singleton, for suppose there were two distinct members w, w' of $af(p)$. Then the subset s such that $w \in s$ and $w' \notin s$ would have to include all the members of $af(p)$, or its complement would. In either case, one of w, w' would have to be missing from $af(p)$.

Since we have a way to express uniqueness of an intension, we can quantify both over worlds and their properties. In order to enforce the structure of the standard model on the future of w , we will need to express properties about the relation R . The abbreviation (\leq) shows how to do this.

$$(\leq) \quad p \leq q =_{df} \Box(p \rightarrow \Diamond q)$$

It is a simple matter to verify that whenever the intensions of p and q are singletons in the future of w , then $p \leq q$ is true at w just in case $w_p R w_q$, where w_p and w_q are the worlds at which p and q are true in the future of w .

Now let us define identity in **SOMA**.

$$(=) \quad p = q =_{df} \Box(p \leftrightarrow q).$$

It is easy to see that $\Box(p \leftrightarrow q)$ is true at w , just in case $a(p)$ and $a(q)$ agree on members in Wf . So $p = q$ is true at w iff $af(p)$ is $af(q)$.

We may define ' $<$ ' from ' \leq ' in the usual way.

$$(<) \quad p < q =_{df} p \leq q \wedge \neg p = q.$$

In order to write (MI) in **SOMA**, we need a way to express that a world has a property. We know that $\Box(p \rightarrow q)$ is true at w just in case the truth set of p is a subset of the truth set of q in the future of w . So in case the intension of p is a singleton containing w_p , $\Box(p \rightarrow q)$ says that the world w_p is in the intension of q . Therefore, we will adopt the following abbreviation.

$$(is) \quad p \text{ is } q =_{df} \Box(p \rightarrow q).$$

3.3.3 Incompleteness of **SOMA**

Now we are ready to formulate arithmetic in **SOMA**. Let SMA be the conjunction of the following sentences.

1. $I0 \wedge 0$
2. $\forall p I p'$
3. $\forall p \forall q ((I p \wedge I q) \rightarrow (p' = q' \rightarrow p = q))$

4. $\forall q(\text{I}q \rightarrow \neg q < 0)$
5. $\forall p\forall q((\text{I}p \wedge \text{I}q) \rightarrow (p' = q \rightarrow (p < q \wedge \forall r((p < r \wedge \neg r = q) \rightarrow q < r)))$
6. $\forall p\forall q\text{I}(p + q)$
7. $\forall p\forall q\text{I}(p \cdot q)$
8. $\forall p(\text{I}p \rightarrow p + 0 = p)$
9. $\forall p\forall q((\text{I}p \wedge \text{I}q) \rightarrow p + q' = (p + q)')$
10. $\forall p(\text{I}p \rightarrow p \cdot 0 = p)$
11. $\forall p\forall q((\text{I}p \wedge \text{I}q) \rightarrow p \cdot q' = (p \cdot q) + p)$

(MII) $\forall p((0 \text{ is } p \wedge \forall q(\text{I}q \rightarrow (q \text{ is } p \rightarrow q' \text{ is } p)) \rightarrow \forall r(\text{I}r \rightarrow r \text{ is } p))$.

Sentences (3)–(5) establish the proper relationship between zero, the successor function and the relation Rf which is expressed by \leq . Sentences (8)–(11) are the axioms of \mathbf{Q} , with propositional quantifiers restricted to I . (MII) is our formulation of the second-order axiom of mathematical induction.

Our next task is to convince you that SMA is true at w just in case the future at w contains a standard model of arithmetic, in the sense of the following lemma.

LEMMA 6. *$a(SMA)(w)$ is T on $\langle W, D, a \rangle$ iff the future $\langle Wf, Rf, af \rangle$ of $\langle W, D, a \rangle$ at w is such that $\langle Wf, af \rangle$ is a standard model of arithmetic and $af(0)$ is a singleton containing w , and Rf is 'less than or equal to' on Wf .*

Proof. (left to right) Let a numeral be a sentence 0_i composed of the propositional constant 0 , followed by i primes ($'$). Sentences (1) and (2) of SMA guarantee that the intension of any numeral is a singleton set in the future of w . The second conjunct of (1) establishes that w is in $a(0)$, and so $af(0)$ is a singleton containing w . Now let w_i be the singleton which is in the extension of numeral 0_i . Sentence (3) guarantees that w_i is not w_j for i not equal to j , and so w_i is not w_{i+1} . (MII) ensures that every member of Wf is w_i for some numeral 0_i , and so there is a one-one mapping between numerals and Wf . By sentences (4) and (5), we know that the w_i form a sequence such that $w_0 Rf w_1, w_1 Rf w_2 \dots$, with w_0 as the least member. By the reflexivity and transitivity of Rf and (5) we may show further that i is less than or equal to j iff $w_i Rf w_j$. So Rf is 'less than or equal to'. Sentences (6) and (7) ensure that the intensions of $(p + q)$ and $(p \cdot q)$ are functions that range over singletons only. The remaining sentences (8)–(11) ensure that $af(+)$ and $af(\cdot)$ correspond to addition and multiplication. We conclude that $\langle Wf, af \rangle$ is indeed a standard model of arithmetic, and $af(0)$ is indeed a singleton containing zero.

(right to left) Suppose that $\langle Wf, Rf, af \rangle$ is the future of $\langle W, R, a \rangle$ at w , and suppose that $\langle Wf, af \rangle$ is a standard model. Suppose that $af(0)$ is a singleton containing w , and that Rf is 'less than or equal to'. Since af is standard, we know that $af(0) = \{w\}$ contains the representative of zero on this model. It follows that $wRfw'$ for every w' in W . Therefore, the future of $\langle W, R, a \rangle$ at w just is $\langle W, R, a \rangle$. Now the reader can verify that sentences (1)–(11) and (MII) are all true at w on $\langle W, R, a \rangle$, and so $a(SMA)(w)$ is T . This completes the proof of Lemma 6. ■

Now we must check that sentences of arithmetic are true just in case their translations into **SOMA** are true in the future of a given w . We define A^* for sentences A of arithmetic as the result of replacing variables and quantifiers of A with prepositional quantifiers restricted to I , and replacing identity in A with the corresponding sentence of **SOMA** according to definition (=).

LEMMA 7. *If $\langle Wf, af \rangle$ is the future of $\langle W, R, a \rangle$ at w , and $\langle Wf, af \rangle$ is a standard model of arithmetic, then A is true on the standard model iff $w \in a(A^*)$ on $\langle W, R, a \rangle$.*

Proof. The proof is by induction on the structure of A . The non-trivial cases occur when A has the shapes $\forall xPx$, and $t = s$. The case for the quantifier runs as follows.

$\forall xPx$ is true in arithmetic
iff Pn is true on the standard model for every numeral n
iff $w \in a(Pn)$ in the future of w , for every numeral n
iff $w \in a(Pq)$ in the future of w for all q such that $af(q)$ is a singleton
iff $w \in a(\forall p(Ip \rightarrow Pp))$.

The case for identity requires first that we show that the extension of any term t in the standard model of arithmetic corresponds to $af(t)$ in $\langle Wf, af \rangle$. This is easily shown by induction on the structure of t . The rest of this case proceeds as follows.

$t = s$ is true in arithmetic
iff $a'(t)$ is $a'(s)$, for the a' of the standard model
iff $af(t)$ is $af(s)$ in the future of w
iff $a(t)(w')$ is $a(s)(w')$ for w' in Wf
iff $w' \in a(t \leftrightarrow s)$ for w' in Wf
iff $w \in a(\Box t \leftrightarrow s)$

This completes the proof of Lemma 7. ■

We are now ready to prove the incompleteness of **SOMA**, using the following theorem.

THEOREM 2. *A is true on the standard model of arithmetic iff $SMA \rightarrow A^*$ is **S.3**-valid in **SOMA**.*

Proof. (left to right) Suppose that A is true on the standard model of arithmetic. Let $\langle W, R, a \rangle$ be any **S4.3**-model of **SOMA**. Let w be any world in W , and suppose that $w \in a(SMA)$. It follows by Lemma 6 that $\langle Wf, af \rangle$ is a standard model of arithmetic, where $\langle Wf, Rf, af \rangle$ is the future of $\langle W, R, a \rangle$ at w . It follows by Lemma 7 that w is in $a(A^*)$. We conclude that $(SMA \rightarrow A^*)$ is **S4.3**-valid in **SOMA**.

(right to left) Suppose that $(SMA \rightarrow A^*)$ is **S4.3**-valid in **SOMA**. Let $\langle W, R, a \rangle$ be the **SOMA** model such that W is the integers, R is the relation 'equal or less than', the intension of 0 is the singleton containing zero, and the intensions of $'$, $+$, and \cdot are the successor function, plus, and times, defined on singleton sets of members of W . $\langle W, R \rangle$ is clearly reflexive, transitive and connected, so $\langle W, R, a \rangle$ is and **S4.3**-model. By Lemma 6, $0 \in a(SMA)$, and so by the validity of $(SMA \rightarrow A^*)$, $0 \in a(A^*)$. However, the future of $\langle W, R, a \rangle$ at zero is a standard model of arithmetic, and so by Lemma 7, A is a true sentence of arithmetic. ■

Theorem 2 establishes that **SOMA** with modality of strength **S4.3** is incomplete. It follows also that **SOMA** is incomplete for all weaker logics (down to **K**). The reason is that when the following sentences of **SOMA** are true at w in a model of **SOMA**, then Rf in the future of w must be reflexive, transitive, and connected.

$$\begin{aligned} & \forall p(\Box p \rightarrow p) \\ & \forall p(\Box p \rightarrow \Box \Box p) \\ & \forall p \forall q((\Diamond p \wedge \Diamond q) \rightarrow (\Diamond(p \wedge q) \vee \Diamond(p \wedge \Diamond q) \vee \Diamond q \wedge \Diamond p)) \end{aligned}$$

So by adding these sentences to SMA , we may carry out the proof of Theorem 2 for any system weaker than **S4.3**.

3.4 Incompleteness of **Q2**

The proof of the incompleteness of **SOMA** can be used to show that **Q2** cannot be axiomatised as long as the propositional modal logic is **S4.3** or weaker. This is done by showing that there is a transformation $*$ that takes us from sentences of **SOMA** to sentences of **Q2**, so that A is valid in **SOMA** just in case A^* is valid in **Q2**. It follows that since **SOMA** can express arithmetic for modalities **S4.3** or less, then so can **Q2**.

The idea behind the transformation is to mimic propositional variables p of **SOMA**, whose intensions amount to functions from W into $\{T, F\}$, using corresponding individual variables x_p , whose intensions take us from W to D . We will arbitrarily select a term t whose extension at a world w picks out the object of D which plays the role of the truth value T for that world.

Then we will represent that p is true at world w , using the **Q2** sentence $x_p = t$.

To simplify the proof, we will assume first that **Q2*** is **Q2** with function symbols $0, ', +, \cdot$. These symbols can be eliminated later in favour of predicate letters of **Q2**. We define A^* for any sentence A of **SOMA**, as the **Q2***-sentence that results from replacing each variable p of A with a corresponding variable x_p of **Q2**, and replacing each propositional variable p with the sentence $x_p = t$. (Of course, we must be sure that the x_p and t are distinct variables.)

Let us prove the following lemma about this transformation.

LEMMA 8. *If $\langle W, R, a \rangle$ is a model of **SOMA**, and $\langle W, R, D, \mathbf{Q2}, a' \rangle$ is a model of **Q2***, and $w' \in a(p)$ iff $a'(x_p)(w') = a'(t)(w')$, for all w' in W , and $D(w')$ contains two members for all w' such that wRw' , then $w \in a(A)$ iff $a(A^*)(w)$ is T .*

Proof. The proof of Lemma 8 is straightforward induction on the structure of A . ■

Now we may show how to set up a correspondence between sentences of **SOMA** and **Q2***, according to the following theorem.

THEOREM 3. *A is valid in **SOMA** iff $\exists x \exists y \Box \neg x = y \rightarrow A^*$ is **Q2***-valid.*

Proof. (left to right) Assume that A is valid in **SOMA**, and consider a **Q2***-model $\langle W, R, D, \mathbf{Q2}, a' \rangle$ such that $\exists x \exists y \Box \neg x = y$ is true at any w in W . Then $D(w')$ contains two objects for every w' such that wRw' . Build a **SOMA** model $\langle W, R, a \rangle$ such that w' is in $a(p)$ iff $a'(x_p)(w')$ is $a(t)(w')$. We have met the conditions for Lemma 8, and so by the validity of A we conclude that $a'(A^*)(w)$ is T .

(right to left) Now assume that $\exists x \exists y \Box \neg x = y \rightarrow A^*$ is **Q2**-valid. Let $\langle W, R, a \rangle$ be any **SOMA**-model, and w any member of W . Now define a **Q2**-model $\langle W, R, D, \mathbf{Q2}, a' \rangle$ as follows. Let D contain the objects T, F , and let $D(w')$ be D for each w' in W . Let $a'(t)(w')$ be T for all w' in W , and let $a'(x_p)(w')$ be T if w' is in $a(p)$, and F otherwise. The value of $a(\exists x \exists y \Box \neg x = y)(w)$ is T , and so, by the validity of $\exists x \exists y \Box \neg x = y \rightarrow A^*$, $a(A^*)(w)$ is T . Since the conditions for Lemma 8 are met, we conclude that w is in $a(A)$. ■

Theorem 3 establishes that **Q2*** is incomplete for all modalities **S4.3** or weaker. It follows that **Q2** is also incomplete, because function symbols of sentences of **Q2*** can be eliminated for corresponding predicate letters of **Q2**. The same sort of argument can be used to show the unaxiomatisability of **QC**, where we have a single domain of quantification. In fact, the proof is easier, since we need only the sentence $\exists x \exists y \Box \neg x = y$ to ensure that the domain contains two objects.

3.5 Systems as Strong as S5

It is interesting to ask whether these results apply to **Q2** and **SOMA** for modalities as strong as **S5**. The answer is that they do not. Kripke has shown (see [Kamp, 1977]) that **Q2S5** is axiomatisable, and Fine [1970] even shows that **SOPML-S5** is decidable. The reason that the proof strategy that we have used does not work for **S5** is that our method depends on our ability to build the structure of the standard model of arithmetic within the kinds of Kripke frames with which we were supplied. In the case of **S5**, however, the frames are equivalence classes, and there is no way to develop the ordering we need to construct the standard model.

APPENDIX

List of Rules

<i>Page</i>		
269	(FUI)	$\frac{\forall xPx}{Et \rightarrow Pt}$ for any term t
269	(FUG)	$\frac{\vdash A \rightarrow (Et \rightarrow Pt)}{\vdash A \rightarrow \forall xPx}$ where t is any term not in $A \rightarrow \forall xPx$
270	(=In)	$t = t$
270	(=Out)	$\frac{t = t'}{Pt \rightarrow Pt'}$ where Pt is an atom
273	(RT)	$\frac{t = t'}{\Box t = t'} \quad \frac{\neg t = t'}{\Box \neg t = t'}$
273	(BF)	$\forall x\Box A \rightarrow \Box\forall xA$
275	(CBF)	$\Box\forall xA \rightarrow \forall x\Box A$
278	(HUI)	$\frac{\forall xPx}{(\exists x[\mathbf{i}]x = t \wedge \dots \wedge \exists x[\mathbf{k}]x = t) \rightarrow Pt}$ where i, \dots, k is a list of integers which records for each occurrence of x in Px , the number of boxes whose scope includes that occurrence.
280	(TUI)	$\frac{\forall xPx}{\exists x\Box x = t \rightarrow Pt}$
297	(GUI)	$\frac{G(\forall xPx)}{G(Et \rightarrow Pt)}$
297	(GUG)	$\frac{\vdash G(Et \rightarrow Pt)}{\vdash G(\forall xPx)}$ where t does not appear in $G(\forall xPx)$. Here $G(B)$ is any sentence with the shape $A_1 \rightarrow A_2 \neg \dots \neg A_i \neg B$ and $G(C)$ is the result of replacing C for B in $G(B)$.

Page

301	(=E)	$\frac{t = t'}{Et \rightarrow Et'}$
302	(E)	Et
303	(RV)	$\frac{x = y}{\Box x = y} \quad \frac{\neg x = y}{\Box \neg x = y} \quad \frac{x = y}{Ex \rightarrow Ey}$
304	(G=)	$\frac{\vdash G(\neg y = t)}{\vdash G(p \wedge \neg p)}$

List of Systems

- PL** = Predicate Logic, First-order Logic (without identity).
S = an arbitrarily selected propositional modal logic as strong or stronger than **K**.
- 269 **MFL** = (FUI) + (FUG) Minimal Free Logic
- 270 **ID** = (=In) + (=Out) Intensional Identity Theory
- 273 **Q1** = **S** + **PL** + **ID** + (RT) + (BF).
- 274 **Q1R** = **S** + **MFL** + **ID** + (RT).
- 275 **QK** = **S** + **PL** with no terms. The necessitation rule is restricted to apply only to closed sentences.
- 277 **QPL** = **S** + **PL**.
- 282 **Q2** cannot be axiomatised, unless modality is as strong as **S5**.
- 284 **QS** = **S** + **MFL** + **ID**.
- 284 **B1–S5** = **S** + **PL** + (BF) + **ID** + axiom of substitution for strong identities.
- 298 **GS** = **S** + (GUI) + (GUG) + **ID**.
- 301 **GQ1R** = **GS** + (RT) + (=E).
- 302 **GQ1** = **GQ1R** + (E).
- 304 **Q3** = **S** + **GS** + (RV) + (G=).
- 304 **Q3–S4** = **S4** + **GS** with $\exists x \Box x = t$ for Et + (RV) + (G=).
 (Thomason's **Q3** [1970] also contains rules for descriptions, and the axiom $\exists x \exists y x = y$ to guarantee that every domain contains at least one individual.)

List of Conditions on Models

A model has the form $\langle W, R, D, Q, a \rangle$
 $\langle W, R \rangle$ is the Kripke frame,
 D is the domain of possible objects,
 a is the assignment function, that gives terms and predicate letters their intensions over W and D ,
 Q is an item that details the nature of the quantifier domain(s).
 For free logic with primitive predicate E we have $a(E)$ is Q .

The truth value $a(A)(w)$ of formula A at world w is defined recursively by the following clauses.

- (\neg) $a(\neg A)(w)$ is T iff $a(A)(w)$ is not T ,
 - (\rightarrow) $a(A \rightarrow B)(w)$ is T iff $a(A)(w)$ is F or $a(A)(w)$ is T ,
 - (\Box) $a(\Box A)(w)$ is T iff if wRw' then $a(A)(w')$ is T
- and another clause for the quantifier which differs in different semantics.

To describe a semantics for quantifier modal logic, we give a description of Q , list any other conditions on the model and then give the truth clause for the quantifier.

273 **Q1**

A **Q1**-model has $Q = \mathbf{Q1} = D$, and meets (aRT) .
 (aRT) $a(t)(w)$ is $a(t)(w')$ for all w, w' in W ,
 $(\mathbf{Q1})$ $a(\forall xA)(w)$ is T iff for all d in $\mathbf{Q1}$, $a(d/x)(A)(w)$ is T .

274 **Q1R**

A **Q1R**-model has $Q = \mathbf{Q1R}$ a function that assigns subsets $D(w)$ to the worlds w of W , and it meets (aRT) .
 $(\mathbf{Q1R})$ $a(\forall xA)(w)$ is T iff for every d in $D(w)$, $a(d/x)(A)(w)$ is T .

277 **QPL**

A **QPL**-model is **Q1R**-model that meets (ND) . Truth values are calculated using (TG) (truth value gaps).
 (ND) If wRw' , then $D(w)$ is a subset of $D(w')$.
 (TG) If $a(t)(w) \notin D(w)$, then any sentence Pt containing t has no truth value.

277 **GK**

A **GK**-model is a **Q1R**-model. Truth values are calculated using (TG). For **GKc**, use clause ($\Box c$) for \Box . For **GKs**, use ($\Box s$).

($\Box c$) $a(\Box A)(w)$ is T iff if wRw' , then A has a value at w and $a(A)(w')$ is T .

($\Box s$) $a(\Box A)(w)$ is T iff if wRw' and A has a value at w , then $a(A)(w')$ is T .

278 **Q3**

A **Q3**-model has $Q = \mathbf{Q1R}$ = a function that assigns a domain $D(w)$ to each possible world. It need not meet condition (aRT). The quantifier clause is (**Q1R**).

280 **Q3L**

A **Q3L**-model is **Q3**-model that meets condition (L) (local terms).

(L) $a(t)(w) \in D(w)$ for all w in W , and all terms t .

281 **QC**

A **QC**-model has $Q = \mathbf{QC}$ = the set of all functions from W into D .

(**QC**) $a(\forall xA)(w)$ is T iff for every f in **QC**, $a(f/x)(A)(w)$ is T .

282 **Q2**

A **Q2**-model has $Q = \mathbf{Q2} = \mathbf{Q1R}$ = a function that assigns a domain $D(w)$ for each of the possible worlds w .

(**Q2**) $a(\forall xA)(w)$ is T iff for every function f from W into D , $a(f/x)(A)(w)$ is T .

284 **QS**

A **QS**-model has $Q = \mathbf{QS}$ = a function that assigns to each world w a subset $S(w)$ of the set **QC** of all functions from W into D .

(**QS**) $a(\forall xA)(w)$ is T iff for every member f of $S(w)$, $a(f/x)(A)(w)$ is T .

CORRESPONDENCE THEORY

1 INTRODUCTION TO THE SUBJECT

Correspondences

When possible worlds semantics arrived around 1960, one of its most charming features was the discovery of simple connections between existing intensional axioms and ordinary properties of the alternative relation among worlds. Decades of syntactic labour had produced a jungle of intensional axiomatic theories, for which a perspicuous semantic setting now became available. For instance, typical completeness theorems appeared such as the following:

A modal formula is a theorem of **S4** if and only if it is true in all *reflexive, transitive* Kripke frames.

Indeed, **S4** may also be shown to be the modal logic of the *partial orders*; which matches the most famous modal logic with perhaps the most basic type of classical relational structure. Such matchings extend to logics higher up in the **S4**-spectrum. For instance, **S4.2** with its additional axiom

$$\Diamond\Box p \rightarrow \Box\Diamond p$$

is complete with respect to those frames which are reflexive, transitive and *directed*, or *confluent*:

$$\forall xyz((Rxy \wedge Rxz) \rightarrow \exists u(Ryu \wedge Rzu))$$

Again, the latter condition is a ‘diamond property’ of classical fame.

Completeness results such as these have inspired a flourishing area of intensional *Completeness Theory*, witness the classic [Seegerberg, 1971]. It took modal logicians some time, however, to realise that there are also direct semantic equivalences involved here, having nothing to do with deduction in modal logics. Indeed, the whole present *Correspondence Theory* arose out of simple observations such as the following, made in the early seventies.

EXAMPLE 1. The *T*-axiom $\Box p \rightarrow p$ is true in a Kripke frame $\langle W, R \rangle$ if and only if *R* is reflexive.

Here, ‘true in a frame’ means true in all worlds, under all assignments to the proposition letters.

Proof. ‘ \Rightarrow ’: Consider any $w \in W$. If $\Box p \rightarrow p$ is true in $\langle W, R \rangle$, then, in particular, it is true at w under the assignment V with

$$V(p) = \{v \in W \mid R w v\}.$$

Thus, $\Box p$ will be at w true by definition — and, hence, also p : i.e. $R w v$.

‘ \Leftarrow ’: By reflexivity, truth at all R -alternatives implies actual truth. ■

EXAMPLE 2. The **S4**-axiom $\Box p \rightarrow \Box \Box p$ is equivalent to transitivity.

Proof. By an analogous argument. ■

EXAMPLE 3. The **S4.2**-axiom $\Diamond \Box p \rightarrow \Box \Diamond p$ defines directedness.

Proof. ‘ \Rightarrow ’: Consider arbitrary $w, v, u \in W$ such that $R w v, R w u$. Let the assignment V have

$$V(p) = \{s \in W \mid R v s\}.$$

Immediately, this gives truth of $\Box p$ at v . Therefore, $\Diamond \Box p$ is true at w , whence $\Box \Diamond p$ must hold as well. It follows that $\Diamond p$ is true at u ; i.e. u has some R -successor in $V(p)$ — whence v, u share a common R -successor.

‘ \Leftarrow ’: If $\Diamond \Box p$ is true at w , say because of some v with $R w v$ verifying $\Box p$, then $\Diamond p$ will be true at all R -successors of w . For, all of these share at least one successor with v , by directedness. ■

Not all correspondences are equally simple. For instance, **S4.2** has a companion logic **S4.1** obtained by enriching **S4** with the ‘McKinsey Axiom’ $\Box \Diamond p \rightarrow \Diamond \Box p$. This converse of the **S4.2** axiom turns out to be much more complex. A well-known completeness theorem says that **S4.1** axiomatises the modal theory of those Kripke frames which are reflexive, transitive as well as *atomic*:

$$\forall x \exists y (R x y \wedge \forall z (R y z \rightarrow z = y)).$$

(Notice that we need *identity* here, in addition to the predicate constant R .) We shall see later in Section 2.2 that the **S4.1** axioms together (just) manage to define the above threefold relational condition, but that the McKinsey Axiom does not define atomicity on its own (it is weaker). Indeed, this simple modal principle does not possess a first-order relational equivalent at all — a discovery made independently by several people around 1975.

Modal Formulas as Conditions on the Alternative Relation

The general picture emerging here is that of modal axioms expressing certain ‘classical’ constraints on the alternative relation in frames where they are valid. With hindsight, this observation is hardly surprising. After all, given

some valuation, the clauses of the basic Kripke truth definition amount to a *translation* from modal formulas into classical ones involving R . Thus, e.g.,

$$\begin{aligned} \Box p \rightarrow p & \text{ becomes } \forall y(Rxy \rightarrow Py) \rightarrow Px \\ \Box p \rightarrow \Box \Box p & \text{ becomes } \forall y(Rxy \rightarrow Py) \rightarrow \\ & \rightarrow \forall y(Rxy \rightarrow \forall z(Ryz \rightarrow Pz)), \end{aligned}$$

while the McKinsey Axiom $\Box \Diamond p \rightarrow \Diamond \Box p$ becomes

$$\forall y(Rxy \rightarrow \exists z(Ryz \wedge Pz)) \rightarrow \exists y(Rxy \wedge \forall z(Ryz \rightarrow Pz)).$$

Here the parameter ‘ x ’ refers to the current world of evaluation, while unary predicate constants P (Q, \dots) denote the sets of worlds where the corresponding proposition letter p (q, \dots) holds.

Let us pause, to realise how, by this simple observation alone, many established results about classical predicate logic can be transferred straightaway to modal logic. For instance, for Kripke frames plus a fixed assignment (the modal ‘models’ of Section 2.1), *Compactness* and *Löwenheim–Skolem* results are immediate. If, e.g. a set of modal formulas is finitely satisfiable in Kripke models (given suitable assignments), then its classical transcription will be finitely satisfied too. Hence, by ordinary compactness, the latter set is simultaneously satisfied in some structure $\langle W, R; P, Q, \dots \rangle$: which forms a Kripke frame cum assignment verifying the original set.

But, this perspective is not quite the one we need.

In the evaluation of modal formulas according to the above truth definition, two factors are intermingled: the relational pattern of the worlds and the particular ‘facts’, i.e. the assignment. But the latter — the particular denotations of constants P, Q, \dots — is not relevant to the role of modal formulas as relational constraints. Indeed, these may even obscure the issue. When, e.g. $V(p)$ equals W , $\Box p \rightarrow p$ holds in all worlds — but this observation is completely uninformative about the true content of this axiom (viz. reflexivity).

In order to arrive at the proper perspective, one simply abstracts from the effects of particular assignments, by means of a *universal* quantification over the unary predicates in the preceding translation. Thus, for instance,

$$\Box(p \vee q) \rightarrow (\Box p \vee \Box q)$$

now becomes

$$\forall P \forall Q (\forall y(Rxy \rightarrow (Py \vee Qy)) \rightarrow (\forall y(Rxy \rightarrow Py) \vee \forall y(Rxy \rightarrow Qy))).$$

Notice that modal formulas now get *second-order* transcriptions, as opposed to the earlier first-order ones.

The parameter ‘ x ’ has remained: the present relational conditions are still ‘local’ in some actual world. A ‘global’ condition is obtained by performing one more universal quantification, this time with respect to this world parameter. The distinction is not without importance. The local version is more suitable for the original Kripke structures $\langle W, R, w_0 \rangle$, in which some ‘actual world’ w_0 figured prominently, as well as for ‘non-normal’ modal semantics, in which certain worlds are distinguished from others. The global reading is the more common one, however, which will be predominant in the sequel.

Again, the very point of view embodied in the above translation is significant — even though some of the earlier transfer phenomena are lost. What is lost, for instance, are most useful forms of compactness, as well as the Löwenheim–Skolem property. There is no automatic guarantee through second-order logic that, if a modal formula is true in some uncountable Kripke frame (i.e. under *all* valuations) it will be true in its countable elementary subframes (again, under all valuations). Still, this very phenomenon will be used to drive a wedge between ‘essentially first-order’ and ‘essentially second-order’ modal axioms in Section 2.2. Moreover, not all is lost. The above transcriptions are very simple second-order formulas, viz. so-called Π_1^1 -sentences, with all second-order quantifiers occurring in a universal prefix in front of a first-order matrix. From classical logic, we still know a few things about Π_1^1 -sentences, that will turn out useful. (Cf. the chapters on Higher Order Logic and Algorithms in Volume 1 of this *Handbook* for background.)

One such thing is involved in the following obvious question. In the light of earlier examples of correspondence, the present second-order transcriptions are exceedingly cumbersome. Compare, e.g. for the T -axiom $\Box p \rightarrow p$,

$$\forall x Rxx \text{ with } \forall x \forall P (\forall y (Rxy \rightarrow Py) \rightarrow Px).$$

Yet it was the discovery of the former simple *first-order* equivalents that motivated the above investigation in the first place. Now for some modal formulas, the second-order complexity may be unavoidable — witness the example of McKinsey’s Axiom. But at least, there arises an obvious basic

QUERY: Which modal formulas define first-order relational conditions — and how do they manage it?

By the above perspective, classical sources provide one immediate answer. A Π_1^1 -sentence is first-order definable if and only if it is preserved under the formation of *ultraproducts*, a fundamental construction in classical model theory. Through the above transcription, the same criterion applies to modal formulas. (The technical ins and outs of this point, as well as of related ones in this introduction, are postponed until the relevant sections: Sections 2.1 and 2.2 in this case.)

Modal Correspondence Theory

The preceding query has been the starting point for a systematic study of classical definability of modal formulas, when viewed as relational principles. Now the mentioned ultraproduct characterisation is a very abstract, global one, rather removed from the actual business of finding correspondences. Also historically, it is a rather late development — and we shall therefore turn to more concrete themes, as they evolved.

At first sight, *proving* first-order definability seems a simple matter: just find an equivalent, and show that it works. Still, there is the question how much system there is to this activity. For instance, Examples 1–3 exhibited regularities in their proofs. And indeed, closer inspection reveals that reflexivity, transitivity and directedness may be obtained from the second-order transcriptions of the **S4.2**-axioms through certain *substitutions* of ‘minimal’ *definable assignments*.

The heuristics behind this method is simply this. If, e.g. $\Box p \rightarrow p$ is true at x , then the most ‘parsimonious’ way of verifying the antecedent (i.e. by having $V(p) = \{y \mid Rxy\}$) carries maximal information about the whole implication. This essentially, is why the substitution of Rxu for Pu in

$$\forall x \forall P (\forall y (Rxy \rightarrow Py) \rightarrow Px)$$

yields the equivalent formula

$$\forall x (\forall y (Rxy \rightarrow Rxy) \rightarrow Rxx).$$

By the universal validity of the antecedent, the latter may be simplified to the usual statement of reflexivity. A completely analogous line of thought produces transitivity from the transcription of $\Box p \rightarrow \Box \Box p$. Some complications arise with antecedents as in $\Diamond \Box p \rightarrow \Box \Diamond p$; but the general idea remains the same. In this way, one discovers a large recursive class of modal formulas with effectively obtainable first-order equivalents.

Nevertheless, this method of substitutions also has definite limits. Notably, it does not work for all first-order definable modal formulas — as will be proved in Section 2.2 for the case of **S4.1**. In connection with this matter, the exact *combinatorial complexity* of the set of first-order definable modal formulas is still unknown — but there are reasons for fearing that it is not even arithmetically definable (let alone, recursive or recursively enumerable).

Disproving first-order definability is a more difficult matter. Indeed, how should one go about this at all? The common pattern in all examples in the literature comes to this: find some semantic preservation property of first-order sentences, which is lacked by the modal formula under consideration. Thus, e.g. the earliest published contribution by the present author was an example showing how the McKinsey Axiom sins against the Löwenheim–

Skolem theorem. It holds in a certain uncountable Kripke frame (to be presented in Section 2.2.) without holding in any of a certain group of its countable elementary subframes. A classical example of this phenomenon occurs when Dedekind Continuity (itself a Π_1^1 -property) is added to the first-order ordering theory of the rationals. The resulting Π_1^1 -sentence has uncountable models (notably, the reals); but, it even lacks countable models altogether.

The modal examples of ‘essentially second-order’ axioms to be found in Section 2.2 will serve to delimit the range of the above method of substitutions. As so often, the McKinsey Axiom again provides an illuminating example. The above heuristics of ‘minimal verification’ typically fails for antecedents such as $\Box\Diamond p$, expressing some dependency — and first-order failure is immediate.

Besides the modal half of the story, so to speak, there also exists the opposite direction, looking from classical formulas to modal ones. Again, this inspires a basic

QUERY. Which first-order relational conditions are modally definable?

The ‘positive’ side of this matter again concerns the establishing of valid equivalences. Thus, for instance, how does one find a modal definition for such a classical favourite as *connectedness*

$$\forall xyz((Rxy \wedge Rxz) \rightarrow (Ryz \vee Rzy))?$$

This time, the heuristics consists in imagining a situation where the property fails, together with a way of ‘maximally exploiting’ this failure through modal formulas. In the above particular case, supposing that $Rxy, Rxz, \neg Ryz, \neg Rzy$, one sets $\Box p$ true at y (with p false at z) and $\Box q$ true at z (with q false at y). This has the effect of verifying the following formula at x :

$$\Diamond(\Box p \wedge \neg q) \wedge \Diamond(\Box q \wedge \neg p).$$

Now, the original property itself will correspond to the negation of this modal ‘failure description’, i.e.

$$\neg(\Diamond(\Box p \wedge \neg q) \wedge \Diamond(\Box q \wedge \neg p)).$$

By some familiar equivalence transformations, this becomes

$$\Box(\Box p \rightarrow q) \vee \Box(\Box q \rightarrow p),$$

a principle known from the literature as Geach’s Axiom.

It remains to be shown, of course, that conversely, failure of this axiom implies failure of connectedness; but this is immediate. In order to cross-check, one might also apply the earlier method of substitutions to (some

suitable transform of) the Geach Axiom: and indeed, connectedness will ensue.

The ‘negative’ side again consists of disproofs. Here as well, these turn out to possess a particular interest — as we are forced to contemplate ‘typical behaviour’ of modal formulas. A standard example is the following. Although reflexivity was modally definable, *irreflexivity* turns out intractable: $\forall x \neg Rxx$. But, failed attempts are no definite refutations. What we need is some semantic property of modal formulas, as relational conditions on Kripke frames, which is not shared by this particular first-order sentence.

At this point, the modal model theory of Section 2.1 comes in. There, one finds that the following mappings play a fundamental role in the transmission of modal truth between Kripke frames: a *p-morphism* is a function f from a frame $\langle W, R_1 \rangle$ to a frame $\langle W_2, R_2 \rangle$ which

1. preserves R_1 , and
2. ‘almost’ preserves R_2 , in the following sense:
‘If $R_2 f(w)v$, then there exists some $u \in W_1$ such that (a) $R_1 wu$ and (b) $f(u) = v$ ’.

Under different names, this notion has had a career in standard logic already, e.g. the ‘Mostowski collapse’ in set theory is of this kind.

For the purposes of the present example, it need only be recorded that subjective *p*-morphisms preserve truth of modal formulas on Kripke frames. But then, irreflexivity may be dismissed: it holds in the frame of the natural numbers with the usual order, but it fails in its *p*-morphic image (!) arising from the contraction to one single reflexive point.

This example will have given a taste of the actual field-work in this area of Correspondence Theory. There also arises the more general question, of course, whether some combination of modally valid preservation requirements manages to *characterise* all and only the modally definable first-order sentences. This is indeed the case, and an elegant result to this effect — involving *p*-morphisms as well as other basic constructions, will be proved in Section 2.4.

The preceding survey by no means exhausts the range of questions that can be investigated in Correspondence Theory — but it does convey the spirit.

Correspondence and Completeness

Three pillars of wisdom support the edifice of Modal Logic. There is the ubiquitous *Completeness Theory*, the present Correspondence, or, more generally, *Definability Theory* — and finally, the *Duality Theory* between Kripke frames and ‘modal algebras’ (cf. Section 2.3 below) has become an area of its own. Connections between the latter two will become apparent as Section

2 unfolds — in particular, the above-mentioned characterisation of modally definable first-order sentences will be obtained as a consequence of the classic Birkhoff Theorem of Universal Algebra, applied to modal algebra.

The relation between correspondence and completeness is less vital to subsequent developments. Moreover, it turns out to be rather complex — and indeed, only partially understood. Nevertheless, for those readers who are familiar with the basic notions of Completeness Theory, the following sketch of issues may serve to bring questions of correspondence closer to traditional concerns.

The early completeness theorems in modal logic were brought under one heading in [Seegerberg, 1971]: ‘modal logic \mathbf{L} is determined by a class \mathfrak{R} of Kripke frames’, i.e. \mathbf{L} axiomatises the modal theory of \mathfrak{R} (on the basis of the minimal logic \mathbf{K}).

As before, two perspectives emerge here. First, one may start with a given class \mathfrak{R} , asking for a recursive axiomatisation \mathbf{L} of its modal theory. In general, there is no guarantee for success here; but there is one helpful observation involving first-order definability.

FACT 4. If \mathfrak{R} is elementary (i.e. defined by a single first-order sentence), then its modal theory is recursively axiomatisable.

Proof. Let $\alpha = \alpha(R, =)$ define \mathfrak{R} . A modal formula φ belongs to the theory of \mathfrak{R} if and only if it holds in all frames in \mathfrak{R} . This may be restated as follows:

$$\alpha \models \forall x \forall P_1 \dots \forall P_n \tau(\varphi);$$

where $\tau(\varphi)$ is the earlier first-order translation of φ , while p_1, \dots, p_n are the proposition letters occurring in the latter formula. Now, the predicate variables P_1, \dots, P_n do not occur in the first-order sentence α , and, therefore the above implication is equivalent to $\alpha \models \forall x \tau(\varphi)$. But this is an ordinary first-order implication. So, since the latter notion is recursively axiomatisable, the same must be true for membership of the modal theory of \mathfrak{R} .

Axiomatisable, yes, but axiomatisable on the basis of the minimal modal logic \mathbf{K} ? Even this is true, choosing a suitable recursive set of axioms as in the proof of Craig’s Theorem in classical logic and noticing that \mathbf{K} contains *modus ponens* (which is all that is needed). ■

Thus, in retrospect, the earlier completeness theorems for reflexive, transitive orders (and other elementary classes) were quite predictable.

The direction from classes of frames to logics is not the current one in modal logic; being more appropriate to areas such as tense logic, where temporal structures often precede temporal theories. Usually, one already possesses a certain logic \mathbf{L} , asking for a class \mathfrak{R} of Kripke frames with respect to which it is complete. (Notice that, if *any* class \mathfrak{R} suffices, then the whole class of Kripke frames validating \mathbf{L} will.)

Nowadays, we know that not all modal logics are in fact *complete* in the above sense, contrary to earlier expectations. This is the content of the celebrated ‘modal incompleteness theorems’ in [Fine, 1974; Thomason, 1974]. But it has been hoped that, at least, all *first-order definable* axiom sets are complete. (Indeed, a defective proof to this effect has circulated.) Even this more modest expectation was frustrated in [van Benthem, 1978]:

FACT 5. The modal logic \mathbf{L} with characteristic axioms

$$\begin{aligned} \Box p &\rightarrow p \\ \Box \Diamond p &\rightarrow \Diamond \Box p \\ (\Diamond p \wedge \Box(p \rightarrow \Box p)) &\rightarrow p \end{aligned}$$

is first-order definable: its frames are just those satisfying the condition

$$\forall xy(Rxy \leftrightarrow x = y).$$

But the characteristic axiom of the modal theory of the latter class of frames, viz. $\Box p \leftrightarrow p$, is not minimally derivable from \mathbf{L} .

The relevant correspondence will be proved in Section 2.2. For the moment, it may be noticed that the third axiom defines a notion of ‘safe return’: from any R -successor of a world x , one can always return to x by following some finite R -chain of R -successors of x .

The relevant argument is highly nontrivial, far outside the range of our earlier method of substitutions. Nevertheless, even the latter has its relevance for completeness theory, as we shall see presently.

What the modal incompleteness theorems show is that the minimal modal logic \mathbf{K} is too weak to produce all modally valid inferences. But of course, there may be stronger reasonable ‘base logics’. One particular example arises from the method of substitutions. For instance, in proving the equivalence of substitution instances with more current first-order conditions, one uses an extremely natural second-order logic \mathbf{K}_2 with the following deductive apparatus:

Some first-order base complete with respect to *modus ponens*,
similar axioms for the second-order quantifiers;

with the following form of ‘first-order instantiation’ allowed for first-order formulas ψ

$$\forall x\varphi(X) \rightarrow \varphi(\psi).$$

Through the earlier second-order transcription, \mathbf{K}_2 may be used as a modal base logic.

Here is an example of some fame. In the metamathematics of arithmetical provability (cf. [Boolos, 1979] or Smoryński’s in a later volume of this *Handbook*), the following two modal axioms are basic:

$$\Box p \rightarrow \Box \Box p, \quad \Box(\Box p \rightarrow p) \rightarrow \Box p \quad (\text{‘Löb’s Axiom’}).$$

The semantic import of the latter will be established in Section 2.2: it holds in those Kripke frames whose alternative relation is transitive, while possessing a well-founded converse. Moreover, transitivity is \mathbf{K}_2 -derivable from Löb's Axiom, by the substitution of

$$Rxu \wedge \forall y(Ruy \rightarrow Rxy) \quad \text{for } Pu.$$

(The antecedent becomes universally valid, while the consequent expresses transitivity.) An advantage of \mathbf{K}_2 over \mathbf{K} ? No, around 1975, Dick de Jongh and Giovanni Sambin found a K -deduction for the first axiom from the second after all. The two deductions are related, but systematic connections between \mathbf{K} -deductions and \mathbf{K}_2 -deductions have not been explored up to date.

Nevertheless, \mathbf{K}_2 is non-conservative over \mathbf{K} in the modal realm. In [van Benthem, 1979b] we find the following incompleteness theorem.

FACT 6. The modal axiom

$$\diamond \Box \perp \vee \Box(\Box(\Box p \rightarrow p) \rightarrow p),$$

with \perp the falsum, defines the same class of Kripke frames as $\diamond \Box \perp \vee \Box \perp$. But, the latter formula is not \mathbf{K} -derivable from the former — even though it is \mathbf{K}_2 -derivable.

Again, there is a correspondence involved here. But the idea is illustrated by a simple \mathbf{K}_2 -deduction at the back of this result:

1. $\forall P(\forall y(Rxy \rightarrow (\forall z(Ryz \rightarrow Pz) \rightarrow Py)) \rightarrow Px) \quad (' \Box(\Box p \rightarrow p) \rightarrow p')$,
2. $\forall y(Rxy \rightarrow (\forall z(Ryz \rightarrow z \neq x) \rightarrow y \neq x)) \rightarrow x \neq x \quad (x \neq u \text{ for } Pu)$,
3. $\neg \forall y(Rxy \rightarrow (\forall z(Ryz \rightarrow z \neq x) \rightarrow y \neq x))$,
4. $\exists y(Rxy \wedge \forall z(Ryz \rightarrow z \neq x) \wedge y = x)$,
5. $Rxx \wedge \forall z(Rxz \rightarrow z \neq x)$
6. $x \neq x$: a contradiction (\perp).

That \mathbf{K}_2 , in its turn, must be modally incomplete (as is any proposed recursively axiomatised base logic) follows from the *general* incompleteness results in [Thomason, 1975].

First-order definability does not imply completeness. But, *when* a modal logic is both first-order definable and complete, it enjoys a very pleasant form of the latter property — viz. with respect to the underlying frame of its own *Henkin model*. ('First-order definability plus completeness imply canonicity': cf. [Fine, 1975; van Benthem, 1980].) Such *canonical* modal logics will be characterised semantically in Section 2.4: notice that many

of the familiar text book examples are of this kind. In fact, a canonical completeness proof, such as that for **S4**, often proceeds by means of first-order conditions on the Henkin model, induced by the corresponding axioms.

The relation between these familiar ‘Henkin arguments’ and the above method of substitutions is at present still rather mysterious. Sahlqvist [1975] contains many examples of parallels; but Fine [1975] presents a problem. The modal formula

$$\diamond\Box(p \vee q) \rightarrow \diamond(\Box p \vee \Box q)$$

axiomatises a canonical modal logic, without being first-order definable. Thus, we are still far from complete clarity in the area between completeness and correspondence.

Variations and Generalisations

Logical model theory may be viewed as a marriage between ontology and language (or ‘mathematics’ and ‘linguistics’). Accordingly, the semantics of propositional modal logic, our paradigm example up till now, exhibits the familiar triangle

$$\begin{array}{ccc} \text{language} & \xrightarrow{\hspace{2cm}} & \text{structures} \\ & \text{interpretation} & \end{array}$$

Or, from the above translational point of view, the components are

$$\begin{array}{ccc} \text{prima facie language} & \xrightarrow{\hspace{2cm}} & \text{representation language} \\ & \text{translation} & \end{array}$$

All these ‘degrees of freedom’ may be varied in intensional logic — and thus there appears a whole family of ‘correspondence theories’. We shall explore some examples of recognised importance in Section 3. Here, let us just think about the various possibilities and their implications.

Even within the domain of propositional modal logic, alternatives have been proposed for Kripke-type relational semantics. Jennings, Johnstone and Schotch [1980] contains the proposal to work with *ternary* alternative relations, employing the following notion of necessity:

$$\Box\varphi \text{ is true at } x \text{ if } \forall yz(Rxyz \rightarrow \varphi(y) \vee \varphi(z)).$$

Their motivation was, amongst others, to create room for ‘non-cumulation’ of necessities: the ‘Aggregation Axiom’

$$\Box p \wedge \Box q \rightarrow \Box(p \wedge q)$$

will no longer be valid. What happens to earlier correspondences in this new light? Old boundaries start shifting; e.g. $\Box p \rightarrow p$ remains first-order definable, but $\Box p \rightarrow \Box\Box p$ becomes essentially second-order on this semantics.

This is compensated for by the phenomenon of formerly unexciting principles, such as the Aggregation Axiom (which was trivially valid before) springing into unexpected bloom:

EXAMPLE 7. $\Box p \wedge \Box q \rightarrow \Box(p \wedge q)$ defines

$$\forall xyz(Rxyz \rightarrow (y = z \vee Rxyy \vee Rxxz)).$$

Proof. ‘ \Rightarrow ’: Suppose the condition fails at x, y, z . Setting

$$V(p) = W = \{z\}, V(q) = W - \{y\},$$

will then verify $\Box p, \Box q$ at x , while $\Box(p \wedge q)$ is falsified (by $Rxyz$).

‘ \Leftarrow ’: Suppose that $\Box p, \Box q$ hold at x , and consider $Rxyz$. Either $y = z$, whence y verifies both p and q (by $Rxyy$ and the truth definition), or $Rxyy$, implying the same conclusion, or $Rxxz$, in which case z verifies both p and q . So, $\Box(p \wedge q)$ holds at x . ■

As for the general theorems, forming the backbone of the subject, nothing essential changes in this ternary semantics.

This example changed both the structures and the form of the truth definition. What may not be generally realised is the variety offered even when fixing the two parameters of ‘language’ and ‘structures’. Therefore, a short digression is undertaken here.

The Kripke truth definition is not sacrosanct — other clauses would have been quite imaginable. Thus, for instance, we may make the following

OBSERVATION 8. The truth definition ‘ $\Box\varphi$ is true at x if $\forall y((Rxy \vee Ryx) \rightarrow \varphi(y))$ ’ yields as a modal base logic **KB**; i.e. the minimal logic **K** plus the Brouwer Axiom $p \rightarrow \Box\Diamond p$.

Proof. The Brouwer Axiom defines *symmetry* of the alternative relation; as may be seen by substituting $u = x$ for Pu . And indeed **KB** is complete with respect to the class of symmetric Kripke frames. Hence, any non-theorem φ of **KB** is falsified on some symmetric frame $\langle W, R \rangle$. But, on symmetric frames R coincides with the relation $\lambda xy. (Rxy \vee Ryx)$ (i.e. R united with its converse \check{R}); whence φ also fails by the new evaluation.

Conversely, if φ has a counter-example $\langle W, R \rangle$ under the new truth definition, then it has $\langle W, R \cup \check{R} \rangle$ for an ordinary symmetric counter-example; whence it is outside of **KB**. ■

Thus, there is a possible *trade-off* between truth definition and requirements on the alternative relation. The exact extent of this phenomenon remains to be investigated. Notice for example how **KB** is equally well generated by the following truth definition:

$$\Box\varphi \text{ is true at } x \text{ if } \forall y((Rxy \wedge Ryx) \rightarrow \varphi(y)).$$

The general principle behind such examples is this.

FACT 9. If $C(R)$ is any condition on R , and $\gamma(x, y)$ some formula in R , = such that

1. If $C(R)$ is satisfied, then R and $\lambda xy.\gamma(x, y)$ coincide,
2. $\lambda xy.\gamma(x, y)$ satisfies C ,

then the modal logic determined by (the Kripke frames obeying) C may also be generated without conditions through the truth definition

$$\Box\varphi \text{ is true at } x \text{ if } \forall y(\gamma(x, y) \rightarrow \varphi(y)).$$

This rather subversive shift in perspective will not be investigated in this contribution. At this point, it merely serves to remind us that not a single aspect of the semantic enterprise is immune to revision.

Leaving the realm of modal logic, of the many intensional candidates for a correspondence perspective, only a few have been explored up to date. In Section 3, some important examples are reviewed briefly, viz. *tense logic*, *conditional logic* and *intuitionistic logic*. These illustrate, in ascending order, certain difficulties which tend to make Correspondence Theory rather more difficult (often also: more exciting) in many cases. These difficulties have to do with ‘pre-conditions’ on the alternative relation (not very serious), and the phenomenon of ‘admissible assignments’ (rather more serious), to be explained in due course. Nevertheless, for instance, Intuitionistic Correspondence Theory will turn out to possess also some elegant features lacked by its modal predecessor.

A few examples, even without proof, will render the above remarks more concrete. In tense logic, the correspondence runs between temporal axioms and properties of the temporal order (‘before’, ‘earlier than’).

EXAMPLE 10 (‘Hamblin’s Axiom’). $(p \wedge Hp) \rightarrow FHp$ defines discreteness of Time:

$$\forall x \exists y > x \forall z < y (z = x \vee z < x).$$

In the logic of counterfactual conditionals, conditional inferences are related to the behaviour of the comparative similar ordering C among alternative worlds.

EXAMPLE 11 (Stalnaker’s Axiom of ‘Conditional Excluded Middle’). $(p \Rightarrow q) \vee (p \Rightarrow \neg q)$ defines linearity of alternative worlds:

$$\forall xyz (y = z \vee Cxyz \vee Cxzy).$$

Finally, in intuitionistic logic, (‘intermediate’) axioms impose constraints upon the possible growth patterns of stages of knowledge.

EXAMPLE 12 ('Weak Excluded Middle'). $\neg p \vee \neg\neg p$ defines 'local convergence' of growing stages, i.e. directedness:

$$\forall xyz((x \subseteq y \wedge x \subseteq z) \rightarrow \exists u(y \subseteq u \wedge z \subseteq u)).$$

Proofs, and further explorations are postponed until the relevant sections. At this stage, the experienced reader may predict that two nuts will be especially difficult to crack for any Correspondence Theory.

The first of these concerns the earlier tacit restriction to *propositional* logic: what happens in the predicate case? In Section 2.5 we shall see that no essential problems seem to arise — although the field remains largely unexplored.

A more formidable problem arises when the truth definition for the intensional operators itself becomes of higher-order complexity. In that case, e.g. a search for possible first-order equivalents of intensional axioms seems rather pointless. This eventuality arises when disjunction is evaluated bar-wise in Beth semantics for intuitionistic logic (i.e. $\varphi \vee \psi$ is true at x if the φ -worlds and ψ -worlds together form a barrier intersecting each branch passing through x).

The last word has not been said here, however. Philosophically, it seems a rather unsatisfactory division of semantic labour to let the truth definition absorb structural complexity (in this case: the second-order behaviour of branches). The latter should be located where it belongs, viz. in the structures themselves. And indeed, the Beth semantics admits of a two-sorted first-order reformulation in terms of nodes and paths, which generates a Correspondence Theory of the usual kind.

All this is not to say that there are no limits to the useful application of a correspondence perspective. But, these are to be found in *philosophical* relevance, rather than technical *impossibility*. One should study correspondences only as long as they serve the purpose of semantic enlightenment — which is the shedding of light upon one conceptual framework by relating it systematically to another.

2 MODALITY

In this chapter, modal correspondence theory will be surveyed against the background of modal model theory and modal algebra, whose basics are explained. (Cf. the chapter by Bull and Segerberg in this volume for the necessary background.)

2.1 Modal Model Theory

The basic structures of modal semantics are introduced: *frames*, *models* and *general frames*. These may be studied either purely classically, or

with a specifically modal purpose. In both cases, the emphasis is not upon such structures in isolation, but upon their ‘categorical context’: what are their relations with other structures, and which of these relations are truth-preserving? Thus, we will introduce the modal preservation operations of *generated subframe*, *disjoint union*, *p-morphic image* and *ultrafilter extension*. Moreover, the fundamental classical formation of *ultraproducts* will be used as well. All these notions will appear again and again in later sections.

Semantic structures. The structures used in the Kripke truth definition are *models* M , i.e. triples $\langle W, R, V \rangle$, where W is a nonempty set of *worlds*, R is a *binary alternative* relation on W , and V is a *valuation* assigning sets of worlds $V(p)$ to proposition letters p . The notion explicated then becomes

$$M \models \varphi[w] \quad : \text{‘}\varphi \text{ is true in } M \text{ at } w\text{’}.$$

In our correspondence theory we also want to see the bare bones: a *frame* F is a couple $\langle W, R \rangle$ as above, but without a valuation. There is nothing intrinsically ‘modal’ about all this, of course. Frames are just the ‘directed graphs’ of Graph Theory.

In Sections 2.3 and 2.4, a third notion of modal structure will be required as well — intermediate, in a sense between models and frames. A *general frame* F is a couple $\langle F, \mathfrak{W} \rangle$, or alternatively, a triple $\langle W, R, \mathfrak{W} \rangle$ such that $F = \langle W, R \rangle$ is a frame, and \mathfrak{W} is a set of subsets of W , closed under the formation of *complements*, *unions* and *modal projections*. Formally,

$$\begin{aligned} \text{if } X \in \mathfrak{W}, & \quad \text{then } W - X \in \mathfrak{W} \\ \text{if } X, Y \in \mathfrak{W}, & \quad \text{then } X \cup Y \in \mathfrak{W} \\ \text{if } X \in \mathfrak{W}, & \quad \text{then } \pi(X) =_{\text{def}} \{w \in W \mid \exists v \in X : R w v\} \in \mathfrak{W}. \end{aligned}$$

The following example illustrates the effect of restricted sets \mathfrak{W} . Consider the frame $\langle N, \leq \rangle$, where N is the set of natural numbers. Its modal theory contains such principles as $\Box p \rightarrow p$, $\Box p \rightarrow \Box \Box p$ and Geach’s Axiom: together forming the logic **S4.3**. Typically left out is the McKinsey Axiom $\Box \Diamond p \rightarrow \Diamond \Box p$; as it may be falsified in some infinite alternation of $p, \neg p$: say by $V(p) = \{2n \mid n \in N\}$. But now, consider the structure $\langle N, \leq, \mathfrak{W} \rangle$, where \mathfrak{W} consists of all *finite* and all *cofinite* subsets of N . It is easily checked that all three closure conditions obtain for \mathfrak{W} . Thus, we have a general frame here. Its logic contains the earlier one (‘a fortiori’); but it also adds principles. Notably, the McKinsey Axiom can no longer be falsified, as the above ‘tell-tale’ valuation is no longer admissible. Thus, **S4.1** holds in this general frame, although it does not in the underlying ‘full frame’. And further increases in the modal theory are possible, by restricting \mathfrak{W} even more; e.g. there is even a most austere choice, viz. $\mathfrak{W} = \{\emptyset, N\}$, which yields a general frame validating the ‘classical logic’ with axiom $\Box p \leftrightarrow p$ — which was still invalid in the previous general frame. Thus, one single underlying frame may still generate a hierarchy of modal logics.

The original algebraic motivation for this notion (due to Thomason [1972]) will be given in Section 2.3. But here already, a direct logical reason may be given. Kripke frames are so-called ‘standard models’ for modal formulas, considered as second-order Π_1^1 -sentences: the universal predicate quantifiers range over *all* sets of possible worlds. An intermediate possibility would have been to allow also ‘general models’ in the sense of Henkin [1950]: in which this second-order range may be restricted, say to some set \mathfrak{W} . Usually, such ranges are to be closed under certain mild conditions of definability — in order to verify reasonable forms of the universal instantiation (or ‘comprehension’) axiom. This, of course, is precisely what happened in the above. The uses of this notion lie partly in modal Completeness Theory, partly in modal algebra. For the moment, it will not be a major concern.

Semantic questions. Given a formal language, interpreted in certain structures, a plethora of questions arises concerning the interplay between more ‘linguistic’ and more ‘structural’ (or ‘mathematical’) notions. We mention only a few fundamental ones.

Arguably the ‘first question’ of any model theory is that concerning the relation between linguistic indistinguishability (equality of modal theories) and structural indistinguishability (isomorphism) of semantic structures. How far do the webs of language and ontology diverge? In classical logic, we know that (first-order) elementary equivalence coincides with isomorphism on the *finite* structures, but no higher up: isomorphism then becomes by far the finer sieve.

Now, the modal language on *models* behaves like the first-order language of the first translation in the introduction: nothing spectacular results. But the second-order notion seems more interesting in this respect. (Equality of second-order theories is quite strong: modulo the Axiom of Constructibility, it even implies isomorphism in all *countable* frames; cf. [Ajtai, 1979]). From Van Benthem [1985], which treats the analogous question for tense logic in Chapter 2.2.1, we extract

THEOREM 13. *Finite Kripke frames that are generated by a single point (cf. below) are isomorphic if and only if they possess the same modal theory. But, the countable Kripke frames $\mathbb{Z} \odot \mathbb{Z}$ (the integers, with each point replaced by a copy of the integers) and $\mathbb{Q} \odot \mathbb{Z}$ (the rationals, treated likewise) possess the same modal theory, without being isomorphic.*

In tense logic, the latter result means that the formal language cannot distinguish between locally discrete/globally discrete and locally discrete/globally dense Time. (The latter may well be that of our World.) In the context of modal logic, no such appealing interpretation is possible, whence we forego further discussion of the above result.

From now on, we will confine attention to a single theme, which again, is characteristic for much of what goes on in Model Theory.

Truth-preserving operations. In evaluating the truth of a modal formula φ at a world w we only have to consider w itself, (possibly) its R -successors, (possibly) their R -successors, etcetera. Thus, only that part of the frame is involved which is ‘ R -generated’ by w , so to speak. In general, one never has to look beyond R -closed environments of w : an observation summed up in the following notion and result.

DEFINITION 14. $M_1 (= \langle W_1, R_1, V_1 \rangle)$ is a *generated submodel* of $M_2 (= \langle W_2, R_2, V_2 \rangle)$ (notation: $M_1 \xrightarrow{S} M_2$) if

1. $W_1 \subseteq W_2$
2. $R_1 = R_2$ restricted to W_1 ,
3. $V_1(p) = V_2(p) \cap W_1$, for all proposition letters p ; i.e. M_1 is an ordinary *submodel* of M_2 , which has the additional feature that
4. W_1 is closed under passing to R_2 -successors.

The next result is the famous ‘Generation Theorem’ of Segerberg [1971].

THEOREM 15. If $M_1 \xrightarrow{S} M_2$, then for all worlds $w \in W_1$ and all modal formulas φ , $M_1 \models \varphi[w]$ iff $M_2 \models \varphi[w]$.

This is what happens inside a single model. When comparisons are desired between evaluation in distinct models, a more external connection is required.

DEFINITION 16. A relation C is a *zigzag connection* between two models M_1, M_2 if

1. domain $(C) = W_1$, range $(C) = W_2$,
 - (a) if Cwv and $w' \in W_1$ with R_1ww' , then $Cw'v'$ for some $v' \in W_2$ with R_2vv' (‘forth choice’)
 - (b) If Cwv and $v' \in W_2$ with R_2vv' , then Cww' for some $w' \in W_1$ with R_1ww' (‘back choice’)
2. if Cwv , then w, v verify the same proposition letters.

Starting from the basic case (3), the back-and-forth clauses ensure that evaluation of successive modalities in modal formulas yield the same results on either side:

THEOREM 17. If M_1 is zigzag-connected to M_2 by C , then, for all worlds $w \in W_1, v \in W_2$ with Cwv , and all modal formulas φ ,

$$M_1 \models \varphi[w] \text{ iff } M_2 \models \varphi[v].$$

Notation. $M_1 \xrightarrow{Z} M_2$ for zigzag-connected models (by some C).

By a result in Van Benthem [1976], the Generation Theorem and the preceding ‘Zigzag Theorem’ combined are characteristic for modal formulas as first-order formulas in the sense of the introduction:

THEOREM 18. *A first-order formula $\varphi(x)$ in the language with R, P, Q, \dots is logically equivalent to some modal transcription if and only if it is invariant for generated submodels and zigzag connections (in the above sense).*

For the case of pure frames, the above notions and results lead to the following three preservation results.

DEFINITION 19. F_1 is a *generated subframe* of F_2 ($F_1 \xrightarrow{S} F_2$) if

1. $W_1 \subseteq W_2$,
2. $R_1 = R_2$ restricted to W_1 ,
3. W_1 is R_2 -closed in W_2 .

In general logic, this type of situation is often described by saying that the ‘converse frame’ $\langle W_2, R_2 \rangle$ is an *end extension* of $\langle W_1, R_1 \rangle$: the added worlds all come ‘at the end’.

From Theorem 15 we derive *preservation* under generated subframes:

COROLLARY 20. *If $F_1 \xrightarrow{S} F_2$, then $F_2 \models \varphi$ implies $F_1 \models \varphi$, for all modal formulas φ .*

Here ‘ $F \models \varphi$ ’ means ‘ φ is true in F ’, in the global second-order sense of the introduction: at all worlds, under all valuations.

But Theorem 15 also has an ‘upward’ directed moral.

DEFINITION 21. The *disjoint union* $\oplus\{F_i \mid i \in I\}$ of a family of frames $F_i = \langle W_i, R_i \rangle$ is the disjoint union of the domains W_i , with the obvious coordinate relations R_i .

Another direct application is *preservation under disjoint unions*:

COROLLARY 22. *If $F_i \models \varphi$ (all $i \in I$), then $\oplus\{F_i \mid i \in I\} \models \varphi$, for all modal formulas φ .*

Next, turning to Theorem 17, one now needs a connection between frames which can be turned into a suitable zigzag relation between models over them.

DEFINITION 23. A *zigzag morphism* from F_1 to F_2 is a function: $W_1 \rightarrow W_2$ satisfying

1. $R_1 w w'$ implies $R_2 f(w) f(w')$,
i.e. f is an ordinary *R-homomorphism*; which has the additional backward property that
2. if $F_2 f(w) v$, then there exists $u \in W_1$ with $R_1 w u$ and $f(u) = v$.

This notion was mentioned under its current, but rather uninformative name of ‘ p -morphism’ in the introduction. Here is one more example:

the map from nodes to levels (counting from the top) is a zigzag morphism from the infinite binary tree (with the descendant relation) onto the natural numbers (with the usual ordering).

Notice also that injective (1-1) zigzag morphisms are even just isomorphisms.

Theorem 17 now implies the ‘ p -morphism’ theorem of Segerberg [1971].

COROLLARY 24. *If f is a zigzag morphism from F_1 onto F_2 , then, for all modal formulas φ , $F_1 \models \varphi$ implies $F_2 \models \varphi$.*

For more ‘local’ versions of these results, the reader is referred to [van Benthem, 1983].

More examples, and applications of Corollaries 20, 22, and 24 will be found in Section 2.4. A quick impression may be gained from the following sample observation (D. C. Makinson). The modal theory of any Kripke frame is either contained in the classical modal logic (characteristic axiom $\Box p \leftrightarrow p$) or the ‘absurd’ modal logic (characteristic axiom $\Box(p \wedge \neg p)$). For, any frame F either contains end points without R -successors, or it is *serial* ($\forall x \exists y Rxy$). In the former case, such an end point by itself forms a generated subframe, and by Corollary 20, the logic of the frame is contained in that of the subframe — which is the absurd one. In the latter case, contraction to one single reflexive point is a zigzag morphism, and by Corollary 24, the logic of the frame is contained in that of the reflexive point — which is the classical one.

We conclude by noting that these three notions are easily adapted to *general frames*, taking due precautions concerning the various sets $\mathfrak{W}_1, \mathfrak{W}_2$. Here are the three necessary additions:

In 19: add ‘ $\mathfrak{W}_1 = \{X \cap W_1 \mid X \in \mathfrak{W}_2\}$ ’.

In 21: add ‘the new \mathfrak{W}_2 remains essentially the old \mathfrak{W}_1 ’ (but for the disjointness procedure used).

In 23: add the following ‘continuity requirement’, reminiscent of topology:

‘for all $X \in \mathfrak{W}_2, f^{-1}[X] \in \mathfrak{W}_1$ ’.

These will be needed in the duality theory of Section 2.3.

Propositions and possible worlds. Another characteristic feature of modal semantics is the analogy between *propositions* and *sets of possible worlds*; as well as (moving up one stage in set-theoretic abstraction) that between *possible worlds* and *maximal sets of propositions*. Indeed, many philosophers would deny that there exist any differences here. Let us investigate.

The ideal setting here are general frames $\langle W, R, \mathfrak{W} \rangle$: the range is clearly identifiable with a collection of ‘propositions’ over W .

Now, if worlds are to be considered as sets of propositions, then some obvious desiderata govern the connection between a world w and propositions X, Y associated with w :

1. $X \in w$ or $Y \in w$ if and only if $X \cup Y \in w$ ('analysis')
2. $X \notin w$ if and only if $W - X \in w$ ('decisiveness').

Accordingly, one considers only subsets w of \mathfrak{W} satisfying these two conditions. These are precisely the so-called *ultrafilters* on \mathfrak{W} .

What about the alternative relation to be imposed?

Again, a common idea is that a world v is R -accessible to w if it 'satisfies all w 's modal prejudices', i.e. whenever $\Box\varphi$ is true at w , φ should be true at v . The same idea may be expressed as follows: whenever φ is true at v , $\Diamond\varphi$ should be true at w . In the present context, this becomes the following stipulation:

$$Rwv \quad \text{if for all } X \in v, \pi(X) \in w.$$

In this process, no new propositions have been created, whence the former propositions X now reappear as sets $\bar{X} = \{w \mid X \in w\}$.

These considerations motivate

DEFINITION 25. The *ultrafilter extension* $ue(G)$ of a general frame $G = \langle W, R, \mathfrak{W} \rangle$ is the general frame $\langle ue(W, \mathfrak{W}), ue(R, \mathfrak{W}), ue(\mathfrak{W}) \rangle$, with

1. $ue(W, \mathfrak{W})$ is the set of all ultrafilters on \mathfrak{W} ,
2. $ue(R, \mathfrak{W})wv$, if for each $X \in \mathfrak{W}$ such that $X \in v, \pi(X) \in w$,
3. $ue(\mathfrak{W})$ is $\{\bar{X} \mid X \in \mathfrak{W}\}$.

What this construction has done is to re-create G one level higher up in the set-theoretic air, so to speak, and some calculation will prove

THEOREM 26. G and $ue(G)$ verify the same modal formulas.

Still, not everything need have remained the same: the world pattern of $\langle W, R \rangle$ may differ from that of $\langle ue(W, \mathfrak{W}), ue(R, \mathfrak{W}) \rangle$. First, each old world $w \in W$ generates an ultrafilter $\{X \in \mathfrak{W} \mid w \in X\}$ and, hence, a corresponding new world in $ue(W, \mathfrak{W})$. But, unless \mathfrak{W} satisfies certain separation principles for worlds, different old worlds may be identified to a single new one. (In the earlier example of $\langle N, \leq, \{\emptyset, N\} \rangle$, only a single new world remains, where there used to be infinitely many!) On the other hand, the construction may also introduce worlds that were not there before. For instance, on the earlier general frame $\langle N, \leq, (\text{co-})\text{finite sets} \rangle$, the co-finite sets form an ultrafilter which induces a 'point at infinity' in the resulting ultrafilter extension. Indeed, it is easily seen that the latter consists of $\langle N, \leq \rangle$ followed by just that infinite point.

In Section 2.3, necessary and sufficient conditions will be formulated guaranteeing that a general frame is ‘stable’ under the construction of ultrafilter extensions. In any case, it turns out that the process stabilises after one step at the most. Now, these considerations also apply to ‘full’ Kripke frames.

DEFINITION 27. The *ultrafilter extension* $ue(F)$ of a frame $F = \langle W, R \rangle$ is the frame $\langle ue(W), ue(R) \rangle$, with

1. $ue(W)$ is the set of all ultrafilters on W ,
2. $ue(R)wv$ if for each $X \subseteq W$ such that $X \in v, \pi(X) \in w$.

This time, Theorem 26 does not hold, however. For, it only says that the modal theory of the general frame $\langle W, R, \text{power set of } W \rangle$ coincides with that of the induced general frame according to Definition 25. Now, the latter is, in general, a restriction of the full frame $\langle ue(W), ue(R) \rangle$. Hence, we can only conclude to *anti-preservation under ultrafilter extensions*:

COROLLARY 28. *If $ue(F) \models \varphi$, then $F \models \varphi$, for all modal formulas φ .*

Still, this structural notion can be made a little more familiar by connecting it with previous model-theoretic operations. First, the above-mentioned connection between old worlds and new worlds is 1-1 this time, and indeed isomorphic (consider suitable singleton sets):

THEOREM 29. *F lies isomorphically embedded in $ue(F)$.*

In general, this cannot be strengthened to ‘embedded as a generated subframe’. But, another connection with the earlier preservation notions may be drawn from [van Benthem, 1979a].

THEOREM 30. *$ue(F)$ is a zigzag-morphic image of some frame F' which is elementarily equivalent to F .*

Proof. One expands F to $(F, X)_{X \subseteq W}$, and then passes on to a suitably saturated elementary extension, by ordinary model theory. From the latter, a canonical function from worlds to ultrafilters on F exists, which turns out to be a zigzag morphism. ■

Ultraproducts and definability. New, modally inspired notions concerning frames have been forged in the above. But old classical constructions may be considered as well. Of the various possibilities, only one is selected here, viz. the formation of ultraproducts. (For many other examples, cf. [van Benthem, 1985, Chapter I.2.1].) Its use has been indicated in the introduction already.

The basic theory (and heuristics) of the notion of ‘ultraproduct’ has been given in the Higher Order Logic chapter in volume 1 of this *Handbook*. (Cf. also [Chang and Keisler, 1973, Chapters 4.1 and 6.1].) We recall some of its outstanding features and uses.

DEFINITION 31. For any family of Kripke frames $\{F_i \mid i \in I\}$ with an ultrafilter U on I , the *ultraproduct* $\Pi_U F_i$ is the frame $\langle W, R \rangle$ with

1. W is the set of classes f_{\sim} , for all functions $f \in \Pi\{W_i \mid i \in I\}$, where f_{\sim} is the equivalence class of f in the relation $f \sim g \Leftrightarrow \{i \in I \mid f(i) = g(i)\} \in U$,
2. R is the set of couples $\langle f_{\sim}, g_{\sim} \rangle$ for which $\{i \in I \mid R_i f(i)g(i)\} \in U$.

This definitional equivalence is lifted by induction to

THEOREM 32 ('Łoś Equivalence'). *For all ultraproducts, and all first-order formulas $\varphi(x_1, \dots, x_n)$,*

$$\Pi_U F_i \models \varphi[f_{\sim}^1, \dots, f_{\sim}^n] \text{ iff } \{i \in I \mid F_i \models \varphi[f^1(i), \dots, f^n(i)]\} \in U.$$

Thus, in particular, all first-order sentences φ are *preserved under ultraproducts* in the following sense:

$$\text{if } F_i \models \varphi(\text{all } i \in I), \text{ then } \Pi_u F_i \models \varphi.$$

Conversely, 'Keisler's Theorem' tells us that this is also enough.

THEOREM 33. *A class of Kripke frames is elementary if and only if both that class and its complement are closed under the formation of ultraproducts and isomorphic images.*

Proof. Cf. [Chang and Keisler, 1973, Chapter 6.2]. ■

A somewhat more liberal notion of definability, viz. by means of arbitrary *sets* of first-order formulas, yields so-called Δ -*elementary* classes. Here the relevant characterisation employs a special case of ultraproducts.

DEFINITION 34. An *ultrapower* $\Pi_U F$ is an ultraproduct with in each coordinate i the same frame F .

Notice that by the Łoś Equivalence, $\Pi_U F$ is *elementarily equivalent* to F , i.e. both frames possess the same first-order theory.

THEOREM 35. *A class of Kripke frames is Δ -elementary if and only if it is closed under the formation of ultraproducts and isomorphic images, while its complement is closed under the formation of ultrapowers.*

All these notions will be used in the modal correspondence theory of the next section. In this connection, it should be observed that, as for the other kinds of modal semantic structure, ultraproducts of *models* and of *general frames* are easily defined using the above heuristics. These will not be used in the sequel however. (Cf. [van Benthem, 1983].)

The above definability question for classical model theory leads to a clear modal task: ‘to characterise the modally definable classes of Kripke frames’. In section 2.4 this matter will be investigated.

We have arrived at the interplay between classical and modal model theory, which lies at the heart of modal correspondence theory.

2.2 Correspondence I: From Modal to Classical Logic

Through the translation given in the Introduction, modal formulas may be viewed as defining constraints on the alternative relation in Kripke frames. Some of these constraints are first-order definable, others are not. Examples are presented of both, after which the former class is explored. A mathematical characterisation is given for it, in terms of ultrapowers, and methods are developed for (dis-)proving membership of the class. The limits of these methods are established as well.

First-order definability. The class of modal formulas to be studied here is defined as follows.

DEFINITION 36. **M1** consists of all modal formulas φ for which a first-order sentence α (in $R, =$) exists such that

$$F \models \varphi \text{ iff } F \models \alpha, \text{ for all Kripke frames } F.$$

Various examples of formulas in **M1** have occurred in the Introduction. For purposes of illustration, see Table 1 below.

As these are all rather easy to establish, some readers may desire a more complex example. Here it is, straight from the incompleteness Example 5 in the Introduction.

THEOREM 37. *The conjunction of the formulas $\Box p \rightarrow p$, $\Box \Diamond p \rightarrow \Diamond \Box p$ and $(\Diamond p \wedge \Box(p \rightarrow \Box p)) \rightarrow p$ is in **M1**.*

Proof. We shall show that this conjunction defines the same class as the classical axiom $\Box p \leftrightarrow p$, i.e. $\forall xy(Rxy \leftrightarrow x = y)$.

The argument requires several stages.

1. $\Box p \rightarrow p$ imposes reflexivity,
2. $\Diamond p \wedge \Box(p \rightarrow \Box p) \rightarrow p$ says the following:
 $\forall xy(Rxy \rightarrow \exists n \exists z_1, \dots, z_n (Rxz_1 \wedge \dots \wedge Rxz_n \wedge \wedge Ryz_1 \wedge \dots \wedge Rz_n x))$.

In other words, from any R -successor y of x , one may return to x by way of some finite chain of R -successors of x . In case the chain is empty, this reduces to just: Ryx .

This (second-order!) equivalence is proved as follows (I. L. Humberstone): ‘ \Rightarrow ’: Consider any y with Rxy . Let the *good points* be those R -successors z

Table 1.

Modal formula	Condition
$\Box p \rightarrow p$	$\forall x Rxx$
$\Box p \rightarrow \Box \Box p$	$\forall xy (Rxy \rightarrow \forall z (Ryz \rightarrow Rxz))$
$\Diamond \Box p \rightarrow \Box \Diamond p$	$\forall xy (Rxy \rightarrow \forall z (Rxz \rightarrow \exists u (Ryu \wedge Rzu)))$
$\Box(p \vee q) \rightarrow \Box p \vee \Box q$	$\forall xy (Rxy \rightarrow \forall z (Rxz \rightarrow z = y))$
$\Box(\Box p \rightarrow q) \vee \Box(\Box q \rightarrow p)$	$\forall xy (Rxy \rightarrow \forall z (Rxz \rightarrow (Ryz \vee Rzy)))$
$p \rightarrow \Box p$	$\forall xy (Rxy \rightarrow y = x)$
$\Box \perp$	$\forall x \neg \exists y Rxy$
$p \rightarrow \Box \Diamond p$	$\forall xy (Rxy \rightarrow Ryx)$

of x which can be reached from y through some finite chain (possibly empty) of R -successors of x . Then, set $V(p)$ equal to the set of all R -successors of good points. This assignment produces the following effects.

1. p is true at y (y being a successor of y , by reflexivity), and, hence, $\Diamond p$ is true at x .
2. Any R -successor of x verifying p is itself a good point, whence all *its* R -successors belong to $V(p)$.

It follows that $\Box(p \rightarrow \Box p)$ is true at x . Therefore, p itself must be true at x : i.e. x is R -successor of some good point, which was precisely to be proved.

‘ \Leftarrow ’: Truth of p in x is discovered by merely following the relevant chain.

3. Now, having secured *reflexivity* and ‘*safe return*’, we can find out what the McKinsey Axiom says in the present context.

First, notice that all R -successors of any point x may be divided up into concentric shells $S_n(x)$, where $S_n(x)$ consists of those R -successors y of x which return to x by n R -arrows (between R -successors of x) but no less. For instance, $S_0(x)$ only consists of x itself, $S_1(x)$ contains immediate R -predecessors. Notice also that, if $y \in S_{n+1}(x)$, then it must have some R -successor in $S_n(x)$.

The McKinsey Axiom makes this whole hierarchy collapse. Set $V(p) = \cup\{S_{2n}(x) \mid n = 0, 1, 2, \dots\}$. Then $\Box \Diamond p$ will be true at x , as follows from the above picture. For, if Rxy , and $y \in S_n(x)$, then either n is even — whence p holds at y (by definition) and so $\Diamond p$ (by reflexivity), or n is odd — whence y has an R -successor in $S_{n-1}(x)$ verifying p : which again verifies $\Diamond p$ at y .

It follows that $\Diamond \Box p$ must be true at x . So, $\Box p$ holds at some R -successor of x . Which one? In the present situation, this can only be

x itself. But then again, this means that there can be no shells $S_n(x)$ with n odd. Thus, there is only $S_0(w) : \forall y(Rxy \rightarrow y = x)$.

4. Combining (1) and (3), the required conclusion follows: the three axioms together imply $\forall xy(Rxy \leftrightarrow y = x)$, and are obviously implied by it. ■

The very unexpectedness of this argument will have made it clear that there is a creative side to establishing correspondences.

Global and local definability. Originally, Kripke introduced frames $\langle W, R, w_0 \rangle$, with a designated ‘actual world’ w_0 . From that point of view, the study of ‘local’ equivalence becomes natural:

$$F \models \varphi[w] \text{ iff } \models \alpha[w],$$

where the first-order formula α has one free variable now. The reader may have noticed already that previous correspondence arguments often provide local versions as well. For instance, we had

$$\begin{aligned} F \models \Box p \rightarrow p[w] & \quad \text{iff} \quad F \models Rxx[w] \\ F \models \Box p \rightarrow \Box \Box p[w] & \quad \text{iff} \quad F \models \forall y(Rxy \rightarrow \forall z(Ryz \rightarrow Rxz))[w]. \end{aligned}$$

The local notion is the more informative one, in that local correspondence of φ with $\alpha(x)$ implies global correspondence of φ with $\forall x\alpha(x)$; but not conversely. Indeed, [van Benthem, 1976] contains an example of a formula in **M1** which has no local first-order equivalent at all! On the other hand, there are also circumstances under which the distinction collapses — e.g. on the *transitive* Kripke frames (W. Dziobiak; cf. [van Benthem, 1981a]).

Finally, a word of warning. Local validity of, e.g. $\Box p \rightarrow \Box \Box p$ means ‘local transitivity’, no more. The frame $\langle N, \{ \langle 0, n \rangle \mid n \in N \} \cup \{ \langle n, n+1 \rangle \mid n \in N \} \rangle$ is locally transitive in 0, without being transitive.

First-order undefinability. There is a threshold of complexity below which second-order phenomena do not occur.

THEOREM 38. *All modal formulas without nestings of modal operators are in M1.*

Proof. Cf. [van Benthem, 1978]: a combinatorial classification suffices. ■

EXAMPLE 39. Löb’s Axiom $\Box(\Box p \rightarrow p) \rightarrow \Box p$ is outside of **M1**.

Proof. It suffices to establish the following Claim: Löb’s Axiom defines transitivity plus well-foundedness of the converse of the alternative relation (i.e. there are no ascending sequences $xRx_1Rx_2Rx_3, \dots$). For, by a well-known classical compactness argument, the latter combination cannot be first-order definable (e.g. notice that it holds in $\langle N, > \rangle$, but not in its non-isomorphic ultrapowers).

First, assume that Löb’s Axiom fails in F ; i.e. for some V and w ,

1. $\langle F, V \rangle \models \Box(\Box p \rightarrow p)[w]$, but
2. $\langle F, V \rangle \not\models \Box p[w]$

Also, assume transitivity of R : we will refute the well-foundedness of \check{R} , by constructing an endless ascending sequence of worlds $wRw_1Rw_2\dots$

Step 1: Chose any w_1 with Rw_1 where p fails (by (2)). By (1), $\Box p \rightarrow p$ is true at w_1 , whence $\Box p$ fails again.

Step 2: chose any w_2 with Rw_1w_2 where p fails. By (1) and transitivity, $\Box p \rightarrow p$ is true at w_2 , etcetera: an endless sequence is on its way.

Next, failure of either of the two relational conditions results in failure of Löb's Axiom. If transitivity fails, say $Rwv, Rvu, \neg Rwu$, then $V(p) = W - \{v, u\}$ verifies $\Box(\Box p \rightarrow p)$ at w , while falsifying $\Box p$.

If well-foundedness fails, say wRw_1Rw_2, \dots , then $V(p) = W - \{w, w_1, w_2, \dots\}$ produces the same effect. ■

More complex undefinability arguments will be discussed later on.

First-order definability and ultraproducts. Modal formulas could be regarded as Π_1^1 -sentences, witness the Introduction. Now, for the latter sentences, ultraproducts provide the touchstone for first-order definability:

THEOREM 40. *A Π_1^1 -sentence in $R, =$ is first-order definable if and only if it is preserved under ultraproducts.*

Proof. ' \Rightarrow ': This follows from the Łoś Equivalence (cf. Section 2.1).

' \Leftarrow ': Consider a typical such sentence:

$$\forall P_1 \dots \forall P_n \varphi(P_1, \dots, P_n, R, =) \quad (\varphi \text{ first-order}).$$

Clearly it is preserved under *isomorphisms* (and so is its negation). Moreover, its negation (a ' Σ_1^1 -sentence') is preserved under *ultraproducts* (cf. [Chang and Keisler, 1973, Chapter 4.1], for the easy argument). So, given the assumption on the sentence itself, Keisler's Theorem (33) applies. ■

COROLLARY 41. *A modal formula is in **M1** if and only if it is preserved under ultraproducts.*

A second application says that no generalisation of our topic is obtained by allowing arbitrary *sets* of defining first-order conditions.

COROLLARY 42. *If a modal formula has a Δ -elementary definition, it has an elementary definition.*

Proof. Δ -elementary classes are closed under the formation of ultraproducts. ■

This characterisation of **M1** is rather aspecific, as it holds for *all* Π_1^1 -sentences. Later on, we will exploit the specifically *modal* character of our formulas to do better. Moreover, the characterisation is rather abstract, as ultraproducts are hard to visualise. Therefore, we now turn to more concrete methods for separating formulas inside **M1** from those outside.

Formulas beyond M1: Compactness and Löwenheim–Skolem arguments. In practice, nonfirst-order definability often shows up in failure of the Compactness and Löwenheim–Skolem theorems. The first was involved in the example of Löb’s Axiom, the second will be presented now.

EXAMPLE 43 (McKinsey’s Axiom). $\Box\Diamond p \rightarrow \Diamond\Box p$ is outside of **M1**.

Proof. Consider the following uncountably infinite Kripke frame

$$F = \langle W, R \rangle:$$

$$\begin{aligned} W &= \{a\} \cup \{b_n, b_n^0, b_n^1 \mid n \in N\} \cup \{c_f \mid f : N \rightarrow \{0, 1\}\} \\ R &= \{\langle a, b_n \rangle, \langle b_n, b_n^0 \rangle, \langle b_n, b_n^1 \rangle, \langle b_n^0, b_n^0 \rangle, \langle b_n^1, b_n^1 \rangle \mid n \in N\} \cup \\ &\quad \{\langle a, c_f \rangle \mid f : N \rightarrow \{0, 1\}\} \cup \{\langle c_f, b_n^{f(n)} \rangle \mid n \in N, f : N \rightarrow \{0, 1\}\}. \end{aligned}$$

We observe two things.

1. $F \models \Box\Diamond p \rightarrow \Diamond\Box p$.

Thanks to the presence of the reflexive endpoints b_n^0, b_n^1 , the validity of the McKinsey Axiom is obvious everywhere, except for a .

So, suppose that, under some valuation V , $\Box\Diamond p$ is true at a . By assumption, $\Diamond p$ is true at each b_n , and hence p is true at b_n^0 or b_n^1 . Now, pick any function $f : N \rightarrow \{0, 1\}$ such that $b_n^{f(n)}$ is a p -world (each $n \in N$). Then $\Box p$ holds at c_f , and hence $\Diamond\Box p$ at a .

By the downward Löwenheim–Skolem theorem, F possesses a *countable* elementary substructure F' whose domain contains (at least) a, b_n, b_n^0, b_n^1 (all $n \in N$). As F is *uncountable*, many worlds (c_f) must be missing in

W' . Fix any one of these, say c_{f_0} . Notice, for a start, that c_{1-f_0} cannot be in W' either. (For, the existence of ‘complementary’ c -worlds is first-order expressible; and F' verifies the same first-order formulas at each of its worlds as F .) Now, setting

$$V(p) = \{b_n^{f_0(n)} \mid n \in N\}$$

will verify $\Box\Diamond p$ at a , while falsifying $\Diamond\Box p$. Thus, we have shown

2. $F' \not\models \Box\Diamond p \rightarrow \Diamond\Box p$.

We may conclude that the McKinsey Axiom is not first-order definable — not being preserved under elementary subframes. ■

In *practice*, failure of Löwenheim–Skolem or compactness properties is an infallible mark of being outside of **M1**. The reader may also think this to be the case in *theory*, by the famous Lindström Theorem. (Cf. Volume 1, chapters by Hodges or van Benthem and Doets.) But there is a little-realised problem: the Lindström Theorem does not work for languages with a fixed finite vocabulary (cf. [van Benthem, 1976]). In our case of $R, =$, there do exist proper extensions of predicate logic satisfying both the Löwenheim and compactness properties. These are not *modal* examples, however — and it may well be the case, for all we know, that a modal formula φ belongs to **M1** if and only if the logic obtained by adding φ to the first-order predicate logic in $R, =$ as a propositional constant has the Löwenheim and compactness properties. Indeed, up till now, all undefinability arguments (including the above) have always been found reducible to *compactness* arguments alone.

The final characterisation of M1. Corollary 41 may be improved by noting the following fact about Kripke frames, connecting the modal and classical notions of Section 2.1.

LEMMA 44. $\Pi_U F_i \xrightarrow{S} \Pi_U \oplus \{F_i \mid i \in I\}$.

Thus, ultraproducts are generated subframes of suitable ultrapowers.

A second idea comes from the preceding section: outside of **M1**, we encountered non preservation under *elementary equivalence*, a notion tied up with ultrapowers by the Keisler–Shelah Theorem (cf. [Chang and Keisler, 1973, Chapter 6.1]). We arrive at the main result of [van Benthem, 1976].

THEOREM 45. (i) A modal formula is in **M1** if and only if (ii) it is preserved under ultrapowers if and only if (iii) it is preserved under elementary equivalence.

Proof. (i) \Rightarrow (iii) \Rightarrow (ii) are immediate. (ii) \Rightarrow (i): If φ is preserved under ultrapowers, then, by Lemma 44, it is also preserved under ultraproducts — because disjoint unions preserve modal truth (Corollary 22). Now apply Corollary 41. ■

Again, this insight saves us some spurious generalisations. Besides ‘ Δ -elementary’, there are two more levels in the definability hierarchy

A Σ -elementary class is defined by an infinite *disjunction* of first-order sentences (Δ -elementary classes by infinite *conjunctions*). The prime example of this phenomenon is *finiteness*. $\Sigma\Delta$ -elementary classes arise from infinite disjunctions of infinite conjunctions, or vice versa: both cases (and all purported ‘higher’ ones) collapse — and the hierarchy stops here, even in classical logic. The reason lies in the simple observation that a class of frames is $\Sigma\Delta$ -elementary if and only if it is closed under *elementary equivalence*.

But the preceding result has a

COROLLARY 46. *Modal formulas are either elementary, or essentially higher-order.*

Unfortunately, even this better characterisation does not yield much *effective* information concerning the members of **M1**. For, there are no syntactic criteria for preservation under ultrapowers. From [van Benthem, 1983], we will cite the catalogue of what little we know.

DIGRESSION 47.

1. Π_1^1 -sentences in $R, =$ of the purely universal form

$$\forall P_1 \dots \forall P_m \forall x_1 \dots \forall x_n \varphi \quad (\varphi \text{ quantifier-free})$$

are preserved under ultrapowers. This tells us that $p \rightarrow \Box p$, i.e.

$$\forall P \forall x (Px \rightarrow \forall y (Rxy \rightarrow Py))$$

must be in **M1**: but that was clear without such heavy artillery.

2. Π_1^1 -sentences in $R, =$ of the universal-existential form

$$\forall P_1 \dots \forall P_m \exists x_1 \dots \exists x_n \varphi \quad (\varphi \text{ quantifier-free})$$

are preserved under ultrapowers. This is of no help whatsoever, as modal formulas have at least one *universal* first-order quantifier ($\forall x$).

3. Further presents will not be forthcoming: *any* Π_1^1 -sentence in $R, =$ is logically equivalent to one of the form

$$\forall P_1 \dots \forall P_m \forall x_1 \dots \forall x_n \exists y_1 \dots \exists y_n \varphi \quad (\varphi \text{ quantifier-free})$$

So, all complexity occurs at this level already.

Thus, other ways are to be developed for describing **M1** effectively.

The method of substitutions. There is a common syntactic pattern to many examples of first-order definable modal formulas: certain antecedents, in combination with certain consequents enable one to ‘read off’ equivalents. Starting from the earlier examples $\Box p \rightarrow p$, $\Diamond \Box p \rightarrow \Box \Diamond p$, one may notice successively that conjunctions and disjunctions are admissible as well; as long as one avoids $\Box \Diamond$ or $\Box(\dots \vee \dots)$ combinations to the left.

A typical instance is the following result from [Sahlqvist, 1975]:

THEOREM 48. *Modal formulas $\varphi \rightarrow \psi$ are in **M1**, provided that*

1. φ is constructed from the forms $p, \Box p, \Box \Box p, \dots, \perp, \top$, using only \wedge, \vee and \Diamond , while
2. φ is constructed from proposition letters, \perp, \top , using \wedge, \vee, \Diamond and \Box .

This theorem accounts for cases such as

$$\Diamond(p \wedge \Box q) \rightarrow \Box(p \vee \Diamond p \vee q)$$

which defines

$$\forall xy(Rxy \rightarrow \forall z(Rxz \rightarrow (z = y \vee Rzy \vee Ryz))).$$

Proof. The heuristics of the Introduction works: for each ‘minimal verification’ of the antecedent, the consequent must hold. For further technical information (e.g. the *monotonicity* of the consequent is vital too), cf. [van Benthem, 1976], which also contains generalisations of the theorem. ■

That $\Box \Diamond$ is fatal, is shown by the McKinsey Axiom. The Fine Axiom $\Diamond \Box(p \vee q) \rightarrow \Diamond(\Box p \vee \Box q)$ does the same for $\Box(\dots \vee \dots)$. Finally, the Löb Axiom (in the equivalent form $\Diamond p \rightarrow \Diamond(p \wedge \Box \neg p)$) demonstrates the danger of ‘negative’ parts in the consequent. Thus, in a sense, we have a ‘best result’ here.

Notice that the class described is rather typical for modal axioms, which often assume this implicational form. Indeed, the most characteristic modal axioms are even simply *reduction principles* of the form

$$(\text{modal operators}) p \rightarrow (\text{modal operators}) p.$$

THEOREM 49. *A modal reduction principle is in **M1** if and only if it is of one of the following four types:*

1. $\vec{M}p \rightarrow \Box \dots \Box \Diamond \dots \Diamond p$,
2. $\Diamond \dots \Diamond \Box \dots \Box p \rightarrow \vec{M}p$,
3. $\Box \dots$ (*i times*) $\dots \Box \vec{M}p \rightarrow \vec{N} \vec{M}p$ (where length $(\vec{N}) = i$),

4. $\vec{N}\vec{M}p \rightarrow \diamond \dots (i \text{ times}) \dots \diamond \vec{M}p$ (where length $(\vec{N}) = i$).

Proof. Cf. [van Benthem, 1976] for the rather laborious argument. ■

Thus at least, important parts of **M1** have been classified. This particular theorem finishes a project begun in [Fitch, 1973].

A general method of proof for Theorem 48 consists of the method of substitutions, introduced in the introduction. Here we shall merely illustrate how it works: a justification may be found in [van Benthem, 1983].

EXAMPLE 50. Write $\diamond \Box p \rightarrow \Box \diamond p$ as

$$\forall P \forall x (\exists y (Rxy \wedge \forall z (Ryz \rightarrow Pz)) \rightarrow \forall u (Rxu \rightarrow \exists v (Ruv \wedge Pv))).$$

Rewrite this to the equivalent

$$\forall xy (Rxy \rightarrow \forall P (\forall z (Ryz \rightarrow Pz) \rightarrow \forall u (Rxu \rightarrow \exists v (Ruv \wedge Pv)))).$$

Substitute for $P : \lambda z. Ryz$, to obtain

$$\forall xy (Rxy \rightarrow (\forall z (Ryz \rightarrow Ryz) \rightarrow \forall u (Rxu \rightarrow \exists v (Ruv \wedge Ryv)))).$$

This is equivalent to

$$\forall xy (Rxy \rightarrow \forall u (Rxu \rightarrow \exists v (Ruv \wedge Ryv))),$$

i.e. *directedness (confluence)*.

Write $\diamond(p \wedge \Box q) \rightarrow \Box(p \vee \diamond p \vee q)$ as

$$\forall xy (Rxy \rightarrow \forall P ((Py \wedge \forall z (Ryz \rightarrow Qz)) \rightarrow \forall u (Rxu \rightarrow (Pu \vee \exists v (Ruv \wedge Pv) \vee Qu)))).$$

Substitute for $P : \lambda z. y = z$, and for $Q : \lambda z. Ryz$, to obtain (an equivalent of) the earlier *connectedness*.

Write $\diamond(p \wedge \Box p) \rightarrow p$ as

$$\forall xy (Rxy \rightarrow \forall P ((Py \wedge \forall z (Ryz \rightarrow Pz)) \rightarrow Px)).$$

Substitute for $P : \lambda z. y = z \vee Ryz$, to obtain (an equivalent of)

$$\forall xy (Rxy \rightarrow (Ryx \vee y = x)).$$

Write $\Box \Box p \rightarrow \Box p$ as

$$\forall x \forall P (\forall y (Rxy \rightarrow \forall z (Ryz \rightarrow Pz)) \rightarrow \forall u (Rxu \rightarrow Pu)).$$

Substitute for $P : \lambda z \cdot R^2xz$; i.e. $\lambda z \cdot \exists v(Rxv \wedge Rvz)$, to obtain (modulo logical equivalence)

$$\forall x \forall u (Rxu \rightarrow \exists v (Rxv \wedge Rvu)),$$

i.e., *density* of the alternative relation.

In general, substitutions will be disjunctions of forms $R^n yz$ ($n = 0, 1, 2, \dots$); the cases 0, 1 standing for $=, R$, respectively.

Despite these advances, the range of the method of substitutions has its limits. To see this, here is an example of a formula in **M1** with a quite different spirit.

EXAMPLE 51. The conjunction of the **K4.1** axioms, i.e. $\Box p \rightarrow \Box \Box p$, $\Box \Diamond p \rightarrow \Diamond \Box p$ is in **M1**.

Proof. $\Box p \rightarrow \Box \Box p$ defined transitivity and, therefore, it suffices to prove the following

CLAIM. On the *transitive* Kripke frames, McKinsey's Axiom defines *atomicity*:

$$\forall x \exists y (Rxy \wedge \forall z (Ryz \rightarrow z = y)).$$

From right to left, the implication is clear. From left to right, however, the argument runs deeper.

Assume that F is a transitive frame, containing a world $w \in W$ such that

$$\forall y (Rwy \rightarrow \exists z (Ryz \wedge z \neq y)).$$

Using some suitable form of the Axiom of Choice (it is as serious as this ...), find a subset X of w 's R -successors such that

1. $\forall y \in W (Rwy \rightarrow \exists z \in X Ryz)$
2. $\forall y \in W (Rwy \rightarrow \exists z \in (W - X) Ryz)$.

Setting $V(p) = X$ then falsifies the McKinsey Axiom at w . ■

This complexity is unavoidable. We can, for example, prove

THEOREM 52. $(\Box p \rightarrow \Box \Box p) \wedge (\Box \Diamond p \rightarrow \Diamond \Box p)$ is not equivalent to any conjunction of its first-order substitution instances.

Proof. Here is where the earlier general frame $\langle N, \leq$, finite and cofinite sets \rangle comes in. First, an ordinary model-theoretic

OBSERVATION. The finite and cofinite sets of natural numbers are precisely those first-order definable in $\langle N, \leq \rangle$, possibly using parameters.

Now, it was noticed already in Section 2.1 that the above formula holds in this general frame — and hence so do all its first-order substitution

instances. But the latter also hold in the full frame $\langle N, \leq \rangle$. So, if our formula were defined by them, it would also hold in the full frame: which it does not. ■

So, although the method of substitutions carves out a large, and important part of **M1**, it does not fully describe the latter class.

The complexity of M1. The method of substitutions describes a part of **M1** which may even be shown to be *recursively enumerable* (cf. [van Benthem, 1983]). But **M1** overflowed its boundaries. Indeed, there are reasons to believe that **M1** is not recursively enumerable — probably not even arithmetically definable. For, in the general case of Π_1^1 -sentences, we know

THEOREM 53. *First-order definability of Π_1^1 -sentences is not an arithmetical notion.*

Proof. (Cf. [van Benthem, 1983] or the Higher Order Logic Chapter in Volume 1 of this *Handbook*.) ■

Other topics. Various other questions had to be omitted here. At least, one example should be mentioned, viz. that of *relative correspondences*. On several occasions, a restriction to *transitive* Kripke frames produced interesting shifts: global and local first-order definability collapse, the McKinsey Axiom becomes elementary, etc. A sample result is in [van Benthem, 1976].

THEOREM 54. *On the transitive Kripke frames, all modal reduction principles are first-order definable.*

Thus, ‘pre-conditions’ on the alternative relation are worth considering. In areas such as tense logic, our temporal intuitions even *require* them.

2.3 Modal Algebra

An alternative to Kripke semantic structures is offered by so-called ‘*modal algebras*’, in which the modal language may be interpreted as well. The realm of modal algebras has its own mathematical structure, with *subalgebras*, *direct products* and *homomorphic images* as key notions. Now, back-and-forth connections may be established between these two realms, through the *Stone Representation*. A categorial parallel emerges between the above triad of notions and the basic triad of Section 2.1: zigzag-morphic images, disjoint unions and generated subframes, respectively. Moreover, the earlier ‘possible worlds construction’ for ultrafilter extensions will be seen to arise naturally from the Stone Representation.

The algebraic perspective. As in other areas of logic, the modal propositional language may also be interpreted in *algebraic* structures. These assume the

form of a Boolean Algebra (needed to interpret the propositional base) enriched with a unary operation, in order to capture the modal operator.

DEFINITION 55. A *modal algebra* is a tuple

$$\mathfrak{A} = \langle A, 0, 1, +, ', * \rangle,$$

where $\langle A, 0, 1, +, ' \rangle$ is a Boolean Algebra and $*$ is a unary operator satisfying the equations

1. $(x + y)^* = x^* + y^*$
2. $0^* = 0$.

Notice that $*$ corresponds to possibility (\diamond): the necessity choice would have yielded equations

- 1'. $(x \cdot y)^* = x^* \cdot y^*$
- 2'. $1^* = 1$.

This algebraic perspective at once yields a completeness result.

THEOREM 56. *A modal formula is derivable in the minimal modal logic \mathbf{K} if and only if it receives value 1 in all modal algebras under all assignments.*

The concept of evaluation at the back of this goes as follows. Let V assign A -values to proposition letters. Then, V may be lifted to all formulas through the recursive clauses

$$\begin{aligned} V(\neg\varphi) &= V(\varphi)' \\ V(\varphi \vee \psi) &= V(\varphi) + V(\psi) \\ V(\diamond\varphi) &= V(\varphi)^*, \text{ etc.} \end{aligned}$$

Thus, a modal formula is read as a ‘polynomial’ in $', +, *$.

The *proof* of the completeness Theorem 56 comes cheap. First, one shows by induction on the length of proofs that all \mathbf{K} -theorems are ‘polynomials identical to 1’. Conversely, one considers the so-called *Lindenbaum Algebra* of the modal language, whose elements are equivalence classes of \mathbf{K} -provably equivalent modal formulas, with operations defined in the obvious way through the connectives. The value 1 in this algebra is awarded to all and only the \mathbf{K} -theorems: hence non- theorems are disqualified as polynomials identical to 1.

Such uses of modal algebra are a joy to some (cf. [Rasiowa and Sikorski, 1970]); to others they show that the algebraic approach is merely ‘syntax in disguise’. After all, the above result may be viewed as a re-axiomatisation of \mathbf{K} , no more. For instance, notice that the hard work in the usual (Henkin type) model-theoretic completeness theorems consists in showing that non-theorems can be refuted in *set-theoretic* (Kripke)-models. To put this into a slogan, which will become fully comprehensible at the end of this chapter:

HENKIN = LINDENBAUM + STONE.

Nevertheless, the algebraic perspective has further uses, which are being discovered only gradually. First, notice that it offers a more general framework than Kripke semantics. For the above Lindenbaum construction to work, one only needs the principle of Replacement of Equivalents; i.e. modally, closure under the rule

$$\text{if } \vdash \varphi \leftrightarrow \psi, \text{ then } \vdash \diamond\varphi \leftrightarrow \diamond\psi.$$

(Algebraically, this just amounts to an identity axiom.)

The above additional equations represent optional further choices.

But even in the realm of the above modal algebra, there exists a whole discipline of universal algebraic notions and results, which turn out to be applicable to modal logic in surprising ways. Two instructive references are [Goldblatt, 1979] and [Blok, 1976]. Here we shall only skim the surface, taking what is needed for the modal definability results of Section 2.4. Thus, we shall need the following three fundamental algebraic notions.

DEFINITION 57. \mathfrak{A}_1 is a modal *subalgebra* of \mathfrak{A}_2 if $A_1 \subseteq A_2$, and the operations of \mathfrak{A}_2 coincide with those of \mathfrak{A}_1 on A_1 .

DEFINITION 58. The *direct product* $\Pi\{\mathfrak{A}_i \mid i \in I\}$ of a family of modal algebras $\{\mathfrak{A}_i \mid i \in I\}$ consists of all functions in the Cartesian product $\Pi\{A_i \mid i \in I\}$, with operations defined component-wise:

$$f + g = (f(i) +_i g(i))_i, \quad f^* = (f(i)^*_i)_i; \text{ etc.}$$

DEFINITION 59. A function f is a *homomorphism* from \mathfrak{A}_1 to \mathfrak{A}_2 if it respects all operations:

$$f(a +_1 b) = f(a) +_2 f(b), \quad f(a^{*1}) = f(a)^{*2}; \text{ etc.}$$

These three operations are fundamental in algebra because they characterise algebraic *equational definability*. This is the content of 'Birkhoff's Theorem':

A class of algebras is defined by the validity of a certain set of algebraic equations (under all assignments) if and only if that class is closed under the formation of subalgebras, direct products and homomorphic images. (For a proof, cf. [Grätzer, 1968].) There is much more to Universal Algebra, of course, but this is what we shall need in the sequel.

Kripke frames induce modal algebras. In order to tap the above resources, a systematic connection is needed between the earlier semantic structures and modal algebras.

To begin with, each Kripke frame $F = \langle W, R \rangle$ gives rise to the following modal algebra

$$A(F) = \langle P(W), \emptyset, W, \cup, -, \pi \rangle$$

where π is the *modal projection* of 2.1:

$$\pi(X) = \{w \in W \mid \exists v \in XRw\} \quad (X \subseteq W).$$

As for truth of modal formulas, it is immediate that a modal formula φ is true in F if and only if its corresponding modal equation $a(\varphi)$ is identical to 1 in the algebra $A(F)$. For instance, truth of

$$\diamond\Box(p \vee q) \rightarrow \diamond(\Box p \vee \Box q),$$

or equivalently

$$\neg\diamond\neg\diamond\neg(p \vee q) \vee \diamond(\neg\diamond\neg p \vee \neg\diamond\neg q)$$

is equivalent to the validity of the identity

$$(x + y)'**' + (x'*' + y'*')^* = 1.$$

Thus, A maps single Kripke frames to modal algebras. But what happens to the characteristic modal connections between frames, as in Section 2.1? We shall take them one by one.

First, if F_1 is a *generated subframe* of F_2 , then the obvious restriction map sending $X \subseteq W_2$ to $X \cap W_1$ is a modal *homomorphism* from $A(F_2)$ onto $A(F_1)$. (The key observation is that R_2 -closure of W_1 guarantees homomorphic respect for the projection operator π .) Next, the algebra induced by a *disjoint union* $\oplus\{F_i \mid i \in I\}$ is isomorphic, in a natural way, to the *direct product* $\prod\{A(F_i) \mid i \in I\}$. One simply associates a set X of worlds in the former with the function $(X \cap W_i)_{i \in I}$.

Finally, and this happy ending will be predictable by now, if F_2 is a zigzag-morphic image of F_1 through f , then the stipulation

$$A(f)(X) =_{\text{def}} f^{-1}[X]$$

defines an isomorphism between $A(F_2)$ and a *subalgebra* of $A(F_1)$. (This time, the two relational clauses in the definition of ‘zigzag morphism’ ensure that $A(f)$ respects projections.) Notice the reversal in direction in the latter case: this is a common phenomenon in these ‘categorical connections’.

Modal algebras induce Kripke structures. There is a road back. Conversely, modal algebras may be ‘represented’ as if they had come from an underlying base frame. The idea of this so-called *Stone Representation* is as follows. (It is due to Jónsson and Tarski around 1950.)

Worlds w are to be created such that an element a in the algebra may be thought of as the set of w ‘in a ’. But then, the desired correspondence between algebraic and set-theoretic operations becomes:

$$\begin{aligned} \text{no set } w \text{ is in } 0, \text{ all sets } w \text{ are in } 1, \\ w \text{ is in } a + b \quad \text{iff} \quad w \text{ is in } a \text{ or } w \text{ is in } b, \\ w \text{ is in } a' \quad \text{iff} \quad w \text{ is not in } a. \end{aligned}$$

Thus, as w searches through A ‘where it belongs’, it picks out a set X such that

$$\begin{aligned} 0 &\notin X, & 1 &\in X, \\ a + b \in X &\text{ iff } & a \in X &\text{ or } b \in X, \\ a' \in X &\text{ iff } & a &\notin X. \end{aligned}$$

Such sets X are called *ultrafilters* on \mathfrak{A} . Thus, let

$$W(\mathfrak{A}) = \text{all ultrafilters on } \mathfrak{A}.$$

A suitable alternative relation may be found through the same motivation as in Section 2.1.

$$\langle w, v \rangle \in R(\mathfrak{A}) \quad \text{iff} \quad \text{for each } a \in A, \text{ if } a \in v, \text{ then } a^* \in w.$$

So, each modal algebra \mathfrak{A} induces a Kripke frame

$$F(\mathfrak{A}) = \langle W(\mathfrak{A}), R(\mathfrak{A}) \rangle.$$

This time, truth in \mathfrak{A} and truth in $F(\mathfrak{A})$ need not correspond, however. For, $F(\mathfrak{A})$ may harbour many more sets of worlds than just those corresponding to the elements a of the algebra — and hence it contains additional potential falsifiers. Thus, the implication goes only one way. The equation $t_1 = t_2$ is valid in \mathfrak{A} , where the polynomials t_1, t_2 correspond to the modal formulas φ_1, φ_2 , when $\varphi_1 \leftrightarrow \varphi_2$ is true in $F(\mathfrak{A})$. A complete equivalence is only restored by changing $F(\mathfrak{A})$ to the *general frame*

$$F(\mathfrak{A}) = \langle W(\mathfrak{A}), R(\mathfrak{A}), \mathfrak{W}(\mathfrak{A}) \rangle,$$

where $\mathfrak{W}(\mathfrak{A})$ consists of all sets of the form

$$\{w \in W(\mathfrak{A}) \mid a \in w\} \quad (a \in A).$$

So, what we now get is a two-way connection between *modal algebras* and *general frames* — and here lies the genesis of the latter notion. Two ways; for, it is easily seen that all previous insights about the mapping A apply equally well to general frames, instead of merely ‘full’ frames.

Again, the interest of the present connection may be gauged by seeing what happens to the three fundamental algebraic operations when translated through F into Kripke-semantic terms.

First, if \mathfrak{A}_1 is a modal *subalgebra* of \mathfrak{A}_2 , then the obvious restriction map sending ultrafilters w on \mathfrak{A}_2 to ultrafilters $w \cap A_1$ on \mathfrak{A}_1 is a *zigzag morphism* from $F(\mathfrak{A}_2)$ onto $F(\mathfrak{A}_1)$.

Next, the *direct product* of a family $\{\mathfrak{A}_i \mid i \in I\}$ has an F -image containing the *disjoint union* $\oplus\{F(\mathfrak{A}_i) \mid i \in I\}$. No isomorphism need obtain, however: a slight flaw in our correspondence.

But finally, if \mathfrak{A}_2 is a *homomorphic image* of \mathfrak{A}_1 through f , then the map $F(f)$, defined by setting

$$F(f)(w) =_{\text{def}} f^{-1}[w],$$

sends \mathfrak{A}_2 -ultrafilters to \mathfrak{A}_1 -ultrafilters, in such a way that it embeds $F(\mathfrak{A}_2)$ isomorphically as a *generated subframe* of $F(\mathfrak{A}_1)$.

Back and forth. So far, so good. Modal algebras induce general frames, and these, in their turn, induce modal algebras. But, what happens on a return-trip?

One case is simple, by construction:

THEOREM 60. $A(F(\mathfrak{A}))$ is isomorphic to \mathfrak{A} .

The converse direction is more difficult. $(F(A(G)))$ need not be isomorphic to F , for general frames G . This is precisely what we noted in connection with ‘possible world constructions’ in Section 2.1. But, as was announced there, it can be ascertained which conditions on general frames G do guarantee such an isomorphism.

DEFINITION 61. A general frame $G = (W, R, \mathfrak{W})$ is *descriptive* if it satisfies *Leibniz’ Principle for identity*:

$$1. \quad \forall xy \in W (x = y \leftrightarrow \forall Z \in \mathfrak{W} (x \in Z \leftrightarrow y \in Z))$$

as well as *Leibniz’ Principle for alternatives*:

$$2. \quad \forall xy \in W (Rxy \leftrightarrow \forall Z \in \mathfrak{W} (y \in Z \rightarrow x \in \pi(Z))).$$

Moreover, it should satisfy *Saturation*:

$$3. \quad \text{each subset of } \mathfrak{W} \text{ with the finite intersection property has a non-empty total intersection.}$$

The following basic result is in [Goldblatt, 1979].

THEOREM 62. $F(A(G))$ is isomorphic to G if and only if G is descriptive.

The standard examples of descriptive frames are the general frames derived from *Henkin models* in modal completeness proofs, by taking for \mathfrak{W} the range of modally definable sets of worlds. It may also be noticed that general frames G which are themselves of the form $F(\mathfrak{A})$ are always descriptive. Thus, for certain theoretical purposes, the ‘proper’ bijective correspondence may be said to be that between modal algebras and descriptive frames, which are ‘stable’ under the possible worlds construction described in Section 2.1.

The categorial connection. The above connections between modal algebras and Kripke structures run deeper than might appear at first sight. The

general picture is that of two mathematical worlds, or ‘categories’, which turn out to be quite similar in structure:

⟨Modal algebras, homomorphisms into⟩
 ⟨General frames, zigzag morphisms into⟩.

The earlier considerations may be summed up in the following two schemata:

$$\begin{array}{ccc}
 G_1 & \xrightarrow{f} & G_2 \\
 \downarrow & & \downarrow \\
 A(G_1) & \xleftarrow{A(f)} & A(G_2)
 \end{array}
 \qquad
 \begin{array}{ccc}
 \mathfrak{A}_1 & \xrightarrow{f} & \mathfrak{A}_2 \\
 \downarrow & & \downarrow \\
 F(\mathfrak{A}_1) & \xleftarrow{F(f)} & F(\mathfrak{A}_2)
 \end{array}$$

So, A, F are what a category theorist would call ‘contravariant’ functors. Therefore, information concerning the one category may sometimes be transferred to the other. Thus, a ‘categorical transfer’ arises, of which we mention a few phenomena. (The following passage can be skipped by readers unfamiliar with Category Theory or Universal Algebra).

The category of modal algebras has among its internal limit constructions the formation of *terminals* (viz. the degenerate single point algebras) and *pull-backs*. Hence, it is closed under *finite limits* in general. Through A, F , we may derive that the category of general frames is closed under *finite co-limits*, specifically under *initials* (allowing the *empty* frame) and *push-outs*. (In this connection, the ‘adjointness’ behaviour of A, F may be investigated.) The preservation behaviour of modal formulas under such limit constructions remains to be studied.

An algebraically well-motivated notion is that of a *free algebra*. What corresponds to these in the realm of general frames? A surprising connection with modal completeness theory appears. The Stone representations of free algebras are essentially *Henkin general frames* (proposition letters correspond to free generators of the algebra). The latter structures were characterised semantically in [Fine, 1975], in terms of certain ‘universal embedding’ properties with respect to zigzag morphisms. This turns out to follow directly, as the dual of the ‘homomorphic extension’ definition of free algebras.

Our final example concerns another algebraic classic, the notion of a *subdirectly irreducible* modal algebra (used with great versatility in [Blok, 1976]). These turn out to correspond almost (not quite) to rooted general frames whose domain consists of one root world together with its R -successors, their R -successors, etcetera. The famous Birkhoff Theorem stating that

Every (modal) algebra is a subdirect product of subdirectly irreducibles,

may then be compared with the simple Kripke-semantic observation that

Every general frame is a zigzag-morphic image of the disjoint union of its rooted generated subframes.

These examples will have made it clear how the categorial connection between modal algebra and possible worlds semantics can be a very rewarding perspective.

2.4 From Classical to Modal Logic

Reversing the direction of the earlier correspondence study (Section 2.2), there arises

DEFINITION 63. $\mathbf{P1}$ is the set of all first-order sentences in $R, =$ for which a modal formula exists defining the same class of Kripke frames.

All earlier examples of formulas in $\mathbf{M1}$ also provide examples for $\mathbf{P1}$, of course. Therefore, here are some more general results straightaway.

Some methods exist for *proving* the existence of modal definitions.

THEOREM 64. *Each first-order sentence of the form $\forall xU\varphi$, where U is a (possibly empty) sequence of restricted universal quantifiers, of the form*

$$\forall u(Rvu \rightarrow \quad (\text{with } u, v \text{ distinct}))$$

followed by a matrix φ of atomic formulas $u = v, Ruv$ combined through \wedge, \vee , belongs to $\mathbf{P1}$.

Proof. The relevant combinatorial argument is based on the heuristics explained in the introduction. Cf. [van Benthem, 1976]. ■

Some examples of formulas of this type are

$$\text{reflexivity: } \forall xRxx, \text{ transitivity: } \forall x\forall y(Rxy \rightarrow \forall z(Ryz \rightarrow Rxz))$$

and

$$\text{connectedness: } \forall x\forall y(Rxy \rightarrow \forall z(Rxz \rightarrow (Rzy \vee Ryz))).$$

Disproving definability proceeds through counter-examples to preservation behaviour.

EXAMPLE 65.

1. $\exists xRxx$ is outside of $\mathbf{P1}$.

It holds in $\langle\{0, 1\}, \{(1, 1)\}\rangle$; but not in its generated subframe $\langle\{0\}, \emptyset\rangle$.

2. $\forall x\forall yRxy$ is outside of $\mathbf{P1}$.

It is preserved under generated subframes, but not under disjoint unions. On $\langle\{0\}, \{(0, 0)\}\rangle$ and $\langle\{1\}, \{(1, 1)\}\rangle$, the relation is universal; but not on $\langle\{0, 1\}, \{(0, 0), (1, 1)\}\rangle$.

3. $\forall x \neg Rxx$ is outside of **P1**.

It is preserved under generated subframes and disjoint unions; but not under zigzag-morphic images, witness the Introduction.

4. $\forall x \exists y (Rxy \wedge Ryy)$ is outside of **P1**.

It is preserved under all three operations mentioned up till now, but not inversely under the formation of ultrafilter extensions. It can be shown to hold in $ue(\langle N, < \rangle)$, while failing in $\langle N, < \rangle$.

An important general result is casting its shadows here [Goldblatt and Thomason, 1974]:

THEOREM 66. *An elementary class of Kripke frames is modally definable if and only if it is closed under the formation of generated subframes, disjoint unions and zigzag-morphic images, while its complement is closed under the formation of ultrafilter extensions.*

Proof. This argument is given in heuristic outline here, as it is one of the most elegant applications of algebraic results in modal semantics.

Evidently, modally definable classes of Kripke frames exhibit all the listed closure phenomena: the surprising direction leads from ‘closure’ to ‘definability’.

First, notice that one closure condition can be added for free, by an earlier result. Theorem 30 implies that our class \mathfrak{K} of frames is itself closed under the formation of ultrafilter extensions: if $F \in \mathfrak{K}$, then the relevant elementary equivalent $F' \in \mathfrak{K}$ (\mathfrak{K} being elementary), and hence so is its zigzag-morphic image $ue(F)$.

Now the obvious strategy is to show that \mathfrak{K} equals $\text{MOD}(\text{Th}_{\text{mod}}(\mathfrak{K}))$, i.e. the class of Kripke frames verifying each modal formula which is valid throughout \mathfrak{K} . The nontrivial inclusion here requires us to show that

if $F^* \models \text{Th}_{\text{mod}}(\mathfrak{K})$, then $F^* \in \mathfrak{K}$, for every Kripke frame F^* .

And here is where an excursion into the realm of modal algebra will help. F^* verifies $\text{Th}_{\text{mod}}(\mathfrak{K})$, and hence $A(F^*)$ verifies the equational theory of the class $\{A(G) \mid G \in \mathfrak{K}\}$. (Recall the earlier correspondence between modal formulas and polynomials.) By Birkhoff’s Theorem, in a suitable version, this implies that $A(F^*)$ must be constructible as a *homomorphic image* of some *subalgebra* of some *direct product* $\prod\{A(G_i) \mid i \in I\}$, with $G_i \in \mathfrak{K}$. In a picture,

$$\begin{array}{ccc}
 & \text{surjective} & \\
 A(F^*) & \longleftarrow & \mathfrak{A} \subseteq \Pi\{A(G_i) \mid i \in I\}. \\
 & \text{homomorphism} &
 \end{array}$$

Now the latter algebra is isomorphic to $A(\oplus\{G_i \mid i \in I\})$, by the earlier duality. Moreover, the latter disjoint union belongs to \mathfrak{R} — by the given closure conditions. So, the picture becomes, for some $G \in \mathfrak{R}$:

$$\begin{array}{ccc}
 & \text{surjective} & \\
 A(F^*) & \longleftarrow & \mathfrak{A} \subseteq A(G). \\
 & \text{homomorphism} &
 \end{array}$$

Now, the transformation F turns this into the corresponding row

$$\begin{array}{ccccc}
 & \text{embedding as} & & \text{surjective} & \\
 FA(F^*) & \longrightarrow & F(\mathfrak{A}) & \longleftarrow & FA(G). \\
 & \text{generated subframe} & & \text{zigzag morphism} &
 \end{array}$$

But then, finally, the following walk through the diagrams suffices. $G \in \mathfrak{R} \Rightarrow FA(G) = ue(G) \in \mathfrak{R}$ (by the above observation) $\Rightarrow F(\mathfrak{A}) \in \mathfrak{R}$ (closure under zigzag images) $\Rightarrow FA(F^*) \in \mathfrak{R}$ (closure under generated subframes) $\Rightarrow F^* \in \mathfrak{R}$ ('anti-closure' under ultrafilter extensions). ■

Actually, this result does not yet characterise **P1**, as it talks about modal definability by any set, finite or *infinite*. The additional strengthenings needed for zeroing in on **P1** are hardly enlightening, however.

The result also says a little bit more. Adding closure under ultrafilter extensions, while removing the condition of elementary definability, yields a characterisation of those classes of Kripke frames definable by means of a *canonical* modal logic in the sense of the Introduction (i.e. one which is complete with respect to its Henkin frames). Moreover, the above proof heuristics may also be used to formulate a general closure condition on classes of Kripke frames necessary and sufficient for definability by means of just *any* set of modal formulas ('SA-constructions'; cf. [Goldblatt and Thomason, 1974]).

As with the earlier ultrapower characterisation of **M1**, the above characterisation gives no *effective* information concerning the formulas in **P1**. What is needed are 'preservation theorems' giving the syntactic cash value of the given four closure conditions. Several of these have been given in [van Benthem, 1976], extending earlier results, e.g. of Feferman and Kreisel.

Here is an idea. Preservation under generated subframes allows only formulas constructed from atomic formulas and their negations, using

\forall, \wedge, \vee as well as *restricted* existential quantifiers $\exists v(Ruv \wedge (u, v \text{ distinct}))$.

Preservation under disjoint unions admits only one single universal quantifier in front: all others are to be *restricted* to the form $\forall v(Ruv \rightarrow)$. Finally, preservation under zigzag images forbids the negations, and we are left with

THEOREM 67. *A first-order sentence is preserved under the formation of generated subframes, disjoint unions and zigzag-morphic images if and only if it is equivalent to one of the form $\forall x\alpha(x)$, where $\alpha(x)$ has been constructed from atomic formulas using only conjunction, disjunction and restricted quantifiers.*

Proof. By elementary chain constructions, as in [Chang and Keisler, 1973, Chapter 3.1]. ■

For preservation under ultrafilter extensions, only some partial results have been found. (After all, the class of sentences preserved under such a complex operation *need* not even be effectively enumerable.)

As for the total complexity of **P1**, this may well be considerable — as was the case with **M1**. Are the two classes perhaps recursive in each other?

2.5 Modal Predicate Logic

As in much technical work in this area, modal *propositional* logic has been studied up till now. Modal *predicate* logic, however important in philosophical applications, is much less understood. (Cf. Chapter 2.5 in this *Handbook*.) Nevertheless, in the case of Correspondence Theory, an excuse for the neglect may be found in Theorem 69 below.

The unfinished state of the art shows already in the fact that no commonly accepted notion of semantic structure, or truth definition exists. Hence, we fix one particular, reasonably motivated choice as a basis for the following sketch of a predicate-logical variant of the earlier theory.

The *language* is the ordinary one of predicate logic, with added modal operators. *Structures* are tuples

$$\mathfrak{M} = \langle W, R, D, V \rangle,$$

where the *skeleton* $\langle W, R, D \rangle$ is a Kripke frame with a *domain function* D assigning sets of individuals D_w to each world $w \in W$. The valuation V supplies the interpretation of the nonlogical vocabulary at each world.

The *truth definition* explicates the notion

$$\text{'}\varphi(x)\text{ is true in } \mathfrak{M} \text{ at } w \text{ for } d\text{'},$$

where the sequence d assigned to the free individual variables x comes from D_w . Its key options are embodied in the clauses for the individual quantifiers: these are to range over D_w , plus that for the modal operator:

$\Box\varphi(x)$ is true at w for d if, for each R -alternative v for w such that d is in D_v , $\varphi(x)$ is true at v for d .

Thus, necessity means ‘truth in all alternatives, where defined’.

As before, truth in a skeleton (at some world, for some sequence of individuals) means truth under all possible valuations. Again, in this way modal axioms start expressing properties of R, D — and their interplay.

The relevant matching ‘working language’ on the classical side will now be a *two-sorted* one: one sort for worlds, another for individuals. Its basic predicates are the two sortal identities, R between worlds, as well as the sort-crossing Exw : ‘ x is in the domain of w ’, or ‘ x exists at w ’.

EXAMPLE 68. The Barcan Formula $\forall x\Box Ax \rightarrow \Box\forall xAx$ defines

$$\forall wv(Rwv \rightarrow \forall x(Exv \rightarrow Exw)).$$

Proof. ‘ \Leftarrow ’: Assume $\forall x\Box Ax$ at w , and consider any R -alternative v . For all $d \in D_v, d \in D_w$ (by the given condition), whence $\Box Ad$ holds at w — and, hence, Ad holds at v .

‘ \Rightarrow ’: The Barcan Formula will hold under the following particular assignment: $V_u(A, d) = 1$ if Rwu and $d \in D_w$.

This V verifies the antecedent, and hence the consequent. The relational condition follows. ■

Thus, the Barcan Formula expresses an interaction between R and D . This is not accidental. For *pure* R -principles, we have the following *conservation* result.

THEOREM 69. *There exists an effective translation from sentences φ of modal predicate logic to formulas $p(\varphi)$ of modal propositional logic such that,*

if φ is equivalent to some pure $R, =$ -sentence α , then $p(\varphi)$ already defines α in the sense of Section 2.2.

Proof. p merely crosses out quantifiers in some suitable way. For full details (here and elsewhere) cf. [van Benthem, 1983]. ■

Besides the Barcan Formula, there are three further fundamental ‘de re/de dicto interchanges’. One of these provides a new example of non-first-order definability.

EXAMPLE 70.

1. $\Box\forall xAx \rightarrow \forall x\Box Ax$ is universally valid,
2. $\exists x\Box Ax \rightarrow \Box\exists xAx$ defines $\forall wv(Rwv \rightarrow \forall x(Exw \rightarrow Exv))$,

3. $\Box\exists xAx \rightarrow \exists x\Box Ax$ defines an essentially higher-order condition on $R, =, E$.

Despite the superficial resemblance to the McKinsey Axiom of section 2.2., the proof for the latter result is quite different from that of Example 43. Interested readers may notice that the above principle holds in worlds with a *finite* chain of overlapping two-element successors:

$$\{1, 2\}, \{2, 3\}, \{3, 4\}, \dots, \{n-1, n\}, \{n, n+1\}.$$

But, it may fail in the presence of *infinite* such chains, and then compactness lurks.

Further systematic reflection on the above ‘positive’ result yields a method of substitutions again, with an outcome like that of Theorem 48:

THEOREM 71. *Formulas of the form $\varphi \rightarrow \psi$, with φ constructed from atomic formulas prefixed by a (possibly empty) sequence of \forall, \Box , using only \wedge, \vee, \exists and \Diamond , and ψ constructed from atomic formulas using $\wedge, \vee, \exists, \Diamond$ as well as \forall, \Box , are all uniformly first-order definable.*

The global mathematical characterisation of first-order definability remains essentially the same in this area, whence it is omitted here.

Something which does *not* generalise easily, however, is the algebraic approach of Section 2.3. This is an endemic problem in classical (and intuitionistic) logic already: elegant algebraization stops at the gates of predicate logic. There could be an area of ‘modal cylindric algebra’ of course (cf. [Henkin *et al.*, 1971]), but none exists yet. (For an interesting related area, cf. the extension of modal propositional algebra to the modal program algebra of dynamic logicians (cf. [Kozen, 1979] or the Dynamic Logic chapter in volume 5 of this *Handbook*.) As a consequence, we still lack an elegant characterisation of the modally definable fragment of the present two-sorted first-order language.

What we do have, however, is such a characterisation for that same language with *parametrised predicate constants* $A(w, -)$ for the predicate constants $A(-)$ of the modal predicate logic. Thus, this is the appropriate language for the *first-order* transcription of the above truth definition. The Barcan Formula, for example, becomes

$$\begin{aligned} \forall x(Ewx \rightarrow \forall v((Ewv \wedge Exv) \rightarrow Avx)) \rightarrow \\ \rightarrow \forall v(Rwv \rightarrow \forall x(Exv \rightarrow Avx)). \end{aligned}$$

As in Theorem 18, two characteristic modal relations suffice for characterising the modal transcriptions among the class of all formulas of this language. In order to end on an optimistic note, here is the relevant result.

First, modal predicate logic knows *generated submodels*, just as in Section 2.1. Moreover, the earlier *zigzag relations* may be enriched so as to incorporate individual back-and-forth choices, as in the Ehrenfeucht–Fraïssé approach to first-order definability.

DEFINITION 72. A *zigzag connection* C between two models M_1, M_2 relates finite sequences (w, x) of equal length (w a world, x a sequence of individuals in the domain of w) in such a way that

1. all such sequences occur: those from M_1 in the domain, those from M_2 in the range of C
2. if $C(w, x)(v, y)$ and $w' \in W_1$, with $R_1 w w', x \in D_w$, then $C(w', x)(v', y)$ for some $v' \in W_2$ with $R_2 v v', y \in D_{v'}$,
and analogously in the opposite direction ('world zigzag')
3. if $C(w, x)(v, y)$ and $d \in D_w$,
then $C(w, x \hat{\ } d)(v, y \hat{\ } e)$ for some $e \in D_v$,
and vice versa. ('individual zigzag')
4. if $C(w, x)(v, y)$, then the map $(x)_i \rightarrow (y)_i$ is a *partial isomorphism* between $\langle D_w, V_w \rangle$ and $\langle D_v, V_v \rangle$.

Now, transcriptions of modal formulas are *invariant* for generated submodels and zigzag connections, in the obvious sense. E.g. the latter have been made precisely in such a way that for modal φ ,

$$\varphi \text{ is true at } w \text{ for } x \quad \text{iff} \quad \varphi \text{ is true at } v \text{ for } y, \quad \text{when } C(w, x)(v, y).$$

THEOREM 73. A formula $\varphi = \varphi(w, x)$ of the two-sorted world/individual language is (equivalent to the transcription of) a modal formula if and only if it is invariant for generated submodels and zigzag connections.

Proof. This follows from the main proof in [van Benthem, 1981b]. ■

On the whole, exciting technical results are yet scarce in modal predicate logic — and Correspondence Theory is no exception.

2.6 Higher-Order Correspondence

Modal formulas define second-order (Π_1^1) conditions on the alternative relation in all cases, and first-order conditions in some. In the perspective of abstract model theory, two possible generalisations arise here.

Instead of the first-order target language, one may consider suitable extensions. For instance, in Theorem 37, the relevant relational condition was definable in $L_{\omega_1, \omega}$: first-order logic with countable conjunctions and disjunctions. Not all modal formulas become definable here, however. E.g. Löb's Axiom defined a form of well-foundedness, which is known to be beyond $L_{\omega_1, \omega}$, or indeed any language of the $L_{\infty, \omega}$ -family. On the other hand, this time for instance, the defining condition is already in 'weak second-order logic' L^2 , allowing quantification over *finite* sets of individuals. Thus,

various wider classes of definability could be considered for modal formulas, short of Π_1^1 . And, in fact, even the latter case itself is interesting. Which Π_1^1 -sentences, for example, admit of modal definitions?

Given the general lack of semantic characterisations for such higher logics, such characterisations for their modal fragments are also difficult to obtain. One observation might be that both $L_{\omega_1\omega}$ and L^2 have the property of *invariance for partial isomorphism* (cf. van Dalen's chapter in Volume 1 of this *Handbook*). It will be of interest to study this preservation condition on modal formulas. In fact, no counter-examples have been discovered yet; but these do exist in tense logic. (The rationals $\langle Q, < \rangle$ and the reals $\langle R, < \rangle$ are a classical example of partially isomorphic structures, but there exists a tense-logical formula expressing Dedekind Completeness, which is valid on the latter, though not on the former frame.)

On the other hand, the modal propositional language could itself be strengthened, notably by the introduction of propositional quantifiers $\forall p, \exists p$, which have occurred in various places in the literature (cf. Garson's chapter in Volume 3 of this *Handbook*). Thus, e.g. $\forall p(\Box\Diamond p \rightarrow \exists q\Diamond\Box q)$ would become an admissible formula, but also $\Box\exists p\Diamond p \rightarrow \Diamond\forall q\Diamond\Box q$. Actually, there is a choice here, whether to allow the propositional quantifiers in the scope of modal operators or not. Henceforth, we consider the second, more restricted option.

In the usual manner, a prenex hierarchy arises here, with all propositional quantifiers in front, of which the original modal formulas form the Π_1^1 -part (universal prefix). The next simplest cases are Σ_1^1 (existential prefix) and Δ_2^1 . In fact, the latter has a reasonable motivation through the modal 'rules' mentioned in Section 3.2 below.

It has been observed by Gabbay that the following rule defines *irreflexivity* of Kripke frames:

$$\text{'if } F \models (\Box p \wedge \neg p) \rightarrow \varphi[w] \text{ (with } \varphi \text{ } p\text{-free), then } F \models \varphi[w]\text{'}$$

The general pattern here is that of ' $F \models \varphi[w]$ only if $F \models \psi[w]$ ', i.e. an implication of two Π_1^1 -formulas, which is Δ_2^1 . (It may be written either in the form $\forall\exists$ or $\exists\forall$.)

Actually, the above specific example is already Σ_1^1 , as it amounts to $\forall pq((\Box p \wedge \neg p) \rightarrow q) \rightarrow \forall qq$, i.e. $\forall p((\Box p \wedge \neg p) \rightarrow \perp) \rightarrow \forall qq$, i.e. $\forall p((\Box p \wedge \neg p) \rightarrow \perp) \rightarrow \perp$, i.e. $\exists p(\Box p \wedge \neg p)$. Another relevant observation is that implications of the above form $\forall \rightarrow \forall$, if first-order definable at all, already have a first-order definable consequent. We do not go into these specific matters here, but note a general issue.

As often in higher-order logic, we are interested in *hierarchy* results. For instance, how much power of first-order definability is added at each stage? It is evident that Σ_1^1 -definability adds essentially just all negations of the (local) principles in **P1** (cf. Section 2.4), while Δ_2^1 adds conjunctions and disjunction across **P1** and the latter 'mirror image'.

QUERY. Does the second-order prenex hierarchy induce an *ascending* corresponding hierarchy of modally definable first-order principles about the alternative relation?

This possibly ascending hierarchy cannot exhaust all first-order principles, as higher-order modal formulas do retain one basic preservation property: their local truth is invariant under passing to generated subframes. (The Generation Theorem 15 yields this consequence all the way up, not just for the original modal Π_1^1 -formulas.) But then, we know what this semantic constraint means in syntactic terms for first-order formulas (cf. [van Benthem, 1976, Chapter 6]). These will be the ‘almost-restricted’ ones consisting of one universal quantifier followed by a compound of atomic formulas with negation, conjunction and restricted quantifiers $\exists y(Rxy \wedge)$.

The other preservation properties of Section 2.1 are lost, however. As was observed earlier, irreflexivity ($\forall x \neg Rxx$) becomes definable and, hence, preservation under zigzag morphisms fails. Anti-preservation under ultrafilter extensions fails, because the earlier example $\forall x \exists y(Rxy \wedge Ryy)$ becomes definable as well. (A straightforward definition uses a propositional quantifier within a modal scope: $\diamond \forall p(\Box p \rightarrow p)$. But there is a nonembedded substitute in the form of $\exists p(\diamond p \wedge \forall q \Box(p \rightarrow (\Box q \rightarrow q)))$.)

Thus, we arrive at the following

QUESTION. Can every almost-restricted first-order formula $\forall x \varphi(x)$ be defined at some level in the modal propositional quantifier hierarchy?

Using ‘simulation’ of restricted first-order quantification by propositional quantifiers, one may indeed handle most obvious cases. Here is one illustration of the procedure

EXAMPLE. Let $\varphi(x)$ be $\exists y(Rxy \wedge \forall z(Ryz \rightarrow (Rzz \vee (Rzy \wedge Rzx))))$. The idea is to define $\{x\}, \{y\}, \{z\}$, in a sense, as far as necessary (i.e. on the set consisting of x , its R -, R^2 - and R^3 -successors) — and then to express all desired relations between these by means of modal formulas:

$$\begin{aligned} & \exists p_x(p_x \wedge \forall q_x(((p_x \wedge q_x) \vee \diamond(p_x \wedge q_x) \vee \diamond \diamond(p_x \wedge q_x) \vee \diamond \diamond \diamond(p_x \wedge q_x)) \rightarrow (\Box(p_x \rightarrow q_x) \wedge \Box \Box(p_x \rightarrow q_x) \wedge \Box \Box \Box(p_x \rightarrow q_x))) \text{ [this} \\ & \text{ makes } p_x \text{ unique to the extent indicated]} \wedge \exists p_y(\diamond p_y \wedge \text{ [same} \\ & \text{ uniqueness statement]} \wedge \forall p_z((\diamond(p_y \wedge \diamond p_z) \wedge \text{ [same uniqueness} \\ & \text{ statement]}) \rightarrow (\forall q_z \Box \Box(p_z \rightarrow (\Box q_z \rightarrow q_z)) \text{ [i.e. ‘} Rzz \text{’]} \vee \diamond \diamond(p_z \wedge \\ & \diamond p_x \wedge \diamond p_y) \text{ [i.e. ‘} Rzy \wedge Rzx \text{’]})))). \end{aligned}$$

Accordingly, our conjecture is that the above question has a positive answer.

We conclude with one further

QUESTION. Does the addition of propositional quantifiers within modal scopes add any power of expression?

3 OTHER INTENSIONAL NOTIONS

Modal logic is only one branch, be it a paradigmatic one, of intensional logic in general. But also in other intensional areas, a Correspondence Theory is possible. In some cases, the generalisation runs smoothly: existing notions and results may be applied at once, or after only minor modification. A case in point is *tense logic*, to be treated in Section 3.1. More challenging generalisations arise when the relevant intensional semantics exhibit strong peculiarities, diverging from the earlier modal case. Sometimes, these assume the form of pre-conditions on the alternative relation; but maybe the most important hurdle is when a restriction is proclaimed on ‘admissible assignments’. Both phenomena occur in *conditional logic*, the topic of Section 3.2. That, even under such circumstances, an interesting Correspondence Theory may remain, is shown by the example of *intuitionistic logic* in Section 3.3.

These two new features do not exhaust the possible semantic variation. One may also move to the interplay of different kinds of intensional operators, for instance, using correspondence to connect different alternative relations.

EXAMPLE. In *dynamic logic*, two modal operators \Box, \Box^* figure, which may be provided with two alternative relations R, R^* . (Recall that $\Box a$ means ‘after every successful computation of a ’, while the intuitive meaning of $\Box^* a$ is to be: ‘after any finite number of runs of a ’.) Now, from a correspondence point of view, the well-known *Seegerberg Axioms*

$$\begin{aligned} \Box^* p &\rightarrow \Box p \\ \Box^* p &\rightarrow \Box \Box^* p \\ \Box^* (p \rightarrow \Box p) &\rightarrow (\Box p \rightarrow \Box^* p) \end{aligned}$$

define precisely the condition that

$$R^* \text{ coincides with the transitive closure of } R.$$

The very exoticness of this example to many readers may help to show that Correspondence Theory is omnipresent.

No systematic developments will be given in the following sections. Their purpose is to convey an impression of notions and themes, through mainly illustrative examples. Indeed, here is where the reader may wish to carry on the torch herself.

3.1 *Tense Logic*

Traditionally, tense-logical structures have been taken to be temporal orders $\langle T, < \rangle$, where T consists of the points in Time, ordered by precedence $<$ (‘earlier than’, ‘before’). The simplest formal language to be chosen has

been that of Prior, adding operators G ('it is always going to be'), H ('it has always been') to some propositional base. We add F ('future'), P ('past') as derived notions. (Cf. the chapter on Basic Tense logic in volume 6 for the necessary background in tense logic.)

Of the amazing diversity of 'ontological' and 'linguistic' questions concerning this temporal semantics, only a few themes will be mentioned here. (Cf. [van Benthem, 1985] for a varied exploration.)

Explaining philosophical dicta. In his famous paper 'The Unreality of Time', the philosopher McTaggart enunciated several temporal principles. One of these reads [McTaggart, 1908]:

"If one of the determinations past, present and future can ever be applied to (an event), then one of them has always been and always will be applicable, though of course not always the same one."

When translated into Priorean axioms, this becomes a list:

1. $Pq \rightarrow H(Fq \vee q \vee Pq)$
2. $Pq \rightarrow GPq$
3. $q \rightarrow HFq$
4. $q \rightarrow GPq$
5. $Fq \rightarrow HFq$
6. $Fq \rightarrow G(Fq \vee q \vee Pq)$.

What do these principles mean? The answer may be obtained through the method of substitutions (fitted to the temporal case — but such generalisations will be presupposed tacitly henceforth).

EXAMPLE 74.

1. defines *left-connectedness*: $\forall x \forall y < x \forall z < x (y < z \vee z < y \vee y = z)$,
2. defines *transitivity*: $\forall x \forall y < x \forall z > x y < z$,
3. defines \top ,
4. defines \top .

If G, H had been interpreted through different relations $<_G, <_H$, then (3) and (4) would have expressed that $<_H$ is the *converse* relation of $<_G$.

5. defines *transitivity* again: $\forall x \forall y > x \forall z < x z < y$,

6. defines *right-connectedness*: $\forall x \forall y > x \forall z > x (y < z \vee z < y \vee y = z)$.

Thus, the McTaggart temporal picture is one of linear flow.

An incompleteness theorem. Simple transfer of earlier modal results establishes the seminal incompleteness result of [Thomason, 1972], in a very simple version.

THEOREM 75. *The tense logic axiomatised by*

$$\begin{array}{ll} H(Hp \rightarrow p) \rightarrow Hp & (\text{L\"ob's Axiom}) \\ GFp \rightarrow FGP & (\text{McKinsey Axiom}) \end{array}$$

is incomplete.

Proof. Specifically, this logic holds in no frame — and yet it is not inconsistent.

First, as to the former statement, recall from Section 2.2 that

1. Löb's Axiom defines *transitivity* of $>$ and *well-foundedness* of $<$.

By the former, $<$ is transitive as well (transitivity is 'independent of the temporal direction', or *isotropic* (cf. [van Benthem, 1985])). Thus, in this special case, Example 51 applies, and we have

2. McKinsey's Axiom defines atomicity: $\forall x \exists y > x \forall z > y z = y$.

A consequence of the latter property is $\forall x \exists y > x y < y$ (cf. Example 65(4)). So, the temporal order must contain instantaneous loops $\dots < y < y < y < \dots$, which contradicts well-foundedness. Therefore, our logic holds in no frame.

Nevertheless, it does hold in a *general* frame, viz. an earlier example from Section 2.1: $\langle N, <, \mathfrak{W} \rangle$, with

$$\mathfrak{W} = \{X \subseteq N \mid X \text{ is finite or } N - X \text{ is finite}\}.$$

The reason was that refutations for the McKinsey Axiom are no longer 'admissible', as these involve infinite alterations. (Thomason gives a speculation at this point concerning the Second Law of Thermodynamics: 'event patterns stabilise'.) But then, the logic cannot be inconsistent: its **K**-theorems hold in all general frames where it is valid. ■

Tense-logical axioms for the temporal order. In [van Benthem, 1985], the following fundamental axioms are derived for any temporal order induced by a *comparative* (in the linguistic sense) 'earlier than'.

1. *irreflexivity*: $\forall x \neg x < x$ ('no vortices in Time')

2. *transitivity*: $\forall x \forall y > x \forall z > y \ z > x$ ('flow')

3. *almost-connectedness*: ('arrows are comparative yard sticks')
 $\forall x \forall y > x \forall z (x < z \vee z < y)$

A version of the latter principle may also be found as the key axiom in Leibniz' relational theory of Space-Time (cf. [Winnie, 1977]).

Which tense-logical axioms correspond? From Section 2.4, we know that (1) is undefinable, (2) yields $Gp \rightarrow GGp$, while (3) just fails to fall under Theorem 67. What the latter result does give is a correspondence between

$$\forall x \forall y > x \forall z > y \forall u > x (y < u \vee u < z)$$

and

$$(F(p \wedge Fq) \wedge Fr) \rightarrow (F(p \wedge Fr) \vee F(r \wedge Fq)).$$

Another example concerns particular temporal orders. One can never hope to fully define such frames categorically by their tense-logical theories. For, by the Generation Theorem, tense-logical formulas cannot distinguish between one single, or several parallel flows of Time — which latter picture is so familiar from contemporary science fiction. Still, if *disjoint unions* of frames are disregarded, we have

THEOREM 76. $\langle N, < \rangle$ is defined categorically by the axioms

$$\begin{aligned} H(Hp \rightarrow p) &\rightarrow Hp \\ Pp &\rightarrow H(Fp \vee p \vee Pp) \\ Fp &\rightarrow G(Fp \vee p \vee Pp) \\ FT & \\ G(Gp \rightarrow p) &\rightarrow (FGp \rightarrow Gp) \end{aligned}$$

The proof is omitted here.

But, e.g. the integers $\langle Z, < \rangle$ cannot be thus defined; as the contraction to a single point remains a zigzag morphism preserving their theory. ($\langle N, < \rangle$ was unafflicted this time: in tense logic, zigzag morphism have *two* backward relational clauses — whence, the earlier contraction fails to quality.)

Time and modality. Combined modal-tense logics with two alternative relations $R, <$ have been repeatedly proposed. For instance, in [White, 1981] we find a logic with characteristic axioms

$$\begin{aligned} Gp \rightarrow GGp, Fp \rightarrow G(Fp \vee p \vee Pp), PT & \quad (\text{D4.3}) \\ Pq \rightarrow \Box Pq & \quad (\text{'irrevocable past'}). \end{aligned}$$

This logic is claimed to be appropriate for an analysis of the famous Diodorean 'Master Argument', identifying *possibility* with *actual or future truth* — a version of what was later to become known as the principle of Plenitude: all metaphysical possibilities are eventually realised in this World.

Our analysis of this claim runs as follows. $Gp \rightarrow GGp$ defines *transitivity* for $<$, the McTaggart Axiom defines right-connectedness; while PT defines *left-succession*: $\forall x \exists y y < x$. The additional ‘mixing postulate’ defines

$$\forall xy(Rxy \rightarrow \forall z(z < x \rightarrow z < y)).$$

CLAIM (1). $\forall xy(Rxy \rightarrow (y < x \vee y = x \vee x < y))$.

Proof. Assume Rxy . Let $z < x$ (by left-succession). Then $z < y$ (‘mix’). The conclusion follows by right-connectedness. ■

CLAIM (2). $\forall xy(Rxy \rightarrow (x < y \vee x = y))$.

Proof. If Rxy and $y < x$, then $y < y$ (‘mix’): *contra* irreflexivity. ■

The outcome is this: *without* ever using transitivity, but *with* irreflexivity (which is presupposed in White’s whole set-up), a relational condition follows which is indeed defined by the Diodorean challenge:

$$\Diamond p \rightarrow (Fp \vee p).$$

This is only one of the many possible semantics for temporal modalities, of course. The correspondence aspect of, e.g. the Occamist ‘branching time’ of [Burgess, 1979] remains to be explored.

Alternative temporal ontologies. Recently ‘interval structures’ have been proposed as an alternative for the above traditional point ontology. From the manifesto of [Humberstone, 1979], a picture emerges of triples

$$\langle I, \subseteq, < \rangle,$$

where \subseteq is *inclusion* among intervals, and $<$ total *precedence*.

Here again, correspondences prove useful in exploring proposed principles. The language has the ordinary tense-logic operators, as well as a modality \Box (‘in all subintervals’). In this notation, Humberstone’s base logic has for its basic axioms

1. $Fp \rightarrow \Box Fp$
2. $F\Diamond p \rightarrow Fp$
3. $\Diamond F\Box p \rightarrow (\Diamond p \vee Fp)$.

By the earlier method of substitutions, equivalents may be found illuminating these:

1. defines $\forall x \forall y > x \forall z \subseteq x y > z$,

a property known as *left monotonicity*,

2. defines $\forall x \forall y > x \forall z \subseteq y \ z > z$,

its dual property of *right monotonicity*. Finally,

3. defines $\forall x \forall y \subseteq x \forall z > y \ (\exists u \subseteq z : u \subseteq x \vee \exists u \subseteq z : u > x)$,

a form of a principle known as *convexity*. ('Stretches of time should be uninterrupted'.)

Starting from the other side, one may impose basic postulates on $\subseteq, <$, asking for definitions in this 'interval tense logic'. For $<$, these might be the earlier-mentioned ones, for \subseteq , a minimum seems to be the requirement of *partial order*, while monotonicity (and convexity) take care of minimal connections between $<, \subseteq$. This would add only two axioms to the preceding ones, viz. **S4** for inclusion. The further condition of *anti-symmetry* is not definable — as may be seen by noting that the map $n \mapsto n$ (modulo 2) is a \subseteq -zigzag morphism sending the anti-symmetric frame $\langle Z, \leq \rangle$ to the non-antisymmetric one $\langle \{0, 1\}, \{ \langle 0, 0 \rangle, \langle 0, 1 \rangle, \langle 1, 0 \rangle, \langle 1, 1 \rangle \} \rangle$.

Many more examples of further correspondences on top of this foundation may be found in Chapter II.3.2 of [van Benthem, 1985].

3.2 Conditionals

From among the teeming multitude of 'conditional logics', three specimens have been included here. As no work of the present kind has been done in this area at all, the following considerations are still very much first steps. (Cf. the Conditional Logic chapter in volume 5 for a discussion of conditional logics.)

Constructive implication

Perhaps the single most effective argument in favour of constructive, as opposed to classical implication is the natural deduction analysis. The *natural* rules for \rightarrow -introduction and \rightarrow -elimination give us only a fragment of all classical pure \rightarrow -tautologies; axiomatised by

$$(A1) \ \varphi \rightarrow (\psi \rightarrow \varphi)$$

$$(A2) \ (\varphi \rightarrow (\psi \rightarrow \chi)) \rightarrow ((\varphi \rightarrow \psi) \rightarrow (\varphi \rightarrow \chi))$$

plus the rule of *modus ponens*. A principle notably outside of this class is Peirce's Law

$$((\varphi \rightarrow \psi) \rightarrow \varphi) \rightarrow \varphi.$$

But really, the same elegance shows up in the Henkin completeness proof. In the usual proof, one starts from a given consistent set — and then has

to extend this arbitrarily to just *any* maximally consistent one, in order to ‘break down’ implications according to the classical truth table. A *canonical* model construction rather uses a unique natural model, viz. that consistent set together with all its consistent extensions, exploiting the evident decomposition rule

$$\Sigma \vdash \varphi \rightarrow \psi \text{ if and only if } \forall \Sigma' \supseteq \Sigma : \text{ if } \Sigma' \vdash \varphi, \text{ then } \Sigma' \vdash \psi.$$

A perfect match arises with the following semantics. Structures are general frames $F = \langle W, R, \mathfrak{W} \rangle$, where R corresponds to the above inclusion relation, and \mathfrak{W} consists of all *R-hereditary* sets of worlds. (Propositions represent *R-cumulative* knowledge on this view.)

A direct study of the above logic on these frames would yield rather clumsy conditions. One case will be exhibited, as it illustrates a variant concept of correspondence, viz. *correspondence for rules* rather than *axioms*.

EXAMPLE 77. Modus Ponens defines the condition ‘every world belongs to some finite *R*-loop’.

Proof. ‘ \Leftarrow ’: Suppose that $xRx_1R \dots Rx_nRx$. Let $V(p), V(q)$ be *R-hereditary* subsets of W , such that $p, p \rightarrow q$ hold at x . Then, successively, p, q hold at x_1, \dots, x_n , and finally at x .

‘ \Rightarrow ’: Suppose that x belongs to no finite *R*-loop. Set $V(p) :=$ the smallest *R-hereditary* set containing $x, V(q) =$ the *R-hereditary* closure of $\{y \mid Rxy\}$. This verifies $p, p \rightarrow q$ at x ; without verifying q . ■

What will be done instead is to postulate the *partial order* behaviour of \subseteq : *reflexivity, transitivity* and *antisymmetry*. Finer peculiarities of (A1), (A2) remain undetectable below this threshold.

Further restrictions on R may now be imposed by stronger axioms; e.g. we can see why Peirce’s Law is characteristic for classical logic.

EXAMPLE 78. Peirce’s Law defines the restriction to single points:

$$\forall xy(Rxy \rightarrow y = x).$$

Proof. ‘ \Leftarrow ’: A simple calculation suffices.

‘ \Rightarrow ’: Suppose that $Rxy, x \neq y$. Set $V(q) = \emptyset, V(p) = \{z \mid Rxz \wedge x \neq z\}$. This makes $(p \rightarrow q) \rightarrow p$ true at x (notice that $p \rightarrow q$ is false at x itself), while falsifying p . (By the way, that V is admissible, i.e. that $V(p)$ is *R-hereditary*, follows from the above general assumption.) ■

But ‘intermediate’ implication axioms exist as well.

EXAMPLE 79. The following principle

$$((p \rightarrow q) \rightarrow p) \rightarrow (((q \rightarrow r) \rightarrow q) \rightarrow p)$$

defines a maximal length 3 for R -chains:

$$\forall xy(Rxy \rightarrow \forall z(Ryz \rightarrow (x = y \vee y = z \vee \forall u(Rzu \rightarrow z = u)))).$$

Proof. Here is the relevant counter-example for the argument in the ‘ \Rightarrow ’-direction. Assume that $xRyRzRu$, while $x \neq y, y \neq z, z \neq u$. Set $V(r) = \emptyset, V(q) = \{v \mid Ruv \wedge u \neq v\} \cup \{v \mid Ryv \wedge \neg Rvz\}, V(p) = \{v \mid Ryv \wedge y \neq v\}$. The principle will be falsified at y . ■

It has not been possible to find other types of intermediate example. Hence, we conclude with a

CONJECTURE. All principles of pure constructive implication define first-order constraints on R ; viz. restrictions to some finite chain length.

Relevant implication

Of the various proposed semantics for relevance logic, here is a perspicuous example from [Gabbay, 1976, Chapter 15]. Structures are now tuples $\langle W, R, V, 0 \rangle$, where 0 is a special world providing a vantage point from which to compare other worlds through the *ternary* relation R . Intuitively, $R_a bc$ is to mean that b is ‘included’ in c , at least from the perspective of a . (One might think of, for example, ‘ a -local inclusion’: $a \cap b \subseteq a \cap c$.) No prior conditions are imposed on this relation.

This is not to say that these are not to be found at all. For instance, it may be shown that the mentioned local inclusion relation is characterised by two *betweenness* axioms:

1. $R_a bc \leftrightarrow R_b ac$ (interchanging boundaries)
2. $(R_a bc \wedge R_d ae \wedge R_d be) \rightarrow R_d ce$

(I.e. if $c \in [a, b], a \in [d, e], b \in [d, e]$, then $c \in [d, e]$: a form of convexity.)

The explication of implication reads as follows:

$\varphi \rightarrow \psi$ is true at a iff, for all b, c such that $R_a bc$, if φ is true at b , then ψ is true at c .

As it stands, this definition makes *no* implication laws universally valid. To obtain at least some indubitable principle, one therefore imposes a restriction on valuations. The most urgent case is that of $p \rightarrow p$. On the above bare semantics, it would correspond to $\forall xyz(R_x yz \rightarrow y = z)$, collapsing the ternary relation. To avoid this, one again requires ‘cumulation’:

valuations V are only to assign subsets X of W subject to the constraint that $\forall xy \in W (R_0 xy \rightarrow (x \in X \rightarrow y \in X))$.

If this constraint is to extend automatically to sets X defined by complex implicational formulas, then a mild form of *transitivity* is to be imposed on the ternary relation after all:

$$\forall xyzu((R_0xy \wedge R_yzu) \rightarrow R_xzu).$$

Notice how this relates perspectives from different vantage points.

But then, if reasonable forms of transitivity have become respectable, we also add (*) $\forall xyzu((R_0xy \wedge R_0yz) \rightarrow R_0xz)$.

Now, at last, some genuine correspondences arise — of a ‘local’ sort (cf. Section 2.2).

EXAMPLE 80.

1. Modus Ponens defines R_000 ,
2. Axiom A1 defines a curious form of ‘transitivity’:
 $\forall xyzu((R_0xy \wedge R_yzu) \rightarrow R_0xu)$.

Proof. (Case (1) only) ‘ \Leftarrow ’: This direction is immediate.

‘ \Rightarrow ’: Let $V(p) = \{0\} \cup \{x \mid R_00x\}$, $V(q) = \{x \mid R_00x\}$. By the above principle (*), both assignments are admissible. Clearly, both p and $p \rightarrow q$ are true at 0, whence also q : i.e. R_000 . ■

Obviously, the second principle is not very plausible — but then, neither is (A1) for a relevance logician.

A more interesting phenomenon in relevance logic, from the present point of view, is the treatment of *negation*. This formerly inconspicuous notion is now interpreted using a ‘reversal operation’⁺ on worlds:

$$\neg\varphi \text{ is true at } a \quad \text{iff} \quad \varphi \text{ is true at } a^+.$$

In this light, new combined correspondences appear, such as that between Contraposition and the reversal law

$$\forall xy(R_0xy \rightarrow R_0y^+x^+).$$

Correspondence Theory may be applied to any kind of semantic entity.

Counterfactual implication

Ramsey told us to evaluate conditionals as follows. Make the minimal adjustment of your stock of beliefs needed to accommodate the antecedent: then see if the consequent follows. Various syntactic and semantic implementations of this view exist, of which that of [Lewis, 1973] has deservedly won the greatest favour. A counterfactual $\varphi \Box \rightarrow \psi$ is true in a world, on his

account, if ψ is true in all worlds most similar to that world *given that* φ holds in them.

As the preceding account has some difficulties in the infinite case, let us consider *finite* models $\langle W, C, V \rangle$, where C is a *ternary* relation of comparative similarity:

$C_x yz$ for: ‘ y is closer to x than z is’.

Lewis gives three basic conditions on the relation ‘no closer’:

1. *transitivity*: $\forall xyz((\neg C_x yz \wedge \neg C_x zu) \rightarrow \neg C_x yu)$,
2. *connectedness*: $\forall xyz(\neg C_x yz \vee \neg C_x zy)$,
3. *egocentrism*: $\forall xy(\neg C_x xy \rightarrow x = y)$.

Rewriting these for ‘closer’, one finds to one’s surprise that (2) is rather weak, being merely

2'. *asymmetry*: $\forall xyz(C_x yz \rightarrow \neg C_x zy)$.

On the other hand, (1) becomes a strong principle

1'. $\forall xyu(C_x yu \rightarrow \forall z(C_x yz \vee C_x zu))$,

which we knew as *almost-connectedness* back in Section 3.1.

From asymmetry and almost-connectedness, one may derive ordinary *transitivity* and *irreflexivity*, whence the three ‘comparative’ axioms of Section 3.1 emerge. These principles justify the appealing picture of ‘similarity spheres’ around the reference world x .

The tendency has been since 1973 to retain only *transitivity* and *irreflexivity* as fundamental pre-conditions on C , leaving various forms of connectedness as optional extras. Thus, one finds an axiomatisation of this austere minimal conditional logic in [Burgess, 1981].

The truth definition in this case may be taken to be the following:

$\varphi \Box \rightarrow \psi$ is true at w if w holds in all φ -worlds C -closest to w .

Indeed, this clause verifies the following list of principles without further ado:

$$\begin{aligned} p \Box \rightarrow p, \\ p \Box \rightarrow q, p \Box \rightarrow r \vdash p \Box \rightarrow q \wedge r, \\ p \wedge q \Box \rightarrow p, \\ p \Box \rightarrow r, q \Box \rightarrow r \vdash p \vee q \Box \rightarrow r. \end{aligned}$$

It is only the last one which requires *transitivity*:

$$p \Box \rightarrow q \wedge r \vdash p \wedge q \Box \rightarrow r.$$

Egocentrism is restored by adding the principle of Modus Ponens:

$$p \Box \rightarrow q, p \vdash q$$

But, the original Lewis logic contained even further principles, such as the formidable

$$((p \vee q) \Box \rightarrow p) \vee \neg((p \vee q) \Box \rightarrow r) \vee q \Box \rightarrow r.$$

What does it express? As it happens, it restores *almost-connectedness*.

Proof. First, the axiom is valid under this additional assumption — by the above discussion.

Next, suppose almost-connectedness fails; i.e. for some xyz we have: $C_x yz, \neg C_x yu, \neg C_x uz$. By transitivity, it follows that $\neg C_x zu$. Now, set $V(p) = \{y\}, V(q) = \{z, u\}, V(r) = \{y, u\}$. Then z is q -closest among the worlds falsifying r . The two $p \vee q$ -closest worlds y, u both verify r . Finally, p fails in the $p \vee q$ -closest world u . Thus, Lewis' axiom has been refuted. ■

Finally, to mention an example outside of Lewis' original logic, there is the Stalnaker principle of 'Conditional Excluded Middle':

$$p \Box \rightarrow q \wedge p \Box \rightarrow \neg q.$$

As was stated in the Introduction, this axiom even requires the similarity order to be a *linear* one. In the present finite case, this means that the above truth definition reduces to:

$$\varphi \Box \rightarrow \psi \text{ is true at } w \text{ if } \psi \text{ holds in the closest } \varphi\text{-alternative to } w.$$

And that was the original Stalnaker explication of conditionals.

The previous examples were all conditional axioms without nestings of $\Box \rightarrow$. This is typical for most current logics in this area. Relational conditions matching these have invariably been found to be first-order ones. Hence, in view of Theorem 38, here is our

CONJECTURE. All counterfactual axioms without nestings of conditionals are first-order definable.

The reason for this restriction lies in the motivation for the present area. Entailment conditionals such as constructive implication, or modal entailment have often been proposed out of dissatisfaction with classical 'nested principles', such as, say, $p \rightarrow (q \rightarrow p)$ or Peirce's Law. The non-nested classical fragment was not called into question. Counterfactual conditionals, however, typically disobey classical implicational logic at the level of non-nested inferences, such as the monotonicity rule from $p \rightarrow q$ to $p \wedge r \rightarrow q$.

Nevertheless, there are intrinsic reasons to be found inside the above semantics for considering nested axioms after all. For, one obvious omission

in the above list of semantic conditions was the lack of *index principles* relating the perspectives of different worlds. For instance, when we read C for a moment as relative proximity in Euclidean space, we find the following *Triangle Inequality*

$$\forall xyz((C_x yz \wedge C_z xy) \rightarrow C_y xz).$$

And there are other elegant principles of this kind.

Now, it is easily seen that such index principles are just what is involved when nested counterfactuals are evaluated: the perspective starts shifting. Thus, it will be rewarding to have correspondences here as well. One, not too exciting example is the following. The Absorption Law

$$p \Box \rightarrow (q \Box \rightarrow r) \vdash (p \wedge q) \Box \rightarrow r$$

defines the index principle

$$\forall xyz(C_x yz \rightarrow \forall u \neg C_y uz).$$

Better examples are still to be found. Indeed, e.g. the counterfactual logic of Euclidean space, the most natural geometric representation of our similarity pictures, is still a mystery.

3.3 Intuitionistic Logic

Constructive conditional logic is only a part of the full intuitionistic logic, whose Kripke semantics extends the earlier constructive models. In this section, a sketch will be given of an Intuitionistic Correspondence Theory. (For details on intuitionistic logic, cf. van Dalen's chapter in volume 7 of this *Handbook*.)

Kripke semantics, intermediate axioms and correspondence.

DEFINITION 81. An *intuitionistic Kripke model* M is a tuple $\langle W, \subseteq, V \rangle$, where \subseteq is a partial order ('possible growth') on W ('stages of knowledge'). The valuation V assigns \subseteq -closed subsets of W to proposition letters ('cumulation of knowledge').

The truth definition has the following familiar pattern,

$$\begin{array}{ll} M \not\models \perp[w] & \text{for all } w \in W, \\ M \models \varphi \rightarrow \psi[w] & \text{if } M \models \psi[v] \text{ for all } v \supseteq w \text{ such that } M \models \varphi[v], \\ M \models \varphi \wedge \psi[w] & \text{if } M \models \varphi[w] \text{ and } M \models \psi[w], \\ M \models \varphi \vee \psi[w] & \text{if } M \models \varphi[w] \text{ or } M \models \psi[w]. \end{array}$$

Negation is defined as usual ($\neg\varphi$ becoming $\varphi \rightarrow \perp$).

The pre-condition of partial order was motivated earlier on. But, other choices may be defended as well. As is well-known, the above semantics was derived from the modal one, through the *Gödel translation* g :

$$\begin{aligned} g(p) &= \Box p \\ g(\varphi \rightarrow \psi) &= \Box(g(\varphi) \rightarrow g(\psi)) \\ g(\varphi \wedge \psi) &= g(\varphi) \wedge g(\psi) \\ g(\varphi \vee \psi) &= g(\varphi) \vee g(\psi) \\ g(\perp) &= \perp. \end{aligned}$$

Now, there is a whole range of modal logics whose ‘intuitionistic fragment’ (through g) coincides with intuitionistic propositional logics. Amongst others, we have the

THEOREM 82. *Let X be any modal logic in the range from **S4** to **S4.Grz** = **S4** plus the Grzegorzcyk Axiom*

$$\Box(\Box(p \rightarrow \Box p) \rightarrow p) \rightarrow p.$$

Then, for all intuitionistic formulas φ , φ is intuitionistically provable in Heyting’s logic if and only if $g(\varphi)$ is a theorem of X .

The earlier modal correspondences yield a corresponding semantic range, between ‘pre-orders’ (*reflexive* and *transitive*) and ‘trees’:

EXAMPLE 83. Grzegorzcyk’s Axiom defines the combination of (i) reflexivity, (ii) transitivity, and (iii) well-foundedness in the following sense: ‘from no w is there an ascending chain $w = w_1 \subseteq w_2 \subseteq \dots$ with $w_i \neq w_{i+1}$ ($i = 1, 2, \dots$)’.

Proof. This goes more or less like the closely related Axiom of Löb. By the way, notice that (iii) implies anti-symmetry. Note also that, semantically, Grzegorzcyk’s axiom alone implies the **S4**-laws: syntactic derivations to match were found around 1979 by W. J. Blok and E. Pledger. ■

Thus, a case may also be made for the *Tree of Knowledge* as a basis for intuitionistic semantics. Nevertheless, we shall stick to partial orders for a start.

Above **S4Grz**, modal logics start producing greater g -fragments — the so-called *intermediate logics*, ascending to full classical logic. Intermediate axioms impose various restrictions on the pattern of growth for knowledge, classical logic forcing the existence of single (‘complete’) nodes.

EXAMPLE 84. (i) Excluded Middle $p \vee \neg p$ defines $\forall x \forall y (x \subseteq y \rightarrow x = y)$.

Proof. ‘ \Leftarrow ’ is immediate.

‘ \Rightarrow ’: Suppose $x \subseteq y, x \neq y$. (By anti-symmetry then $y \not\subseteq x$.) Set $V(p) = \{z \mid y \subseteq z\}$. This falsifies both p and $\neg p$ at x . ■

(ii) *Weak Excluded Middle* $\neg p \vee \neg\neg p$ defines directedness.

Proof. ‘ \Leftarrow ’: Suppose that $\neg p$ fails at x ; say p holds at $y \supseteq x$. Then consider any $z \supseteq x$. As it shares a common successor with y , and $V(p)$ is \subseteq -hereditary, it has a successor verifying p , whence $\neg p$ fails at z . So $\neg\neg p$ holds at x .

‘ \Rightarrow ’: Suppose that $x \subseteq y, z$, where y, z share no common successors. Set $V(p) = \{u \mid z \subseteq u\}$. (Like above, this is a \subseteq -closed set.) Notice that $x, y \notin V(p)$. It follows that $\neg p$ fails at x (consider z), but $\neg\neg p$ fails as well (consider y). ■

(iii) *Conditional Choice* $(p \rightarrow q) \vee (q \rightarrow p)$ defines connectedness.

Proof. ‘ \Leftarrow ’: Suppose that $p \rightarrow q$ fails at x ; i.e. some $y \supseteq x$ has p true, but q false. Now consider any $z \supseteq x$ such that q holds. Either $z \subseteq x$, but then, by \subseteq -heredity, q is true at y (*quod non*), or $y \subseteq z$, and so, again by \subseteq -heredity, p is true at z , i.e. $q \rightarrow p$ is true at x .

‘ \Rightarrow ’: Let $x \subseteq y, z$ with $y \not\subseteq z, z \not\subseteq y$. Set $V(p) = \{u \mid y \subseteq u\}, V(q) = \{u \mid z \subseteq u\}$. Then $p \rightarrow q$ fails at x (watch y), and $q \rightarrow p$ fails as well (watch z). ■

Much more forbidding principles than these have been proposed as intermediate axioms. But surprisingly, these usually turned out to be first-order definable:

EXAMPLE 85. (i) The Stability Principle $(\neg\neg p \rightarrow p) \rightarrow (p \vee \neg p)$ defines

$$\forall x \neg \exists y z (x \subseteq y \wedge x \subseteq z \wedge \neg \exists u (y \subseteq u \wedge z \subseteq u) \wedge \wedge \forall u (\forall s (u \subseteq s \rightarrow \exists t (s \subseteq t \wedge z \subseteq t)) \rightarrow \neg \exists v (u \subseteq v \wedge y \subseteq v))).$$

(ii) The Kreisel-Putnam Axiom $(\neg p \rightarrow (q \vee r)) \rightarrow ((\neg p \rightarrow q) \vee (\neg p \rightarrow r))$ defines

$$\forall x \neg \exists y z (x \subseteq y \wedge x \subseteq z \wedge \neg y \subseteq z \wedge \neg z \subseteq y \wedge \wedge \forall u ((x \subseteq u \wedge u \subseteq y \wedge u \subseteq z) \rightarrow \exists v (u \subseteq v \wedge \neg y \subseteq v \wedge \neg z \subseteq v))).$$

No matter how complex such axioms may seem at first sight, proofs of the above assertions are quite simple exercises in ‘imagining what a counterexample would look like’.

This recurrent experience led to the following *conjecture* in [van Benthem, 1976]:

All intermediate axioms express first-order constraints on growth of knowledge.

Two conjectures refuted. The earlier hope was all but given up in the first version of this chapter; as ‘Scott’s Rule’ turned out to be an essentially

higher-order intermediate inference. The relevant argument was sharpened somewhat by P. Rodenburg:

THEOREM 86. *Scott's Axiom $((\neg\neg p \rightarrow p) \rightarrow (p \vee \neg p)) \rightarrow (\neg p \vee \neg\neg p)$ defines no first-order condition on partial orders.*

Proof. An elaborate Löwenheim–Skolem argument works, in the spirit of Example 43. As an illustration of the non-triviality of our present subject matter, it follows here.

Step 1: Consider the following Kripke frame $\langle W, \subseteq \rangle$:

W consists of the *infinite binary tree* T , together with, for each node c in T and each \subseteq -hereditary, *cofinal* set X in T_c (i.e. the subtree with root c), some point d_X^c . \subseteq is the usual order on T , together with

- $c \subseteq d_X^c \subseteq x$, for all $x \in X$
- $d_X^c \subseteq d_{X'}^c$, if $X' \subseteq X$.

CLAIM. *Scott's Axiom is true in $\langle W, \subseteq \rangle$.*

PROOF. First, let $c \in T$ be a putative refutation. I.e., for some valuation V ,

1. $(\neg\neg p \rightarrow p) \rightarrow p \vee \neg p$ is true at c ,
2. $\neg p \vee \neg\neg p$ is false at c .

Then consider the node d_X^c , where X is the cofinal hereditary set

$$T_c \cap (V(p) \cup V(\neg p)).$$

One verifies successively that $\neg\neg p \rightarrow p$ is true at d_X^c , whereas both $p, \neg p$ are false. (E.g. if p were true at d_X^c , then p is true throughout X , whence $\neg\neg p$ is true at c — whereas (2) says the opposite.) Thus, we have a contradiction with (1).

A similar argument works for the case where c is of the form d_X^c itself. ■

Step 2: A matter of cardinality:

CLAIM. *The above Kripke frame is uncountable.*

PROOF. In particular, there are 2^{\aleph_0} nodes of the form d_X^c . For, each subset Y of N may be coded as follows, using (distinct) hereditary cofinal subsets Y^+ of the infinite binary tree. Let $Y = \{y_1, y_2, y_3, \dots\}$.

etc. going down the extreme right branch using the extreme left branches to code y_1, y_2, y_3, \dots

For all nodes not arrived at in this way, one makes Y^+ cofinal by means of the following stipulation:

Step 3: Take any *countable* elementary substructure F of $\langle W, \subseteq \rangle$ containing the original binary tree. ■

CLAIM. *Scott's Axiom may be falsified in F .*

PROOF. Consider T as a double tree

and again T_{c^2} a countable sequence of 'trees on a string':

Let D_{X_1}, D_{X_2}, \dots be an enumeration of the points $d_X^{C_0}$ remaining in F . Notice that, for each $i \in N$,

1. finite intersections $T_i \cap X_1 \cap \dots \cap X_n$ are still hereditary cofinal in T_i ,
2. the total intersection $T_i \cap \{X_j \mid j = 1, 2, \dots\}$ is empty.

As for the latter observation, it suffices to see that the assertion

$$\forall x \exists d_X^{C_0} \text{ with } d^{C_0} \not\subseteq x,$$

which holds in $\langle W, \subseteq \rangle$, can be expressed in first-order terms in $\langle W, \subseteq \rangle$; and, hence, it has remained valid in the elementary substructure F .

Now, define

$$\begin{aligned} X_1^* &= X_1 \\ X_{n+1}^* &= X_1 \cap \dots \cap X_k \text{ for the smallest } k \text{ such that } T_{n+1} \cap X_1 \cap \\ &\quad \dots \cap X_k \not\subseteq T_{n+1} \cap X_n^*. \end{aligned}$$

Scott's Axiom may now be falsified at c^0 , by setting

$$X^* = \cup \{T_i \cap X_i^* \mid i = 1, 2, \dots\}, V(p) = \{y \mid \exists x \subseteq y \ x \in X^*\}.$$

to see this, notice, that successively,

1. each point d_{X_i} has a successor (in T_i) outside of $V(p)$,
2. $(\neg \neg p \rightarrow p) \rightarrow p \vee \neg p$ holds at c^0 ,

3. $\neg p \vee \neg\neg p$ fails at c^0 . ■

We conclude that Scott's Axiom is not first-order definable — not being preserved under elementary subframes. ■

This complex behaviour disappears on better-behaved structures.

OBSERVATION 87. On *trees*, Scott's Axiom defines the first-order condition

$$\forall x \neg \exists y z u (x \subseteq y \wedge x \subseteq z \wedge z \subseteq u \wedge z \neq u \wedge \neg \exists v (y \subseteq v \wedge z \subseteq v)).$$

This, and other experiences of its kind, led to a revised guess in the first version of this chapter: On trees, all intermediate axioms express first-order constraints on descentance. A proof sketch was added, involving *semantic tableaux* as 'patterns of falsification', to be realised in trees.

This conjecture was 'almost' refuted in [Rodenburg, 1982]. The semantic tableau method runs into problems with *disjunctions*, and indeed we have the following counter-example.

EXAMPLE 88. Consider the formula

$$\phi = ((\neg p \wedge \neg q \wedge \neg r) \rightarrow (p \wedge q \wedge r)) \rightarrow (\neg p \wedge \neg q \wedge \neg r)$$

with the simultaneous substitution of: $p \& q$ for p , $p \& \neg q$ for q , and $\neg p \& q$ for r . This ϕ is not first-order definable on partial orders. On suitably tree-like structures, it expresses the lack of '3-forks' of immediate successors as well as the absence of infinite comb-like structures.

On trees, this negative example probably still works — but there is an instructive difficulty here. The class of trees itself has a higher-order definition; Π_1^1 , to be precise. Therefore, current model-theoretic arguments for disproving first-order definability (compactness, Löwenheim–Skolem) run the risk of employing constructions leading outside of this class. Higher-order preconditions are a problem for our Correspondence Theory.

To illustrate this from a purely classical angle, the reader may consider a related problem, showing how soon the familiar methods of model theory fail us. *Finiteness* is first-order undefinable on *partial orders*, even on *trees*. It is thus definable on *linear trees*, however, viz. by 'every non-initial node has an immediate predecessor'. What about the (at most) binary trees? This intermediate case seems to be open.

The state of the subject. The progress of science is sometimes startling. Where the first version of this chapter (1981) had some tentative examples, enlightenment reigns in the report [Rodenburg, 1982]. Of its many topics, only a few will be mentioned here.

First, there are several semantic options — as indicated above, ranging from *partial orders* via 'downward linear orders' to *trees*. But moreover,

there is a legitimate choice of language. Despite appearances, it is the *disjunction* clause which is now strongly constructive in intuitionistic Kripke semantics. ('Choose *now!*' Classical logic would have a more humane clause in this setting: $\Box\Diamond(\varphi \vee \psi)$, i.e. ' φ or ψ eventually'.) Thus, it is of interest to consider both the full language and its \vee -free fragment.

The semantic tableau method mentioned above, in combination with the above counter-examples, has led to the results in the following scheme:

All formulas first-order definable	Partial orders	Downward linear orders	Trees
without \vee	YES	YES	YES
with \vee	NO	NO	?

But there are also matters of 'fine structure'. For instance, Scott's Axiom had only one proposition letter — and for such intuitionistic formulas we have the beautiful Rieger–Nishimura lattice. Now, Scott's Axiom merely seemed a fit candidate for a counter-example among the intermediate axioms existing in the literature. Rodenburg has proved that it is also *minimal* in the Rieger–Nishimura lattice with respect to non first-order definability. (More precisely, an intuitionistic formula with one proposition letter is first-order definable on the partial orders if and only if it is equivalent to one of A_1, \dots, A_9 in the lattice.)

In the counter-examples needed for the latter result, a uniform method may be seen at work: *compactness*, in the form that sets of formulas which are finitely satisfiable in *finite* models are also simultaneously satisfiable (in some *infinite* model). Now, indeed, intuitionistic truth has a close connection with truth in finite submodels (cf. [Smoryński, 1973]). Our question is whether this may lead to the following improvement in the mathematical characterisation of first-order definability as given in Section 2.2.

CONJECTURE. An intuitionistic formula φ is first-order definable if and only if φ is preserved under *ultraproducts of finite frames*.

Intuitionistic definability. As with the direction 'from intensional to classical', the case 'from classical to intuitionistic definability' shows many resemblances with our earlier modal study. For instance, a Goldblatt–Thomason type characterisation was proved in [van Benthem, 1983] (cf. our earlier Theorem 66):

A first-order constraint on the growth pattern is intuitionistically definable if and only if it is preserved under the formation of *generated subframes, disjoint unions, zigzag-morphic images, filter extensions* and '*filter inversions*'.

Merely in order to illustrate this topic, which has a wider semantic significance, here is a sketch of the representation theory in the background.

On the algebraic side, the intuitionistic language may be interpreted in *Heyting Algebras* $\langle A, 0, 1, +, \cdot, \Rightarrow \rangle$ satisfying suitable postulates. Now, each *Kripke (general) frame* in the above sense induces such a Heyting Algebra, through its \subseteq -hereditary sets, provided with suitable, obvious operations. But also conversely, a *filter representation* now takes Heyting Algebras to Kripke general frames. Indeed, the earlier categorial duality (cf. Section 2.3) is again forthcoming.

The more general semantic interest of the construction is this. Despite the superficial similarity with structures consisting of the ‘complete’ possible worlds, intuitionistic Kripke models should be regarded as patterns of stages of *partial* information. This comes out quite nicely in the above representation, where ‘worlds’ are no longer complete *ultrafilters*, but merely filters (in the \vee -free case) or ‘splitting’ filters (for the full language). Filters F merely satisfy the closure condition that

$$a, b \in F \text{ iff } a \cdot b \in F,$$

a minimal requirement on partial information. Also quite suggestively, the ‘modal’ alternative relation collapses into inclusion (‘growth’):

$$\forall a \Rightarrow b \in F \quad \forall a \in F' : b \in F' \quad \text{iff} \quad F \subseteq F'.$$

The present-day supporters of ‘partial models’ and ‘information semantics’ would do well to study intuitionistic logic.

Predicate logic. Again, correspondence phenomena do not stop at the frontier of predicate logic. This will be illustrated by means of some intuitionistic examples.

Kripke models $M = \langle W, \subseteq, D, V \rangle$ will now be of the usual variety; in particular satisfying

1. $\forall xy(x \subseteq y \rightarrow D_w \subseteq D_v)$ (*monotonicity*)
2. $\forall xy(x \subseteq y \rightarrow \forall \vec{d} \in D_x (V_x(P, \vec{d}) = 1 \rightarrow V_y(P, \vec{d}) = 1)$ (*heredity*).

But other varieties, say with maps between the domains (cf. [Goldblatt, 1979]) would be suitable as well.

The ‘de re/de dicto’ interchange principles of Section 2.5 now have their obvious counterparts in the following quartetto:

1. $\neg \exists x Ax \rightarrow \forall x \neg Ax,$
2. $\forall x \neg Ax \rightarrow \neg \exists x Ax,$
3. $\exists x \neg Ax \rightarrow \neg \forall x Ax,$

$$4. \neg\forall xAx \rightarrow \exists x\neg Ax.$$

The first three of these are universally valid on the present semantics. That they already hide quite some complexity is shown by the Gödel translation of (3):

$$\Box(\exists x\Box\neg\Box Ax \rightarrow \Box\neg\Box\forall x\Box Ax),$$

or

$$\Box(\exists x\Box\Diamond\neg Ax \rightarrow \Box\Diamond\exists x\Diamond\neg Ax).$$

No wonder that (3), e.g. does not define precisely the above monotonicity constraint on domains — even though its modal cousin $\exists x\Box Ax \rightarrow \Box\exists xAx$ did.

The first really complex principle in Section 2.5 was the converse implication $\Box\exists xAx \rightarrow \exists x\Box Ax$. We shall now investigate its intuitionistic cousin (4) — a rejected classical law.

EXAMPLE 89.

1. $\neg\forall xAx \rightarrow \exists x\neg Ax$ implies that all domains are equal:

$$\forall xy(x \subseteq y \rightarrow D_x = D_y)$$

2. On frames with constant finite domain, $\neg\forall xAx \rightarrow \exists x\neg Ax$ expresses the first-order condition that

$$\forall x (\exists!d d \in D_x \vee \forall y(x \subseteq y \rightarrow \forall z(x \subseteq z \rightarrow \exists u(y \subseteq u \wedge z \subseteq u))).$$

Proof. Ad 1. Suppose that $x \subseteq y$, but $D_x \subsetneq D_y$. Make A true at y for all $d \in D_x$, and similarly at all $y' \supseteq y$. This stipulation defines an admissible assignment verifying $\neg\forall xAx$ at x , while falsifying $\exists x\neg Ax$.

Ad 2. First, if $|D_x| = 1$, then trivially, $\neg\forall xAx \rightarrow \exists x\neg Ax$ holds at x . (Recall that all domains are equal.)

Next, if $|D_x| > 1$, then one may argue as follows. If \subseteq is *directed* above x in the above sense, then the assumption that $\exists x\neg Ax$ *fails* at x can be exploited to show that $\neg\forall xAx$ must fail as well.

For, let $D_x = \{d_1, \dots, d_k\}$. By the assumption, Ad_i will be true at some $x_i \supseteq x$ ($1 \leq i \leq k$). Then, by successive applications of directedness, there will be found a common successor $y \supseteq x_1, \dots, y \supseteq x_k$, where $\forall xAx$ is true (by heredity). This falsifies $\neg\forall xAx$ at x .

If on the other hand, for some x , $|D_x| > 1$ while \subseteq is not directed above x , then, say, there exist $x_1 \supseteq x, x_2 \supseteq x$ without common successors. Then pick any object $d \in D_x$, making A true at x_1 and all its \subseteq -successors *for all objects except d* ; while making A true at x_2 and all its \subseteq -successors *for d only*. This assignment verifies $\neg\forall xAx$ at x , while falsifying $\exists x\neg Ax$. ■

Thus, a classical quantifier axiom may express an interesting purely relational constraint on \subseteq .

Now, intuitionists are fond of saying that (4) is valid for *finite* domains: as we have seen, however, it does impose constraints even then. They go on to say that an extrapolation to the infinite case would be illegitimate. At least, our principle becomes much more complex then.

THEOREM 90. $\neg\forall xAx \rightarrow \exists x\neg Ax$ is not first-order definable in general.

Proof. Consider the following structure, in which all worlds have a common domain N .

i.e. $\langle W, \subseteq \rangle$ has the relational pattern of

$$\langle N \oplus (\omega_1 \odot \mathbb{Z}), \leq \rangle.$$

CLAIM. $\neg\forall xAx \rightarrow \exists x\neg Ax$ is true in this frame.

PROOF. Starting from any world x , assume that $\exists x\neg Ax$ fails. Then, for each $n \in N$, An must hold at some $(\alpha_n, k_n) > x$. As the cofinality of ω_1 exceeds ω , there exists some $\beta < \omega_1$ such that $(\beta, 0) > (\alpha_n, k_n) (n \in N)$. Now, by heredity, $\forall xAx$ must hold at $(\beta, 0)$ — whence $\neg\forall xAx$ is false at x . ■

Next, by the Löwenheim–Skolem theorem (as ever), this frame has *countable* elementary subframes. (Indeed, $\langle IN, \leq \rangle$ itself is one.) But in these, our principle may be falsified using some countable cofinal sequence x_0, x_1, \dots making $A0$ true from x_0 upward, $A1$ from x_1 upward, etcetera. As in earlier arguments, the conclusion of the theorem follows. ■

To finish this list of examples, it may be noted that a famous weaker variant of the above axiom does indeed define a first-order constraint.

EXAMPLE 91. Markov’s Principle

$$\forall x(Ax \vee \neg Ax) \wedge \neg\neg\exists xAx \rightarrow \exists xAx$$

defines the relational condition

$$\forall x\exists y \supseteq x \forall z \supseteq y \forall d(Edz \rightarrow Edx).$$

Correspondence Theory remains surprising.

Post-Script: quantum logic.

Correspondences have not proved uniformly successful in intensional contexts. It seems only fair to finish with a more problematic example.

A possible worlds semantics for *quantum logic* was proposed in [Goldblatt, 1974]. Kripke frames are now regarded as sets of ‘states’ of some physical system, provided with a relation of ‘orthogonality’ (\perp). From its physical motivation, two pre-conditions follow for \perp , viz. *irreflexivity* and *symmetry*. But in addition, there is also a restriction to ‘admissible ranges’ for propositions, in the sense that these sets $X \subseteq W$ are to be *orthogonally closed*:

$$\forall x \in (W - X) \exists y \in (W - X) (\neg x \perp y \wedge \forall z \in X y \perp z).$$

The key truth clauses are those for conjunction (interpreted as usual), and negation, interpreted as follows:

$$\neg \varphi \text{ is true at } x \quad \text{if} \quad x \text{ is orthogonal to all } \varphi\text{-worlds.}$$

This semantics validates the usual principles for quantum logic, when \vee is defined in terms of \neg, \wedge by the De Morgan law. But, one key principle remains invalid, viz. the *ortho-modularity axiom*

$$p \leftrightarrow (p \wedge q) \vee (p \wedge \neg(p \wedge q)).$$

This axiom has a natural motivation in the Hilbert Space semantics for quantum logic — being the key stone in the representation of ortho-modular lattices as subspace algebras of suitable vector spaces. Thus, a minimal expectation would be that an enlightening correspondence is forthcoming with some constraint on the orthogonality relation \perp .

In reality, no such thing has happened. Quantum logicians pass onto *general* frames, into whose very definition validity of ortho-modularity has been built in. Despite this cover-up, the fact remains that the relational possible worlds perspective fails to do its correspondence duties here. A set-back, or an indication that facile *over-applicability* of Kripke semantics need not be feared for?

4 CONCLUSION

At a purely technical level, Correspondence Theory is an applied subject. Classical tools have been borrowed from model theory and universal algebra. In return to these mother disciplines, the subject offers a good range of (counter-)examples, as well as prospects for generalisability to other suitably chosen fragments of higher-order logic. (Cf. [van Benthem, 1983].)

From a more philosophical point of view, the whole enterprise may be described as finding out what possible worlds semantics really does for us.

It is one thing to make conceptual proposals, and another to really probe their depths. The systematic study of connections between intensional and classical perspectives upon possible world structures is an exploration of the benefits gained by the semantics. This chapter started with the observation that ‘complex’ modal axioms turned out to express ‘simple’ classical requirements (i.e. first-order ones). We have investigated the range and limits of this, and related phenomena. Especially these limits have become quite clear — and, with them, the limits of fruitful application of Kripke semantics. This philosophical conclusion holds for all semantics, of course. But we have earned the moral right to say it, through honest toil.

ACKNOWLEDGEMENTS

The classical introduction to a systematic modal model theory remains [Seegerberg, 1971]. Some first applications of more sophisticated tools from classical model theory may be found in [Fine, 1975]. The algebraic connection was developed beyond the elementary level by L. Esakia, S. K. Thomason, R. I. Goldblatt and W. J. Blok. Two good surveys are [Blok, 1976] and [Goldblatt, 1979]. The proper perspective upon modal logic as a fragment of second-order logic was given in [Thomason, 1975]. An early appearance of correspondence theory proper is made in [Sahlqvist, 1975], full surveys are found in [van Benthem, 1983] for the case of modal logic and [van Benthem, 1985] for the case of tense logic. Other case studies are still in a preliminary state, with the exception of the intuitionistic treatise [Rodenburg, 1982].

University of Amsterdam

APPENDIX (1997)

This chapter first appeared in 1984. In the meantime, Modal Logic has evolved, but the basic structure of our original presentation remains valid. Therefore, we have left the old text unchanged, and merely added a short chronicle of further developments, including some answers to open questions. Generally speaking, correspondence methods have become a useful technical tool in pure and applied Modal Logic, without forming a major research area in their own right. A more principled motivation is given in van Benthem [1996a], where correspondence analysis is viewed as a central part in the philosophical quest for logical ‘core theories’ of semantic phenomena in language and computation. In particular, correspondences suggest the introduction of new many-sorted models, inducing decidable geometries of ‘states’ and ‘paths’ in the study of time and computation.

Extensions to Other Branches of Intensional Logic

The first significant extension of correspondence theory concerns *Intuitionistic Logic*. This involves the new feature that all valuations must be restricted to hereditary ones, leading only to formulas whose truth is preserved upward in the relational ordering. Rodenburg [1986] investigates this area in detail. In particular, he shows that the implication-conjunction fragment is totally first-order, whereas disjunctions can lead to non-first-orderness. Moreover, he introduces semantic tableau methods for explicit description of first-order correspondents. A final interesting feature is Rodenburg's analysis of intuitionistic Beth models which employ a second-order truth condition: a disjunction is true when its disjuncts 'bar' all future paths. These also turn out to be amenable to correspondence analysis, over two-sorted frames with both points and paths. Restricted valuations also occur with the ternary relational models of *Relevant Logic*. A full correspondence analysis is given in Kurtonina [1995], which analyses the special effects of working with features like distinguished points (actual worlds), non-standard connectives (including a new product conjunction), as well as the much poorer non-Boolean fragments found in categorial logics for grammatical analysis (cf. [van Benthem, 1991; Moortgat, 1996]). Further extensions have been made to *Epistemic Logic* [van der Hoek, 1992] and *Partial Logics* [Thijsse, 1992; Jaspars, 1994; Huertas, 1994]. Correspondence with restricted valuations for 'convex' propositions has also been proposed in standard *Temporal Logic* (cf. van Benthem [1983; 1986; 1995b]). But also, most axioms for richer interval-based versions have first-order 'Sahlqvist forms' [Venema, 1991]. Zanardo [1994] gives correspondences for modal-temporal models of branching space-time. Finally, correspondence methods have turned out very useful in *Algebraic Logic*. Venema [1991], Marx and Venema [1996] present a systematic study of relational algebra and cylindric algebra along these lines, pointing out the Sahlqvist form of most familiar algebraic axioms, and calculating their frame constraints on algebraic 'atom structures'. This establishes a much wider bridge between algebraic logic and modal logic than our earlier duality.

Restricted Frame Classes

Correspondence behaviour may change on special frame classes. In this chapter, we have looked at some effects of a restriction to transitive frames. But one can also investigate non-first-order frame classes. Van Benthem [1989a] considers *finite frames*, where, amongst others, the McKinsey axiom still defines a non-first-order condition. In this area, standard compactness-based model-theoretic techniques no longer work, and they must be replaced by a more careful combinatorial analysis with Ehrenfeucht-Fraïssé games of model comparison. (More generally, the finite model theory of modal logic

is still undeveloped. Rosen [1995] proves some interesting transfer results, showing better finite model-theoretic behaviour than for first-order logic in general.) Doets [1987] takes up modal Ehrenfeucht games in great depth, investigating, amongst others, correspondence over *countable* and over *well-founded* frames. (For instance, the so-called Fine Axiom turns out to be first-order over countable frames.)

Complexity

This chapter contains some results on the (high) complexity of definability problems for monadic Φ_1^1 -formulas. It turns out much harder to deal with the modal fragment of these. A lower bound for the complexity of first-orderness of modal formulas has been found in Chagrova [1991]: **M1** is *undecidable*. It seems likely that her methods (involving reductions of Minsky machine computation to correspondence statements) can also be made to yield non-arithmetical complexity. Conversely, undecidability of modal definability for first-order statements has been proved by Wolter [1993]: that is, **P1** is undecidable, too. A more general investigation of time and space complexity for modal logics, and the ‘jumps’ that may occur with different operator vocabularies, may be found in Spaan [1993]. It has improved decidability results for the so-called ‘subframe logics’ defined in Fine [1985], as well as ‘transfer’ of complexity bounds from components to compounds in poly-modal logics (cf. [Kracht and Wolter, 1991]).

Correspondence and Completeness

The main business of modal logic has been the search for completeness theorems over various frame classes. Correspondence theory bypasses this deductive information, focussing on direct semantic definability. Nevertheless, Kracht [1993] shows how the two enterprises can be merged, by a suitably generalized form of modal definability. Perhaps the most powerful result of this kind is the generalized Sahlqvist Theorem in Venema [1991], which shows that over suitably rich modal languages (possessing matched versions for each modality accessing all directions of its alternative relation), and allowing natural additional rules of inference beyond the minimal modal logic, the correspondence and the completeness version of the Sahlqvist Theorem converge in their proofs. The essential observation in the argument is as follows. In standard Henkin models for these richer systems, unlike in the standard case, all definable subsets employed in the correspondence proof (such as singletons or successor sets) are modally definable. Direct frame correspondences for modal rules of inference may be found in van Benthem [1985]. Over frames, the latter correspond to non- Φ_1^1 second-order formulas, but except for a few scattered observations in the literature, correspondence theory for modal rules of inference remains underexplored.

Duality with Algebraic Logic

Algebraic methods have been invaluable in finding key results on correspondence, such as the Goldblatt-Thomason characterization of the modally definable first-order formulas. Nevertheless, a purely model-theoretic reanalysis has been given in van Benthem [1993b], revolving around saturated models instead of descriptive frames. There is no definite preference here, as it is precisely the interplay between algebraic and model-theoretic viewpoints that remains fruitful. For new uses of correspondence methods in algebraic logic, as well as new set-theoretic representations for Boolean algebras with additional modal operators, see Marx [1995], Mikulas [1995]. For instance, Marx has an in-depth study of the duality between algebraic amalgamation and logical interpolation. The latter methods no longer employ simple binary relations as in the Jónsson-Tarski Stone representation, but more complex set-theoretic constructs. (Modal correspondences over finitary relations occur in van Benthem [1992], with a finite neighbourhood semantics for logic programs.) Developing a systematic correspondence theory over such generalized relational structures then becomes the next challenge.

Extended Modal Logics

Perhaps the most striking development in modal logic over the past ten years has been the systematic use of more powerful formalisms, with stronger modal operators over relational frames. A straightforward step is ‘poly-modal logic’, which gives the same expressive power over frames with more alternative relations. Examples of the latter trend are the indexed modalities $\langle i \rangle$ of propositional dynamic logic (cf. [Harel, 1984; Goldblatt, 1987; Harel *et al.*, 1998]), or n -ary modalities accessing $(n + 1)$ -ary alternative relations, as happens in relevant or categorial logics (cf. [Dunn, 2001; Kurtonina, 1995]). The correspondence theory of such extensions is straightforward, whereas there are interesting issues of ‘transfer’ for axiomatic completeness, finite model property, or computational complexity: cf. [Spaan, 1993; Fine and Schurz, 1996]. Transfer may depend very much on the connections between the various modalities. A case in point is modal predicate logic, whose theory has rapidly expanded over the past decade. Van Benthem [1993a] surveys some striking contributions by Ghilardi and Shehtman.

More interesting, from a correspondence point of view, is an increase in expressive power over the original binary relational frames. For temporal logic, the latter research line was initiated by Kamp’s Theorem on functional completeness of the {Since, Until} language over continuous linear orders. In modal logic, the first systematic work emanated from the ‘Sofia School’: cf., e.g., [Gargov and Passy, 1990; Goranko, 1990], Vakarelov [1991; 1996]. These papers study addition of various new operators, such as a universal

modality ranging over all worlds (relationally accessible or not), or various operations on poly-modalities, such as ‘program intersection’. New frame constructions were invented to deal with these, such as ‘duplication’. De Rijke [1992] investigates the ‘difference modality’ (“in at least one different world”), which has turned out to be useful and yet tractable. A more general program for extending modal logic (viewed as a general ‘theory of information’) occurs in van Benthem [1990] but the technical perspective is also clear in the pioneering paper Gabbay [1981]. Finally, de Rijke [1993] is an extensive model-theoretic investigation of definability and correspondence for extended modal languages, producing generalized versions for many results in this chapter (such as frame preservation theorems or effective correspondence algorithms). Still another angle on all this will follow below.

Alternatives: Direct Frame Theory

One may also analyze the frame content of modal logics more directly in terms of mathematical properties of graphs. Fine [1985] is a pioneer of this trend, emphasizing the good behaviour of ‘subframe logics’ which are complete for frame classes that are closed under taking subframes. (Such logics make no ‘existential commitments’.) First-orderness is not a prominent consideration here: e.g., Löb’s Axiom defines a simple subframe logic. Zakharyashev [1992; 1995] is a sophisticated study of modal logic from this viewpoint. Nevertheless, his direct classification of modal logics into three stages of frame preservation behaviour may again be reflected in second-order syntax and hence result in a form of correspondence theory at that higher level. A forthcoming monograph by Chagrov and Zakharyashev provides much more background, including references to earlier Russian sources (going back to Jankov in the sixties). Another excellent source, for many of the topics listed here, is the survey chapter [Chagrov *et al.*, 1996].

Models, Bisimulation and Invariance

Another noticeable shift of emphasis in the current literature leads away from frames to *models* as the primary objects of semantic interest. This move makes all of basic modal logic first-order, via our standard translation. The main questions then address what makes modal logics special as subspecies of first-order logic. In particular, what is the basic semantic invariance for basic modal logic, which should play a role like Ehrenfeucht games or ‘partial isomorphism’ in first-order model theory? A key result here is the semantic characterization of the modal fragment of first-order logic (modulo logical equivalence) as precisely those formulas in one free variable which are invariant for generated submodels and our ‘zigzag relations’ [van Benthem, 1976]. In modern jargon, this says that these for-

mulas are precisely the ones *invariant for bisimulation*. The latter link was also developed in Hennessy & Milner [1985], which matches modal formalisms in different strengths with coarser or finer process equivalences. For up-to-date expositions of the resulting analogies between modal logics and computational process theories, cf. [van Benthem and Bergstra, 1995; van Benthem *et al.*, 1994], as well as various contributions in the volume [Ponse *et al.*, 1995]. This development has led to a new look at connections between modal formalisms and first-order logic. For instance, there are striking analogies between the meta-theories of both logics, whose precise extent and explanation is explored in de Rijke [1993], and Andréka, van Benthem & Némethi [1998]. In particular, the latter paper investigates the hierarchy of *finite-variable fragments* for first-order logic as a candidate for a general account of modal logic (cf. [Gabbay, 1981; van Benthem, 1991] for this view). Typically, modal formulas need only two variables over worlds in their standard translation, temporal formulas only three, and so on. Finite-variable fragments are natural, and may be considered as functionally complete modal formalisms (cf. the insightful game-based analysis of Kamp's Theorem in Immerman & Kozen [1987]). Nevertheless, Andréka, van Benthem & Némethi [1998] also turn up an array of negative properties, and eventually propose another classification for modal languages in terms of restricting atoms for *bounded quantifiers*. The resulting 'guarded fragments' can be analyzed much like the basic modal language, including analogous bisimulation techniques. In particular, these bisimulations now relate finite sequences of objects instead of single worlds, as in many-dimensional modal logics (cf. [Marx and Venema, 1996] for the theory of such formalisms). Their correspondence theory, taken with respect to natural generalized frame conditions for arbitrary first-order relations, still remains to be understood. [van Benthem, 1996b] is a general study of dynamic logics for computation and cognition, pursued via these techniques. One of its central concerns is expressive completeness of modal process logics vis-à-vis process equivalences like bisimulation.

Connections with Higher-Order Logic and Set Theory

From first-order correspondence, forays can be made into higher-order definability. Sometimes, this move is suggested by the modal language itself. E.g., in propositional dynamic logic, program iteration naturally translates into a countable disjunction of finite repetitions. Thus, translation into the *infinitary* standard language $L_{\omega_1\omega}$ seems the evident route. Infinitary frame correspondences were briefly considered in van Benthem [1983], and their modal model theory is explored in [de Rijke, 1993; van Benthem and Bergstra, 1995]. Of course, one may restore a balance here, and consider an infinitary modal counterpart of L_ω , allowing arbitrary set conjunctions and disjunctions, which would be the most natural formalism invariant for

bisimulation. Barwise and Moss [1995] take this line, linking up truth on models and correspondence on frames. (Another perspective on infinitary modal logic is given in [Barwise and van Benthem, 1996].) Among a number of original results, they prove that a modal formula has all its infinitary substitution instances true in a model M iff it is true (in the usual second-order sense) on the frame collapse of that model taken with respect to the maximal bisimulation over M . As a direct consequence, frame correspondences for modal formulas imply model correspondences in infinitary modal logic. (The issue of good converses is still open). The original motivation for this type of investigation was that it relates modal logics to (non-well-founded) set theories. Linkages of this kind are further explored in d'Agostino [1995] which also raises the issue of more complex correspondences for modal axioms. For instance, she shows that the second-order Löb Axiom holds in a frame iff that frame is transitive while its collapse with respect to the maximal bisimulation is irreflexive. More generally, then, the interesting point about many correspondences is not that they must always reduce modal axioms to first-order ones, but rather the fact that they reformulate modal principles to any more perspicuous classical formalism. Another natural candidate of the latter kind is second-order monadic Φ_1^1 logic (cf. [Doets and van Benthem, 2001]). In particular, Doets [1989] shows how modal completeness theorems can sometimes be extended to cover this whole language. Moreover, many effective translation methods (see below) turn out to work for this broader language anyway. Finally, van Benthem [1989b] points out how first-order correspondence theory, suitably restated for second-order Φ_1^1 formulas, is a natural generalization which handles so-called computable forms of Circumscription in the AI literature (which involves reasoning from a second-order 'predicate-minimal' closure for first-order axioms; cf. [Lifshitz, 1985]).

Translations

Correspondence has become a conspicuous theme in the computational literature on theorem proving with intensional logics. A number of algorithms have been proposed, some of them rediscoveries of the Substitution Method and its ilk (cf. [Simmons, 1994]) and even much older results in second-order logic [Doherty, Łukasiewicz and Szalas, 1994], others working with new 'functional' translations better geared towards complete standard Skolemization and Resolution (cf. Ohlbach [1991; 1993]). One interesting feature of some of these algorithms is that they also produce useful equivalents for second-order modal principles. For instance, the typically non-first-order McKinsey Axiom gets a natural equivalent quantifying over both individual worlds and Skolem functions witnessing its (non-Sahlqvist) antecedent. Finally, we mention the use of set-theoretic interpretations of the standard translation in d'Agostino, van Benthem, Montanari & Policriti [1995], which

read the universal modality as describing a power set. This translation also works with an explicit axiom system for general frames plus one axiom stating that the relational successors of any point in a frame form a set. This shift in perspective reduces theorem proving in modal logics to deduction in weak computational set theories. Many of these translations can also be formulated so as to deal with extended modal formalisms or larger fragments of second-order logic.

Designing New Logics

Finally, correspondence techniques have been used in ‘deconstructing’ standard logics and designing new ones. For instance, one can interpret first-order predicate logic over possible worlds models (‘labelled transition systems’) with assignments replaced by abstract states connected by abstract relations R_x modelling variable shifts. Then, standard predicate-logical validities turn out to express interesting frame properties, constraining possible computations, e.g., by Church-Rosser confluence properties (which match the first-order axiom $\exists y \forall x \phi \rightarrow \forall x \exists y \phi$). Moreover, one may want to impose certain restrictions on admissible valuations, such as ‘heredity constraints’ for axioms $P_y \rightarrow \forall x P_y$ or $P_y \rightarrow [y/x]P_x$ (van Benthem [1997; 1996b] have details). These abstract models reflect certain dependencies between admissible object values that may exist for individual variables. This theme is investigated more explicitly in [Alechina and van Benthem, 1993; Alechina, 1995], which design new generalized quantifier logics over ‘dependence models’, first proposed by Michiel van Lambalgen — where again the force of possible axioms is measured at least initially in terms of (Sahlqvist) frame correspondences. Related modal approaches to first-order logic are found in [Venema, 1991; Marx, 1995].

ADDED IN PRINT (1999)

Handbooks appear according to their own rhythms. Two years have elapsed since the updates were written for this Appendix. Here are a few further items of interest. D’Agostino [1998] contains new material on definability in infinitary modal logics, a topic also pursued further by Barwise and Moss. Meyer Viol [1995] has examples of correspondence for intuitionistic predicate logic showing how intermediate axioms can be quite surprising in their content. Hollenberg [1998] is an extensive study of definability, invariance and safety in modal process languages. Gerbrandy [1998] has interesting theorems on modal definability and bisimulation invariance in a setting of non-well-founded set theory, with applications to dynamic logic of epistemic updates. Grädel [1999] is an excellent survey of progress made on the program of decidable guarded first-order languages extending modal logic,

including also fixed-point operators. Van Benthem [1998] is an up-to-date survey of the definability/correspondence paradigm, and the corresponding ‘tandem approach’ to modal and classical logics. Finally, two modern texts on modal logic that take correspondence seriously are Blackburn, de Rijke and Venema [1999] and van Benthem [1999].

Handbook of Philosophical Logic

2nd Edition

Volume 4

edited by Dov M. Gabbay and F. Guentner

CONTENTS

Editorial Preface Dov M. Gabbay	vii
Conditional Logic D. Nute and C. B. Cross	1
Dynamic Logic D. Harel, D. Kozen, and J. Tiuryn	99
Logics for Defeasible Argumentation H. Prakken and G. Vreeswijk	219
Preference Logic S. O. Hansson	319
Diagrammatic Logic E. Hammer	395
Index	423

PREFACE TO THE SECOND EDITION

It is with great pleasure that we are presenting to the community the second edition of this extraordinary handbook. It has been over 15 years since the publication of the first edition and there have been great changes in the landscape of philosophical logic since then.

The first edition has proved invaluable to generations of students and researchers in formal philosophy and language, as well as to consumers of logic in many applied areas. The main logic article in the *Encyclopaedia Britannica* 1999 has described the first edition as ‘the best starting point for exploring any of the topics in logic’. We are confident that the second edition will prove to be just as good.!

The first edition was the second handbook published for the logic community. It followed the North Holland one volume *Handbook of Mathematical Logic*, published in 1977, edited by the late Jon Barwise. The four volume *Handbook of Philosophical Logic*, published 1983–1989 came at a fortunate temporal junction at the evolution of logic. This was the time when logic was gaining ground in computer science and artificial intelligence circles.

These areas were under increasing commercial pressure to provide devices which help and/or replace the human in his daily activity. This pressure required the use of logic in the modelling of human activity and organisation on the one hand and to provide the theoretical basis for the computer program constructs on the other. The result was that the *Handbook of Philosophical Logic*, which covered most of the areas needed from logic for these active communities, became their bible.

The increased demand for philosophical logic from computer science and artificial intelligence and computational linguistics accelerated the development of the subject directly and indirectly. It directly pushed research forward, stimulated by the needs of applications. New logic areas became established and old areas were enriched and expanded. At the same time, it socially provided employment for generations of logicians residing in computer science, linguistics and electrical engineering departments which of course helped keep the logic community thriving. In addition to that, it so happens (perhaps not by accident) that many of the Handbook contributors became active in these application areas and took their place as time passed on, among the most famous leading figures of applied philosophical logic of our times. Today we have a handbook with a most extraordinary collection of famous people as authors!

The table below will give our readers an idea of the landscape of logic and its relation to computer science and formal language and artificial intelligence. It shows that the first edition is very close to the mark of what was needed. Two topics were not included in the first edition, even though

they were extensively discussed by all authors in a 3-day Handbook meeting. These are:

- a chapter on non-monotonic logic
- a chapter on combinatory logic and λ -calculus

We felt at the time (1979) that non-monotonic logic was not ready for a chapter yet and that combinatory logic and λ -calculus was too far removed.¹ Non-monotonic logic is now a very major area of philosophical logic, alongside default logics, labelled deductive systems, fibring logics, multi-dimensional, multimodal and substructural logics. Intensive re-examinations of fragments of classical logic have produced fresh insights, including at time decision procedures and equivalence with non-classical systems.

Perhaps the most impressive achievement of philosophical logic as arising in the past decade has been the effective negotiation of research partnerships with fallacy theory, informal logic and argumentation theory, attested to by the Amsterdam Conference in Logic and Argumentation in 1995, and the two Bonn Conferences in Practical Reasoning in 1996 and 1997.

These subjects are becoming more and more useful in agent theory and intelligent and reactive databases.

Finally, fifteen years after the start of the Handbook project, I would like to take this opportunity to put forward my current views about logic in computer science, computational linguistics and artificial intelligence. In the early 1980s the perception of the role of logic in computer science was that of a specification and reasoning tool and that of a basis for possibly neat computer languages. The computer scientist was manipulating data structures and the use of logic was one of his options.

My own view at the time was that there was an opportunity for logic to play a key role in computer science and to exchange benefits with this rich and important application area and thus enhance its own evolution. The relationship between logic and computer science was perceived as very much like the relationship of applied mathematics to physics and engineering. Applied mathematics evolves through its use as an essential tool, and so we hoped for logic. Today my view has changed. As computer science and artificial intelligence deal more and more with distributed and interactive systems, processes, concurrency, agents, causes, transitions, communication and control (to name a few), the researcher in this area is having more and more in common with the traditional philosopher who has been analysing

¹I am really sorry, in hindsight, about the omission of the non-monotonic logic chapter. I wonder how the subject would have developed, if the AI research community had had a theoretical model, in the form of a chapter, to look at. Perhaps the area would have developed in a more streamlined way!

such questions for centuries (unrestricted by the capabilities of any hardware).

The principles governing the interaction of several processes, for example, are abstract and similar to principles governing the cooperation of two large organisations. A detailed rule based effective but rigid bureaucracy is very much similar to a complex computer program handling and manipulating data. My guess is that the principles underlying one are very much the same as those underlying the other.

I believe the day is not far away in the future when the computer scientist will wake up one morning with the realisation that he is actually a kind of formal philosopher!

The projected number of volumes for this Handbook is about 18. The subject has evolved and its areas have become interrelated to such an extent that it no longer makes sense to dedicate volumes to topics. However, the volumes do follow some natural groupings of chapters.

I would like to thank our authors and readers for their contributions and their commitment in making this Handbook a success. Thanks also to our publication administrator Mrs J. Spurr for her usual dedication and excellence and to Kluwer Academic Publishers for their continuing support for the Handbook.

Dov Gabbay
King's College London

Logic	IT			
	Natural language processing	Program control specification, verification, concurrency	Artificial intelligence	Logic programming
Temporal logic	Expressive power of tense operators. Temporal indices. Separation of past from future	Expressive power for recurrent events. Specification of temporal control. Decision problems. Model checking.	Planning. Time dependent data. Event calculus. Persistence through time—the Frame Problem. Temporal query language. temporal transactions.	Extension of Horn clause with time capability. Event calculus. Temporal logic programming.
Modal logic. Multi-modal logics	generalised quantifiers	Action logic	Belief revision. Inferential databases	Negation by failure and modality

				Of great importance to the future. Just starting
			A new theory of logical agent	A new kind of model

CONDITIONAL LOGIC

Prior to 1968 several writers had explored the conditions for the truth or assertability of conditionals, but this work did not result in an attempt to provide formal models for the semantical structure of conditionals. It had also been suggested that a proper logic for conditionals might be provided by combining modal operators with material conditionals in some way, but this suggestion never led to any widely accepted formal logic for conditionals.¹ Then Stalnaker [1968] provided both a formal semantics for conditionals and an axiomatic system of conditional logic. This important paper effectively inaugurated that branch of philosophical logic which we today call conditional logic. Nearly all the work on the logic of conditionals for the next ten years, and a great deal of work since then, has either followed Stalnaker's lead in investigating possible worlds semantics for conditionals or posed problems for such an approach. But in 1978, Peter Gärdenfors [1978] initiated a new line of inquiry focused on the use of conditionals to represent policies for belief revision. Thus, two main lines of development appeared, one an ontological approach concerned with truth or assertability conditions for conditionals and the other an epistemological approach focused on conditionals and change of belief.

With these two major lines of development, the material which has appeared on conditionals is prodigious. Consequently, we have had to focus upon certain aspects of conditional logic and to give other aspects less attention. We have followed the trend set in the literature and given the most attention to the analysis of so-called subjunctive conditionals as they are used in ordinary discourse and to triviality results for the Ramsey test. Accordingly, our discussion of conditionals and belief revision will be more heavily technical than our discussion of subjunctive conditionals. Other topics are discussed in less detail. Some of the important papers which it has not been possible to review are included in the accompanying bibliography, but the bibliography itself is far from complete.

1 ONTOLOGICAL CONDITIONALS

1.1 Introduction

Conditional logic is, in the first place, concerned with the investigation of the logical and semantical properties of a certain class of sentences occurring

¹Another suggestion which has never been fully developed (but see Hunter [1980; 1982] is that an adequate theory of ordinary conditionals may be derived from relevance logic. We will say no more about this suggestion than it seems to us that conditional logic and relevance logic are concerned with very different problems, and it would be a tremendous coincidence if the correct logic for the conditionals of ordinary usage should turn out to resemble some version of relevance logic at all closely.

in a natural language. We will draw our examples from English, but much of what we have to say can be applied, with due caution, to other natural languages.

Paradigmatically, a conditional declarative sentence in English is one which contains the words ‘if’ and ‘then’. Examples include

1. If it is raining, then we are taking a taxi.

and

2. If I were warm, then I would remove my jacket.

We could delete the occurrences of ‘then’ in (1) and (2) and we would still have perfectly acceptable sentences of English. In the case of (2), we can omit both ‘if’ and ‘then’ if we change the word order. Example (2) surely says the same thing as

3. Were I warm, I would remove my jacket.

Other conditionals in which neither ‘if’ nor ‘then’ occur include

4. When I find a good man, I will praise him.

and

5. You will need my number should you ever wish to call me.

Notice that all of these examples involve two component sentences or clauses, one expressing some sort of condition and another expressing some sort of claim which in some way depends upon the condition. The conditional or ‘if’ part of a conditional sentence is called the antecedent, and the main or ‘then’ part its consequent even when ‘if’ and ‘then’ do not actually occur. Notice that the antecedent precedes the consequent in (1)–(4), but the consequent comes first in (5). These examples should give the reader a fair idea of the types of sentences with which conditional logic is concerned.

While the verbs in (1) are in the indicative mood, those in (2) are in the subjunctive mood. Researchers often rephrase (2), forming a new conditional in which the verbs contained in antecedent and consequent are in the indicative mood. This practice implicitly assumes that (2) has the same content as

6. If it were the case that I am warm, then it would be the case that I remove my jacket.

Even without the rephrasing, it is sometimes said that ‘I am warm’ is the antecedent of both (2) and (6). Thus the mood of the verbs in the grammatical antecedent and consequent of (2) are taken logically to be a component of the conditional construction, while the logical antecedent and consequent

are viewed as containing verbs in the indicative mood. Seen in this way, the conditional constructions in (1) and (2) look quite different and investigators have as a consequence made a distinction between indicative conditionals like (1) and subjunctive conditional like (2). This distinction is important because it appears that these two kinds of conditionals have different logical and semantical properties.

Much of the work done in conditional logic has focused on conditionals having antecedents and consequents which are false. Such conditionals are called counterfactuals. In actual practice, little distinction is made between counterfactuals and subjunctive conditionals which have true antecedents or consequents. Authors frequently refer to conditionals in the subjunctive mood as counterfactuals regardless of whether their antecedents or consequents are true or false. Another special kind of conditional is the so-called counterlegal conditional whose antecedent is incompatible with physical law. An example is

7. If the gravitational constant were to take on a slightly higher value in the immediate vicinity of the earth, then people would suffer bone fractures more frequently.

Also recognized are counteridenticals like

8. If I were the pope, I would support the use of the pill in India.

and countertemporals like

9. If it were 3.00 a.m., it would be dark outside.

Analysis of these special conditionals may involve special difficulties, but we can say very little about these special problems in a paper of this length.

Two other interesting conditional constructions are the even-if construction used in

10. It would rain even if the shaman did not do his dance.

and the might construction used in

11. If you don't take the umbrella, you might get wet.

We might paraphrase (10) using the word 'still' to get

12. It would still rain if the shaman did not do his dance.

even-if and might conditionals have somewhat different properties from those of other conditionals. It is believed by many, though, that these two kinds of conditionals can be analyzed in terms of subjunctive conditionals once we have an acceptable analysis of these. The strategy in this

paper will be to concentrate on the many proposals for subjunctive conditionals, returning later (briefly) to the topics of indicative, even-if and might conditionals.

We will use two different symbols to represent indicative and subjunctive conditionals. For indicative conditionals we will use the double arrow \Rightarrow , and for the subjunctive conditional we will use the corner $>$. (Where context makes our intention clear, we will sometimes use symbols and formulas autonomously to refer to themselves.) With these devices we may represent (1) as

13. It is raining \Rightarrow I am taking a taxi.

and represent (2) as

14. I am warm $>$ I remove my jacket.

Frequently we will have no particular antecedent or consequent in mind as we discuss one or the other of these two kinds of conditionals and as we examine forms which arguments involving these conditionals may take. In these cases we will use standard notation for classical first-order logic augmented by our symbols for indicative and subjunctive conditionals to represent the forms of sentences and arguments under discussion. We assume, as have nearly all investigators, that conditionals have truth values and may therefore appear as arguments for truth-functional operators.

Students in introductory symbolic logic courses are normally taught to treat English conditionals as material conditionals. By material conditionals we mean certain truth-functional compounds of simpler sentences. A material condition $\phi \rightarrow \psi$ is true just in case ϕ is false or ψ is true. There can be little doubt that neither material implication nor any other truth function can be used by itself to provide an adequate representation of the logical and semantical properties of English conditionals or, presumably, the conditionals of any other language.

Consider the following two examples.

15. If I were seven feet tall, then I would be over two meters tall.

16. If I were seven feet tall, then I would be less than two yards tall.

In fact one of the authors is more than two yards tall but less than two meters tall, so for him the common antecedent and the two consequents of (15) and (16) are all false. Yet surely (15) is true while (16) is false. When both the antecedent and the consequent of an English subjunctive conditional are false, the conditional may be either true or false. Now consider two more examples.

17. If I were eight feet tall, I would be less than seven feet tall.

18. If I were seven feet tall, I would be over six feet tall.

Here we have two conditionals each of which has a false antecedent and a true consequent. but the first of these conditionals is false and the second is true. The moral of these examples is that when the antecedent of an English subjunctive conditional is false, the truth value of the conditional is not determined by the truth values of the antecedent and the consequent of the conditional alone. Some other factors must be involved in determining the truth values of such conditionals.

But what about English conditionals with true antecedents? It is generally accepted that any conditional with a true antecedent and a false consequent is false, but the situation is more controversial where the conditionals with true antecedents and true consequents are concerned. Some researchers have maintained that all such conditionals are true while others have claimed that such conditionals are sometimes false. Later we will consider some of the issues involved in this controversy. For now we simply recognize that there are some very good reasons for rejecting the view that all English conditionals can be represented adequately by material implication or by any other truth function.

1.2 *Cotenability theories of conditionals*

Chisholm [1946], Goodman [1955], Sellars [1958], Rescher [1964] and others have proposed accounts of conditionals which share some important features. Borrowing a term from Goodman, we can call these proposals *cotenability* theories of conditionals. The basic idea which these proposals share is that the conditional $\phi > \psi$ is true in case ϕ , together with some set of laws and true statements, entails ψ .

A crucial problem for such an analysis is that of determining the appropriate set of true statements to involve in the truth condition for a particular conditional. If the antecedent of the conditional is false, then of course its negation is true. But any proposition together with its negation will entail anything. The set of true statements upon which the truth of the conditional is to depend must at least be logically compatible with the antecedent of the conditional or the conditional will turn out to be trivially true on such an account. But logical compatibility is not enough either. We can have a true proposition χ such that ϕ and χ are logically compatible but such that $\chi > \neg\phi$ is also true. Then we should not wish to include χ in the set of propositions upon which the evaluation of $\phi > \psi$ depends. Goodman said of such a χ that it is not cotenable with ϕ . So Goodman's ultimate position is that $\phi > \psi$ is true just in case ψ is entailed by ϕ together with the set of all physical laws and the set of all true propositions cotenable with ϕ , i.e. with the set of all true propositions such that no member of that set counterfactually implies the negation of ϕ and the negation of no member

of that set is counterfactually implied by ϕ . Such an account is obviously circular since the truth conditions for counterfactuals are given in terms of cotenability, while cotenability is defined in terms of the truth values of various counterfactual conditionals.

Although this is certainly a serious problem, it is not the only problem which theories of this type encounter. As a result of the role which law plays in such a theory, all counterlegal conditionals are counted as trivially true, and this is counterintuitive. Furthermore, even if we could provide a noncircular account of cotenability, another problem arises for conditionals which are *not* counterlegal. Suppose two true propositions χ and θ are each cotenable with ϕ , but that $\chi \wedge \theta$ is not. In selecting the set of propositions upon which the evaluation of $\phi > \psi$ shall rest we must omit either χ or θ since otherwise our conditional will be trivially true once again. But which of these two propositions shall we omit?

Most recent work in conditional logic is compatible with cotenability theory even though no attempt is made to define and use the notion of cotenability. We might view the resultant theories at least in part as attempts to determine, without ever specifying exactly what cotenability is, the logical and semantical properties which conditionals must have if the cotenability approach is essentially correct for conditionals without counterlegal antecedents. Indeed, the vagueness deliberately built into many of these recent theories suggests that our notion of cotenability, if we have one, varies according to our purposes and the context in which we use a conditional.²

1.3 *Strict Conditionals*

We have seen that the truth value of a conditional is not always determined by the actual truth values of its antecedent and consequent, but perhaps it is determined by the truth values which its antecedent and consequent take in some other possible worlds. One way such an analysis might be developed is suggested by the role laws play in the cotenability theories. Perhaps we should look not only at the truth values of the antecedent and the consequent in the actual world, but also at their truth values in all possible worlds which have the same laws as does our own. When two worlds obey the same physical laws, we can say that each is a physical alternative of the other. The proposal, then, is that $\phi > \psi$ is true if ψ is true at every physical alternative to the actual world at which ϕ is true. Suppose we say a proposition is physically necessary if and only if it is true at every physical alternative to the actual worlds, and suppose we express

²Bennett [1974] and Loewer [1978] arrive at opposite conclusions concerning the question whether Lewis's semantics is compatible with cotenability theory. Their discussions are instructive for other semantics as well.

the claim that a proposition ϕ is physically necessary by $\Box\phi$. Then the proposal we are considering is that the following equivalence always holds:

$$19. (\phi > \psi) \leftrightarrow \Box(\phi \rightarrow \psi).$$

Another way of arriving at (19) is the following. English subjunctive conditionals are not truth-functional because they say more than that the antecedent is false or the consequent is true. The additional content is a claim that there is some sort of connection between the antecedent and the consequent. The kind of connection which seems to occur to people most readily in this context is a physical or causal connection. How can we represent this additional content in our formalization of English subjunctive conditionals? One way is to interpret $\phi > \psi$ as involving the claim that it is physically impossible that ϕ be true and ψ false. Once again we come up with (19). A proposal resembling the one we have outlined can be found in [Burks, 1951], although we do not wish to suggest that Burks arrived at his account by exactly the same line of reasoning as we have suggested.

We can generalize the proposal represented by (19). We might suppose that the basic form of (19) is correct but that the sort of necessity involved in English subjunctive conditionals is not pure physical necessity. One reason for suspecting this is that the notion of cotenability has been ignored. It is not simply a consequence of physical law that Jane would develop hives if she were to eat strawberries; it is also in part a consequence of her having a particular physical make-up. In evaluating the claim that Jane would become ill if she were to eat strawberries, we do not count the fact that in some worlds which share the same physical laws as our own but in which Jane has a radically different physical make-up, she is able to eat strawberries with impunity, as a legitimate reason for rejecting this claim. Another reason for seeking a different kind of necessity for the analysis of conditionals is that some conditionals may be true because of connections between their antecedents and consequents which are not physical connections at all. Consider, for example, conditionals such as ‘If you deserted your family you would be a cad’, which seems to be founded on normative rather than physical connections. The general theory we are considering, then, is that English subjunctive conditionals are strict conditionals of some sort, i.e. that their logical form is given by the equivalence (19). There remains the problem of determining which kind of necessity is involved in these conditionals.

Regardless of the kind of necessity we choose in such an analysis of conditionals, we should expect our modal logic to have certain minimal properties. By a modal logic we mean any set \bar{L} of sentences formed from the symbols of classical sentential logic together with the symbol \Box in the usual ways, provided that \bar{L} contains all tautologies and is closed under the rule *modus ponens*. We should expect that for any tautology ϕ our modal logic will contain $\Box\phi$. We should also expect our modal logic to contain all substitution

instances of the following thesis:

$$20. \Box(\phi \rightarrow \psi) \rightarrow (\Box\phi \rightarrow \Box\psi).$$

But when we define our conditionals according to (19), our logic will then also contain all substitution instances of the following theses:

$$\text{Transitivity: } [(\phi > \psi) \wedge (\chi > \phi)] \rightarrow (\chi > \psi)$$

$$\text{Contraposition: } (\phi > \neg\psi) \rightarrow (\psi > \neg\phi)$$

$$\text{Strengthening antecedents: } (\phi > \psi) \rightarrow [(\phi \wedge \chi) > \psi].$$

But none of these theses seem to be reliable for English subjunctive conditionals. As a counterexample to Transitivity, consider the following conditionals:

21. If Carter had not lost the election in 1980, Reagan would not have been President in 1981.
22. If Carter had died in 1979, he would not have lost the election in 1980.
23. If Carter had died in 1979, Reagan would not have been President in 1981.

(21) and (22) are true, but it is far from clear that (23) is true. As a counterexample to Contraposition, consider:

24. If it were to rain heavily at noon, the farmer would not irrigate his field at noon.
25. If the farmer were to irrigate his field at noon, it would not rain heavily at noon.

And finally, for Strengthening Antecedents, consider:

26. If the left engine were to fail, the pilot would make an emergency landing.
27. If the left engine were to fail and the right wing were to shear off, the pilot would make an emergency landing.

Since even very weak modal logics will contain all substitution instances of these three theses, and since most speakers of English find counterexamples of the sort we have considered convincing, most investigators are convinced that English conditionals are not a variety of strict conditional.

1.4 *Minimal Change Theories*

While treating ordinary conditionals as strict conditionals does not seem too promising, investigators have still found the possible worlds semantics often associated with modal logic very attractive. The basic intuition, that a conditional is true just in case its consequent is true at every member of some set of worlds at which its antecedent is true, may yet be salvageable. We can avoid Transitivity, etc. if we allow that the set of worlds involved in the truth conditions for different conditionals may be different. But we do not wish to allow that this set of worlds be chosen arbitrarily for a given conditional.

Stalnaker [1968] proposes that the conditional $\phi > \psi$ is true just in case ψ is true at the world most like the actual world at which ϕ is true. According to Stalnaker, in evaluating a conditional we add the antecedent of the conditional to our set of beliefs and modify our set of beliefs as little as possible in order to accommodate the new belief tentatively adopted. Then we consider whether the consequent of the conditional would be true if this revised set of beliefs were all true. In the ideal case, we would have a belief about every single matter of fact before and after this operation of adding the antecedent of the conditional to our stock of beliefs. Possible worlds correspond to these epistemically ideal situations. Stalnaker's assumption, then, is that at least when the antecedent of a conditional is logically possible, there is always a unique possible world at which the antecedent is true and which is more like the actual world than is any other world at which the antecedent is true. We will call this Stalnaker's Uniqueness Assumption.

On some fairly reasonable assumptions about the notion of similarity of worlds, Stalnaker's truth conditions generate a very interesting logic for conditionals. Essentially these assumptions are that any world is more similar to itself than is any other world, that the ϕ -world closest to world i (that is, the world at which ϕ is true which is more similar to i than is any other world at which ϕ is true) is always at least as close as the $\phi \wedge \psi$ -world closest to i , and that if the ϕ -world closest to i is a ψ -world and the ψ -world closest to i is a ϕ -world, then the ϕ -world closest to i and the ψ -world closest to i are the same world.

The model theory Stalnaker develops is complicated by his use of the notion of an absurd world, a world at which every sentence is true. This invention is motivated by the need to provide truth conditions for conditionals with impossible antecedents. Stalnaker's semantics can be simplified by omitting this device and adjusting the rest of the model theory accordingly. When we do this, we produce what could be called simplified Stalnaker models. Such a model is an ordered quadruple $\langle I, R, s, [] \rangle$ where I is a set of possible worlds, R is a binary reflexive (accessibility) relation on I , s is a partial world selection function which, when defined, assigns to sentence ϕ and a world i in I a world $s(\phi, i)$ (the ϕ -world closest to i), and $[]$ is a

function which assigns to each sentence ϕ a subset $[\phi]$ of I (all those worlds in I at which ϕ is true). Stalnaker's assumptions about the similarity of worlds become a set of restrictions on the items of these models:

- (S1) $s(\phi, i) \in [\phi]$;
- (S2) $\langle i, s(\phi, i) \rangle \in R$;
- (S3) if $s(\phi, i)$ is not defined then for all $j \in I$ such that $\langle i, j \rangle \in R$, $j \notin [\phi]$;
- (S4) if $i \in [\phi]$ then $s(\phi, i) = i$;
- (S5) if $s(\phi, i) \in [\psi]$ and $s(\psi, i) \in [\phi]$, then $s(\phi, i) = s(\psi, i)$;
- (S6) $i \in [\phi > \psi]$ if and only if $s(\phi, i) \in [\psi]$ or $s(\phi, i)$ is undefined.

Until otherwise indicated, we will understand by a conditional logic any set \bar{L} of sentences which can be constructed from the symbols of classical sentential logic together with the symbol $>$, provided that \bar{L} contains all tautologies and is closed under the inference rule *modus ponens*. The conditional logic determined by Stalnaker's model theory is the smallest conditional logic which is closed under the two inference rules

RCEC: from $\phi \leftrightarrow \psi$, to infer $(\chi > \phi) \leftrightarrow (\chi > \psi)$

RCK: from $(\phi_1 \wedge \dots \wedge \phi_n) \rightarrow \psi$, to infer $[(\chi > \phi_1) \wedge \dots \wedge (\chi > \phi_n)] \rightarrow (\chi > \psi)$, $n \geq 0$

and which contains all substitution instances of the theses

ID: $\phi > \phi$

MP: $(\phi > \psi) \rightarrow (\phi \rightarrow \psi)$

MOD: $(\neg\phi > \phi) \rightarrow (\psi > \phi)$

CSO: $[(\phi > \psi) \wedge (\psi > \phi)] \rightarrow [(\phi > \chi) \leftrightarrow (\psi > \chi)]$

CV: $[(\phi > \psi) \wedge \neg(\phi > \neg\chi)] \rightarrow [(\phi \wedge \chi) > \psi]$

CEM: $(\phi > \psi) \vee (\phi > \neg\psi)$

Together with *modus ponens* and the set of tautologies, these rules and theses can be viewed as an axiomatization of Stalnaker's logic, which he calls **C2**. While Stalnaker supplies a rather different axiomatization for **C2**, these rules and theses enjoy the advantage that they allow easy comparison of **C2** with other conditional logics. Several of these rules and theses are due to Chellas [1975]. It can be shown that a sentence is a member of **C2** if and only if that sentence is true at every world in every simplified

Stalnaker model. Thus we say that the class of simplified Stalnaker models determines or characterizes the conditional logic **C2**. None of Transitivity, Contraposition, and Strengthening Antecedents is contained in **C2**.

A variation of the semantics developed by Stalnaker treats the function s as taking sets of worlds rather than sentences as arguments and values. In this variation, s is a function which assigns to each subset A of I and each member i of I a subset $s(A, i)$ of I . Then $\phi > \psi$ will be true at i just in case $s([\phi], i) \subseteq [\psi]$. By setting our semantics up in this way, we ensure that we can substitute one antecedent for another in a conditional provided that the two antecedents are true at exactly the same worlds, and we can do this without any additional restrictions on the function s . Since many authors have called sets of worlds propositions, we could call Stalnaker's original semantics a sentential semantics and the present variation on Stalnaker's semantics a propositional semantics to represent this difference in the kind of argument the function s takes. As we look at alternatives to Stalnaker's semantics we will always consider the sentential forms of these semantics although equivalent propositional forms will often be available. Equivalence of the two versions of a particular semantics is guaranteed so long as the conditional logic characterized by the sentential version is closed under substitution of provable equivalents, i.e. so long as it is closed under both RCEC and

RCEA: from $\phi \leftrightarrow \psi$ to infer $(\phi > \chi) \leftrightarrow (\psi > \chi)$.

C2 is closed under RCEA as is any conditional logic closed under RCK and containing all substitution instances of CSO. The difference between sentential and propositional formulations of a particular kind of model theory becomes important if we wish to consider conditional logics which are not closed under RCEA. Reasons for considering such 'non-classical' logics are discussed in Section 1.7 below. For parallel development of sentential and propositional versions of certain kinds of model theories for conditional logics, see [Nute, 1980b].

Lewis [1973b; 1973c] questions Stalnaker's assumptions about the similarity of worlds and thus his semantics for conditionals. It is Stalnaker's Uniqueness Assumption which Lewis rejects. Lewis argues that there may be no unique ϕ -world which is closer to i than is any other ϕ -world. As an example, Lewis asks us to consider a straight line printed in a book and to suppose that this line were longer than it is. No matter what greater length we choose for the line, there is a shorter length which is still greater than the actual length of the line. The conclusion is that worlds which differ from the actual world only in the length of the sample line may be more and more like the actual world as the length of the line in those worlds comes closer to the line's actual length. But none of these worlds is the closest world at which the line is longer. In fact, examples of this sort can also be offered against an assumption about similarity of worlds which is

weaker than Stalnaker's Uniqueness Assumption. This assumption, which Lewis calls the Limit Assumption, is that, at least for a sentence ϕ which is logically possible, there is always at least one ϕ -world which is as much like i as is any other ϕ -world. Both the Uniqueness Assumption and the weaker Limit Assumption are highly suspect.

If we follow Lewis's advice and drop the Uniqueness Assumption, we must give up Conditional Excluded Middle (CEM). But this is exactly the feature of Stalnaker's logic which is most often cited as objectionable. Both disjuncts in CEM will be true if ϕ is impossible and hence s is not defined for ϕ and the actual world. On the other hand, if ϕ is possible, then ψ must be either true or false at the nearest ϕ -world. Lewis ([1973b], p. 80) offers the following as a counterexample to CEM:

28a It is not the case that if Bizet and Verdi were compatriots, Bizet would be Italian; and it is not the case that if Bizet and Verdi were compatriots, Bizet would not be Italian; nevertheless, if Bizet and Verdi were compatriots, Bizet either would or would not be Italian.

Lewis [1973b] admits that (28a) sounds, offhand, like a contradiction, but he insists that the cost of respecting this offhand opinion is too high:

However little there is to choose for closeness between worlds where Bizet and Verdi are compatriots by both being Italian and worlds where they are compatriots by both being French, the selection function still must choose. I do not think it *can* choose—not if it is based entirely on comparative similarity, anyhow. Comparative similarity permits ties, and Stalnaker's selection function does not.³

Van Fraassen [1974] has employed the notion of supervaluation in defense of CEM. The suggestion is that in actual practice we do not depend upon a single world selection function s in evaluating conditionals. Instead we consider a number of different ways in which we might measure the similarity of worlds, each with its appropriate world selection function. Each world selection function provides a way of evaluating conditionals. A sentence can also have the property that it is true regardless of which world selection function we use. We can call such a sentence supertrue. If we accept Stalnaker's semantics together with a multiplicity of world selection functions, it turns out that every instance of CEM is supertrue even though it may be the case that neither disjunct of some instance of CEM is supertrue. In fact, all the members of **C2** are supertrue when we apply Van Fraassen's method of supervaluation, and the method mandates the following reinterpretation of the Bizet-Verdi example:

³[Lewis, 1973b], p. 80.

28b ‘If Bizet and Verdi were compatriots, Bizet would be Italian’ is not supertrue; and ‘If Bizet and Verdi were compatriots, Bizet would not be Italian’ is not supertrue; nevertheless, ‘If Bizet and Verdi were compatriots, Bizet either would or would not be Italian’ is supertrue. (The relevant instance of CEM is also supertrue: ‘Either Bizet would be Italian if Bizet and Verdi were compatriots, or Bizet would not be Italian if Bizet and Verdi were compatriots.’)

In the Bizet-Verdi example, what Lewis accounts for as a tie in comparative world similarity, the method of supervaluation accounts for as a case of indeterminacy in the choice of a closest compatriot-world.

Lewis [1973b] admits that offhand opinion seems to favor CEM, but, Stalnaker [1981a] shows that there is systematic intuitive evidence for CEM: the apparent absence of scope ambiguities in conditionals where Lewis’ theory predicts we should find them. Consider the following dialogue (see [Stalnaker, 1981a], pp. 93–95):

X: President Carter has to appoint a woman to the Supreme Court.

Y: Who do you think he has to appoint?

X: He doesn’t have to appoint any particular woman; he just has to appoint some woman or other.

There is a clear scope ambiguity in X’s statement, and this scope ambiguity explains why X’s response to Y makes sense: Y reads X as having intended ‘a woman’ to have wide scope, and X’s response corrects Y by making it clear that X intended ‘a woman’ to have narrow scope. Now compare this dialogue to another, in which necessity is replaced by the past-tense operator:

X: President Carter appointed a woman to the Supreme Court.

Y: Who do you think he appointed?

X: He didn’t appoint any particular woman; he just appointed some woman or other.

In this case X’s response does not make sense. There is no semantically distinct narrow scope reading that X could have had in mind, so there is no room for Y to have misunderstand X’s statement. Finally, consider a dialogue involving a conditional instead of a necessity or past tense statement:

X: President Carter would have appointed a woman to the Supreme Court last year if there had been a vacancy.

Y: Who do you think he would have appointed?

X: He wouldn't have appointed any particular woman; he just would have appointed some woman or other.

If Lewis' analysis of counterfactuals is correct, then in this dialogue, as in the first dialogue, one should perceive an ambiguity in the scope of 'a woman' in X's statement, and X's response should make sense as a correction of Y's misinterpretation. In fact there is no room for Y to have misunderstood X's statement, and X's response simply doesn't make sense. In this respect, the third dialogue parallels the second dialogue, not the first, and the apparent lack of a scope ambiguity in X's statement in the third dialogue is evidence for CEM.⁴

If Stalnaker's example does not convince one to accept CEM, it is quite possible to formulate a logic and a semantics for conditionals which resembles Stalnaker's but which does not include CEM. Lewis [1971; 1973b; 1973c] suggests more than one way of doing this. The first way is to replace the Uniqueness Assumption with the weaker Limit Assumption. Instead of looking at the closest antecedent-world, we look at all closest antecedent-worlds. These functions might better be called class selection functions rather than world selection functions. It is also not necessary to incorporate the accessibility relation into our models for conditionals if we use class selection functions since, if we make a certain reasonable assumption, we can define such a relation in terms of our class selection function. The assumption is that if ϕ is possible at all at i , then there is at least one closest ϕ -world for our selection function to pick out. Our models are then ordered triples $\langle I, f, [] \rangle$ such that I and $[]$ are as before and f is a function which assigns to each sentence ϕ and each world i in I a subset of I (all the ϕ -worlds closest to i). By restricting these models appropriately, we can characterize a logic very similar to Stalnaker's **C2**. This logic, which Lewis calls **VC**, is the smallest conditional logic which is closed under the same rules as those listed for **C2** and which contains all those theses used in defining **C2** except that we replace CEM with

CS: $(\phi \wedge \psi) \rightarrow (\phi > \psi)$.

CS is contained by **C2** although CEM is not contained by **VC**.⁵ A sentence

⁴A different sort of argument for CEM can be found in [Cross, 1985], which adopts Bennett's [1982] analysis of 'even if' conditionals and argues for the validity of CEM based on the intuitive validity of the following formulas:

$$\begin{aligned} &(\text{e } \phi > \psi) \rightarrow (\phi > \psi) \\ &(\psi \wedge \neg(\phi > \neg\psi)) \rightarrow (\text{e } \phi > \psi), \end{aligned}$$

where $(\text{e } \phi > \psi)$ means 'Even if ϕ , ψ '. The argument turns on the fact that in any system of conditional logic that includes classical propositional logic and RCEC, CEM is a theorem iff

$$(\psi \wedge \neg(\phi > \neg\psi)) \rightarrow (\phi > \psi)$$

is a theorem.

⁵This and other independence results cited in this paper are provided in Nute [1979;

is a member of **VC** if and only if it is true at every world in every class selection function model which satisfies the following restrictions:

- (CS1): if $j \in f(\phi, i)$ then $j \in [\phi]$;
- (CS2): if $i \in [\phi]$ then $f(\phi, i) = \{i\}$;
- (CS3): if $f(\phi, i)$ is empty then $f(\psi, i) \cap [\phi]$ is also empty;
- (CS4): if $f(\phi, i) \subseteq [\psi]$ and $f(\psi, i) \subseteq [\phi]$, then $f(\phi, i) = f(\psi, i)$;
- (CS5): if $f(\phi, i) \cap [\psi] \neq \emptyset$, then $f(\phi \wedge \psi, i) \subseteq f(\phi, i)$;
- (CS6): $i \in [\phi > \psi]$ iff $f(\phi, i) \subseteq [\psi]$.

Although Lewis endorses **VC** as the proper logic for subjunctive conditionals, he finds the Limit Assumption and, hence, the version of class selection function semantics we have developed, to be no more satisfactory than the Uniqueness Assumption. Consequently, Lewis proposes an alternative semantics for subjunctive conditionals. This alternative is also based on the similarity of worlds. The difference is in the way Lewis uses similarity in giving the truth conditions for conditionals. A conditional $\phi > \psi$ with a logically possible antecedent ϕ is true at a world i , according to Lewis, if there is a $\phi \wedge \psi$ -world which is closer to i than is any $\phi \wedge \neg\psi$ -world. Lewis uses nested systems of spheres in his models to indicate the relative similarity of worlds. A system-of-spheres model is an ordered triple $\langle I, \$, [] \rangle$ such that I and $[]$ are as before and $\$$ is a function which assigns to each i in I a nested set $\$_i$ of subsets of I (the spheres about i). If there is some sphere S about i such that j is in S but k isn't in S , then j is closer to or more similar to i than is k . To characterize the logic **VC**, we must adopt the following restrictions of system-of-spheres models:

- (SOS1): $\{i\} \in \$_i$;
- (SOS2): $i \in [\phi > \psi]$ if and only if $\$_i \cap [\phi]$ is empty or there is an $S \in \$_i$ such that $S \cap [\phi]$ is not empty and $S \cap [\phi] \subseteq [\psi]$.

While Lewis rejects the Limit Assumption, it should be noted that in those cases in which there is a closest ϕ -world to i the conditions for a conditional with antecedent ϕ being true at i are exactly the same for system-of-spheres models as for the type of class selection function model we examined earlier. For this reason we classify Lewis's semantics as a minimal change semantics to contrast it with other accounts which lack this feature.

Pollock [1976] also develops a minimal change semantics for conditionals. In fact, Pollock's semantics is a type of class selection function semantics. There are two primary reasons why Pollock rejects Lewis's semantics and the

1980b].

conditional logic **VC**. First Pollock rejects the thesis **CV**, a thesis which is unavoidable in Lewis's semantics. Second Pollock embraces the Generalized Consequence Principle:

GCP: If Γ is a set of sentences such that $\phi > \psi$ is true for each $\psi \in \Gamma$, and if Γ entails χ , then $\phi > \chi$ is true.

GCP does not hold in all system-of-spheres models, but it does hold in all class selection function models.⁶

The conditional logic **SS** which Pollock favors is the smallest conditional logic closed under the rules listed for **VC** and containing all those theses used in defining **VC** except that we replace **CV** with

CA: $[(\phi > \psi) \wedge (\chi > \psi)] \rightarrow [(\phi \vee \chi) > \psi]$.

This again gives us a weaker system since CA is contained by **VC** while **CV** is not contained by **SS**. Obviously, **SS** is not determined by the class of class selection function models which satisfy conditions (CS1)–(CS6) since this class of models characterizes the logic **VC**. Let's replace the condition (CS5) with

(CS5') $f(\phi \vee \psi, i) \subseteq f(\phi, i) \cup f(\psi, i)$.

Then **SS** is determined by the class of all class selection function models which satisfy this new set of conditions.

One reason for Pollock's lack of concern for Lewis's counterexamples to the Limit Assumption may be that Pollock conceives of what would count as a minimal change quite differently from the way Lewis does. Pollock [1976] offers a detailed account of the notion of a minimal change, an account

⁶To see how GCP might fail in Lewis's semantics, consider the example Lewis uses to show that for a particular ϕ there may be no ϕ -world closest to i . The example, which we considered earlier, involves a line printed on a page of [Lewis, 1973b]. Lewis invites us to consider worlds in which this line is longer than its actual length, which we will suppose to be exactly one inch. If the only way in which these worlds differ from the actual world is in the length of Lewis's line, then it is plausible that we rank these worlds in their similarity to the actual world according to how close to one inch Lewis's line is in each of these worlds. But no matter how close to one inch the line is, so long as it is longer than one inch there will be another such world in which it is closer to an inch in length. This means that for any length m greater than one inch, there is a world in which the line is longer than one inch and in which the line does not have length m which is nearer the actual world than is any world in which the line has length m . but then Lewis's truth conditions for conditionals dictate that if the line were longer than one inch, its length would not be m , and this is true for any length m greater than the actual length of the line. then consider the set Γ of sentences of the form 'Lewis's line is not length m ' where m ranges over every length greater than the actual length of Lewis's line. But Γ entails the sentence 'Lewis's line is not greater than one inch in length'. Applying GCP, we conclude that if Lewis's line were greater than one inch in length, then it would not be greater than one inch in length. This conclusion is not intuitively reasonable nor is it true at any world in the system-of-spheres model which Lewis describes in his discussion.

which is later modified in [Pollock, 1981]. The later view, which avoids many problems of the earlier view, will be discussed here.

While Stalnaker, Lewis and others maintain that the notions of similarity of worlds and of minimal change are vague notions which may change given different purposes and contexts, thus accounting for the vagueness we often find in the use of conditionals, Pollock claims that the similarity relation is not vague but quite definite. Pollock's account rests upon his use of two epistemological notions, that of a subjunctive generalisation and that of a simple state of affairs. Subjunctive generalisations are statements of the form 'Any F would be a G '; The truth of some subjunctive generalisations like 'Anyone who drank from the Chisholm's bottle would die' depends upon contingent matters of fact, in this case the fact that Chisholm's bottle contains strychnine and the fact that people have a certain physical make-up. Other subjunctive generalisations like 'Any creature with a physical make up like ours who drank strychnine would die' do not depend for their truth on contingent matters of fact in the same way. Pollock calls the former 'weak' subjunctive generalisations and the latter 'strong' subjunctive generalisations. Some subjunctive generalisations are supposed by Pollock to be directly confirmable by their instances, and these he calls basic. The problem of confirmation is discussed in [Pollock, 1984]. The second crucial ingredient in Pollock's analysis is the notion of a simple state of affairs. A state of affairs is simple if it can be known non-inductively to be the case without first coming to know some other state(s) of affairs which entail(s) it.

The actual world is supposed by Pollock to be determined by the set of true basic strong subjunctive generalisations together with the set of true simple states of affairs. The justification conditions for a subjunctive conditional $\phi > \psi$ are stated in terms of making minimal changes in these two sets in order to accommodate ϕ . The first step is to generate all maximal subsets of the set of true basic strong subjunctive generalisations which are consistent with ϕ . For each such maximally ϕ -consistent set N of true basic strong subjunctive generalisations, we then generate all sets of true simple states of affairs which are maximally consistent with $N \cup \{\phi\}$. Finally, we consider every possible world at which ϕ , every member of some maximally ϕ -consistent set N of true basic strong subjunctive generalisations, and every member of some set S of true simple states of affairs maximally consistent with $N \cup \{\phi\}$ are all true. If ψ is true at all such worlds, then $\phi > \psi$ is true at the actual world. The set of worlds determined by this procedure serves as the value of a class selection function.

If we try to define a relative similarity relation for worlds based upon Pollock's analysis of minimal change, we come up with a partial order rather than the 'complete' order assumed by Lewis and, apparently, by Stalnaker. Because we can have two worlds j and k such that their similarity to a

third world i is incomparable, the thesis CV does not hold for Pollock's semantics.⁷ A simple model of Pollock's sort which rejects CV as well as another thesis which has been attributed to Pollock's conditional logic **SS** is developed in [Mayer, 1981].

Several authors have proposed theories which resemble Pollock's in important respects. One of these is Blue [1981] who suggests that we think of subjunctive conditionals as metalinguistic statements about a certain semantic relation between an antecedent set of sentences in an object language and another sentence of the object language viewed as a consequent. A theory (set of sentences of the object language) and the set of true basic (atomic and negations of atomic) sentences of the language play roles similar to those played by laws (true basic strong subjunctive generalisations) and simple states of affairs in Pollock's account. One problem with Blue's proposal is that treating conditional metalinguistically as he does prevents iteration of conditionals without climbing a hierarchy of metalanguages. Another problem concerns the role which temporal relations between the basic sentences plays in his theory, a problem for other theories as well. (This problem is discussed in Section 1.8 below.) For a more detailed discussion of Blue's view, see [Nute, 1981c].

The similarity of an account like Pollock's or Blue's to the cotenability theories of conditionals should be obvious. A conditional is true just in case its consequent is entailed (Blue uses a somewhat different relation) by its

⁷Pollock has offered various counterexamples to CV, the most recent of which involves a circuit having among its components two light bulbs L_1 and L_2 , three simple switches A , B , and C , and a power source. These components are supposed to be wired together in such a way that bulb L_1 is lit exactly when switch A is closed or both switches B and C are closed, while bulb L_2 is lit exactly when switch A is closed or switch B is closed. At the moment, both bulbs are unlit and all three switches are open. Then the following conditionals are true:

$$(5a) \quad \neg(L_2 > \neg L_1)$$

$$(5b) \quad \neg[(L_2 \wedge L_1) > \neg(B \wedge C)]$$

The justification for (5a) is that one way to bring it about that L_2 (i.e. that bulb L_2 is lit) is to bring it about that A (i.e. that switch A is closed), but $A > L_1$ is true. The justification for (5b) is that one way to make L_1 and L_2 both true is to close both B and C . Pollock claims that the following counterfactual is also true:

$$(5c) \quad L_2 > \neg(B \wedge C)$$

If Pollock is correct, then these three counterfactuals comprise a counterexample to CV. Pollock's argument for (5c) is that L_2 requires only A or B , and to also make C the case is a gratuitous change and should therefore not be allowed. But this is an oversimplification. It is not true that only A , B , and C are involved. Other changes which must be made if L_2 is to be lit include the passage of current through certain lengths of wire where no current is now passing, etc. Which path would the current take if L_2 were lit? We will probably be forced to choose between current passing through a certain piece of wire or switch C being closed. It is difficult to say exactly what the choices may be without a diagram of the kind of circuit Pollock envisions, but without such a diagram it is also difficult to judge whether closing switch C is gratuitous in the case of (5c) as Pollock claims.

antecedent together with some subset of the set of laws or theoretical truths and some (cotenable) set of simple states of affairs or basic sentences.

Veltman [1976] and Kratzer [1979; 1981] also propose theories of conditionals which resemble Pollock's in important respects. We will discuss Kratzer's view, although the two are similar. Kratzer suggests what can be called a premise or a partition semantics for subjunctive conditionals. Like Pollock, she associates with each world i a set H_i of propositions or states of affairs which uniquely determines that world. The set H_i is called a partition for i or a precise set for i . Kratzer proposes that we evaluate a subjunctive conditional $\phi > \psi$ by considering ϕ -consistent subsets of H_i . $\phi > \psi$ is true at a world i if and only if each ϕ -consistent subset X of H_i is contained in some ϕ -consistent subset Y of H such that $Y \cup \{\phi\}$ entails ψ . Kratzer points out that if every ϕ -consistent subset of H_i is contained in some maximally ϕ -consistent subset of H_i , then this truth condition is equivalent to the condition that $\phi > \psi$ is true at i just in case ψ is entailed by $X \cup \{\phi\}$ for every maximally ϕ -consistent subset X of H_i .

If we assume that every ϕ -consistent subset of H_i is contained in some maximally ϕ -consistent subset of H_i , the specialized version of Kratzer's semantics we obtain looks very much like Pollock's. Lewis [1981a] notes that this assumption plays the same role in premise semantics that the Limit Assumption plays in class selection function semantics. In fact, Lewis shows that on this assumption Kratzer's premise semantics is formally equivalent to Pollock's semantics. Given this equivalence, these two semantics will determine exactly the same conditional logic **SS**.

Even if we assume that the required maximal sets always exist and adopt a version of premise semantics which is formally equivalent to Pollock's semantics, Kratzer's position would still differ radically from Pollock's since she does not assign to laws and simple states of affairs a privileged role in her analysis. Nor does she prefer Blue's object language theory and basic sentences for such a role. The set of premises which we associate with a world and use in the evaluation of conditionals varies, according to Kratzer, as the purposes and circumstances of the language users vary. Thus Kratzer reintroduces the vagueness which so many investigators have observed in ordinary usage and which Pollock and Blue would deny or at least eliminate.

Apparently Kratzer does not accept the Limit Assumption, in her case the assumption that the required maximal sets always exist. Yet in [Kratzer, 1981] she describes what she calls the most intuitive analysis of counterfactuals, saying that

The truth of counterfactuals depends on everything which is the case in the world under consideration: in assessing them, we have to consider all the possibilities of adding as many facts to the antecedent as consistency permits.

This certainly suggests maximal antecedent-consistent subsets of a premise set (the Limit Assumption) and a minimal change semantics. But if the Limit Assumption is unacceptable, this initial intuition must be modified. Kratzer's modification takes the form of the truth condition reported earlier. Besides the Limit Assumption, Kratzer's semantics also fails to support the GCP. One principle which does remain, a principle common to all the semantics discussed in this section, is the thesis CS. Beginning with some sort of minimalist intuition, all of these authors claim subjunctive conditionals with true antecedents have the same truth values as their consequents. When the antecedent of the conditional is true, the actual world is the unique closest antecedent world and hence the only world to be considered in evaluating the conditional.

If Lewis's counterexamples to the Limit Assumption are conclusive, we must conclude that all the semantics for subjunctive conditionals which we have discussed in this section must be inadequate except for Lewis' system-of-spheres semantics and the general version of Kratzer's premise semantics. And if the GCP is a principle which we wish to preserve, then Lewis's semantics and Kratzer's semantics are also inadequate. Besides these difficulties, minimal change theories have been criticized because they endorse the thesis CS. As was mentioned in Section 1.1, many researchers claim that some conditionals with true antecedent and consequent are false. For an excellent polemic against the minimal change theorists on this issue, see [Bennett, 1974].

1.5 *Small Change Theories*

Åqvist [1973] presents a very interesting analysis of conditionals in which the conditionals in which the conditional operator is defined in terms of material implication and some unusual monadic operators. Simplifying a bit, Åqvist's semantics involves ordered quintuplets $\langle I, i, R, f, [] \rangle$ such that I and $[]$ are as in other models we have discussed, i is a member of I , R is an accessibility relation on I , and f is a function which assigns to each sentence ϕ a subset $f(\phi)$ of $[\phi]$ such that for every member j of $f(\phi)$, $\langle i, j \rangle \in R$. A sentence $*\phi$ whose primary connective is the monadic star operator $*$ is true at a world j in I just in case $j \in f(\phi)$. The usual truth conditions are provided for a necessity operator, so that $\Box\phi$ is true at j in I just in case for every world k such that $\langle j, k \rangle \in R$, ϕ is true at k , i.e. just in case $k \in [\phi]$. Finally, a conditional $\phi > \psi$ is true at a world j just in case $\Box(*\phi \rightarrow \psi)$ is true at i . Åqvist modifies this semantics in an appendix. The modification involves a set of models of the sort described, each with the same set of possible worlds, the same accessibility relation, and the same valuation function, but each with its own designated world and selection function. The resulting semantics turns out once again to be equivalent to a version of class selection semantics.

While the interesting formal details of Åqvist's theory are quite different from those of other investigators, the most significant feature of his account may be his suggestion that a class selection function might properly pick out for a sentence ϕ and a world i all those ϕ -worlds which are 'sufficiently' similar to i rather than only those ϕ -worlds which are 'most' similar to i . By changing the intended interpretation for the class selection function, we avoid the trivialisation of the truth conditions for conditionals in all those cases where the Limit Assumption in either of its forms fails. At the same time, class selection function semantics supports the GCP. Åqvist's suggestion looks very promising.

A similar approach is taken by Nute, [1975a; 1975b; 1980b], but the semantics Nute proposes is explicitly a version of class selection function semantics. This model theory differs from versions of class selection function semantics we examined earlier in two important ways. First the intended interpretation is different, i.e. there is a different informal explanation to be given for the role which the class selection functions play in the models. Second the restriction (CS2) is replaced by the weaker restriction

$$(CS2') \quad \text{if } i \in [\phi] \text{ then } i \in f(\phi, i).$$

The second change is related to the first. Surely any world is more similar to itself than is any other. Thus, if f picks out for ϕ and i the ϕ -worlds closest to i , and if i is itself a ϕ -world, then f will pick out i and nothing else for ϕ and i . The objection to the thesis CS, though can be thought of as a claim that there may be other worlds sufficiently similar to the actual world so that in some cases we should consider these worlds in evaluating conditionals with true antecedents. When we modify our earlier semantics for Lewis's system **VC** by replacing (CS2) with (CS2'), the resulting class of models characterizes the logic which Lewis [1973b] calls **VW**. **VW** is the smallest conditional logic which is closed under all the rules and contains all the theses listed for **VC** except for the thesis CS. By weakening our semantics further we can characterize a logic which is closed under all the rules and contains all the theses of **VW** except CV. This, of course, would give us a logic for which Pollock's **SS** would be a proper extension.

Although many count it as an advantage of small change class selection function semantics that such theories allow us to avoid CS, it should be noted that such semantics do not commit us to a rejection of CS. As we have seen, both Lewis's **VC** and Pollock's **SS** are characterized by classes of class selection function models. For those who favor CS, it is still possible to avoid the difficulties of the Limit Assumption and embrace the GCP by adopting one of these versions of the class selection function semantics but giving a small change interpretation of the selection functions upon which such a semantics depends.

It is possible to avoid CS within the restrictions of a minimal change semantics. We can do this by 'coarsening' our similarity relation, to use

Lewis's phrase, counting worlds as equally similar to some third world despite fairly large differences in these worlds. For example, we might count some worlds other than i as being just as similar to i as is i itself. When we do this for a minimal change version of class selection function semantics, the formal results are exactly the same as those proposed earlier in this section and the resulting logic is **VW**. Of course, we must still cope with Lewis's objections to the Limit Assumption. But it is even possible to avoid CS within Lewis's system-of-spheres semantics. All we need to do is replace the restriction (SOS1) with the following:

(SOS1') $i \in \cap s_i$.

The class of all those system-of-spheres models which satisfy (SOS1') and (SOS2) determines the conditional logic **VW**. While such a concession to the critics of CS is possible within the confines of Lewis's semantics, Lewis does not favor such a move. We should also remember that the resulting semantics still does not support the GCP.

Since we can formulate a kind of minimal change semantics which avoids the controversial thesis CS, the only advantage we have shown for small change theories is that they avoid the problems of the Limit Assumption while giving support for the GCP. But this advantage may be illusory. Loewer [1978] shows that for many versions of class selection function semantics we can always view the selection function as picking out closest worlds. For a model of such a semantics, we can define a relative similarity relation R between the worlds of the model in terms of the model's selection function f . It can then be shown that for a sentence ϕ and a world i , $j \in f(\phi, i)$ if and only if j is a ϕ -world which is at least as close to i with respect to R as is any other ϕ -world. Consider such a model and consider a proposition ϕ which is true at world j just in case there are infinitely many worlds closer to i with respect to R than is j . There will be no ϕ -world closest to i . Consequently $f(\phi, i)$ will be empty and any conditional with ϕ as antecedent will be trivially true. How seriously we view this example depends upon our attitude toward the assumption that there exists a proposition which has the properties attributed to ϕ . If we take propositions to be sets of worlds, then the existence of such a proposition is very plausible. We should also note that this argument involves a not so subtle change in our semantics. Until now we have been thinking of our selection functions as taking sentences as arguments rather than propositions. If we restrict ourselves to sentences it is very unlikely that our language for conditional logic will contain a sentence which expresses the troublesome proposition. Nevertheless, it is not entirely clear that every small change version of class selection function semantics will automatically avoid the problems associated with the Limit Assumption.

There is another advantage which can be claimed for small change theories which doesn't involve the logic of conditionals. If, for example, **VW**

is the correct logic for conditionals, we have seen that it is possible to take either the minimal change or the small change approach to semantics for conditionals and still provide a semantics which determines **VW**. But even if agreement is reached about which sentences are valid, these two approaches are still likely to result in different assignments of truth values to contingent conditional sentences. Suppose for example that Fred's lawn is just slightly too short to come into contact with the blades of his lawnmower. Thus his lawnmower will not cut the grass at present. Suppose further that the engine on Fred's lawnmower is so weak that it will only cut about a quarter of an inch of grass. If the height of the grass is more than a quarter of an inch greater than the blade height, the mower will stall. Then is the following sentence true or false?

29. If the grass were higher, Fred's mower would cut it.

On the minimal change approach, whether we use class selection function semantics or system-of-spheres semantics, the answers to this question must be 'yes' for there will be worlds at which the lawn is higher than the blade height but no more than a quarter inch higher than the blade height, which are closer to the actual world than is any world at which the grass is more than a quarter inch higher than the blade height. But the correct answer to the question would seem to be 'no'. If someone were to assert (29) we would likely object, 'Not if the grass were much higher'. This shows that we are inclined to consider changes which are more than minimally small in our evaluations of conditionals. We might avoid particular examples of this sort by 'coarsening' the similarity relation, but it may be possible to generate such examples for any similarity relation no matter how coarse.

All of the small change theories we have considered propose semantics which are at least equivalent to some version of class selection function semantics. There is, however, at least one small change theory which does not share this feature. Warmbröd [1981] presents what he calls a pragmatic theory of conditionals. This theory is based on similarity of worlds but in a radically different way than are any of the theories we have yet examined. According to Warmbröd, the set of worlds we use in evaluating a conditional is determined not by the antecedent of that particular conditional but rather by all the antecedents of conditionals occurring in the piece of discourse containing that particular conditional. Thus a conditional is always evaluated relative to a piece of discourse rather than in isolation. For any piece of discourse D and world i we select a set of worlds S which satisfies the following conditions:

- (W1) if $\phi > \psi$ occurs in D and ϕ is logically possible, then some world j in S is a ϕ -world;
- (W2) for some $\phi > \psi$ occurring in D , $j \in S$ if and only if j is at least as close to i as are the closest ϕ -worlds to i .

Condition (W1) ensures that S is what Warmbröd calls *normal* for D and (W2) ensures that S is what Warmbröd calls *standard* for some antecedent occurring in D . (Warmbröd formulates his theory in terms of an accessibility relation, but the semantics provided here is formally equivalent.) Then a conditional $\phi > \psi$ is true at i with respect to D if and only if $\phi \rightarrow \psi$ is true at every world in S . The resulting semantics resembles both class selection function semantics and an analysis of conditionals as strict conditionals, but it differs from each of these approaches in important respects.

Like other proposals which treat subjunctive conditionals as being strict conditionals, Warmbröd's theory validates Transitivity, Contraposition, and Strengthening Antecedents. Warmbröd argues that the evidence against these theses can be explained away. Apparent counterexamples to transitivity, for example, depend according to Warmbröd on the use of different sets S in the evaluation of the sentences involved in the putative counterexamples. Consider the example (21)–(23) in Section 1.3 above. According to Warmbröd, this example can be a counterexample to Transitivity only if there is some set of worlds S which contains worlds at which Carter did not lose in 1980, contains some worlds at which Carter died in 1979, which is normal for these two antecedents, and for which the material conditional corresponding to (21) and (22) are true at all members of S while the material conditional corresponding to (23) is false at some world in S . But this, Warmbröd claims, is exactly what does not happen. The apparent counterexample depends upon an equivocation, a shift of the set S during the course of the argument.

Warmbröd's theory has a certain attraction. It is certainly true that Transitivity and other controversial theses are harmless in many contexts, and it is certainly true that these theses are frequently used in ordinary discourse. The problem is to provide an account of the difference between those situations in which the thesis is reliable and those in which it is not. Warmbröd's strategy is to consider the thesis to be always reliable and then to provide a way of falsifying the premises in unhappy cases. An alternative approach is to count these theses as being invalid and then to look for those features of context which sometimes allow us to use them with impunity. We think the second strategy is safer. It is probably better to occasionally overlook a good argument than it is to embrace a bad one. Or to put a bit differently, it is better to force the argument to bear the burden of proof rather than to consider it sound until proven unsound.

Another problem with Warmbröd's theory is that it suggests that we should find apparent counterexamples to certain theses which have until now been considered uncontroversial. For example, we should find apparent counterexamples for CA. (See [Nute, 1981b] for details.)

Warmbröd's semantics also runs into difficulty with the Limit Assumption. The requirement (W2) that S be standard for some antecedent in D involves the Limit Assumption explicitly, although Warmbröd's semantics

may tolerate small, non-minimal changes for some of the antecedents in a piece of discourse, it demands that only minimal changes be considered for at least one such antecedent. Of course, we might be able to modify (W2) in such a way as to avoid this problem. There remains, though, the nagging suspicion that none of the small change theories we have considered will in the end be able to escape the Limit Assumption, with all its difficulties, in some form or other.

1.6 *Maximal Change Theories*

Both minimal change theories and small change theories of conditionals are based on the premise that a conditional $\phi > \psi$ is true at i just in case ψ is true at some ϕ - world(s) satisfying certain conditions. The difference, of course, is that for the one approach it is sufficient that ψ be true at all closest ϕ -worlds while the other requires that ψ be true at all ϕ -worlds which are reasonably or sufficiently close to i . There is a third type of theory which shares the same basic premise as these two but which does not require that the worlds upon which the evaluation of $\phi > \psi$ at i depends be very close or similar to i at all. According to this way of looking at conditionals, all that is required is that the relevant worlds resemble i in certain very minimal respects. Otherwise the relevant worlds may differ from i to any degree whatever. We might even think of this approach as requiring us to consider worlds which differ from i maximally except for the narrowly defined features which must be shared with i .

One theory of this sort is developed by Gabbay [1972]. To facilitate comparison, we will simplify Gabbay's account of conditionals rather drastically. When we do this, Gabbay's semantics for conditionals resembles the class selection function semantics we have discussed, but there are some very important differences. A simplified Gabbay model is an ordered triple $\langle I, g, [] \rangle$ such that I and $[]$ are as in earlier models, and g is a function which assigns to sentences ϕ and ψ and world i in I a subset $g(\phi, \psi, i)$ of I . A conditional $\phi > \psi$ is true at i in such a model just in case $g(\phi, \psi, i) \subseteq [\phi \rightarrow \psi]$. The difference between this and class selection function semantics of the sort we have seen previously is obvious: the selection function g takes both antecedent and consequent as argument. This means that quite different sets of worlds might be involved in the truth conditions for two conditionals having exactly the same antecedent. This change in the formal semantics reflects a difference in Gabbay's attitude toward conditionals and toward the way in which we evaluate conditionals. When we evaluate $\phi > \psi$, we are not concerned to preserve as much as we can of the actual world in entertaining ϕ ; instead we are concerned to preserve only those features of the actual world which are relevant to the truth of ψ , or perhaps to the effect ϕ would have on the truth of ψ . In actual practice the kind of similarity which is required is supposed by Gabbay to be determined by ϕ , by ψ , and

also by general knowledge and particular circumstances which hold in i at the time when the conditional is uttered. What this involves is left vague, but it is not more vague than the notions of similarity assumed in earlier theories.

When we modify Gabbay's semantics in this way, we must impose three restrictions on the resulting models:

- (G1) $i \in g(\phi, \psi, i)$;
- (G2) if $[\phi] = [\psi]$ and $[\chi] = [\theta]$ then $g(\phi, \chi, i) = g(\psi, \theta, i)$;
- (G3) $g(\phi, \psi, i) = g(\phi, \neg\psi, i) = g(\neg\phi, \psi, i)$.

With these restrictions Gabbay's semantics determines the smallest conditional logic which is closed under RCEC and the following two rules:

RCEA: from $\phi \leftrightarrow \psi$, to infer $(\phi > \chi) \leftrightarrow (\psi > \chi)$.

RCE: from $\phi \rightarrow \psi$, to infer $\phi > \psi$.

We will call this logic \mathbf{G} . At the end of [Gabbay, 1972], a conjectured axiomatisation of \mathbf{G} is presented, but it was later shown to be unsound and incomplete in [Nute, 1977], where the axiomatisation of \mathbf{G} presented here was conjectured to be sound and complete (see [Nute, 1980b]). Working independently, David Butcher [1978] also disproved Gabbay's conjecture, and proved the soundness and completeness of \mathbf{G} for the Gabbay semantics (see [Butcher, 1983a]).

It is obvious that \mathbf{G} is the weakest conditional logic we have yet considered. We can characterize a stronger logic if we place additional restrictions on our Gabbay models, but we may not be able to guarantee a sufficiently strong logic without restricting our models to the point where they become formally equivalent to models we examined earlier. Consider, for example the theses

CC: $[(\phi > \psi) \wedge (\phi > \chi)] \rightarrow [\phi > (\psi \wedge \chi)]$

CM: $[\phi > (\psi \wedge \chi)] \rightarrow [(\phi > \psi) \wedge (\phi > \chi)]$.

To ensure that our conditional logic contains CC and CM, we could impose the following restriction on Gabbay's semantics:

(G4) $g(\phi, \psi, i) = g(\phi, \chi, i)$.

Once we do this we have eliminated the most distinctive feature of Gabbay's semantics. According to David Butcher [1983a], it is possible to ensure CC and CM by adopting conditions weaker than (G4). However, Butcher has indicated that these conditions are problematic for other reasons.⁸

⁸Many of these issues are also discussed in Butcher [1978; 1983a].

A rather different and very specialized maximal change theory has been developed in two different forms by Fetzer and Nute [1979; 1980] and by Nute [1981a]. Both forms of this theory are intended not as analyses of ordinary subjunctive conditionals as they are used in ordinary discourse, but rather as analyses of scientific, nomological, or causal conditionals, i.e. of subjunctive conditionals as they are used in the very special circumstances of scientific investigation. Formally the two theories propose class selection function semantics for scientific conditionals, but the intended interpretation is quite different from that of any theory we have yet considered.

In the version of the theory developed by Fetzer and Nute the selection function f is intended to pick out for a sentence ϕ and a world i the set of all those ϕ -worlds at which all the individuals mentioned in ϕ possess, in so far as the truth of ϕ will allow, all those dispositional properties which they permanently possess in i . This forces us to ignore all features of worlds except those assumed by the underlying theory of causality to affect the causal efficacy of the situation, events, etc., described in ϕ . We are forced, in other words, to consider worlds which preserve only these features and otherwise differ maximally from the world at which the scientific conditional is being evaluated. In this way we can ensure that the conditional in question is true if but only if the antecedent and the consequent are related causally or nomologically in an appropriate manner. Physical law statements are then analysed as universal generalisations or sets of universal generalisations of such scientific conditionals.

The view subsequently developed in [Nute, 1981a] departs a bit from the requirement of maximal specificity which we seek in our scientific pronouncements and in doing so comes closer to representing a kind of conditional used in ordinary discourse. Nute suggests that the selection function f selects for a sentence ϕ and a world i all those ϕ -worlds at which all those individuals mentioned in ϕ possess, so far as the truth of ϕ allows, not only all those dispositional properties which they permanently possess in i but also all those dispositional properties which they accidentally or as a matter of particular fact possess in i . For example, a particular piece of litmus paper permanently possesses the tendency to turn red when dipped in an acidic solution, since it could not lose this tendency and still be litmus paper, but it only accidentally possesses the tendency to reflect blue light, since it could certainly lose this disposition through being dipped in acid and yet still be litmus paper. Where it is impossible to accommodate ϕ without giving up some of the dispositional properties possessed by individuals mentioned in ϕ , preference is given to dispositions which are possessed permanently. On this account, but not on the account developed by Fetzer and Nute conjointly, the following conditional is true where x is a piece of litmus paper which is in fact blue:

30. If x were cut in half, it would be blue.

Nute [1981a] suggests that many ordinary conditionals may have such truth conditions, or may be abbreviations of other more explicit conditionals which have such truth conditions.

Each of the theories presented in this section is in fact only a fragment of a more complex theory. It is impossible to discuss the larger theories in any greater detail and the reader is encouraged to consult the original publications. What allows us to consider them under a single category is their departure from the premise that the truth of a conditional depends upon what happens in antecedent- worlds which are very much like the actual world. Each of these theories assumes and even requires that the divergence from the actual world be rather larger than minimal or small change theories would indicate.

1.7 *Disjunctive Antecedents*

One thesis in particular has caused considerable controversy among the investigators of conditional logic. This thesis is Simplification of Disjunctive Antecedents:

$$\text{SDA: } [(\phi \vee \psi) > \chi] \rightarrow [(\phi > \chi) \wedge (\psi > \chi)].$$

The intuitive plausibility of SDA has been suggested in [Fine, 1975], in [Nute, 1975b] and in [Ellis *et al.*, 1977]. Unfortunately, any conditional logic which contains SDA and which is also closed under substitution of provable equivalents will also contain the objectionable thesis Strengthening Antecedents. If we add SDA to any of the logics we have discussed, then Transitivity and Contraposition will be contained in the extended logic as well.⁹ Ellis *et al.* suggest that the evidence for SDA is so strong and the problems involved in trying to incorporate SDA into any account of conditionals based upon possible worlds semantics is so great that the possibility of an adequate possible worlds semantics for ordinary subjunctive conditionals is quite eliminated. With all the problems which the various theories encounter, the possible worlds approach has still proven to be a powerful tool for the investigation of the logical and semantical properties of conditionals and we should be unwilling to abandon it without first trying to defend it against such a charge.

The first line of defence has been a ‘translation lore’ approach to the problem of disjunctive antecedents. It is first noted that, despite the intuitive appeal of SDA, there are examples from ordinary discourse which show that SDA is not entirely reliable. The following sentences comprise one such example:

⁹As further evidence of the problematic character of SDA, David Butcher [1983b] has shown that any logic containing SDA and CS will contain $\phi \rightarrow \Box\phi$, where $\Box\phi$ is defined as $\neg\phi > \phi$.

- 31a. If the United States devoted more than half of its national budget to defence or to education, it would devote more than half of its national budget to defence.
- 31b. If the United States devoted more than half of its national budget to education, it would devote more than half of its national budget to defence.

Contrary to what we should expect if SDA were completely reliable, it looks very much as if (31a) is true even though (31b) cannot be true. Fine [1975], Loewer [1976], McKay and Van Inwagen [1977] and others have suggested that those examples which we take to be evidence for SDA actually have a quite different logical form from that which supporters of SDA suppose them to have. While a sentence like (31a) really does have the form $(\phi \vee \psi) > \chi$, a sentence like

32. If the world's population were smaller or agricultural productivity were greater, fewer people would starve.

has the quite different logical form $(\phi > \chi) \wedge (\psi > \chi)$. According to this suggestion, the word 'or' represents wide scope conjunction rather than narrow scope disjunction in (32). Since we can obviously simplify a conjunction, this confusion about the logical form of sentences like (32) results in the mistaken commitment to a thesis like SDA.

This would be a neat solution to the problem if it would work, but the translation lore approach has a serious flaw. According to the translation theorist, the two sentences (31a) and (32) have different logical forms even though they share the same surface or grammatical structure. We can point out an obvious difference in surface structure since one of the apparent disjuncts in the antecedent of (31a) is also the consequent of (31a), a feature which (32) lacks. But we can easily produce examples where this is not the case. Suppose after asserting (31a) a speaker went on to assert

33. So if the United States devoted over half its national budget to defence or education, my Lockheed stock would be worth much more than it is.

It would be very reasonable to accept this conditional but at the same time to reject the following conditional:

34. So if the United States devoted over half of its national budget to education, my Lockheed stock would be worth much more than it is.

The occurrence of the same component sentence in antecedent and consequent is not a necessary condition for the failure of SDA and cannot be used as a criterion for distinguishing those cases in which English conditional with 'or' in their antecedents are of the logical form $(\phi \vee \psi) > \chi$ from

those in which they are of the logical form $(\phi > \chi) \wedge (\psi > \chi)$. We cannot decide on purely syntactical grounds which of the two possible symbolisations is proper for an English conditional with ‘or’ in its antecedent. Loewer [1976] suggests that this decision may be made on pragmatic grounds, but it is difficult to see what the distinguishing criterion is to be except that English conditionals with disjunctive antecedents are to be symbolized as $(\phi > \chi) \wedge (\psi > \chi)$ when simplification of their disjunctive antecedents is legitimate and to be symbolized as $(\phi \vee \psi) > \chi$ when such simplification is not legitimate. Until Loewer’s suggestion concerning the pragmatic pressures which prompt one symbolisation rather than another can be provided with sufficient detail, the translation lore account of disjunctive conditional does not provide us with an adequate solution to our problem.

We find an interesting variation on the translation lore solution in [Humberstone, 1978] and in [Hilpinen, 1981]. Both suggest the use of an antecedent forming operator like Åqvist’s $*$. We will discuss Hilpinen’s theory here since it differs the most from Åqvist’s view. Hilpinen’s analysis utilizes two separate operators which we can represent as If and Then. The If operator attaches to a sentence ϕ to produce an antecedent If ϕ . the Then operator connects an antecedent α and a sentence ϕ to form a conditional α Then ϕ . The role of the dyadic truth functional connectives is expanded so that \vee , for example, can connect two antecedents α and β to form a new antecedent $\alpha \vee \beta$. An important difference between Hilpinen’s If operator and Åqvist’s $*$ is that for Åqvist $*\phi$ is a sentence or proposition bearing a truth value while for Hilpinen If ϕ is not. Finally Hilpinen proposes that sentences like (31a) be symbolized as If $(\phi \vee \psi)$ Then χ while sentences like (32) be symbolized as (If $\phi \vee$ If ψ) Then χ . Hilpinen then accepts a rule similar to SDA for sentences having the latter form but not for sentences having the former. This proposal allows us to incorporate a rule like SDA into our conditional logic while avoiding Strengthening Antecedents, etc., and, unlike other versions of the translation lore approach, Hilpinen’s proposal seems to suggest how it might be possible for sentences like (31a) and (32) to have a legitimate scope ambiguity in their syntactical structure, like the scope ambiguity in ‘President Carter has to appoint a woman’. In fact, however, the ambiguity postulated by Hilpinen’s proposal does not seem simply to be a scope ambiguity. The sentence ‘President Carter has to appoint a woman’ is ambiguous with respect to the scope of the phrase ‘a woman’, but the phrase ‘a woman’ has the same syntactical function and the same semantics on both readings of the sentence. The same cannot be said of the word ‘or’ in Hilpinen’s account of disjunctive antecedents: on one resolution of the ambiguity, what ‘or’ connects in examples like (31a) and (32) are sentences; on the other resolution of the ambiguity, ‘or’ connects phrases that are not sentences. It is difficult to see how the ambiguity in (31a) and (32) can be simply a scope ambiguity if ‘or’ does not have the same syntactical role in both readings of a given sentence.

Another approach to disjunctive antecedents is developed by Nute [1975b; 1978b] and [1980b]. Formally the problem with SDA is that it together with substitution of provable equivalents results in Strengthening Antecedents and other unhappy results. The translation theorist's suggestion is that we abandon SDA. Nute's suggestion, on the other hand, is that we abandon substitution of provable equivalents, at least for antecedents of subjunctive conditionals. One fairly strong logic which does not allow substitution of provably equivalent antecedents is the smallest conditional logic which is closed under RCEC and RCK and contains ID, MP, MOD, CV, and SDA. Logics of this sort have been called 'non-classical' or 'hyperintensional' to contrast them with those intensional logics which are closed under substitution of provable equivalents. Classical logics (those closed under substitution of provable equivalents) are preferred by most investigators.

Besides the fact that non-classical logics are much less elegant than classical logics, Nute's proposal has other very serious difficulties. First, substitution of certain provable equivalents within antecedents appears to be perfectly harmless. For example, we can surely substitute $\psi \vee \phi$ for $\phi \vee \psi$ in $(\phi \vee \psi) > \chi$ with impunity. How are we to decide which substitutions are to be allowed and which are not? Non-classical conditional logics which allow extensive substitutions are developed in Nute [1978b] and [1980b]. But these systems are extremely cumbersome and there still is the extra-formal problem of justifying the particular choice of substitutions which are to be allowed in the logic. Second, we are still left with the apparent counterexamples to SDA like (31a). Nute suggests a pluralist position, maintaining that there are actually several different conditionals in common use. For some of these conditionals SDA is reliable while for others it is not. The conditional involved in (31a), it is claimed, is unusual and should not be represented in the same way as other subjunctive conditionals. While there is good reason to admit a certain pluralism, to admit, for example, the distinction between subjunctive and indicative conditionals, Nute's proposal is little more than a new translation lore in disguise. The translation lore we discussed earlier at least has the virtue that it attempts to explain the perplexities surrounding disjunctive antecedents in terms of a widely accepted set of logical operators without requiring the recognition of any new conditional operators. Non-classical logic appears to be a dead end so far as the problem of disjunctive antecedents is concerned.

A completely different solution is suggested in [Nute, 1980a], a solution based upon the account of conversational score keeping developed in [Lewis, 1979b]. Basically, the proposal concerns the way in which the class selection function (or the system-of-spheres if Lewis-style semantics is employed) becomes more and more definite as a linguistic exchange proceeds. During a conversation, the participants tend to restrict the selection function which they use to interpret conditionals in such a way as to accommodate claims made by their fellow participants. This growing set of restrictions on the se-

lection function forms part of what Lewis calls the score of the conversation at any given stage. Some accommodations, of course, will not be forthcoming since some participant will be unwilling to evaluate conditionals in the way which these accommodations would require. Each restriction on the selection function which the participants implicitly accept will also rule out other restrictions which might otherwise have been allowed. Nute's suggestion is that our inclination is to restrict the selection function in such a way to make SDA reliable, but that this inclination can be overridden in certain circumstances by our desire to accommodate the utterance of another speaker. When we hear the utterance of a sentence like (31a), for example, we restrict our selection function so that SDA becomes unreliable for sentences which have 'the United States devotes more than half its national budget to defence or education' as antecedent. Once (31a) is accommodated in this way, this restriction on the selection function remains in effect so long as the conversational context does not change. Nute completes his account by formulating some 'accommodation' rules for class selection functions. By offering a pragmatic account of the way in which the selection function becomes restricted during the course of a conversation, and by paying attention to the inclination to restrict the selection function in such a way as to make SDA reliable whenever possible, it may be possible to explain the fact that SDA is usually reliable while at the same time avoiding the many difficulties involved in accepting SDA as a thesis of our conditional logic.

This proposal is similar in certain respects to Loewer's [1976]. Like Loewer, Nute is recognising the important role which pragmatic features play in our use of conditionals with disjunctive antecedents. However, Nute's use of Lewis's notion of conversational score keeping results in an account which provides more details about what these pragmatic features might be than does Loewer's account. We also notice that Nute's suggestions might provide the criterion which Loewer needs to distinguish those conditionals which should be symbolized $s(\phi \vee \psi) > \chi$ from those which should be symbolized as $(\phi > \chi) \wedge (\psi > \chi)$. But once the distinction is explained in terms of the evolving restrictions on class selection functions, there is no need to require that these conditionals be symbolized differently. The point of Nute's theory is that all such conditionals have the same logical form, but the reliability of SDA will depend on contextual features.

There is also considerable similarity between Nute's second proposal and Warmbröd's semantics for conditionals which was discussed in Section 1.5. In fact, Warmbröd's semantics is offered at least in part as an alternative to Nute's proposed solution to the problem of disjunctive antecedents. The important similarity between the two approaches is that both recognize that the interpretation of a conditional is a function not of the conditional alone but also of the situation within which the conditional is used. The important difference is that Warmbröd's semantics makes SDA, Transitivity, Contraposition, Strengthening Antecedents, etc. valid and uses pragmatic

considerations to explain and guard us from those cases where it seems to be a mistake to rely upon these principles, while Nute ultimately rejects all of these principles, but uses pragmatic considerations to explain why it is perfectly reasonable to use at least one of these theses, SDA, in many situations.

Warmbrød also offers a translation lore as part of his account. His suggestion about the way in which we should symbolize English conditionals with disjunctive antecedents is essentially that of Fine, Lewis, Loewer, and others, but he offers purely syntactic criteria for determining which symbolisation is appropriate in a particular case. His semantics is offered as a justification for his translation lore in an attempt to make his rules for symbolisation appear less *ad hoc*. Warmbrød points out some difficulties with Nute's rules of accommodation for class selection functions, and his translation rules might be used as a model for improving the formulation of Nute's rules. Nute's theory of disjunctive antecedents in terms of conversational score might also be proposed as an alternative justification for Warmbrød's translation rules.

1.8 *The Direction of Time*

We turn now to a problem alluded to in Section 1.4, a problem which concerns the role temporal relations play in the truth conditions for subjunctive conditionals. Actually, there are two different sets of problems to be considered. One of these involves the use of tensed language in conditionals and the other does not depend essentially on the use of tense and conditionals together. We will consider the latter set of problems in this section and save problems concerning tense for the next section.

A particularly thorny problem for logicians working on conditionals has to do with so-called backtracking conditionals, i.e. conditionals having antecedents concerned with events or states of affairs occurring or obtaining at times later than those involved in the consequents of the conditional. It is widely held that such conditionals are rarely true, and that when they are true they usually involve much more complicated antecedents and consequents than do the more usual true non-backtracking conditionals. Consider, for example, the two conditionals:

35. If Hinckley had been a better shot, Reagan would be dead.

36. If Reagan were dead, Hinckley would have been a better shot.

The first of these two conditionals is an ordinary non-backtracking conditional, while the second is a backtracking conditional. The first is very plausible and perhaps true, while the second is surely false. The problem with (36) which makes it so much less plausible than (35) is that Reagan might have died subsequent to the assassination attempt from any number

of causes which would not involve an improvement of Hinckley's aim. The problem for the logician or semanticist is to explain why non-backtracking conditionals are more often true than are backtracking conditionals.

The primary goal of Lewis [1979a] is to explain this phenomenon. Lewis's proposal makes explicit, extensive use of the technical notion of a miracle. In a certain sense miracles do not occur at all in Lewis's analysis: rather a miracle occurs in one world relative to another world. No event ever occurs in any world which violates the physical laws of that world, but events can certainly occur in one world which violate the physical laws of some other world. These are the kinds of miracles Lewis relies upon. Assuming complete determinism, which Lewis does at least for the sake of argument, any world which shares a common history with the actual world up to a certain point in time but which diverges from the actual world after that time cannot obey the same physical laws as does the actual worlds. Basically Lewis proposes that the worlds most similar to the actual world in which some counterfactual sentence ϕ is true are those worlds which share their history with the actual world up until a brief transitional period beginning just prior to the times involved in the truth conditions for ϕ . In the case of (35) this might mean that everything happens exactly as it did except that Hinckley miraculously aimed better than he actually did. This might only require something as small as a neuron firing at a slightly different time than it actually did. This is about as small a miracle as we could hope for. Once this miracle occurs, events are assumed by Lewis to once again follow their lawful course with the result, perhaps, that Reagan is mortally wounded. In the case of (36), on the other hand, Reagan might be dead if the FBI agent miraculously failed to jump in front of Reagan, if Reagan miraculously moved in such a way that the bullet struck him differently, or even if Reagan miraculously had a massive stroke at any time after the assassination attempt. Even if events followed their lawful course after any of these miracles, Hinckley's aim would not be improved.

Lewis notes that the vagueness of conditionals requires that there may be various ways of determining the relative similarity of worlds, different ways being employed on different occasions. There is one way of resolving vagueness which Lewis considers to be standard, and it is this way which provides us with the explanation of (35) and (36) given above. This standard resolution of vagueness is expressed in the following guidelines for determining the relative similarity of worlds:

- (L1) It is of the first importance to avoid big, complicated, varied, widespread violations of law.
- (L2) It is of the second importance to maximize the spatio-temporal region throughout which perfect match of particular fact prevails.

- (L3) It is of the third importance to avoid even small, simple, localized violations of law.
- (L4) It is of little or no importance to secure approximate similarity of particular fact, even in matters that concern us greatly.

Lewis would maintain that application of these guidelines together with his system-of-spheres semantics for subjunctive conditionals will have the desired result of making (35) at least plausible while making (36) clearly false.

One major objection to Lewis's account is that once we allow miracles in order to produce a world which diverges from the actual world, there is nothing in Lewis's guidelines to prevent us from allowing another small miracle in order to get the worlds to converge once again. Since Lewis's guidelines place a higher priority on maximising the area of perfect match of particular facts over the avoidance of small, localized violations of law, we should prefer a small convergence miracle to a future which is radically different. Lewis's response to such a suggestion is that divergence miracles tend to be much smaller than convergence miracles or, what amounts to the same thing, that past events are overdetermined to a greater extent than are future events. If correct, then Lewis's guidelines would place greater importance on avoidance of a large convergence miracle than on maximising the area of perfect match of a particular fact. and careful consideration of examples indicates that Lewis's suggestion is at least plausible, although no conclusive argument has been provided. In [Nute, 1980b] examples of very simple worlds are given in which convergence miracles could be quite small and in which Lewis's guidelines would thus dictate that for some counterfactual antecedents the nearest antecedent worlds are those in which such small convergence miracles occur. In these examples, we get the (intuitively) wrong result when we apply Lewis's standard method for resolving the vagueness of conditionals. Lewis [1979a] warns that his guidelines might not work for very simple worlds, though, so the force of Nute's examples is uncertain. Lewis's guidelines may give an adequate explanation for our use of conditionals in the context of a complex world like the actual world, and since our intuitions are developed for such a world they may be unreliable when applied to very simple worlds.

If we consider Lewis's proposal in the context of a probabilistic world, we discover that we no longer need employ the troublesome notion of a miracle. Instead of a miracle, we can accommodate a counterfactual antecedent in a probabilistic world by going back to some underdetermined state of affairs among the causal antecedents of the events or states of affairs which must be eliminated if the antecedent is to be true and change them accordingly. Since these states of affairs were underdetermined to begin with, they could have been otherwise without any violation of the probabilistic laws governing the

universe. But if we do this, Lewis's emphasis on maximising the spatio-temporal area of perfect match of particular fact would require that we always change a more recent rather than an earlier causal antecedent when we have a choice. This consequence is very much like the Requirement of Temporal Priority in [Pollock, 1976], a principle which is superseded by the more complex account to be discussed below. Such a principle is unacceptable. Suppose, for example, that Fred left his coat unattended in a certain room yesterday. Today he returned to the room and found the coat had not been disturbed. Suppose that both yesterday and earlier today a number of people have been in the room who had an opportunity to take the coat. Then a principle like Lewis's L2 or Pollock's RTP will dictate that if the coat had been taken, it would have been taken today rather than yesterday. Other things being equal, the later the coat is taken the greater the area of perfect match of particular fact. But this is counterintuitive. (In fact, experience teaches that unguarded objects tend to disappear earlier rather than later.) While Lewis's theory is intended to explain why many backtracking conditionals are false, a consequence of the theory is that some very unattractive backtracking conditionals turn out to be true. In fact, this particular problem plagues Lewis's analysis whether the world is determined or probabilistic.

As it is presented, Lewis's account does rely upon miracles. As a result, Lewis in effect treats all counterfactual conditionals as also being counter-legals. This is the feature of his account which most writers have found objectionable. Pollock, Blue, and others place a much higher priority on preservation of all law than on preservation of particular fact no matter how large the divergence of particular fact might be. Given such priorities, and given a deterministic world of the sort Lewis supposes, any change in what happens will result in a world which is different at every moment in the past and every moment in the future. If we adopt such a position, how can we hope to explain the asymmetry between normal and backtracking counterfactual conditionals?

Probably the most sophisticated attempt to deal with these problems within the framework of a non-miraculous analysis of counterfactuals is that developed by John Pollock [1976; 1981]. Pollock has refined his account between 1976 and 1981, but we will try to explain what we take to be his latest position on conditionals and temporal relations. Pollock says that a state of affairs P has historical antecedents if there is a set of true simple states of affairs Γ such that all times of members of Γ are earlier than the time of P and Γ nominally implies P . Γ nominally implies P just in case Γ together with the set of universal generalisations of material implications corresponding to Pollock's true strong subjunctive generalisations entail P (or entail a sentence ϕ which is true just in case P obtains). Pollock next defines a nomic pyramid which is supposed to be a set of states of affairs which contains every historical antecedent of each of its members. Then P

undercuts another state of affairs Q if and only if for every set Γ of true states of affairs such that Γ is a nomic pyramid and $Q \in \Gamma$, Γ nominally implies that P does not obtain. In revising his set S of true simple states of affairs to accommodate a particular counterfactual antecedent P , Pollock tells us that we are to minimize the deletion of members of S which are not undercut by P . (We hope the reader will forgive the vacillation here since Pollock talks about entailment and other logical relations holding between states of affairs where most authors prefer to speak of sentences or propositions.)

Perhaps this procedure will give us the correct results for backtracking and non-backtracking conditionals as Pollock suggests it will if the world is deterministic, but problems arise if we allow the possibility that there may be indeterministic states of affairs which lack historical antecedents. Consider a modified version of an example taken from [Pollock, 1981]. Suppose that protons sometimes emit photons when subjected to a strong magnetic field under a set of circumstances C , but suppose also that protons never emit photons under circumstances C if they are not also subjected to a strong magnetic field. As a background condition, let us assume that circumstances C obtain. Now let ϕ be true just in case a certain proton is subjected to a strong magnetic field at time t and let ψ be true just in case the same proton emits a photon shortly after t . Suppose that both ϕ and ψ are true. Assuming that no other states of affairs nomologically relevant to ψ obtain, we would intuitively say that $\neg\phi > \neg\psi$ is true, i.e. if the proton hadn't been subjected to the magnetic field at t , then it would not have emitted a photon shortly after t . But Pollock cannot say this. Since ψ has no historical antecedents in Pollock's sense, it cannot be undercut by $\neg\phi$. Because Pollock does not recognize historical antecedents of states of affairs when the nomological connection involved is merely probable, he must say that $\neg\phi > \psi$ is true.

Pollock's earlier account, which included the Requirement of Temporal Priority, and Lewis's account with its principle L2, in either its original miraculous formulation or the probabilistic, non-miraculous version, both tend to make objectionable backtracking conditionals true when they are intended to explain why they should be false. Blue [1981] includes a feature in his analysis which produces the same result in much the same way. While Pollock's latest theory of counterfactuals avoids examples like that of the unattended coat, it nevertheless encounters new problems with backtracking conditionals in the context of a probabilistic universe. It makes certain backtracking counterfactuals false which our intuitions say are true while making others true which appear to be false. Yet these are the only positive proposals known to the authors at the time of this writing. Other work in the area such as [Nute, 1980b] and [Post, 1981] is essentially critical. An adequate explanation of the role the temporal order plays in the truth conditions for conditionals is still a very live issue.

1.9 *Tense*

There are relatively few papers among the large literature on conditionals which attempt an account of English sentences which involve both tense and conditional constructions. Two of the earliest are [Thomason and Gupta, 1981] and [Van Fraassen, 1981]. Both of these papers attempt the obvious, a fairly straightforward conjunction of tense and conditional operators within a single formal language. Basic items in the semantics for this language are a set of moments, an earlier-than relation on the set of moments which orders moments into tree-like structures, and an equivalence relation which holds between two moments when they are ‘co-present’. A branch on one of these trees plays the role of a possible world in the semantics. Such a branch is called a history, and sentences of the language are interpreted as having truth values at a moment-history pair, i.e. at a moment in a history. Note that a moment is not a clock time but rather a time-slice belonging to each history that passes through it.

The tense operators in the language include two past-tense operators P and H , two future-tense operators F and G , and a ‘settledness’ or historical necessity operator S . $P\phi$ is true at moment i in history h just in case ϕ is true at some moment j in h where j is earlier than i . $H\phi$ is true at some moment i in h if and only if ϕ is true at j in h for every moment j in h which is earlier than i . $F\phi$ is true at i in h if ϕ is true at a moment later than i in h , and $G\phi$ is true at i in h if ϕ is true at every moment later than i in h . $S\phi$ is true at i in h if and only if ϕ is true at i in every history h' which contains i . For a further discussion of semantics for such tense operators, see Burgess [1984] (Chapter 2.2 of this *Handbook*).

In both of these papers, that part of the semantics which is used to interpret conditionals is patterned after the semantics of Stalnaker. A conditional $\phi > \psi$ is true at a moment i in a history h just in case ψ is true at the pair $\langle i', h' \rangle$ at which ϕ is true which is closest or most similar to the pair $\langle i, h \rangle$. Much of the discussion in the two papers is devoted to the effort to assure that certain theses which the authors favor are valid in their model theories. The measures needed to ensure some of the desired theses within the context of a Stalnakerian semantics are quite complicated, but the set of theses that represents the most important contribution of the account of [Thomason and Gupta, 1981], namely the doctrine of Past Predominance, turns out to be quite tractable model theoretically.

According to Past Predominance, similarities and differences with respect to the present and past have lexical priority over similarities and differences with respect to the future in any evaluation of how close $\langle i, h \rangle$ is to $\langle i', h' \rangle$, where i and i' are co-present moments. This doctrine affects the interaction between the settledness operator S and the conditional. For example, Past Predominance implies the validity of the following thesis:

$$(\neg S\neg\phi \wedge S\psi) \rightarrow (\phi > \psi).$$

This thesis is clearly operative in the reasoning that leads to the two-box solution to Newcomb's Problem: 'If it's not settled that I won't take both boxes but it is settled that there is a million dollars in the opaque box, then if I take both boxes there will (still) be a million dollars in the opaque box.'¹⁰ Cross [1990b] shows that since, concerning the selection of a closest moment-history pair, Past Predominance places no constraints on what is true at past or future moments, Past Predominance can be formalized and axiomatized in terms of settledness and the conditional using ordinary possible worlds models in which relations of temporal priority between moments are not represented.

The issue of how the conditional interacts with tense operators, such as P , H , F and G , is more problematic. The accounts presented by Thomason and Gupta and by Van Fraassen adopt the hypothesis that English sentences involving both tense and conditional constructions can be adequately represented in a formal language containing a conditional operator and the tense operators mentioned above. Nute [1983] argues that this is a mistake. Consider an example discussed in [Thomason and Gupta, 1981]:

37. If Max missed the train he would have taken the bus.

According to Thomason and Gupta, this and other English sentences of similar grammatical form are of the logical form $P(\phi > F\psi)$. Nute argues that this is not true. To see why, consider a second example. Suppose we have a computer that upon request will give us a 'random' integer between 1 and 12. Suppose further that what the computer actually does is increment a certain location in memory by a certain amount every time it performs other operations of certain sorts. When asked to return a random number, it consults this memory location and uses the value stored there in its computation. Thus the 'random' number one gets depends upon when one requests it. We just now left the keyboard to roll a pair of dice. If anyone cares, we rolled a 9. Consider the following conditional:

38. If we had used the computer instead of dice, we would have got a 5 instead of a 9.

It is certainly true that there is a time in the past such that if we had used the computer at that time we would have got a 5, so a sentence corresponding to (38) of the form $P(\phi > F\psi)$ is certainly true. Yet (38) itself is not true. Depending upon when we used the computer and what operations the computer had performed before we used it, we could have obtained any integer from 1 to 12.

Perhaps we are simply using the wrong combination of operators. Instead of $P(\phi > F\psi)$, perhaps sentences like (37) and (38) are of the form $H(\phi > F\psi)$. A problem with this suggestion is that such conditionals do

¹⁰See [Gibbard and Harper, 1981].

not normally concern every time prior to the time at which they are uttered but only certain times or periods of time which are determined by context. Suppose in a football game Walker carries the ball into the end zone for a touchdown. During the course of his run, he came very close to the sideline. Consider the conditional

39. If Walker had stepped on the sideline, he would not have scored.

Can this sentence be of the form $H(\phi > F\psi)$? Surely not, for Walker could have stepped on the sideline many times in the past, and probably did, yet he did score on this particular play. Perhaps we can patch things up further by introducing a new tense operator H^* which has truth conditions similar to H except that it only concerns times going a certain distance into the past, the distance to be determined by context. Once again, Nute argues, this will not work. Consider the conditional

40. If Fred had received an invitation, he would have gone to the party.

This sentence might very well be accepted even though Fred would not have gone to the party had he received an invitation five minutes before the party began. The period of time involved does not begin with the present moment and extend back to some past moment determined by context. Indeed if this were the case, for (40) to be true it would even have to be true that Fred would have gone to the party if he had received an invitation after the party ended.

It would seem, then, that if a context-dependent operator is to be the solution to the problem Nute describes, then the contextually determined period of time involved in the truth conditions for English sentences of the sort we have been investigating must be some subset of past times, but one that need not be a continuous interval extending back from the present moment. This is the solution suggested by Thomason [1985].¹¹ Nute [1991] argues for a different approach: the introduction of a new tensed conditional operator, i.e. an operator which involves in its truth conditions both differences in time and differences in world.

Using a class selection function semantics for this task, we could let our selection function f pick out for a sentence ϕ , a moment or time i , and a history or world h a set $f(\phi, i, h)$ of pairs $\langle i', h' \rangle$ of times and histories at which ϕ is true and which are otherwise similar enough to $\langle i, h \rangle$ for our consideration. We would introduce into our formal language a new conditional operator, say $\rangle PF \rangle$, and sentences of the form $\phi \rangle PF \rangle \psi$ would be true in an appropriate model at $\langle i, h \rangle$ if and only if for every pair $\langle i', h' \rangle \in$

¹¹The following example may be linguistic evidence for this sort of context-dependence in tensed constructions not involving conditionals: a dean, worried about faculty absenteeism, asks a department chair, 'Was Professor X always in his classroom last term?' the correct answer may be 'Yes' even though Professor X was not in his classroom at times last term when his classes were not scheduled to meet.

$f(\phi, i, h)$ such that there is a time j in h' which is copresent with i and later than i' , ψ is true at $\langle j, h' \rangle$. It appears that three more operators of this sort will be needed, together with appropriate truth conditions. These operators may be represented as $\rangle PP \rangle$, $\rangle FF \rangle$, and $\rangle FP \rangle$. These operators would be used to represent sentences like

41. If Fred had gone to the party, he would have had to have received an invitation.
42. If Fred were to receive an invitation, he would go to the party.
43. If Fred were to go to the party, he would have to have received an invitation.

Notice that (41) and (43) are types of backtracking conditionals. Since such conditionals are rarely true, we may use the operators $\rangle PP \rangle$ and $\rangle FP \rangle$ infrequently. This may also account for the clumsiness of the English locution which we must use to clearly express what is intended by (41) and (43).

A number of other interesting problems concerning tense and conditionals occur to us. One of these is the way in which the consequent may affect the times included in the pairs picked by a class selection function. Consider the sentences

44. If he had broken his leg, he would have missed the game.
45. If he had broken his leg, the mend would have shown on his X-ray.

The times at which the leg might have been broken varies in the truth conditions for these two conditionals. This suggests that a semantics like Gabbay's which makes both antecedent and consequent arguments for the class selection function might after all be the preferred semantics. Another possibility is that despite its awkwardness we must introduce some sort of context-dependent tense operator like the operator H^* discussed earlier. When we represent (44) as $H^*(\phi > F\psi)$, H^* has the whole of the conditional within its scope and can consider the consequent in determining which times are appropriate. A third possibility is that the consequent does not figure as an argument for the selection function but it does figure as part of the context which determines the selection function which is, in fact, used during a particular piece of discourse. This sort of approach utilizes the concept of conversational score discussed in Section 1.7 of this paper. One piece of evidence in favor of this approach is the fact that it would be unusual to assert both (44) and (45) in the same conversation. Whichever of these two sentences was asserted first, the antecedent of the other would likely be modified in some appropriate way to indicate that a change in the times to be considered was required. Besides these interesting puzzles, we need

also to explain the fact that we maintain the distinction between indicative and subjunctive conditionals involving present and past tense much more carefully than we do where the future tense is concerned. These topics are considered in more detail in [Nute, 1982 and 1991] and [Nute, 1991].

1.10 *Other Conditionals*

Besides the subjunctive conditionals we have been considering, we also want an analysis for the might conditionals, the even-if conditionals, and the indicative conditionals mentioned in Section 1.1. It is time we took another look at these important classes of conditionals.

Most authors who discuss the might and the even-if conditional constructions propose that their logical structure can be defined by reference to subjunctive conditionals. Lewis [1973b] and Pollock [1976] suggest that English sentences having the form ‘If ϕ were the case, then ψ might be the case’ should be symbolized as $\neg(\phi > \neg\psi)$. Stalnaker [1981a] presents strong linguistic evidence against this suggestion, but the suggestion has achieved wide acceptance nonetheless.

Pollock [1976] also offers a symbolisation of even-if conditionals. English sentences of the form ‘ ϕ even if ψ ’, he suggests, should be symbolized as $\phi \wedge (\psi > \phi)$. The adequacy of this suggestion may depend upon our choice of conditional logic and particularly upon whether we accept the thesis CS. If we accept both CS and Pollock’s proposal, then ‘ ϕ even if ψ ’ will be true whenever both ϕ and ψ are true. An alternative analysis of even-if conditionals is developed in [Gardenförs, 1979]. Gardenförs’s objection to Pollock’s proposal seems to be that a person who knows that both ϕ and ψ are true might still reject an assertion of the sentence ‘ ϕ even if ψ ’. Normally, says Gardenförs, one does not assert ‘ ϕ even if ψ ’ when one knows that ψ is true; an assertion of ‘ ϕ even if ψ ’ presupposes that ϕ is true and ψ is false. Even when the presupposition that ψ is false turns out to be incorrect, Gardenförs argues that there is a presumption that the falsity of ψ would not interfere with the truth of ϕ . Consequently, Gardenförs suggests that ‘ ϕ even if ψ ’ has the same truth conditions as $(\psi > \phi) \wedge (\neg\psi > \phi)$. Another suggestion comes from Jonathan Bennett [1982]. Bennett gives a comprehensive account of even-if conditionals, fitting them into the context of uses of ‘even’ that don’t involve ‘if’, and uses of ‘if’ that don’t involve ‘even’. That is, Bennett rejects the treatment of ‘even if’ as an idiom with no internal structure.

The first of three proposals we will consider concerning the analysis of indicative conditionals, which can be found in [Lewis, 1973b; Jackson, 1987] and elsewhere, is that indicative conditionals have the same truth conditions as do material conditionals, paradoxes of implication and problems with Transitivity, Contraposition, and Strengthening Antecedents notwithstanding. It is difficult and perhaps impossible to find really persuasive

counterexamples to Transitivity and Strengthening Antecedents using only indicative conditionals, but apparent counterexamples to Contraposition are easy to construct. Consider, for example, the following two sentences:

46. If it is after 3 o'clock, it is not much after 3 o'clock.

47. If it is much after 3 o'clock, it is not after 3 o'clock.

It is easy to imagine situations in which (46) would be true or appropriate, but are there any situations in which (47) would be true or appropriate? Another problem with this analysis concerns denials of indicative conditionals. Stalnaker [1975] offers an interesting example:

48. If the butler didn't do it, then Fred did it.

Being quite sure that Fred didn't do it, we would deny this conditional. At the same time, we may believe that the butler did it, and therefore when we hear someone say what we would express by

49. Either the butler did it or Fred did it.

We might respond, "Yes, one of them did it, but it wasn't Fred". Yet (48) and (49) are equivalent if (48) has the same truth conditions as the corresponding material conditional.

One possible response to these criticisms is that we must distinguish between the truth conditions for an indicative conditional and the assertion conditions for that conditional. It may be that a conditional is true even though certain conventions make it inappropriate to assert the conditional. This might lead us to say that (47) is true even though it would be inappropriate to assert it. We might also attempt to explain away the paradoxes of implication in this way, relying on the assumed convention that it is misleading and therefore inappropriate to assert a weaker sentence ϕ when we are in a position to assert a stronger sentence ψ which entails ϕ . For example, it is inappropriate to assert $\phi \vee \psi$ when one knows that ϕ is true. Just so, the argument goes, it is inappropriate to assert $\phi \Rightarrow \psi$ when one is in a position to assert either $\neg\phi$ or ψ . and in general we may reject other putative counterexamples to the proposal that indicative conditionals have the same truth conditions as material conditionals by saying that in these cases not all the assertion conditions are met for some conditional rather than admit that the truth conditions for the conditional are not met. This line of defence is suggested, for example, by [Grice, 1967; Lewis, 1973b; Lewis, 1976] and by [Clark, 1971].

A second proposal is that indicative conditionals are Stalnaker conditionals, i.e. that Stalnaker's world selection function semantics is the correct semantics for indicative conditionals and Stalnaker's conditional logic **C2** is the proper logic for these conditionals. This suggestion is found in [Stalnaker, 1975] and in [Davis, 1979]. While both Stalnaker and Davis propose

the same model theory for indicative and subjunctive conditionals, both also suggest that the properties of the world selection function appropriate to indicative conditionals are different from those of the world selection function appropriate to subjunctive conditionals.

The difference for Stalnaker has to do with the presuppositions involved in the utterance of the conditional. During the course of a conversation, the participants come to share certain presuppositions. In evaluating an indicative conditional $\phi \Rightarrow \psi$, Stalnaker says that we look for the closest ϕ -world at which all of these presuppositions are true. In the case of a subjunctive conditional, on the other hand, we may look outside this ‘context set’ for the closest ϕ -world. Of course the overall closest ϕ -world may not be a world at which all of the presuppositions are true since making ϕ true could tend to make one of the presuppositions false. This means that different worlds may be chosen by the selection function used to evaluate indicative conditionals and the selection function used to evaluate subjunctive conditionals.

While accepting Stalnaker’s model theory for both indicative and subjunctive conditionals, Davis offers a different distinction between the world selection function appropriate to indicative conditionals and that the appropriate to subjunctive conditionals. In fact, Davis claims that Stalnaker’s analysis of subjunctive conditionals is actually the correct analysis of indicative conditionals. To evaluate an indicative conditional $\phi \rightarrow \psi$, Davis says we look at the ϕ -world which bears the greatest overall similarity to the actual world to see if it is a ψ -world. For a subjunctive conditional $\phi > \psi$, we look at the ϕ -world which most resembles the actual world up until just before what Davis calls the time of reference of ϕ . Apparently, the time of reference of ϕ is the time at which events reported by ϕ occur, or states of affairs described by ϕ obtain, or etc.

A third proposal, due to Adams [1966; 1975b; 1975a; 1981], holds that indicative conditionals lack truth conditions altogether. They do, however, have probabilities and these probabilities are just the corresponding standard conditional probabilities. Thus $\text{pr}(\phi \Rightarrow \psi) = \text{pr}(\phi \wedge \psi) / \text{pr}(\phi)$, at least in those cases where $\text{pr}(\phi)$ is non-zero. We must remember that Adams does not identify the probability of a conditional with the probability that that conditional is true since he rejects the very notion of truth values for conditionals. Adams proposes that an argument involving indicative conditionals is valid just in case its structure makes it possible to ensure that the probability of the conclusion exceeds any arbitrarily chosen value less than 1 by ensuring that the probabilities of each of the premises exceeds some appropriate value less than 1. In other words, we can push the probability of the conclusion arbitrarily high by pushing the probabilities of the premises suitably high. When an argument is valid in this sense, Adams says that the conclusion of the argument is ‘*p*-entailed’ by its premises and the argument itself is ‘*p*-sound’.

Since Adams rejects truth values for conditionals, conditionals can cer-

tainly not occur as arguments for truth functions. Given his identification of the probability of a conditional with the corresponding standard conditional probability, this further entails that conditionals may not occur within the scope of the conditional operator. Adams attempts to justify this consequence of this theory by suggesting that we don't really understand sentences which involve the embedding of one conditional within another in any case. This claim, though is far from obvious. Such sentences as

50. If this glass will break if it is dropped on the carpet, then it will break if it is dropped on the bare wooden floor.

seem absolutely ordinary and at least as comprehensible as most other indicative conditionals. the inability to handle such conditionals must count as a disadvantage of Adams's theory.

In [Adams, 1977] it is shown that p -soundness is equivalent to soundness in Lewis's system-of-spheres semantics. This implies that the proper logic for indicative conditionals is the 'first-degree fragment' of Lewis's **VC**. By the first degree fragment of **VC** We mean the set of all those sentences in **VC** within which no conditional operator occurs within the scope of any other operator. Since the logic Adams proposes for indicative conditionals can be supported by a semantics which also allows us to interpret sentences involving iterated conditional operators, we will need very strong reasons to accept Adam's account with its restrictions rather than some possible worlds account like Lewis's.

In fact it may be possible to reconcile Lewis's view that the truth conditions for indicative conditionals are the same as those for the corresponding material conditionals with Adams work on the probabilities of conditionals and p -entailment. Lewis [1973b] suggests that the truth conditions for $\phi \Rightarrow \psi$ are given by $\phi \rightarrow \psi$ while the assertion conditions for $\phi \Rightarrow \psi$ are given by the corresponding standard conditional probability. Jackson [1987] also entertains such a possibility. If we accept this, then we might accept Adams's theory as a basis for an adequate account of the logic of assertion conditions for indicative conditionals. Since we would be assuming that conditionals have truth values as well as probabilities, we could also overcome the restrictions of Adams's theory and assign probabilities to conditionals which have other conditionals embedded in them. One problem with this approach, though, is that it would seem to require that we identify the probability of a conditional with the probability that the conditional is true. When we do this and also take the probability of a conditional to be the corresponding standard conditional probability, serious problems arise as is shown in [Lewis, 1976] and in [Stalnaker, 1976]. These difficulties will be discussed briefly in Section 3.

2 EPISTEMIC CONDITIONALS

The idea that there is an important connection between conditionals and belief change seems to have been inspired by this suggestion of Frank Ramsey's:

If two people are arguing “if p will q ?” and are both in doubt as to p , they are adding p hypothetically to their stock of knowledge and arguing on that basis about q .¹²

The issue of how, precisely, to formalize Ramsey's suggestion and extend it from the case where p is in doubt to the general case has received a great deal of attention—too much attention to permit an exhaustive survey here. We will focus here on the Gärdenfors triviality result for the Ramsey test (see [Gärdenfors, 1986]) and related results, and the implications of these results for the project of formalizing the Ramsey test for conditionals. Despite the narrowness of this topic our discussion will not mention all worthy contributions to the subject.

Sections 2.1 and 2.2 provide a general framework for formalizing belief change and the Ramsey test. Section 2.3 makes connections between this framework and the literature on belief change and the Ramsey test. Section 2.4 presents the Ramsey test itself, and Section 2.5 presents versions of several triviality results found in the literature, including a version of Gärdenfors' 1986 result that subsumes several of the definitions of triviality found in the literature. Section 2.6 examines how triviality can be avoided, and section 2.7 examines systems of conditional logic associated with the Ramsey test. We will provide proofs for some of the results stated below and in other cases refer the reader to the literature.

2.1 Languages

By a *Boolean language* we will mean any logical language containing at least the propositional constant ' \perp ', the binary operator ' \wedge ', and the unary operator ' \neg '. We will assume that ' \top ' is defined as ' $\neg\perp$ ' and that any other needed Boolean operators are defined. We do not assume anything at this stage about how the operators and propositional constant of a Boolean language are interpreted, but it will turn out that in most cases ' \wedge ', ' \neg ', and ' \perp ' will receive classical truth-functional interpretations. We will use the symbol ' \vdash ' as a variable ranging over logical inference relations. Effective immediately we will cease using quotes when mentioning formulas and logical symbols.

We define a language (whether Boolean or nonBoolean) to be of type \mathcal{L}_0 iff it contains the propositional constants \top and \perp but does not contain the

¹²[Ramsey, 1990], p. 155.

binary conditional operator $>$. We next define two language-types for doing conditional logic. A language, whether Boolean or nonBoolean, is of type \mathcal{L}_1 iff it contains \top and \perp and the only $>$ -conditionals allowed as formulas are first-degree or “flat” conditionals, i.e. conditionals $\phi > \psi$ where ϕ, ψ are conditional-free. We define a language, whether Boolean or nonBoolean, to be of type \mathcal{L}_2 (a “full” conditional language) iff it contains \top and \perp and allows arbitrary nesting of conditionals in formulas.

2.2 A general framework for belief change

We will describe belief change using a framework that is related to the AGM (Alchourrón, Gärdenfors, Makinson) framework for belief revision.¹³ Our framework extends that of AGM and is adapted (with further enrichment) from the notion of an *enriched belief revision model* introduced in [Cross, 1990a].

For a given language L containing \top, \perp as formulas, let WFF_L be the set of all formulas of L and let \mathcal{K}_L be $\mathcal{P}(\text{WFF}_L) \sim \{\emptyset\}$ (where $\mathcal{P}(\text{WFF}_L)$ is the powerset of WFF_L). For a given inference relation \vdash and set Γ of formulas of L , define $\text{Cn}_\vdash(\Gamma)$ (the \vdash -consequence set for Γ) to be $\{\phi : \Gamma \vdash \phi\}$, and let $\mathcal{T}_{L,\vdash} = \{\Gamma : \Gamma \subseteq \text{WFF}_L \text{ and } \text{Cn}_\vdash(\Gamma) = \Gamma\}$ be the set of all theories in L with respect to \vdash . A set Γ is \vdash -consistent iff $\Gamma \not\vdash \perp$.

We next define the notion of a *belief change model*:

(DefBCM) A *belief change model* on a language L containing \top, \perp as formulas is an ordered septuple

$$\langle \mathbf{K}, \mathcal{I}, \vdash, K_\perp, -, *, s \rangle$$

whose components are as follows:

1. $\mathbf{K} \subseteq \mathcal{K}_L$ and \vdash is a subset of $\mathcal{P}(\text{WFF}_L) \times \text{WFF}_L$;
2. \mathcal{I} and K_\perp are sets of formulas meeting the following requirements:
 - (a) $K_\perp \in \mathbf{K}$;
 - (b) $\top, \perp \in \mathcal{I}$;
 - (c) K_\perp is the set of all formulas of L or a fragment of L ;
 - (d) \mathcal{I} is the set of all formulas of L or a fragment of L , and $\mathcal{I} \subseteq K_\perp$.
 - (e) $K \subseteq K_\perp$ for all $K \in \mathbf{K}$.
3. $-$ and $*$ are binary functions mapping each $K \in \mathbf{K}$ and each $\phi \in \mathcal{I}$ to sets K_ϕ^- and K_ϕ^* , respectively, where $K_\phi^- \subseteq K_\perp$ and $K_\phi^* \subseteq K_\perp$;

¹³See [Alchourrón *et al.*, 1985] and [Gärdenfors, 1988].

4. s is a function taking values in $\mathcal{P}(\text{WFF}_L)$, where $\mathbf{K} \subseteq \text{dom}(s) \subseteq \mathcal{P}(\text{WFF}_L)$.

A *classical belief change model* is a belief change model defined on a Boolean language whose logical consequence relation \vdash includes all classical truth-functional entailments and respects the deduction theorem for the material conditional. A *deductively closed belief change model* is a belief change model for which $K = \text{Cn}_{\vdash}(K) \cap K_{\perp}$ and $K_{\phi}^{-} = \text{Cn}_{\vdash}(K_{\phi}^{-}) \cap K_{\perp}$ and $K_{\phi}^{*} = \text{Cn}_{\vdash}(K_{\phi}^{*}) \cap K_{\perp}$ for all $K \in \mathbf{K}$ and all $\phi \in \mathcal{I}$. Note that in a deductively closed belief change model on language L , belief sets are theories in the fragment of L represented by K_{\perp} and not necessarily theories in L itself.

Informally, the items in a belief change model can be described as follows. \mathbf{K} represents the set of all possible belief states recognized by the model; often \mathbf{K} will be a subset of $\mathcal{T}_{L,\vdash}$ but not always. \mathcal{I} represents the set of all formulas eligible to serve as inputs for contraction and revision. \vdash is an inference relation defined on L and will in most cases be an extension of truth-functional propositional logic. K_{\perp} contains all of the formulas of that fragment of L from which the belief sets in \mathbf{K} are constructed and represents the absurd belief state; thus every belief set in \mathbf{K} is a subset of K_{\perp} . For each $K \in \mathbf{K}$ and each $\phi \in \mathcal{I}$, K_{ϕ}^{-} represents the result of *contracting* K to remove ϕ (if possible), whereas K_{ϕ}^{*} represents the result of *revising* K to include ϕ as a new belief. Revision is normally assumed to involve not only adding the given formula to the given belief set but also resolving any inconsistencies thereby created. For the sake of generality, we have not stipulated that $K_{\phi}^{-}, K_{\phi}^{*} \in \mathbf{K}$, though this will usually be the case. Finally, s is the *support function* for the model, which determines for each belief state K (and perhaps for other sets, as well) the set of formulas of L supported by K . For belief sets K in belief change models for which the Ramsey test holds, $s(K)$ will contain Ramsey test conditionals even if K does not.

2.3 Comparisons

With an eye toward our presentation of the basic triviality result for the Ramsey test we will briefly review differing positions about the elements making up a belief change model. The list of authors we mention here is not exhaustive but constitutes a representative sample of the diversity of positions taken with respect to belief change models and their elements in discussions of the Ramsey test.

Belief states: the language of the model and the set \mathbf{K}

Seegerberg places no restrictions on the language in his discussion of the triviality result in [Seegerberg, 1989]. Gärdenfors ([1988] and elsewhere),

Rott [1989], and Cross [1990a] all adopt a type- \mathcal{L}_2 language for their Ramsey test belief change models, whereas Makinson [1990], Morreau [1992], Hansson ([1992], section III), Arló-Costa [1995], and Levi ([1996] and elsewhere) restrict themselves to a type- \mathcal{L}_1 language. Hansson, Arló-Costa, and Levi allow only the type- \mathcal{L}_0 formulas of a type- \mathcal{L}_1 language to belong to the sets that individuate belief states. Makinson and Morreau, like Gärdenfors, Rott, Segerberg, and Cross, do not restrict the membership of belief-state-individuating sets to type- \mathcal{L}_0 formulas.

Most authors on the Ramsey test follow Gärdenfors in representing the set of all possible belief states as a set of theories. One exception is Hansson [1992], who takes each possible belief state to be represented by a pair consisting of a set of formulas and a revision operator that defines the dynamic properties of the belief state. For Hansson, the set of formulas in question is a *belief base*, a set of conditional-free formulas that need not be deductively closed. The belief base of a belief state is a (not necessarily finite) axiom set for the belief state, the idea being to allow different belief states to be associated with the same deductively closed theory. A belief state in Hansson's model can still be individuated by means of its belief base, however, because the revision operator of a belief state is a function of that belief state's belief base. Morreau [1992] also gives a two-component analysis of belief states, but in Morreau's analysis the two components are a set of "worlds" (truth-value assignments to atomic formulas) and a selection function (of the Stalnaker-Lewis variety) that determines which conditionals are believed in the belief state. A third exception is Rott [1991], who identifies belief states with epistemic entrenchment relations and notes that a nonabsurd belief set can be recovered from an epistemic entrenchment relation that supports at least one strict entrenchment: the belief set will be the set of all formulas strictly more entrenched than \perp .

Among those authors who take belief states to be deductively closed theories, most follow Gärdenfors in assuming that not every theory corresponds to a possible belief state. On this issue Segerberg and Makinson are exceptions. In their respective extensions of Gärdenfors' basic triviality result Segerberg and Makinson assume that revision is defined on *all* theories in a given language rather than on a nonempty subset of the set of all theories for that language.¹⁴

We note above that Hansson, Arló-Costa, and Levi allow only conditional-free formulas into the sets that individuate belief states.¹⁵ Why exclude conditionals from these sets? In Levi's view, the formulas eligible for membership in the theories that individuate belief states are precisely those statements about which agents can be concerned to avoid error. Levi argues against including conditionals in the theories that individuate belief

¹⁴See [Segerberg, 1989] and [Makinson, 1990].

¹⁵See, for example, [Hansson, 1992], [Arló-Costa, 1995], [Levi, 1996], and [Arló-Costa and Levi, 1996].

states because in his view conditionals do not have truth conditions or truth values and so are not sentences about which agents can be concerned to avoid error.¹⁶ On Levi's view, a conditional $\phi > \psi$ in a type- \mathcal{L}_1 language is acceptable relative to a belief set K in a type- \mathcal{L}_0 language iff $\neg\psi$ is not epistemically possible relative to the result of revising K to include ϕ , and the negated conditional $\neg(\phi > \psi)$ is acceptable relative to K iff $\neg\psi$ is epistemically possible relative to the revision of K to include ϕ . The part of this view governing negated conditionals, the negative Ramsey test, will be discussed later.¹⁷ An important consequence of Levi's view is the thesis that conditionals are "parasitic" on conditional-free statements in the following sense: the set of conditionals supported by a given belief state is determined by the conditional-free formulas accepted in that belief state or a subset thereof. Hansson [1992] shows, however, that it is possible to motivate a parasitic account of conditionals without taking a position on whether conditionals have truth conditions or truth values.

Gärdenfors [1988] criticizes Levi's view of conditionals on the grounds that it fails to account for iterated conditionals, a species of conditional about which Levi has expressed skepticism, but Levi [1996] and Hansson [1992] show that iterated conditionals can be accounted for (if necessary) even if conditionals do not have truth conditions or truth values. Levi [1996] points out, however, that axiom schema (MP) fails to be valid in the sense he favors if iterated conditionals are allowed.¹⁸ In this connection Levi exploits examples like the following, which was described by McGee [1985] as a counterexample to *modus ponens*:

Opinion polls taken just before the 1980 election showed the Republican Ronald Reagan decisively ahead of the Democrat Jimmy Carter, with the other Republican in the race, John Anderson, a distant third. Those apprised of the poll results believed, with good reason:

If a Republican wins the election, then if it's not Reagan who wins it will be Anderson.
A Republican will win the election.

Yet they will not have good reason to believe

If it's not Reagan who wins, it will be Anderson.¹⁹

¹⁶See [Levi, 1988] and [Levi, 1996], for example. As Arló-Costa and Levi [1996] point out, Ramsey agreed that conditionals lack truth conditions and truth values: this is clear from the context of the quote from Ramsey with which we began Section 2.

¹⁷For the most recent account of Levi's views on this topic, see [Levi, 1996].

¹⁸See [Levi, 1996], pp. 105-112.

¹⁹[McGee, 1985], p. 462.

Arló-Costa [1998] embraces iterated conditionals and uses McGee’s example to argue, via the Ramsey test, against the following principle of invariance for iterated *supposition*.

(K*INV) If $\phi \in K \neq K_{\perp}$, then $(K_{\phi}^*)^* = K_{\psi}^*$.

Supposition, i.e. hypothetical revision of belief “for the sake of argument,” is the notion of revision that Arló-Costa [1998] and Levi [1996] both associate with Ramsey test conditionals. Since (K*INV) holds in any deductively closed classical belief change model that satisfies (K*3) and (K*4), Arló-Costa takes McGee’s example as evidence against (K*4) as a principle governing supposition.

Contraction and revision inputs: the set \mathcal{I}

Gärdenfors does not exclude conditionals from the class of formulas eligible to be inputs for belief change in the models he formulates, but Morreau, Arló-Costa, and Levi do. In Levi’s case this restriction clearly follows from his view that conditionals have neither truth conditions nor truth values, and Arló-Costa appears to agree with this view. Morreau’s exclusion of conditionals as revision inputs appears to be an artifact of the nontriviality theorem he proves for the Ramsey test ([Morreau, 1992], THEOREM 14, p. 48) rather than indicative of a philosophical position about the status of conditionals.

Logical consequence and support: \vdash and s

Most authors on the Ramsey test follow Gärdenfors in assuming a compact background logic \vdash that includes all truth functional propositional entailments while respecting the deduction theorem for the material conditional, but there has been research on the Ramsey test in frameworks where the background logic is nonclassical or not necessarily classical. For example, Segerberg’s triviality result in [Segerberg, 1989] assumes only the minimal constraints of Reflexiveness, Transitivity, and Monotony for \vdash ,²⁰ and in [Gärdenfors, 1987] Gärdenfors credits Peter Lavers with having established in an unpublished note a triviality result for the Ramsey test in which \vdash is defined to be *minimal logic*²¹ instead of an extension of classical truth-functional logic. Also, Cross and Thomason [1987; 1992] investigate a four-valued system of conditional logic that is motivated by an application of the Ramsey test in the context of the nonmonotonic logic of multiple inheritance with exceptions in semantic networks.

²⁰See the definition of a Segerberg belief change model near the end of section 2.3.

²¹Minimal logic has modus ponens as its only inference rule and every instance of the following schemata as axioms:

Levi [1988] introduces the function RL , which maps a conditional-free belief set to a conditional-laden belief set via the Positive and Negative Ramsey tests. Cross [1990a] formulates a version of the triviality result proved in [Gärdenfors, 1986] in a framework where an extension \vdash of classical logic is coupled with a not-necessarily-monotonic consequence operation cl . Makinson [1990] does the same, calling his not-necessarily-monotonic consequence operation C . Hansson [1992] makes use of a function s which maps each belief state to the set of all formulas the belief state “supports.” Support functions are also adopted by Arló-Costa [1995] and by Arló-Costa and Levi [1996]. Our view is that Levi’s RL , Cross’ cl , Makinson’s C , and Hansson’s s should be regarded as variations on the same theoretical construct, and we will follow Hansson in calling this construct a *support function* and in using s to represent it. More on this in Section 2.6 below.

The following postulates are examples of requirements that might be imposed on s . Assume a belief change model on a language L , and assume that Γ ranges over $\text{dom}(s)$, which always includes \mathbf{K} as a subset:

(Identity over \mathbf{K}) $s(K) = K$ for all $K \in \mathbf{K}$.

(Monotonicity over \mathbf{K}) For all $H, K \in \mathbf{K}$, if $H \subseteq K$ then $s(H) \subseteq s(K)$.

(Reflexivity) $\Gamma \subseteq s(\Gamma)$.

(Closure) $\text{Cn}_{\vdash}[s(\Gamma)] = s(\Gamma)$.

(Consistency) If Γ is \vdash -consistent then $s(\Gamma)$ is \vdash -consistent.

(Superclassicality) $\text{Cn}_{\vdash}(\Gamma) \subseteq s(\Gamma)$.

(Transitivity) $s(\Gamma) = s[s(\Gamma)]$.

(Reasoning by Cases) $s(\Gamma \cup \{\phi\}) \cap s(\Gamma \cup \{\neg\phi\}) \subseteq s(\Gamma)$ for all Γ, ϕ such that $\Gamma \cup \{\phi\} \in \text{dom}(s)$ and $\Gamma \cup \{\neg\phi\} \in \text{dom}(s)$.

(Conservativeness) L has type- \mathcal{L}_0 fragment L_0 and for all $\phi \in \text{WFF}_{L_0}$, $\phi \in s(\Gamma)$ iff $\phi \in \text{Cn}_{\vdash}(\Gamma)$.

None of Gärdenfors, Morreau, or Segerberg uses the notion of a support function: they assume, in effect, that $s(K) = K$ for all $K \in \mathbf{K}$.

1. $(\phi \wedge \psi) \rightarrow \phi$.
2. $(\phi \wedge \psi) \rightarrow \psi$.
3. $\phi \rightarrow (\phi \vee \psi)$.
4. $\psi \rightarrow (\phi \vee \psi)$.
5. $(\phi \rightarrow \chi) \rightarrow [(\psi \rightarrow \chi) \rightarrow ((\phi \vee \psi) \rightarrow \chi)]$.
6. $(\phi \rightarrow \psi) \rightarrow [(\phi \rightarrow \chi) \rightarrow ((\phi \rightarrow (\psi \wedge \chi)))]$.
7. $[\phi \rightarrow (\psi \rightarrow \chi)] \rightarrow [(\phi \rightarrow \psi) \rightarrow (\psi \rightarrow \chi)]$.
8. $\phi \rightarrow (\psi \rightarrow \phi)$.

The formula $\neg\phi$ is defined to be $\phi \rightarrow \perp$. This axiomatization is found in [Segerberg, 1968].

Contraction and revision: postulates for belief change

Since $-$ and $*$ are to represent functions legitimately describable as contraction and revision, respectively, it is appropriate to consider additional conditions on these functions. Which additional conditions should be imposed is a matter of dispute, and some of the additional postulates that will be under consideration are listed below. In the case of postulates (K^{+1}) , (K^{-1}) , (K^{-2}) , (K^{-3}) , (K^{-4}) , (K^{-5}) , (K^{-6}) , (K^{-7}) , (K^{-8}) , (K^{*1}) , (K^{*2}) , (K^{*3}) , (K^{*4}) , (K^{*5}) , (K^{*6}) , (K^{*7}) , (K^{*8}) , (K^{*L}) , (K^{*M}) , and (K^{*P}) we follow the labeling used in [Gärdenfors, 1988]. Please note that we have not adopted any of the postulates given below in the definition of *belief change model*. In each postulate, the variable K is understood to range over \mathbf{K} ; also ϕ, ψ are understood to range over \mathcal{I} . We begin with a definition of a third important belief change operation: expansion.

Definition of and postulate for expansion

$$(Def+) \quad K_{\phi}^{+} = \text{Cn}_{\vdash}(K \cup \{\phi\}) \cap K_{\perp}.$$

$$(K^{+1}) \quad K_{\phi}^{+} \in \mathbf{K}. \quad (K_{\phi}^{+} \text{ is a belief set.})$$

Postulates for contraction

$$(K^{-1}) \quad K_{\phi}^{-} \in \mathbf{K}. \quad (K_{\phi}^{-} \text{ is a belief set.})$$

$$(K^{-2}) \quad K_{\phi}^{-} \subseteq K.$$

$$(K^{-3}) \quad \text{If } \phi \notin K, \text{ then } K_{\phi}^{-} = K.$$

$$(K^{-4}) \quad \text{If } \not\vdash \phi, \text{ then } \phi \notin K_{\phi}^{-}.$$

$$(K^{-4w}) \quad \text{If } \not\vdash \phi \text{ and } K \neq K_{\perp}, \text{ then } \phi \notin K_{\phi}^{-}.$$

$$(K^{-5}) \quad \text{If } \phi \in K, \text{ then } K \subseteq (K_{\phi}^{-})_{\phi}^{+}.$$

$$(K^{-6}) \quad \text{If } \vdash \phi \leftrightarrow \psi, \text{ then } K_{\phi}^{-} = K_{\psi}^{-}.$$

$$(K^{-7}) \quad K_{\phi}^{-} \cap K_{\psi}^{-} \subseteq K_{\phi \wedge \psi}^{-}.$$

$$(K^{-8}) \quad \text{If } \phi \notin K_{\phi \wedge \psi}^{-}, \text{ then } K_{\phi \wedge \psi}^{-} \subseteq K_{\phi}^{-}.$$

Postulates for revision

$$(K^{*1}) \quad K_{\phi}^{*} \in \mathbf{K}. \quad (K_{\phi}^{*} \text{ is a belief set.})$$

$$(K^{*2}) \quad \phi \in K_{\phi}^{*}.$$

- (K*3) $K_\phi^* \subseteq K_\phi^+$.
- (K*4) If $\neg\phi \notin K$, then $K_\phi^+ \subseteq K_\phi^*$.
- (K*4s) If $\neg\phi \notin K$, then $K_\phi^+ = K_\phi^*$.
- (K*4ss) If $K_\phi^+ \neq K_\perp$, then $K_\phi^+ = K_\phi^*$.
- (K*4w) If $\phi \in K \neq K_\perp$, then $K \subseteq K_\phi^*$.
- (K*5) $K_\phi^* = K_\perp$ iff $\vdash \neg\phi$.
- (K*5w) If $K_\phi^* = K_\perp$, then $\vdash \neg\phi$.
- (K*5ws) If $K_\phi^* = K_\perp$, then $\text{Cn}_+(\{\phi\}) = K_\perp$.
- (K*C) If $K \neq K_\perp$ and $K_\phi^* = K_\perp$, then $\vdash \neg\phi$.
- (K*6) If $\vdash \phi \leftrightarrow \psi$, then $K_\phi^* = K_\psi^*$.
- (K*6s) If $\psi \in K_\phi^*$ and $\phi \in K_\psi^*$, then $K_\phi^* = K_\psi^*$.
- (K*7) $K_{\phi \wedge \psi}^* \subseteq (K_\phi^*)_\psi^+$.
- (K*7') $K_\phi^* \cap K_\psi^* \subseteq K_{\phi \vee \psi}^*$.
- (K*8) If $\neg\psi \notin K_\phi^*$, then $(K_\phi^*)_\psi^+ \subseteq K_{\phi \wedge \psi}^*$.
- (K*L) If $\neg(\phi > \neg\psi) \in K$, then $(K_\phi^*)_\psi^+ \subseteq K_{\phi \wedge \psi}^*$.
- (K*M) If $s(K) \subseteq s(K')$, then $K_\phi^* \subseteq K_\phi'^*$.
- (K*IM) If $K \neq K_\perp \neq K'$ and $s(K) \subseteq s(K')$, then $K_\phi'^* \subseteq K_\phi^*$.
- (K*T) If $K \neq K_\perp$, then $K_\top^* = K$.
- (K*P) If $\neg\phi \notin K$, then $K \subseteq K_\phi^*$.
- (K*P \mathcal{I}) If $\neg\phi \notin K$ then $K \cap \mathcal{I} \subseteq K_\phi^* \cap \mathcal{I}$.
- (LI) $K_\phi^* = (K_{\neg\phi}^-)_\phi^+$.

A few other postulates will be identified as needed.

Our treatment of contraction and revision is not general enough to include every treatment of contraction and revision as a special case. For example, in the formalization of belief revision in [Morreau, 1992], the revision operation is nondeterministic, i.e. its value for a given belief set K and proposition ϕ is a set of belief sets rather than a belief set. We will not attempt to formalize nondeterministic contraction or revision. Also, for

Levi, contraction and revision are to be evaluated by means of a measure of *informational value*, which we do not explicitly formalize.

The contraction operation, which we include in every belief change model, is not often used in the presentation of triviality results for the Ramsey test. Exceptions to this pattern include Cross [1990a] and Makinson [1990], who involve contraction explicitly in their respective formulations of triviality results for the Ramsey test.

A catalog of belief change models

We conclude our discussion of comparisons by defining several categories of belief change model that illustrate how the framework defined above can be made to reflect the differing assumptions of a subset of authors who have written on belief revision and the Ramsey test. In associating a name with a class of belief change models we do not claim that the person named defined this class of models; rather, we claim that the belief change models associated with this name are the appropriate counterpart in our framework of models that the named person did define in the context of work on the Ramsey test. Note that postulates on contraction and revision are not part of these definitions.

1. By a *Gärdenfors belief change model* (see, for example, [Gärdenfors, 1986], [Gärdenfors, 1987], and [Gärdenfors, 1988]) we will mean a deductively closed classical belief change model $\langle \mathbf{K}, \mathcal{I}, \vdash, K_{\perp}, -, *, s \rangle$ defined on a type- \mathcal{L}_2 language L where $\mathcal{I} = \text{WFF}_L = K_{\perp}$, and $\text{dom}(s) = \mathbf{K}$, and s satisfies Identity over \mathbf{K} .
2. By a *Seegerberg belief change model* (see [Seegerberg, 1989]) we will mean a belief change model $\langle \mathbf{K}, \mathcal{I}, \vdash, K_{\perp}, -, *, s \rangle$, defined on any language, such that the following hold: $\mathbf{K} = \mathcal{T}_{L, \vdash}$; $\mathcal{I} = \text{WFF}_L = K_{\perp}$; $\text{dom}(s) = \mathbf{K}$; s satisfies identity over \mathbf{K} ; and Cn_{\vdash} meets the following requirements, for all $\Delta, \Gamma \subseteq \text{WFF}_L$:
 - (Reflexivity for \vdash) $\Gamma \subseteq \text{Cn}_{\vdash}(\Gamma)$.
 - (Monotonicity for \vdash) If $\Delta \subseteq \Gamma$, then $\text{Cn}_{\vdash}(\Delta) \subseteq \text{Cn}_{\vdash}(\Gamma)$.
 - (Transitivity for \vdash) $\text{Cn}_{\vdash}(\Gamma) = \text{Cn}_{\vdash}[\text{Cn}_{\vdash}(\Gamma)]$.
3. By a *Makinson belief change model* (see [Makinson, 1990]) we will mean a belief change model $\langle \mathbf{K}, \mathcal{I}, \vdash, K_{\perp}, -, *, s \rangle$ defined on a type- \mathcal{L}_1 language L and satisfying the following: $\mathbf{K} = \{\Gamma : \Gamma \subseteq \text{WFF}_L \text{ and } s(\Gamma) = \Gamma\}$; $\mathcal{I} = \text{WFF}_L = K_{\perp}$, \vdash is classical propositional consequence; $\text{dom}(s) = \mathcal{P}(\text{WFF}_L)$; and s satisfies Superclassicality, Transitivity, and Reasoning by Cases.²²

²²Note that in a Makinson belief change model s satisfies both Reflexivity and Closure. Closure holds since Superclassicality and Transitivity for s imply that for each $\Gamma \subseteq \text{WFF}_L$, we have $s(\Gamma) \subseteq \text{Cn}_{\vdash}[s(\Gamma)] \subseteq s[s(\Gamma)] = s(\Gamma)$.

4. By a *Morreau belief change model* (see [Morreau, 1992]) we will mean a deductively closed classical belief change model $\langle \mathbf{K}, \mathcal{I}, \vdash, K_{\perp}, -, *, s \rangle$ defined on a type- \mathcal{L}_1 language L whose type- \mathcal{L}_0 fragment is L_0 and where the following hold: $\mathcal{I} = \text{WFF}_{L_0}$; $K_{\perp} = \text{WFF}_L$; $\text{dom}(s) = \mathbf{K}$; and s satisfies Identity over \mathbf{K} .
5. By a *Hansson belief change model* (see [Hansson, 1992], section 3) we will mean a classical belief change model $\langle \mathbf{K}, \mathcal{I}, \vdash, K_{\perp}, -, *, s \rangle$ defined on a type- \mathcal{L}_1 language L whose type- \mathcal{L}_0 fragment is L_0 and where the following hold: $\mathbf{K} \subseteq \mathcal{P}(\text{WFF}_{L_0})$; $\mathcal{I} = \text{WFF}_{L_0} = K_{\perp}$; $\text{dom}(s) = \mathbf{K}$; and s satisfies Reflexivity, Conservativeness, and Closure.
6. By an *Arló-Costa/Levi belief change model* (see [Arló-Costa, 1990], [Arló-Costa, 1995], [Arló-Costa and Levi, 1996], and [Levi, 1996]) we will mean a deductively closed classical belief change model $\langle \mathbf{K}, \mathcal{I}, \vdash, K_{\perp}, -, *, s \rangle$ defined on a type- \mathcal{L}_1 language L whose type- \mathcal{L}_0 fragment is L_0 and where the following hold: $\mathcal{I} = \text{WFF}_{L_0} = K_{\perp}$; $\text{dom}(s) = \mathbf{K}$; and s satisfies Reflexivity, Conservativeness, and Closure.

As we have already noted, our belief change models do not capture every feature of every belief revision model appearing in the literature on the Ramsey test, and the models we associate with the names of authors in some cases omit some of the structure that these authors include in their own respective accounts of what constitutes a belief revision model. On the other hand, we have stipulated more detail for the models we associate with certain authors than do the authors themselves. For example, none of Gärdenfors, Morreau, or Segerberg uses the notion of a support function s in the sources cited above, and neither Gärdenfors, nor Makinson, nor Segerberg restricts the applicability of contraction and revision to a subset \mathcal{I} of the set of formulas of the language on which the model is defined. Finally, as was pointed out earlier, the contraction operation, which we include in every belief change model, is not often discussed in connection with the Ramsey test. In general, the stipulation of extra detail will serve to highlight tacit assumptions and make comparisons easier.

2.4 The Ramsey test for conditionals

Ramsey's original suggestion can be put as follows: if an agent's beliefs entail neither ϕ nor $\neg\phi$, then the agent's beliefs support $\phi > \psi$ iff his or her initial beliefs together with ϕ entail ψ , i.e.

$$\text{(RTR)} \quad \text{For all } K \in \mathbf{K} \text{ and all } \phi \in \mathcal{I} \text{ such that } \phi, \neg\phi \notin K \text{ and all } \psi \in K_{\perp}, \\ \phi > \psi \in s(K) \text{ iff } \psi \in K_{\phi}^+.$$

This suggestion covers only the case in which the epistemic status of ϕ is undetermined. What about the case in which the agent's initial beliefs

entail ϕ and the case in which the agent's initial beliefs entail $\neg\phi$? Stalnaker [1968] suggests the following rule for evaluating a conditional in the general case:

First, add the antecedent (hypothetically) to your stock of beliefs; second, make whatever adjustments are required to maintain consistency (without modifying the hypothetical belief in the antecedent); finally, consider whether or not the consequent is true.²³

Stalnaker's proposal handles the general case by substituting the operation of revision for that of expansion in Ramsey's original proposal. In our framework Stalnaker's suggestion amounts to the following:

(RT) For all $K \in \mathbf{K}$ and all $\phi \in \mathcal{I}$ and all $\psi \in K_{\perp}$, $\phi > \psi \in s(K)$ iff $\psi \in K_{\phi}^*$.

Revision postulates (K*3) and (K*4) jointly entail

(K*4s) If $\neg\phi \notin K$ then $K_{\phi}^+ = K_{\phi}^*$.

Hence, if (K*3), (K*4) are assumed, then (RT) agrees with (RTR) in the case where neither ϕ nor $\neg\phi$ belongs to K . That is, if (K*3) and (K*4) hold, then (RT) can be considered an extension of Ramsey's original proposal. In [Gärdenförs, 1978] and in later writings Gärdenförs adopts Stalnaker's version of the Ramsey test for type- \mathcal{L}_2 languages and assumes, in addition, the following: every formula of a type- \mathcal{L}_2 language L is an eligible input for revision and an eligible member of a belief set, i.e. $\mathcal{I} = \text{WFF}_L = K_{\perp}$, and a conditional, like any other formula, is accepted with respect to (supported by) a belief set K iff it belongs to K , i.e. $s(K) = K$ for all $K \in \mathbf{K}$.

We have already noted that Levi, in contrast to Gärdenförs, excludes conditionals as revision inputs and as members of belief sets. Levi's view is that the conditional $\phi > \psi$ in a type- \mathcal{L}_1 language expresses the attitude of an agent for whom $\neg\psi$ is not epistemically possible relative to K_{ϕ}^* , and the negated conditional $\neg(\phi > \psi)$ expresses the attitude of an agent for whom $\neg\psi$ is epistemically possible relative to K_{ϕ}^* . Assuming a type- \mathcal{L}_1 language L with type- \mathcal{L}_0 fragment L_0 , and assuming that $\mathbf{K} \subseteq \mathcal{T}_{L_0, \vdash}$ and $\mathcal{I} = \text{WFF}_{L_0} = K_{\perp}$, Levi's view amounts in our framework to the conjunction of the following:

(PRTL) For all $\phi \in \mathcal{I}$ and all $\psi \in K_{\perp}$ and all $K \in \mathbf{K}$ such that $K \neq K_{\perp}$, $\phi > \psi \in s(K)$ iff $\psi \in K_{\phi}^*$.

(NRTL) For all $\phi \in \mathcal{I}$ and all $\psi \in K_{\perp}$ and all $K \in \mathbf{K}$ such that $K \neq K_{\perp}$, $\neg(\phi > \psi) \in s(K)$ iff $\psi \notin K_{\phi}^*$.

²³[Stalnaker, 1968], p. 44. (The page reference is to [Harper *et al.*, 1981], where [Stalnaker, 1968] is reprinted.)

Note that in both (PRTL) and (NRTL), unlike in (RT), K is restricted to \vdash -consistent members of \mathbf{K} . Note also that the adoption of (RT) (or of (PRTL) without (NRTL)) places no constraints on how negated conditionals are related to belief change.

Other versions of the Ramsey test appearing in the literature include the following, due to Hans Rott, who, like Gärdenfors, assumes a language L of type \mathcal{L}_2 and no restrictions on which formulas can appear as members of belief sets or as revision inputs (i.e. $\mathcal{I} = \text{WFF}_L = K_\perp$):

- (R1) For all $K \in \mathbf{K}$ and all $\phi \in \mathcal{I}$ and all $\psi \in K_\perp$, $\phi > \psi \in K$ iff $\psi \in K_\phi^*$ and $\psi \notin K$.
- (R2) For all $K \in \mathbf{K}$ and all $\phi \in \mathcal{I}$ and all $\psi \in K_\perp$, $\phi > \psi \in K$ iff $\psi \in K_\phi^*$ and $\psi \notin K_{\neg\phi}^*$.
- (R3) For all $K \in \mathbf{K}$ and all $\phi \in \mathcal{I}$ and all $\psi \in K_\perp$, $\phi > \psi \in K$ iff $\psi \in (K_\psi^-)^*$.

Here we follow the labeling in [Gärdenfors, 1987]. The interest of (R1)-(R3) stems in part from the fact that whereas (RT) can be used with (K*3) and (K*4) to derive the following thesis (U), none of (R1)-(R3) can be so used:

- (U) If $\phi \in K$ and $\psi \in K$, then $\phi > \psi \in K$.

Thesis (U) is related to the strong centering axiom CS of \mathbf{VC} , and Rott [1986] suggests that (U) should be rejected. Since none of (R1)-(R3) entails (K*M), one of the assumptions of Gärdenfors' 1986 triviality result for the Ramsey test, (R1)-(R3) might seem worth investigating as alternatives to (RT), but Gärdenfors [1987] shows that (R1)-(R3) do not avoid the problem faced by (RT). Consider the Weak Ramsey Test:

- (WRT) For all $K \in \mathbf{K}$ and all $\phi \in \mathcal{I}$ and all $\psi \in K_\perp$ such that $\phi \vee \psi \notin K$, $\phi > \psi \in K$ iff $\psi \in K_\phi^*$.

Each of (R1)-(R3) entails (WRT), and Gärdenfors [1987] proves a triviality result that holds for any version of the Ramsey test which entails (WRT), including (R1)-(R3) and (RT).²⁴

2.5 Triviality results for the Ramsey test

The basic result

Many versions of the basic triviality result for the Ramsey test have appeared in the literature, all of them variations on the result proved by Gärdenfors [1986]. All proofs of the basic triviality result we know of exploit the same maneuver, however, one which Hansson [1992] makes explicit:

²⁴See also [Gärdenfors, 1988], Chapter 7, Corollary 7.15

in terms of our framework, the finding of *forking support sets* within a belief change model.

(DefFORK) A belief change model $\langle \mathbf{K}, \mathcal{I}, \vdash, K_{\perp}, -, *, s \rangle$ will be said to *contain forking support sets* iff there exist $H, J, K \in \mathbf{K}$, such that $H = \text{Cn}_{\vdash}(H) \cap K_{\perp}$, and $J = \text{Cn}_{\vdash}(J) \cap K_{\perp}$, and $K = \text{Cn}_{\vdash}(K) \cap K_{\perp} \neq K_{\perp}$, and $H \cap \mathcal{I} \not\subseteq J$, and $J \cap \mathcal{I} \not\subseteq H$, and $s(H) \subseteq s(K)$, and $s(J) \subseteq s(K)$.

For Gärdenfors and Segerberg belief change models this condition can be stated in the form in which Hansson originally formulated it:

PROPOSITION 1. *A Gärdenfors or Segerberg belief change model $\langle \mathbf{K}, \mathcal{I}, \vdash, K_{\perp}, -, *, s \rangle$ contains forking support sets iff there exist $H, J, K \in \mathbf{K}$, where $H, J \subseteq K \neq K_{\perp}$, $H \not\subseteq J$, and $J \not\subseteq H$.*

This proposition follows from the fact that in Gärdenfors and Segerberg belief change models (i) $s(K) = K = \text{Cn}_{\vdash}(K)$ for all $K \in \mathbf{K}$, and (ii) \mathcal{I} and K_{\perp} both exhaust the formulas of the language of the model.

Next we present the main lemmas for the basic triviality result:

LEMMA 2. *If (RT) holds in a belief change model, then so does (K^*M) .*

Proof. Trivial; left to reader. ■

Postulate (K^*M) is a postulate of monotonicity for belief revision. We discuss Gärdenfors' argument against (K^*M) in Section 2.6 below.

LEMMA 3. *No classical belief change model containing forking support sets satisfies (K^*2) , (K^*C) , (K^*P) , and (K^*M) .*

Proof. Assume for *reductio* that $\langle \mathbf{K}, \mathcal{I}, \vdash, K_{\perp}, -, *, s \rangle$ is a classical belief change model that contains forking support sets and satisfies (K^*2) , (K^*C) , (K^*P) , and (K^*M) . For clarity, we follow the example of [Rott, 1989] in numbering the steps in the *reductio* argument.

- (1) $H = \text{Cn}_{\vdash}(H) \cap K_{\perp}$, $J = \text{Cn}_{\vdash}(J) \cap K_{\perp}$, (DefFORK)
 $K = \text{Cn}_{\vdash}(K) \cap K_{\perp} \neq K_{\perp}$, $H \cap \mathcal{I} \not\subseteq J$,
 $J \cap \mathcal{I} \not\subseteq H$, and $s(H), s(J) \subseteq s(K)$,
 for some $H, J, K \in \mathbf{K}$
- (2) $\phi \in (H \cap \mathcal{I}) \sim J$, for some ϕ (1)
- (3) $\psi \in (J \cap \mathcal{I}) \sim H$, for some ψ (1)
- (4) $\neg(\phi \wedge \psi) \in \mathcal{I}$ (2), (3), (DefBCM)
- (5) $\neg\neg(\phi \wedge \psi) \notin H$ (3), classicality of \vdash , fact that $H = \text{Cn}_{\vdash}(H) \cap K_{\perp}$
- (6) $H \subseteq H_{\neg(\phi \wedge \psi)}^*$ (4), (5), (K^*P)

- | | | |
|------|---|--|
| (7) | $\phi \in H_{\neg(\phi \wedge \psi)}^*$ | (2), (6) |
| (8) | $\neg\neg(\phi \wedge \psi) \notin J$ | (2), classicality of \vdash , fact that $J = \text{Cn}_{\vdash}(J) \cap K_{\perp}$ |
| (9) | $J \subseteq J_{\neg(\phi \wedge \psi)}^*$ | (4), (8), (K*P) |
| (10) | $\psi \in J_{\neg(\phi \wedge \psi)}^*$ | (3), (9) |
| (11) | $H_{\neg(\phi \wedge \psi)}^*, J_{\neg(\phi \wedge \psi)}^* \subseteq K_{\neg(\phi \wedge \psi)}^*$ | (1), (4), (K*M) |
| (12) | $\phi, \psi \in K_{\neg(\phi \wedge \psi)}^*$ | (7), (10), (11) |
| (13) | $\neg(\phi \wedge \psi) \in K_{\neg(\phi \wedge \psi)}^*$ | (4), (K*2) |
| (14) | $K_{\neg(\phi \wedge \psi)}^*$ is \vdash -inconsistent | (12), (13), classicality of \vdash |
| (15) | K is \vdash -consistent | classicality of \vdash , fact that $K = \text{Cn}_{\vdash}(K) \cap K_{\perp} \neq K_{\perp}$ |
| (16) | $\vdash \neg\neg(\phi \wedge \psi)$ | (14), (15), (K*C) |
| (17) | $\not\vdash \neg\neg(\phi \wedge \psi)$ | (5), classicality of \vdash , fact that $H = \text{Cn}_{\vdash}(H) \cap K_{\perp}$ |

Since (17) contradicts (16), this completes the proof. \blacksquare

Lemmas 2 and 3 suffice to prove the following:

THEOREM 4. *No classical belief change model defined on a language of type \mathcal{L}_1 or type \mathcal{L}_2 and containing forking support sets satisfies (K*2), (K*C), (K*P), and (RT).*

Note that we have not assumed that \mathbf{K} is a set of theories either in the language of the model or in the fragment thereof represented by K_{\perp} . We have not even assumed (K*1): that the sets produced by revision always belong to \mathbf{K} . It is however required that the belief sets H , J , and K used in the proof be theories in the fragment of the language represented by K_{\perp} .

Do we have a triviality result? Not yet: we do not yet have a criterion of triviality. The following criteria have appeared in the literature:

1. A belief change model is *Gärdenfors nontrivial* iff there is a $K' \in \mathbf{K}$ and $\phi, \psi, \chi \in \mathcal{I}$ such that $\neg\phi, \neg\psi, \neg\chi \notin \text{Cn}_{\vdash}(K')$ and $\vdash \neg(\phi \wedge \psi)$ and $\vdash \neg(\phi \wedge \chi)$ and $\vdash \neg(\psi \wedge \chi)$.
2. A belief change model is *Rott nontrivial* iff there is a $K' \in \mathbf{K}$ and $\phi, \psi \in \mathcal{I}$ such that $\phi \not\vdash \psi$ and $\psi \not\vdash \phi$ and $\phi \vee \psi, \neg\phi \vee \psi, \phi \vee \neg\psi, \neg\phi \vee \neg\psi \notin \text{Cn}_{\vdash}(K')$.
3. A belief change model is *Seegerberg nontrivial* iff there exist $\phi, \psi, \chi \in \mathcal{I}$ such that $\phi \not\vdash \psi$ and $\psi \not\vdash \phi$ and $\text{Cn}_{\vdash}\{\phi, \psi, \chi\} = K_{\perp}$ and $\text{Cn}_{\vdash}(\{\phi\}), \text{Cn}_{\vdash}(\{\psi\}), \text{Cn}_{\vdash}(\{\phi, \psi\}) \in \mathbf{K}$.

Recall that a support function s is *monotone over \mathbf{K}* iff $s(H) \subseteq s(K)$ for all $H, K \in \mathbf{K}$ such that $H \subseteq K$. A support function can be monotone

over \mathbf{K} even if it is a *nonmonotonic* consequence operation provided that \mathbf{K} does not exhaust $\text{dom}(s)$. For example, s is monotone over \mathbf{K} (but not necessarily over $\text{dom}(s)$) in all Makinson belief change models, since in a Makinson belief change model $s(K) = K$ for all $K \in \mathbf{K}$. Recall that the operation of expansion is defined by (Def+); it turns out that if (K^+1) and the monotonicity of s over \mathbf{K} are assumed, then nontriviality by any of the above criteria will imply the existence of forking support sets:

LEMMA 5. *A classical belief change model defined on a language of type \mathcal{L}_1 or \mathcal{L}_2 contains forking support sets if it satisfies (K^+1) and its support function is monotone over \mathbf{K} and it is Gärdenfors nontrivial.²⁵*

Proof. Suppose that the model is Gärdenfors nontrivial; we will show that it contains forking support sets. Let K' , ϕ , ψ , and χ be as in the definition of Gärdenfors nontriviality; also, let $H = K'_{\phi \vee \psi}^+$; let $J = K'_{\phi \vee \chi}^+$; and let $K = K'_{\phi}^+$. Then by (Def+) and the classicality of \vdash , $H = \text{Cn}_{\vdash}(H) \cap K_{\perp}$, $J = \text{Cn}_{\vdash}(J) \cap K_{\perp}$, and $K = \text{Cn}_{\vdash}(K) \cap K_{\perp} \neq K_{\perp}$. (Def+) and the classicality of \vdash also imply that $H, J \subseteq K$, hence by the monotonicity of s we have that $s(H), s(J) \subseteq s(K)$. $H \cap \mathcal{I} \not\subseteq J$ holds because $\phi \vee \psi \in (H \cap \mathcal{I}) \sim J$; $J \cap \mathcal{I} \not\subseteq H$ holds because $\phi \vee \chi \in (J \cap \mathcal{I}) \sim H$. ■

LEMMA 6. *A classical belief change model defined on a language of type \mathcal{L}_1 or \mathcal{L}_2 contains forking support sets if it satisfies (K^+1) and its support function is monotone over \mathbf{K} and it is Rott nontrivial.²⁶*

Proof. Like the proof of Lemma 5, but let $H = K'_{\phi \vee \psi}^+$; let $J = K'_{\phi \vee \neg\psi}^+$, let $K = K'_{\neg\phi}^+$, where K' , ϕ , and ψ are as in the definition of Rott nontriviality. $H \cap \mathcal{I} \not\subseteq J$ holds because $\phi \vee \psi \in (H \cap \mathcal{I}) \sim J$; $J \cap \mathcal{I} \not\subseteq H$ holds because $\phi \vee \neg\psi \in (J \cap \mathcal{I}) \sim H$. ■

LEMMA 7. *A classical belief change model defined on a language of type \mathcal{L}_1 or \mathcal{L}_2 contains forking support sets if it satisfies (K^+1) and its support function is monotone over \mathbf{K} and it is Segerberg nontrivial.*

Proof. Like the proof of Lemma 5, but let $H = \text{Cn}_{\vdash}(\{\phi\})$, $J = \text{Cn}_{\vdash}(\{\psi\})$, $K = \text{Cn}_{\vdash}(\{\phi, \psi\})$, where ϕ , ψ , and χ are as in the definition of Segerberg nontriviality. ■

Theorem 4 and Lemmas 5, 6, and 7 immediately imply Theorem 8, the basic triviality result for the Ramsey test:

THEOREM 8. *No classical belief change model defined on a language of type \mathcal{L}_1 or \mathcal{L}_2 that satisfies (K^+1) , (K^*2) , (K^*C) , (K^*P) , and (RT) and*

²⁵See [Gärdenfors, 1986].

²⁶See [Rott, 1989].

whose support function is monotonic over \mathbf{K} is Gärdenfors nontrivial or Rott nontrivial or Segerberg nontrivial.

The basic result of [Gärdenfors, 1986] can be derived by applying Theorem 8 to Gärdenfors belief change models.

Gärdenfors [1987; 1988] notes that (K^*P) and (K^*2) can be replaced by (K^*4) in the triviality result he proves there, and this same replacement can be made in Theorem 8, with a corresponding change in Lemma 3 and its proof.²⁷ As was mentioned in Section 2.3 above, Segerberg has proved a version of the Gärdenfors result in which the constraints on \vdash are limited to Reflexivity, Transitivity, and Monotonicity. The counterpart in our framework of Segerberg's result is the following:

THEOREM 9. *No Segerberg nontrivial Segerberg belief change model satisfies (K^*M) , (K^*4ss) , and (K^*5ws) .*²⁸

If contraction and revision are assumed to be related by the Levi Identity (LI) in a deductively closed belief change model, then triviality results for the Ramsey test can be formulated in terms of contraction rather than in terms of revision. In particular, we have the following as a corollary of Theorem 8:²⁹

THEOREM 10. *No deductively closed classical belief change model defined on a language of type \mathcal{L}_1 or \mathcal{L}_2 that satisfies (K^+1) , (K^-3) , (K^-4w) , (LI), and (RT) and whose support function is monotonic over \mathbf{K} is Gärdenfors nontrivial or Rott nontrivial or Segerberg nontrivial.*

Proof. It suffices to note that where \vdash is classical, we have the following: (Def+) and (LI) jointly imply (K^*2) ; (LI) and (K^-4w) jointly imply (K^*C) ; (Def+), (K^-3) , and (LI) jointly imply (K^*P) . ■

Makinson [1990] proves a variant of Theorem 10 for type- \mathcal{L}_1 languages that replaces (K^-4w) and weakens both (RT) and (LI) while making stronger assumptions about s than merely that it is monotone over \mathbf{K} :

THEOREM 11. *Let $\langle \mathbf{K}, \mathcal{I}, \vdash, K_\perp, -, *, s \rangle$ be a Makinson belief change model defined on a language L of type \mathcal{L}_1 . Define postulates (RTM), (K^-4c) , and (MI) as follows:*

(RTM) *For all $\phi, \psi \in \text{WFF}_{L_0}$, where L_0 is the type- \mathcal{L}_0 fragment of L ,*
 $\phi > \psi \in s(K)$ *iff* $\psi \in K_\phi^*$.

²⁷Steps (6), (9), and (13) must be differently justified.

²⁸See [Segerberg, 1989]. Segerberg's version of the Gärdenfors triviality result makes no assumption about which operators are available in the language, hence χ is used in the definition of Segerberg nontriviality to play the role that $\neg(\phi \wedge \psi)$ plays in the proof of Lemma 3. Also, Segerberg's result does not assume that the language contains both \top and \perp , which we assume here in (DefBCM).

²⁹A similar result is proved in [Cross, 1990a].

(K⁻4c) If $\phi \in s(K_\phi^-)$, then $\phi \in s(\emptyset)$.

(MI) $K_{\neg\phi}^- \subseteq K_\phi^* \subseteq s(K_{\neg\phi}^- \cup \{\phi\})$.

Then we have the following:

(1) *Limiting Case.* If (RTM), (K⁻4c), and (MI) hold for $K = K_\perp$, then the model is trivial in the sense that $s(\emptyset) = K_\perp$.

(2) *Principal Case.* If (RTM), (K⁻3), (K⁻4c), and (MI) hold for all $K \in \mathbf{K}$ such that $K \neq K_\perp$, then the model is trivial in the sense that there are no conditional-free formulas ϕ and ψ of L such that $\phi \wedge \psi \notin s(\emptyset)$ and $\phi \notin s(\{\psi\})$ and $\psi \notin s(\{\phi\})$ and $s[s(\{\phi\}) \cup s(\{\psi\})] \neq K_\perp$.

The Limiting Case generalizes Theorem 12 discussed below. It is the Principal Case that more closely corresponds to Theorem 10. (K⁻4c) neither entails nor is entailed by (K⁻4), its AGM counterpart, but (MI), which we will refer to as Makinson’s Inequality, is the result of weakening (LI), the Levi Identity, to say that a revision of K to include ϕ must lie “between” $K_{\neg\phi}^-$ and $s(K_{\neg\phi}^- \cup \{\phi\})$. Since, as we have seen, (LI), (Def+), and (K⁻3) entail (K*P), one might expect that replacing (LI) with (MI) would leave (K*P) unsupported, but this is not the case: (MI), (Def+), and (K⁻3) already entail (K*P). Making up for the fact that (MI) is weaker than (LI) are Makinson’s strengthened assumptions about s : that it satisfies Superclassicality, Transitivity, and Reasoning by Cases. Makinson [1990] points out that these conditions are known not to imply that s is monotone over its entire domain ($\mathcal{P}(\text{WFF}_L)$), but since contraction and revision in a Makinson belief change model are defined only on K such that $s(K) = K$, s is nevertheless monotone “where it counts”, namely over the set \mathbf{K} of belief sets on which contraction and revision are defined. Several authors (e.g. Grahne [1991], Hansson [1992], and Morreau [1992]) have concluded from Makinson’s result that nonmonotonic consequence does not provide a way out of the Gärdenfors triviality result. In fact, adopting a nonmonotonic consequence operation *does* provide a way out, provided that this consequence relation plays the role of a support function s that is nonmonotonic over the belief sets to which contraction and revision are applied. Indeed, it is by adopting such support functions that Hansson, Arló-Costa and Levi are able to make the Ramsey test nontrivial, though these authors do not describe the support function as a consequence operation. (See also Section 2.6 below.)

Theorem 8 and its variants pose a dilemma: which of an inconsistent set of constraints on belief change models should be rejected? We return to this later in Section 2.6 below.

*The problem with (K*5w)*

In the version of Theorem 8 that Gärdenfors proves in [Gärdenfors, 1988], postulate (K*C) is replaced by the stronger (K*5w), but Arló-Costa [1990] proves that (K*5w) faces problems that have nothing to do with (K*P). Arló-Costa's result, which is not so much a triviality result as an impossibility result, can be formulated as follows in our framework:

THEOREM 12. *There is no Gärdenfors belief change model defined on a language of type \mathcal{L}_1 or \mathcal{L}_2 in which $\not\vdash \perp$, (K*5w), and (RT) hold.*

Whereas Gärdenfors' results against the Ramsey test exploit the fact that (RT) entails (K*M), Arló-Costa's result exploits the fact that (RT) entails the following, which Arló-Costa calls "Unsuccess":

(US) If $K = K_\perp$, then $K_\phi^* = K_\perp$.

In other words, the Ramsey test requires revision into inconsistency if the initial belief state is already inconsistent, regardless whether the revision input is a consistent proposition. Contrary to this, (K*5w) prohibits revision into inconsistency when the revision input is a consistent proposition, regardless whether the initial belief state is consistent. The labeling of (US) as a postulate of "unsuccess" is appropriate since (K*5w), which (US) contradicts, follows from (Def+), (LI), and the Postulate of Success for *contraction* (K⁻4).

Arló-Costa's result can be strengthened to include belief change models in which $s(K) = K$ does not always hold:

THEOREM 13. *There is no deductively closed classical belief change model defined on a language of type \mathcal{L}_1 or \mathcal{L}_2 whose support function satisfies Reflexivity and Closure and in which $\not\vdash \perp$, (K*5w), and (RT) hold.*

Proof. Let a deductively closed classical belief change model on a language of type \mathcal{L}_1 or \mathcal{L}_2 be given and suppose for reductio that $\not\vdash \perp$, that s satisfies Reflexivity and Closure, and that the model satisfies (K*5w) and (RT).

First we prove (US). Let $K = K_\perp$; then we have

$$\begin{aligned} K &\subseteq s(K) && \text{Reflexivity of } s \\ &= \text{Cn}_+[s(K)] && \text{Closure of } s \end{aligned}$$

Since $\perp \in K_\perp = K$ we have $s(K) = \text{WFF}_L$, by the classicality of \vdash . Next, let $\psi \in K_\perp$, and let $\phi \in \mathcal{I}$. Since $s(K) = \text{WFF}_L$, we have $\phi > \psi \in s(K)$. Hence by (RT) we have $B \in K_\phi^*$. Thus $K_\perp \subseteq K_\phi^*$; the converse inclusion holds by (DefBCM), so $K_\phi^* = K_\perp$, as required to show (US).

By (DefBCM) $K_\perp \in \mathbf{K}$ and $\neg\perp \in \mathcal{I}$; by (US) we have $(K_\perp)_{\neg\perp}^* = K_\perp$. By hypothesis $\not\vdash \perp$, hence by the classicality of \vdash we have not only $(K_\perp)_{\neg\perp}^* = K_\perp$ but also $\not\vdash \neg\neg\perp$, which contradicts (K*5w). ■

The Limiting Case of Theorem 11, like Theorem 13, is a strengthening of Theorem 12. The problem posed by Theorems 12 and 13 can be solved by retreating from (K^*5w) to something weaker, such as the postulate (K^*C) mentioned in Theorem 8, or by restricting the applicability of the Ramsey test, as Aró-Costa and Levi both do by adopting (PRTL) (see Section 2.4 above), which eliminates K_{\perp} from the domain of belief sets to which the Ramsey test can be applied.

The negative Ramsey test

Levi has argued (see, for example, [Levi, 1988] and [Levi, 1996]) that a negated conditional $\neg(\phi > \psi)$ expresses the propositional attitude of an agent for whom $\neg\psi$ is a serious (i.e. epistemic) possibility relative to K_{ϕ}^* . Abstracting from Levi’s requirements on what is allowed to be a revision input, the result is this thesis, the negative Ramsey test:

(NRTL) For all $\phi \in \mathcal{I}$ and all $\psi \in K_{\perp}$ and all $K \in \mathbf{K}$ such that $K \neq K_{\perp}$,
 $\neg(\phi > \psi) \in s(K)$ iff $\psi \notin K_{\phi}^*$.

Rott [1989] takes the view that adopting both the negative Ramsey test and the Ramsey test amounts to an assumption of autoepistemic omniscience. Given the view of Gärdenfors, Rott, and others that conditionals and negated conditionals belong in belief sets along with other beliefs (so that s satisfies Identity over \mathbf{K}), the conjunction of (RT) and (NRTL) does amount to a kind of epistemic omniscience. That is, if s satisfies Identity over \mathbf{K} , then “closing” each belief set under (RT) and (NRTL) amounts to an idealization that parallels the idealization represented by “closing” each belief set under \vdash . On Levi’s view, conditionals do not express propositions and so are not objects of belief, thus on Levi’s view the positive and negative Ramsey tests cannot be said to represent an idealization concerning what *beliefs* an agent holds. For Levi, what the positive and negative Ramsey tests represent is not a pair of closure conditions on the unary propositional attitude of belief but rather a definition of a binary propositional attitude toward the antecedent and consequent of a conditional that an agent is said to ‘accept’.

Regardless how the issue of autoepistemic omniscience is resolved, the adoption of (NRTL) has consequences. Gärdenfors, Lindström, Morreau, and Rabinowicz [1991] prove what they consider to be a triviality result for (NRTL) with assumptions weaker than those needed for Gärdenfors’ 1986 triviality result for (RT); in particular, (K^*P) is not needed. In our framework their result is equivalent to the following:

THEOREM 14. *If $\langle \mathbf{K}, \mathcal{I}, \vdash, K_{\perp}, -, *, s \rangle$ is a belief change model defined on a language of type \mathcal{L}_1 or \mathcal{L}_2 for which both (NRTL) and (K^*T) hold and for which s satisfies Identity over \mathbf{K} , then there are no $K, K' \in \mathbf{K}$ such that $K \neq K_{\perp} \neq K'$ and $K' \neq K \subseteq K'$.*

The latter can be derived as a corollary of the following stronger result:

THEOREM 15. *If $\langle \mathbf{K}, \mathcal{I}, \vdash, K_{\perp}, -, *, s \rangle$ is a belief change model defined on a language of type \mathcal{L}_1 or \mathcal{L}_2 for which both (NRTL) and (K*T) hold and for which s is monotone over \mathbf{K} , then there are no $K, K' \in \mathbf{K}$ such that $K \neq K_{\perp} \neq K'$ and $K' \neq K \subseteq K'$.*

Proof. Suppose that $\langle \mathbf{K}, \mathcal{I}, \vdash, K_{\perp}, -, *, s \rangle$ is a belief change model defined on a language of type \mathcal{L}_1 or \mathcal{L}_2 such that s is monotone over \mathbf{K} .

First we prove that (NRTL) implies (K*IM): assume (NRTL) and suppose that $K, K' \in \mathbf{K}$ and $\phi \in \mathcal{I}$ and $K \neq K_{\perp} \neq K'$ and $s(K) \subseteq s(K')$, and let $\psi \notin K_{\phi}^*$. Then by (NRTL) $\neg(\phi > \psi) \in s(K)$, hence $\neg(\phi > \psi) \in s(K')$. By (NRTL) it follows that $\psi \notin K'_{\phi}^*$, as required to establish (K*IM).

Now suppose for reductio that $\langle \mathbf{K}, \mathcal{I}, \vdash, K_{\perp}, -, *, s \rangle$ satisfies both (NRTL) and (K*T), that s is monotone over \mathbf{K} , and there are $K, K' \in \mathbf{K}$ such that $K \neq K_{\perp} \neq K'$ and $K' \neq K \subseteq K'$. Since $K \subseteq K'$ we have $s(K) \subseteq s(K')$ by the monotonicity of s . By (DefBCM) we know that $\top \in \mathcal{I}$, so we have $K'_{\top}^* \subseteq K_{\top}^*$ by (K*IM). But $K_{\top}^* = K$ and $K'_{\top}^* = K'$ by (K*T), hence $K' \subseteq K$, which contradicts $K' \neq K \subseteq K'$, completing the reductio. \blacksquare

Note that neither theorem assumes that all members of \mathbf{K} must be deductively closed, nor does either result include any assumption about \vdash . In [Gärdenfors *et al.*, 1991] Theorem 14 is presented as a triviality result because the authors maintain that a model of belief change is trivial if it contains no consistent, conditional-laden belief sets K, K' such that K is a proper subset of K' . As Rott [1989], Morreau [1992], and Hansson [1992] point out, however, it is a substantive (and, they argue, mistaken) assumption to hold that principles of belief revision that are justified in the context of conditional-free belief sets (e.g. the closure of \mathbf{K} under expansions) can be carried over without modification to conditional-laden belief sets. More on this in Section 2.6 below. One might therefore respond to Theorem 14 by questioning the criterion of triviality: perhaps a model of belief change whose belief sets are conditional-laden should not be classified as trivial simply because it contains no consistent K, K' such that K is a proper subset of K' , even though a belief change model with conditional-free belief sets would be trivial in that case. But if the criterion of triviality espoused by Gärdenfors, *et al* [1991] is appropriate for conditional-free belief sets, then what about Theorem 15, which *does* cover belief change models with conditional-free belief sets? Our discussion in Section 2.6 below may appear to suggest that the problem raised by Theorems 14 and 15 might ultimately

be solved by giving up the monotonicity of s over \mathbf{K} , but even that is not guaranteed to be enough. Consider this result:³⁰

THEOREM 16. *No classical belief change model defined on a language of type- \mathcal{L}_1 or type- \mathcal{L}_2 that satisfies (K^*T) , $(PRTL)$, and $(NRTL)$, and whose support function satisfies Conservativeness and Closure, is Gärdenfors nontrivial or Rott nontrivial or Segerberg nontrivial.*

Proof. By Lemmas 5, 6, and 7, it suffices to show that no classical belief change model defined on a language of type- \mathcal{L}_1 or type- \mathcal{L}_2 that satisfies (K^*T) , $(PRTL)$, and $(NRTL)$, and whose support function satisfies Conservativeness and Closure, contains forking support sets.

Consider a classical belief change model $\langle \mathbf{K}, \mathcal{I}, \vdash, K_\perp, -, *, s \rangle$ defined on a language of type- \mathcal{L}_1 or type- \mathcal{L}_2 that satisfies (K^*T) , $(PRTL)$, and $(NRTL)$, and whose support function satisfies Conservativeness and Closure. Note first that since s satisfies Conservativeness and Closure, s must also satisfy Consistency.

Suppose the model contains forking support sets. Then there exist $H, J, K \in \mathbf{K}$ such that $H = \text{Cn}_\vdash(H) \cap K_\perp$, and $J = \text{Cn}_\vdash(J) \cap K_\perp$, and $K = \text{Cn}_\vdash(K) \cap K_\perp \neq K_\perp$, and $H \cap \mathcal{I} \not\subseteq J$, and $J \cap \mathcal{I} \not\subseteq H$, and $s(H) \subseteq s(K)$, and $s(J) \subseteq s(K)$.

Since $J \cap \mathcal{I} \not\subseteq H$ we have $\phi \in J$ but $\phi \notin H$ for some conditional-free ϕ . By (K^*T) we have $H = H_\top^*$ and $J = J_\top^*$ and $K = K_\top^*$, hence $\phi \in J_\top^*$ and $\phi \notin H_\top^*$. By $(PRTL)$ we have $\top > \phi \in s(J)$, and by $(NRTL)$ we have $\neg(\top > \phi) \in s(H)$. We also have $\top > \phi \in s(K)$, since $s(J) \subseteq s(K)$; hence $s(K)$ is not \vdash -consistent. This contradicts the \vdash -consistency of K , since s satisfies Consistency. \blacksquare

As Theorem 16 shows, $(NRTL)$, (K^*T) and $(PRTL)$ cannot be nontrivially combined, even in a broad category of models where s is not monotone over \mathbf{K} , unless we abandon the Rott, Gärdenfors, and Segerberg criteria of nontriviality.

2.6 Resolving the conflict

On giving up (RT)

Gärdenfors interprets Theorem 8 as forcing a choice between (K^*P) and the Ramsey test (RT), and he has argued (see, e.g., [Gärdenfors, 1986], pp. 86-87 and [Gärdenfors, 1988], p. 59 and p. 159) that (K^*M) and with it (RT) should be rejected. In this connection he offers the following example:

Let us assume that Miss Julie, in her present state of belief K , believes that her own blood group is O and that Johan is her

³⁰The authors thank Horacio Arló-Costa for showing us the proof of this result in correspondence.

father, but she does not know anything about Johan's blood group. Let A be the proposition that Johan's blood group is AB and C the proposition that Johan is Miss Julie's father. If she were to revise her beliefs by adding the proposition A , she would still believe that C , that is, $C \in K_A^*$. But in fact she now learns that a person with blood group AB can never have a child with blood group O. This information, which entails $C \rightarrow \neg A$, is consistent with her present state of belief K , and thus her new state of belief, call it K' , is an expansion of K . If she then revises K' by adding the information that Johan's blood group is AB, she will no longer believe that Johan is her father, that is $C \notin K'_A$. Thus (K*M) is violated. ([Gärdenfors, 1986], pp. 86-87)

The example assumes that s satisfies Identity over \mathbf{K} , so let us assume that as well. In reply to Gärdenfors one might say that if (RT) and Identity over \mathbf{K} are assumed, then the presence of conditionals in belief sets prevents this example from being a counterexample to (K*M): if (RT) and Identity over \mathbf{K} are assumed, then since we have $C \in K_A^*$ and $C \notin K'_A$ it follows that $A > C \in K$ and $A > C \notin K'$, in which case $K \not\subseteq K'$, i.e. K' is not an expansion of K . But to accept this, Gärdenfors argues, would violate certain intuitions:

[I]f we assume (RT) and not only (K*M), then Miss Julie would have believed $A > C$ in K . But then the information that a person with blood group AB can never have a child with blood group O, would *contradict* her beliefs in K , which violates our intuitions that this information is indeed consistent with her beliefs in K . ([Gärdenfors, 1986], p. 87)

Let B stand for the statement that a person with blood group AB can never have a child with blood group O. Gärdenfors has claimed in a context where s satisfies Identity over \mathbf{K} that if (RT) holds, then Miss Julie's beliefs in K contradict B , but this claim requires further justification: how exactly does K contradict B ? We might suppose that B entails $\mathbf{L}(C \rightarrow \neg A)$, where \mathbf{L} is an alethic nomological necessity operator expressing the modal force of B . Assuming (RT) and Identity over \mathbf{K} , the question whether K contradicts B depends on whether the set $\{C, B, A > C\}$ is consistent, and this can be assumed to depend on whether the set $\{C, \mathbf{L}(C \rightarrow \neg A), A > C\}$ is consistent. But the latter set *is* consistent if the semantics for $>$ is not tied to nomological necessity. For example, given a selection function semantics for $>$ and an accessibility relation semantics for \mathbf{L} , all of C , $A > C$, and $\mathbf{L}(C \rightarrow \neg A)$ can be true at possible world w if none of the A -worlds selected relative to w happen to be nomologically accessible at w .³¹ So in

³¹For a less abstract version of essentially this point, see [Cross, 1990a], pp. 229-232.

order to sustain Gärdenfors' claim in the passage cited above, the claim that K contradicts B if (RT) holds (and if s satisfies Identity), we would have to assume the right sort of semantic connection between Ramsey test conditionals and the nomological modality in B , but the case for assuming that connection is not at all obvious: Ramsey test conditionals, after all, are *epistemic*. And if K indeed does not contradict B , then the same conditional that prevents the example from being a counterexample to (K*M) makes the example a counterexample to (K*P): since $K' = K_B^*$, and since $C \in K_A^*$ but $C \notin K_A'^*$, it follows that if (RT) holds, then $A > C \in K \not\subseteq K_B^* \not\Rightarrow A > C$ even though $\neg B \notin K$.

So it might be argued that the presence of Ramsey test conditionals in belief sets will render (K*M) intuitively innocuous while providing perfectly reasonable counterexamples to (K*P). Still, the arguments in favor of (K*P) seem strong. One argument appeals to the Bayesian model of rationality. Suppose that an agent's belief state is represented as a probability function P . According to Bayesian doctrine, upon becoming certain of ϕ a rational agent in belief state P revises her belief state by conditionalizing on ϕ , assuming $P(\phi) > 0$. If this doctrine is correct and if an agent's belief set consists of those statements to which she assigns unit probability, then (K*P) reduces to a theorem of probability theory: if $P(\neg\phi) \neq 1$ and $P(\psi) = 1$, then $P(\psi|\phi) = 1$. A second argument appeals to the doctrine that revision can be defined in terms of contraction and expansion via the Levi Identity (LI), which prescribes the following: to revise with ϕ , first contract relative to $\neg\phi$ and then expand with ϕ . If \vdash is classical and if (LI), (Def+), and (K-3) hold, then (K*P) follows, the role of (K-3) being to require any contraction of K to be vacuous if the proposition contracted does not belong to K : if one does not believe a given proposition then no prior belief need be discarded when one contracts one's beliefs to exclude that proposition—it is already excluded.

As Theorem 10 shows, we can incorporate the second of these arguments for (K*P) directly into the triviality result by recasting Theorem 8 in terms of an inconsistency between (RT), (LI), and postulates (K+1), (K-3), and (K-4w). (K-3) deals with what is in some sense the degenerate case of contraction: contraction with respect to an absent proposition. Postulate (K-4w) is similarly weak: it requires only that a contraction should really *be* a contraction in any case where a logically contingent proposition is contracted from a logically consistent belief set. Both postulates are very weak constraints on contraction, and their weakness makes the case against (RT) seem strong, as long as we assume that s satisfies Identity over \mathbf{K} or at least Monotonicity over \mathbf{K} .

Is there a weakened version of (RT) that is compatible with the other postulates mentioned in Theorem 8? Lindström and Rabinowicz [1992] show that there is. They suggest replacing (RT) with a condition whose counterpart in our framework is the following:

(SRT) For all $K \in \mathbf{K}$ and all $\phi \in \mathcal{I}$ and all $\psi \in K_{\perp}$, $\phi > \psi \in s(K)$ iff $\psi \in K'_{\phi}$ for all $K' \in \mathbf{K}$ such that $K \subseteq K'$.

Like Gärdenfors, Lindström and Rabinowicz do not distinguish between K and $s(K)$, and in a context where this distinction is not made (i.e. where s satisfies Identity over \mathbf{K}), replacing (RT) with (SRT) has the effect of excluding from belief sets many of the conditionals that must be present in them if (RT) and Identity over \mathbf{K} are assumed. For example, in Gärdenfors' Miss Julie case, (RT) and Identity over \mathbf{K} force the conclusion that $A > C \in K$ and $A > C \notin K'_A$, since $C \in K_A^*$ and $C \notin K'_A$, giving us a counterexample to (K*P) since $\neg B \notin K$ and $K' = K_B^*$. If (SRT) and Identity over \mathbf{K} are assumed instead, then the falsity of (K*P) no longer follows. The question whether $A > C$ belongs to K depends not simply on K_A^* but on the revision behaviour of all belief sets that include K as a subset, and similarly for the question whether $A > C$ belongs to K' .

*On giving up (K*P)*

Should the Ramsey test be preserved at the expense of (K*P)? The answer is certainly *yes* if the Ramsey test is applied to the notion of theory change to which Katsuno and Mendelzon in [Katsuno and Mendelzon, 1992] attach the label *update*. They write:

... [*U*]pdate, consists of bringing the knowledge base up to date when the world described by it changes. For example, most database updates are of this variety, e.g. "increase Joe's salary by 5%". Another example is the incorporation into the knowledge base of changes caused in the world by the actions of a robot.³²

Update, according to Katsuno and Mendelzon, contrasts with *revision*:³³

... [*R*]evision, is used when we are obtaining new information about a static world. For example, we may be trying to diagnose a faulty circuit and want to incorporate into the knowledge base the results of successive tests, where newer results may contradict old ones. We claim the AGM postulates describe only revision.³⁴

Katsuno and Mendelzon represent knowledge bases as formulas χ and introduce a binary modal connective to represent the update operation. Following [Grahne, 1991] we will use the symbol ' \circ ' for this operation; then the

³²[Katsuno and Mendelzon, 1992], p. 183.

³³See also [Winslett, 1990].

³⁴*Ibid.*

formula $\chi \circ \phi$ is the knowledge base that results from updating knowledge base χ with new information ϕ .

Grahne [1991] provides an interpretation of the Ramsey test in terms of update. Given a type- \mathcal{L}_2 language that includes the binary connective ‘ \circ ’ Grahne simply adds to Lewis’ system **VCU** the following (validity preserving) rule of inference:

RR: From $\chi \rightarrow (\phi > \psi)$ infer $(\chi \circ \phi) \rightarrow \psi$, and from $(\chi \circ \phi) \rightarrow \psi$ infer $\chi \rightarrow (\phi > \psi)$.

Grahne calls the resulting logical system **VCU²**. In Grahne’s framework, the formula $\chi \circ \phi$ is true in possible world w iff w belongs to the set of closest worlds to w' in which ϕ is true for at least one world w' in which χ is true.

Grahne proves soundness, completeness, decidability, and nontriviality results for **VCU²**, and he notes that **VCU²** fails to satisfy the following principle:

(U*4s) If $\not\vdash \neg(\chi \wedge \phi)$, then $\vdash (\chi \circ \phi) \leftrightarrow (\chi \wedge \phi)$.

(U*4s) states that if ϕ is consistent with knowledge base χ , then the result of updating χ with ϕ is a formula logically equivalent to $\chi \wedge \phi$. Grahne cites the following example to illustrate the failure of (U*4s), which is the update counterpart of revision postulate (K*4s):

A room has two objects in it, a book and a magazine. Suppose p_1 means that the book is on the floor, and p_2 means that the magazine is on the floor. Let the knowledge base be $(p_1 \vee p_2) \wedge \neg(p_1 \wedge p_2)$, i.e. either the book or the magazine is on the floor, but not both. Now we order a robot to put the book on the floor, that is, our new piece of knowledge is p_1 . If this change is taken as a revision [so that (K*4s) is assumed], then we find that since the knowledge base is consistent with p_1 , our new knowledge base will be equivalent to $p_1 \wedge \neg p_2$, i.e. the book is on the floor and the magazine is not.

But the above change is inadequate. After the robot moves the book to the floor, all we know is that the book is on the floor; why should we conclude that the magazine is not on the floor?³⁵

That is, upon updating to include p_1 , we should *give up* something we believed in our initial epistemic state, namely $\neg(p_1 \wedge p_2)$, even though the new information p_1 is consistent with our initial epistemic state. Apparently, then, we have made a belief change using a method that does not satisfy an appropriate counterpart of (K*P). Isaac Levi disagrees. The mechanism which underlies update is *imaging*: the “image” of a set S of possible worlds

³⁵[Grahne, 1991], pp. 274–275.

under ϕ is the set of worlds each of which is one of the closest ϕ -worlds to some world belonging to S . Levi [Levi, 1996] argues that while imaging may be useful for describing how changes over time in the state of a system (such as the room in Grahne's example) are regulated, such changes are not an example of *belief* change. We may, of course, have *beliefs* about how changes in a system over time are regulated, but an analysis of Grahne's example along the lines recommended by Levi would show it to be a straightforward case in which belief revision took place via *expansion*: if t is a time before the book was moved and t' is a time just after the book is moved and if propositional variables p_1 and p_2 are replaced by formulas containing predicates P_1 and P_2 , where $P_i u$ means that p_i is true at time u , then our initial epistemic state can be represented as $(P_1 t \vee P_2 t) \wedge \neg(P_1 t \wedge P_2 t)$, and upon learning of the change in the position of the book our new epistemic state is $(P_1 t \vee P_2 t) \wedge \neg(P_1 t \wedge P_2 t) \wedge P_1 t'$.

On giving up (K⁺1)

Gärdenfors interprets Theorem 8 as forcing a choice between (RT) and (K*P), but Rott [1989], Morreau [1992], and Hansson [1992] have argued that (K⁺1) is the real culprit.

Postulates (K*3) and (K*4) entail (K*4s): if ϕ is consistent with K , then a revision to accept ϕ should be the result of expanding K with ϕ . Rott [1989] argues that (K*4s), while fine for belief revision in a type- \mathcal{L}_0 language, is an inappropriate requirement on belief revision in a language with Ramsey test conditionals. Once (K*4s) is rejected in the context of Ramsey test conditionals, Rott argues, (K⁺1) is robbed of any intuitive basis: the only reason for thinking that belief change models should be closed under expansion would be the assumption that expansion is a species of revision. Why think that expansion is a species of revision in the first place? One could justify (K*4s) as the qualitative analog of the Bayesian doctrine that upon becoming certain of ϕ a rational agent whose belief state is represented by probability function P revises her belief state by conditionalizing on ϕ if $P(\phi) > 0$. This doctrine supports (K*4s) because if $P(\phi) > 0$, then the set $\{\psi : P(\psi|\phi) = 1\}$ is precisely the result of expanding the set $\{\psi : P(\psi) = 1\}$ with ϕ . But, Morreau [1992] counters, Bayesian doctrine supports (K*4s) in this way only for belief sets over a type- \mathcal{L}_0 language.

Still, one might argue, regardless whether revision ever leads from a belief set to one of its expansions, should not the expansion of every belief set in a belief change model be available in the model as a possible *starting point* for revision? Not so, argues Morreau [1992]: a belief change model over which (RT) holds and in which belief sets contain conditionals incorporates the idealizing assumption that the conditionals an agent believes form a complete and correct record of how the agent would revise his or her beliefs.

Not just any collection of theories in a conditional language can be the belief sets of a Ramsey test respecting belief change model because not just any theory will conform to the idealization. Morreau interprets the Gärdenfors triviality result as showing in particular that the idealization required by the Ramsey test cannot be achieved in a nontrivial belief change model that respects (K^+1) while incorporating conditionals in belief sets.

But are there in fact nontrivial belief change models containing conditional-laden belief sets in which (RT) holds but (K^+1) does not? Morreau's Example 6 ([Morreau, 1992], p. 41), which we adapt to our framework, confirms that there are. Let L be a type- \mathcal{L}_1 language and let L_0 be its type- \mathcal{L}_0 fragment. Assume that L_0 contains at least two distinct atomic formulas. Let \vdash_0 be truth-functional consequence, and assume (Def+), and let \mathbf{K}_0 be the set of all \vdash_0 -theories in L_0 . Define a belief revision operation \star as follows for all $\mu \in \mathbf{K}_0$ and all formulas ϕ of L_0 :

$$\mu_\phi^\star = \begin{cases} \mu & \text{if } \perp \in \mu; \\ \mu_\phi^+ & \text{if } \perp \notin \mu \text{ and } \neg\phi \notin \mu; \\ \text{Cn}_{\vdash_0}(\{\phi\}) & \text{otherwise.} \end{cases}$$

Let $\mathcal{I}_0 = \text{WFF}_{L_0} = K_{\perp_0}$; let $\text{dom}(s_0) = \mathbf{K}_0$; and let $s_0(K) = K$ for all $K \in \mathbf{K}_0$. Letting the contraction operation $(-_0)$ be arbitrary, note that $\langle \mathbf{K}_0, \mathcal{I}_0, \vdash_0, K_{\perp_0}, -_0, \star, s_0 \rangle$ satisfies (K^+1) , (K^*2) , (K^*C) , and (K^*P) , but not (RT). Using \mathbf{K}_0 and \star we construct a second, Ramsey test supporting belief change model with conditional-laden belief sets as follows: for each $\mu \in \mathbf{K}_0$, let $K_\mu = \text{Cn}_{\vdash_0}(\mu \cup \{\phi > \psi : \psi \in \mu_\phi^\star\})$. Let $\mathbf{K} = \{K_\mu : \mu \in \mathbf{K}_0\}$; let $(K_\mu)_\phi^\star = K_{\mu_\phi^\star}$; let $\mathcal{I} = \text{WFF}_{L_0}$ (as before); let $K_\perp = \text{WFF}_L$; let $\text{dom}(s) = \mathbf{K}$; and let $s(K) = K$ for all $K \in \mathbf{K}$. Letting contraction $(-)$ again be arbitrary, $\langle \mathbf{K}, \mathcal{I}, \vdash_0, K_\perp, -, *, s \rangle$ satisfies (K^*2) , (K^*C) , and (RT), but this model, unlike the first, does not satisfy (K^+1) or (K^*P) .³⁶ For example, let A, B be distinct atomic formulas of L_0 , and let $\mu' = \text{Cn}_{\vdash_0}(\{B\})$; thus $\mu' \in \mathbf{K}_0$. Since $\neg A \notin \mu'$, we have that $\mu'_A{}^\star = \mu'_A{}^+ = \text{Cn}_{\vdash_0}(\{A, B\})$. Accordingly, $A > B \in K_{\mu'} \in \mathbf{K}$, but note that $(K_{\mu'})_{\neg A}^+$ does not belong to \mathbf{K} , for there is no $\mu \in \mathbf{K}_0$ such that both $\neg A$ and $A > B$ belong to K_μ .

The second belief change model constructed above is the result of closing the first model under the Ramsey test (restricted to non-nested conditionals), and both models are Gärdenfors nontrivial. The Gärdenfors nontriviality of the second model is established by $K_{\text{Cn}_{\vdash_0}(\emptyset)}$, which belongs to \mathbf{K} , and $A \wedge \neg B$, $B \wedge \neg A$, and $A \wedge B$ which belong to L . In addition to this example Morreau provides a general recipe for constructing nontrivial models of belief revision in a type- \mathcal{L}_1 language L whose type- \mathcal{L}_0 fragment is L_0 and where (K^*1) , (K^*2) , (K^*C) , (RT), and $(K^*P_{\mathcal{I}})$ hold and $\mathcal{I} = \text{WFF}_{L_0}$.

³⁶The model does satisfy a weakened version of (K^*P) , however, as Morreau points out:

$(K^*P_{\mathcal{I}})$ For all $\phi \in \mathcal{I}$, if $\neg\phi \notin K$ then $K \cap \mathcal{I} \subseteq K_\phi^* \cap \mathcal{I}$.

Where does the triviality proof break down when applied to Morreau's example? Hansson [1992] proves a theorem that provides the answer: Morreau's example is one of a set of belief change models in which forking support sets cannot be constructed. The counterpart of Hansson's theorem in our framework is the following:

THEOREM 17. *Suppose that $\langle \mathbf{K}, \mathcal{I}, \vdash, K_{\perp}, -, *, s \rangle$ is a belief change model defined on a language L of type \mathcal{L}_1 or \mathcal{L}_2 and that \vdash includes all truth-functional entailments and respects the deduction theorem for the material conditional. Suppose also that $\text{dom}(s) = \mathbf{K}$, that $s(K) \subseteq \text{WFF}_L$ for all $K \in \mathbf{K}$, and that s satisfies the following for all $K \in \mathbf{K}$, all $\phi \in \mathcal{I}$ and all $\psi, \chi \in K_{\perp}$:*

1. *If $\Gamma \subseteq s(K)$ and $\Gamma \vdash \psi$ then $\psi \in s(K)$.*
2. *If K is \vdash -consistent and $\psi \in s(K)$, then $\neg\psi \notin s(K)$.*
3. *If K is \vdash -consistent and $\not\vdash \neg\phi$ and $\phi > \psi$, $\phi > \chi \in s(K)$, then $\not\vdash \neg(\psi \wedge \chi)$.*
4. *If $\phi > (\psi \wedge \phi) \in \text{WFF}_L$ and $\psi \in s(K)$ and $\phi \notin s(K)$ and $\neg\phi \notin s(K)$, then $\phi > (\psi \wedge \phi) \in s(K)$.*

Suppose that $K_1, K_2, K \in \mathbf{K} \sim \{K_{\perp}\}$ and that $s(K_1)$ and $s(K_2)$ are both subsets of $s(K)$. Then either $s(K_1) \subseteq s(K_2)$ or $s(K_2) \subseteq s(K_1)$.

Conditions 1 and 2 are equivalent to Closure and Consistency for s , respectively. Note that the Ramsey test itself is not assumed: the point is that simply having conditionals in a belief change model that meets these four conditions ensures that forking support sets cannot be constructed.

On giving up the monotonicity of s over \mathbf{K}

Rott [1989; 1991] suggests that nonmonotonic reasoning may provide a solution to the dilemma posed by the Gärdenfors triviality result, and Cross [1990a] argues that Gärdenfors' triviality result should be interpreted as showing not that the Ramsey test should be abandoned but that, given the Ramsey test, s must be nonmonotonic over \mathbf{K} , i.e. for some $H, K \in \mathbf{K}$ $H \subseteq K$ but $s(H) \not\subseteq s(K)$.³⁷ Makinson counters in [Makinson, 1990] with a triviality result for models in which s is permitted to be nonmonotonic, but Makinson's result does not bear on the suggestion endorsed by Cross and by Rott. More on this below.

Other authors have brought nonmonotonic reasoning into the discussion of the Ramsey test without advertising it as such. For example, in [Hansson, 1992] Hansson writes:

³⁷Since the monotonicity of s is not assumed in Theorem 13, however, it is clear that the problem for (RT) posed by (K*5) cannot be solved by making s nonmonotonic.

... the addition of an indicative sentence that is compatible with all previously supported indicative sentences typically withdraws the support of conditional sentences that were previously supported.³⁸

The type- \mathcal{L}_1 statements that are in Hansson's sense *supported by* a given "indicative" (i.e. conditional-free) belief base K represent what Cross (and possibly Rott) would classify as the nonmonotonic consequences of K . Hansson and Cross both think of the sets that individuate belief states as belief bases and define contraction and revision as operations on these sets, but Cross' belief bases differ from Hansson's in two respects: first, whereas Hansson's belief bases are conditional-free, Cross' are not; secondly, whereas Hansson's belief bases are not closed under \vdash or closed under s , in Cross' enriched belief revision models belief bases are closed under \vdash , though not under s . That is, for Hansson, belief states are individuated in terms of sets that function as belief bases with respect to both \vdash and s , whereas for Cross, belief states are individuated in terms of sets that function as belief bases only with respect to s . For Hansson, belief bases need not be closed under \vdash and are never closed under s . Makinson [1990], like Cross [1990a], supplements the classical \vdash with a not-necessarily-monotonic s ,³⁹ and like Cross, Makinson explicitly advertises s as a consequence operation. But in Makinson's discussion revision and contraction are defined only on K that are closed under s , and the proof of Makinson's triviality theorem, whose counterpart here is Theorem 11 above, requires a belief change model containing three belief sets closed under s . Makinson's triviality result does not apply to belief change models in which \mathbf{K} contains *no* K such that $s(K) = K$, and such authors as Arló-Costa and Levi (see [Levi, 1988], [Arló-Costa, 1995], and [Arló-Costa and Levi, 1996]) avoid Makinson's triviality result precisely by requiring $s(K) \neq K$ for all $K \in \mathbf{K}$.

As we noted above, Hansson does not explicitly speak of the support function as a consequence operation, nor does Arló-Costa or Levi. Yet, if one looks at the conditions that Hansson, Arló-Costa, and Levi place on the support function, mirrored here in the definitions of Hansson and Arló-Costa/Levi belief change models as the requirements of Reflexivity, Conservativeness, and Closure, it seems natural to think of s as a nonmonotonic consequence operation. But if we do think of s in a Hansson or Arló-Costa/Levi belief change model as a nonmonotonic consequence operation, what sort of nonmonotonic reasoning does it represent? In [Moore, 1983] Robert Moore distinguishes two types of nonmonotonic reasoning:

By default reasoning, we mean drawing plausible inferences from less than conclusive evidence in the absence of any information

³⁸[Hansson, 1992], p. 526.

³⁹Makinson uses the symbol C and Cross the symbol cl for s .

to the contrary. The examples about birds being able to fly are of this type.⁴⁰

He continues:

Default reasoning is nonmonotonic because, to use a term from philosophy, it is *defeasible*. Its conclusions are tentative, so, given better information, they may be withdrawn.⁴¹

Default reasoning, according to Moore, contrasts with *autoepistemic reasoning*, or reasoning about one's state of belief. Moore writes:

Autoepistemic reasoning is nonmonotonic because the meaning of an autoepistemic statement is context-sensitive; it depends on the theory in which the statement is embedded.⁴²

For example, if $\diamond\phi$ is defined as being accepted in belief state K just in case $\neg\phi$ is not accepted in K , then $\diamond\phi$ is an autoepistemic statement in Moore's sense. If the support function s in a belief change model is thought of as a nonmonotonic consequence operation, then how should s be classified with respect to Moore's distinction? It depends on the properties s is assumed to have.

If a belief change model satisfies some version of the Ramsey test (e.g. (RT), (PRTL), or (NRTL)), then the support function of that model is *at least* a form of autoepistemic reasoning. This is clear since the acceptability of a Ramsey test conditional for a given agent is in part a function of the agent's current epistemic state, and this holds true regardless whether conditionals themselves are objects of belief.⁴³ Moreover, the context sensitivity to which Moore refers in the passage just quoted is clearly present in the support function of any belief change model that satisfies (RT), and indeed this context sensitivity was exploited by Morreau [1992] in his construction of a nontrivial Ramsey test, by Lindström and Rabinowicz [1995] and Lindström [1996] in a proposed indexical interpretation of conditionals,⁴⁴ by Hansson [1992] in his accounts of type- \mathcal{L}_1 conditionals and iterated conditionals, respectively, and by Boutilier and Goldszmidt [1995] in their account of the revision of conditional belief sets.

Given a support function s for a belief change model that satisfies a version of the Ramsey test, can s be not only a mechanism for autoepistemic reasoning but a mechanism for default reasoning, too? This depends on whether s can be used to make ampliative inferences to conclusions that

⁴⁰[Moore, 1983], p. 273.

⁴¹[Moore, 1983], p. 274.

⁴²[Moore, 1983], p. 274.

⁴³Rott [1989] and Morreau [1992] explicitly adopt the view that Ramsey test conditionals are autoepistemic.

⁴⁴See also [Döring, 1997].

are not epistemically context-sensitive from premises that are not epistemically context-sensitive. Since Hansson, Arló-Costa, and Levi assume that s satisfies Conservativeness, it is clear that for them s is an operation of autoepistemic reasoning but *not* an operation of default reasoning: $s(K)$ will contain conditionals, i.e. autoepistemic statements, that are not logical consequences of K , but no conditional-free formula gets into $s(K)$ without being a logical consequence of K , which is itself conditional-free for any $K \in \text{dom}(s)$ according to Hansson, Arló-Costa, and Levi. Cross and Makinson, on the other hand, do not require the support function to satisfy Conservativeness; accordingly, they allow belief change models in which s supports default reasoning. No distinction between $s(K)$ and K exists for Morreau, Gärdenfors, and Segerberg, hence the issue of the status of s does not arise in their respective cases.

2.7 Logics for Ramsey test conditionals

Gärdenfors [1978] proves the soundness and completeness of David Lewis' system of conditional logic **VC** with respect to an epistemic, Ramsey test semantics for the conditional. Several other authors have proposed variants of Gärdenfors' Ramsey test semantics, including variants that generalize Gärdenfors' semantics, but it will be convenient for our purposes to adopt formalisms similar to those of [Arló-Costa, 1995] and [Arló-Costa and Levi, 1996].

Primitive belief revision models

Since the conditional is to be given a *semantics* in terms of belief revision, the notion of a belief set must be defined in terms that do not assume a logic for the conditional. To this end we define *primitive belief sets*, *primitive expansion*, and *primitive belief revision models*.

For a Boolean language L of type \mathcal{L}_1 or \mathcal{L}_2 let a *primitive belief set* defined on this language be any set K of formulas of L meeting three requirements:

(pBS1) $K \neq \emptyset$;

(pBS2) if $\phi \in K$ and $\psi \in K$, then $\phi \wedge \psi \in K$;

(pBS3) if $\phi \in K$ and $\phi \rightarrow \psi$ is a truth-functional tautology, then $\psi \in K$.

If $K \subseteq K'$ and K, K' are both primitive belief sets, then K' is a *primitive expansion* of K . The *operation* of primitive expansion is defined as follows:

(DEF+) $K_\phi^+ = \{\psi : \phi \rightarrow \psi \in K\}$.

It is easy to see that if K is a primitive belief set, then so is K_ϕ^+ . Finally, let us define the notion of a *primitive belief revision model* on L :

(DefpBRM) A *primitive belief revision model* (or pBRM) on a Boolean language L is an ordered quadruple $\langle \mathbf{K}, *, K_{\perp}, s \rangle$ whose components are as follows:

1. $K_{\perp} = \text{WFF}_{L'}$, where L' is L or a fragment of L ;
2. \mathbf{K} is a nonempty set of primitive belief sets defined on L' , and if $K \in \mathbf{K}$ then \mathbf{K} contains every primitive expansion of K on L' ;
3. $*$ is a function mapping each $K \in \mathbf{K}$ and each formula $\phi \in K_{\perp}$ to a primitive belief set K_{ϕ}^* belonging to \mathbf{K} ;
4. s is a function mapping each $K \in \mathbf{K}$ to a primitive belief set $s(K)$ of formulas of L , where s satisfies the following:
 - (a) if $\phi \in K_{\perp}$ and $\phi \in s(K)$ then $\phi \in K$;
 - (b) $K \subseteq s(K)$ if $K_{\perp} \neq K \in \mathbf{K}$.

Note that while K and $s(K)$ must both be primitive belief sets, they need not be primitive belief sets of the same language. When referring to the belief revision postulates (K*1), (K*2), etc., in the context of primitive belief revision models we will assume that ϕ and ψ range over K_{\perp} .

A primitive belief revision model $\langle \mathbf{K}, *, K_{\perp}, s \rangle$ defined on a Boolean language L is a *Gärdenfors pBRM* iff L is of type \mathcal{L}_2 and $K_{\perp} = \text{WFF}_L$ and s is the identity function on K and s satisfies the following unrestricted version of the positive Ramsey test:

(pRTG) For all $K \in \mathbf{K}$, if $\phi, \psi \in K_{\perp}$, then $(\phi > \psi) \in s(K)$ iff $\psi \in K_{\phi}^*$.

A primitive belief revision model $\langle \mathbf{K}, *, K_{\perp}, s \rangle$ defined on a Boolean language L is an *Arló-Costa/Levi pBRM* iff L is of type \mathcal{L}_1 and K_{\perp} is the set of all formulas of the largest conditional-free fragment of L and s satisfies the following versions of both the positive and negative Ramsey tests:

(pPRT) For all $K \in \mathbf{K}$ such that $K \neq K_{\perp}$, if $\phi, \psi \in K_{\perp}$, then $(\phi > \psi) \in s(K)$ iff $\psi \in K_{\phi}^*$.

(pNRT) For all $K \in \mathbf{K}$ such that $K \neq K_{\perp}$, if $\phi, \psi \in K_{\perp}$, then $\neg(\phi > \psi) \in s(K)$ iff $\psi \notin K_{\phi}^*$.

Positive and negative validity

In [Arló-Costa, 1995] (and in [Arló-Costa and Levi, 1996], with Isaac Levi) Arló-Costa distinguishes between positive and negative concepts of validity. The concepts are distinct in Arló-Costa/Levi pBRMs, though not in Gärdenfors pBRMs.

A formula ϕ is *positively valid (PV) relative to* $\langle \mathbf{K}, *, K_{\perp}, s \rangle$, where the latter is a primitive belief revision model, iff $\phi \in s(K)$ for all K such that

$K_{\perp} \neq K \in \mathbf{K}$; and ϕ is *positively valid relative to a set of belief revision models* iff ϕ is positively valid relative to each member of the set. ϕ is *negatively valid (NV) relative to $\langle \mathbf{K}, *, K_{\perp}, s \rangle$* iff $\neg\phi \notin s(K)$ for each K such that $K_{\perp} \neq K \in \mathbf{K}$; and ϕ is *negatively valid relative to a set of belief revision models* iff ϕ is negatively valid relative to each member of the set.

Notions of entailment can be associated with positive and negative validity, respectively. Given a set Γ of formulas of a type- \mathcal{L}_1 or type- \mathcal{L}_2 language L , and a formula ϕ of L , Γ *positively entails* ϕ ($\Gamma \models_+ \phi$) with respect to a primitive belief revision model $\langle \mathbf{K}, *, K_{\perp}, s \rangle$ iff $\phi \in s(K)$ for every K such that $\Gamma \subseteq s(K)$ and $K_{\perp} \neq K \in \mathbf{K}$. By contrast, Γ *negatively entails* ϕ ($\Gamma \models_- \phi$) with respect to a primitive belief revision model $\langle \mathbf{K}, *, K_{\perp}, s \rangle$ iff there is no K such that $K_{\perp} \neq K \in \mathbf{K}$ and $\Gamma \cup \{\neg\phi\} \subseteq s(K)$.

In a Gärdenfors pBRM, positive and negative validity coincide:

PROPOSITION 18. *Relative to any Gärdenfors pBRM defined on a language L of type \mathcal{L}_2 , a formula ϕ of L is positively valid iff ϕ is negatively valid.*

Proof. Let $\langle \mathbf{K}, *, K_{\perp}, s \rangle$ be a Gärdenfors pBRM defined on a language L of type \mathcal{L}_2 , and let ϕ be a formula of L . First, suppose that ϕ is positively valid relative to $\langle \mathbf{K}, *, K_{\perp}, s \rangle$ and choose an arbitrary K such that $K_{\perp} \neq K \in \mathbf{K}$. Then $\phi \in s(K)$, but since $s(K) = K \neq K_{\perp}$ we have $\neg\phi \notin s(K)$, as required. Conversely, assume that ϕ is negatively valid relative to $\langle \mathbf{K}, *, K_{\perp}, s \rangle$ and choose an arbitrary K such that $K_{\perp} \neq K \in \mathbf{K}$. Assume for *reductio* that $\phi \notin s(K)$. Since s is the identity function, we have that $\phi \notin K$, in which case $K_{-\phi}^+ \neq K_{\perp}$. Since \mathbf{K} is closed under primitive expansions, we have in addition that $K_{-\phi}^+ \in \mathbf{K}$. Thus, $\neg\phi \in s(K_{-\phi}^+)$ and $K_{\perp} \neq K_{-\phi}^+ \in \mathbf{K}$, which is contrary to the negative validity of ϕ . ■

Positive and negative validity do not coincide in Arló-Costa/Levi pBRMs, however. The negative Ramsey test prevents it. Consider the following pair of lemmas regarding the thesis (CS):

LEMMA 19. *For any type- \mathcal{L}_1 language L , if ϕ, ψ are conditional-free, then $(\phi \wedge \psi) \rightarrow (\phi > \psi)$ is negatively valid in an Arló-Costa/Levi pBRM defined on L iff the model satisfies $(K^* \not\vdash w)$.*

The latter is equivalent to Observation 4.7 of [Arló-Costa and Levi, 1996].

LEMMA 20. *For any type- \mathcal{L}_1 language L containing at least one atomic formula χ other than \top and \perp , there are conditional-free ϕ and ψ such that $(\phi \wedge \psi) \rightarrow (\phi > \psi)$ is not positively valid in any Arló-Costa/Levi pBRM defined on L that satisfies $(K^* \exists)$ and contains a primitive belief set K where $\neg\chi, \chi \notin K$.*

Proof. Suppose L is a type- \mathcal{L}_1 language containing at least one atomic formula χ different from \top and \perp , and consider an Arló-Costa/Levi pBRM

$\langle \mathbf{K}, *, K_{\perp}, s \rangle$ defined on L that satisfies (K*3) and contains a primitive belief set K such that $\neg\chi, \chi \notin K$. Suppose for *reductio* that $(\phi \wedge \psi) \rightarrow (\phi > \psi)$ is positively valid for all conditional-free ϕ and ψ . Then, in particular $(\top \wedge \chi) \rightarrow (\top > \chi)$ is positively valid relative to $\langle \mathbf{K}, *, K_{\perp}, s \rangle$. By (K*3) we have $K_{\top}^* \subseteq K_{\top}^+ = K$. Since, in addition, $\neg\chi, \chi \notin K$ we have that $\neg\chi, \chi \notin K_{\top}^*$. Since $\chi \notin K_{\top}^*$, it follows by the Negative Ramsey test that $\neg(\top > \chi) \in s(K)$, hence by the positive validity of $(\top \wedge \chi) \rightarrow (\top > \chi)$ relative to $\langle \mathbf{K}, *, K_{\perp}, s \rangle$ we have that $\neg(\top \wedge \chi) \in s(K)$. Since $\neg(\top \wedge \chi)$ is conditional-free, it follows that $\neg(\top \wedge \chi) \in K$. Since primitive belief sets are deductively closed, we have $\neg\chi \in K$, contrary to assumption. ■

The proof just given is derived from that given by Arló-Costa for Observation 3.14 in [Arló-Costa, 1995]. Finally, we state the following obvious but necessary lemma:

LEMMA 21. *For some type- \mathcal{L}_1 language L , there is an Arló-Costa/Levi pBRM defined on L that satisfies (K*3) and (K*4w) and also contains a primitive belief set K where $\neg\phi, \phi \notin K$ for some conditional-free formula ϕ of L .*

These three lemmas suffice to show the following:

THEOREM 22. *There are Arló-Costa/Levi pBRMs relative to which at least some formulas of the form $(\phi \wedge \psi) \rightarrow (\phi > \psi)$ are negatively valid but not positively valid.*

Interestingly, despite Theorem 22, $\{\phi \wedge \psi\} \models_+ \phi > \psi$ holds relative to every Arló-Costa/Levi pBRM that satisfies (K*4w).⁴⁵

Belief revision models for VC

Gärdenfors provides an epistemic semantics for **VC** based on negative validity. He begins with a minimal conditional logic **CM** defined as follows:

Axiom schemata

Taut: All truth-functional tautologies;

CC: $[(\phi > \psi) \wedge (\phi > \chi)] \rightarrow [\phi > (\psi \wedge \chi)]$;

CN: $\phi > \top$.

Rules of inference

Modus Ponens From ϕ and $\phi \rightarrow \psi$ to infer ψ ;

RCM: From $\psi \rightarrow \chi$ to infer $(\phi > \psi) \rightarrow (\phi > \chi)$.

⁴⁵See OBSERVATION 3.15 in [Arló-Costa, 1995].

Gärdenfors [1978] proves a soundness/completeness theorem for **CM** that is equivalent to the following:

THEOREM 23. *A formula of any type \mathcal{L}_2 language is a theorem of **CM** iff it is negatively valid in every Gärdenfors pBRM.*

Gärdenfors then proves the following:

THEOREM 24. *A formula is a theorem of **VC** iff it is derivable from **CM** together with (ID), (CSO'), (CS), (MP), (CA), and (CV) as additional axiom schemata:*

$$ID: \quad \phi > \phi$$

$$CSO' : \quad [(\phi > \psi) \wedge (\psi > \phi)] \rightarrow [(\phi > \chi) \rightarrow (\psi > \chi)]$$

$$CS: \quad (\phi \wedge \psi) \rightarrow (\phi > \psi)$$

$$MP: \quad (\phi > \psi) \rightarrow (\phi \rightarrow \psi)$$

$$CA: \quad [(\phi > \chi) \wedge (\psi > \chi)] \rightarrow [(\phi \vee \psi) > \chi]$$

$$CV: \quad [(\phi > \psi) \wedge \neg(\phi > \neg\chi)] \rightarrow [(\phi \wedge \chi) > \psi]$$

An epistemic semantics for **VC** is obtained by restricting attention to Gärdenfors pBRMs that satisfy constraints corresponding to axioms ID, CSO', CS, MP, CA, and CV. Gärdenfors [1978] proves lemmas equivalent to the following:

LEMMA 25. *Where \mathcal{M} is any Gärdenfors pBRM,*

1. *all instances of ID are negatively valid in \mathcal{M} iff \mathcal{M} satisfies (K*2);*
2. *all instances of CSO' are negatively valid in \mathcal{M} iff \mathcal{M} satisfies (K*6s);*
3. *all instances of CS are negatively valid in \mathcal{M} iff \mathcal{M} satisfies (K*4w);*
4. *all instances of MP are negatively valid in \mathcal{M} iff \mathcal{M} satisfies (K*3);*
5. *if \mathcal{M} satisfies (K*2), (K*6s), (K*4w), and (K*3), then all instances of CA are negatively valid in \mathcal{M} if \mathcal{M} satisfies (K*7);*
6. *if all instances of ID, CSO', CS, and MP are negatively valid in \mathcal{M} , then \mathcal{M} satisfies (K*7) if all instances of CA are negatively valid in \mathcal{M} ;*
7. *if \mathcal{M} satisfies (K*2), (K*6s), (K*4w), and (K*3), then all instances of CV are negatively valid in \mathcal{M} if \mathcal{M} satisfies (K*L);*
8. *if all instances of ID, CSO', CS, and MP are negatively valid in \mathcal{M} , then \mathcal{M} satisfies (K*L) if all instances of CV are negatively valid in \mathcal{M} .*

Theorem 24 and Lemma 25 allow the soundness and completeness result of Theorem 23 to be extended to yield the following:

THEOREM 26. *A formula is a theorem of \mathbf{VC} iff it is negatively valid in all Gärdenfors pBRMs that satisfy (K^*2) , (K^*3) , (K^*4w) , (K^*6s) , (K^*7) , and (K^*L) .*

This theorem shows that if \mathbf{VC} is translated into a theory of belief revision on Gärdenfors pBRMs using that version of the Ramsey test which is built into the notion of a Gärdenfors pBRM, then the resulting theory of belief revision is defined by (K^*1) (which is built into the definition of a pBRM), (K^*2) , (K^*3) , (K^*4w) , (K^*6s) , (K^*7) , and (K^*L) . The absence of (K^*5w) should not be surprising, given Theorem 13. Since in a Gärdenfors pBRM (K^*3) , (K^*4w) , and $(\text{DEF}+)$ imply (K^*T) , and since (K^*T) together with $(\text{DEF}+)$, (K^*6s) and (K^*8) imply (K^*P) , and given Theorem 8, the absence of (K^*8) should not be surprising.

A conditional logic that approximates AGM belief revision

Whereas Gärdenfors [1978] sets out to find epistemic models for Lewis's system \mathbf{VC} of conditional logic, Arló-Costa [1995] sets out to find a system of conditional logic whose primitive belief revision models are defined at least approximately by the AGM belief revision postulates for transitive relational partial meet contraction (see [Gärdenfors, 1988], Chapters 3–4). The result is the system \mathcal{EF} , which is defined only on languages of type \mathcal{L}_1 (languages of *flat* conditionals). \mathcal{EF} has the following axioms and rules, where ϕ , ψ , and χ are conditional free:

Axiom schemata

Taut: All truth-functional tautologies

ID: $\phi > \phi$

MP: $(\phi > \psi) \rightarrow (\phi \rightarrow \psi)$

CC: $[(\phi > \psi) \wedge (\phi > \chi)] \rightarrow [\phi > (\psi \wedge \chi)]$

CA: $[(\phi > \chi) \wedge (\psi > \chi)] \rightarrow [(\phi \vee \psi) > \chi]$

CV: $[(\phi > \psi) \wedge \neg(\phi > \neg\chi)] \rightarrow [(\phi \wedge \chi) > \psi]$

CN: $\phi > \top$

CD: $\neg(\phi > \perp)$ for all non-tautologous ϕ .

Rules of inference

Modus Ponens: From ϕ and $\phi \rightarrow \psi$ to infer ψ .

RCM: From $\psi \rightarrow \chi$ to infer $(\phi > \psi) \rightarrow (\phi > \chi)$.

RCEA: From $\phi \leftrightarrow \psi$ to infer $(\phi > \chi) \leftrightarrow (\psi > \chi)$.

One obvious difference between **VC** and Arló-Costa's \mathcal{EF} is that \mathcal{EF} is defined for type \mathcal{L}_1 languages only whereas **VC** is defined for type \mathcal{L}_2 languages. Another difference is that **CS**, an axiom of **VC**, is not a theorem of \mathcal{EF} . A third difference is that **CD**, an axiom of \mathcal{EF} , is not a theorem of **VC**.

Arló-Costa's epistemic semantics for \mathcal{EF} is crucially different from Gärdenfors' epistemic semantics for **VC** in that the semantics of \mathcal{EF} is defined in terms of positive validity over Arló-Costa/Levi pBRMs rather than in terms of negative validity over Gärdenfors pBRMs. Positive and negative validity coincide in Gärdenfors pBRMs (see Proposition 18) but not in Arló-Costa/Levi pBRMs (see Theorem 22). Which notion of validity should then be adopted? Arló-Costa and Levi argue that positive validity should be adopted rather than negative validity both because positive validity is more intuitive and because in Arló-Costa/Levi models, which satisfy the Negative Ramsey Test favored by Arló-Costa and Levi, the inference rule *modus ponens* does not preserve negative validity.⁴⁶

Consider a type- \mathcal{L}_1 language L ; relative to L the logical system **Flat CM** is the smallest set of formulas of L that contains all instances of the axiom schemata of Gärdenfors' **CM** and is closed under the rules of **CM**. Note that \mathcal{EF} is an extension of **Flat CM**. Arló-Costa [1995] proves the completeness of \mathcal{EF} with respect to an epistemic semantics (based on positive validity) by proving a result equivalent to Theorem 31 below. We begin with a series of results to be used as lemmas for Theorem 31:⁴⁷

THEOREM 27. *A formula of any type \mathcal{L}_1 language L is a theorem of **Flat CM** iff it is positively valid in every Arló-Costa/Levi pBRM defined on L .*

THEOREM 28. *Let \mathcal{CM}^+ be the result of extending **Flat CM** by adding the rule (RCEA) (restricted to the conditionals of a type- \mathcal{L}_1 language). A formula is derivable in \mathcal{CM}^+ iff it is positively valid in the class of all Arló-Costa/Levi pBRMs that satisfy (K^*6) .*

THEOREM 29. *Let \mathcal{CMU}^+ be the result of extending \mathcal{CM}^+ by adding $\neg(\phi > \perp)$ for every non-tautologous conditional-free ϕ . A formula is derivable in \mathcal{CMU}^+ iff it is positively valid in the class of all Arló-Costa/Levi pBRMs that satisfy (K^*6) and (K^*C) .*

⁴⁶See [Arló-Costa and Levi, 1996], pp. 239-240.

⁴⁷Our formulation of these results reflects the organization found in [Arló-Costa and Levi, 1996].

LEMMA 30. *Where \mathcal{M} is any Arló-Costa/Levi pBRM,*

1. *all instances of ID are positively valid in \mathcal{M} iff \mathcal{M} satisfies (K*2);*
2. *all instances of MP are positively valid in \mathcal{M} iff \mathcal{M} satisfies (K*3);*
3. *all instances of CA are positively valid in \mathcal{M} iff \mathcal{M} satisfies (K*7');*
4. *if all instances of ID are positively valid in \mathcal{M} , then all instances of CV are positively valid in \mathcal{M} if \mathcal{M} satisfies (K*8);*

Theorems 27, 28, and 29, together with Lemma 30 and the fact that (K*7) and (K*7') are equivalent in any pBRM that satisfies (K*2) and (K*6), yield the following completeness theorem for \mathcal{EF} :⁴⁸

THEOREM 31. *A formula of any type \mathcal{L}_1 language L is a theorem of \mathcal{EF} iff it is positively valid in every Arló-Costa/Levi pBRM defined on L satisfying (K*2), (K*3), (K*C), (K*6), (K*7), and (K*8).*

Postulates (K*1), (K*2), (K*3), (K*4), (K*5), (K*6), (K*7), and (K*8) jointly capture that notion of revision that is derivable via the Levi Identity (LI) from the AGM notion of transitively relational partial meet contraction (*AGM Revision*, for short).⁴⁹ Since (K*1) holds in all pBRMs, \mathcal{EF} comes very close to capturing AGM Revision, but (K*1) and the postulates mentioned in Theorem 31 define a notion of revision (\mathcal{EF} Revision, for short) that is strictly weaker than AGM revision in two respects.

First, whereas AGM revision includes (K*4), \mathcal{EF} revision does not. It turns out that (K*4) does not correspond to the positive validity of any type- \mathcal{L}_1 formula. Still, (K*4) does correspond to a certain positive entailment, as Arló-Costa [1995] shows:

PROPOSITION 32. *If \mathcal{M} is an Arló-Costa/Levi pBRM defined on a type- \mathcal{L}_1 language L , then \mathcal{M} satisfies (K*4) iff*

$$\{\phi \rightarrow \psi, \neg(\top > \neg\phi)\} \models_+ \phi > \psi$$

holds in \mathcal{M} for all conditional-free formulas ϕ and ψ of L .

This result is equivalent to OBSERVATION 3.16 of [Arló-Costa, 1995]. Note that Proposition 32 does *not* establish conditions for the positive validity of

$$(\phi \rightarrow \psi) \rightarrow [\neg(\top > \neg\phi) \rightarrow (\phi > \psi)].$$

But if nesting of conditionals is allowed, then (K*4) can be associated with the positive validity of nested conditionals of the form $[(\phi \rightarrow \psi) \wedge \neg(\top >$

⁴⁸Arló-Costa [1995] notes that Theorems 27 and 29 and Lemma 30 suffice to yield completeness theorem for the type- \mathcal{L}_1 fragment of David Lewis' system VW.

⁴⁹See, for example, [Gärdenfors, 1988], Chapters 3 and 4.

$\neg\phi)] > (\phi > \psi)$ (see THEOREM 8.1 and OBSERVATION 8.3 in [Arló-Costa, 1995]). In general, $\Gamma \cup \{\phi\} \models_+ \psi$ is not equivalent to $\Gamma \models_+ \phi > \psi$ in an Arló-Costa/Levi pBRM, but this equivalence does hold for certain ϕ and ψ when $\Gamma = \emptyset$ (see OBSERVATION 3.17 of [Arló-Costa, 1995]).

A second difference between \mathcal{EF} revision and AGM revision is this: whereas AGM Revision includes (K*5), which entails (K*5w), \mathcal{EF} revision includes neither (K*5) nor (K*5w) but instead includes (K*C). The only difference between (K*5w) and (K*C) is that (K*5w) places a constraint on the revision of all belief sets that (K*C) places just on the revision of consistent belief sets. In particular, where ϕ is nontautologous, (K*5w) requires $(K_\perp)_\phi^*$ to be distinct from K_\perp (and therefore, actually, a contraction of K_\perp), whereas (K*C) implies no such requirement. Theorem 29 reveals that (K*C) is secured in Arló-Costa/Levi pBRMs via (pNRT) and the positive validity of negated conditionals of the form $\neg(\phi > \perp)$, where ϕ is nontautologous. These negated conditionals also belong to K_\perp , of course, but allowing K to take K_\perp as a value in (pNRT) is not an option. Allowing K to take K_\perp as a value in (pPRT) also does not help: Theorem 13 shows that (K*5w) and a consistent underlying logic cannot be combined with the positive Ramsey test in that case. Still, leaving aside the revision of K_\perp , it is true, as Arló-Costa [1995] has shown, that AGM revision of *nonabsurd* belief sets can be specified in terms of positive validity in a type- \mathcal{L}_2 language or in terms of positive validity and positive entailment in a type- \mathcal{L}_1 language.

3 OTHER TOPICS

Our discussion of the major kinds of conditionals is far from exhaustive. We have looked at several different approaches to the problem of providing an adequate formal semantics and logic for various kinds of conditionals without being able to demonstrate that one approach is clearly superior to all the others. Furthermore, there are many problems involved in the analysis of conditionals which we either have not discussed at all or have only just mentioned in passing. In this section we will look at several of these, giving each the very briefest attention.

One issue which has received much attention is the relationship between conditionals and probability. Stalnaker [1970] proposed that the probability that a conditional is true should be identical with the standard conditional probability. Lewis demonstrates in [Lewis, 1976], however, that this assumption can only be true if we restrict our probability functions to those which assign only a small finite number of distinct values to propositions. Stalnaker [1976] provides a different proof for a similar result, a proof which does not depend upon certain assumptions which Lewis used and which some investigators have questioned. Van Fraassen [1976] avoids

these Triviality Results for a weakened, non-classical version of Stalnaker's conditional logic **C2**. Lewis [1976] shows, however, that we can embrace a result which resembles Stalnaker's while avoiding the Triviality Result. Lewis's suggestion depends upon a technique which he calls imaging. This technique, which provides an alternative method for determining conditional probabilities, requires that in conditionalising a probability assignment with respect to ϕ , i.e. in modifying the assignment in a way which produces a new assignment which assigns probability 1 to ϕ , all the probability which was originally assigned to each $\neg\phi$ -world i would be transferred to the ϕ -world closest to i . Lewis demonstrates that if we accept Stalnaker's semantics and if we assign conditional probabilities in this new, non-standard way, then the probability that a conditional is true turns out to be identical with the conditional probability even when the probabilities of truth for conditionals take on infinitely many different values. Lewis's imaging techniques can be adapted to semantics other than Stalnaker's. Nute [1980b] adapts Lewis's imaging technique to class selection function semantics, producing a notion of subjunctive probability which differs from both the standard conditional probability and the probability that the corresponding conditional is true. While promising in some ways, Nute's account is extremely cumbersome. Gärdenfors [1982] presents a generalized form of imaging and shows that conditional probability cannot be described even in terms of generalized imaging. Other papers on conditionals and probability include [Döring, 1994; Fetzer and Nute, 1979; Fetzer and Nute, 1980; Hájek, 1994; Hall, 1994; Lance, 1991; Lewis, 1981b; Lewis, 1986; McGee, 1989; Nute, 1981a; Stalnaker and Jeffrey, 1994]. For a careful and comprehensive survey of results relating the probabilities of conditionals to conditional probabilities see [Hájek and Hall, 1994].

The relationship between causation and conditionals has certainly not been overlooked either. Many authors like Jackson [1977] and Kwart [1980; 1986] assign a special role to causation in their analyses of counterfactual conditionals. Others like Lewis [1973a] and Swain [1978] attempt to provide analyses of causation in terms of counterfactual dependence. Still others like Fetzer and Nute [1979; 1980] have tried to develop a semantics for a special kind of causal conditional. These special causal conditionals have then been employed in the formulation of a single-case propensity interpretation of law statements.

Conditional logic also has applications in deontic logic (see, for example, [Hilpinen, 1981]), in decision theory (see, for example, [Gibbard and Harper, 1981; Stalnaker, 1981a]), and in nonmonotonic logic (for a summary of some of this work, see [Nute, 1994]). In addition, there has been significant attention in recent years to the issue of whether so-called future indicative conditionals (e.g. 'If Oswald doesn't shoot President Kennedy, then someone else will') should be classified as indicative or as subjunctive (see, for example, [Bennett, 1988; Bennett, 1995; Dudman, 1984; Dudman, 1989;

Dudman, 1994; Jackson, 1990]). For a careful and comprehensive review of this and other recent topics of discussion see [Edgington, 1995]. It is not possible in this essay to discuss or even to list all of the material that can be found in the literature on conditional logic and its applications.

4 LIST OF SOME IMPORTANT RULES, THESES, AND LOGICS

In this section we collect some of the most important rules and theses of conditional logic together with definitions for a few of the better known conditional logics.

Rules

RCEC: from $\phi \leftrightarrow \psi$, to infer $(\chi > \phi) \leftrightarrow (\chi > \psi)$.

RCK: from $(\phi_1 \wedge \dots \wedge \phi_n) \rightarrow \psi$, to infer $[(\chi > \phi_1)(\wedge \dots (\chi > \phi_n))] \rightarrow (\chi > \psi)$, $n \geq 0$.

RCEA: from $\phi \leftrightarrow \psi$, to infer $(\phi > \chi) \leftrightarrow (\psi > \chi)$.

RCE: from $\phi \rightarrow \psi$, to infer $\phi > \psi$.

RCM: from $\psi \rightarrow \chi$, to infer $(\phi > \psi) \rightarrow (\phi > \chi)$.

RR: from $\chi \rightarrow (\phi > \psi)$ infer $(\chi \circ \phi) \rightarrow \psi$, and from $(\chi \circ \phi) \rightarrow \psi$ infer $\chi \rightarrow (\phi > \psi)$.

Theses

Transitivity: $[(\phi > \psi) \wedge (\chi > \phi)] \rightarrow (\chi > \psi)$

Contraposition: $(\phi > \neg\psi) \rightarrow (\psi > \neg\phi)$

Strengthening Antecedents: $(\phi > \psi) \rightarrow [(\phi \wedge \chi) > \psi]$

ID: $\phi > \phi$

MP: $(\phi > \psi) \rightarrow (\phi \rightarrow \psi)$

MOD: $(\neg\phi > \phi) \rightarrow (\psi > \phi)$

CSO: $[(\phi > \psi) \wedge (\psi > \phi)] \rightarrow [(\phi > \chi) \leftrightarrow (\psi > \chi)]$

CSO': $[(\phi > \psi) \wedge (\psi > \phi)] \rightarrow [(\phi > \chi) \rightarrow (\psi > \chi)]$

CV: $[(\phi > \psi) \wedge \neg(\phi > \neg\chi)] \rightarrow [(\phi \wedge \chi) > \psi]$

CEM: $(\phi > \psi) \vee (\phi > \neg\psi)$

CS: $(\phi \wedge \psi) \rightarrow (\phi > \psi)$

- CC: $[(\phi > \psi) \wedge (\phi > \chi)] \rightarrow [\phi > \psi \wedge \chi]$
 CM: $[\phi > (\psi \wedge \chi)] \rightarrow [(\phi > \psi) \wedge (\phi > \chi)]$
 CA: $[(\phi > \psi) \wedge (\chi > \psi)] \rightarrow [(\phi \vee \chi) > \psi]$
 SDA: $[(\phi \vee \psi) > \chi] \rightarrow [(\phi > \chi) \wedge (\psi > \chi)]$
 CN: $\phi > \top$
 CT: $(\neg\phi > \perp) \rightarrow \phi$
 CU: $\neg(\phi > \perp) \rightarrow ((\phi > \perp) > \perp)$
 CD: $\neg(\phi > \perp)$ for all non-tautologous ϕ .

Recall that in Section 1 we defined a conditional logic as any collection \overline{L} of sentences formed in the usual way from the symbols of classical sentential logic together with a conditional operator $>$, such that \overline{L} is closed under *modus ponens* and \overline{L} contains every tautology. We now modify this definition as follows, adopting the terminology of Section 2, to take different language types for conditional logic into account: let a conditional logic on a Boolean language L of type \mathcal{L}_1 or type \mathcal{L}_2 be any collection \overline{L} of sentences of L such that \overline{L} is closed under *modus ponens* and \overline{L} contains every tautology.

Logics for full conditional languages

For a given Boolean language L of type \mathcal{L}_2 , each of the following is the smallest conditional logic on L closed under all the rules and containing all the theses associated with it below.

- CM:** RCM, CC, CN
VW: RCEC, RCK; ID, MOD, CSO, MP, CV
SS: RCEC, RCK; ID, MOD, CSO, MP, CA, CS
VC: RCEC, RCK; ID, MOD, CSO, MP, CV, CS
VCU: RCEC, RCK; ID, MOD, CSO, MP, CV, CS, CT, CU
VCU²: RCEC, RCK, RR; ID, MOD, CSO, MP, CV, CS, CT, CU (with \circ as an additional binary operator)
C2: RCEC, RCK; ID, MOD, CSO, MP, CV, CEM

Neither of **VW** and **SS** is an extension of the other, and neither of **VCU** and **C2** is an extension of the other. **VCU²** is an extension of **VCU**, and **C2** and **VCU** are both extensions of **VC**, which is an extension of both **VW** and **SS**. **VW** and **SS** are both extensions of **CM**. For the definitions

of several weaker conditional logics, see [Lewis, 1973b; Chellas, 1975; Nute, 1980b].

Logics for languages of “flat” conditionals

If L is a Boolean language of type \mathcal{L}_1 , then each of the following logics is the smallest conditional logic on L closed under all the rules and containing all the theses associated with it below.

Flat CM: RCM, CC, CN

Flat VW: RCEC, RCK; ID, MOD, CSO, MP, CV

Flat VC: RCEC, RCK; ID, MOD, CSO, MP, CV, CS

\mathcal{EF} : RCM, RCEA, ID, MP, CC, CA, CV, CN, CD

Flat CM is contained in **Flat VW**, which is contained in both **Flat VC** and \mathcal{EF} , but neither of **Flat VC** and \mathcal{EF} is contained in the other. For a discussion of the logic of flat conditionals aimed at being as true as possible to Ramsey’s ideas, see [Levi, 1996], Chapter 4.

Acknowledgements

Sections 1, 3 and 4 are primarily the work of the first author, but revised from the first edition of this *Handbook* with input from the second author. Section 2 is primarily the work of the second author.

We are grateful to Lennart Åqvist, Horacio Arló-Costa, Ermanno Ben-civenga, John Burgess, David Butcher, Michael Dunn, Dov Gabbay, Christopher Gauker, Franz Guentner, Hans Kamp, David Lewis and Christian Rohrer for their helpful comments and suggestions on material contained in this paper. We are also grateful to Richmond Thomason for help in assembling our list of references. Finally, we thank Kluwer and the editor of the *Journal of Philosophical Logic* for permission to use material from [Nute, 1981b] in this article.

DYNAMIC LOGIC

PREFACE

Dynamic Logic (DL) is a formal system for reasoning about programs. Traditionally, this has meant formalizing correctness specifications and proving rigorously that those specifications are met by a particular program. Other activities fall into this category as well: determining the equivalence of programs, comparing the expressive power of various programming constructs, synthesizing programs from specifications, etc. Formal systems too numerous to mention have been proposed for these purposes, each with its own peculiarities.

DL can be described as a blend of three complementary classical ingredients: first-order predicate logic, modal logic, and the algebra of regular events. These components merge to form a system of remarkable unity that is theoretically rich as well as practical.

The name *Dynamic Logic* emphasizes the principal feature distinguishing it from classical predicate logic. In the latter, truth is *static*: the truth value of a formula φ is determined by a valuation of its free variables over some structure. The valuation and the truth value of φ it induces are regarded as immutable; there is no formalism relating them to any other valuations or truth values. In Dynamic Logic, there are explicit syntactic constructs called *programs* whose main role is to change the values of variables, thereby changing the truth values of formulas. For example, the program $x := x + 1$ over the natural numbers changes the truth value of the formula “ x is even”.

Such changes occur on a metalogical level in classical predicate logic. For example, in Tarski’s definition of truth of a formula, if $u : \{x, y, \dots\} \rightarrow \mathbb{N}$ is a valuation of variables over the natural numbers \mathbb{N} , then the formula $\exists x \ x^2 = y$ is defined to be true under the valuation u iff there exists an $a \in \mathbb{N}$ such that the formula $x^2 = y$ is true under the valuation $u[x/a]$, where $u[x/a]$ agrees with u everywhere except x , on which it takes the value a . This definition involves a metalogical operation that produces $u[x/a]$ from u for all possible values $a \in \mathbb{N}$. This operation becomes explicit in DL in the form of the program $x := ?$, called a *nondeterministic* or *wildcard assignment*. This is a rather unconventional program, since it is not effective; however, it is quite useful as a descriptive tool. A more conventional way to obtain a square root of y , if it exists, would be the program

(1) $x := 0$; **while** $x^2 < y$ **do** $x := x + 1$.

In DL, such programs are first-class objects on a par with formulas, complete with a collection of operators for forming compound programs inductively

from a basis of primitive programs. To discuss the effect of the execution of a program α on the truth of a formula φ , DL uses a modal construct $\langle \alpha \rangle \varphi$, which intuitively states, “It is possible to execute α starting from the current state and halt in a state satisfying φ .” There is also the dual construct $[\alpha] \varphi$, which intuitively states, “If α halts when started in the current state, then it does so in a state satisfying φ .” For example, the first-order formula $\exists x x^2 = y$ is equivalent to the DL formula $\langle x := ? \rangle x^2 = y$. In order to instantiate the quantifier effectively, we might replace the nondeterministic assignment inside the $\langle \rangle$ with the **while** program (1); over \mathbb{N} , the two formulas would be equivalent.

Apart from the obvious heavy reliance on classical logic, computability theory and programming, the subject has its roots in the work of [Thiele, 1966] and [Engeler, 1967] in the late 1960’s, who were the first to advance the idea of formulating and investigating formal systems dealing with properties of programs in an abstract setting. Research in program verification flourished thereafter with the work of many researchers, notably [Floyd, 1967], [Hoare, 1969], [Manna, 1974], and [Salwicki, 1970]. The first precise development of a DL-like system was carried out by [Salwicki, 1970], following [Engeler, 1967]. This system was called Algorithmic Logic. A similar system, called Monadic Programming Logic, was developed by [Constable, 1977]. Dynamic Logic, which emphasizes the modal nature of the program/assertion interaction, was introduced by [Pratt, 1976].

Background material on mathematical logic, computability, formal languages and automata, and program verification can be found in [Shoenfield, 1967] (logic), [Rogers, 1967] (recursion theory), [Kozen, 1997a] (formal languages, automata, and computability), [Keisler, 1971] (infinitary logic), [Manna, 1974] (program verification), and [Harel, 1992; Lewis and Papadimitriou, 1981; Davis *et al.*, 1994] (computability and complexity). Much of this introductory material as it pertains to DL can be found in the authors’ text [Harel *et al.*, 2000].

There are by now a number of books and survey papers treating logics of programs, program verification, and Dynamic Logic [Apt and Olderog, 1991; Backhouse, 1986; Harel, 1979; Harel, 1984; Parikh, 1981; Goldblatt, 1982; Goldblatt, 1987; Knijnenburg, 1988; Cousot, 1990; Emerson, 1990; Kozen and Tiuryn, 1990]. In particular, much of this chapter is an abbreviated summary of material from the authors’ text [Harel *et al.*, 2000], to which we refer the reader for a more complete treatment. Full proofs of many of the theorems cited in this chapter can be found there, as well as extensive introductory material on logic and complexity along with numerous examples and exercises.

1 REASONING ABOUT PROGRAMS

1.1 Programs

For us, a *program* is a recipe written in a formal language for computing desired output data from given input data.

EXAMPLE 1. The following program implements the Euclidean algorithm for calculating the greatest common divisor (gcd) of two integers. It takes as input a pair of integers in variables x and y and outputs their gcd in variable x :

```

while  $y \neq 0$  do
  begin
     $z := x \bmod y$ ;
     $x := y$ ;
     $y := z$ 
  end

```

The value of the expression $x \bmod y$ is the (nonnegative) remainder obtained when dividing x by y using ordinary integer division.

Programs normally use *variables* to hold input and output values and intermediate results. Each variable can assume values from a specific *domain of computation*, which is a structure consisting of a set of data values along with certain distinguished constants, basic operations, and tests that can be performed on those values, as in classical first-order logic. In the program above, the domain of x , y , and z might be the integers \mathbb{Z} along with basic operations including integer division with remainder and tests including \neq . In contrast with the usual use of variables in mathematics, a variable in a program normally assumes different values during the course of the computation. The value of a variable x may change whenever an assignment $x := t$ is performed with x on the left-hand side.

In order to make these notions precise, we will have to specify the programming language and its semantics in a mathematically rigorous way. In this section we give a brief introduction to some of these languages and the role they play in program verification.

1.2 States and Executions

As mentioned above, a program can change the values of variables as it runs. However, if we could freeze time at some instant during the execution of the program, we could presumably read the values of the variables at that instant, and that would give us an instantaneous snapshot of all information that we would need to determine how the computation would proceed from that point. This leads to the concept of a *state*—intuitively, an instantaneous description of reality.

Formally, we will define a *state* to be a function that assigns a value to each program variable. The value for variable x must belong to the domain associated with x . In logic, such a function is called a *valuation*. At any given instant in time during its execution, the program is thought to be “in” some state, determined by the instantaneous values of all its variables. If an assignment statement is executed, say $x := 2$, then the state changes to a new state in which the new value of x is 2 and the values of all other variables are the same as they were before. We assume that this change takes place instantaneously; note that this is a mathematical abstraction, since in reality basic operations take some time to execute.

A typical state for the gcd program above is $(15, 27, 0, \dots)$, where (say) the first, second, and third components of the sequence denote the values assigned to x , y , and z respectively. The ellipsis “ \dots ” refers to the values of the other variables, which we do not care about, since they do not occur in the program.

A program can be viewed as a transformation on states. Given an initial (input) state, the program will go through a series of intermediate states, perhaps eventually halting in a final (output) state. A sequence of states that can occur from the execution of a program α starting from a particular input state is called a *trace*. As a typical example of a trace for the program above, consider the initial state $(15, 27, 0)$ (we suppress the ellipsis). The program goes through the following sequence of states:

$$(15, 27, 0), (15, 27, 15), (27, 27, 15), (27, 15, 15), (27, 15, 12), (15, 15, 12), \\ (15, 12, 12), (15, 12, 3), (12, 12, 3), (12, 3, 3), (12, 3, 0), (3, 3, 0), (3, 0, 0).$$

The value of x in the last (output) state is 3, the gcd of 15 and 27.

The binary relation consisting of the set of all pairs of the form (input state, output state) that can occur from the execution of a program α , or in other words, the set of all first and last states of traces of α , is called the *input/output relation* of α . For example, the pair $((15, 27, 0), (3, 0, 0))$ is a member of the input/output relation of the gcd program above, as is the pair $((-6, -4, 303), (2, 0, 0))$. The values of other variables besides x , y , and z are not changed by the program. These values are therefore the same in the output state as in the input state. In this example, we may think of the variables x and y as the *input variables*, x as the *output variable*, and z as a *work variable*, although formally there is no distinction between any of the variables, including the ones not occurring in the program.

1.3 Programming Constructs

In subsequent sections we will consider a number of programming constructs. In this section we introduce some of these constructs and define a few general classes of languages built on them.

In general, programs are built inductively from *atomic programs* and *tests* using various *program operators*.

While Programs

A popular choice of programming language in the literature on DL is the family of deterministic **while** programs. This language is a natural abstraction of familiar imperative programming languages such as Pascal or C. Different versions can be defined depending on the choice of tests allowed and whether or not nondeterminism is permitted.

The language of **while** programs is defined inductively. There are atomic programs and atomic tests, as well as program constructs for forming compound programs from simpler ones.

In the propositional version of Dynamic Logic (PDL), atomic programs are simply letters a, b, \dots from some alphabet. Thus PDL abstracts away from the nature of the domain of computation and studies the pure interaction between programs and propositions. For the first-order versions of DL, atomic programs are *simple assignments* $x := t$, where x is a variable and t is a term. In addition, a *nondeterministic* or *wildcard assignment* $x := ?$ or *nondeterministic choice* construct may be allowed.

Tests can be *atomic tests*, which for propositional versions are simply propositional letters p , and for first-order versions are atomic formulas $p(t_1, \dots, t_n)$, where t_1, \dots, t_n are terms and p is an n -ary relation symbol in the vocabulary of the domain of computation. In addition, we include the *constant tests* **1** and **0**. Boolean combinations of atomic tests are often allowed, although this adds no expressive power. These versions of DL are called *poor test*.

More complicated tests can also be included. These versions of DL are sometimes called *rich test*. In rich test versions, the families of programs and tests are defined by mutual induction.

Compound programs are formed from the atomic programs and tests by induction, using the *composition*, *conditional*, and *while* operators. Formally, if φ is a test and α and β are programs, then the following are programs:

- $\alpha ; \beta$
- **if** φ **then** α **else** β
- **while** φ **do** α .

We can also parenthesize with **begin** ... **end** where necessary. The gcd program of Example 1 above is an example of a **while** program.

The semantics of these constructs is defined to correspond to the ordinary operational semantics familiar from common programming languages.

Regular Programs

Regular programs are more general than **while** programs, but not by much. The advantage of regular programs is that they reduce the relatively more complicated **while** program operators to much simpler constructs. The deductive system becomes comparatively simpler too. They also incorporate a simple form of nondeterminism.

For a given set of atomic programs and tests, the set of *regular programs* is defined as follows:

- (i) any atomic program is a program
- (ii) if φ is a test, then $\varphi?$ is a program
- (iii) if α and β are programs, then $\alpha ; \beta$ is a program;
- (iv) if α and β are programs, then $\alpha \cup \beta$ is a program;
- (v) if α is a program, then α^* is a program.

These constructs have the following intuitive meaning:

- (i) Atomic programs are basic and indivisible; they execute in a single step. They are called *atomic* because they cannot be decomposed further.
- (ii) The program $\varphi?$ tests whether the property φ holds in the current state. If so, it continues without changing state. If not, it blocks without halting.
- (iii) The operator $;$ is the *sequential composition* operator. The program $\alpha ; \beta$ means, “Do α , then do β .”
- (iv) The operator \cup is the *nondeterministic choice* operator. The program $\alpha \cup \beta$ means, “Nondeterministically choose one of α or β and execute it.”
- (v) The operator $*$ is the *iteration* operator. The program α means, “Execute α some nondeterministically chosen finite number of times.”

Keep in mind that these descriptions are meant only as intuitive aids. A formal semantics will be given in Section 2.2, in which programs will be interpreted as binary input/output relations and the programming constructs above as operators on binary relations.

The operators $\cup, ;, *$ may be familiar from automata and formal language theory (see [Kozen, 1997a]), where they are interpreted as operators on sets of strings over a finite alphabet. The language-theoretic and relation-theoretic semantics share much in common; in fact, they have the same equational theory, as shown in [Kozen, 1994a].

The operators of deterministic **while** programs can be defined in terms of the regular operators:

- (2) **if** φ **then** α **else** β $\stackrel{\text{def}}{=} \varphi? ; \alpha \cup \neg\varphi? ; \beta$
 (3) **while** φ **do** α $\stackrel{\text{def}}{=} (\varphi? ; \alpha)^* ; \neg\varphi?$

The class of **while** programs is equivalent to the subclass of the regular programs in which the program operators \cup , $?$, and $*$ are constrained to appear only in these forms.

Recursion

Recursion can appear in programming languages in several forms. Two such manifestations are *recursive calls* and *stacks*. Under certain very general conditions, the two constructs can simulate each other. It can also be shown that recursive programs and **while** programs are equally expressive over the natural numbers, whereas over arbitrary domains, **while** programs are strictly weaker. **While** programs correspond to what is often called *tail recursion* or *iteration*.

R.E. Programs

A *finite computation sequence* of a program α , or *seq* for short, is a finite-length string of atomic programs and tests representing a possible sequence of atomic steps that can occur in a halting execution of α . Seqs are denoted σ, τ, \dots . The set of all seqs of a program α is denoted $CS(\alpha)$. We use the word “possible” loosely— $CS(\alpha)$ is determined by the syntax of α alone. Because of tests that evaluate to false, $CS(\alpha)$ may contain seqs that are never executed under any interpretation.

The set $CS(\alpha)$ is a subset of A^* , where A is the set of atomic programs and tests occurring in α . For **while** programs, regular programs, or recursive programs, we can define the set $CS(\alpha)$ formally by induction on syntax. For example, for regular programs,

$$\begin{aligned} CS(a) &\stackrel{\text{def}}{=} \{a\}, \quad a \text{ an atomic program or test} \\ CS(\mathbf{skip}) &\stackrel{\text{def}}{=} \{\varepsilon\} \\ CS(\mathbf{fail}) &\stackrel{\text{def}}{=} \emptyset \\ CS(\alpha ; \beta) &\stackrel{\text{def}}{=} \{\sigma ; \tau \mid \sigma \in CS(\alpha), \tau \in CS(\beta)\} \\ CS(\alpha \cup \beta) &\stackrel{\text{def}}{=} CS(\alpha) \cup CS(\beta) \\ CS(\alpha^*) &\stackrel{\text{def}}{=} CS(\alpha)^* \\ &= \bigcup_{n \geq 0} CS(\alpha^n), \end{aligned}$$

where

$$\begin{aligned}\alpha^0 &\stackrel{\text{def}}{=} \mathbf{skip} \\ \alpha^{n+1} &\stackrel{\text{def}}{=} \alpha^n ; \alpha.\end{aligned}$$

For example, if a is an atomic program and p an atomic formula, then the program

$$\mathbf{while } p \mathbf{ do } a = (p? ; a)^* ; \neg p?$$

has as seqs all strings of the form

$$(p? ; a)^n ; \neg p? = \underbrace{p? ; a ; p? ; a ; \cdots ; p? ; a}_n ; \neg p?$$

for all $n \geq 0$. Note that each seq σ of a program α is itself a program, and

$$CS(\sigma) = \{\sigma\}.$$

While programs and regular programs give rise to regular sets of seqs, and recursive programs give rise to context-free sets of seqs. Taking this a step further, we can define an *r.e. program* to be simply a recursively enumerable set of seqs. This is the most general programming language we will consider in the context of DL; it subsumes all the others in expressive power.

Nondeterminism

We should say a few words about the concept of *nondeterminism* and its role in the study of logics and languages, since this concept often presents difficulty the first time it is encountered.

In some programming languages we will consider, the traces of a program need not be uniquely determined by their start states. When this is possible, we say that the program is *nondeterministic*. A nondeterministic program can have both divergent and convergent traces starting from the same input state, and for such programs it does not make sense to say that the program halts on a certain input state or that it loops on a certain input state; there may be different computations starting from the same input state that do each.

There are several concrete ways nondeterminism can enter into programs. One construct is the *nondeterministic* or *wildcard assignment* $x := ?$. Intuitively, this operation assigns an arbitrary element of the domain to the variable x , but it is not determined which one.¹ Another source of nondeterminism is the unconstrained use of the choice operator \cup in regular

¹This construct is often called *random assignment* in the literature. This terminology is misleading, because it has nothing at all to do with probability.

programs. A third source is the iteration operator $*$ in regular programs. A fourth source is r.e. programs, which are just r.e. sets of seqs; initially, the seq to execute is chosen nondeterministically. For example, over \mathbb{N} , the r.e. program

$$\{x := n \mid n \geq 0\}$$

is equivalent to the regular program

$$x := 0; (x := x + 1)^*.$$

Nondeterministic programs provide no explicit mechanism for resolving the nondeterminism. That is, there is no way to determine which of many possible next steps will be taken from a given state. This is hardly realistic. So why study nondeterminism at all if it does not correspond to anything operational? One good answer is that nondeterminism is a valuable tool that helps us understand the expressiveness of programming language constructs. It is useful in situations in which we cannot necessarily predict the outcome of a particular choice, but we may know the range of possibilities. In reality, computations may depend on information that is out of the programmer's control, such as input from the user or actions of other processes in the system. Nondeterminism is useful in modeling such situations.

The importance of nondeterminism is not limited to logics of programs. Indeed, the most important open problem in the field of computational complexity theory, the $P=NP$ problem, is formulated in terms of nondeterminism.

1.4 Program Verification

Dynamic Logic and other program logics are meant to be useful tools for facilitating the process of producing correct programs. One need only look at the miasma of buggy software to understand the dire need for such tools. But before we can produce correct software, we need to know what it means for it to be correct. It is not good enough to have some vague idea of what is supposed to happen when a program is run or to observe it running on some collection of inputs. In order to apply formal verification tools, we must have a formal specification of correctness for the verification tools to work with.

In general, a *correctness specification* is a formal description of how the program is supposed to behave. A given program is *correct* with respect to a correctness specification if its behavior fulfills that specification. For the gcd program of Example 1, the correctness might be specified informally by the assertion

If the input values of x and y are positive integers c and d , respectively, then

- (i) the output value of x is the gcd of c and d , and
- (ii) the program halts.

Of course, in order to work with a formal verification system, these properties must be expressed formally in a language such as first-order logic.

The assertion (ii) is part of the correctness specification because programs do not necessarily halt, but may produce infinite traces for certain inputs. A finite trace, as for example the one produced by the gcd program above on input state $(15,27,0)$, is called *halting*, *terminating*, or *convergent*. Infinite traces are called *looping* or *divergent*. For example, the program

while $x > 7$ **do** $x := x + 3$

loops on input state $(8, \dots)$, producing the infinite trace

$(8, \dots), (11, \dots), (14, \dots), \dots$

Dynamic Logic can reason about the behavior of a program that is manifested in its input/output relation. It is not well suited to reasoning about program behavior manifested in intermediate states of a computation (although there are close relatives, such as Process Logic and Temporal Logic, that are). This is not to say that all interesting program behavior is captured by the input/output relation, and that other types of behavior are irrelevant or uninteresting. Indeed, the restriction to input/output relations is reasonable only when programs are supposed to halt after a finite time and yield output results. This approach will not be adequate for dealing with programs that normally are not supposed to halt, such as operating systems.

For programs that are supposed to halt, correctness criteria are traditionally given in the form of an *input/output specification* consisting of a formal relation between the input and output states that the program is supposed to maintain, along with a description of the set of input states on which the program is supposed to halt. The input/output relation of a program carries all the information necessary to determine whether the program is correct relative to such a specification. Dynamic Logic is well suited to this type of verification.

It is not always obvious what the correctness specification ought to be. Sometimes, producing a formal specification of correctness is as difficult as producing the program itself, since both must be written in a formal language. Moreover, specifications are as prone to bugs as programs. Why bother then? Why not just implement the program with some vague specification in mind?

There are several good reasons for taking the effort to produce formal specifications:

1. Often when implementing a large program from scratch, the programmer may have been given only a vague idea of what the finished product is supposed to do. This is especially true when producing software for a less technically inclined employer. There may be a rough informal description available, but the minor details are often left to the programmer. It is very often the case that a large part of the programming process consists of taking a vaguely specified problem and making it precise. The process of formulating the problem precisely can be considered a *definition* of what the program is supposed to do. And it is just good programming practice to have a very clear idea of what we want to do before we start doing it.
2. In the process of formulating the specification, several unforeseen cases may become apparent, for which it is not clear what the appropriate action of the program should be. This is especially true with error handling and other exceptional situations. Formulating a specification can define the action of the program in such situations and thereby tie up loose ends.
3. The process of formulating a rigorous specification can sometimes suggest ideas for implementation, because it forces us to isolate the issues that drive design decisions. When we know all the ways our data are going to be accessed, we are in a better position to choose the right data structures that optimize the tradeoffs between efficiency and generality.
4. The specification is often expressed in a language quite different from the programming language. The specification is *functional*—it tells *what* the program is supposed to do—as opposed to *imperative*—*how* to do it. It is often easier to specify the desired functionality independent of the details of how it will be implemented. For example, we can quite easily express what it means for a number x to be the gcd of y and z in first-order logic without even knowing how to compute it.
5. Verifying that a program meets its specification is a kind of sanity check. It allows us to give two solutions to the problem—once as a functional specification, and once as an algorithmic implementation—and lets us verify that the two are compatible. Any incompatibilities between the program and the specification are either bugs in the program, bugs in the specification, or both. The cycle of refining the specification, modifying the program to meet the specification, and re-verifying until the process converges can lead to software in which we have much more confidence.

Partial and Total Correctness

Typically, a program is designed to implement some functionality. As mentioned above, that functionality can often be expressed formally in the form of an input/output specification. Concretely, such a specification consists of an *input condition* or *precondition* φ and an *output condition* or *post-condition* ψ . These are properties of the input state and the output state, respectively, expressed in some formal language such as the first-order language of the domain of computation. The program is supposed to halt in a state satisfying the output condition whenever the input state satisfies the input condition. We say that a program is *partially correct* with respect to a given input/output specification φ, ψ if, whenever the program is started in a state satisfying the input condition φ , then if and when it ever halts, it does so in a state satisfying the output condition ψ . The definition of partial correctness does not stipulate that the program halts; this is what we mean by *partial*.

A program is *totally correct* with respect to an input/output specification φ, ψ if

- it is partially correct with respect to that specification; and
- it halts whenever it is started in a state satisfying the input condition φ .

The input/output specification imposes no requirements when the input state does not satisfy the input condition φ —the program might as well loop infinitely or erase memory. This is the “garbage in, garbage out” philosophy. If we really do care what the program does on some of those input states, then we had better rewrite the input condition to include them and say formally what we want to happen in those cases.

For example, in the gcd program of Example 1, the output condition ψ might be the condition (i) stating that the output value of x is the gcd of the input values of x and y . We can express this completely formally in the language of first-order number theory. We may try to start off with the input specification $\varphi_0 = \mathbf{1}$ (*true*); that is, no restrictions on the input state at all. Unfortunately, if the initial value of y is 0 and x is negative, the final value of x will be the same as the initial value, thus negative. If we expect all gcds to be positive, this would be wrong. Another problematic situation arises when the initial values of x and y are both 0; in this case the gcd is not defined. Therefore, the program as written is not partially correct with respect to the specification φ_0, ψ .

We can remedy the situation by providing an input specification that rules out these troublesome input values. We can limit the input states to those in which x and y are both nonnegative and not both zero by taking

the input specification

$$\varphi_1 = (x \geq 0 \wedge y > 0) \vee (x > 0 \wedge y \geq 0).$$

The gcd program of Example 1 above would be partially correct with respect to the specification φ_1, ψ . It is also totally correct, since the program halts on all inputs satisfying φ_1 .

Perhaps we want to allow any input in which not both x and y are zero. In that case, we should use the input specification $\varphi_2 = \neg(x = 0 \wedge y = 0)$. But then the program of Example 1 is not partially correct with respect to φ_2, ψ ; we must amend the program to produce the correct (positive) gcd on negative inputs.

1.5 Exogenous and Endogenous Logics

There are two main approaches to modal logics of programs: the *exogenous* approach, exemplified by Dynamic Logic and its precursor Hoare Logic [Hoare, 1969], and the *endogenous* approach, exemplified by Temporal Logic and its precursor, the invariant assertions method of [Floyd, 1967]. A logic is *exogenous* if its programs are explicit in the language. Syntactically, a Dynamic Logic program is a well-formed expression built inductively from primitive programs using a small set of program operators. Semantically, a program is interpreted as its input/output relation. The relation denoted by a compound program is determined by the relations denoted by its parts. This aspect of *compositionality* allows analysis by structural induction.

The importance of compositionality is discussed in [van Emde Boas, 1978]. In Temporal Logic, the program is fixed and is considered part of the structure over which the logic is interpreted. The current location in the program during execution is stored in a special variable for that purpose, called the *program counter*, and is part of the state along with the values of the program variables. Instead of program operators, there are temporal operators that describe how the program variables, including the program counter, change with time. Thus Temporal Logic sacrifices compositionality for a less restricted formalism. We discuss Temporal Logic further in Section 14.2.

2 PROPOSITIONAL DYNAMIC LOGIC (PDL)

Propositional Dynamic Logic (PDL) plays the same role in Dynamic Logic that classical propositional logic plays in classical predicate logic. It describes the properties of the interaction between programs and propositions that are independent of the domain of computation. Since PDL is a subsystem of first-order DL, we can be sure that all properties of PDL that we discuss in this section will also be valid in first-order DL.

Since there is no domain of computation in PDL, there can be no notion of assignment to a variable. Instead, primitive programs are interpreted as arbitrary binary relations on an abstract set of states K . Likewise, primitive assertions are just atomic propositions and are interpreted as arbitrary subsets of K . Other than this, no special structure is imposed.

This level of abstraction may at first appear too general to say anything of interest. On the contrary, it is a very natural level of abstraction at which many fundamental relationships between programs and propositions can be observed.

For example, consider the PDL formula

$$(4) \quad [\alpha](\varphi \wedge \psi) \leftrightarrow [\alpha]\varphi \wedge [\alpha]\psi.$$

The left-hand side asserts that the formula $\varphi \wedge \psi$ must hold after the execution of program α , and the right-hand side asserts that φ must hold after execution of α and so must ψ . The formula (4) asserts that these two statements are equivalent. This implies that to verify a conjunction of two postconditions, it suffices to verify each of them separately. The assertion (4) holds universally, regardless of the domain of computation and the nature of the particular α , φ , and ψ .

As another example, consider

$$(5) \quad [\alpha; \beta]\varphi \leftrightarrow [\alpha][\beta]\varphi.$$

The left-hand side asserts that after execution of the composite program $\alpha; \beta$, φ must hold. The right-hand side asserts that after execution of the program α , $[\beta]\varphi$ must hold, which in turn says that after execution of β , φ must hold. The formula (5) asserts the logical equivalence of these two statements. It holds regardless of the nature of α , β , and φ . Like (4), (5) can be used to simplify the verification of complicated programs.

As a final example, consider the assertion

$$(6) \quad [\alpha]p \leftrightarrow [\beta]p$$

where p is a primitive proposition symbol and α and β are programs. If this formula is true under all interpretations, then α and β are *equivalent* in the sense that they behave identically with respect to any property expressible in PDL or any formal system containing PDL as a subsystem. This is because the assertion will hold for any substitution instance of (6). For example, the two programs

$$\begin{aligned} \alpha &= \mathbf{if} \varphi \mathbf{ then} \gamma \mathbf{ else} \delta \\ \beta &= \mathbf{if} \neg\varphi \mathbf{ then} \delta \mathbf{ else} \gamma \end{aligned}$$

are equivalent in the sense of (6).

2.1 Syntax

Syntactically, PDL is a blend of three classical ingredients: propositional logic, modal logic, and the algebra of regular expressions. There are several versions of PDL, depending on the choice of program operators allowed. In this section we will introduce the basic version, called *regular PDL*. Variations of this basic version will be considered in later sections.

The language of regular PDL has expressions of two sorts: *propositions* or *formulas* φ, ψ, \dots and *programs* $\alpha, \beta, \gamma, \dots$. There are countably many *atomic symbols* of each sort. Atomic programs are denoted a, b, c, \dots and the set of all atomic programs is denoted Π_0 . Atomic propositions are denoted p, q, r, \dots and the set of all atomic propositions is denoted Φ_0 . The set of all programs is denoted Π and the set of all propositions is denoted Φ . Programs and propositions are built inductively from the atomic ones using the following operators:

Propositional operators:

\rightarrow	implication
$\mathbf{0}$	falsity

Program operators:

$;$	composition
\cup	choice
$*$	iteration

Mixed operators:

$[]$	necessity
$?$	test

The definition of programs and propositions is by mutual induction. All atomic programs are programs and all atomic propositions are propositions. If φ, ψ are propositions and α, β are programs, then

$\varphi \rightarrow \psi$	propositional implication
$\mathbf{0}$	propositional falsity
$[\alpha]\varphi$	program necessity

are propositions and

$\alpha ; \beta$	sequential composition
$\alpha \cup \beta$	nondeterministic choice
α^*	iteration
$\varphi?$	test

are programs. In more formal terms, we define the set Π of all programs and the set Φ of all propositions to be the smallest sets such that

- $\Phi_0 \subseteq \Phi$
- $\Pi_0 \subseteq \Pi$
- if $\varphi, \psi \in \Phi$, then $\varphi \rightarrow \psi \in \Phi$ and $\mathbf{0} \in \Phi$
- if $\alpha, \beta \in \Pi$, then $\alpha; \beta$, $\alpha \cup \beta$, and $\alpha^* \in \Pi$
- if $\alpha \in \Pi$ and $\varphi \in \Phi$, then $[\alpha]\varphi \in \Phi$
- if $\varphi \in \Phi$ then $\varphi? \in \Pi$.

Note that the inductive definitions of programs Π and propositions Φ are intertwined and cannot be separated. The definition of propositions depends on the definition of programs because of the construct $[\alpha]\varphi$, and the definition of programs depends on the definition of propositions because of the construct $\varphi?$. Note also that we have allowed all formulas as tests. This is the *rich test* version of PDL.

Compound programs and propositions have the following intuitive meanings:

$[\alpha]\varphi$ “It is necessary that after executing α , φ is true.”

$\alpha; \beta$ “Execute α , then execute β .”

$\alpha \cup \beta$ “Choose either α or β nondeterministically and execute it.”

α^* “Execute α a nondeterministically chosen finite number of times (zero or more).”

$\varphi?$ “Test φ ; proceed if true, fail if false.”

We avoid parentheses by assigning precedence to the operators: unary operators, including $[\alpha]$, bind tighter than binary ones, and $;$ binds tighter than \cup . Thus the expression

$$[\alpha; \beta^* \cup \gamma^*]\varphi \vee \psi$$

should be read

$$([\alpha; (\beta^*)] \cup (\gamma^*))\varphi \vee \psi.$$

Of course, parentheses can always be used to enforce a particular parse of an expression or to enhance readability. Also, under the semantics to be given in the next section, the operators $;$ and \cup will turn out to be associative, so we may write $\alpha; \beta; \gamma$ and $\alpha \cup \beta \cup \gamma$ without ambiguity. We often omit the symbol $;$ and write the composition $\alpha; \beta$ as $\alpha\beta$.

The propositional operators \wedge , \vee , \neg , \leftrightarrow , and $\mathbf{1}$ can be defined from \rightarrow and $\mathbf{0}$ in the usual way.

The possibility operator $\langle \rangle$ is the modal dual of the necessity operator $[]$. It is defined by

$$\langle \alpha \rangle \varphi \stackrel{\text{def}}{=} \neg [\alpha] \neg \varphi.$$

The propositions $[\alpha]\varphi$ and $\langle \alpha \rangle \varphi$ are read “box $\alpha \varphi$ ” and “diamond $\alpha \varphi$,” respectively. The latter has the intuitive meaning, “There is a computation of α that terminates in a state satisfying φ .”

One important difference between $\langle \rangle$ and $[]$ is that $\langle \alpha \rangle \varphi$ implies that α terminates, whereas $[\alpha]\varphi$ does not. Indeed, the formula $[\alpha]\mathbf{0}$ asserts that no computation of α terminates, and the formula $[\alpha]\mathbf{1}$ is always true, regardless of α .

In addition, we define

$$\begin{aligned} \mathbf{skip} &\stackrel{\text{def}}{=} \mathbf{1?} \\ \mathbf{fail} &\stackrel{\text{def}}{=} \mathbf{0?} \\ \mathbf{if } \varphi_1 \rightarrow \alpha_1 \mid \cdots \mid \varphi_n \rightarrow \alpha_n \mathbf{ fi} &\stackrel{\text{def}}{=} \varphi_1?; \alpha_1 \cup \cdots \cup \varphi_n?; \alpha_n \\ \mathbf{do } \varphi_1 \rightarrow \alpha_1 \mid \cdots \mid \varphi_n \rightarrow \alpha_n \mathbf{ od} &\stackrel{\text{def}}{=} \left(\bigcup_{i=1}^n \varphi_i?; \alpha_i \right)^*; \left(\bigwedge_{i=1}^n \neg \varphi_i \right)? \\ \mathbf{if } \varphi \mathbf{ then } \alpha \mathbf{ else } \beta &\stackrel{\text{def}}{=} \mathbf{if } \varphi \rightarrow \alpha \mid \neg \varphi \rightarrow \beta \mathbf{ fi} \\ &= \varphi?; \alpha \cup \neg \varphi?; \beta \\ \mathbf{while } \varphi \mathbf{ do } \alpha &\stackrel{\text{def}}{=} \mathbf{do } \varphi \rightarrow \alpha \mathbf{ od} \\ &= (\varphi?; \alpha)^*; \neg \varphi? \\ \mathbf{repeat } \alpha \mathbf{ until } \varphi &\stackrel{\text{def}}{=} \alpha; \mathbf{while } \neg \varphi \mathbf{ do } \alpha \\ &= \alpha; (\neg \varphi?; \alpha)^*; \varphi? \\ \{ \varphi \} \alpha \{ \psi \} &\stackrel{\text{def}}{=} \varphi \rightarrow [\alpha] \psi. \end{aligned}$$

The programs **skip** and **fail** are the program that does nothing (no-op) and the failing program, respectively. The ternary **if-then-else** operator and the binary **while-do** operator are the usual *conditional* and *while loop* constructs found in conventional programming languages. The constructs **if-|-fi** and **do-|-od** are the *alternative guarded command* and *iterative guarded command* constructs, respectively. The construct $\{ \varphi \} \alpha \{ \psi \}$ is the Hoare partial correctness assertion. We will argue later that the formal definitions of these operators given above correctly model their intuitive behavior.

2.2 Semantics

The semantics of PDL comes from the semantics for modal logic. The structures over which programs and propositions of PDL are interpreted

are called *Kripke frames* in honor of Saul Kripke, the inventor of the formal semantics of modal logic. A *Kripke frame* is a pair

$$\mathfrak{K} = (K, \mathbf{m}_{\mathfrak{K}}),$$

where K is a set of elements u, v, w, \dots called *states* and $\mathbf{m}_{\mathfrak{K}}$ is a *meaning function* assigning a subset of K to each atomic proposition and a binary relation on K to each atomic program. That is,

$$\begin{aligned} \mathbf{m}_{\mathfrak{K}}(p) &\subseteq K, & p \in \Phi_0 \\ \mathbf{m}_{\mathfrak{K}}(a) &\subseteq K \times K, & a \in \Pi_0. \end{aligned}$$

We will extend the definition of the function $\mathbf{m}_{\mathfrak{K}}$ by induction below to give a meaning to all elements of Π and Φ such that

$$\begin{aligned} \mathbf{m}_{\mathfrak{K}}(\varphi) &\subseteq K, & \varphi \in \Phi \\ \mathbf{m}_{\mathfrak{K}}(\alpha) &\subseteq K \times K, & \alpha \in \Pi. \end{aligned}$$

Intuitively, we can think of the set $\mathbf{m}_{\mathfrak{K}}(\varphi)$ as the set of states *satisfying* the proposition φ in the model \mathfrak{K} , and we can think of the binary relation $\mathbf{m}_{\mathfrak{K}}(\alpha)$ as the set of input/output pairs of states of the program α .

Formally, the meanings $\mathbf{m}_{\mathfrak{K}}(\varphi)$ of $\varphi \in \Phi$ and $\mathbf{m}_{\mathfrak{K}}(\alpha)$ of $\alpha \in \Pi$ are defined by mutual induction on the structure of φ and α . The basis of the induction, which specifies the meanings of the atomic symbols $p \in \Phi_0$ and $a \in \Pi_0$, is already given in the specification of \mathfrak{K} . The meanings of compound propositions and programs are defined as follows.

$$\begin{aligned} \mathbf{m}_{\mathfrak{K}}(\varphi \rightarrow \psi) &\stackrel{\text{def}}{=} (K - \mathbf{m}_{\mathfrak{K}}(\varphi)) \cup \mathbf{m}_{\mathfrak{K}}(\psi) \\ \mathbf{m}_{\mathfrak{K}}(\mathbf{0}) &\stackrel{\text{def}}{=} \emptyset \\ \mathbf{m}_{\mathfrak{K}}([\alpha]\varphi) &\stackrel{\text{def}}{=} K - (\mathbf{m}_{\mathfrak{K}}(\alpha) \circ (K - \mathbf{m}_{\mathfrak{K}}(\varphi))) \\ &= \{u \mid \forall v \in K \text{ if } (u, v) \in \mathbf{m}_{\mathfrak{K}}(\alpha) \text{ then } v \in \mathbf{m}_{\mathfrak{K}}(\varphi)\} \\ (7) \quad \mathbf{m}_{\mathfrak{K}}(\alpha; \beta) &\stackrel{\text{def}}{=} \mathbf{m}_{\mathfrak{K}}(\alpha) \circ \mathbf{m}_{\mathfrak{K}}(\beta) \\ &= \{(u, v) \mid \exists w \in K (u, w) \in \mathbf{m}_{\mathfrak{K}}(\alpha) \text{ and } (w, v) \in \mathbf{m}_{\mathfrak{K}}(\beta)\} \\ \mathbf{m}_{\mathfrak{K}}(\alpha \cup \beta) &\stackrel{\text{def}}{=} \mathbf{m}_{\mathfrak{K}}(\alpha) \cup \mathbf{m}_{\mathfrak{K}}(\beta) \\ (8) \quad \mathbf{m}_{\mathfrak{K}}(\alpha^*) &\stackrel{\text{def}}{=} \mathbf{m}_{\mathfrak{K}}(\alpha)^* = \bigcup_{n \geq 0} \mathbf{m}_{\mathfrak{K}}(\alpha)^n \\ \mathbf{m}_{\mathfrak{K}}(\varphi?) &\stackrel{\text{def}}{=} \{(u, u) \mid u \in \mathbf{m}_{\mathfrak{K}}(\varphi)\}. \end{aligned}$$

The operator \circ in (7) is relational composition. In (8), the first occurrence of $*$ is the iteration symbol of PDL, and the second is the reflexive transitive closure operator on binary relations. Thus (8) says that the program α^* is interpreted as the reflexive transitive closure of $\mathbf{m}_{\mathfrak{K}}(\alpha)$.

We write $\mathfrak{K}, u \models \varphi$ and $u \in \mathbf{m}_{\mathfrak{K}}(\varphi)$ interchangeably, and say that u *satisfies* φ in \mathfrak{K} , or that φ is *true* at state u in \mathfrak{K} . We may omit the \mathfrak{K} and write $u \models \varphi$

when \mathfrak{R} is understood. The notation $u \not\models \varphi$ means that u does not satisfy φ , or in other words that $u \notin \mathfrak{m}_{\mathfrak{R}}(\varphi)$. In this notation, we can restate the definition above equivalently as follows:

$$\begin{aligned}
u \models \varphi \rightarrow \psi &\stackrel{\text{def}}{\iff} u \models \varphi \text{ implies } u \models \psi \\
&u \not\models \mathbf{0} \\
u \models [\alpha]\varphi &\stackrel{\text{def}}{\iff} \forall v \text{ if } (u, v) \in \mathfrak{m}_{\mathfrak{R}}(\alpha) \text{ then } v \models \varphi \\
(u, v) \in \mathfrak{m}_{\mathfrak{R}}(\alpha\beta) &\stackrel{\text{def}}{\iff} \exists w (u, w) \in \mathfrak{m}_{\mathfrak{R}}(\alpha) \text{ and } (w, v) \in \mathfrak{m}_{\mathfrak{R}}(\beta) \\
(u, v) \in \mathfrak{m}_{\mathfrak{R}}(\alpha \cup \beta) &\stackrel{\text{def}}{\iff} (u, v) \in \mathfrak{m}_{\mathfrak{R}}(\alpha) \text{ or } (u, v) \in \mathfrak{m}_{\mathfrak{R}}(\beta) \\
(u, v) \in \mathfrak{m}_{\mathfrak{R}}(\alpha^*) &\stackrel{\text{def}}{\iff} \exists n \geq 0 \exists u_0, \dots, u_n \ u = u_0, \ v = u_n, \\
&\text{and } (u_i, u_{i+1}) \in \mathfrak{m}_{\mathfrak{R}}(\alpha), \ 0 \leq i \leq n-1 \\
(u, v) \in \mathfrak{m}_{\mathfrak{R}}(\varphi?) &\stackrel{\text{def}}{\iff} u = v \text{ and } u \models \varphi.
\end{aligned}$$

The defined operators inherit their meanings from these definitions:

$$\begin{aligned}
\mathfrak{m}_{\mathfrak{R}}(\varphi \vee \psi) &\stackrel{\text{def}}{=} \mathfrak{m}_{\mathfrak{R}}(\varphi) \cup \mathfrak{m}_{\mathfrak{R}}(\psi) \\
\mathfrak{m}_{\mathfrak{R}}(\varphi \wedge \psi) &\stackrel{\text{def}}{=} \mathfrak{m}_{\mathfrak{R}}(\varphi) \cap \mathfrak{m}_{\mathfrak{R}}(\psi) \\
\mathfrak{m}_{\mathfrak{R}}(\neg\varphi) &\stackrel{\text{def}}{=} K - \mathfrak{m}_{\mathfrak{R}}(\varphi) \\
\mathfrak{m}_{\mathfrak{R}}(\langle\alpha\rangle\varphi) &\stackrel{\text{def}}{=} \{u \mid \exists v \in K \ (u, v) \in \mathfrak{m}_{\mathfrak{R}}(\alpha) \text{ and } v \in \mathfrak{m}_{\mathfrak{R}}(\varphi)\} \\
&= \mathfrak{m}_{\mathfrak{R}}(\alpha) \circ \mathfrak{m}_{\mathfrak{R}}(\varphi) \\
\mathfrak{m}_{\mathfrak{R}}(\mathbf{1}) &\stackrel{\text{def}}{=} K \\
\mathfrak{m}_{\mathfrak{R}}(\mathbf{skip}) &\stackrel{\text{def}}{=} \mathfrak{m}_{\mathfrak{R}}(\mathbf{1}?) = \iota, \text{ the identity relation} \\
\mathfrak{m}_{\mathfrak{R}}(\mathbf{fail}) &\stackrel{\text{def}}{=} \mathfrak{m}_{\mathfrak{R}}(\mathbf{0}?) = \emptyset.
\end{aligned}$$

In addition, the **if-then-else**, **while-do**, and guarded commands inherit their semantics from the above definitions, and the input/output relations given by the formal semantics capture their intuitive operational meanings. For example, the relation associated with the program **while** φ **do** α is the set of pairs (u, v) for which there exist states u_0, u_1, \dots, u_n , $n \geq 0$, such that $u = u_0$, $v = u_n$, $u_i \in \mathfrak{m}_{\mathfrak{R}}(\varphi)$ and $(u_i, u_{i+1}) \in \mathfrak{m}_{\mathfrak{R}}(\alpha)$ for $0 \leq i < n$, and $u_n \notin \mathfrak{m}_{\mathfrak{R}}(\varphi)$.

This version of PDL is usually called *regular PDL* and the elements of Π are called *regular programs* because of the primitive operators \cup , $;$, and $*$, which are familiar from regular expressions. Programs can be viewed as regular expressions over the atomic programs and tests. In fact, it can be shown that if p is an atomic proposition symbol, then any two test-free programs α, β are equivalent as regular expressions—that is, they represent the same regular set—if and only if the formula $\langle\alpha\rangle p \leftrightarrow \langle\beta\rangle p$ is valid.

EXAMPLE 2. Let p be an atomic proposition, let a be an atomic program, and let $\mathfrak{K} = (K, \mathfrak{m}_{\mathfrak{K}})$ be a Kripke frame with

$$\begin{aligned} K &= \{u, v, w\} \\ \mathfrak{m}_{\mathfrak{K}}(p) &= \{u, v\} \\ \mathfrak{m}_{\mathfrak{K}}(a) &= \{(u, v), (u, w), (v, w), (w, v)\}. \end{aligned}$$

The following diagram illustrates \mathfrak{K} .

In this structure, $u \models \langle a \rangle \neg p \wedge \langle a \rangle p$, but $v \models [a] \neg p$ and $w \models [a] p$. Moreover, every state of \mathfrak{K} satisfies the formula

$$\langle a^* \rangle [(aa)^*] p \wedge \langle a^* \rangle [(aa)^*] \neg p.$$

2.3 Computation Sequences

Let α be a program. Recall from Section 1.3 that a *finite computation sequence* of α is a finite-length string of atomic programs and tests representing a possible sequence of atomic steps that can occur in a halting execution of α . These strings are called *seqs* and are denoted σ, τ, \dots . The set of all such sequences is denoted $CS(\alpha)$. We use the word “possible” here loosely— $CS(\alpha)$ is determined by the syntax of α alone, and may contain strings that are never executed in any interpretation. The formal definition of $CS(\alpha)$ was given in Section 1.3.

Note that each finite computation sequence β of a program α is itself a program, and $CS(\beta) = \{\beta\}$. Moreover, the following proposition is not difficult to prove by induction on the structure of α :

PROPOSITION 3.

$$\mathfrak{m}_{\mathfrak{K}}(\alpha) = \bigcup_{\sigma \in CS(\alpha)} \mathfrak{m}_{\mathfrak{K}}(\sigma).$$

2.4 Satisfiability and Validity

The definitions of satisfiability and validity of propositions come from modal logic. Let $\mathfrak{K} = (K, \mathfrak{m}_{\mathfrak{K}})$ be a Kripke frame and let φ be a proposition. We have defined in Section 2.2 what it means for $\mathfrak{K}, u \models \varphi$. If $\mathfrak{K}, u \models \varphi$ for some

$u \in K$, we say that φ is *satisfiable* in \mathfrak{K} . If φ is satisfiable in some \mathfrak{K} , we say that φ is *satisfiable*.

If $\mathfrak{K}, u \models \varphi$ for all $u \in K$, we write $\mathfrak{K} \models \varphi$ and say that φ is *valid* in \mathfrak{K} . If $\mathfrak{K} \models \varphi$ for all Kripke frames \mathfrak{K} , we write $\models \varphi$ and say that φ is *valid*.

If Σ is a set of propositions, we write $\mathfrak{K} \models \Sigma$ if $\mathfrak{K} \models \varphi$ for all $\varphi \in \Sigma$. A proposition ψ is said to be a *logical consequence* of Σ if $\mathfrak{K} \models \psi$ whenever $\mathfrak{K} \models \Sigma$, in which case we write $\Sigma \models \psi$. (Note that this is *not* the same as saying that $\mathfrak{K}, u \models \psi$ whenever $\mathfrak{K}, u \models \Sigma$.) We say that an inference rule

$$\frac{\varphi_1, \dots, \varphi_n}{\varphi}$$

is *sound* if φ is a logical consequence of $\{\varphi_1, \dots, \varphi_n\}$.

Satisfiability and validity are dual in the same sense that \exists and \forall are dual and $\langle \rangle$ and $[]$ are dual: a proposition is valid (in \mathfrak{K}) if and only if its negation is not satisfiable (in \mathfrak{K}).

EXAMPLE 4. Let p, q be atomic propositions, let a, b be atomic programs, and let $\mathfrak{K} = (K, m_{\mathfrak{K}})$ be a Kripke frame with

$$\begin{aligned} K &= \{s, t, u, v\} \\ m_{\mathfrak{K}}(p) &= \{u, v\} \\ m_{\mathfrak{K}}(q) &= \{t, v\} \\ m_{\mathfrak{K}}(a) &= \{(t, v), (v, t), (s, u), (u, s)\} \\ m_{\mathfrak{K}}(b) &= \{(u, v), (v, u), (s, t), (t, s)\}. \end{aligned}$$

The following figure illustrates \mathfrak{K} .

The following formulas are valid in \mathfrak{K} .

$$\begin{aligned} p &\leftrightarrow [(ab^*a)^*]p \\ q &\leftrightarrow [(ba^*b)^*]q. \end{aligned}$$

Also, let α be the program

$$\alpha = (aa \cup bb \cup (ab \cup ba)(aa \cup bb)^*(ab \cup ba))^*.$$

Thinking of α as a regular expression, α generates all words over the alphabet $\{a, b\}$ with an even number of occurrences of each of a and b . It can be shown that for any proposition φ , the proposition $\varphi \leftrightarrow [\alpha]\varphi$ is valid in \mathfrak{K} .

EXAMPLE 5. The formula

$$p \wedge [a^*]((p \rightarrow [a]\neg p) \wedge (\neg p \rightarrow [a]p)) \leftrightarrow [(aa)^*]p \wedge [a(aa)^*]\neg p$$

is valid. Both sides assert in different ways that p is alternately true and false along paths of execution of the atomic program a .

2.5 Basic Properties

THEOREM 6. *The following are valid formulas of PDL:*

- (i) $\langle \alpha \rangle (\varphi \vee \psi) \leftrightarrow \langle \alpha \rangle \varphi \vee \langle \alpha \rangle \psi$
- (ii) $[\alpha] (\varphi \wedge \psi) \leftrightarrow [\alpha] \varphi \wedge [\alpha] \psi$
- (iii) $\langle \alpha \rangle \varphi \wedge [\alpha] \psi \rightarrow \langle \alpha \rangle (\varphi \wedge \psi)$
- (iv) $[\alpha] (\varphi \rightarrow \psi) \rightarrow ([\alpha] \varphi \rightarrow [\alpha] \psi)$
- (v) $\langle \alpha \rangle (\varphi \wedge \psi) \rightarrow \langle \alpha \rangle \varphi \wedge \langle \alpha \rangle \psi$
- (vi) $[\alpha] \varphi \vee [\alpha] \psi \rightarrow [\alpha] (\varphi \vee \psi)$
- (vii) $\langle \alpha \rangle \mathbf{0} \leftrightarrow \mathbf{0}$
- (viii) $[\alpha] \varphi \leftrightarrow \neg \langle \alpha \rangle \neg \varphi$.
- (ix) $\langle \alpha \cup \beta \rangle \varphi \leftrightarrow \langle \alpha \rangle \varphi \vee \langle \beta \rangle \varphi$
- (x) $[\alpha \cup \beta] \varphi \leftrightarrow [\alpha] \varphi \wedge [\beta] \varphi$
- (xi) $\langle \alpha ; \beta \rangle \varphi \leftrightarrow \langle \alpha \rangle \langle \beta \rangle \varphi$
- (xii) $[\alpha ; \beta] \varphi \leftrightarrow [\alpha] [\beta] \varphi$
- (xiii) $\langle \varphi ? \rangle \psi \leftrightarrow (\varphi \wedge \psi)$
- (xiv) $[\varphi ?] \psi \leftrightarrow (\varphi \rightarrow \psi)$.

THEOREM 7. *The following are sound rules of inference of PDL:*

- (i) *Modal generalization (GEN):*

$$\frac{\varphi}{[\alpha] \varphi}$$

- (ii) *Monotonicity of $\langle \alpha \rangle$:*

$$\frac{\varphi \rightarrow \psi}{\langle \alpha \rangle \varphi \rightarrow \langle \alpha \rangle \psi}$$

(iii) *Monotonicity of $[\alpha]$* :

$$\frac{\varphi \rightarrow \psi}{[\alpha]\varphi \rightarrow [\alpha]\psi}$$

The *converse operator* $^-$ is a program operator with semantics

$$\mathfrak{m}_{\mathfrak{R}}(\alpha^-) = \mathfrak{m}_{\mathfrak{R}}(\alpha)^- = \{(v, u) \mid (u, v) \in \mathfrak{m}_{\mathfrak{R}}(\alpha)\}.$$

Intuitively, the converse operator allows us to “run a program backwards;” semantically, the input/output relation of the program α^- is the output/input relation of α . Although this is not always possible to realize in practice, it is nevertheless a useful expressive tool. For example, it gives us a convenient way to talk about *backtracking*, or rolling back a computation to a previous state.

THEOREM 8. *For any programs α and β ,*

- (i) $\mathfrak{m}_{\mathfrak{R}}((\alpha \cup \beta)^-) = \mathfrak{m}_{\mathfrak{R}}(\alpha^- \cup \beta^-)$
- (ii) $\mathfrak{m}_{\mathfrak{R}}((\alpha ; \beta)^-) = \mathfrak{m}_{\mathfrak{R}}(\beta^- ; \alpha^-)$
- (iii) $\mathfrak{m}_{\mathfrak{R}}(\varphi?^-) = \mathfrak{m}_{\mathfrak{R}}(\varphi?)$
- (iv) $\mathfrak{m}_{\mathfrak{R}}(\alpha^{*-}) = \mathfrak{m}_{\mathfrak{R}}(\alpha^{-*})$
- (v) $\mathfrak{m}_{\mathfrak{R}}(\alpha^{--}) = \mathfrak{m}_{\mathfrak{R}}(\alpha)$.

THEOREM 9. *The following are valid formulas of PDL:*

- (i) $\varphi \rightarrow [\alpha]\langle\alpha^-\rangle\varphi$
- (ii) $\varphi \rightarrow [\alpha^-]\langle\alpha\rangle\varphi$
- (iii) $\langle\alpha\rangle[\alpha^-]\varphi \rightarrow \varphi$
- (iv) $\langle\alpha^-\rangle[\alpha]\varphi \rightarrow \varphi$.

The iteration operator * is interpreted as the reflexive transitive closure operator on binary relations. It is the means by which iteration is coded in PDL. This operator differs from the other operators in that it is infinitary in nature, as reflected by its semantics:

$$\mathfrak{m}_{\mathfrak{R}}(\alpha^*) = \mathfrak{m}_{\mathfrak{R}}(\alpha)^* = \bigcup_{n < \omega} \mathfrak{m}_{\mathfrak{R}}(\alpha)^n$$

(see Section 2.2). This introduces a level of complexity to PDL beyond the other operators. Because of it, PDL is not compact: the set

$$(9) \quad \{\langle\alpha^*\rangle\varphi\} \cup \{\neg\varphi, \neg\langle\alpha\rangle\varphi, \neg\langle\alpha^2\rangle\varphi, \dots\}$$

is finitely satisfiable but not satisfiable. Because of this infinitary behavior, it is rather surprising that PDL should be decidable and that there should be a finitary complete axiomatization.

The properties of the $*$ operator of PDL come directly from the properties of the reflexive transitive closure operator $*$ on binary relations. In a nutshell, for any binary relation R , R^* is the \subseteq -least reflexive and transitive relation containing R .

THEOREM 10. *The following are valid formulas of PDL:*

- (i) $[\alpha^*]\varphi \rightarrow \varphi$
- (ii) $\varphi \rightarrow \langle \alpha^* \rangle \varphi$
- (iii) $[\alpha^*]\varphi \rightarrow [\alpha]\varphi$
- (iv) $\langle \alpha \rangle \varphi \rightarrow \langle \alpha^* \rangle \varphi$
- (v) $[\alpha^*]\varphi \leftrightarrow [\alpha^*\alpha^*]\varphi$
- (vi) $\langle \alpha^* \rangle \varphi \leftrightarrow \langle \alpha^*\alpha^* \rangle \varphi$
- (vii) $[\alpha^*]\varphi \leftrightarrow [\alpha^{**}]\varphi$
- (viii) $\langle \alpha^* \rangle \varphi \leftrightarrow \langle \alpha^{**} \rangle \varphi$
- (ix) $[\alpha^*]\varphi \leftrightarrow \varphi \wedge [\alpha][\alpha^*]\varphi.$
- (x) $\langle \alpha^* \rangle \varphi \leftrightarrow \varphi \vee \langle \alpha \rangle \langle \alpha^* \rangle \varphi.$
- (xi) $[\alpha^*]\varphi \leftrightarrow \varphi \wedge [\alpha^*](\varphi \rightarrow [\alpha]\varphi).$
- (xii) $\langle \alpha^* \rangle \varphi \leftrightarrow \varphi \vee \langle \alpha^* \rangle (\neg \varphi \wedge \langle \alpha \rangle \varphi).$

Semantically, α^* is a reflexive and transitive relation containing α , and Theorem 10 captures this. That α^* is reflexive is captured in (ii); that it is transitive is captured in (vi); and that it contains α is captured in (iv). These three properties are captured by the single property (x).

Reflexive Transitive Closure and Induction

To prove properties of iteration, it is not enough to know that α^* is a reflexive and transitive relation containing α . So is the universal relation $K \times K$, and that is not very interesting. We also need some way of capturing the idea that α^* is the *least* reflexive and transitive relation containing α . There are several equivalent ways this can be done:

(RTC) The *reflexive transitive closure rule*:

$$\frac{(\varphi \vee \langle \alpha \rangle \psi) \rightarrow \psi}{\langle \alpha^* \rangle \varphi \rightarrow \psi}$$

(LI) The *loop invariance rule*:

$$\frac{\psi \rightarrow [\alpha] \psi}{\psi \rightarrow [\alpha^*] \psi}$$

(IND) The *induction axiom* (box form):

$$\varphi \wedge [\alpha^*](\varphi \rightarrow [\alpha] \varphi) \rightarrow [\alpha^*] \varphi$$

(IND) The *induction axiom* (diamond form):

$$\langle \alpha^* \rangle \varphi \rightarrow \varphi \vee \langle \alpha^* \rangle (\neg \varphi \wedge \langle \alpha \rangle \varphi)$$

The rule (RTC) is called the *reflexive transitive closure rule*. Its importance is best described in terms of its relationship to the valid PDL formula of Theorem 10(x). Observe that the right-to-left implication of this formula is obtained by substituting $\langle \alpha^* \rangle \varphi$ for R in the expression

$$(10) \quad \varphi \vee \langle \alpha \rangle R \rightarrow R.$$

Theorem 10(x) implies that $\langle \alpha^* \rangle \varphi$ is a solution of (10); that is, (10) is valid when $\langle \alpha^* \rangle \varphi$ is substituted for R . The rule (RTC) says that $\langle \alpha^* \rangle \varphi$ is the *least* such solution with respect to logical implication. That is, it is the least PDL-definable set of states that when substituted for R in (10) results in a valid formula.

The dual propositions labeled (IND) are jointly called the PDL *induction axiom*. Intuitively, the box form of (IND) says, “If φ is true initially, and if, after any number of iterations of the program α , the truth of φ is preserved by one more iteration of α , then φ will be true after any number of iterations of α .” The diamond form of (IND) says, “If it is possible to reach a state satisfying φ in some number of iterations of α , then either φ is true now, or it is possible to reach a state in which φ is false but becomes true after one more iteration of α .”

Note that the box form of (IND) bears a strong resemblance to the induction axiom of Peano arithmetic:

$$\varphi(0) \wedge \forall n (\varphi(n) \rightarrow \varphi(n+1)) \rightarrow \forall n \varphi(n).$$

Here $\varphi(0)$ is the basis of the induction and $\forall n (\varphi(n) \rightarrow \varphi(n+1))$ is the induction step, from which the conclusion $\forall n \varphi(n)$ can be drawn. In the PDL axiom (IND), the basis is φ and the induction step is $[\alpha^*](\varphi \rightarrow [\alpha]\varphi)$, from which the conclusion $[\alpha^*]\varphi$ can be drawn.

2.6 Encoding Hoare Logic

The Hoare partial correctness assertion $\{\varphi\} \alpha \{\psi\}$ is encoded as $\varphi \rightarrow [\alpha]\psi$ in PDL. The following theorem says that under this encoding, Dynamic Logic subsumes Hoare Logic.

THEOREM 11. *The following rules of Hoare Logic are derivable in PDL:*

(i) *Composition rule:*

$$\frac{\{\varphi\} \alpha \{\sigma\}, \{\sigma\} \beta \{\psi\}}{\{\varphi\} \alpha; \beta \{\psi\}}$$

(ii) *Conditional rule:*

$$\frac{\{\varphi \wedge \sigma\} \alpha \{\psi\}, \{\neg\varphi \wedge \sigma\} \beta \{\psi\}}{\{\sigma\} \text{ if } \varphi \text{ then } \alpha \text{ else } \beta \{\psi\}}$$

(iii) **While rule:**

$$\frac{\{\varphi \wedge \psi\} \alpha \{\psi\}}{\{\psi\} \text{ while } \varphi \text{ do } \alpha \{\neg\varphi \wedge \psi\}}$$

(iv) *Weakening rule:*

$$\frac{\varphi' \rightarrow \varphi, \{\varphi\} \alpha \{\psi\}, \psi \rightarrow \psi'}{\{\varphi'\} \alpha \{\psi'\}}$$

3 FILTRATION AND DECIDABILITY

The *small model property* for PDL says that if φ is satisfiable, then it is satisfied at a state in a Kripke frame with no more than $2^{|\varphi|}$ states, where $|\varphi|$ is the number of symbols of φ . This result and the technique used to prove it, called *filtration*, come directly from modal logic. This immediately gives a naive decision procedure for the satisfiability problem for PDL: to determine whether φ is satisfiable, construct all Kripke frames with at most $2^{|\varphi|}$ states and check whether φ is satisfied at some state in one of them. Considering only interpretations of the primitive formulas and primitive programs appearing in φ , there are roughly $2^{2^{|\varphi|}}$ such models, so this algorithm is too inefficient to be practical. A more efficient algorithm will be described in Section 5.

3.1 The Fischer–Ladner Closure

Many proofs in simpler modal systems use induction on the well-founded subformula relation. In PDL, the situation is complicated by the simultaneous inductive definitions of programs and propositions and by the behavior of the $*$ operator, which make the induction proofs somewhat tricky. Nevertheless, we can still use the well-founded subexpression relation in inductive proofs. Here an *expression* can be either a program or a proposition. Either one can be a subexpression of the other because of the mixed operators $[]$ and $?$.

We start by defining two functions

$$\begin{aligned} FL & : \Phi \rightarrow 2^\Phi \\ FL^\square & : \{[\alpha]\varphi \mid \alpha \in \Psi, \varphi \in \Phi\} \rightarrow 2^\Phi \end{aligned}$$

by simultaneous induction. The set $FL(\varphi)$ is called the *Fischer–Ladner closure* of φ . The filtration construction for PDL uses the Fischer–Ladner closure of a given formula where the corresponding proof for propositional modal logic would use the set of subformulas.

The functions FL and FL^\square are defined inductively as follows:

- (a) $FL(p) \stackrel{\text{def}}{=} \{p\}$, p an atomic proposition
- (b) $FL(\varphi \rightarrow \psi) \stackrel{\text{def}}{=} \{\varphi \rightarrow \psi\} \cup FL(\varphi) \cup FL(\psi)$
- (c) $FL(\mathbf{0}) \stackrel{\text{def}}{=} \{\mathbf{0}\}$
- (d) $FL([\alpha]\varphi) \stackrel{\text{def}}{=} FL^\square([\alpha]\varphi) \cup FL(\varphi)$
- (e) $FL^\square([a]\varphi) \stackrel{\text{def}}{=} \{[a]\varphi\}$, a an atomic program

- (f) $FL^\square([\alpha \cup \beta]\varphi) \stackrel{\text{def}}{=} \{[\alpha \cup \beta]\varphi\} \cup FL^\square([\alpha]\varphi) \cup FL^\square([\beta]\varphi)$
- (g) $FL^\square([\alpha ; \beta]\varphi) \stackrel{\text{def}}{=} \{[\alpha ; \beta]\varphi\} \cup FL^\square([\alpha][\beta]\varphi) \cup FL^\square([\beta]\varphi)$
- (h) $FL^\square([\alpha^*]\varphi) \stackrel{\text{def}}{=} \{[\alpha^*]\varphi\} \cup FL^\square([\alpha][\alpha^*]\varphi)$
- (i) $FL^\square([\psi?]\varphi) \stackrel{\text{def}}{=} \{[\psi?]\varphi\} \cup FL(\psi).$

This definition is apparently quite a bit more involved than for mere subexpressions. In fact, at first glance it may appear circular because of the rule (h). The auxiliary function FL^\square is introduced for the express purpose of avoiding any such circularity. It is defined only for formulas of the form $[\alpha]\varphi$ and intuitively produces those elements of $FL([\alpha]\varphi)$ obtained by breaking down α and ignoring φ .

LEMMA 12.

- (i) *If $[\alpha]\psi \in FL(\varphi)$, then $\psi \in FL(\varphi)$.*
- (ii) *If $[\rho?]\psi \in FL(\varphi)$, then $\rho \in FL(\varphi)$.*
- (iii) *If $[\alpha \cup \beta]\psi \in FL(\varphi)$, then $[\alpha]\psi \in FL(\varphi)$ and $[\beta]\psi \in FL(\varphi)$.*
- (iv) *If $[\alpha ; \beta]\psi \in FL(\varphi)$, then $[\alpha][\beta]\psi \in FL(\varphi)$ and $[\beta]\psi \in FL(\varphi)$.*
- (v) *If $[\alpha^*]\psi \in FL(\varphi)$, then $[\alpha][\alpha^*]\psi \in FL(\varphi)$.*

Even after convincing ourselves that the definition is noncircular, it may not be clear how the size of $FL(\varphi)$ depends on the length of φ . Indeed, the right-hand side of rule (h) involves a formula that is larger than the formula on the left-hand side. However, it can be shown by induction on subformulas that the relationship is linear:

LEMMA 13.

- (i) *For any formula φ , $\#FL(\varphi) \leq |\varphi|$.*
- (ii) *For any formula $[\alpha]\varphi$, $\#FL^\square([\alpha]\varphi) \leq |\alpha|$.*

3.2 Filtration

Given a PDL proposition φ and a Kripke frame $\mathfrak{K} = (K, \mathfrak{m}_{\mathfrak{K}})$, we define a new frame $\mathfrak{K}/FL(\varphi) = (K/FL(\varphi), \mathfrak{m}_{\mathfrak{K}/FL(\varphi)})$, called the *filtration of \mathfrak{K} by $FL(\varphi)$* , as follows. Define a binary relation \equiv on states of \mathfrak{K} by:

$$u \equiv v \stackrel{\text{def}}{\iff} \forall \psi \in FL(\varphi) (u \in \mathfrak{m}_{\mathfrak{K}}(\psi) \iff v \in \mathfrak{m}_{\mathfrak{K}}(\psi)).$$

In other words, we collapse states u and v if they are not distinguishable by any formula of $FL(\varphi)$. Let

$$\begin{aligned} [u] &\stackrel{\text{def}}{=} \{v \mid v \equiv u\} \\ K/FL(\varphi) &\stackrel{\text{def}}{=} \{[u] \mid u \in K\} \\ \mathfrak{m}_{\mathfrak{K}/FL(\varphi)}(p) &\stackrel{\text{def}}{=} \{[u] \mid u \in \mathfrak{m}_{\mathfrak{K}}(p)\}, \quad p \text{ an atomic proposition} \\ \mathfrak{m}_{\mathfrak{K}/FL(\varphi)}(a) &\stackrel{\text{def}}{=} \{([u], [v]) \mid (u, v) \in \mathfrak{m}_{\mathfrak{K}}(a)\}, \quad a \text{ an atomic program.} \end{aligned}$$

The map $\mathfrak{m}_{\mathfrak{K}/FL(\varphi)}$ is extended inductively to compound propositions and programs as described in Section 2.2.

The following key lemma relates \mathfrak{K} and $\mathfrak{K}/FL(\varphi)$. Most of the difficulty in the following lemma is in the correct formulation of the induction hypotheses in the statement of the lemma. Once this is done, the proof is a fairly straightforward induction on the well-founded subexpression relation.

LEMMA 14 (Filtration Lemma). *Let \mathfrak{K} be a Kripke frame and let u, v be states of \mathfrak{K} .*

- (i) *For all $\psi \in FL(\varphi)$, $u \in \mathfrak{m}_{\mathfrak{K}}(\psi)$ iff $[u] \in \mathfrak{m}_{\mathfrak{K}/FL(\varphi)}(\psi)$.*
- (ii) *For all $[\alpha]\psi \in FL(\varphi)$,*
 - (a) *if $(u, v) \in \mathfrak{m}_{\mathfrak{K}}(\alpha)$ then $([u], [v]) \in \mathfrak{m}_{\mathfrak{K}/FL(\varphi)}(\alpha)$;*
 - (b) *if $([u], [v]) \in \mathfrak{m}_{\mathfrak{K}/FL(\varphi)}(\alpha)$ and $u \in \mathfrak{m}_{\mathfrak{K}}([\alpha]\psi)$, then $v \in \mathfrak{m}_{\mathfrak{K}}(\psi)$.*

Using the filtration lemma, we can prove the small model theorem easily.

THEOREM 15 (Small Model Theorem). *Let φ be a satisfiable formula of PDL. Then φ is satisfied in a Kripke frame with no more than $2^{|\varphi|}$ states.*

Proof. If φ is satisfiable, then there is a Kripke frame \mathfrak{K} and state $u \in \mathfrak{K}$ with $u \in \mathfrak{m}_{\mathfrak{K}}(\varphi)$. Let $FL(\varphi)$ be the Fischer-Ladner closure of φ . By the filtration lemma (Lemma 14), $[u] \in \mathfrak{m}_{\mathfrak{K}/FL(\varphi)}(\varphi)$. Moreover, $\mathfrak{K}/FL(\varphi)$ has no more states than the number of truth assignments to formulas in $FL(\varphi)$, which by Lemma 13(i) is at most $2^{|\varphi|}$. ■

It follows immediately that the satisfiability problem for PDL is decidable, since there are only finitely many possible Kripke frames of size at most $2^{|\varphi|}$ to check, and there is a polynomial-time algorithm to check whether a given formula is satisfied at a given state in a given Kripke frame. A more efficient algorithm exists (see Section 5).

The completeness proof for PDL also makes use of the filtration lemma (Lemma 14), but in a somewhat stronger form. We need to know that it also holds for *nonstandard Kripke frames* as well as the standard Kripke frames defined in Section 2.2.

A *nonstandard Kripke frame* is any structure $\mathfrak{N} = (N, m_{\mathfrak{N}})$ that is a Kripke frame in the sense of Section 2.2 in every respect, except that $m_{\mathfrak{N}}(\alpha^*)$ need not be the reflexive transitive closure of $m_{\mathfrak{N}}(\alpha)$, but only a reflexive, transitive binary relation containing $m_{\mathfrak{N}}(\alpha)$ satisfying the PDL axioms for $*$ (Axioms 17(vii) and (viii) of Section 4.1).

LEMMA 16 (Filtration for Nonstandard Models). *Let \mathfrak{N} be a nonstandard Kripke frame and let u, v be states of \mathfrak{N} .*

- (i) *For all $\psi \in FL(\varphi)$, $u \in m_{\mathfrak{N}}(\psi)$ iff $[u] \in m_{\mathfrak{N}/FL(\varphi)}(\psi)$.*
- (ii) *For all $[\alpha]\psi \in FL(\varphi)$,*
 - (a) *if $(u, v) \in m_{\mathfrak{N}}(\alpha)$ then $([u], [v]) \in m_{\mathfrak{N}/FL(\varphi)}(\alpha)$;*
 - (b) *if $([u], [v]) \in m_{\mathfrak{N}/FL(\varphi)}(\alpha)$ and $u \in m_{\mathfrak{N}}([\alpha]\psi)$, then $v \in m_{\mathfrak{N}}(\psi)$.*

4 DEDUCTIVE COMPLETENESS OF PDL

4.1 A Deductive System

The following list of axioms and rules constitutes a sound and complete Hilbert-style deductive system for PDL.

Axiom System 17.

- (i) *Axioms for propositional logic*
- (ii) $[\alpha](\varphi \rightarrow \psi) \rightarrow ([\alpha]\varphi \rightarrow [\alpha]\psi)$
- (iii) $[\alpha](\varphi \wedge \psi) \leftrightarrow [\alpha]\varphi \wedge [\alpha]\psi$
- (iv) $[\alpha \cup \beta]\varphi \leftrightarrow [\alpha]\varphi \wedge [\beta]\varphi$
- (v) $[\alpha; \beta]\varphi \leftrightarrow [\alpha][\beta]\varphi$
- (vi) $[\psi?]\varphi \leftrightarrow (\psi \rightarrow \varphi)$
- (vii) $\varphi \wedge [\alpha][\alpha^*]\varphi \leftrightarrow [\alpha^*]\varphi$
- (viii) $\varphi \wedge [\alpha^*](\varphi \rightarrow [\alpha]\varphi) \rightarrow [\alpha^*]\varphi$

In PDL with converse $^-$, we also include

- (ix) $\varphi \rightarrow [\alpha]\langle\alpha^- \rangle\varphi$
- (x) $\varphi \rightarrow [\alpha^-]\langle\alpha \rangle\varphi$

Rules of Inference

$$(MP) \quad \frac{\varphi, \varphi \rightarrow \psi}{\psi}$$

$$(GEN) \quad \frac{\varphi}{[\alpha]\varphi}$$

□

The axioms (ii) and (iii) and the two rules of inference are not particular to PDL, but come from modal logic. The rules (MP) and (GEN) are called *modus ponens* and (*modal*) *generalization*, respectively.

Axiom (viii) is called the *PDL induction axiom*. Intuitively, (viii) says: “Suppose φ is true in the current state, and suppose that after any number of iterations of α , if φ is still true, then it will be true after one more iteration of α . Then φ will be true after any number of iterations of α .” In other words, if φ is true initially, and if the truth of φ is preserved by the program α , then φ will be true after any number of iterations of α .

We write $\vdash \varphi$ if the proposition φ is a theorem of this system, and say that φ is *consistent* if $\not\vdash \neg\varphi$; that is, if it is not the case that $\vdash \neg\varphi$. A set Σ of propositions is *consistent* if all finite conjunctions of elements of Σ are consistent.

The soundness of these axioms and rules over Kripke frames can be established by elementary arguments in relational algebra using the semantics of Section 2.2.

We write $\vdash \varphi$ if the formula φ is provable in this deductive system. A formula φ is *consistent* if $\not\vdash \neg\varphi$, that is, if it is not the case that $\vdash \neg\varphi$; that a finite set Σ of formulas is *consistent* if its conjunction $\bigwedge \Sigma$ is consistent; and that an infinite set of formulas is *consistent* if every finite subset is consistent.

Axiom System 17 is complete: all valid formulas of PDL are theorems. This fact can be proved by constructing a nonstandard Kripke frame from maximal consistent sets of formulas, then using the filtration lemma for nonstandard models (Lemma 16) to collapse this nonstandard model to a finite standard model.

THEOREM 18 (Completeness of PDL). *If $\models \varphi$ then $\vdash \varphi$.*

In classical logics, a completeness theorem of the form of Theorem 18 can be adapted to handle the relation of logical consequence $\varphi \models \psi$ between formulas because of the deduction theorem, which says

$$\varphi \vdash \psi \Leftrightarrow \vdash \varphi \rightarrow \psi.$$

Unfortunately, the deduction theorem fails in PDL, as can be seen by taking $\psi = [a]p$ and $\varphi = p$. However, the following result allows Theorem

18, as well as the deterministic exponential-time satisfiability algorithm described in the next section, to be extended to handle the logical consequence relation:

THEOREM 19. *Let φ and ψ be any PDL formulas. Then*

$$\varphi \models \psi \Leftrightarrow \models [(a_1 \cup \dots \cup a_n)^*] \varphi \rightarrow \psi,$$

where a_1, \dots, a_n are all atomic programs appearing in φ or ψ . Allowing infinitary conjunctions, if Σ is a set of formulas in which only finitely many atomic programs appear, then

$$\Sigma \models \psi \Leftrightarrow \models \bigwedge \{[(a_1 \cup \dots \cup a_n)^*] \varphi \mid \varphi \in \Sigma\} \rightarrow \psi,$$

where a_1, \dots, a_n are all atomic programs appearing in Σ or ψ .

5 COMPLEXITY OF PDL

The small model theorem (Theorem 15) gives a naive deterministic algorithm for the satisfiability problem: construct all Kripke frames of at most $2^{|\varphi|}$ states and check whether φ is satisfied at any state in any of them. Although checking whether a given formula is satisfied in a given state of a given Kripke frame can be done quite efficiently, the naive satisfiability algorithm is highly inefficient. For one thing, the models constructed are of exponential size in the length of the given formula; for another, there are $2^{2^{O(|\varphi|)}}$ of them. Thus the naive satisfiability algorithm takes double exponential time in the worst case.

There is a more efficient algorithm [Pratt, 1979b] that runs in deterministic single-exponential time. One cannot expect to improve this significantly due to a corresponding lower bound.

THEOREM 20. *There is an exponential-time algorithm for deciding whether a given formula of PDL is satisfiable.*

THEOREM 21. *The satisfiability problem for PDL is EXPTIME-complete.*

COROLLARY 22. *There is a constant $c > 1$ such that the satisfiability problem for PDL is not solvable in deterministic time $c^{n/\log n}$, where n is the size of the input formula.*

EXPTIME-hardness can be established by constructing a formula of PDL whose models encode the computation of a given linear-space-bounded one-tape alternating Turing machine M on a given input x of length n over M 's input alphabet. Since the membership problem for alternating polynomial-space machines is EXPTIME-hard [Chandra *et al.*, 1981], so is the satisfiability problem for PDL.

It is interesting to compare the complexity of satisfiability in PDL with the complexity of satisfiability in propositional logic. In the latter, satisfiability is *NP*-complete; but at present it is not known whether the two complexity classes *EXPTIME* and *NP* differ. Thus, as far as current knowledge goes, the satisfiability problem is no easier in the worst case for propositional logic than for its far richer superset PDL.

As we have seen, current knowledge does not permit a significant difference to be observed between the complexity of satisfiability in propositional logic and in PDL. However, there is one easily verified and important behavioral difference: propositional logic is *compact*, whereas PDL is not.

Compactness has significant implications regarding the relation of logical consequence. If a propositional formula φ is a consequence of a set Γ of propositional formulas, then it is already a consequence of some finite subset of Γ ; but this is not true in PDL.

Recall that we write $\Gamma \models \varphi$ and say that φ is a *logical consequence* of Γ if φ is satisfied in any state of any Kripke frame \mathfrak{K} all of whose states satisfy all the formulas of Γ . That is, if $\mathfrak{K} \models \Gamma$, then $\mathfrak{K} \models \varphi$.

An alternative interpretation of logical consequence, not equivalent to the above, is that in any Kripke frame, the formula φ holds in any state satisfying all formulas in Γ . Allowing infinite conjunctions, we might write this as $\models \bigwedge \Gamma \rightarrow \varphi$. This is not the same as $\Gamma \models \varphi$, since $\models \bigwedge \Gamma \rightarrow \varphi$ implies $\Gamma \models \varphi$, but not necessarily vice versa. A counterexample is provided by $\Gamma = \{p\}$ and $\varphi = [a]p$. However, if Γ contains only finitely many atomic programs, we can reduce the problem $\Gamma \models \varphi$ to the problem $\models \bigwedge \Gamma' \rightarrow \varphi$ for a related Γ' , as shown in Theorem 19.

Under either interpretation, compactness fails:

THEOREM 23. *There is an infinite set of formulas Γ and a formula φ such that $\models \bigwedge \Gamma \rightarrow \varphi$ (hence $\Gamma \models \varphi$), but for no proper subset $\Gamma' \subsetneq \Gamma$ is it the case that $\Gamma' \models \varphi$ (hence neither is it the case that $\models \bigwedge \Gamma' \rightarrow \varphi$).*

As shown in Theorem 19, logical consequences $\Gamma \models \varphi$ for finite Γ are no more difficult to decide than validity of single formulas. But what if Γ is infinite? Here compactness is the key factor. If Γ is an r.e. set and the logic is compact, then the consequence problem is r.e.: to check whether $\Gamma \models \varphi$, the finite subsets of Γ can be effectively enumerated, and checking $\Gamma \models \varphi$ for finite Γ is a decidable problem.

Since compactness fails in PDL, this observation does us no good, even when Γ is known to be recursively enumerable. However, the following result shows that the situation is much worse than we might expect: even if Γ is taken to be the set of substitution instances of a single formula of PDL, the consequence problem becomes very highly undecidable. This is a rather striking manifestation of PDL's lack of compactness.

Let φ be a given formula. The set S_φ of *substitution instances* of φ is the set of all formulas obtained by substituting a formula for each atomic proposition appearing in φ .

THEOREM 24. *The problem of deciding whether $S_\varphi \models \psi$ is Π_1^1 -complete. The problem is Π_1^1 -hard even for a particular fixed φ .*

6 NONREGULAR PDL

In this section we enrich the class of regular programs in PDL by introducing programs whose control structure requires more than a finite automaton. For example, the class of *context-free programs* requires a pushdown automaton (PDA), and moving up from regular to context-free programs is really going from iterative programs to ones with parameterless recursive procedures. Several questions arise when enriching the class of programs of PDL, such as whether the expressive power of the logic grows, and if so whether the resulting logics are still decidable. It turns out that *any* nonregular program increases PDL's expressive power and that the validity problem for PDL with context-free programs is undecidable. The bulk of the section is then devoted to the difficult problem of trying to characterize the borderline between decidable and undecidable extensions. On the one hand, validity for PDL with the addition of even a single extremely simple nonregular program is already Π_1^1 -complete; but on the other hand, when we add another equally simple program, the problem remains decidable. Besides these results, which pertain to very specific extensions, we discuss some broad decidability results that cover many languages, including some that are not even context-free. Since no similarly general undecidability results are known, we also address the weaker issue of whether nonregular extensions admit the finite model property and present a negative result that covers many cases.

6.1 Nonregular Programs

Consider the following self-explanatory program:

(11) **while** p **do** a ; **now do** b **the same number of times**

This program is meant to represent the following set of computation sequences:

$$\{(p? ; a)^i ; \neg p? ; b^i \mid i \geq 0\}.$$

Viewed as a language over the alphabet $\{a, b, p, \neg p\}$, this set is not regular, thus cannot be programmed in PDL. However, it can be represented by the following parameterless recursive procedure:

```

proc  $V$  {
  if  $p$  then {  $a$ ; call  $V$ ;  $b$  }
  else return
}

```

The set of computation sequences of this program is captured by the context-free grammar

$$V \rightarrow \neg p? \mid p?aVb.$$

We are thus led to the idea of allowing context-free programs inside the boxes and diamonds of PDL. From a pragmatic point of view, this amounts to extending the logic with the ability to reason about parameterless recursive procedures. The particular representation of the context-free programs is unimportant; we can use pushdown automata, context-free grammars, recursive procedures, or any other formalism that can be effectively translated into these.

In the rest of this section, a number of specific programs will be of interest, and we employ special abbreviations for them. For example, we define:

$$\begin{aligned}
 a^\Delta b a^\Delta &\stackrel{\text{def}}{=} \{a^i b a^i \mid i \geq 0\} \\
 a^\Delta b^\Delta &\stackrel{\text{def}}{=} \{a^i b^i \mid i \geq 0\} \\
 b^\Delta a^\Delta &\stackrel{\text{def}}{=} \{b^i a^i \mid i \geq 0\}.
 \end{aligned}$$

Note that $a^\Delta b^\Delta$ is really just a nondeterministic version of the program (11) in which there is simply no p to control the iteration. In fact, (11) could have been written in this notation as $(p?a)^\Delta \neg p?b^\Delta$.² In programming terms, we can compare the regular program $(ab)^*$ with the nonregular one $a^\Delta b^\Delta$ by observing that if a is “purchase a loaf of bread” and b is “pay \$1.00,” then the former program captures the process of paying for each loaf when purchased, while the latter one captures the process of paying for them all at the end of the month.

It turns out that enriching PDL with even a single arbitrary nonregular program increases expressive power.

If L is any language over atomic programs and tests, then $\text{PDL} + L$ is defined exactly as PDL, but with the additional syntax rule stating that for any formula φ , the expression $\langle L \rangle \varphi$ is a new formula. The semantics of $\text{PDL} + L$ is like that of PDL with the addition of the clause

$$m_{\bar{R}}(L) \stackrel{\text{def}}{=} \bigcup_{\beta \in L} m_{\bar{R}}(\beta).$$

²It is noteworthy that the results of this section do not depend on nondeterminism. For example, the negative Theorem 28 holds for the deterministic version (11) too. Also, most of the results in this section involve nonregular programs over atomic programs only, but can be generalized to allow tests as well.

Note that $\text{PDL} + L$ does not allow L to be used as a formation rule for new programs or to be combined with other programs. It is added to the programming language as a single new stand-alone program only.

If PDL_1 and PDL_2 are two extensions of PDL , we say that PDL_1 is *as expressive as* PDL_2 if for each formula φ of PDL_2 there is a formula ψ of PDL_1 such that $\models \varphi \leftrightarrow \psi$. If PDL_1 is as expressive as PDL_2 but PDL_2 is not as expressive as PDL_1 , we say that PDL_1 is *strictly more expressive than* PDL_2 .

Thus, one version of PDL is strictly more expressive than another if anything the latter can express the former can too, but there is something the former can express that the latter cannot.

A language is *test-free* if it is a subset of Π_0^* ; that is, if its seqs contain no tests.

THEOREM 25. *If L is any nonregular test-free language, then $\text{PDL} + L$ is strictly more expressive than PDL .*

We can view the decidability of regular PDL as showing that propositional-level reasoning about iterative programs is computable. We now wish to know if the same is true for recursive procedures. We define *context-free* PDL to be PDL extended with context-free programs, where a *context-free program* is one whose seqs form a context-free language. The precise syntax is unimportant, but for definiteness we might take as programs the set of context-free grammars G over atomic programs and tests and define

$$\mathfrak{m}_{\mathfrak{R}}(G) \stackrel{\text{def}}{=} \bigcup_{\beta \in CS(G)} \mathfrak{m}_{\mathfrak{R}}(\beta),$$

where $CS(G)$ is the set of computation sequences generated by G as described in Section 1.3.

THEOREM 26. *The validity problem for context-free PDL is undecidable.*

Theorem 26 leaves several interesting questions unanswered. What is the level of undecidability of context-free PDL ? What happens if we want to add only a small number of specific nonregular programs? The first of these questions arises from the fact that the equivalence problem for context-free languages is co-r.e.-complete, or complete for Π_1^0 in the arithmetic hierarchy. Hence, all Theorem 26 shows is that the validity problem for context-free PDL is Π_1^0 -hard, while it might in fact be worse. The second question is far more general. We might be interested in reasoning only about deterministic or linear context-free programs,³ or we might be interested only in a few special context-free programs such as $a^\Delta b a^\Delta$ or $a^\Delta b^\Delta$. Perhaps PDL

³A *linear program* is one whose seqs are generated by a context-free grammar in which there is at most one nonterminal symbol on the right-hand side of each rule. This corresponds to a family of recursive procedures in which there is at most one recursive call in each procedure.

remains decidable when these programs are added. The general question is to determine the borderline between the decidable and the undecidable when it comes to enriching the class of programs allowed in PDL.

Interestingly, if we wish to consider such simple nonregular extensions as $\text{PDL} + a^\Delta b a^\Delta$ or $\text{PDL} + a^\Delta b^\Delta$, we will not be able to prove undecidability by the technique used for context-free PDL in Theorem 26, since standard problems that are undecidable for context-free languages, such as equivalence and inclusion, are decidable for classes containing the regular languages and the likes of $a^\Delta b a^\Delta$ and $a^\Delta b^\Delta$. Moreover, we cannot prove decidability by the technique used for PDL in Section 3.2, since logics like $\text{PDL} + a^\Delta b a^\Delta$ and $\text{PDL} + a^\Delta b^\Delta$ do not enjoy the finite model property. Thus, if we want to determine the decidability status of such extensions, we will have to work harder.

THEOREM 27. *There is a satisfiable formula in $\text{PDL} + a^\Delta b^\Delta$ that is not satisfied in any finite structure.*

For $\text{PDL} + a^\Delta b a^\Delta$, the news is worse than mere undecidability:

THEOREM 28. *The validity problem for $\text{PDL} + a^\Delta b a^\Delta$ is Π_1^1 -complete.*

The Π_1^1 result holds also for PDL extended with the two programs $a^\Delta b^\Delta$ and $b^\Delta a^\Delta$.

It is easy to show that the validity problem for context-free PDL in its entirety remains in Π_1^1 . Together with the fact that $a^\Delta b a^\Delta$ is a context-free language, this yields an answer to the first question mentioned earlier: context-free PDL is Π_1^1 -complete. As to the second question, Theorem 28 shows that the high undecidability phenomenon starts occurring even with the addition of one very simple nonregular program.

We now turn to nonregular programs over a single letter. Consider the language of powers of 2:

$$a^{2^*} \stackrel{\text{def}}{=} \{a^{2^i} \mid i \geq 0\}.$$

Here we have:

THEOREM 29. *The validity problem for $\text{PDL} + a^{2^*}$ is undecidable.*

It is actually possible to prove this result for powers of any fixed $k \geq 2$. Thus PDL with the addition of any language of the form $\{a^{k^i} \mid i \geq 0\}$ for fixed $k \geq 2$ is undecidable. Another class of one-letter extensions that has been proven to be undecidable consists of Fibonacci-like sequences:

THEOREM 30. *Let f_0, f_1 be arbitrary elements of \mathbb{N} with $f_0 < f_1$, and let F be the sequence f_0, f_1, f_2, \dots generated by the recurrence $f_i = f_{i-1} + f_{i-2}$ for $i \geq 2$. Let $a^F \stackrel{\text{def}}{=} \{a^{f_i} \mid i \geq 0\}$. Then the validity problem for $\text{PDL} + a^F$ is undecidable.*

In both these theorems, the fact that the sequences of a 's in the programs grow exponentially is crucial to the proofs. Indeed, we know of no

undecidability results for any one-letter extension in which the lengths of the sequences of a 's grow subexponentially. Particularly intriguing are the cases of squares and cubes:

$$\begin{aligned} a^{*2} &\stackrel{\text{def}}{=} \{a^{i^2} \mid i \geq 0\}, \\ a^{*3} &\stackrel{\text{def}}{=} \{a^{i^3} \mid i \geq 0\}. \end{aligned}$$

Are $\text{PDL} + a^{*2}$ and $\text{PDL} + a^{*3}$ undecidable?

There is a decidability result for a slightly restricted version of the squares extension, which seems to indicate that the full unrestricted version $\text{PDL} + a^{*2}$ is decidable too. However, we conjecture that for cubes the problem is undecidable. Interestingly, several classical open problems in number theory reduce to instances of the validity problem for $\text{PDL} + a^{*3}$. For example, while no one knows whether every integer greater than 10000 is the sum of five cubes, the following formula is valid if and only if the answer is yes:

$$[(a^{*3})^5]p \rightarrow [a^{10001}a^*]p.$$

(The 5-fold and 10001-fold iterations have to be written out in full, of course.) If $\text{PDL} + a^{*3}$ were decidable, then we could compute the answer in a simple manner, at least in principle.

6.2 Decidable Extensions

We now turn to positive results. Theorem 27 states that $\text{PDL} + a^\Delta b^\Delta$ does not have the finite model property. Nevertheless, we have the following:

THEOREM 31. *The validity problem for $\text{PDL} + a^\Delta b^\Delta$ is decidable.*

When contrasted with Theorem 28, the decidability of $\text{PDL} + a^\Delta b^\Delta$ is very surprising. We have two of the simplest nonregular languages— $a^\Delta b a^\Delta$ and $a^\Delta b^\Delta$ —which are extremely similar, yet the addition of one to PDL yields high undecidability while the other leaves the logic decidable.

Theorem 31 was proved originally by showing that, although $\text{PDL} + a^\Delta b^\Delta$ does not always admit finite models, it does admit finite *pushdown models*, in which transitions are labeled not only with atomic programs but also with push and pop instructions for a particular kind of stack. A close study of the proof (which relies heavily on the idiosyncrasies of the language $a^\Delta b^\Delta$) suggests that the decidability or undecidability has to do with the manner in which an automaton accepts the languages involved. For example, in the usual way of accepting $a^\Delta b a^\Delta$, a pushdown automaton (PDA) reading an a will carry out a push or a pop, depending upon its location in the input word. However, in the standard way of accepting $a^\Delta b^\Delta$, the a 's are always pushed and the b 's are always popped, regardless of the location; the input symbol alone determines what the automaton does. More recent work, which we now set out to describe, has yielded a general decidability result

that confirms this intuition. It is of special interest due to its generality, since it does not depend on specific programs.

Let $M = (Q, \Sigma, \Gamma, q_0, z_0, \delta)$ be a PDA that accepts by empty stack. We say that M is *simple-minded* if, whenever $\delta(q, \sigma, \gamma) = (p, b)$, then for each q' and γ' , either $\delta(q', \sigma, \gamma') = (p, b)$ or $\delta(q', \sigma, \gamma')$ is undefined. A context-free language is said to be *simple-minded* (a simple-minded CFL) if there exists a simple-minded PDA that accepts it.

In other words, the action of a simple-minded automaton is determined uniquely by the input symbol; the state and stack symbol are only used to help determine whether the machine halts (rejecting the input) or continues. Note that such an automaton is necessarily deterministic.

It is noteworthy that simple-minded PDAs accept a large fragment of the context-free languages, including $a^\Delta b^\Delta$ and $b^\Delta a^\Delta$, as well as all balanced parenthesis languages (Dyck sets) and many of their intersections with regular languages.

THEOREM 32. *If L is accepted by a simple-minded PDA, then $\text{PDL} + L$ is decidable.*

We can obtain another general decidability result involving languages accepted by deterministic stack automata. A stack automaton is a one-way PDA whose head can travel up and down the stack reading its contents, but can make changes only at the top of the stack. Stack automata can accept non-context-free languages such as $a^\Delta b^\Delta c^\Delta$ and its generalizations $a_1^\Delta a_2^\Delta \dots a_n^\Delta$ for any n , as well as many variants thereof. It would be nice to be able to prove decidability of PDL when augmented by any language accepted by such a machine, but this is not known. What has been proven, however, is that if each word in such a language is preceded by a new symbol to mark its beginning, then the enriched PDL is decidable:

THEOREM 33. *Let $e \notin \Pi_0$, and let L be a language over Π_0 that is accepted by a deterministic stack automaton. If we let eL denote the language $\{eu \mid u \in L\}$, then $\text{PDL} + eL$ is decidable.*

While Theorems 32 and 33 are general and cover many languages, they do not prove decidability of $\text{PDL} + a^\Delta b^\Delta c^\Delta$, which may be considered the simplest non-context-free extension of PDL. Nevertheless, the constructions used in the proofs of the two general results have been combined to yield:

THEOREM 34. *$\text{PDL} + a^\Delta b^\Delta c^\Delta$ is decidable.*

As explained, we know of no undecidable extension of PDL with a polynomially growing language, although we conjecture that the cubes extension is undecidable. Since the decidability status of such extensions seems hard to determine, we now address a weaker notion: the presence or absence of a finite model property. The technique used in Theorem 27 to show that $\text{PDL} + a^\Delta b^\Delta$ violates the finite model property does not work for one-letter alphabets. Nevertheless, we now state a general result leading to many one-

letter extensions that violate the finite model property. In particular, the theorem will yield the following:

PROPOSITION 35 (squares and cubes). *The logics $\text{PDL} + a^{*2}$ and $\text{PDL} + a^{*3}$ do not have the finite model property.*

PROPOSITION 36 (polynomials). *For every polynomial of the form*

$$p(n) = c_i n^i + c_{i-1} n^{i-1} + \cdots + c_0 \in \mathbb{Z}[n]$$

with $i \geq 2$ and positive leading coefficient $c_i > 0$, let $S_p = \{p(m) \mid m \in \mathbb{N}\} \cap \mathbb{N}$. Then $\text{PDL} + a^{S_p}$ does not have the finite model property.

PROPOSITION 37 (sums of primes). *Let p_i be the i^{th} prime (with $p_1 = 2$), and define*

$$S_{\text{sop}} \stackrel{\text{def}}{=} \left\{ \sum_{i=1}^n p_i \mid n \geq 1 \right\}.$$

Then $\text{PDL} + a^{S_{\text{sop}}}$ does not have the finite model property.

PROPOSITION 38 (factorials). *Let $S_{\text{fac}} \stackrel{\text{def}}{=} \{n! \mid n \in \mathbb{N}\}$. Then $\text{PDL} + a^{S_{\text{fac}}}$ does not have the finite model property.*

The finite model property fails for any sufficiently fast-growing integer linear recurrence, not just the Fibonacci sequence, although we do not know whether these extensions also render PDL undecidable. A k^{th} -order integer linear recurrence is an inductively defined sequence

$$(12) \quad \ell_n \stackrel{\text{def}}{=} c_1 \ell_{n-1} + \cdots + c_k \ell_{n-k} + c_0, \quad n \geq k,$$

where $k \geq 1$, $c_0, \dots, c_k \in \mathbb{N}$, $c_k \neq 0$, and $\ell_0, \dots, \ell_{k-1} \in \mathbb{N}$ are given.

PROPOSITION 39 (linear recurrences). *Let $S_{\text{lr}} = \{\ell_n \mid n \geq 0\}$ be the set defined inductively by (12). The following conditions are equivalent:*

- (i) $a^{S_{\text{lr}}}$ is nonregular;
- (ii) $\text{PDL} + a^{S_{\text{lr}}}$ does not have the finite model property;
- (iii) not all $\ell_0, \dots, \ell_{k-1}$ are zero and $\sum_{i=1}^k c_i > 1$.

7 OTHER VARIANTS OF PDL

7.1 Deterministic Programs

Nondeterminism arises in PDL in two ways:

- atomic programs can be interpreted in a structure as (not necessarily single-valued) binary relations on states; and

- the programming constructs $\alpha \cup \beta$ and α^* involve nondeterministic choice.

Many modern programming languages have facilities for concurrency and distributed computation, certain aspects of which can be modeled by non-determinism. Nevertheless, the majority of programs written in practice are still deterministic. Here we investigate the effect of eliminating either one or both of these sources of nondeterminism from PDL.

A program α is said to be (*semantically*) *deterministic* in a Kripke frame \mathfrak{K} if its traces are uniquely determined by their first states. If α is an atomic program a , this is equivalent to the requirement that $m_{\mathfrak{K}}(a)$ be a partial function; that is, if both (s, t) and $(s, t') \in m_{\mathfrak{K}}(a)$, then $t = t'$. A *deterministic Kripke frame* $\mathfrak{K} = (K, m_{\mathfrak{K}})$ is one in which all atomic a are semantically deterministic.

The class of *deterministic while programs*, denoted DWP, is the class of programs in which

- the operators \cup , $?$, and $*$ may appear only in the context of the conditional test, **while** loop, **skip**, or **fail**;
- tests in the conditional test and **while** loop are purely propositional; that is, there is no occurrence of the $\langle \rangle$ or $[]$ operators.

The class of *nondeterministic while programs*, denoted WP, is the same, except unconstrained use of the nondeterministic choice construct \cup is allowed. It is easily shown that if α and β are semantically deterministic in \mathfrak{K} , then so are **if** φ **then** α **else** β and **while** φ **do** α .

By restricting either the syntax or the semantics or both, we obtain the following logics:

- DPDL (deterministic PDL), which is syntactically identical to PDL, but interpreted over deterministic structures only;
- SPDL (strict PDL), in which only deterministic **while** programs are allowed; and
- SDPDL (strict deterministic PDL), in which both restrictions are in force.

Validity and satisfiability in DPDL and SDPDL are defined just as in PDL, but with respect to deterministic structures only. If φ is valid in PDL, then φ is also valid in DPDL, but not conversely: the formula

$$(13) \langle a \rangle \varphi \rightarrow [a] \varphi$$

is valid in DPDL but not in PDL. Also, SPDL and SDPDL are strictly less expressive than PDL or DPDL, since the formula

$$(14) \langle (a \cup b)^* \rangle \varphi$$

is not expressible in SPDL, as shown in [Halpern and Reif, 1983].

THEOREM 40. *If the axiom scheme*

$$(15) \langle a \rangle \varphi \rightarrow [a] \varphi, \quad a \in \Pi_0$$

is added to Axiom System 17, then the resulting system is sound and complete for DPDL.

THEOREM 41. *Validity in DPDL is deterministic exponential-time complete.*

Now we turn to SPDL, in which atomic programs can be nondeterministic but can be composed into larger programs only with deterministic constructs.

THEOREM 42. *Validity in SPDL is deterministic exponential-time complete.*

The final version of interest is SDPDL, in which both the syntactic restrictions of SPDL and the semantic ones of DPDL are adopted. The exponential-time lower bound fails here, and we have:

THEOREM 43. *The validity problem for SDPDL is complete in polynomial space.*

The question of relative power of expression is of interest here. Is DPDL < PDL? Is SDPDL < DPDL? The first of these questions is inappropriate, since the syntax of both languages is the same but they are interpreted over different classes of structures. Considering the second, we have:

THEOREM 44. SDPDL < DPDL *and* SPDL < PDL.

In summary, we have the following diagram describing the relations of expressiveness between these logics. The solid arrows indicate added expressive power and broken ones a difference in semantics. The validity problem is exponential-time complete for all but SDPDL, for which it is *PSPACE*-complete. Straightforward variants of Axiom System 17 are complete for all versions.

7.2 Representation by Automata

A PDL program represents a regular set of computation sequences. This same regular set could possibly be represented exponentially more succinctly

by a finite automaton. The difference between these two representations corresponds roughly to the difference between **while** programs and flowcharts.

Since finite automata are exponentially more succinct in general, the upper bound of Section 5 could conceivably fail if finite automata were allowed as programs. Moreover, we must also rework the deductive system of Section 4.1.

However, it turns out that the completeness and exponential-time decidability results of PDL are not sensitive to the representation and still go through in the presence of finite automata as programs, provided the deductive system of Section 4.1 and the techniques of Sections 4 and 5 are suitably modified, as shown in [Pratt, 1979b; Pratt, 1981b] and [Harel and Sherman, 1985].

In recent years, the automata-theoretic approach to logics of programs has yielded significant insight into propositional logics more powerful than PDL, as well as substantial reductions in the complexity of their decision procedures. Especially enlightening are the connections with automata on infinite strings and infinite trees. By viewing a formula as an automaton and a treelike model as an input to that automaton, the satisfiability problem for a given formula becomes the emptiness problem for a given automaton. Logical questions are thereby transformed into purely automata-theoretic questions.

We assume that nondeterministic finite automata are given in the form

$$(16) \quad M = (n, i, j, \delta),$$

where $\bar{n} = \{0, \dots, n-1\}$ is the set of states, $i, j \in \bar{n}$ are the start and final states respectively, and δ assigns a subset of $\Pi_0 \cup \{\varphi? \mid \varphi \in \Phi\}$ to each pair of states. Intuitively, when visiting state ℓ and seeing symbol a , the automaton may move to state k if $a \in \delta(\ell, k)$.

The fact that the automata (16) have only one accept state is without loss of generality. If M is an arbitrary nondeterministic finite automaton with accept states F , then the set accepted by M is the union of the sets accepted by M_k for $k \in F$, where M_k is identical to M except that it has unique accept state k . A desired formula $[M]\varphi$ can be written as a conjunction

$$\bigwedge_{k \in F} [M_k]\varphi$$

with at most quadratic growth.

We now obtain a new logic APDL (*automata* PDL) by defining Φ and Π inductively using the clauses for Φ from Section 2.1 and letting $\Pi = \Pi_0 \cup \{\varphi? \mid \varphi \in \Phi\} \cup F$, where F is the set of automata of the form (16).

Axioms 17(iv), (v), and (vii) are replaced by:

$$(17) \quad [n, i, j, \delta]\varphi \leftrightarrow \bigwedge_{\substack{k \in \bar{n} \\ \alpha \in \delta(i, k)}} [\alpha][n, k, j, \delta]\varphi, \quad i \neq j$$

$$(18) \quad [n, i, i, \delta]\varphi \leftrightarrow \varphi \wedge \bigwedge_{\substack{k \in \bar{n} \\ \alpha \in \delta(i, k)}} [\alpha][n, k, i, \delta]\varphi.$$

The induction axiom 17(viii) becomes

$$(19) \quad \left(\bigwedge_{k \in \bar{n}} [n, i, k, \delta](\varphi_k \rightarrow \bigwedge_{\substack{m \in \bar{n} \\ \alpha \in \delta(k, m)}} [\alpha]\varphi_m) \right) \rightarrow (\varphi_i \rightarrow [n, i, j, \delta]\varphi_j).$$

These and other similar changes can be used to prove:

THEOREM 45. *Validity in APDL is decidable in exponential time.*

THEOREM 46. *The axiom system described above is complete for APDL.*

7.3 Converse

The *converse operator* $-$ is a program operator that allows a program to be “run backwards”:

$$\mathbf{m}_{\mathfrak{R}}(\alpha^-) \stackrel{\text{def}}{=} \{(s, t) \mid (t, s) \in \mathbf{m}_{\mathfrak{R}}(\alpha)\}.$$

PDL with converse is called CPDL.

The following identities allow us to assume without loss of generality that the converse operator is applied to atomic programs only.

$$\begin{aligned} (\alpha; \beta)^- &\leftrightarrow \beta^-; \alpha^- \\ (\alpha \cup \beta)^- &\leftrightarrow \alpha^- \cup \beta^- \\ \alpha^{*-} &\leftrightarrow \alpha^{-*}. \end{aligned}$$

The converse operator strictly increases the expressive power of PDL, since the formula $\langle \alpha^- \rangle \mathbf{1}$ is not expressible without it.

THEOREM 47. $\text{PDL} < \text{CPDL}$.

Proof. Consider the structure described in the following figure:

In this structure, $s \models \langle a^- \rangle \mathbf{1}$ but $u \not\models \langle a^- \rangle \mathbf{1}$. On the other hand, it can be shown by induction on the structure of formulas that if s and u agree on all atomic formulas, then no formula of PDL can distinguish between the two. ■

More interestingly, the presence of the converse operator implies that the operator $\langle \alpha \rangle$ is *continuous* in the sense that if A is any (possibly infinite) family of formulas possessing a join $\bigvee A$, then $\bigvee \langle \alpha \rangle A$ exists and is logically equivalent to $\langle \alpha \rangle \bigvee A$. In the absence of the converse operator, one can construct nonstandard models for which this fails.

The completeness and exponential time decidability results of Sections 4 and 5 can be extended to CPDL provided the following two axioms are added:

$$\begin{aligned} \varphi &\rightarrow [\alpha] \langle \alpha^- \rangle \varphi \\ \varphi &\rightarrow [\alpha^-] \langle \alpha \rangle \varphi. \end{aligned}$$

The filtration lemma (Lemma 14) still holds in the presence of $\bar{}$, as does the finite model property.

7.4 Well-foundedness

If α is a deterministic program, the formula $\varphi \rightarrow \langle \alpha \rangle \psi$ asserts the total correctness of α with respect to pre- and postconditions φ and ψ , respectively. For *nondeterministic* programs, however, this formula does not express the right notion of total correctness. It asserts that φ implies that *there exists* a halting computation sequence of α yielding ψ , whereas we would really like to assert that φ implies that *all* computation sequences of α terminate and yield ψ . Let us denote the latter property by

$$TC(\varphi, \alpha, \psi).$$

Unfortunately, this is not expressible in PDL.

The problem is intimately connected with the notion of *well-foundedness*. A program α is said to be *well-founded* at a state u_0 if there exists no infinite sequence of states u_0, u_1, u_2, \dots with $(u_i, u_{i+1}) \in m_{\mathcal{R}}(\alpha)$ for all $i \geq 0$. This property is not expressible in PDL either, as we will see.

Several very powerful logics have been proposed to deal with this situation. The most powerful is perhaps the propositional μ -calculus, which is essentially propositional modal logic augmented with a least fixpoint operator μ . Using this operator, one can express any property that can be formulated as the least fixpoint of a monotone transformation on sets of states defined by the PDL operators. For example, the well-foundedness of a program α is expressed

$$(20) \quad \mu X. [\alpha] X$$

in this logic.

Two somewhat weaker ways of capturing well-foundedness without resorting to the full μ -calculus have been studied. One is to add to PDL an explicit predicate **wf** for well-foundedness:

$$\mathbf{m}_{\mathcal{R}}(\mathbf{wf} \alpha) \stackrel{\text{def}}{=} \{s_0 \mid \neg \exists s_1, s_2, \dots \forall i \geq 0 (s_i, s_{i+1}) \in \mathbf{m}_{\mathcal{R}}(\alpha)\}.$$

Another is to add an explicit predicate **halt**, which asserts that all computations of its argument α terminate. The predicate **halt** can be defined inductively from **wf** as follows:

$$(21) \quad \mathbf{halt} a \stackrel{\text{def}}{\iff} \mathbf{1}, \quad a \text{ an atomic program or test,}$$

$$(22) \quad \mathbf{halt} \alpha; \beta \stackrel{\text{def}}{\iff} \mathbf{halt} \alpha \wedge [\alpha] \mathbf{halt} \beta,$$

$$(23) \quad \mathbf{halt} \alpha \cup \beta \stackrel{\text{def}}{\iff} \mathbf{halt} \alpha \wedge \mathbf{halt} \beta,$$

$$(24) \quad \mathbf{halt} \alpha^* \stackrel{\text{def}}{\iff} \mathbf{wf} \alpha \wedge [\alpha^*] \mathbf{halt} \alpha.$$

These constructs have been investigated under the various names **loop**, **repeat**, and Δ . The predicates **loop** and **repeat** are just the complements of **halt** and **wf**, respectively:

$$\mathbf{loop} \alpha \stackrel{\text{def}}{\iff} \neg \mathbf{halt} \alpha$$

$$\mathbf{repeat} \alpha \stackrel{\text{def}}{\iff} \neg \mathbf{wf} \alpha.$$

Clause (24) is equivalent to the assertion

$$\mathbf{loop} \alpha^* \stackrel{\text{def}}{\iff} \mathbf{repeat} \alpha \vee \langle \alpha^* \rangle \mathbf{loop} \alpha.$$

It asserts that a nonhalting computation of α^* consists of either an infinite sequence of halting computations of α or a finite sequence of halting computations of α followed by a nonhalting computation of α .

Let RPDL and LPDL denote the logics obtained by augmenting PDL with the **wf** and **halt** predicates, respectively.⁴ It follows from the preceding discussion that

$$\text{PDL} \leq \text{LPDL} \leq \text{RPDL} \leq \text{the propositional } \mu\text{-calculus}.$$

Moreover, all these inclusions are known to be strict.

The logic LPDL is powerful enough to express the total correctness of nondeterministic programs. The total correctness of α with respect to precondition φ and postcondition ψ is expressed

$$\frac{TC(\varphi, \alpha, \psi)}{\varphi \rightarrow \mathbf{halt} \alpha \wedge [\alpha] \psi} \stackrel{\text{def}}{\iff}$$

⁴The L in LPDL stands for “loop” and the R in RPDL stands for “repeat.” We retain these names for historical reasons.

Conversely, **halt** can be expressed in terms of TC :

$$\mathbf{halt} \alpha \Leftrightarrow TC(\mathbf{1}, \alpha, \mathbf{1}).$$

THEOREM 48. $PDL < LPDL$.

THEOREM 49. $LPDL < RPD$.

It is possible to extend Theorem 49 to versions CRPDL and CLPDL in which converse is allowed in addition to **wf** or **halt**. Also, the proof of Theorem 47 goes through for LPDL and RPD, so that $\langle a^- \rangle \mathbf{1}$ is not expressible in either. Theorem 48 goes through for the converse versions too. We obtain the situation illustrated in the following figure, in which the arrows indicate $<$ and the absence of a path between two logics means that each can express properties that the other cannot.

The filtration lemma fails for all **halt** and **wf** versions as in Theorem 48. However, satisfiable formulas of the μ -calculus (hence of RPD and LPDL) do have finite models. This finite model property is not shared by CLPDL or CRPDL.

THEOREM 50. *The CLPDL formula*

$$\neg \mathbf{halt} a^* \wedge [a^*] \mathbf{halt} a^{*-}$$

is satisfiable but has no finite model.

As it turns out, Theorem 50 does not prevent CRPDL from being decidable.

THEOREM 51. *The validity problems for CRPDL, CLPDL, RPD, LPDL, and the propositional μ -calculus are all decidable in deterministic exponential time.*

Obviously, the simpler the logic, the simpler the arguments needed to show exponential time decidability. Over the years all these logics have been gradually shown to be decidable in exponential time by various authors using various techniques. Here we point to the exponential time decidability of the propositional μ -calculus with forward and backward modalities, proved in [Vardi, 1998b], from which all these can be seen easily to follow. The proof in [Vardi, 1998b] is carried out by exhibiting an exponential time decision procedure for two-way alternating automata on infinite trees.

As mentioned above, RPD possesses the finite (but not necessarily the small and not the collapsed) model property.

THEOREM 52. *Every satisfiable formula of RPD, LPDL, and the propositional μ -calculus has a finite model.*

CRPDL and CLPDL are extensions of PDL that, like $\text{PDL} + a^\Delta b^\Delta$ (Theorems 27 and 31), are decidable despite lacking a finite model property.

Complete axiomatizations for RPD and LPDL can be obtained by embedding them into the μ -calculus (see Section 14.4).

7.5 Concurrency

Another interesting extension of PDL concerns concurrent programs. One can define an intersection operator \cap such that the binary relation on states corresponding to the program $\alpha \cap \beta$ is the intersection of the binary relations corresponding to α and β . This can be viewed as a kind of concurrency operator that admits transitions to those states that both α and β would have admitted.

Here we consider a different and perhaps more natural notion of concurrency. The interpretation of a program will not be a binary relation on states, which relates initial states to possible final states, but rather a relation between a states and *sets* of states. Thus $m_{\mathcal{R}}(\alpha)$ will relate a start state u to a collection of sets of states U . The intuition is that starting in state u , the (concurrent) program α can be run with its concurrent execution threads ending in the set of final states U . The basic concurrency operator will be denoted here by \wedge , although in the original work on concurrent Dynamic Logic [Peleg, 1987b; Peleg, 1987c; Peleg, 1987a] the notation \cap is used.

The syntax of *concurrent* PDL is the same as PDL, with the addition of the clause:

- if $\alpha, \beta \in \Pi$, then $\alpha \wedge \beta \in \Pi$.

The program $\alpha \wedge \beta$ means intuitively, “Execute α and β in parallel.”

The semantics of concurrent PDL is defined on Kripke frames $\mathfrak{K} = (K, m_{\mathfrak{K}})$ as with PDL, except that for programs α ,

$$m_{\mathfrak{K}}(\alpha) \subseteq K \times 2^K.$$

Thus the meaning of α is a collection of *reachability pairs* of the form (u, U) , where $u \in K$ and $U \subseteq K$. In this brief description of concurrent PDL, we require that structures assign to atomic programs *sequential*, non-parallel, meaning; that is, for each $a \in \Pi_0$, we require that if $(u, U) \in m_{\mathfrak{K}}(a)$, then $\#U = 1$. The true parallelism will stem from applying the concurrency operator to build larger sets U in the reachability pairs of compound programs. For details, see [Peleg, 1987b; Peleg, 1987c].

The relevant results for this logic are the following:

THEOREM 53. PDL $<$ concurrent PDL.

THEOREM 54. *The validity problem for concurrent PDL is decidable in deterministic exponential time.*

Axiom System 17, augmented with the following axiom, can be shown to be complete for concurrent PDL:

$$\langle \alpha \wedge \beta \rangle \varphi \leftrightarrow \langle \alpha \rangle \varphi \wedge \langle \beta \rangle \varphi.$$

8 FIRST-ORDER DYNAMIC LOGIC (DL)

In this section we begin the study of first-order Dynamic Logic. The main difference between first-order DL and the propositional version PDL discussed in previous sections is the presence of a first-order structure \mathfrak{A} , called the *domain of computation*, over which first-order quantification is allowed. States are no longer abstract points, but *valuations* of a set of variables over A , the *carrier* of \mathfrak{A} . Atomic programs in DL are no longer abstract binary relations, but *assignment statements* of various forms, all based on assigning values to variables during the computation. The most basic example of such an assignment is the *simple assignment* $x := t$, where x is a variable and t is a term. The atomic formulas of DL are generally taken to be atomic first-order formulas.

In addition to the constructs of PDL, the basic DL syntax contains individual variables ranging over A , function and predicate symbols for distinguished functions and predicates of \mathfrak{A} , and quantifiers ranging over A , exactly as in classical first-order logic. More powerful versions of the logic contain array and stack variables and other constructs, as well as primitive operations for manipulating them, and assignments for changing their values. Sometimes the introduction of a new construct increases expressive power and sometimes not; sometimes it has an effect on the complexity of

deciding satisfiability and sometimes not. Indeed, one of the central goals of research has been to classify these constructs in terms of their relative expressive power and complexity.

In this section we lay the groundwork for this by defining the various logical and programming constructs we shall need.

8.1 Basic Syntax

The language of first-order Dynamic Logic is built upon classical first-order logic. There is always an underlying first-order vocabulary Σ , which involves a vocabulary of function symbols and predicate (or relation) symbols. On top of this vocabulary, we define a set of *programs* and a set of *formulas*. These two sets interact by means of the modal construct $[]$ exactly as in the propositional case. Programs and formulas are usually defined by mutual induction.

Let $\Sigma = \{f, g, \dots, p, r, \dots\}$ be a finite first-order vocabulary. Here f and g denote typical function symbols of Σ , and p and r denote typical relation symbols. Associated with each function and relation symbol of Σ is a fixed *arity* (number of arguments), although we do not represent the arity explicitly. We assume that Σ always contains the equality symbol $=$, whose arity is 2. Functions and relations of arity 0, 1, 2, 3 and n are called *nullary*, *unary*, *binary*, *ternary*, and *n-ary*, respectively. Nullary functions are also called *constants*. We shall be using a countable set of *individual variables* $V = \{x_0, x_1, \dots\}$.

We always assume that Σ contains at least one function symbol of positive arity. A vocabulary Σ is *polyadic* if it contains a function symbol of arity greater than one. Vocabularies whose function symbols are all unary are called *monadic*.

A vocabulary Σ is *rich* if either it contains at least one predicate symbol besides the equality symbol or the sum of arities of the function symbols is at least two. Examples of rich vocabularies are: two unary function symbols, or one binary function symbol, or one unary function symbol and one unary predicate symbol. A vocabulary that is not rich is *poor*. Hence a poor vocabulary has just one unary function symbol and possibly some constants, but no relation symbols other than equality. The main difference between rich and poor vocabularies is that the former admit exponentially many pairwise non-isomorphic structures of a given finite cardinality, whereas the latter admit only polynomially many.

We say that the vocabulary Σ is *mono-unary* if it contains no function symbols other than a single unary one. It may contain constants and predicate symbols.

The definitions of DL programs and formulas below depend on the vocabulary Σ , but in general we shall not make this dependence explicit unless we have some specific reason for doing so.

Atomic Formulas and Programs

In all versions of DL that we will consider, atomic formulas are atomic formulas of the first-order vocabulary Σ ; that is, formulas of the form $r(t_1, \dots, t_n)$, where r is an n -ary relation symbol of Σ and t_1, \dots, t_n are terms of Σ .

As in PDL, programs are defined inductively from atomic programs using various programming constructs. The meaning of a compound program is given inductively in terms of the meanings of its constituent parts. Different classes of programs are obtained by choosing different classes of atomic programs and programming constructs.

In the basic version of DL, an atomic program is a *simple assignment* $x := t$, where $x \in V$ and t is a term of Σ . Intuitively, this program assigns the value of t to the variable x . This is the same form of assignment found in most conventional programming languages.

More powerful forms of assignment such as stack and array assignments and nondeterministic “wildcard” assignments will be discussed later. The precise choice of atomic programs will be made explicit when needed, but for now, we use the term *atomic program* to cover all of these possibilities.

Tests

As in PDL, DL contains a test operator $?$, which turns a formula into a program. In most versions of DL that we shall discuss, we allow only quantifier-free first-order formulas as tests. We sometimes call these versions *poor test*. Alternatively, we might allow any first-order formula as a test. Most generally, we might place no restrictions on the form of tests, allowing any DL formula whatsoever, including those that contain other programs, perhaps containing other tests, etc. These versions of DL are labeled *rich test* as in Section 2.1. Whereas programs can be defined independently from formulas in poor test versions, rich test versions require a mutually inductive definition of programs and formulas.

As with atomic programs, the precise logic we consider at any given time depends on the choice of tests we allow. We will make this explicit when needed, but for now, we use the term *test* to cover all possibilities.

Regular Programs

For a given set of atomic programs and tests, the set of *regular programs* is defined as in PDL (see Section 2.1):

- any atomic program or test is a program;
- if α and β are programs, then $\alpha ; \beta$ is a program;
- if α and β are programs, then $\alpha \cup \beta$ is a program;
- if α is a program then α^* is a program.

While Programs

Much of the literature on DL is concerned with the class of **while programs** (see Section 2.1). Formally, *deterministic while programs* form the subclass of the regular programs in which the program operators \cup , $?$, and $*$ are constrained to appear only in the forms

$$\begin{aligned}
 \text{skip} &\stackrel{\text{def}}{=} 1? \\
 \text{fail} &\stackrel{\text{def}}{=} 0? \\
 (25) \text{ if } \varphi \text{ then } \alpha \text{ else } \beta &\stackrel{\text{def}}{=} (\varphi?; \alpha) \cup (\neg\varphi?; \beta) \\
 (26) \text{ while } \varphi \text{ do } \alpha &\stackrel{\text{def}}{=} (\varphi?; \alpha)^*; \neg\varphi?
 \end{aligned}$$

The class of *nondeterministic while programs* is the same, except that we allow unrestricted use of the nondeterministic choice construct \cup . Of course, unrestricted use of the sequential composition operator is allowed in both languages.

Restrictions on the form of atomic programs and tests apply as with regular programs. For example, if we are allowing only poor tests, then the φ occurring in the programs (25) and (26) must be a quantifier-free first-order formula.

The class of deterministic **while programs** is important because it captures the basic programming constructs common to many real-life imperative programming languages. Over the standard structure of the natural numbers \mathbb{N} , deterministic **while programs** are powerful enough to define all partial recursive functions, and thus over \mathbb{N} they are as expressive as regular programs. A similar result holds for a wide class of models similar to \mathbb{N} , for a suitable definition of “partial recursive functions” in these models. However, it is not true in general that **while programs**, even nondeterministic ones, are universally expressive. We discuss these results in Section 12.

Formulas

A *formula* of DL is defined in way similar to that of PDL, with the addition of a rule for quantification. Equivalently, we might say that a formula of DL is defined in a way similar to that of first-order logic, with the addition of a rule for modality. The basic version of DL is defined with regular programs:

- the false formula $\mathbf{0}$ is a formula;
- any atomic formula is a formula;
- if φ and ψ are formulas, then $\varphi \rightarrow \psi$ is a formula;
- if φ is a formula and $x \in V$, then $\forall x \varphi$ is a formula;

- if φ is a formula and α is a program, then $[\alpha]\varphi$ is a formula.

The only missing rule in the definition of the syntax of DL are the tests. In our basic version we would have:

- if φ is a quantifier-free first-order formula, then $\varphi?$ is a test.

For the rich test version, the definitions of programs and formulas are mutually dependent, and the rule defining tests is simply:

- if φ is a formula, then $\varphi?$ is a test.

We will use the same notation as in propositional logic that $\neg\varphi$ stands for $\varphi \rightarrow \mathbf{0}$. As in first-order logic, the first-order existential quantifier \exists is considered a defined construct: $\exists x \varphi$ abbreviates $\neg\forall x \neg\varphi$. Similarly, the modal construct $\langle \rangle$ is considered a defined construct as in Section 2.1, since it is the modal dual of $[\]$. The other propositional constructs \wedge , \vee , \leftrightarrow are defined as in Section 2.1. Of course, we use parentheses where necessary to ensure unique readability.

Note that the individual variables in V serve a dual purpose: they are both program variables and logical variables.

8.2 Richer Programs

Seqs and R.E. Programs

Some classes of programs are most conveniently defined as certain sets of seqs. Recall from Section 2.3 that a *seq* is a program of the form $\sigma_1; \dots; \sigma_k$, where each σ_i is an assignment statement or a quantifier-free first-order test. Each regular program α is associated with a unique set of seqs $CS(\alpha)$ (Section 2.3). These definitions were made in the propositional context, but they apply equally well to the first-order case; the only difference is in the form of atomic programs and tests.

Construing the word in the broadest possible sense, we can consider a *program* to be an arbitrary set of seqs. Although this makes sense semantically—we can assign an input/output relation to such a set in a meaningful way—such programs can hardly be called executable. At the very least we should require that the set of seqs be recursively enumerable, so that there will be some effective procedure that can list all possible executions of a given program. However, there is a subtle issue that arises with this notion. Consider the set of seqs

$$\{x_i := f^i(c) \mid i \in \mathbb{N}\}.$$

This set satisfies the above restriction, yet it can hardly be called a program. It uses infinitely many variables, and as a consequence it might change a

valuation at infinitely many places. Another pathological example is the set of seqs

$$\{x_{i+1} := f(x_i) \mid i \in \mathbb{N}\},$$

which not only could change a valuation at infinitely many locations, but also depends on infinitely many locations of the input valuation.

In order to avoid such pathologies, we will require that each program use only finitely many variables. This gives rise to the following definition of *r.e. programs*, which is the most general family of programs we will consider. Specifically, an r.e. program α is a Turing machine that enumerates a set of seqs over a finite set of variables. The set of seqs enumerated will be called $CS(\alpha)$. By $FV(\alpha)$ we will denote the finite set of variables that occur in seqs of $CS(\alpha)$.

An important issue connected with r.e. programs is that of *bounded memory*. The assignment statements or tests in an r.e. program may have infinitely many terms with increasingly deep nesting of function symbols (although, as discussed, these terms only use finitely many variables), and these could require an unbounded amount of memory to compute. We define a set of seqs to be *bounded memory* if the depth of terms appearing in it is bounded. In fact, without sacrificing computational power, we could require that all terms be of the form $f(x_1, \dots, x_n)$ in a bounded-memory set of seqs.

Arrays and Stacks

Interesting variants of the programming language we use in DL arise from allowing auxiliary data structures. We shall define versions with *arrays* and *stacks*, as well as a version with a nondeterministic assignment statement called *wildcard assignment*.

Besides these, one can imagine augmenting **while** programs with many other kinds of constructs such as blocks with declarations, recursive procedures with various parameter passing mechanisms, higher-order procedures, concurrent processes, etc. It is easy to arrive at a family consisting of thousands of programming languages, giving rise to thousands of logics. Obviously, we have had to restrict ourselves. It is worth mentioning, however, that certain kinds of recursive procedures are captured by our stack operations, as explained below.

Arrays

To handle arrays, we include a countable set of *array variables*

$$V_{\text{array}} = \{F_0, F_1, \dots\}.$$

Each array variable has an associated *arity*, or number of arguments, which we do not represent explicitly. We assume that there are countably many

variables of each arity $n \geq 0$. In the presence of array variables, we equate the set V of individual variables with the set of nullary array variables; thus $V \subseteq V_{\text{array}}$.

The variables in V_{array} of arity n will range over n -ary functions with arguments and values in the domain of computation. In our exposition, elements of the domain of computation play two roles: they are used both as *indices* into an array and as *values* that can be stored in an array. One might equally well introduce a separate sort for array indices; although conceptually simple, this would complicate the notation and would give no new insight.

We extend the set of first-order terms to allow the unrestricted occurrence of array variables, provided arities are respected.

The classes of *regular programs with arrays* and *deterministic and nondeterministic while programs with arrays* are defined similarly to the classes without, except that we allow *array assignments* in addition to simple assignments. Array assignments are similar to simple assignments, but on the left-hand side we allow a term in which the outermost symbol is an array variable:

$$F(t_1, \dots, t_n) := t.$$

Here F is an n -ary array variable and t_1, \dots, t_n, t are terms, possibly involving other array variables. Note that when $n = 0$, this reduces to the ordinary simple assignment.

Recursion via an Algebraic Stack

We now consider DL in which the programs can manipulate a stack. The literature in automata theory and formal languages often distinguishes a stack from a pushdown store. In the former, the automaton is allowed to inspect the contents of the stack but to make changes only at the top. We shall use the term stack to denote the more common pushdown store, where the only inspection allowed is at the top of the stack.

The motivation for this extension is to be able to capture recursion. It is well known that recursive procedures can be modeled using a stack, and for various technical reasons we prefer to extend the data-manipulation capabilities of our programs than to introduce new control constructs. When it encounters a recursive call, the stack simulation of recursion will push the return location and values of local variables and parameters on the stack. It will pop them upon completion of the call. The LIFO (last-in-first-out) nature of stack storage fits the order in which control executes recursive calls.

To handle the stack in our stack version of DL, we add two new atomic programs

$$\mathbf{push}(t) \quad \text{and} \quad \mathbf{pop}(y),$$

where t is a term and $y \in V$. Intuitively, **push**(t) pushes the current value of t onto the top of the stack, and **pop**(y) pops the top value off the top of the stack and assigns that value to the variable y . If the stack is empty, the pop operation does not change anything. We could have added a test for stack emptiness, but it can be shown to be redundant. Formally, the stack is simply a finite string of elements of the domain of computation.

The classes of *regular programs with stack* and *deterministic and non-deterministic while programs with stack* are obtained by augmenting the respective classes of programs with the **push** and **pop** operations as atomic programs in addition to simple assignments.

In contrast to the case of arrays, here there is only a single stack. In fact, expressiveness changes dramatically when two or more stacks are allowed. Also, in order to be able to simulate recursion, the domain must have at least two distinct elements so that return addresses can be properly encoded in the stack. One way of doing this is to store the return address itself in unary using one element of the domain, then store one occurrence of the second element as a delimiter symbol, followed by domain elements constituting the current values of parameters and local variables.

The kind of stack described here is often termed *algebraic*, since it contains elements from the domain of computation. It should be contrasted with the Boolean stack described next.

Parameterless Recursion via a Boolean Stack

An interesting special case is when the stack can contain only two distinct elements. This version of our programming language can be shown to capture recursive procedures without parameters or local variables. This is because we only need to store return addresses, but no actual data items from the domain of computation. This can be achieved using two values, as described above. We thus arrive at the idea of a Boolean stack.

To handle such a stack in this version of DL, we add three new kinds of atomic programs and one new test. The atomic programs are

push-1 **push-0** **pop**,

and the test is simply **top?**. Intuitively, **push-1** and **push-0** push the corresponding distinct Boolean values on the stack, **pop** removes the top element, and the test **top?** evaluates to true iff the top element of the stack is **1**, but with no side effect.

With the test **top?** only, there is no explicit operator that distinguishes a stack with top element **0** from the empty stack. We might have defined such an operator, and in a more realistic language we would certainly do so. However, it is mathematically redundant, since it can be simulated with the operators we already have.

Wildcard Assignment

The nondeterministic assignment $x := ?$ is a device that arises in the study of fairness; see [Apt and Plotkin, 1986]. It has often been called *random assignment* in the literature, although it has nothing to do with randomness or probability. We shall call it *wildcard assignment*. Intuitively, it operates by assigning a nondeterministically chosen element of the domain of computation to the variable x . This construct together with the $[]$ modality is similar to the first-order universal quantifier, since it will follow from the semantics that the two formulas $[x := ?]\varphi$ and $\forall x \varphi$ are equivalent. However, wildcard assignment may appear in programs and can therefore be iterated.

8.3 *Semantics*

In this section we assign meanings to the syntactic constructs described in the previous sections. We interpret programs and formulas over a first-order structure \mathfrak{A} . Variables range over the carrier of this structure. We take an *operational* view of program semantics: programs change the values of variables by sequences of simple assignments $x := t$ or other assignments, and flow of control is determined by the truth values of tests performed at various times during the computation.

States as Valuations

An instantaneous snapshot of all relevant information at any moment during the computation is determined by the values of the program variables. Thus our *states* will be *valuations* u, v, \dots of the variables V over the carrier of the structure \mathfrak{A} . Our formal definition will associate the pair (u, v) of such valuations with the program α if it is possible to start in valuation u , execute the program α , and halt in valuation v . In this case, we will call (u, v) an *input/output pair* of α and write $(u, v) \in \mathfrak{m}_{\mathfrak{A}}(\alpha)$. This will result in a Kripke frame exactly as in Section 2.

Let $\mathfrak{A} = (A, \mathfrak{m}_{\mathfrak{A}})$ be a first-order structure for the vocabulary Σ . We call \mathfrak{A} the *domain of computation*. Here A is a set, called the *carrier* of \mathfrak{A} , and $\mathfrak{m}_{\mathfrak{A}}$ is a *meaning function* such that $\mathfrak{m}_{\mathfrak{A}}(f)$ is an n -ary function $\mathfrak{m}_{\mathfrak{A}}(f) : A^n \rightarrow A$ interpreting the n -ary function symbol f of Σ , and $\mathfrak{m}_{\mathfrak{A}}(r)$ is an n -ary relation $\mathfrak{m}_{\mathfrak{A}}(r) \subseteq A^n$ interpreting the n -ary relation symbol r of Σ . The equality symbol $=$ is always interpreted as the identity relation.

For $n \geq 0$, let $A^n \rightarrow A$ denote the set of all n -ary functions in A . By convention, we take $A^0 \rightarrow A = A$. Let A^* denote the set of all finite-length strings over A .

The structure \mathfrak{A} determines a Kripke frame, which we will also denote by \mathfrak{A} , as follows. A *valuation* over \mathfrak{A} is a function u assigning an n -ary function over A to each n -ary array variable. It also assigns meanings to

the stacks as follows. We shall use the two unique variable names STK and $BSTK$ to denote the algebraic stack and the Boolean stack, respectively. The valuation u assigns a finite-length string of elements of A to STK and a finite-length string of Boolean values $\mathbf{1}$ and $\mathbf{0}$ to $BSTK$. Formally:

$$\begin{aligned} u(F) &\in A^n \rightarrow A, \quad \text{if } F \text{ is an } n\text{-ary array variable,} \\ u(STK) &\in A^*, \\ u(BSTK) &\in \{\mathbf{1}, \mathbf{0}\}^*. \end{aligned}$$

By our convention $A^0 \rightarrow A = A$, and assuming that $V \subseteq V_{\text{array}}$, the individual variables (that is, the nullary array variables) are assigned elements of A under this definition:

$$u(x) \in A \text{ if } x \in V.$$

The valuation u extends uniquely to terms t by induction. For an n -ary function symbol f and an n -ary array variable F ,

$$\begin{aligned} u(f(t_1, \dots, t_n)) &\stackrel{\text{def}}{=} \mathfrak{m}_{\mathfrak{A}}(f)(u(t_1), \dots, u(t_n)) \\ u(F(t_1, \dots, t_n)) &\stackrel{\text{def}}{=} u(F)(u(t_1), \dots, u(t_n)). \end{aligned}$$

The *function-patching* operator is defined as follows: if X and D are sets, $f : X \rightarrow D$ is any function, $x \in X$, and $d \in D$, then $f[x/d] : X \rightarrow D$ is the function defined by

$$f[x/d](y) \stackrel{\text{def}}{=} \begin{cases} d, & \text{if } x = y \\ f(y), & \text{otherwise.} \end{cases}$$

We will be using this notation in several ways, both at the logical and metalogical levels. For example:

- If u is a valuation, x is an individual variable, and $a \in A$, then $u[x/a]$ is the new valuation obtained from u by changing the value of x to a and leaving the values of all other variables intact.
- If F is an n -ary array variable and $f : A^n \rightarrow A$, then $u[F/f]$ is the new valuation that assigns the same value as u to the stack variables and to all array variables other than F , and

$$u[F/f](F) = f.$$

- If $f : A^n \rightarrow A$ is an n -ary function and $\bar{a} = a_1, \dots, a_n \in A^n$ and $a \in A$, then the expression $f[\bar{a}/a]$ denotes the n -ary function that agrees with f everywhere except for input \bar{a} , on which it takes the value a . More precisely,

$$f[\bar{a}/a](\bar{b}) = \begin{cases} a, & \text{if } \bar{b} = \bar{a} \\ f(\bar{b}), & \text{otherwise.} \end{cases}$$

We call valuations u and v *finite variants* of each other if

$$u(F)(a_1, \dots, a_n) = v(F)(a_1, \dots, a_n)$$

for all but finitely many array variables F and n -tuples $a_1, \dots, a_n \in A^n$. In other words, u and v differ on at most finitely many array variables, and for those F on which they do differ, the functions $u(F)$ and $v(F)$ differ on at most finitely many values.

The relation “is a finite variant of” is an equivalence relation on valuations. Since a halting computation can run for only a finite amount of time, it can execute only finitely many assignments. It will therefore not be able to cross equivalence class boundaries; that is, in the binary relation semantics given below, if the pair (u, v) is an input/output pair of the program α , then v is a finite variant of u .

We are now ready to define the *states* of our Kripke frame. For $a \in A$, let w_a be the valuation in which the stacks are empty and all array and individual variables are interpreted as constant functions taking the value a everywhere. A *state* of \mathfrak{A} is any finite variant of a valuation w_a . The set of states of \mathfrak{A} is denoted $S^{\mathfrak{A}}$.

Call a state *initial* if it differs from some w_a only at the values of individual variables.

It is meaningful, and indeed useful in some contexts, to take as states the set of *all* valuations. Our purpose in restricting our attention to states as defined above is to prevent arrays from being initialized with highly complex oracles that would compromise the value of the relative expressiveness results of Section 12.

Assignment Statements

As in Section 2.2, with every program α we associate a binary relation

$$\mathfrak{m}_{\mathfrak{A}}(\alpha) \subseteq S^{\mathfrak{A}} \times S^{\mathfrak{A}}$$

(called the *input/output relation* of α), and with every formula φ we associate a set

$$\mathfrak{m}_{\mathfrak{A}}(\varphi) \subseteq S^{\mathfrak{A}}.$$

The sets $\mathfrak{m}_{\mathfrak{A}}(\alpha)$ and $\mathfrak{m}_{\mathfrak{A}}(\varphi)$ are defined by mutual induction on the structure of α and φ .

For the basis of this inductive definition, we first give the semantics of all the assignment statements discussed earlier.

- The array assignment $F(t_1, \dots, t_n) := t$ is interpreted as the binary relation

$$\begin{aligned} \mathfrak{m}_{\mathfrak{A}}(F(t_1, \dots, t_n) := t) \\ \stackrel{\text{def}}{=} \{ (u, u[F/u(F)][u(t_1), \dots, u(t_n)/u(t)]) \mid u \in S^{\mathfrak{A}} \}. \end{aligned}$$

In other words, starting in state u , the array assignment has the effect of changing the value of F on input $u(t_1), \dots, u(t_n)$ to $u(t)$, and leaving the value of F on all other inputs and the values of all other variables intact. For $n = 0$, this definition reduces to the following definition of simple assignment:

$$\mathbf{m}_{\mathfrak{A}}(x := t) \stackrel{\text{def}}{=} \{(u, u[x/u(t)]) \mid u \in S^{\mathfrak{A}}\}.$$

- The push operations, $\mathbf{push}(t)$ for the algebraic stack and $\mathbf{push-1}$ and $\mathbf{push-0}$ for the Boolean stack, are interpreted as the binary relations

$$\begin{aligned} \mathbf{m}_{\mathfrak{A}}(\mathbf{push}(t)) &\stackrel{\text{def}}{=} \{(u, u[STK/(u(t) \cdot u(STK))]) \mid u \in S^{\mathfrak{A}}\} \\ \mathbf{m}_{\mathfrak{A}}(\mathbf{push-1}) &\stackrel{\text{def}}{=} \{(u, u[BSTK/(1 \cdot u(BSTK))]) \mid u \in S^{\mathfrak{A}}\} \\ \mathbf{m}_{\mathfrak{A}}(\mathbf{push-0}) &\stackrel{\text{def}}{=} \{(u, u[BSTK/(0 \cdot u(BSTK))]) \mid u \in S^{\mathfrak{A}}\}, \end{aligned}$$

respectively. In other words, $\mathbf{push}(t)$ changes the value of the algebraic stack variable STK from $u(STK)$ to the string $u(t) \cdot u(STK)$, the concatenation of the value $u(t)$ with the string $u(STK)$, and everything else is left intact. The effects of $\mathbf{push-1}$ and $\mathbf{push-0}$ are similar, except that the special constants $\mathbf{1}$ and $\mathbf{0}$ are concatenated with $u(BSTK)$ instead of $u(t)$.

- The pop operations, $\mathbf{pop}(y)$ for the algebraic stack and \mathbf{pop} for the Boolean stack, are interpreted as the binary relations

$$\begin{aligned} \mathbf{m}_{\mathfrak{A}}(\mathbf{pop}(y)) &\stackrel{\text{def}}{=} \{(u, u[STK/\mathbf{tail}(u(STK))][y/\mathbf{head}(u(STK), \\ &\quad u(y))]) \mid u \in S^{\mathfrak{A}}\} \\ \mathbf{m}_{\mathfrak{A}}(\mathbf{pop}) &\stackrel{\text{def}}{=} \{(u, u[BSTK/\mathbf{tail}(u(BSTK))]) \mid u \in S^{\mathfrak{A}}\}, \end{aligned}$$

respectively, where

$$\begin{aligned} \mathbf{tail}(a \cdot \sigma) &\stackrel{\text{def}}{=} \sigma \\ \mathbf{tail}(\varepsilon) &\stackrel{\text{def}}{=} \varepsilon \\ \mathbf{head}(a \cdot \sigma, b) &\stackrel{\text{def}}{=} a \\ \mathbf{head}(\varepsilon, b) &\stackrel{\text{def}}{=} b \end{aligned}$$

and ε is the empty string. In other words, if $u(STK) \neq \varepsilon$, this operation changes the value of STK from $u(STK)$ to the string obtained by

deleting the first element of $u(STK)$ and assigns that element to the variable y . If $u(STK) = \varepsilon$, then nothing is changed. Everything else is left intact. The Boolean stack operation **pop** changes the value of $BSTK$ only, with no additional changes. We do not include explicit constructs to test whether the stacks are empty, since these can be simulated. However, we do need to be able to refer to the value of the top element of the Boolean stack, hence we include the **top?** test.

- The Boolean test program **top?** is interpreted as the binary relation

$$\mathfrak{m}_{\mathfrak{A}}(\mathbf{top?}) \stackrel{\text{def}}{=} \{(u, u) \mid u \in S^{\mathfrak{A}}, \mathbf{head}(u(BSTK)) = \mathbf{1}\}.$$

In other words, this test changes nothing at all, but allows control to proceed iff the top of the Boolean stack contains **1**.

- The wildcard assignment $x := ?$ for $x \in V$ is interpreted as the relation

$$\mathfrak{m}_{\mathfrak{A}}(x := ?) \stackrel{\text{def}}{=} \{(u, u[x/a]) \mid u \in S^{\mathfrak{A}}, a \in A\}.$$

As a result of executing this statement, x will be assigned some arbitrary value of the carrier set A , and the values of all other variables will remain unchanged.

Programs and Formulas

The meanings of compound programs and formulas are defined by mutual induction on the structure of α and φ exactly as in the propositional case (see Section 2.2).

Seqs and R.E. Programs

Recall that an r.e. program is a Turing machine enumerating a set $CS(\alpha)$ of seqs. If α is an r.e. program, we define

$$\mathfrak{m}_{\mathfrak{A}}(\alpha) \stackrel{\text{def}}{=} \bigcup_{\sigma \in CS(\alpha)} \mathfrak{m}_{\mathfrak{A}}(\sigma).$$

Thus, the meaning of α is defined to be the union of the meanings of the seqs in $CS(\alpha)$. The meaning $\mathfrak{m}_{\mathfrak{A}}(\sigma)$ of a seq σ is determined by the meanings of atomic programs and tests and the sequential composition operator.

There is an interesting point here regarding the translation of programs using other programming constructs into r.e. programs. This can be done for arrays and stacks (for Booleans stacks, even into r.e. programs with bounded memory), but not for wildcard assignment. Since later in the book we shall be referring to the r.e. set of seqs associated with such programs, it

is important to be able to carry out this translation. To see how this is done for the case of arrays, for example, consider an algorithm for simulating the execution of a program by generating only ordinary assignments and tests. It does not generate an array assignment of the form $F(t_1, \dots, t_n) := t$, but rather “remembers” it and when it reaches an assignment of the form $x := F(t_1, \dots, t_n)$ it will aim at generating $x := t$ instead. This requires care, since we must keep track of changes in the variables inside t and t_1, \dots, t_n and incorporate them into the generated assignments.

Formulas

Here are the semantic definitions for the constructs of formulas of DL. The semantics of atomic first-order formulas is the standard semantics of classical first-order logic.

$$(27) \quad \mathfrak{m}_{\mathfrak{A}}(\mathbf{0}) \stackrel{\text{def}}{=} \emptyset$$

$$(28) \quad \mathfrak{m}_{\mathfrak{A}}(\varphi \rightarrow \psi) \stackrel{\text{def}}{=} \{u \mid \text{if } u \in \mathfrak{m}_{\mathfrak{A}}(\varphi) \text{ then } u \in \mathfrak{m}_{\mathfrak{A}}(\psi)\}$$

$$(29) \quad \mathfrak{m}_{\mathfrak{A}}(\forall x \varphi) \stackrel{\text{def}}{=} \{u \mid \forall a \in A \ u[x/a] \in \mathfrak{m}_{\mathfrak{A}}(\varphi)\}$$

$$(30) \quad \mathfrak{m}_{\mathfrak{A}}([\alpha]\varphi) \stackrel{\text{def}}{=} \{u \mid \forall v \text{ if } (u, v) \in \mathfrak{m}_{\mathfrak{A}}(\alpha) \text{ then } v \in \mathfrak{m}_{\mathfrak{A}}(\varphi)\}.$$

Equivalently, we could define the first-order quantifiers \forall and \exists in terms of the wildcard assignment:

$$(31) \quad \forall x \varphi \leftrightarrow [x := ?]\varphi$$

$$(32) \quad \exists x \varphi \leftrightarrow \langle x := ? \rangle \varphi.$$

Note that for *deterministic* programs α (for example, those obtained by using the **while** programming language instead of regular programs and disallowing wildcard assignments), $\mathfrak{m}_{\mathfrak{A}}(\alpha)$ is a partial function from states to states; that is, for every state u , there is at most one v such that $(u, v) \in \mathfrak{m}_{\mathfrak{A}}(\alpha)$. The partiality of the function arises from the possibility that α may not halt when started in certain states. For example, $\mathfrak{m}_{\mathfrak{A}}(\mathbf{while\ 1\ do\ skip})$ is the empty relation. In general, the relation $\mathfrak{m}_{\mathfrak{A}}(\alpha)$ need not be single-valued.

If K is a given set of syntactic constructs, we refer to the version of Dynamic Logic with programs built from these constructs as *Dynamic Logic with K* or simply as $\text{DL}(K)$. Thus, we have $\text{DL}(\text{r.e.})$, $\text{DL}(\text{array})$, $\text{DL}(\text{stk})$, $\text{DL}(\text{bstk})$, $\text{DL}(\text{wild})$, and so on. As a default, these logics are the poor-test versions, in which only quantifier-free first-order formulas may appear as tests. The unadorned DL is used to abbreviate $\text{DL}(\text{reg})$, and we use $\text{DL}(\text{dreg})$ to denote DL with **while** programs, which are really deterministic regular programs. Again, **while** programs use only poor tests. Combinations such as $\text{DL}(\text{dreg}+\text{wild})$ are also allowed.

8.4 Satisfiability and Validity

The concepts of satisfiability, validity, etc. are defined as for PDL in Section 2 or as for first-order logic under the standard semantics.

Let $\mathfrak{A} = (A, \mathfrak{m}_{\mathfrak{A}})$ be a structure, and let u be a state in $S^{\mathfrak{A}}$. For a formula φ , we write $\mathfrak{A}, u \models \varphi$ if $u \in \mathfrak{m}_{\mathfrak{A}}(\varphi)$ and say that u *satisfies* φ in \mathfrak{A} . We sometimes write $u \models \varphi$ when \mathfrak{A} is understood. We say that φ is \mathfrak{A} -*valid* and write $\mathfrak{A} \models \varphi$ if $\mathfrak{A}, u \models \varphi$ for all u in \mathfrak{A} . We say that φ is *valid* and write $\models \varphi$ if $\mathfrak{A} \models \varphi$ for all \mathfrak{A} . We say that φ is *satisfiable* if $\mathfrak{A}, u \models \varphi$ for some \mathfrak{A}, u .

For a set of formulas Δ , we write $\mathfrak{A} \models \Delta$ if $\mathfrak{A} \models \varphi$ for all $\varphi \in \Delta$.

Informally, $\mathfrak{A}, u \models [\alpha]\varphi$ iff every terminating computation of α starting in state u terminates in a state satisfying φ , and $\mathfrak{A}, u \models \langle \alpha \rangle \varphi$ iff there exists a computation of α starting in state u and terminating in a state satisfying φ . For a pure first-order formula φ , the metastatement $\mathfrak{A}, u \models \varphi$ has the same meaning as in first-order logic.

9 RELATIONSHIPS WITH STATIC LOGICS

9.1 Uninterpreted Reasoning

In contrast to the propositional version PDL discussed in Sections 2–7, DL formulas involve variables, functions, predicates, and quantifiers, a state is a mapping from variables to values in some domain, and atomic programs are assignment statements. To give semantic meaning to these constructs requires a first-order structure \mathfrak{A} over which to interpret the function and predicate symbols. Nevertheless, we are not obliged to assume anything special about \mathfrak{A} or the nature of the interpretations of the function and predicate symbols, except as dictated by first-order semantics. Any conclusions we draw from this level of reasoning will be valid under all possible interpretations. *Uninterpreted reasoning* refers to this style of reasoning.

For example, the formula

$$p(f(x), g(y, f(x))) \rightarrow \langle z := f(x) \rangle p(z, g(y, z))$$

is true over any domain, irrespective of the interpretations of p , f , and g .

Another example of a valid formula is

$$\begin{aligned} z = y \wedge \forall x f(g(x)) = x \\ \rightarrow [\mathbf{while} \ p(y) \ \mathbf{do} \ y := g(y)] \langle \mathbf{while} \ y \neq z \ \mathbf{do} \ y := f(y) \rangle \mathbf{1}. \end{aligned}$$

Note the use of $[]$ applied to $\langle \rangle$. This formula asserts that under the assumption that f “undoes” g , any computation consisting of applying g some number of times to z can be backtracked to the original z by applying f some number of times to the result.

We now observe that three basic properties of classical (uninterpreted) first-order logic, the *Löwenheim–Skolem theorem*, *completeness*, and *compactness*, fail for even fairly weak versions of DL.

The Löwenheim–Skolem theorem for classical first-order logic states that if a formula φ has an infinite model then it has models of all infinite cardinalities. Because of this theorem, classical first-order logic cannot define the structure of elementary arithmetic

$$\mathbb{N} = (\omega, +, \cdot, 0, 1, =)$$

up to isomorphism. That is, there is no first-order sentence that is true in a structure \mathfrak{A} if and only if \mathfrak{A} is isomorphic to \mathbb{N} . However, this can be done in DL.

PROPOSITION 55. *There exists a formula $\Theta_{\mathbb{N}}$ of DL(dreg) that defines \mathbb{N} up to isomorphism.*

The Löwenheim–Skolem theorem does not hold for DL, because $\Theta_{\mathbb{N}}$ has an infinite model (namely \mathbb{N}), but all models are isomorphic to \mathbb{N} and are therefore countable.

Besides the Löwenheim–Skolem Theorem, compactness fails in DL as well. Consider the following countable set Γ of formulas:

$$\{\langle \text{while } p(x) \text{ do } x := f(x) \rangle \mathbf{1}\} \cup \{p(f^n(x)) \mid n \geq 0\}.$$

It is easy to see that Γ is not satisfiable, but it is finitely satisfiable, i.e. each finite subset of it is satisfiable.

Worst of all, completeness cannot hold for any deductive system as we normally think of it (a finite effective system of axioms schemes and finitary inference rules). The set of theorems of such a system would be r.e., since they could be enumerated by writing down the axioms and systematically applying the rules of inference in all possible ways. However, the set of valid statements of DL is not recursively enumerable. In fact, we will describe in Section 10 exactly how bad the situation is.

This is not to say that we cannot say anything meaningful about proofs and deduction in DL. On the contrary, there is a wealth of interesting and practical results on axiom systems for DL that we will cover in Section 11.

In this section we investigate the power of DL relative to classical static logics on the uninterpreted level. In particular, *rich test DL of r.e. programs* is equivalent to the infinitary language $L_{\omega_1^{\text{ck}}, \omega}$. Some consequences of this fact are drawn in later sections.

First we introduce a definition that allows to compare different variants of DL. Let us recall from Section 8.3 that a state is *initial* if it differs from a constant state w_a only at the values of individual variables. If DL_1 and DL_2 are two variants of DL over the same vocabulary, we say that DL_2 is *as expressive as* DL_1 and write $\text{DL}_1 \leq \text{DL}_2$ if for each formula φ in DL_1 there is a formula ψ in DL_2 such that $\mathfrak{A}, u \models \varphi \leftrightarrow \psi$ for all structures \mathfrak{A} and initial

states u . If DL_2 is as expressive as DL_1 but DL_1 is not as expressive as DL_2 , we say that DL_2 is *strictly more expressive than* DL_1 , and write $DL_1 < DL_2$. If DL_2 is as expressive as DL_1 and DL_1 is as expressive as DL_2 , we say that DL_1 and DL_2 are of *equal expressive power*, or are simply *equivalent*, and write $DL_1 \equiv DL_2$. We will also use these notions for comparing versions of DL with static logics such as $L_{\omega\omega}$.

There is a technical reason for the restriction to initial states in the above definition. If DL_1 and DL_2 have access to different sets of data types, then they may be trivially incomparable for uninteresting reasons, unless we are careful to limit the states on which they are compared. We shall see examples of this in Section 12.

Also, in the definition of $DL(K)$ given in Section 8.4, the programming language K is an explicit parameter. Actually, the particular first-order vocabulary Σ over which $DL(K)$ and K are considered should be treated as a parameter too. It turns out that the relative expressiveness of versions of DL is sensitive not only to K , but also to Σ . This second parameter is often ignored in the literature, creating a source of potential misinterpretation of the results. For now, we assume a fixed first-order vocabulary Σ .

Rich Test Dynamic Logic of R.E. Programs

We are about to introduce the most general version of DL we will ever consider. This logic is called *rich test Dynamic Logic of r.e. programs*, and it will be denoted $DL(\text{rich-test r.e.})$. Programs of $DL(\text{rich-test r.e.})$ are r.e. sets of seqs as defined in Section 8.2, except that the seqs may contain tests $\varphi?$ for any previously constructed formula φ .

The formal definition is inductive. All atomic programs are programs and all atomic formulas are formulas. If φ, ψ are formulas, α, β are programs, $\{\alpha_n \mid n \in \omega\}$ is an r.e. set of programs over a finite set of variables (free or bound), and x is a variable, then

- $\mathbf{0}$
- $\varphi \rightarrow \psi$
- $[\alpha]\varphi$
- $\forall x \varphi$

are formulas and

- $\alpha ; \beta$
- $\{\alpha_n \mid n \in \omega\}$
- $\varphi?$

are programs. The set $CS(\alpha)$ of computation sequences of a rich test r.e. program α is defined as usual.

The language $L_{\omega_1\omega}$ is the language with the formation rules of the first-order language $L_{\omega\omega}$, but in which countably infinite conjunctions and disjunctions $\bigwedge_{i \in I} \varphi_i$ and $\bigvee_{i \in I} \varphi_i$ are also allowed. In addition, if $\{\varphi_i \mid i \in I\}$ is recursively enumerable, then the resulting language is denoted $L_{\omega_1^{\text{ck}}\omega}$ and is sometimes called *constructive* $L_{\omega_1\omega}$.

PROPOSITION 56. $\text{DL}(\text{rich-test r.e.}) \equiv L_{\omega_1^{\text{ck}}\omega}$.

Since r.e. programs as defined in Section 8.2 are clearly a special case of general rich-test r.e. programs, it follows that $\text{DL}(\text{rich-test r.e.})$ is as expressive as $\text{DL}(\text{r.e.})$. In fact they are not of the same expressive power.

THEOREM 57. $\text{DL}(\text{r.e.}) < \text{DL}(\text{rich-test r.e.})$.

Henceforth, we shall assume that the first-order vocabulary Σ contains at least one function symbol of positive arity. Under this assumption, DL can easily be shown to be strictly more expressive than $L_{\omega\omega}$:

THEOREM 58. $L_{\omega\omega} < \text{DL}$.

COROLLARY 59.

$$L_{\omega\omega} < \text{DL} < \text{DL}(\text{r.e.}) < \text{DL}(\text{rich-test r.e.}) \equiv L_{\omega_1^{\text{ck}}\omega}.$$

The situation with the intermediate versions of DL, e.g. $\text{DL}(\text{stk})$, $\text{DL}(\text{bstk})$, $\text{DL}(\text{wild})$, etc., is of interest. We deal with the relative expressive power of these in Section 12.

9.2 Interpreted Reasoning

Arithmetical Structures

This is the most detailed level we will consider. It is the closest to the actual process of reasoning about concrete, fully specified programs. Syntactically, the programs and formulas are as on the uninterpreted level, but here we assume a fixed structure or class of structures.

In this framework, we can study programs whose computational behavior depends on (sometimes deep) properties of the particular structures over which they are interpreted. In fact, almost any task of verifying the correctness of an actual program falls under the heading of interpreted reasoning.

One specific structure we will look at carefully is the natural numbers with the usual arithmetic operations:

$$\mathbb{N} = (\omega, 0, 1, +, \cdot, =).$$

Let $-$ denote the (first-order-definable) operation of subtraction and $\text{gcd}(x, y)$ denote the first-order-definable operation giving the greatest common divisor of x and y . The following formula of DL is \mathbb{N} -valid, i.e., true in

all states of \mathbb{N} :

$$(33) \quad x = x' \wedge y = y' \wedge xy \geq 1 \rightarrow \langle \alpha \rangle (x = \text{gcd}(x', y'))$$

where α is the **while** program of Example 1 or the regular program

$$(x \neq y?; ((x > y?; x := x - y) \cup (x < y?; y := y - x)))^* x = y?.$$

Formula (33) states the correctness and termination of an actual program over \mathbb{N} computing the greatest common divisor.

As another example, consider the following formula over \mathbb{N} :

$$\forall x \geq 1 \langle (\text{if even}(x) \text{ then } x := x/2 \text{ else } x := 3x + 1)^* \rangle (x = 1).$$

Here $/$ denotes integer division, and **even**() is the relation that tests if its argument is even. Both of these are first-order definable. This innocent-looking formula asserts that starting with an arbitrary positive integer and repeating the following two operations, we will eventually reach 1:

- if the number is even, divide it by 2;
- if the number is odd, triple it and add 1.

The truth of this formula is as yet unknown, and it constitutes a problem in number theory (dubbed “the $3x + 1$ problem”) that has been open for over 60 years. The formula $\forall x \geq 1 \langle \alpha \rangle \mathbf{1}$, where α is

$$\text{while } x \neq 1 \text{ do if even}(x) \text{ then } x := x/2 \text{ else } x := 3x + 1,$$

says this in a slightly different way.

The specific structure \mathbb{N} can be generalized, resulting in the class of *arithmetical structures*. Briefly, a structure \mathfrak{A} is *arithmetical* if it contains a first-order-definable copy of \mathbb{N} and has first-order definable functions for coding finite sequences of elements of \mathfrak{A} into single elements and for the corresponding decoding.

Arithmetical structures are important because (i) most structures arising naturally in computer science (e.g., discrete structures with recursively defined data types) are arithmetical, and (ii) any structure can be extended to an arithmetical one by adding appropriate encoding and decoding capabilities. While most of the results we present for the interpreted level are given in terms of \mathbb{N} alone, many of them hold for any arithmetical structure, so their significance is greater.

Expressive Power over \mathbb{N}

The results of Corollary 59 establishing that

$$L_{\omega\omega} < \text{DL} < \text{DL(r.e.)} < \text{DL(rich-test r.e.)}$$

were on the uninterpreted level, where all structures are taken into account. Thus first-order logic, regular DL, and DL(rich-test r.e.) form a sequence of increasingly more powerful logics when interpreted uniformly over all structures.

What happens if one fixes a structure, say \mathbb{N} ? Do these differences in expressive power still hold? We now address these questions.

First, we introduce notation for comparing expressive power over \mathbb{N} . If DL_1 and DL_2 are variants of DL (or static logics, such as $L_{\omega\omega}$) and are defined over the vocabulary of \mathbb{N} , we write $DL_1 \leq_{\mathbb{N}} DL_2$ if for each $\varphi \in DL_1$ there is $\psi \in DL_2$ such that $\mathbb{N} \models \varphi \leftrightarrow \psi$. We define $<_{\mathbb{N}}$ and $\equiv_{\mathbb{N}}$ from $\leq_{\mathbb{N}}$ in a way analogous to the definition of $<$ and \equiv from \leq .

It turns out that over \mathbb{N} , DL is no more expressive than first-order logic $L_{\omega\omega}$. This is true even for finite-test DL. The result is stated for \mathbb{N} , but is actually true for any arithmetical structure.

THEOREM 60. $L_{\omega\omega} \equiv_{\mathbb{N}} DL \equiv_{\mathbb{N}} DL(\text{r.e.})$.

The significance of this result is that in principle, one can carry out all reasoning about programs interpreted over \mathbb{N} in the first-order logic $L_{\omega\omega}$ by translating each DL formula into an equivalent first-order formula. The translation is effective. Moreover, Theorem 60 holds for any arithmetical structure containing the requisite coding power. As mentioned earlier, every structure can be extended to an arithmetical one.

However, the translation of Theorem 60 produces unwieldy formulas having little resemblance to the original ones. This mechanism is thus somewhat unnatural and does not correspond closely to the type of arguments one would find in practical program verification. In Section 11, a remedy is provided that makes the process more orderly.

We now observe that over \mathbb{N} , DL(rich-test r.e.) has considerably more power than the equivalent logics of Theorem 60. This too is true for any arithmetical structure.

THEOREM 61. *Over \mathbb{N} , DL(rich-test r.e.) defines precisely the Δ_1^1 (hyperarithmetical) sets.*

Theorems 60 and 61 say that over \mathbb{N} , the languages DL and DL(r.e.) define the arithmetic (first-order definable) sets and DL(rich-test r.e.) defines the hyperarithmetical or Δ_1^1 sets. Since the inclusion between these classes is strict—for example, first-order number theory is hyperarithmetical but not arithmetic—we have

COROLLARY 62. $DL(\text{r.e.}) <_{\mathbb{N}} DL(\text{rich-test r.e.})$.

10 COMPLEXITY OF DL

This section addresses the complexity of first-order Dynamic Logic.

Since all versions of DL subsume first-order logic, the truth, satisfiability, or validity of a given formula can be no easier to establish than in $L_{\omega\omega}$. Also, since DL(r.e.) is subsumed by $L_{\omega_1^{\text{ck}}\omega}$, these questions are no harder to establish than in $L_{\omega_1^{\text{ck}}\omega}$. These bounds hold for both uninterpreted and interpreted levels of reasoning.

10.1 *The Uninterpreted Level*

In this section we discuss the complexity of the validity problem for DL. By the remarks above, this problem is between Σ_1^0 and Π_1^1 . That is, as a lower bound it is undecidable and can be no better than recursively enumerable, and as an upper bound it is in Π_1^1 . This is a rather large gap, so we are still interested in determining more precise complexity bounds for DL and its variants. An interesting related question is whether there is some nontrivial⁵ fragment of DL that is in Σ_1^0 , since this would allow a complete axiomatization.

In the following, we consider these questions for full DL(reg), but we also consider two important subclasses of formulas for which better upper bounds are derivable:

- partial correctness assertions of the form $\psi \rightarrow [\alpha]\varphi$, and
- termination or total correctness assertions of the form $\psi \rightarrow \langle \alpha \rangle \varphi$,

where φ and ψ are first-order formulas. The results are stated for regular programs, but they remain true for the more powerful programming languages too. They also hold for deterministic **while** programs.

We state the results without mentioning the underlying first-order vocabulary Σ . For the upper bounds this is irrelevant. For the lower bounds, we assume the Σ contains a unary function symbol and ternary predicate symbols.

THEOREM 63. *The validity problem for DL is Π_1^1 -hard, even for formulas of the form $\exists x [\alpha]\varphi$, where α is a regular program and φ is first-order.*

THEOREM 64. *The validity problem for DL and DL(rich-test r.e.), as well as all intermediate versions, is Π_1^1 -complete.*

To soften the negative flavor of these results, we now observe that the special cases of unquantified one-program DL(r.e.) formulas have easier validity problems (though, as mentioned, they are still undecidable).

⁵*Nontrivial* here means containing $L_{\omega\omega}$ and allowing programs with iteration. The reason for this requirement is that loop-free programs add no expressive power over first-order logic.

THEOREM 65. *The validity problem for the sublanguage of DL (r.e.) consisting of formulas of the form $\langle \alpha \rangle \varphi$, where φ is first-order and α is an r.e. program, is Σ_1^0 -complete.*

It is easy to see that the result holds for formulas of the form $\psi \rightarrow \langle \alpha \rangle \varphi$, where ψ is also first-order. Thus, termination assertions for nondeterministic programs with first-order tests (or total correctness assertions for deterministic programs), on the uninterpreted level of reasoning, are recursively enumerable and therefore axiomatizable. We shall give an explicit axiomatization in Section 11.

We now turn to partial correctness.

THEOREM 66. *The validity problem for the sublanguage of DL (r.e.) consisting of formulas of the form $[\alpha] \varphi$, where φ is first-order and α is an r.e. program, is Π_2^0 -complete. The Π_2^0 -completeness property holds even if we restrict α to range over deterministic **while** programs.*

Theorem 66 extends easily to partial correctness assertions; that is, to formulas of the form $\psi \rightarrow [\alpha] \varphi$, where ψ is also first-order. Thus, while Π_2^0 is obviously better than Π_1^1 , it is noteworthy that on the uninterpreted level of reasoning, the truth of even simple correctness assertions for simple programs is not r.e., so that no finitary complete axiomatization for such validities can be given.

10.2 The Interpreted Level

The characterizations of the various versions of DL in terms of classical static logics established in Section 9.2 provide us with the precise complexity of the validity problem over \mathbb{N} .

THEOREM 67. *The \mathbb{N} -validity problem for DL (dreg) and DL (rich-test r.e.), as well as all intermediate versions, when defined over the vocabulary of \mathbb{N} , is hyperarithmetical (Δ_1^1) but not arithmetic.*

10.3 Spectral Complexity

We now introduce the *spectral complexity* of a programming language. As mentioned, this notion provides a measure of the complexity of the halting problem for programs over finite interpretations.

Recall that a *state* is a finite variant of a constant valuation w_a for some $a \in A$ (see Section 8.3), and a state w is *initial* if it differs from w_a for individual variables only. Thus, an initial state can be uniquely defined by specifying its relevant portion of values on individual variables. For $m \in \mathbb{N}$, we call an initial state w an *m-state* if for some $a \in A$ and for all $i \geq m$, $w(x_i) = a$. An *m-state* can be specified by an $(m + 1)$ -tuple of values (a_0, \dots, a_m) that represent values of w for the first $m + 1$ individual variables x_0, \dots, x_m . Call an *m-state* $w = (a_0, \dots, a_m)$ *Herbrand-like* if the

set $\{a_0, \dots, a_m\}$ generates A ; that is, if every element of A can be obtained as a value of a term in the state w .

We are now ready to define the notion of a *spectrum* of a programming language. Let K be a programming language and let $\alpha \in K$ and $m \geq 0$. The m^{th} *spectrum* of α is the set

$$SP_m(\alpha) \stackrel{\text{def}}{=} \{ \ulcorner \mathfrak{A}_w \urcorner \mid \mathfrak{A} \text{ is a finite } \Sigma\text{-structure, } w \text{ is an } m\text{-state in } \mathfrak{A}, \\ \text{and } \mathfrak{A}, w \models \langle \alpha \rangle \mathbf{1} \}.$$

The *spectrum* of K is the set

$$SP(K) \stackrel{\text{def}}{=} \{ SP_m(\alpha) \mid \alpha \in K, m \in \mathbb{N} \}.$$

Given $m \geq 0$, observe that structures in $S_n^{\Sigma \cup \{c_0, \dots, c_m\}}$ can be viewed as structures of the form \mathfrak{A}_w for a certain Σ -structure \mathfrak{A} and an m -state w in \mathfrak{A} . This representation is unique.

In this section we establish the complexity of spectra; that is, the complexity of the halting problem in finite interpretations. Let us fix $m \geq 0$, a rich vocabulary Σ , and new constants c_0, \dots, c_m . Since not every binary string is of the form $\ulcorner \mathfrak{A} \urcorner$ for some Σ -structure \mathfrak{A} and m -state w in \mathfrak{A} , we will restrict our attention to strings that are of this form. Let

$$H_m^\Sigma \stackrel{\text{def}}{=} \{ \ulcorner \mathfrak{A} \urcorner \mid \mathfrak{A} \in S_n^{\Sigma \cup \{c_0, \dots, c_m\}} \text{ for some } n \geq 1 \}.$$

It is easy to show that the language H_m^Σ is in *LOGSPACE* for every vocabulary Σ and $m \geq 0$.

We are now ready to connect complexity classes with spectra. Let K be any programming language and let $C \subseteq 2^{\{0,1\}^*}$ be a family of sets. We say that $SP(K)$ *captures* C , denoted $SP(K) \approx C$, if

- $SP(K) \subseteq C$, and
- for every $X \in C$ and $m \geq 0$, if $X \subseteq H_m^\Sigma$, then there is a program $\alpha \in K$ such that $SP_m(\alpha) = X$.

For example, if C is the class of all sets recognizable in polynomial time, then $SP(K) \approx P$ means that

- the halting problem over finite interpretations for programs from K is decidable in polynomial time, and
- every polynomial-time-recognizable set of codes of finite interpretations is the spectrum of some program from K .

We conclude this section by characterizing the spectral complexity of some of the programming languages introduced in Section 8.

THEOREM 68. *Let Σ be a rich vocabulary. Then*

(i) $SP(\text{dreg}) \subseteq LOGSPACE$.

(ii) $SP(\text{reg}) \subseteq NLOGSPACE$.

Moreover, if Σ is mono-unary, then $SP(\text{dreg})$ captures $LOGSPACE$ and $SP(\text{reg})$ captures $NLOGSPACE$.

THEOREM 69. *Over a rich vocabulary Σ , $SP(\text{dstk})$ and $SP(\text{stk})$ capture P .*

THEOREM 70. *If Σ is a rich vocabulary, then $SP(\text{darray})$ and $SP(\text{array})$ capture $PSPACE$.*

11 AXIOMATIZATION OF DL

11.1 Uninterpreted Reasoning

Recall from Section 10.1 that validity in DL is Π_1^1 -complete, but only r.e. when restricted to simple termination assertions. This means that termination (or total correctness when the programs are deterministic) can be fully axiomatized in the standard sense. This we do first, and we then turn to the problem of axiomatizing full DL.

Since the validity problem for such termination assertions is r.e., it is of interest to find a nicely-structured complete axiom system. We propose the following.

Axiom System S1

Axiom Schemes

- all instances of valid first-order formulas;
- all instances of valid formulas of PDL;
- $\varphi[x/t] \rightarrow \langle x := t \rangle \varphi$, where φ is a first-order formula.

Inference Rules

- modus ponens:

$$\frac{\varphi, \varphi \rightarrow \psi}{\psi}$$

We denote provability in Axiom System S1 by \vdash_{S1} .

THEOREM 71. *For any DL formula of the form $\varphi \rightarrow \langle \alpha \rangle \psi$, for first-order φ and ψ and program α containing first-order tests only,*

$$\models \varphi \rightarrow \langle \alpha \rangle \psi \quad \Leftrightarrow \quad \vdash_{S1} \varphi \rightarrow \langle \alpha \rangle \psi.$$

Given the high undecidability of validity in DL, we cannot hope for a complete axiom system in the usual sense. Nevertheless, we do want to provide an orderly axiomatization of valid DL formulas, even if this means that we have to give up the finitary nature of standard axiom systems.

Below we present a complete infinitary axiomatization S2 of DL that includes an inference rule with infinitely many premises. Before doing so, however, we must get a certain technical complication out of the way. We would like to be able to consider valid first-order formulas as axiom schemes, but instantiated by general formulas of DL. In order to make formulas amenable to first-order manipulation, we must be able to make sense of such notions as “a free occurrence of x in φ ” and the substitution $\varphi[x/t]$. For example, we would like to be able to use the axiom scheme of the predicate calculus $\forall x \varphi \rightarrow \varphi[x/t]$, even if φ contains programs.

The problem arises because the dynamic nature of the semantics of DL may cause a single occurrence of a variable in a DL formula to act as both a free and bound occurrence. For example, in the formula $\langle \mathbf{while} \ x \leq 99 \ \mathbf{do} \ x := x + 1 \rangle$, the occurrence of x in the expression $x + 1$ acts as both a free occurrence (for the first assignment) and as a bound occurrence (for subsequent assignments).

There are several reasonable ways to deal with this, and we present one for definiteness. Without loss of generality, we assume that whenever required, all programs appear in the special form

$$(34) \quad \langle \bar{z} := \bar{x}; \alpha; \bar{x} := \bar{z} \rangle \varphi$$

where $\bar{x} = (x_1, \dots, x_n)$ and $\bar{z} = (z_1, \dots, z_n)$ are tuples of variables, $\bar{z} := \bar{x}$ stands for

$$z_1 := x_1; \dots; z_n := x_n$$

(and similarly for $\bar{x} := \bar{z}$), the x_i do not appear in α , and the z_i are new variables appearing nowhere in the relevant context outside of the program α . The idea is to make programs act on the “local” variables z_i by first copying the values of the x_i into the z_i , thus freezing the x_i , executing the program with the z_i , and then restoring the x_i . This form can be easily obtained from any DL formula by consistently changing all variables of any program to new ones and adding the appropriate assignments that copy and then restore the values. Clearly, the new formula is equivalent to the old. Given a DL formula in this form, the following are bound occurrences of variables:

- all occurrences of x in a subformula of the form $\exists x \varphi$;
- all occurrences of z_i in a subformula of the form (34) (note, though, that z_i does not occur in φ at all);
- all occurrences of x_i in a subformula of the form (34) except for its occurrence in the assignment $z_i := x_i$.

Every occurrence of a variable that is not bound is free. Our axiom system will have an axiom that enables free translation into the special form discussed, and in the sequel we assume that the special form is used whenever required (for example, in the assignment axiom scheme below).

As an example, consider the formula:

$$\begin{aligned} \forall x (\langle y := f(x); x := g(y, x) \rangle p(x, y)) &\rightarrow \\ \langle z_1 := h(z); z_2 := y; z_2 := f(z_1); z_1 := g(z_2, z_1); x := z_1; \\ y := z_2 \rangle p(x, y). \end{aligned}$$

Denoting $\langle y := f(x); x := g(y, x) \rangle p(x, y)$ by φ , the conclusion of the implication is just $\varphi[x/h(z)]$ according to the convention above; that is, the result of replacing all free occurrences of x in φ by $h(z)$ after φ has been transformed into special form. We want the above formula to be considered a legal instance of the assignment axiom scheme below.

Axiom System S2

Axiom Schemes

- all instances of valid first-order formulas;
- all instances of valid formulas of PDL;
- $\langle x := t \rangle \varphi \leftrightarrow \varphi[x/t]$;
- $\varphi \leftrightarrow \widehat{\varphi}$, where $\widehat{\varphi}$ is φ in which some occurrence of a program α has been replaced by the program $z := x$; α' ; $x := z$ for z not appearing in φ , and where α' is α with all occurrences of x replaced by z .

Inference Rules

- modus ponens:

$$\frac{\varphi, \varphi \rightarrow \psi}{\psi}$$

- generalization:

$$\frac{\varphi}{[\alpha]\varphi} \quad \text{and} \quad \frac{\varphi}{\forall x \varphi}$$

- infinitary convergence:

$$\frac{\varphi \rightarrow [\alpha^n]\psi, n \in \omega}{\varphi \rightarrow [\alpha^*]\psi}$$

Provability in Axiom System S2, denoted by \vdash_{S2} , is the usual concept for systems with infinitary rules of inference; that is, deriving a formula using the infinitary rule requires infinitely many premises to have been previously derived.

Axiom System S2 consists of an axiom for assignment, facilities for propositional reasoning about programs and first-order reasoning with no programs (but with programs possibly appearing in instantiated first-order formulas), and an infinitary rule for $[\alpha^*]$. The dual construct, $\langle \alpha^* \rangle$, is taken care of by the “unfolding” validity of PDL:

$$\langle \alpha^* \rangle \varphi \leftrightarrow (\varphi \vee \langle \alpha; \alpha^* \rangle \varphi).$$

THEOREM 72. *For any formula φ of DL,*

$$\models \varphi \Leftrightarrow \vdash_{S2} \varphi.$$

11.2 Interpreted Reasoning

Proving properties of real programs very often involves reasoning on the interpreted level, where one is interested in \mathfrak{A} -validity for a particular structure \mathfrak{A} . A typical proof might use induction on the length of the computation to establish an invariant for partial correctness or to exhibit a decreasing value in some well-founded set for termination. In each case, the problem is reduced to the problem of verifying some domain-dependent facts, sometimes called *verification conditions*. Mathematically speaking, this kind of activity is really an effective transformation of assertions about programs into ones about the underlying structure.

For DL, this transformation can be guided by a direct induction on program structure using an axiom system that is complete *relative to* any given arithmetical structure \mathfrak{A} . The essential idea is to exploit the existence, for any given DL formula, of a first-order equivalent in \mathfrak{A} , as guaranteed by Theorem 60. In the axiom systems we construct, instead of dealing with the Π_1^1 -hardness of the validity problem by an infinitary rule, we take all \mathfrak{A} -valid first-order formulas as additional axioms. Relative to this set of axioms, proofs are finite and effective.

For partial correctness assertions of the form $\varphi \rightarrow [\alpha]\psi$ with φ and ψ first-order and α containing first-order tests, it suffices to show that DL reduces to the first-order logic $L_{\omega\omega}$, and there is no need for the natural numbers to be present. Thus, Axiom System S3 below works for finite structures too. Axiom System S4 is an *arithmetically complete* system for full DL that does make explicit use of natural numbers.

It follows from Theorem 66 that for partial correctness formulas we cannot hope to obtain a completeness result similar to the one proved in Theorem 71 for termination formulas. A way around this difficulty is to consider only *expressive* structures.

A structure \mathfrak{A} for the first-order vocabulary Σ is said to be *expressive* for a programming language K if for every $\alpha \in K$ and for every first-order formula φ , there exists a first-order formula ψ_L such that $\mathfrak{A} \models \psi_L \leftrightarrow [\alpha]\varphi$. Examples of structures that are expressive for most programming languages are finite structures and arithmetical structures.

Axiom System S3

Axiom Schemes

- all instances of valid formulas of PDL;
- $\langle x := t \rangle \varphi \leftrightarrow \varphi[x/t]$ for first-order φ .

Inference Rules

- modus ponens:

$$\frac{\varphi, \varphi \rightarrow \psi}{\psi}$$

- generalization:

$$\frac{\varphi}{[\alpha]\varphi}.$$

Note that Axiom System S3 is really the axiom system for PDL from Section 4 with the addition of the assignment axiom. Given a DL formula φ and a structure \mathfrak{A} , denote by $\mathfrak{A} \vdash_{S3} \varphi$ provability of φ in the system obtained from Axiom System S3 by adding the following set of axioms:

- all \mathfrak{A} -valid first-order sentences.

THEOREM 73. *For every expressive structure \mathfrak{A} and for every formula ξ of DL of the form $\varphi \rightarrow [\alpha]\psi$, where φ and ψ are first-order and α involves only first-order tests, we have*

$$\mathfrak{A} \models \xi \Leftrightarrow \mathfrak{A} \vdash_{S_3} \xi.$$

Now we present an axiom system S4 for full DL. It is similar in spirit to S3 in that it is complete relative to the formulas valid in the structure under consideration. However, this system works for arithmetical structures only. It is not tailored to deal with other expressive structures, notably finite ones, since it requires the use of the natural numbers. The kind of completeness result stated here is thus termed *arithmetical*.

As in Section 9.2, we state the results for the special structure \mathbb{N} , omitting the technicalities needed to deal with general arithmetical structures. The main difference is that in \mathbb{N} we can use variables n , m , etc., knowing that their values will be natural numbers. We can thus write $n + 1$, for example, assuming the standard interpretation. When working in an unspecified arithmetical structure, we have to precede such usage with appropriate predicates that guarantee that we are indeed talking about that part of the domain that is isomorphic to the natural numbers. For example, we would often have to use the first-order formula, call it $\text{nat}(n)$, which is true precisely for the elements representing natural numbers, and which exists by the definition of an arithmetical structure.

Axiom System S4

Axiom Schemes

- all instances of valid first-order formulas;
- all instances of valid formulas of PDL;
- $\langle x := t \rangle \varphi \leftrightarrow \varphi[x/t]$ for first-order φ .

Inference Rules

- modus ponens:

$$\frac{\varphi, \varphi \rightarrow \psi}{\psi}$$

- generalization:

$$\frac{\varphi}{[\alpha]\varphi} \quad \text{and} \quad \frac{\varphi}{\forall x \varphi}$$

- convergence:

$$\frac{\varphi(n+1) \rightarrow \langle \alpha \rangle \varphi(n)}{\varphi(n) \rightarrow \langle \alpha^* \rangle \varphi(0)}$$

for first order φ and variable n not appearing in α .

REMARK 74. For general arithmetical structures, the $+1$ and 0 in the rule of convergence denote suitable first-order definitions.

As in Axiom System S3, denote by $\mathfrak{A} \vdash_{S4} \varphi$ provability of φ in the system obtained from Axiom System S4 by adding all \mathfrak{A} -valid first-order sentences as axioms.

THEOREM 75. *For every formula ξ of DL,*

$$\mathbb{N} \models \xi \Leftrightarrow \mathbb{N} \vdash_{S4} \xi.$$

The use of the natural numbers as a device for counting down to 0 in the convergence rule of Axiom System S4 can be relaxed. In fact, any well-founded set suitably expressible in any given arithmetical structure suffices. Also, it is not necessary to require that an execution of α causes the truth of the parameterized $\varphi(n)$ in that rule to decrease exactly by 1; it suffices that the decrease is positive at each iteration.

In closing, we note that appropriately restricted versions of all axiom systems of this section are complete for DL (dreg). In particular, as pointed out in Section 2.6, the Hoare **while**-rule

$$\frac{\varphi \wedge \xi \rightarrow [\alpha] \varphi}{\varphi \rightarrow [\mathbf{while} \ \xi \ \mathbf{do} \ \alpha] (\varphi \wedge \neg \xi)}$$

results from combining the generalization rule with the induction and test axioms of PDL, when $*$ is restricted to appear only in the context of a **while** statement; that is, only in the form $(\xi?; p)^*; (\neg \xi)?$.

12 EXPRESSIVENESS OF DL

The subject of study in this section is the relative expressive power of languages. We will be primarily interested in comparing, on the uninterpreted level, the expressive power of various versions of DL. That is, for programming languages P_1 and P_2 we will study whether $\text{DL}(P_1) \leq \text{DL}(P_2)$ holds. Recall from Section 9 that the latter relation means that for each formula φ in $\text{DL}(P_1)$, there is a formula ψ in $\text{DL}(P_2)$ such that $\mathfrak{A}, u \models \varphi \leftrightarrow \psi$ for all structures \mathfrak{A} and initial states u .

Studying the expressive power of logics rather than the computational power of programs allows us to compare, for example, deterministic and

nondeterministic programming languages. Also, we will see that the answer to the fundamental question “ $DL(P_1) \leq DL(P_2)$?” may depend crucially on the vocabulary over which we consider logics and programs. For this reason we always make clear in the theorems of this section our assumptions on the vocabulary.

THEOREM 76. *Let Σ be a rich vocabulary. Then*

- (i) $DL(\text{stk}) \leq DL(\text{array})$.
- (ii) $DL(\text{stk}) \equiv DL(\text{array})$ iff $P = PSPACE$.

Moreover, the same holds for deterministic regular programs with an algebraic stack and deterministic regular programs with arrays.

THEOREM 77. *Over a monadic vocabulary, nondeterministic regular programs with a Boolean stack have the same computational power as nondeterministic regular programs with an algebraic stack.*

Now we investigate the role that nondeterminism plays in the expressive power of logics of programs. As we shall see, the general conclusion is that for a programming language of sufficient computational power, nondeterminism does not increase the expressive power of the logic.

We start our discussion of the role of nondeterminism with the basic case of regular programs. Recall that DL and DDL denote the logics of nondeterministic and deterministic regular programs, respectively.

We can now state the main result that separates the expressive power of deterministic and nondeterministic **while** programs.

THEOREM 78. *For every vocabulary containing at least two unary function symbols or at least one function symbol of arity greater than one, DDL is strictly less expressive than DL ; that is, $DDL < DL$.*

It turns out that Theorem 78 cannot be extended to vocabularies containing just one unary function symbol without solving a well known open problem in complexity theory.

THEOREM 79. *For every rich mono-unary vocabulary, the statement “ DDL is strictly less expressive than DL ” is equivalent to $LOGSPACE \neq NLOGSPACE$.*

We now turn our attention to the discussion of the role nondeterminism plays in the expressive power of regular programs with a Boolean stack. For a vocabulary containing at least two unary function symbols, nondeterminism increases the expressive power of DL over regular programs ‘ with a Boolean stack.

For the rest of this section, we let the vocabulary contain two unary function symbols.

THEOREM 80. *For a vocabulary containing at least two unary function symbols or a function symbol of arity greater than two, $DL(\text{dbstk}) < DL(\text{bstk})$.*

It turns out that for programming languages that use sufficiently strong data types, nondeterminism does not increase the expressive power of Dynamic Logic.

THEOREM 81. *For every vocabulary,*

- (i) $\text{DL}(\text{dstk}) \equiv \text{DL}(\text{stk});$
- (ii) $\text{DL}(\text{darray}) \equiv \text{DL}(\text{array}).$

We will discuss the role of unbounded memory of programs for the expressive power of the corresponding logic. However, this result depends on assumptions about the vocabulary Σ .

Recall from Section 8.2 that an r.e. program α has *bounded memory* if the set $CS(\alpha)$ contains only finitely many distinct variables from V , and if in addition the nesting of function symbols in terms that occur in seqs of $CS(\alpha)$ is bounded. This restriction implies that such a program can be simulated in all interpretations by a device that uses a fixed finite number of registers, say x_1, \dots, x_n , and all its elementary steps consist of either performing a test of the form

$$r(x_{i_1}, \dots, x_{i_m})?,$$

where r is an m -ary relation symbol of Σ , or executing a simple assignment of either of the following two forms:

$$x_i := f(x_{i_1}, \dots, x_{i_k}) \qquad x_i := x_j.$$

In general, however, such a device may need a very powerful control (that of a Turing machine) to decide which elementary step to take next.

An example of a programming language with bounded memory is the class of regular programs with a Boolean stack. Indeed, the Boolean stack strengthens the control structure of a regular program without introducing extra registers for storing algebraic elements. It can be shown without much difficulty that regular programs with a Boolean stack have bounded memory. On the other hand, regular programs with an algebraic stack or with arrays are programming languages with unbounded memory.

For monadic vocabularies, the class of nondeterministic regular programs with a Boolean stack is computationally equivalent to the class of nondeterministic regular programs with an algebraic stack. For deterministic programs, the situation is slightly different.

THEOREM 82.

- (i) *For every vocabulary containing a function symbol of arity greater than one, $\text{DL}(\text{dbstk}) < \text{DL}(\text{dstk})$ and $\text{DL}(\text{bstk}) < \text{DL}(\text{stk})$.*
- (ii) *For all monadic vocabularies, $\text{DL}(\text{bstk}) \equiv \text{DL}(\text{stk})$.*

- (iii) For all mono-unary vocabularies, $DL(\text{dbstk}) \equiv DL(\text{dstk})$.
- (iv) For all monadic vocabularies containing at least two function symbols, $DL(\text{dbstk}) < DL(\text{dstk})$.

Regular programs with a Boolean stack are situated between pure regular programs and regular programs with an algebraic stack. We start our discussion by comparing the expressive power of regular programs with and without a Boolean stack. The only known definite answer to this problem is given in the following result, which covers the case of deterministic programs only.

THEOREM 83.

- (i) Let the vocabulary be rich and mono-unary. Then

$$DL(\text{dreg}) \equiv DL(\text{dstk}) \Leftrightarrow LOGSPACE = P.$$

- (ii) If the vocabulary contains at least one function symbol of arity greater than one or at least two unary function symbols, then $DL(\text{dreg}) < DL(\text{dbstk})$.

It is not known whether Theorem 83(ii) holds for nondeterministic programs, and neither is its statement known to be equivalent to any of the well known open problems in complexity theory. In contrast, it follows from Theorems 83(i) and 82(iii) that for rich mono-unary vocabularies, $DL(\text{dreg}) \equiv DL(\text{dbstk})$ if and only if $LOGSPACE = P$. Hence, this problem cannot be solved without solving one of the major open problems in complexity theory.

The wildcard assignment statement $x := ?$ discussed in Section 8.2 chooses an element of the domain of computation nondeterministically and assigns it to x . It is a device that represents *unbounded nondeterminism* as opposed to the binary nondeterminism of the nondeterministic choice construct \cup . The programming language of regular programs augmented with wildcard assignment is not an acceptable programming language, since a wildcard assignment can produce values that are outside the substructure generated by the input.

Our first result shows that wildcard assignment increases the expressive power in quite a substantial way; it cannot be simulated even by r.e. programs.

THEOREM 84. Let the vocabulary Σ contain two constants c_1, c_2 , a binary predicate symbol p , the symbol $=$ for equality, and no other function or predicate symbols. There is a formula of $DL(\text{wild})$ that is equivalent to no formula of $DL(\text{r.e.})$, thus $DL(\text{wild}) \not\leq DL(\text{r.e.})$.

It is not known whether any of the logics with unbounded memory are reducible to DL(wild).

When both wildcard and array assignments are allowed, it is possible to define the finiteness of (the domain of) a structure, but not in the logics with either of the additions removed. Thus, having both memory and non-determinism unbounded provides more power than having either of them bounded.

THEOREM 85. *Let vocabulary Σ contain only the symbol of equality. There is a formula of DL(array+wild) equivalent to no formula of either DL(array) or DL(wild).*

13 VARIANTS OF DL

In this section we consider some restrictions and extensions of DL. We are interested mainly in questions of comparative expressive power on the uninterpreted level. In arithmetical structures these questions usually become trivial, since it is difficult to go beyond the power of first-order arithmetic without allowing infinitely many distinct tests in programs (see Theorems 60 and 61). In regular DL this luxury is not present.

13.1 Algorithmic Logic

Algorithmic Logic (AL) is the predecessor of Dynamic Logic. The basic system was defined by [Salwicki, 1970] and generated an extensive amount of subsequent research carried out by a group of mathematicians working in Warsaw. Two surveys of the first few years of their work can be found in [Banachowski *et al.*, 1977] and [Salwicki, 1977].

The original version of AL allowed deterministic **while** programs and formulas built from the constructs

$$\alpha\varphi \quad \cup \alpha\varphi \quad \cap \alpha\varphi$$

corresponding in our terminology to

$$\langle \alpha \rangle \varphi \quad \langle \alpha^* \rangle \varphi \quad \bigwedge_{n \in \omega} \langle \alpha^n \rangle \varphi,$$

respectively, where α is a deterministic **while** program and φ is a quantifier-free first-order formula.

In [Mirkowska, 1980; Mirkowska, 1981a; Mirkowska, 1981b], AL was extended to allow nondeterministic **while** programs and the constructs

$$\nabla \alpha\varphi \quad \Delta \alpha\varphi$$

corresponding in our terminology to

$$\langle \alpha \rangle \varphi \quad \mathbf{halt}(\alpha) \wedge [\alpha]\varphi \wedge \langle \alpha \rangle \varphi,$$

respectively. The latter asserts that all traces of α are finite and terminate in a state satisfying φ .

A feature present in AL but not in DL is the set of “dynamic terms” in addition to dynamic formulas. For a first-order term t and a deterministic **while** program α , the meaning of the expression αt is the value of t after executing program α . If α does not halt, the meaning is undefined. Such terms can be systematically eliminated; for example, $P(x, \alpha t)$ is replaced by $\exists z (\langle \alpha \rangle (z = t) \wedge P(x, z))$.

The emphasis in the early research on AL was in obtaining infinitary completeness results, developing normal forms for programs, investigating recursive procedures with parameters, and axiomatizing certain aspects of programming using formulas of AL. As an example of the latter, the algorithmic formula

$$(\mathbf{while} \ s \neq \varepsilon \ \mathbf{do} \ s := \mathbf{pop}(s))\mathbf{1}$$

can be viewed as an axiom connected with the data structure *stack*. One can then investigate the consequences of such axioms within AL, regarding them as properties of the corresponding data structures.

Complete infinitary deductive systems for first-order and propositional versions are given in [Mirkowska, 1980; Mirkowska, 1981a; Mirkowska, 1981b]. The infinitary completeness results for AL are usually proved by the algebraic methods of [Rasiowa and Sikorski, 1963].

[Constable, 1977], [Constable and O’Donnell, 1978] and [Goldblatt, 1982] present logics similar to AL and DL for reasoning about deterministic **while** programs.

13.2 Well-Foundedness

As in Section 7 for PDL, we consider adding to DL assertions to the effect that programs can enter infinite computations. Here too, we shall be interested both in LDL and in RDL versions; i.e., those in which **halt** α and **wf** α , respectively, have been added inductively as new formulas for any program α . As mentioned there, the connection with the more common notation **repeat** α and **loop** α (from which the L and R in the names LDL and RDL derive) is by:

$$\begin{aligned} \mathbf{loop} \ \alpha &\stackrel{\text{def}}{\iff} \neg \mathbf{halt} \ \alpha \\ \mathbf{repeat} \ \alpha &\stackrel{\text{def}}{\iff} \neg \mathbf{wf} \ \alpha. \end{aligned}$$

We now state some of the relevant results. The first concerns the addition of **halt** α :

THEOREM 86. LDL \equiv DL.

In contrast to this, we have:

THEOREM 87. LDL < RDL.

Turning to the validity problem for these extensions, clearly they cannot be any harder to decide than that of DL, which is Π_1^1 -complete. However, the following result shows that detecting the absence of infinite computations of even simple uninterpreted programs is extremely hard.

THEOREM 88. *The validity problems for formulas of the form $\varphi \rightarrow \mathbf{wf}\alpha$ and formulas of the form $\varphi \rightarrow \mathbf{halt}\alpha$, for first-order φ and regular α , are both Π_1^1 -complete. If α is constrained to have only first-order tests then the $\varphi \rightarrow \mathbf{wf}\alpha$ case remains Π_1^1 -complete but the $\varphi \rightarrow \mathbf{halt}\alpha$ case is r.e.; that is, it is Σ_1^0 -complete.*

We just mention here that the additions to Axiom System S4 of Section 11 that are used to obtain an arithmetically complete system for RDL are the axiom

$$[\alpha^*](\varphi \rightarrow \langle \alpha \rangle \varphi) \rightarrow (\varphi \rightarrow \neg \mathbf{wf} \alpha)$$

and the inference rule

$$\frac{\varphi(n+1) \rightarrow [\alpha]\varphi(n), \neg\varphi(0)}{\varphi(n) \rightarrow \mathbf{wf} \alpha}$$

for first-order φ and n not occurring in α .

13.3 Probabilistic Programs

There is wide interest recently in programs that employ probabilistic moves such as coin tossing or random number draws and whose behavior is described probabilistically (for example, α is “correct” if it does what it is meant to do with probability 1). To give one well known example taken from [Miller, 1976] and [Rabin, 1980], there are fast probabilistic algorithms for checking primality of numbers but no known fast nonprobabilistic ones. Many synchronization problems including digital contract signing, guaranteeing mutual exclusion, etc. are often solved by probabilistic means.

This interest has prompted research into formal and informal methods for reasoning about probabilistic programs. It should be noted that such methods are also applicable for reasoning probabilistically about ordinary programs, for example, in average-case complexity analysis of a program, where inputs are regarded as coming from some set with a probability distribution.

[Kozen, 1981d] provided a formal semantics for probabilistic first-order **while** programs with a random assignment statement $x := ?$. Here the term “random” is quite appropriate (contrast with Section 8.2) as the statement essentially picks an element out of some fixed distribution over the domain D . This domain is assumed to be given with an appropriate set of measurable subsets. Programs are then interpreted as measurable functions on a certain measurable product space of copies of D .

In [Feldman and Harel, 1984] a probabilistic version of first-order Dynamic Logic, $Pr(DL)$, was investigated on the interpreted level. Kozen's semantics is extended as described below to a semantics for formulas that are closed under Boolean connectives and quantification over reals and integers and that employ terms of the form $Fr(\varphi)$ for first-order φ . In addition, if α is a **while** program with nondeterministic assignments and φ is a formula, then $\{\alpha\}\varphi$ is a new formula.

The semantics assumes a domain D , say the reals, with a measure space consisting of an appropriate family of *measurable subsets* of D . The states μ, ν, \dots are then taken to be the positive measures on this measure space. Terms are interpreted as functions from states to real numbers, with $Fr(\varphi)$ in μ being the *frequency* (or simply, the *measure*) of φ in μ . Frequency is to positive measures as probability is to probability measures. The formula $\{\alpha\}\varphi$ is true in μ if φ is true in ν , the state (i.e., measure) that is the result of applying α to μ in Kozen's semantics. Thus $\{\alpha\}\varphi$ means "after α , φ " and is the construct analogous to $\langle \alpha \rangle \varphi$ of DL.

For example, in $Pr(DL)$ one can write

$$Fr(1) = 1 \rightarrow \{\alpha\}Fr(1) \geq p$$

to mean, " α halts with probability at least p ." The formula

$$\begin{aligned} Fr(1) = 1 \rightarrow & [i := 1; x := ?; \mathbf{while} \ x > 1/2 \ \mathbf{do} \ (x := ?; i := i + 1)] \\ & \forall n \ ((n \geq 1 \rightarrow Fr(i = n) = 2^{-n}) \wedge \\ & \quad (n < 1 \rightarrow Fr(i = n) = 0)) \end{aligned}$$

is valid in all structures in which the distribution of the random variable used in $x := ?$ is a uniform distribution on the real interval $[0, 1]$.

An axiom system for $Pr(DL)$ was proved in [Feldman and Harel, 1984] to be complete relative to an extension of first-order analysis with integer variables, and for discrete probabilities first-order analysis with integer variables was shown to suffice.

14 OTHER APPROACHES

Here we discuss briefly some topics closely related to Dynamic Logic.

14.1 Logic of Effective Definitions

The Logic of Effective Definitions (LED), introduced by [Tiuryn, 1981a], was intended to study notions of computability over abstract models and to provide a universal framework for the study of logics of programs over such models. It consists of first-order logic augmented with new atomic formulas of the form $\alpha = \beta$, where α and β are *effective definitional schemes* (the latter notion is due to [Friedman, 1971]):

```

if  $\varphi_1$  then  $t_1$ 
  else if  $\varphi_2$  then  $t_2$ 
    else if  $\varphi_3$  then  $t_3$ 
      else if ...

```

where the φ_i are quantifier-free formulas and t_i are terms over a bounded set of variables, and the function $i \mapsto (\varphi_i, t_i)$ is recursive. The formula $\alpha = \beta$ is defined to be true in a state if both α and β terminate and yield the same value, or neither terminates.

Model theory and infinitary completeness of LED are treated in [Tiuryn, 1981a].

Effective definitional schemes in the definition of LED can be replaced by any programming language K , giving rise to various logical formalisms. The following result, which relates LED to other logics discussed here, is proved in [Meyer and Tiuryn, 1981; Meyer and Tiuryn, 1984].

THEOREM 89. *For every vocabulary L , LED \equiv DL(r.e.).*

14.2 Temporal Logic

Temporal Logic (TL) is an alternative application of modal logic to program specification and verification. It was first proposed as a useful tool in program verification by [Pnueli, 1977] and has since been developed by many authors in various forms. This topic is surveyed in depth in [Emerson, 1990] and [Gabbay *et al.*, 1994].

TL differs from DL chiefly in that it is *endogenous*; that is, programs are not explicit in the language. Every application has a single program associated with it, and the language may contain program-specific statements such as **at** L , meaning “execution is currently at location L in the program.” There are two competing semantics, giving rise to two different theories called *linear-time* and *branching-time* TL. In the former, a model is a linear sequence of program states representing an execution sequence of a deterministic program or a possible execution sequence of a nondeterministic or concurrent program. In the latter, a model is a tree of program states representing the space of all possible traces of a nondeterministic or concurrent program. Depending on the application and the semantics, different syntactic constructs can be chosen. The relative advantages of linear and branching time semantics are discussed in [Lamport, 1980; Emerson and Halpern, 1986; Emerson and Lei, 1987; Vardi, 1998a].

Modal constructs used in TL include

$\Box\varphi$	“ φ holds in all future states”
$\Diamond\varphi$	“ φ holds in some future state”
$\bigcirc\varphi$	“ φ holds in the next state”
$\varphi \mathbf{until} \psi$	“there exists some strictly future point t at which ψ will be satisfied and all points strictly between the current state and t satisfy φ ”

for linear-time logic, as well as constructs for expressing

“for all traces starting from the present state . . . ”

“for some trace starting from the present state . . . ”

for branching-time logic.

Temporal logic is useful in situations where programs are not normally supposed to halt, such as operating systems, and is particularly well suited to the study of concurrency. Many classical program verification methods such as the *intermittent assertions method* are treated quite elegantly in this framework.

Temporal logic has been most successful in providing tools for proving properties of concurrent *finite state* protocols, such as solutions to the *dining philosophers* and *mutual exclusion* problems, which are popular abstract versions of synchronization and resource management problems in distributed systems.

The induction principle of TL takes the form:

$$(35) \quad \varphi \wedge \Box(\varphi \rightarrow \bigcirc\varphi) \rightarrow \Box\varphi.$$

Note the similarity to the PDL induction axiom (Axiom 17(viii)):

$$\varphi \wedge [\alpha^*](\varphi \rightarrow [\alpha]\varphi) \rightarrow [\alpha^*]\varphi.$$

This is a classical program verification method known as *inductive* or *invariant assertions*.

The operators \bigcirc , \Diamond , and \Box can all be defined in terms of **until**:

$$\begin{aligned} \bigcirc\varphi &\Leftrightarrow \neg(\mathbf{0 until} \neg\varphi) \\ \Diamond\varphi &\Leftrightarrow \varphi \vee (\mathbf{1 until} \varphi) \\ \Box\varphi &\Leftrightarrow \varphi \wedge \neg(\mathbf{1 until} \neg\varphi), \end{aligned}$$

but not vice-versa. It has been shown in [Kamp, 1968] and [Gabbay *et al.*, 1980] that the **until** operator is powerful enough to express anything that can be expressed in the first-order theory of $(\omega, <)$. It has also been shown in [Wolper, 1981; Wolper, 1983] that there are very simple predicates that cannot be expressed by **until**; for example, “ φ is true at every multiple of 4.”

The **until** operator has been shown to be very useful in expressing properties of programs that are not properties of the input/output relation, such as: “If process p requests a resource before q does, then it will receive it before q does.” Indeed, much of the research in TL has concentrated on providing useful methods for proving these and other kinds of properties (see [Manna and Pnueli, 1981; Gabbay *et al.*, 1980]).

Concurrency and Nondeterminism

Unlike DL, TL can be applied to programs that are not normally supposed to halt, such as operating systems, because programs are interpreted as *traces* instead of pairs of states.

Up to now we have only considered deterministic, single-process programs. There is no reason however not to apply TL to *nondeterministic* and *concurrent (multiprocessor)* systems, in which next states are not unique. The computation is no longer a single trace, but many different traces are possible. We can assemble them all together to get a *computation tree* in which each node represents a state accessible from the start state.

As above, an *invariance property* is a property of the form $\Box\varphi$. However, the dual \Diamond of the operator \Box defined in this way does not really capture what we mean by *eventuality* or *liveness* properties. We would like to be able to say that *every* possible trace in the computation tree has a state satisfying φ . For instance, a nondeterministic program is *total* if there is no chance of an infinite trace out of the start state s ; that is, every trace out of s satisfies $\Diamond\mathbf{halt}$. The dual \Diamond of \Box as defined by $\Diamond\varphi = \neg\Box\neg\varphi$ does not really express this. It says instead

$$s \models \Diamond\varphi \Leftrightarrow \text{there is some node } t \text{ in the tree below } s \text{ such that } t \models \varphi.$$

This is not a very useful statement.

One way to fix this is to introduce the branching time operator **A** that says, “For all traces in the tree ...,” and then use \Box , \Diamond in the sense of linear TL applied to the trace quantified by **A**. The dual of **A** is **E**, which says, “There exists a trace in the tree” Thus, in order to say that the computation tree starting from the current state satisfies a safety or invariance property, we would write

$$\mathbf{A}\Box\varphi,$$

which says, “For all traces π out of the current state, π satisfies $\Box\varphi$,” and to say that the tree satisfies an eventuality property, we would write

$$\mathbf{A}\Diamond\varphi,$$

which says, “For all traces π out of the current state, π satisfies $\Diamond\varphi$; that is, φ occurs somewhere along the trace π .” The logic with the linear temporal

operators augmented with the trace quantifiers **A** and **E** is known as CTL; see [Emerson, 1990; Emerson and Halpern, 1986; Emerson and Halpern, 1985; Emerson and Lei, 1987; Emerson and Sistla, 1984].

Complexity and Deductive Completeness

A useful axiomatization of linear-time TL without the until operator is given by the axioms

$$\begin{aligned}
\Box(\varphi \rightarrow \psi) &\rightarrow (\Box\varphi \rightarrow \Box\psi) \\
\Box(\varphi \wedge \psi) &\leftrightarrow \Box\varphi \wedge \Box\psi \\
\Diamond\varphi &\leftrightarrow \varphi \vee \Box\Diamond\varphi \\
\bigcirc(\varphi \vee \psi) &\leftrightarrow \bigcirc\varphi \vee \bigcirc\psi \\
\bigcirc(\varphi \wedge \psi) &\leftrightarrow \bigcirc\varphi \wedge \bigcirc\psi \\
\varphi \wedge \Box(\varphi \rightarrow \bigcirc\varphi) &\rightarrow \Box\varphi \\
\forall x \varphi(x) &\rightarrow \varphi(t) \quad (t \text{ is free for } x \text{ in } \varphi) \\
\forall x \Box\varphi &\rightarrow \Box\forall x \varphi
\end{aligned}$$

and rules

$$\frac{\varphi, \varphi \rightarrow \psi}{\psi} \quad \frac{\varphi}{\Box\varphi} \quad \frac{\varphi}{\forall x \varphi}.$$

Compare the axioms of PDL (Axioms 17). The propositional fragment of this deductive system is complete for linear-time propositional TL, as shown in [Gabbay *et al.*, 1980].

[Sistla and Clarke, 1982] and [Emerson and Halpern, 1985] have shown that the validity problem for most versions of propositional TL is *PSPACE*-complete for linear structures and *EXPTIME*-complete for branching structures.

Embedding TL in DL

TL is subsumed by DL. To embed propositional TL into PDL, take an atomic program a to mean “one step of program p .” In the linear model, the TL constructs $\bigcirc\varphi$, $\Box\varphi$, $\Diamond\varphi$, and φ **until** ψ are then expressed by $[a]\varphi$, $[a^*]\varphi$, $\langle a^* \rangle\varphi$, and $\langle (a; \varphi?)^* ; a \rangle\psi$, respectively.

14.3 Process Logic

Dynamic Logic and Temporal Logic embody markedly different approaches to reasoning about programs. This dichotomy has prompted researchers to search for an appropriate process logic that combines the best features of both. An appropriate candidate should combine the ability to reason

about programs compositionally with the ability to reason directly about the intermediate states encountered during the course of a computation.

[Pratt, 1979c], [Parikh, 1978b], [Nishimura, 1980], and [Harel *et al.*, 1982b] all suggested increasingly more powerful propositional-level formalisms in which the basic idea is to interpret formulas in *traces* rather than in states. In particular, [Harel *et al.*, 1982b] present a system called *Process Logic* (PL), which is essentially a union of TL and test-free regular PDL. That paper proves that the satisfiability problem is decidable and gives a complete finitary axiomatization.

Syntactically, we have programs α, β, \dots and propositions φ, ψ, \dots as in PDL. We have atomic symbols of each type and compound expressions built up from the operators $\rightarrow, \mathbf{0}, ;, \cup, *, ?$ (applied to Boolean combinations of atomic formulas only), ω , and $[]$. In addition we have the temporal operators **first** and **until**. The temporal operators are available for expressing and reasoning about trace properties, but programs are constructed compositionally as in PDL. Other operators are defined as in PDL (see Section 2.1) except for **skip**, which is handled specially.

Semantically, both programs and propositions are interpreted as sets of traces. We start with a Kripke frame $\mathfrak{K} = (K, \mathfrak{m}_{\mathfrak{K}})$ as in Section 2.2, where K is a set of *states* s, t, \dots and the function $\mathfrak{m}_{\mathfrak{K}}$ interprets atomic formulas p as subsets of K and atomic programs a as binary relations on K . The temporal operators are defined as in TL.

Trace models satisfy (most of) the PDL axioms. As in Section 14.2, define

$$\begin{aligned} \mathbf{halt} &\stackrel{\text{def}}{\iff} \mathbf{0} \\ \mathbf{fin} &\stackrel{\text{def}}{\iff} \diamond \mathbf{halt} \\ \mathbf{inf} &\stackrel{\text{def}}{\iff} \neg \mathbf{fin}, \end{aligned}$$

which say that the trace is of length 0, of finite length, or of infinite length, respectively. Define two new operators $\llbracket \]$ and $\langle\langle \ \rangle\rangle$:

$$\begin{aligned} \llbracket \alpha \rrbracket \varphi &\stackrel{\text{def}}{\iff} \mathbf{fin} \rightarrow [\alpha] \varphi \\ \langle\langle \alpha \rangle\rangle \varphi &\stackrel{\text{def}}{\iff} \neg \llbracket \alpha \rrbracket \neg \varphi \iff \mathbf{fin} \wedge \langle \alpha \rangle \varphi. \end{aligned}$$

The $*$ operator is the same as in PDL. It can be shown that the two PDL axioms

$$\begin{aligned} \varphi \wedge [\alpha] [\alpha^*] \varphi &\leftrightarrow [\alpha^*] \varphi \\ \varphi \wedge [\alpha^*] (\varphi \rightarrow [\alpha] \varphi) &\rightarrow [\alpha^*] \varphi \end{aligned}$$

hold by establishing that

$$\begin{aligned} \bigcup_{n \geq 0} \mathfrak{m}_{\mathfrak{K}}(\alpha^n) &= \mathfrak{m}_{\mathfrak{K}}(\alpha^0) \cup (\mathfrak{m}_{\mathfrak{K}}(\alpha) \circ \bigcup_{n \geq 0} \mathfrak{m}_{\mathfrak{K}}(\alpha^n)) \\ &= \mathfrak{m}_{\mathfrak{K}}(\alpha^0) \cup ((\bigcup_{n \geq 0} \mathfrak{m}_{\mathfrak{K}}(\alpha^n)) \circ \mathfrak{m}_{\mathfrak{K}}(\alpha)). \end{aligned}$$

As mentioned, the version of PL of [Harel *et al.*, 1982b] is decidable (but, it seems, in nonelementary time only) and complete. It has also been shown that if we restrict the semantics to include only finite traces (not a necessary restriction for obtaining the results above), then PL is no more expressive than PDL. Translations of PL structures into PDL structures have also been investigated, making possible an elementary time decision procedure for deterministic PL; see [Halpern, 1982; Halpern, 1983]. An extension of PL in which **first** and **until** are replaced by regular operators on formulas has been shown to be decidable but nonelementary in [Harel *et al.*, 1982b]. This logic perhaps comes closer to the desired objective of a powerful decidable logic of traces with natural syntactic operators that is closed under attachment of regular programs to formulas.

14.4 The μ -Calculus

The μ -calculus was suggested as a formalism for reasoning about programs in [Scott and de Bakker, 1969] and was further developed in [Hitchcock and Park, 1972], [Park, 1976], and [de Bakker, 1980].

The heart of the approach is μ , the *least fixpoint* operator, which captures the notions of iteration and recursion. The calculus was originally defined as a first-order-level formalism, but propositional versions have become popular.

The μ operator binds relation variables. If $\varphi(X)$ is a logical expression with a free relation variable X , then the expression $\mu X.\varphi(X)$ represents the least X such that $\varphi(X) = X$, if such an X exists. For example, the reflexive transitive closure R^* of a binary relation R is the least binary relation containing R and closed under reflexivity and transitivity; this would be expressed in the first-order μ -calculus as

$$(36) \quad R^* \stackrel{\text{def}}{=} \mu X(x, y).(x = y \vee \exists z (R(x, z) \wedge X(z, y))).$$

This should be read as, “the least binary relation $X(x, y)$ such that either $x = y$ or x is related by R to some z such that z and y are already related by X .” This captures the usual fixpoint formulation of reflexive transitive closure. The formula (36) can be regarded either as a recursive program computing R^* or as an inductively defined assertion that is true of a pair (x, y) iff that pair is in the reflexive transitive closure of R .

The existence of a least fixpoint is not guaranteed except under certain restrictions. Indeed, the formula $\neg X$ has no fixpoint, therefore $\mu X.\neg X$ does not exist. Typically, one restricts the application of the binding operator μX to formulas that are *positive* or *syntactically monotone* in X ; that is, those formulas in which every free occurrence of X occurs in the scope of an even number of negations. This implies that the relation operator $X \mapsto \varphi(X)$ is (semantically) monotone, which by the Knaster–Tarski theorem ensures the existence of a least fixpoint.

The first-order μ -calculus can define all sets definable by first-order induction and more. In particular, it can capture the input/output relation of any program built from any of the DL programming constructs we have discussed. Since the first-order μ -calculus also admits first-order quantification, it is easily seen to be as powerful as DL.

It was shown by [Park, 1976] that finiteness is not definable in the first-order μ -calculus with the monotonicity restriction, but well-foundedness is. Thus this version of the μ -calculus is independent of $L_{\omega_1^{\text{ck}}\omega}$ (and hence of DL (r.e.)) in expressive power. Well-foundedness of a binary relation R can be written

$$\forall x (\mu X(x). \forall y (R(y, x) \rightarrow X(y))).$$

A more severe syntactic restriction on the binding operator μX is to allow its application only to formulas that are *syntactically continuous* in X ; that is, those formulas in which X does not occur free in the scope of any negation or any universal quantifier. It can be shown that this syntactic restriction implies semantic continuity, so the least fixpoint is the union of \emptyset , $\varphi(\emptyset)$, $\varphi(\varphi(\emptyset))$, \dots . As shown in [Park, 1976], this version is strictly weaker than $L_{\omega_1^{\text{ck}}\omega}$.

In [Pratt, 1981a] and [Kozen, 1982; Kozen, 1983], propositional versions of the μ -calculus were introduced. The latter version consists of propositional modal logic with a least fixpoint operator. It is the most powerful logic of its type, subsuming all known variants of PDL, game logic of [Parikh, 1983], various forms of temporal logic (see Section 14.2), and other seemingly stronger forms of the μ -calculus ([Vardi and Wolper, 1986b]). In the following presentation we focus on this version, since it has gained fairly widespread acceptance; see [Kozen, 1984; Kozen and Parikh, 1983; Streett, 1985b; Streett and Emerson, 1984; Vardi and Wolper, 1986b; Walukiewicz, 1993; Walukiewicz, 1995; Walukiewicz, 2000; Stirling, 1992; Mader, 1997; Kaivola, 1997].

The language of the propositional μ -calculus, also called the *modal μ -calculus*, is syntactically simpler than PDL. It consists of the usual propositional constructs \rightarrow and $\mathbf{0}$, atomic modalities $[a]$, and the least fixpoint operator μ . A greatest fixpoint operator dual to μ can be defined:

$$\nu X. \varphi(X) \stackrel{\text{def}}{\iff} \neg \mu X. \neg \varphi(\neg X).$$

Variables are monadic, and the μ operator may be applied only to syntactically monotone formulas. As discussed above, this ensures monotonicity of the corresponding set operator. The language is interpreted over Kripke frames in which atomic propositions are interpreted as sets of states and atomic programs are interpreted as binary relations on states.

The propositional μ -calculus subsumes PDL. For example, the PDL formula $\langle a^* \rangle \varphi$ for atomic a can be written $\mu X. (\varphi \vee \langle a \rangle X)$. The formula

$\mu X.\langle a \rangle[a]X$, which expresses the existence of a forced win for the first player in a two-player game, and the formula $\mu X.[a]X$, which expresses well-foundedness and is equivalent to $\mathbf{wf} a$ (see Section 7), are both inexpressible in PDL, as shown in [Streett, 1981; Kozen, 1981c]. [Niwinski, 1984] has shown that even with the addition of the **halt** construct, PDL is strictly less expressive than the μ -calculus.

The propositional μ -calculus satisfies a finite model theorem, as first shown in [Kozen, 1988]. Progressively better decidability results were obtained in [Kozen and Parikh, 1983; Vardi and Stockmeyer, 1985; Vardi, 1985b], culminating in a deterministic exponential-time algorithm of [Emerson and Jutla, 1988] based on an automata-theoretic lemma of [Safra, 1988]. Since the μ -calculus subsumes PDL, it is *EXPTIME*-complete.

In [Kozen, 1982; Kozen, 1983], an axiomatization of the propositional μ -calculus was proposed and conjectured to be complete. The axiomatization consists of the axioms and rules of propositional modal logic, plus the axiom

$$\varphi[X/\mu X.\varphi] \rightarrow \mu X.\varphi$$

and rule

$$\frac{\varphi[X/\psi] \rightarrow \psi}{\mu X.\varphi \rightarrow \psi}$$

for μ . Completeness of this deductive system for a syntactically restricted subset of formulas was shown in [Kozen, 1982; Kozen, 1983]. Completeness for the full language was proved by [Walukiewicz, 1995; Walukiewicz, 2000]. This was quickly followed by simpler alternative proofs by [Ambler *et al.*, 1995; Bonsangue and Kwiatkowska, 1995; Hartonas, 1998]. [Bradfield, 1996] showed that the alternating μ/ν hierarchy (least/greatest fixpoints) is strict. An interesting open question is the complexity of *model checking*: does a given formula of the propositional μ -calculus hold in a given state of a given Kripke frame? Although some progress has been made (see [Bhat and Cleaveland, 1996; Cleaveland, 1996; Emerson and Lei, 1986; Sokolsky and Smolka, 1994; Stirling and Walker, 1989]), it is still unknown whether this problem has a polynomial-time algorithm.

The propositional μ -calculus has become a popular system for the specification and verification of properties of transition systems, where it has had some practical impact ([Steffen *et al.*, 1996]). Several recent papers on model checking work in this context; see [Bhat and Cleaveland, 1996; Cleaveland, 1996; Emerson and Lei, 1986; Sokolsky and Smolka, 1994; Stirling and Walker, 1989]. A comprehensive introduction can be found in [Stirling, 1992].

14.5 Kleene Algebra

Kleene algebra (KA) is the algebra of regular expressions. It is named for the mathematician S. C. Kleene (1909–1994), who among his many other

achievements invented regular expressions and proved their equivalence to finite automata in [Kleene, 1956].

Kleene algebra has appeared in various guises and under many names in relational algebra [Ng, 1984; Ng and Tarski, 1977], semantics and logics of programs [Kozen, 1981b; Pratt, 1988], automata and formal language theory [Kuich, 1987; Kuich and Salomaa, 1986], and the design and analysis of algorithms [Aho *et al.*, 1975; Tarjan, 1981; Mehlhorn, 1984; Iwano and Steiglitz, 1990; Kozen, 1991b]. As discussed in Section 13, Kleene algebra plays a prominent role in dynamic algebra as an algebraic model of program behavior.

Beginning with the monograph of [Conway, 1971], many authors have contributed over the years to the development of the algebraic theory; see [Backhouse, 1975; Krob, 1991; Kleene, 1956; Kuich and Salomaa, 1986; Sakarovitch, 1987; Kozen, 1990; Bloom and Ésik, 1992; Hopkins and Kozen, 1999]. See also [Kozen, 1996] for further references.

A *Kleene algebra* is an algebraic structure $(K, +, \cdot, *, 0, 1)$ satisfying the axioms

$$\begin{aligned}
 \alpha + (\beta + \gamma) &= (\alpha + \beta) + \gamma \\
 \alpha + \beta &= \beta + \alpha \\
 \alpha + 0 &= \alpha + \alpha = \alpha \\
 \alpha(\beta\gamma) &= (\alpha\beta)\gamma \\
 1\alpha &= \alpha 1 = \alpha \\
 \alpha(\beta + \gamma) &= \alpha\beta + \alpha\gamma \\
 (\alpha + \beta)\gamma &= \alpha\gamma + \beta\gamma \\
 0\alpha &= \alpha 0 = 0 \\
 (37) \quad 1 + \alpha\alpha^* &= 1 + \alpha^*\alpha = \alpha^* \\
 (38) \quad \beta + \alpha\gamma \leq \gamma &\rightarrow \alpha^*\beta \leq \gamma \\
 (39) \quad \beta + \gamma\alpha \leq \gamma &\rightarrow \beta\alpha^* \leq \gamma
 \end{aligned}$$

where \leq refers to the natural partial order on K :

$$\alpha \leq \beta \stackrel{\text{def}}{\iff} \alpha + \beta = \beta.$$

In short, a KA is an idempotent semiring under $+$, \cdot , 0 , 1 such that $\alpha^*\beta$ is the least solution to $\beta + \alpha x \leq x$ and $\beta\alpha^*$ is the least solution to $\beta + x\alpha \leq x$. The axioms (37)–(39) say essentially that $*$ behaves like the asterate operator on sets of strings or reflexive transitive closure on binary relations. This particular axiomatization is from [Kozen, 1991a; Kozen, 1994a], but there are other competing ones.

The axioms (38) and (39) correspond to the reflexive transitive closure rule (RTC) of PDL (Section 2.5). Instead, we might postulate the equivalent

axioms

$$(40) \quad \alpha\gamma \leq \gamma \rightarrow \alpha^*\gamma \leq \gamma$$

$$(41) \quad \gamma\alpha \leq \gamma \rightarrow \gamma\alpha^* \leq \gamma,$$

which correspond to the loop invariance rule (LI). The induction axiom (IND) is inexpressible in KA, since there is no negation.

A Kleene algebra is **-continuous* if it satisfies the infinitary condition

$$(42) \quad \alpha\beta^*\gamma = \sup_{n \geq 0} \alpha\beta^n\gamma$$

where

$$\beta^0 \stackrel{\text{def}}{=} 1 \quad \beta^{n+1} \stackrel{\text{def}}{=} \beta\beta^n$$

and where the supremum is with respect to the natural order \leq . We can think of (42) as a conjunction of the infinitely many axioms $\alpha\beta^n\gamma \leq \alpha\beta^*\gamma$, $n \geq 0$, and the infinitary Horn formula

$$\left(\bigwedge_{n \geq 0} \alpha\beta^n\gamma \leq \delta \right) \rightarrow \alpha\beta^*\gamma \leq \delta.$$

In the presence of the other axioms, the **-continuity* condition (42) implies (38)–(41) and is strictly stronger in the sense that there exist Kleene algebras that are not **-continuous* [Kozen, 1990].

The fundamental motivating example of a Kleene algebra is the family of regular sets of strings over a finite alphabet, but other classes of structures share the same equational theory, notably the binary relations on a set. In fact it is the latter interpretation that makes Kleene algebra a suitable choice for modeling programs in dynamic algebras. Other more unusual interpretations are the min, + algebra used in shortest path algorithms (see [Aho *et al.*, 1975; Tarjan, 1981; Mehlhorn, 1984; Kozen, 1991b]) and KAs of convex polyhedra used in computational geometry as described in [Iwano and Steiglitz, 1990].

Axiomatization of the equational theory of the regular sets is a central question going back to the original paper of [Kleene, 1956]. A completeness theorem for relational algebras was given in an extended language by [Ng, 1984; Ng and Tarski, 1977]. Axiomatization is a central focus of the monograph of [Conway, 1971], but the bulk of his treatment is infinitary. [Redko, 1964] proved that there is no finite equational axiomatization. Schematic equational axiomatizations for the algebra of regular sets, necessarily representing infinitely many equations, have been given by [Krob, 1991] and [Bloom and Ésik, 1993]. [Salomaa, 1966] gave two finitary complete axiomatizations that are sound for the regular sets but not sound in general over other standard interpretations, including relational interpretations. The axiomatization given above is a finitary universal Horn axiomatization that

is sound and complete for the equational theory of standard relational and language-theoretic models, including the regular sets [Kozen, 1991a; Kozen, 1994a]. Other work on completeness appears in [Krob, 1991; Boffa, 1990; Boffa, 1995; Archangelsky, 1992].

The literature contains a bewildering array of inequivalent definitions of Kleene algebras and related algebraic structures; see [Conway, 1971; Pratt, 1988; Pratt, 1990; Kozen, 1981b; Kozen, 1991a; Aho *et al.*, 1975; Mehlhorn, 1984; Kuich, 1987; Kozen, 1994b]. As demonstrated in [Kozen, 1990], many of these are strongly related. One important property shared by most of them is closure under the formation of $n \times n$ matrices. This was proved for the axiomatization above in [Kozen, 1991a; Kozen, 1994a], but the idea essentially goes back to [Kleene, 1956; Conway, 1971; Backhouse, 1975]. This result gives rise to an algebraic treatment of finite automata in which the automata are represented by their transition matrices.

The equational theory of Kleene algebra is *PSPACE*-complete [Stockmeyer and Meyer, 1973]; thus it is apparently less complex than PDL, which is *EXPTIME*-complete (Theorem 21), although the strict separation of the two complexity classes is still open.

Kleene Algebra with Tests

From a practical standpoint, many simple program manipulations such as loop unwinding and basic safety analysis do not require the full power of PDL, but can be carried out in a purely equational subsystem using the axioms of Kleene algebra. However, *tests* are an essential ingredient, since they are needed to model conventional programming constructs such as conditionals and **while** loops and to handle assertions. This motivates the definition of the following variant of KA introduced in [Kozen, 1996; Kozen, 1997b].

A *Kleene algebra with tests* (KAT) is a Kleene algebra with an embedded Boolean subalgebra. Formally, it is a two-sorted algebra

$$(K, B, +, \cdot, *, \bar{}, 0, 1)$$

such that

- $(K, +, \cdot, *, 0, 1)$ is a Kleene algebra
- $(B, +, \cdot, \bar{}, 0, 1)$ is a Boolean algebra
- $B \subseteq K$.

The unary negation operator $\bar{}$ is defined only on B . Elements of B are called *tests* and are written φ, ψ, \dots . Elements of K (including elements of B) are written α, β, \dots . In PDL, a test would be written $\varphi?$, but in KAT we dispense with the symbol $?$.

This deceptively concise definition actually carries a lot of information. The operators $+$, \cdot , 0 , 1 each play two roles: applied to arbitrary elements of K , they refer to nondeterministic choice, composition, fail, and skip, respectively; and applied to tests, they take on the additional meaning of Boolean disjunction, conjunction, falsity, and truth, respectively. These two usages do not conflict—for example, sequential testing of two tests is the same as testing their conjunction—and their coexistence admits considerable economy of expression.

For applications in program verification, the standard interpretation would be a Kleene algebra of binary relations on a set and the Boolean algebra of subsets of the identity relation. One could also consider trace models, in which the Kleene elements are sets of traces (sequences of states) and the Boolean elements are sets of states (traces of length 0). As with KA, one can form the algebra $n \times n$ matrices over a KAT (K, B) ; the Boolean elements of this structure are the diagonal matrices over B .

KAT can express conventional imperative programming constructs such as conditionals and while loops as in PDL. It can perform elementary program manipulation such as loop unwinding, constant propagation, and basic safety analysis in a purely equational manner. The applicability of KAT and related equational systems in practical program verification has been explored in [Cohen, 1994a; Cohen, 1994b; Cohen, 1994c; Kozen, 1996; Kozen and Patron, 2000].

There is a language-theoretic model that plays the same role in KAT that the regular sets play in KA, namely the algebra of regular sets of *guarded strings*, and a corresponding completeness result was obtained by [Kozen and Smith, 1996]. Moreover, KAT is complete for the equational theory of relational models, as shown in [Kozen and Smith, 1996]. Although less expressive than PDL, KAT is also apparently less difficult to decide: it is *PSPACE*-complete, the same as KA, as shown in [Cohen *et al.*, 1996].

In [Kozen, 1999a], it is shown that KAT subsumes propositional Hoare Logic in the following sense. The partial correctness assertion $\{\varphi\} \alpha \{\psi\}$ is encoded in KAT as the equation $\varphi \alpha \bar{\psi} = 0$, or equivalently $\varphi \alpha = \varphi \alpha \psi$. If a rule

$$\frac{\{\varphi_1\} \alpha_1 \{\psi_1\}, \dots, \{\varphi_n\} \alpha_n \{\psi_n\}}{\{\varphi\} \alpha \{\psi\}}$$

is derivable in propositional Hoare Logic, then its translation, the universal Horn formula

$$\varphi_1 \alpha_1 \bar{\psi}_1 = 0 \wedge \dots \wedge \varphi_n \alpha_n \bar{\psi}_n = 0 \rightarrow \varphi \alpha \bar{\psi} = 0,$$

is a theorem of KAT. For example, the **while** rule of Hoare logic (see Section 2.6) becomes

$$\sigma \varphi \alpha \bar{\varphi} = 0 \rightarrow \varphi (\sigma \alpha)^* \bar{\sigma} \bar{\sigma} \varphi = 0.$$

More generally, all relationally valid Horn formulas of the form

$$\gamma_1 = 0 \wedge \cdots \wedge \gamma_n = 0 \quad \rightarrow \quad \alpha = \beta$$

are theorems of KAT [Kozen, 1999a].

Horn formulas are important from a practical standpoint. For example, commutativity conditions are used to model the idea that the execution of certain instructions does not affect the result of certain tests. In light of this, the complexity of the universal Horn theory of KA and KAT are of interest. There are both positive and negative results. It is shown in [Kozen, 1997c] that for a Horn formula $\Phi \rightarrow \varphi$ over $*$ -continuous Kleene algebras,

- if Φ contains only commutativity conditions $\alpha\beta = \beta\alpha$, the universal Horn theory is Π_1^0 -complete;
- if Φ contains only monoid equations, the problem is Π_2^0 -complete;
- for arbitrary finite sets of equations Φ , the problem is Π_1^1 -complete.

On the other hand, commutativity assumptions of the form $\alpha\varphi = \varphi\alpha$, where φ is a test, and assumptions of the form $\gamma = 0$ can be eliminated without loss of efficiency, as shown in [Cohen, 1994a; Kozen and Smith, 1996]. Note that assumptions of this form are all we need to encode Hoare Logic as described above.

In typed Kleene algebra introduced in [Kozen, 1998; Kozen, 1999b], elements have types $s \rightarrow t$. This allows Kleene algebras of nonsquare matrices, among other applications. It is shown in [Kozen, 1999b] that Hoare Logic is subsumed by the type calculus of typed KA augmented with a typecast or coercion rule for tests. Thus Hoare-style reasoning with partial correctness assertions reduces to typechecking in a relatively simple type system.

14.6 Dynamic Algebra

Dynamic algebra provides an abstract algebraic framework that relates to PDL as Boolean algebra relates to propositional logic. A *dynamic algebra* is defined to be any two-sorted algebraic structure (K, B, \cdot) , where $B = (B, \rightarrow, 0)$ is a Boolean algebra, $K = (K, +, \cdot, *, 0, 1)$ is a Kleene algebra (see Section 14.5), and $\cdot : K \times B \rightarrow B$ is a scalar multiplication satisfying algebraic constraints corresponding to the dual forms of the PDL axioms (Axioms 17). For example, all dynamic algebras satisfy the equations

$$\begin{aligned} (\alpha\beta) \cdot \varphi &= \alpha \cdot (\beta \cdot \varphi) \\ \alpha \cdot 0 &= 0 \\ 0 \cdot \varphi &= 0 \\ \alpha \cdot (\varphi \vee \psi) &= \alpha \cdot \varphi \vee \alpha \cdot \psi, \end{aligned}$$

which correspond to the PDL validities

$$\begin{aligned} \langle \alpha ; \beta \rangle \varphi &\leftrightarrow \langle \alpha \rangle \langle \beta \rangle \varphi \\ \langle \alpha \rangle \mathbf{0} &\leftrightarrow \mathbf{0} \\ \langle \mathbf{0} ? \rangle \varphi &\leftrightarrow \mathbf{0} \\ \langle \alpha \rangle (\varphi \vee \psi) &\leftrightarrow \langle \alpha \rangle \varphi \vee \langle \alpha \rangle \psi, \end{aligned}$$

respectively. The Boolean algebra B is an abstraction of the formulas of PDL and the Kleene algebra K is an abstraction of the programs.

The interaction of scalar multiplication with iteration can be axiomatized in a finitary or infinitary way. One can postulate

$$(43) \quad \alpha^* \cdot \varphi \leq \varphi \vee (\alpha^* \cdot (\neg \varphi \wedge (\alpha \cdot \varphi)))$$

corresponding to the diamond form of the PDL induction axiom (Axiom 17(viii)). Here $\varphi \leq \psi$ in B iff $\varphi \vee \psi = \psi$. Alternatively, one can postulate the stronger axiom of **-continuity*:

$$(44) \quad \alpha^* \cdot \varphi = \sup_n (\alpha^n \cdot \varphi).$$

We can think of (44) as a conjunction of infinitely many axioms $\alpha^n \cdot \varphi \leq \alpha^* \cdot \varphi$, $n \geq 0$, and the infinitary Horn formula

$$\left(\bigwedge_{n \geq 0} \alpha^n \cdot \varphi \leq \psi \right) \rightarrow \alpha^* \cdot \varphi \leq \psi.$$

In the presence of the other axioms, (44) implies (43) [Kozen, 1980b], and is strictly stronger in the sense that there are dynamic algebras that are not **-continuous* [Pratt, 1979a].

A standard Kripke frame $\mathfrak{K} = (U, \mathfrak{m}_{\mathfrak{K}})$ of PDL gives rise to a **-continuous* dynamic algebra consisting of a Boolean algebra of subsets of U and a Kleene algebra of binary relations on U . Operators are interpreted as in PDL, including $\mathbf{0}$ as $\mathbf{0}?$ (the empty program), $\mathbf{1}$ as $\mathbf{1}?$ (the identity program), and $\alpha \cdot \varphi$ as $\langle \alpha \rangle \varphi$. Nonstandard Kripke frames (see Section 3.2) also give rise to dynamic algebras, but not necessarily **-continuous* ones. A dynamic algebra is *separable* if any pair of distinct Kleene elements can be distinguished by some Boolean element; that is, if $\alpha \neq \beta$, then there exists $\varphi \in B$ with $\alpha \cdot \varphi \neq \beta \cdot \varphi$.

Research directions in this area include the following.

- *Representation theory.* It is known that any separable dynamic algebra is isomorphic to some possibly nonstandard Kripke frame. Under certain conditions, “possibly nonstandard” can be replaced by “standard,” but not in general, even for **-continuous* algebras [Kozen, 1980b; Kozen, 1979c; Kozen, 1980a].

- *Algebraic methods in PDL.* The small model property (Theorem 15) and completeness (Theorem 18) for PDL can be established by purely algebraic considerations [Pratt, 1980a].
- *Comparative study of alternative axiomatizations of $*$.* For example, it is known that separable dynamic algebras can be distinguished from standard Kripke frames by a first-order formula, but even $L_{\omega_1\omega}$ cannot distinguish the latter from $*$ -continuous separable dynamic algebras [Kozen, 1981b].
- *Equational theory of dynamic algebras.* Many seemingly unrelated models of computation share the same equational theory, namely that of dynamic algebras [Pratt, 1979b; Pratt, 1979a].

In addition, many interesting questions arise from the algebraic viewpoint, and interesting connections with topology, classical algebra, and model theory have been made [Kozen, 1979b; Némethi, 1980].

15 BIBLIOGRAPHICAL NOTES

Systematic program verification originated with the work of [Floyd, 1967] and [Hoare, 1969]. Hoare Logic was introduced in [Hoare, 1969]; see [Cousot, 1990; Apt, 1981; Apt and Olderog, 1991] for surveys.

The *digital abstraction*, the view of computers as state transformers that operate by performing a sequence of discrete and instantaneous primitive steps, can be attributed to [Turing, 1936]. Finite-state transition systems were defined formally by [McCulloch and Pitts, 1943]. State-transition semantics is based on this idea and is quite prevalent in early work on program semantics and verification; see [Hennessy and Plotkin, 1979]. The relational-algebraic approach taken here, in which programs are interpreted as binary input/output relations, was introduced in the context of DL by [Pratt, 1976].

The notions of partial and total correctness were present in the early work of [Hoare, 1969]. Regular programs were introduced by [Fischer and Ladner, 1979] in the context of PDL. The concept of nondeterminism was introduced in the original paper of [Turing, 1936], although he did not develop the idea. Nondeterminism was further developed by [Rabin and Scott, 1959] in the context of finite automata.

[Burstall, 1974] suggested using modal logic for reasoning about programs, but it was not until the work of [Pratt, 1976], prompted by a suggestion of R. Moore, that it was actually shown how to extend modal logic in a useful way by considering a separate modality for every program. The first research devoted to propositional reasoning about programs seems to be that of [Fischer and Ladner, 1977; Fischer and Ladner, 1979] on PDL. As

mentioned in the Preface, the general use of logical systems for reasoning about programs was suggested by [Engeler, 1967].

Other semantics besides Kripke semantics have been studied; see [Berman, 1979; Nishimura, 1979; Kozen, 1979b; Trnkova and Reiterman, 1980; Kozen, 1980b; Pratt, 1979b]. Modal logic has many applications and a vast literature; good introductions can be found in [Hughes and Cresswell, 1968; Chellas, 1980]. Alternative and iterative guarded commands were studied in [Gries, 1981]. Partial correctness assertions and the Hoare rules given in Section 2.6 were first formulated by [Hoare, 1969]. Regular expressions, on which the regular program operators are based, were introduced by [Kleene, 1956]. Their algebraic theory was further investigated by [Conway, 1971]. They were first applied in the context of DL by [Fischer and Ladner, 1977; Fischer and Ladner, 1979]. The axiomatization of PDL given in Axioms 17 was formulated by [Seegerberg, 1977]. Tests and converse were investigated by various authors; see [Peterson, 1978; Berman, 1978; Berman and Paterson, 1981; Streett, 1981; Streett, 1982; Vardi, 1985b]. The continuity of the diamond operator in the presence of reverse is due to [Trnkova and Reiterman, 1980].

The filtration argument and the small model property for PDL are due to [Fischer and Ladner, 1977; Fischer and Ladner, 1979]. Nonstandard Kripke frames for PDL were studied by [Berman, 1979; Berman, 1982], [Parikh, 1978a], [Pratt, 1979a; Pratt, 1980a], and [Kozen, 1979c; Kozen, 1979b; Kozen, 1980a; Kozen, 1980b; Kozen, 1981b].

The axiomatization of PDL used here (Axiom System 17) was introduced by [Seegerberg, 1977]. Completeness was shown independently by [Gabbay, 1977] and [Parikh, 1978a]. A short and easy-to-follow proof is given in [Kozen and Parikh, 1981]. Completeness is also treated in [Pratt, 1978; Pratt, 1980a; Berman, 1979; Nishimura, 1979; Kozen, 1981a].

The exponential-time lower bound for PDL was established by [Fischer and Ladner, 1977; Fischer and Ladner, 1979] by showing how PDL formulas can encode computations of linear-space-bounded alternating Turing machines.

Deterministic exponential-time algorithms were first given in [Pratt, 1978; Pratt, 1979b; Pratt, 1980b].

Theorem 24 showing that the problem of deciding whether $\Gamma \models \psi$, where Γ is a fixed r.e. set of PDL formulas, is Π_1^1 -complete is due to [Meyer *et al.*, 1981].

The computational difficulty of the validity problem for nonregular PDL and the borderline between the decidable and undecidable were discussed in [Harel *et al.*, 1983]. The fact that any nonregular program adds expressive power to PDL, Theorem 25, first appeared explicitly in [Harel and Singerman, 1996]. Theorem 26 on the undecidability of context-free PDL was observed by [Ladner, 1977].

Theorems 27 and 28 are from [Harel *et al.*, 1983]. An alternative proof of Theorem 28 using tiling is supplied in [Harel, 1985]; see [Harel *et al.*, 2000]. The existence of a primitive recursive one-letter extension of PDL that is undecidable was shown already in [Harel *et al.*, 1983], but undecidability for the particular case of a^{2^*} , Theorem 29, is from [Harel and Paterson, 1984]. Theorem 30 is from [Harel and Singerman, 1996].

As to decidable extensions, Theorem 31 was proved in [Koren and Pnueli, 1983]. The more general results of Section 6.2, namely Theorems 32, 33, and 34, are from [Harel and Raz, 1993], as is the notion of a simple-minded PDA. The decidability of emptiness for pushdown and stack automata on trees that is needed for the proofs of these is from [Harel and Raz, 1994]. A better bound on the complexity of the emptiness results can be found in [Peng and Iyer, 1995].

A sufficient condition for PDL with the addition of a program over a single letter alphabet not to have the finite model property is given in [Harel and Singerman, 1996].

Completeness and exponential time decidability for DPDL, Theorem 40 and the upper bound of Theorem 41, are proved in [Ben-Ari *et al.*, 1982] and [Valiev, 1980]. The lower bound of Theorem 41 is from [Parikh, 1981]. Theorems 43 and 44 on SDPDL are from [Halpern and Reif, 1981; Halpern and Reif, 1983].

That tests add to the power of PDL is proved in [Berman and Paterson, 1981]. It is also known that the test-depth hierarchy is strict [Berman, 1978; Peterson, 1978] and that rich-test PDL is strictly more expressive than poor-test PDL [Peterson, 1978; Berman, 1978; Berman and Paterson, 1981]. These results also hold for SDPDL.

The results on programs as automata (Theorems 45 and 46) appear in [Pratt, 1981b]. Alternative proofs are given in [Harel and Sherman, 1985]; see [Harel *et al.*, 2000]. In recent years, the development of the automata-theoretic approach to logics of programs has prompted renewed inquiry into the complexity of automata on infinite objects, with considerable success. See [Courcoubetis and Yannakakis, 1988; Emerson, 1985; Emerson and Jutla, 1988; Emerson and Sistla, 1984; Manna and Pnueli, 1987; Muller *et al.*, 1988; Pecuchet, 1986; Safra, 1988; Sistla *et al.*, 1987; Streett, 1982; Vardi, 1985a; Vardi, 1985b; Vardi, 1987; Vardi and Stockmeyer, 1985; Vardi and Wolper, 1986b; Vardi and Wolper, 1986a; Arnold, 1997a; Arnold, 1997b]; and [Thomas, 1997]. Especially noteworthy in this area is the result of [Safra, 1988] involving the complexity of converting a nondeterministic automaton on infinite strings into an equivalent deterministic one. This result has already had a significant impact on the complexity of decision procedures for several logics of programs; see [Courcoubetis and Yannakakis, 1988; Emerson and Jutla, 1988; Emerson and Jutla, 1989]; and [Safra, 1988].

Intersection of programs was studied in [Harel *et al.*, 1982a]. That the axioms for converse yield completeness for CPDL is proved in [Parikh, 1978a].

The complexity of PDL with converse and various forms of well-foundedness constructs is studied in [Vardi, 1985b]. Many authors have studied logics with a least-fixpoint operator, both on the propositional and first-order levels ([Scott and de Bakker, 1969; Hitchcock and Park, 1972; Park, 1976; Pratt, 1981a; Kozen, 1982; Kozen, 1983; Kozen, 1988; Kozen and Parikh, 1983; Niwinski, 1984; Streett, 1985a; Vardi and Stockmeyer, 1985]). The version of the propositional μ -calculus presented here was introduced in [Kozen, 1982; Kozen, 1983].

That the propositional μ -calculus is strictly more expressive than PDL with **wf** was shown in [Niwinski, 1984] and [Streett, 1985a]. That this logic is strictly more expressive than PDL with **halt** was shown in [Harel and Sherman, 1982]. That this logic is strictly more expressive than PDL was shown in [Streett, 1981].

The **wf** construct (actually its complement, **repeat**) is investigated in [Streett, 1981; Streett, 1982], in which Theorems 48 (which is actually due to Pratt) and 50–52 are proved. The **halt** construct (actually its complement, **loop**) was introduced in [Harel and Pratt, 1978] and Theorem 49 is from [Harel and Sherman, 1982]. Finite model properties for the logics LPDL, RPD, CLPDL, CRPDL, and the propositional μ -calculus were established in [Streett, 1981; Streett, 1982] and [Kozen, 1988]. Decidability results were obtained in [Streett, 1981; Streett, 1982; Kozen and Parikh, 1983; Vardi and Stockmeyer, 1985]; and [Vardi, 1985b]. Deterministic exponential-time completeness was established in [Emerson and Jutla, 1988] and [Safra, 1988]. For the strongest variant, CRPDL, exponential-time decidability follows from [Vardi, 1998b].

Concurrent PDL is defined and studied in [Peleg, 1987b]. Additional versions of this logic, which employ various mechanisms for communication among the concurrent parts of a program, are considered in [Peleg, 1987c; Peleg, 1987a]. These papers contain many results concerning expressive power, decidability and undecidability for concurrent PDL with communication.

Other work on PDL not described here includes work on nonstandard models, studied in [Berman, 1979; Berman, 1982] and [Parikh, 1981]; PDL with Boolean assignments, studied in [Abrahamson, 1980]; and restricted forms of the consequence problem, studied in [Parikh, 1981].

First-order DL was defined in [Harel *et al.*, 1977], where it was also first named Dynamic Logic. That paper was carried out as a direct continuation of the original work of [Pratt, 1976].

Many variants of DL were defined in [Harel, 1979]. In particular, DL(bst)k is very close to the context-free Dynamic Logic investigated there.

Uninterpreted reasoning in the form of program schematology has been a common activity ever since the work of [Iarov, 1960]. It was given con-

siderable impetus by the work of [Luckham *et al.*, 1970] and [Paterson and Hewitt, 1970]; see also [Greibach, 1975]. The study of the correctness of interpreted programs goes back to the work of Turing and von Neumann, but seems to have become a well-defined area of research following [Floyd, 1967], [Hoare, 1969] and [Manna, 1974].

Embedding logics of programs in $L_{\omega_1\omega}$ is based on observations of [Engeler, 1967]. Theorem 57 is from [Meyer and Parikh, 1981]. Theorem 60 is from [Harel, 1979] (see also [Harel, 1984] and [Harel and Kozen, 1984]); it is similar to the expressiveness result of [Cook, 1978]. Theorem 61 and Corollary 62 are from [Harel and Kozen, 1984].

Arithmetical structures were first defined by [Moschovakis, 1974] under the name *acceptable structures*. In the context of logics of programs, they were reintroduced and studied in [Harel, 1979].

The Π_1^1 -completeness of DL was first proved by Meyer, and Theorem 63 appears in [Harel *et al.*, 1977]. An alternative proof is given in [Harel, 1985]; see [Harel *et al.*, 2000]. Theorem 65 is from [Meyer and Halpern, 1982]. That the fragment of DL considered in Theorem 66 is not r.e., was proved by [Pratt, 1976]. Theorem 67 follows from [Harel and Kozen, 1984].

The name “spectral complexity” was proposed by [Tiuryn, 1986], although the main ideas and many results concerning this notion were already present in [Tiuryn and Urzyczyn, 1983] (see [Tiuryn and Urzyczyn, 1988] for the full version). This notion is an instance of the so-called *second-order spectrum* of a formula. First-order spectra were investigated by [Sholz, 1952], from which originates the well known *Spectralproblem*. The reader can find more about this problem and related results in the survey paper by [Börger, 1984]. The notion of a natural chain is from [Urzyczyn, 1983]. The results presented here are from [Tiuryn and Urzyczyn, 1983; Tiuryn and Urzyczyn, 1988]. A result similar to Theorem 69 in the area of finite model theory was obtained by [Sazonov, 1980] and independently by [Gurevich, 1983]. Higher-order stacks were introduced in [Engelfriet, 1983] to study complexity classes. Higher-order arrays and stacks in DL were considered by [Tiuryn, 1986], where a strict hierarchy within the class of elementary recursive sets was established. The main tool used in the proof of the strictness of this hierarchy is a generalization of Cook’s auxiliary pushdown automata theorem for higher-order stacks, which is due to [Kowalczyk *et al.*, 1987].

[Meyer and Halpern, 1982] showed completeness for termination assertions (Theorem 71). Infinitary completeness for DL (Theorem 72) is based upon a similar result for Algorithmic Logic (see Section 13.1) by [Mirkowska, 1971]. The proof sketch presented in [Harel *et al.*, 2000] is an adaptation of Henkin’s proof for $L_{\omega_1\omega}$ appearing in [Keisler, 1971].

The notion of relative completeness and Theorem 73 are due to [Cook, 1978]. The notion of arithmetical completeness and Theorem 75 is from [Harel, 1979].

The use of invariants to prove partial correctness and of well-founded sets to prove termination are due to [Floyd, 1967]. An excellent survey of such methods and the corresponding completeness results appears in [Apt, 1981].

Some contrasting negative results are contained in [Clarke, 1979], [Lipton, 1977], and [Wand, 1978].

Many of the results on relative expressiveness presented herein answer questions posed in [Harel, 1979]. Similar uninterpreted research, comparing the expressive power of classes of programs (but detached from any surrounding logic) has taken place under the name *comparative schematology* quite extensively ever since [Ianov, 1960]; see [Greibach, 1975] and [Manna, 1974].

Theorems 76, 79 and 83(i) result as an application of the so-called *spectral theorem*, which connects expressive power of logics with complexity classes. This theorem was obtained by [Tiuryn and Urzyczyn, 1983; Tiuryn and Urzyczyn, 1984; Tiuryn and Urzyczyn, 1988]. A simplified framework for this approach and a statement of this theorem together with a proof is given in [Harel *et al.*, 2000].

Theorem 78 appears in [Berman *et al.*, 1982] and was proved independently in [Stolboushkin and Taitlin, 1983]. An alternative proof is given in [Tiuryn, 1989]. These results extend in a substantial way an earlier and much simpler result for the case of regular programs without equality in the vocabulary, which appears in [Halpern, 1981]. A simpler proof of the special case of the quantifier-free fragment of the logic of regular programs appears in [Meyer and Winklmann, 1982]. Theorem 79 is from [Tiuryn and Urzyczyn, 1984].

Theorem 80 is from [Stolboushkin, 1983]. The proof, as in the case of regular programs (see [Stolboushkin and Taitlin, 1983]), uses Adian's result from group theory ([Adian, 1979]). Results on the expressive power of DL with deterministic **while** programs and a Boolean stack can be found in [Stolboushkin, 1983; Kfoury, 1985]. Theorem 81 is from [Tiuryn and Urzyczyn, 1983; Tiuryn and Urzyczyn, 1988].

[Erimbetov, 1981; Tiuryn, 1981b; Tiuryn, 1984; Kfoury, 1983; Kfoury and Stolboushkin, 1997] contain results on the expressive power of DL over programming languages with bounded memory. [Erimbetov, 1981] shows that $DL(dreg) < DL(dstk)$. The main proof technique is pebble games on finite trees.

Theorem 83 is from [Urzyczyn, 1987]. There is a different proof of this result, using Adian structures, which appears in [Stolboushkin, 1989]. Theorem 77 is from [Urzyczyn, 1988], which also studies programs with Boolean arrays.

Wildcard assignments were considered in [Harel *et al.*, 1977] under the name *nondeterministic assignments*. Theorem 84 is from [Meyer and Winklmann, 1982]. Theorem 85 is from [Meyer and Parikh, 1981].

In our exposition of the comparison of the expressive power of logics, we have made the assumption that programs use only quantifier-free first-order tests. It follows from the results of [Urzyczyn, 1986] that allowing full first-order tests in many cases results in increased expressive power. [Urzyczyn, 1986] also proves that adding array assignments to nondeterministic r.e. programs increases the expressive power of the logic. This should be contrasted with the result of [Meyer and Tiuryn, 1981; Meyer and Tiuryn, 1984] to the effect that for deterministic r.e. programs, array assignments do not increase expressive power.

[Makowsky, 1980] considers a weaker notion of equivalence between logics common in investigations in abstract model theory, whereby models are extended with interpretations for additional predicate symbols. With this notion it is shown in [Makowsky, 1980] that most of the versions of logics of programs treated here become equivalent.

Algorithmic logic was introduced by [Salwicki, 1970]. [Mirkowska, 1980; Mirkowska, 1981a; Mirkowska, 1981b] extended **AL** to allow nondeterministic **while** programs and studied the operators ∇ and Δ . Complete infinitary deductive systems for propositional and first-order versions were given by [Mirkowska, 1980; Mirkowska, 1981a; Mirkowska, 1981b] using the algebraic methods of [Rasiowa and Sikorski, 1963]. Surveys of early work in **AL** can be found in [Banachowski *et al.*, 1977; Salwicki, 1977]. [Constable, 1977; Constable and O'Donnell, 1978; Goldblatt, 1982] presented logics similar to **AL** and **DL** for reasoning about deterministic **while** programs.

Nonstandard Dynamic Logic was introduced by [Németi, 1981] and [Andréka *et al.*, 1982a; Andréka *et al.*, 1982b] and studied in [Csirmaz, 1985]. See [Makowsky and Sain, 1986] for more information and further references.

The **halt** construct (actually its complement, **loop**) was introduced in [Harel and Pratt, 1978], and the **wf** construct (actually its complement, **repeat**) was investigated for **PDL** in [Streett, 1981; Streett, 1982]. Theorem 86 is from [Meyer and Winklmann, 1982], Theorem 87 is from [Harel and Peleg, 1985], Theorem 88 is from [Harel, 1984], and the axiomatizations of **LDL** and **PDL** are discussed in [Harel, 1979; Harel, 1984].

Dynamic algebra was introduced in [Kozen, 1980b] and [Pratt, 1979b] and studied by numerous authors; see [Kozen, 1979c; Kozen, 1979b; Kozen, 1980a; Kozen, 1981b; Pratt, 1979a; Pratt, 1980a; Pratt, 1988; Németi, 1980; Trnkova and Reiterman, 1980]. A survey of the main results appears in [Kozen, 1979a].

The PhD thesis [Ramshaw, 1981] contains an engaging introduction to the subject of probabilistic semantics and verification. [Kozen, 1981d] provided a formal semantics for probabilistic programs. The logic $Pr(\text{DL})$ was presented in [Feldman and Harel, 1984], along with a deductive system that is complete for Kozen's semantics relative to an extension of first-order analysis. Various propositional versions of probabilistic **DL** have been proposed

in [Reif, 1980; Makowsky and Tiomkin, 1980; Feldman, 1984; Parikh and Mahoney, 1983; Kozen, 1985]. The temporal approach to probabilistic verification has been studied in [Lehmann and Shelah, 1982; Hart *et al.*, 1982; Courcoubetis and Yannakakis, 1988; Vardi, 1985a]. Interest in the subject of probabilistic verification has undergone a recent revival; see [Morgan *et al.*, 1999; Segala and Lynch, 1994; Hansson and Jonsson, 1994; Jou and Smolka, 1990; Baier and Kwiatkowska, 1998; Huth and Kwiatkowska, 1997; Blute *et al.*, 1997].

Concurrent DL is defined and studied in [Peleg, 1987b]. Additional versions of this logic, which employ various mechanisms for communication among the concurrent parts of a program, are also considered in [Peleg, 1987c; Peleg, 1987a].

LOGICS FOR DEFEASIBLE ARGUMENTATION

1 INTRODUCTION

Logic is the science that deals with the formal principles and criteria of validity of patterns of inference. This chapter surveys logics for a particular group of patterns of inference, namely those where arguments for and against a certain claim are produced and evaluated, to test the tenability of the claim. Such reasoning processes are usually analysed under the common term ‘defeasible argumentation’. We shall illustrate this form of reasoning with a dispute between two persons, *A* and *B*. They disagree on whether it is morally acceptable for a newspaper to publish a certain piece of information concerning a politician’s private life.¹ Let us assume that the two parties have reached agreement on the following points.

- (1) The piece of information *I* concerns the health of person *P*;
- (2) *P* does not agree with publication of *I*;
- (3) Information concerning a person’s health is information concerning that person’s private life

A now states the moral principle that

- (4) Information concerning a person’s private life may not be published if that person does not agree with publication.

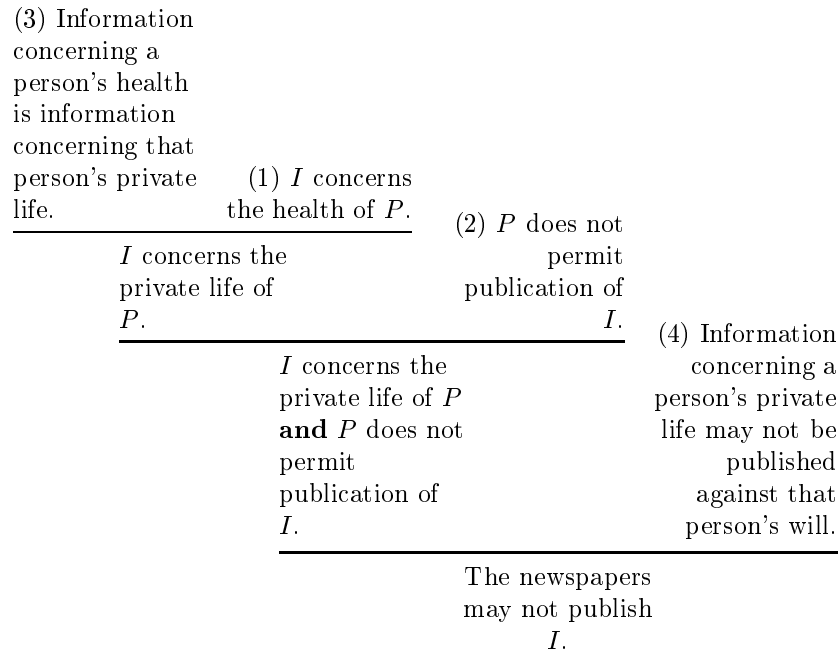

and *A* says “So the newspapers may not publish *I*” (Fig. 1, page 220). Although *B* accepts principle (4) and is therefore now committed to (1-4), *B* still refuses to accept the conclusion that the newspapers may not publish *I*. *B* motivates his refusal by replying that:

- (5) *P* is a cabinet minister
- (6) *I* is about a disease that might affect *P*’s political functioning
- (7) Information about things that might affect a cabinet minister’s political functioning has public significance

Furthermore, *B* maintains that there is also the moral principle that

- (8) Newspapers may publish any information that has public significance

¹Adapted from [Sartor, 1994].

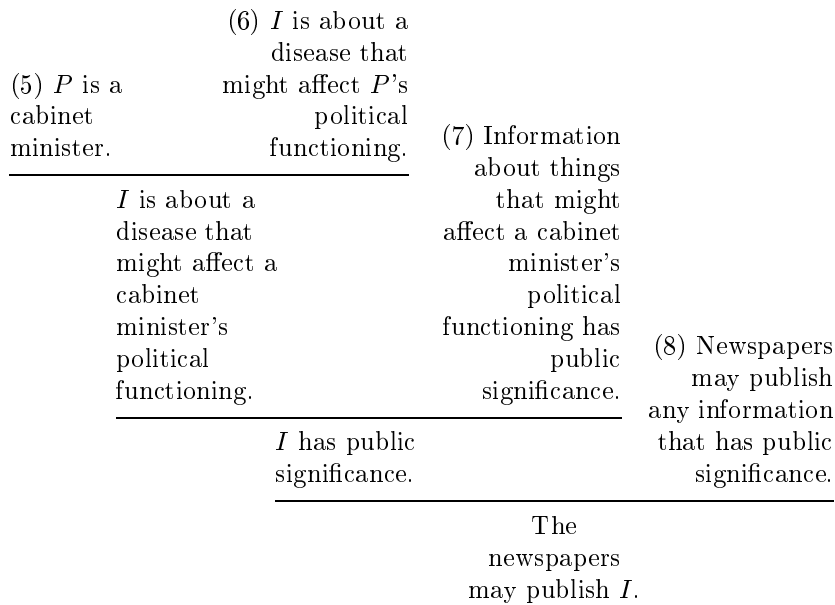

Figure 1. *A*'s argument.

B concludes by saying that therefore the newspapers may write about *P*'s disease (Fig. 2, page 221). *A* agrees with (5–7) and even accepts (8) as a moral principle, but *A* does not give up his initial claim. (It is assumed that *A* and *B* are both male.) Instead he tries to defend it by arguing that he has the stronger argument: he does so by arguing that in this case

- (9) The likelihood that the disease mentioned in *I* affects *P*'s functioning is small.
- (10) If the likelihood that the disease mentioned in *I* affects *P*'s functioning is small, then principle (4) has priority over principle (8).

Thus it can be derived that the principle used in *A*'s first argument is stronger than the principle used by *B* (Fig. 3, page 222), which makes *A*'s first argument stronger than *B*'s, so that it follows after all that the newspapers should be silent about *P*'s disease.

Let us examine the various stages of this dispute in some detail. Intuitively, it seems obvious that the accepted basis for discussion after *A* has stated (4) and *B* has accepted it, viz. (1,2,3,4), warrants the conclusion that the piece of information *I* may not be published. However, after *B*'s counterargument and *A*'s acceptance of its premises (5–8) things have changed.

Figure 2. *B*'s argument.

At this stage the joint basis for discussion is (1-8), which gives rise to two conflicting arguments. Moreover, (1-8) does not yield reasons to prefer one argument over the other: so at this point *A*'s conclusion has ceased to be warranted. But then *A*'s second argument, which states a preference between the two conflicting moral principles, tips the balance in favour of his first argument: so after the basis for discussion has been extended to (1-10), we must again accept *A*'s moral claim as warranted.

This chapter is about logical systems that formalise this kind of reasoning. We shall call them 'logics for defeasible argumentation', or 'argumentation systems'. As the example shows, these systems lack one feature of 'standard', deductive logic (say, first-order predicate logic, FOL). The notion of 'warrant' that we used in explaining the example is clearly not the same as first-order logical consequence, which has the property of monotonicity: in FOL any conclusion that can be drawn from a given set of premises, remains valid if we add new premises to this set. So according to FOL, if *A*'s claim is implied by (1-4), it is surely also implied by (1-8). From the point of view of FOL it is pointless for *B* to accept (1-4) and yet state a counterargument; *B* should also have refused to accept one of the premises, for instance, (4).

(9) The likelihood that the disease mentioned in <i>I</i> affects <i>P</i> 's functioning is small.	(10) If the likelihood that the disease mentioned in <i>I</i> affects <i>P</i> 's functioning is small, then principle (4) has priority over principle (8).
---	---

Principle (4) has priority
over principle (8).

Figure 3. *A*'s priority argument.

Does this mean that our informal account of the example is misleading, that it conceals a subtle change in the interpretation of, say, (4) as the dispute progresses? This is not so easy to answer in general. Although in some cases it might indeed be best to analyse an argument move like *B*'s as a reinterpretation of a premise, in other cases this is different. In actual reasoning, rules are not always neatly labelled with an exhaustive list of possible exceptions; rather, people are often forced to apply 'rules of thumb' or 'default rules', in the absence of evidence to the contrary, and it seems natural to analyse an argument like *B*'s as an attempt to provide such evidence to the contrary. When the example is thus analysed, the force of the conclusions drawn in it can only be captured by a consequence notion that is nonmonotonic: although *A*'s claim is warranted on the basis of (1–4), it is not warranted on the basis of (1–8).

Such nonmonotonic consequence notions have been studied over the last twenty years in an area of artificial intelligence called 'nonmonotonic reasoning' (recently the term 'defeasible reasoning' has also become popular), and logics for defeasible argumentation are largely a result of this development. Some might say that the lack of the property of monotonicity disqualifies these notions from being notions of logical consequence: isn't the very idea of calling an inference 'logical' that it is (given the premises) beyond any doubt? We are not so sure. Our view on logic is that it studies criteria of warrant, that is, criteria that determine the degree according to which it is reasonable to accept logical conclusions, even though some of these conclusions are established non-deductively: sometimes it is reasonable to accept a conclusion of an argument even though this argument is not strong enough to establish its conclusion with absolute certainty.

Several ways to formalise nonmonotonic, or defeasible reasoning have been studied. This chapter is not meant to survey all of them but only discusses the argument-based approach, which defines notions like argument, counterargument, attack and defeat, and defines consequence notions in terms of the interaction of arguments for and against certain conclusions. This approach was initiated by the philosopher John Pollock [1987], based

on his earlier work in epistemology, e.g. [1974], and the computer scientist Ronald Loui [1987]. As we shall see, argumentation systems are able to incorporate the traditional, monotonic notions of logical consequence as a special case, for instance, in their definition of what an argument is.

The field of defeasible argumentation is relatively young, and researchers disagree on many issues, while the formal meta-theory is still in its early stages. Yet we think that the field has sufficiently matured to devote a handbook survey to it.² We aim to show that there are also many similarities and connections between the various systems, and that many differences are variations on a few basic notions, or are caused by different focus or different levels of abstraction. Moreover, we shall show that some recent developments pave the way for a more elaborate meta-theory of defeasible argumentation.

Although when discussing individual systems we aim to be as formal as possible, when comparing them we shall mostly use conceptual or quasi-formal terms. We shall also report on some formal results on this comparison, but it is not our aim to present new technical results; this we regard as a task for further research in the field.

The structure of this chapter is as follows. In Section 2 we give an overview of the main approaches in nonmonotonic reasoning, and argue why the study of this kind of reasoning is relevant not only for artificial intelligence but also for philosophy. In Section 3 we give a brief conceptual sketch of logics for defeasible argumentation, and we argue that it is not obvious that they need a model-theoretic semantics. In Section 4 we become formal, studying how semantic consequence notions for argumentation systems can be defined given a set of arguments ordered by a defeat relation. This discussion is still abstract, leaving the structure of arguments and the origin of the defeat relation largely unspecified. In Section 5 we become more concrete, in discussing particular logics for defeasible argumentation. Then in Section 6 we discuss one way in which argumentation systems can be formulated, viz. in the form of rules for dispute. We end this chapter in Section 7 with some concluding remarks, and with a list of the main open issues in the field.

2 NONMONOTONIC LOGICS: OVERVIEW AND PHILOSOPHICAL RELEVANCE

Before discussing argumentation systems, we place them in the context of the study of nonmonotonic reasoning, and discuss why this study deserves a place in philosophical logic.

²For a survey of this topic from a computer science perspective, see [Chesñevar *et al.*, 1999].

2.1 *Research in nonmonotonic reasoning*

Although this chapter is not about nonmonotonic logics in general, it is still useful to give a brief impression of this field, to put systems for defeasible argumentation in context. Several styles of nonmonotonic logics exist. Most of them take as the basic ‘nonstandard’ unit the notion of a default, or defeasible conditional or rule: this is a conditional that can be qualified with phrases like ‘typically’, ‘normally’ or ‘unless shown otherwise’ (the two principles in our example may be regarded as defaults). Defaults do not guarantee that their consequent holds whenever their antecedent holds; instead they allow us in such cases to defeasibly derive their consequent, i.e., if nothing is known about exceptional circumstances. Most nonmonotonic logics aim to formalise this phenomenon of ‘default reasoning’, but they do so in different ways.

Firstly, they differ in whether the above qualifications are regarded as extra conditions in the antecedent of a default, as aspects of the use of a default, or as inherent in the meaning of a defeasible conditional operator. In addition, within each of these views on defaults, nonmonotonic logics differ in the technical means by which they formalise it. Let us briefly review the main approaches. (More detailed overviews can be found in e.g. [Brewka, 1991] and [Gabbay *et al.*, 1994].)

Preferential entailment

Preferential entailment, e.g. [Shoham, 1988], is a model-theoretic approach based on standard first-order logic, which weakens the standard notion of entailment. The idea is that instead of checking *all* models of the premises to see if the conclusion holds, only some of the models are checked, viz. those in which as few exceptions to the defaults hold as possible. This technique is usually combined with the ‘extra condition’ view on defaults, by adding a special ‘normality condition’ to their antecedent, as in

$$(1) \quad \forall x. \text{Birds}(x) \wedge \neg \text{ab}_1(x) \supset \text{Canfly}(x)$$

Informally, this reads as ‘Birds can fly, unless they are abnormal with respect to flying’. Let us now also assume that Tweety is a bird:

$$(2) \quad \text{Bird}(\text{Tweety})$$

We want to infer from (1) and (2) that $\text{Canfly}(\text{Tweety})$, since there is no reason to believe that $\text{ab}_1(\text{Tweety})$. This inference is formalised by only looking at those models of (1,2) where the extension of the ab_i predicates are minimal (with respect to set inclusion). Thus, since on the basis of (1) and (2) nothing is known about whether Tweety is an abnormal bird, there are both FOL-models of these premises where $\text{ab}_1(\text{Tweety})$ is satisfied and FOL-models where this is not satisfied. The idea is then that we can

disregard the models satisfying $\text{ab}_1(\textit{Tweety})$, and only look at the models satisfying $\neg \text{ab}_1(\textit{Tweety})$; clearly in all those models $\text{Canfly}(\textit{Tweety})$ holds.

The defeasibility of this inference can be shown by adding $\text{ab}_1(\textit{Tweety})$ to the premises. Then all models of the premises satisfy $\text{ab}_1(\textit{Tweety})$, and the preferred models are now those in which the extension of ab_1 is $\{\textit{Tweety}\}$. Some of those models satisfy $\text{Canfly}(\textit{Tweety})$ but others satisfy $\neg \text{Canfly}(\textit{Tweety})$, so we cannot any more draw the conclusion $\text{Canfly}(\textit{Tweety})$.

A variant of this approach is Poole's [1988] 'abductive framework for default reasoning'. Poole also represents defaults with normality conditions, but he does not define a new semantics. Instead, he recommends a new way of using first-order logic, viz. for constructing 'extensions' of a theory. Essentially, extensions can be formed by adding as many normality statements to a theory as is consistently possible. The standard first-order models of a theory extension correspond to the preferred models of the original theory.

Intensional semantics for defaults

There are also intensional approaches to the semantics of defaults, e.g. [Delgrande, 1988; Asher & Morreau, 1990]. The idea is to interpret defaults in a possible-worlds semantics, and to evaluate their truth in a model by focusing on a subset of the set of possible worlds within a model. This is similar to the focusing on certain models of a theory in preferential entailment. On the other hand, intensional semantics capture the defeasibility of defaults not with extra normality conditions, but in the meaning of the conditional operator. This development draws its inspiration from the similarity semantics for counterfactuals in conditional logics, e.g. [Lewis, 1973]. In these logics a counterfactual conditional is interpreted as follows: $\varphi \Rightarrow \psi$ is true just in case ψ is true in a subset of the possible worlds in which φ is true, viz. in the possible worlds which resemble the actual world as much as possible, given that in them φ holds. Now with respect to defeasible conditionals the idea is to define in a similar way a possible-worlds semantics for defeasible conditionals. A defeasible conditional $\varphi \Rightarrow \psi$ is roughly interpreted as 'in all most normal worlds in which φ holds, ψ holds as well'. Obviously, if read in this way, then modus ponens is not valid for such conditionals, since even if φ holds in the actual world, the actual world need not be a normal world. This is different for counterfactual conditionals, where the actual world is always among the worlds most similar to itself. This difference makes that intensional defeasible logics need a component that is absent in counterfactual logics, and which is similar to the selection of the 'most normal' models in preferential entailment: in order to derive default conclusions from defeasible conditionals, the actual world is assumed to be as normal as possible given the premises. It is this assumption that makes the resulting conclusions defeasible: it validates modus ponens for those

defaults for which there is no evidence of exceptions.

Consistency and non-provability statements

Yet another approach is to somehow make the expression possible of consistency or non-provability statements. This is, for instance, the idea behind Reiter's [1980] *default logic*, which extends first-order logic with constructs that technically play the role of inference rules, but that express domain-specific generalisations instead of logical inference principles. In default logic, the Tweety default can be written as follows.

$$\text{Bird}(x) : \text{Canfly}(x) / \text{Canfly}(x)$$
