Fluoric acid dissolves the oxide of nickel with difficulty, and affords crystals of a bright green colour.

6. Borate of Nickel.

The compound of boracic acid and nickel can only be formed by double affinity, by adding the borate of soda, for instance, to a solution of nickel in acids.

7. Phosphate of Nickel.

Phosphoric acid has not a very strong affinity for the oxide of nickel. The solution which is formed is scarcely of a green colour, and does not afford crystals.

8. Carbonate of Nickel.

Liquid carbonic acid, exposed to the contact of nickel, did not appear, to Bergman, to combine with the metal. But when nickel is precipitated from its solutions by means of alkaline carbonates, the precipitate acquires a greater weight than when the pure alkali is employed; from which it is concluded, that part of the carbonic acid has combined with the oxide.

9. Arseniate of Nickel.

Arsenic acid forms with the oxide of nickel a green saline mass, which is obtained by precipitating the oxide of nickel from its solution in acids, by means of an alkaline arseniate. The arseniate of nickel is in the form of powder, which is scarcely soluble in water.

10. Tungstate, molybdate, chromate, and columbate of nickel. Unknown.

14. Acetate of Nickel.

Acetic acid dissolves the oxide of nickel, and forms a salt in rhomboidal crystals, which are of a deep green colour.

15. Oxalate of Nickel.

With the assistance of heat, oxalic acid acts upon nickel, and a pale green powder precipitates. This salt is scarcely soluble in water. It may be formed also, by precipitating nickel from its solutions in sulphuric, nitric, and muriatic acids, by means of oxalic acid.

16. Tartrate of Nickel.

This salt, and the combinations of the oxide of nickel with the other acids, are unknown.

II. Action of Alkalies.

The fixed alkalies dissolve the oxide of nickel, but in small quantity. They assume a yellow colour; but this oxide is very soluble in ammonia; the solution of which is of a deep-blue colour, and of a peculiar shade. When it is evaporated, it precipitates in the form of a blackish brown powder, which passes from blue to green. Most of the metals separate the nickel from this solution.

162[illegible] Fixed alkalies.

163[illegible] Ammonia.

III. Action of the Earths.

1. Many of the earths, as silica and alumina, have no action on nickel; but others, as barytes and strontites, convert the oxide in solution into an orange red. If it contain arsenic or cobalt, the glass, which is coloured with nickel, becomes of a blue or violet colour.

2. The nitrates and the hyperoxymuriates very readily decompose the salts of nickel, and reduce it to the state of oxide. With the boracic and phosphoric salts it assumes a pale red colour. The nitrate of potash detonates feebly with nickel, but has the property of detecting the smallest trace of cobalt, which could not have been discovered by any other reagent.

So far as is known, this metal has not been applied to much use. There is, however, little doubt, that it might be employed for enamels, and for colouring glass, porcelain, and pottery. Fourcroy observes, that it is probably employed in some of the secret processes of these manufactures, as it is brought in considerable quantities from Saxony to Paris. 163[illegible] Uses.

Sect. XI. *Of Manganese and its Combinations.*

1. A substance was long employed in the manufacture of glass, which, on account of its property of depriving glass of its colour, was known under the name of *glassmaker's soap;* from its appearance it was called *black magnesia*, or *manganese*. But although it was long employed in manufactures, nothing was known of its intimate nature or constituent parts. It was generally considered as an ore of iron, because it was found sometimes combined with the oxide of this metal. By others it was arranged among the ores of zinc, supposing that it was some combination of this metal. To Bergman and Scheele we are indebted for the first accurate knowledge of its nature. Bergman, in a dissertation which he published in 1774, announces it as a peculiar 163[illegible] History.

nga- ;, &c. peculiar metal, on account of its weight, its property of colouring glass, and of affording a white precipitate with the alkaline prussiates. Scheele, in the same year, presented to the academy of Stockholm a memoir, containing his researches concerning the nature and peculiar properties of this mineral. From these experiments he concludes that this mineral is the oxide of a peculiar metal, totally distinct from all others. Gahn, the pupil of Bergman, was the first who obtained the metal in its pure state, from the native oxide of manganese. His experiments have been repeated by others, and the results of Scheele and of Bergman fully confirmed.

633 2. Manganese is most generally found in the state of oxide. Of this there are three principal varieties, the white, the red, and the black. 1. The first, or the white ore of manganese, contains the smallest proportion of iron and of oxygen. Sometimes it is crystallized. This ore soon tarnishes in the air by absorbing oxygen. 2. The red ore of manganese contains more iron than the former. It is either friable, or hard as it is found in carbonate of lime, on shistus, or accompanying ores of iron; or in lamellated masses, radiated or crystallized in pyramids, rhomboids, or in short brittle needles. 3. The black or the brown ore is frequently crystallized like the red. It is also found in solid masses having a metallic or dull earthy appearance, mixed with quartz and other stony bodies. The specific gravity is 4.0. Manganese has been found native by Lapeyrouse in some iron mines in France. It was in the form of small flattened metallic buttons, of a lamellated texture. But it has been supposed that the manganese in this state is alloyed with iron.

634 ration : me- 3. Manganese is procured in the metallic state by the following process. The native oxide of manganese is reduced to a fine powder, and formed into a paste with water. Part of it is then made into a ball, and introduced into a crucible lined with charcoal. A thick stratum of charcoal is placed at the bottom of the crucible, and the ball of manganese is to be surrounded and covered with the same substance, and the crucible, which is inverted and luted to the other, is to be filled with it. The whole is then to be exposed to a very strong heat, not less than 160° Wedgwood, for more than an hour. When the apparatus cools, the metal is found in the bottom of the crucible, or in the midst of the scoriæ, in the form of globules, which amount to nearly one-third of the manganese employed. But if the heat has been too low, it will be found in grains.

35 rties. 4. Manganese is of a grayish white colour, with considerable brilliancy, and of a granular texture. The specific gravity is 6.850. It has neither taste nor smell. In hardness it is equal to iron. It is one of the most brittle of the metals, and at the same time one of the most infusible, requiring a temperature of 160° Wedgwood to melt it. When in the state of powder it is often attracted by the magnet, on account of the iron, from which it can only be separated with great difficulty.

36 n of 5. When this metal is exposed to the air, it is soon tarnished. It becomes gray, brown, and black, and at last falls down into powder, which is found to have acquired considerable addition to its weight. But when it is heated in the open air, it passes more rapidly through the different changes of colour, in proportion as it combines with oxygen, to the absorption of which these changes are owing. It appears, therefore, that manganese, like some of the other metals, combines with different portions of oxygen, forming different oxides. The black oxide, which is manganese, combined with oxygen in the greatest proportion, is found native in great abundance. The red oxide is supposed to contain the oxygen in the next proportion. This also exists native, and it may be found by distilling the black oxide made into a paste with concentrated sulphuric acid in a retort to dryness. It is deprived of a great quantity of oxygen, which is given out in the state of gas. The residuum is then to be mixed with water, which is to be filtered. This solution, which is sulphate of manganese, is of a red colour. By adding an alkali, a precipitate is formed, which is the red oxide of manganese. The white oxide is also prepared by depriving the black oxide of part of its oxygen. This is effected by pouring nitric acid on the black oxide of manganese, with the addition of sugar, which absorbs the oxygen, and converts it into the white oxide. The latter is then dissolved in the acid, from which it may be precipitated by potash. The precipitate is in the form of a white powder. The proportion of manganese and oxygen in the white and brown oxides of manganese, according to Bergman, and in the black, according to Fourcroy, are,

Manganese, &c. 1637 Oxides. 1638 Black. 1639 Red. 1640 White.

	White Oxide.	Brown Oxide.	Black Oxide.
Manganese	80	74	60
Oxygen	20	26	40
	100	100	100

When these oxides are exposed to the air, they absorb oxygen, and are again converted into the black oxide with the greater proportion of oxygen.

6. It is from the black oxide of manganese that chemists generally procure oxygen gas. The most economical process is that which has been already described in the chapter on oxygen. This is by exposing it to a red heat in an iron bottle. The manganese is reduced to the state of red oxide by being deprived of the difference of the quantity of oxygen between the black and the brown oxides. The same manganese may be employed after it has been for some time exposed to the air, and occasionally moistened with water. This process, however, goes on much more slowly than is generally supposed. We have kept several quantities of manganese, which had furnished abundance of oxygen, and had ceased to give out more in a red heat, exposed to the air for many months, and frequently moistened with water, but when it was again heated to redness, it did not yield above $\frac{1}{10}$ part of the original quantity from the native manganese. 1641 Furnishes oxygen.

7. Manganese is capable of combining with a still larger proportion of oxygen than that contained in the black oxide. This combination takes place when that oxide is exposed for some time to a moderate red heat, in intimate mixture with an equal weight or a much larger proportion of pure potash, or nitrate of potash. Oxygen is then acquired from the air, or from the decomposition of the nitric acid; and a compound is formed which is in fact a *manganesiate of potash*, *i. e.* the manganese 1642 Manganesic acid.

Manganese, &c. manganese now acquires acid properties; a *manganesic acid* is produced, which combines to form this neutral salt with the potash. This is of a beautiful green colour when the quantity of potash is small, and of a red colour when it is large. When exposed for a time to the air, or largely diluted with water, it becomes colourless. These changes acquired for it the name of the *chameleon mineral* when its nature was unknown.

8. Manganese does not enter into combination with azote, hydrogen, or carbon. It is by means of charcoal, that the oxide of manganese is reduced, by being deprived of its oxygen; and what has been supposed to be a compound of manganese and carbon, is a carburet of iron, or carbon combined with the iron, with which manganese is almost always alloyed.

1643 Phosphuret and sulphuret. 9. Phosphorus combines very readily with manganese. Pelletier formed the phosphuret of manganese by fusing a mixture of equal parts of manganese in the metallic state, and phosphoric glass, with about $\frac{1}{8}$ part of charcoal in powder; or by fusing equal parts of the two former without the charcoal; or by projecting small bits of phosphorus on manganese heated to redness in a crucible. The phosphuret obtained by any of these processes is of a white colour, of a granulated texture, and brittle, and much disposed to crystallize. It undergoes no change by exposure to the air. It was covered with an opaque, vitreous matter of a yellowish colour. It is more fusible than the manganese itself. When it is exposed to the action of the blow-pipe, the phosphorus burns, and the metal is oxidated *.

* *Ann. de Chim.* iii. 137.

10. Bergman failed in forming a compound with sulphur and manganese by direct combination. But he succeeded in combining sulphur with oxide of manganese. Three parts of sulphur, and eight parts of the oxide, exposed to heat in a glass retort, formed a greenish yellow mass, which effervesced with acids, and emitted sulphurated hydrogen gas. Scheele has observed, that a part of the sulphur is converted into sulphurous acid during the process.

1644 Affinities. 11. Manganese enters into combination with the acids, and forms salts with them. The order of the affinities of the oxides of manganese for the acids, according to Bergman, is the following:

Oxide of Manganese.

Oxalic acid,
Citric,
Phosphoric,
Fluoric,
Muriatic,
Sulphuric,
Succinic,
Nitric,
Saclactic,
Succinic,
Tartaric,
Lactic,
Acetic,
Prussic.
Carbonic.

I. Salts of Manganese.

1. Sulphate of Manganese.

1. Concentrated sulphuric acid acts on manganese, even in the cold; but the action is more powerful if the acid be diluted with two or three parts of water. Hydrogen gas is given out, and there remains behind in the liquid, a black, spongy mass, which is the carburet of iron. The solution is colourless, and it affords by evaporation, transparent, colourless crystals. Sulphuric acid does not combine with the black oxide of manganese, till it is deprived of part of its oxygen, and reduced to the state of red or white oxide; but the acid combines with either of the two latter oxides, forming salts possessed of distinct properties. There are, therefore, two sulphates of manganese, which may be distinguished, from the colour of the base or oxide, by the names of white and red sulphates. 164[illegible] Two sulphates.

2. *White sulphate of manganese.*—This is the compound of sulphuric acid and the white oxide of manganese. This oxide combines with the acid without effervescence, and forms a colourless solution, which yields, by evaporation, transparent rhomboidal crystals, which have a very bitter taste. This salt is decomposed by heat; the acid is driven off, and oxygen gas is given out. It is decomposed also by the pure alkalies, and a precipitate is formed, of the white oxide of manganese, which soon becomes brown by exposure to the air, in consequence of the absorption of its oxygen. The alkaline carbonates precipitate a carbonate of manganese, which does not absorb the oxygen from the air, and does not become black like the former. It is the white sulphate of manganese, which is obtained by dissolving the metal in diluted sulphuric acid. In this process the manganese combines with the oxygen of the water, which is decomposed, and is converted into the white oxide, which unites with the sulphuric acid, to form the sulphate. The hydrogen of the water is driven off in the state of gas, so that the salt formed in this way occasions an effervescence. This salt may also be formed by dissolving the black oxide in sulphuric acid, but in this case it is necessary, as Scheele discovered, to add some vegetable matter, as sugar, honey, or gum, to absorb the superabundant quantity of oxygen, which prevents the solution of the manganese in the acid. When, therefore, the black oxide is reduced to the state of white oxide, by depriving it of part of its oxygen, it combines with the acid, and forms white sulphate of manganese, as in the former processes. 164[illegible] With [illegible] white oxide.

3. *Red Sulphate of Manganese.*—If the black oxide of manganese be distilled to dryness with sulphuric acid, diluted with half its weight of water, and if the residuum be washed with water, a reddish or violet-coloured solution, which is the red sulphate of manganese, is obtained. By evaporation it affords thin crystalline masses, which have no regular form. These are also of a reddish colour. The alkalies occasion a red precipitate, which becomes black by exposure to the air. This sulphate may be also formed by the direct combination of the red oxide with the acid. 164[illegible] With [illegible] red ox[illegible]

Bergman has observed, that the red oxide of manganese is intermediate between the black and the white; that it is more soluble in sulphuric acid than the former, and less soluble than the latter; that the red forms a red-coloured sulphate, while the white affords a colourless sulphate.

4. Sulphurous acid acts feebly or scarcely at all on manganese; but it dissolves the black oxide readily, and

and without effervescence. There is not formed, however, a sulphite of manganese; for the sulphurous acid deprives the black oxide of a portion of its oxygen, and thus converts it into a white oxide, while the acid itself is converted into sulphuric acid. The white oxide is then dissolved in the sulphuric acid, and forms the white sulphate of manganese.

2. Nitrate of Manganese.

648 1. Nitric acid dissolves manganese with effervescence, and with the evolution of nitrous gas. There remains behind a black, spongy mass, which is carburet of iron, and insoluble. The solution thus formed is of a dark colour, on account of the iron which it contains; for it does not appear that the red oxide of manganese combines with nitric acid. The white oxide of manganese dissolves very readily in nitric acid, and without effervescence, or the emission of nitrous gas. This solution, if the oxide be pure, is colourless. It does not afford crystals, even by slow evaporation. The black oxide of manganese cannot be dissolved in nitric acid, but by long digestion; but by adding some vegetable matters, as honey, sugar, oils, or even some of the metals, to deprive the oxide of part of its oxygen, the combination is effected. Carbonic acid gas, which is formed by the union of the carbon of the vegetable matters with the oxygen of the manganese, is given out during the process.

2. Nitrous acid dissolves the oxide of manganese much more readily than the nitric acid. No effervescence takes place, because the oxygen of the manganese combines with the nitrous acid, and forms nitric acid, which latter combines with the oxide of manganese, reduced to the state of white oxide; and thus there is formed, not a nitrite, but a nitrate of manganese.

3. Muriate of Manganese.

49 1. Manganese is dissolved with effervescence, and with the evolution of hydrogen gas, in liquid muriatic acid. The white oxide combines with the acid, without effervescence, and without the separation of any gas, because it is sufficiently oxidated, to be dissolved in this acid. The black oxide is dissolved with equal facility in muriatic acid as in the other acids. In this case an effervescence takes place, with the disengagement of oxymuriatic acid gas. The nature of this action is obvious. Part of the muriatic acid combines with part of the oxygen of the manganese, and forms oxymuriatic acid, which is disengaged in the state of gas. The black oxide is deprived of part of its oxygen, and converted into the white oxide, which latter dissolves in the remaining part of the muriatic acid, and forms a muriate of manganese. This salt, being a compound of the white oxide of manganese and muriatic acid, may be called the *white muriate of manganese*. If any combustible matter be added, the solution of the black oxide of manganese in this acid goes on, without the production of oxymuriatic acid.

2. Oxymuriatic acid readily parts with its oxygen to manganese, which is thus converted into the white oxide. It combines also with the oxides of manganese, and forms solutions of a brown, red, or violet colour, which afford crystals of the same colour. There is, therefore, a red muriate of manganese.

It is from the black oxide of manganese that oxymuriatic acid is obtained, either by adding to the oxide muriatic acid, part of which combines with the oxygen of the manganese, and is converted into oxymuriatic acid; or, by adding sulphuric acid to a mixture of the black oxide of manganese and muriate of soda. The sulphuric acid decomposes the latter, and the muriatic acid being disengaged, combines with part of the oxygen of the manganese, and forms oxymuriatic acid.

4. Fluate of Manganese.

Fluoric acid has little action on manganese or its oxides; but a fluate of manganese may be formed by double affinity, by adding an alkaline fluate to the nitrate or muriate of manganese. The fluate of manganese thus formed, is not very soluble in water. Its other properties are unknown.

5. Borate of Manganese.

This salt may be formed in the same way as the former. It is equally soluble in water, and its other properties are also unknown.

6. Phosphate of Manganese.

A phosphate of manganese may be formed in the same way as the two former salts. It is not very soluble in water, and its other properties have not been examined.

7. Carbonate of Manganese.

Liquid carbonic acid dissolves a small portion of manganese, as well as of its black oxide. When this solution is exposed to the air, the oxide is gradually precipitated, and appears on the surface in the form of a white pellicle. Bergman has remarked, that during the combination of manganese with carbonic acid, there is evolved an odour somewhat analogous to that of burnt fat.

8. Arseniate of Manganese.

Arsenic acid combines with the white oxide of manganese, and forms an arseniate. The arsenious acid, or white oxide of arsenic, deprives the black oxide of manganese of part of its oxygen, and passes to the state of arsenic acid, and then combines with the manganese, now reduced to the state of white oxide. When the arsenic acid is nearly saturated with the oxide, the solution becomes thick, and small crystals make their appearance. This salt, when heated, does not melt, nor is the arsenic sublimed, without the addition of charcoal.

9. Tungstate of Manganese,
10. Molybdate of Manganese,
11. Chromate of Manganese,
12. Columbate of Manganese.
} Unknown.

13. Acetate of Manganese.

Acetic acid dissolves part of the black oxide of manganese, but acts very feebly on the metal itself. This acid may be employed to separate manganese from iron; for when it is added to a solution containing both these metals, the acid combines with the manga- 1650 Process for separating iron.

nese,

Manganese, &c.

nese, for which it has a stronger affinity, and leaves the oxide of iron. Several successive solutions and evaporations are necessary to separate the whole of the iron, which is known when the solution becomes colourless, and when it affords a white precipitate with prussiate of potash. The solution of acetate of manganese does not crystallize, and when evaporated to dryness, it soon deliquesces *.

14. Oxalate of Manganese.

Oxalic acid forms a salt with the oxide of manganese, which, when the solution is saturated, precipitates in the form of white powder. It may be formed also by adding oxalic acid to the sulphate, nitrate, and muriate of manganese in solution.

15. Tartrate of Manganese.

This salt may be formed by double affinity, by adding tartrate of potash to the solution of manganese in sulphuric or nitric acids. The black oxide of manganese is dissolved in tartaric acid, and gives a black coloured solution. When it is heated, an effervescence takes place; the acid is partially decomposed, carbonic acid gas is evolved, and the solution at last becomes colourless.

16. Citrate of Manganese.

Citric acid, in its combination with the black oxide of manganese, exhibits the same phenomena as the former.

17. Benzoate of Manganese.

Benzoic acid readily combines with the white oxide of manganese. By evaporation, crystals in the form of small scales are obtained, which are little altered by exposure to the air, and are soluble in water.

II. Action of Alkalies on Manganese.

1651 Pure alkalies. It has been already stated, that potash acts on the black oxide of manganese, so as to give origin to the absorption of an additional quantity of oxgyen, and the formation of a metallic acid. Soda, in its pure state, has a similar agency. This agency is also exerted with the white oxide of this metal, and with the metal itself. According to some recent experiments of Forhhammer,
1652 Mineral chameleon. it appears that two different acids may be formed in this manner; that, in fact, *chameleon mineral*, in its green state, consists of a *manganeseous* acid in union with potash; and, in its red state, contains the acid formerly mentioned, the *manganesic*.

1653 Ammonia. 2. Scheele had observed the change which ammonia undergoes by the action of oxide of manganese, in the distillation of this oxide with the muriate of ammonia. He suspected that the ammonia was partially decomposed, and to this decomposition he ascribes the formation of a gas, which he obtained by this process, and which he found to be different from carbonic acid. Berthollet has shewn, that in this process, the hydrogen, leaving the ammonia which is decomposed, combines with the oxygen of the oxide of manganese, and forms water; and the azote, the other component part of ammonia, is set at liberty.

A very interesting experiment was contrived by Dr Milner, which illustrates the reciprocal action, and decompositions of the oxide of manganese and ammonia. He filled a tube with oxide of manganese, exposed it to a red heat, and made a stream of ammoniacal gas pass through it. The gas was decomposed, and its azote combining with the oxygen of the oxide, formed nitrous gas. 165 Curious experiment.

Some of the alkaline salts have peculiar effects on the oxides of manganese and their compounds. The sulphates have the property of destroying the colour of glass, which has been communicated by manganese; but for this effect a high temperature is necessary. The nitrates readily burn this metal, and oxidate it strongly. Melted nitre gives a violet or red colour to glass, which has been rendered colourless, by restoring to it the oxygen of which it has been deprived by the fusion of the glass. With the nitrate of potash and the black oxide of manganese, heated in a crucible to redness, a compound is formed, similar to that which is the result of the direct combination of the oxide with the alkali.

The alkaline phosphates and borates fused by means of the blow-pipe, with the oxide of manganese, produce various colours according to the degree of oxidation, and the intensity of the heat.

A white precipitate is formed, by adding hydrosulphuret of potash to the salts of manganese, and a yellowish-white precipitate is obtained, by means of the triple prussiate of potash.

III. Action of the Earths on Manganese.

There is no action between manganese and any of the earths; but its oxide combines with them, and forms vitreous matters, which are of different colours, according to the degree of oxidation of the manganese, and its mixture with iron. In general, these colours are green, brown, black, or yellowish green. 165 Colours of glass.

Manganese and its oxides are of great importance, both in chemistry and in the arts. This must be obvious, from the minute detail of its properties and combinations, which has now been given. 165 Uses.

Sect. XII. *Of Bismuth and its Combinations.*

1. Bismuth, it would appear, was known to the ancients, to the alchemists, and some of the earliest mineralogists; but it was considered merely as a variety of some other metal, and generally of tin and lead. Hence it was distinguished by the name of *green tin*, *gray lead*, and *white antimony*. It was not till the year 1753, when its properties were particularly examined by Pott and Geoffroy the younger, that it was ascertained to be a peculiar metal. Darcet and Rouelle afterwards instituted a set of experiments on this metal, and discovered more of its properties. Monnet and Beaumé investigated its principal combinations at still greater length; and Bergman examined, with more accuracy, some of its compounds and precipitates. 165 History.

2. Bismuth is found native in the state of sulphuret and in that of oxide. Native bismuth is easily distinguished by its colour, brittleness, and fusibility. The sulphuret of bismuth is of a bluish gray, sometimes with a yellowish shade, and is in irregular masses, or crystallized 165 Ores.

* *Ann. de Chim.* xli. p. 249.

lized in the form of small prisms. It has a brilliant, lamellated fracture. The native oxide of bismuth accompanies the metal, or is found on the surface of the sulphuret. It is of a greenish yellow colour.

1659 3. Bismuth is easily extracted from its ores. The mineral, after being reduced to powder, and well washed, is mixed with about $\frac{1}{4}$ of its weight of black flux, is put into a crucible lined with charcoal, and well covered. It is then exposed to a moderate heat, which must be quickly applied, to prevent the metal from being sublimed. By this process a metallic button is obtained.

1660 In the humid way, the ore of bismuth being reduced to powder, is dissolved in nitric acid, and precipitated from this solution by water. If the native bismuth be combined with any other metals, they remain in the solution. The sulphuret of bismuth is also dissolved in the same acid by boiling. The sulphur is separated, as the metal, being oxidated, combines with the acid. The native oxide is treated in the same way, and is precipitated by water.

1661 4. Bismuth is of a white colour, inclining to yellow, exhibiting a texture composed of large brilliant plates. Its specific gravity is 9.822. It has scarcely either tase or smell. By a violent stroke of the hammer it is broken, and divides into small fragments of a lamellated structure; the figure of its particles is the regular octahedron. It has considerable hardness; and by hammering, its density may be increased. It has very little elasticity, and no ductility. Bismuth is very fusible. When it is exposed to the temperature of 490°, according to Guyton, it melts; and, if after fusion it be allowed to cool slowly, it crystallizes in parallelopipeds which cross each other at right angles. This metal crystallizes more easily and more regularly than any other yet known. If the heat be long continued after the fusion, and sufficiently strong; and if the process be conducted in close vessels, it sublimes, and attaches itself to the upper part of the apparatus, where it crystallizes in brilliant plates.

5. Bismuth is but slightly affected by exposure to the air in the cold. It loses its brilliancy, and is covered with a fine powder of a yellowish gray colour; but, when it is heated in contact with air, the surface is soon covered with an iridescent pellicle, which, by agitation and continuing the heat, is converted into a greenish gray or brown-coloured oxide. It acquires about $\frac{1}{12}$ of addition to its weight. By continuing the heat, and occasionally stirring the fused metal, it becomes of an orange-yellow colour, and acquires a farther addition to its weight. If the metal in fusion be exposed to a red heat, it takes fire with a slight explosion, burns with a bluish flame, and is sublimed in the form of a

1662 yellowish vapour, which, being condensed and collected, is known under the name of *flowers of bismuth*. It appears then, that bismuth combines with oxygen in two proportions. The first, or the smaller proportion, is that of the brown oxide; and the second is the yellow oxide or flowers of bismuth.

1663 6. There is no action between bismuth and azote, hydrogen, or carbon. It combines but in very small proportion with phosphorus, forming a phosphuret. When phosphorus is dropped into bismuth in fusion, it seems to unite with it, according to Pelletier, in the proportion of four parts in the hundred. But the properties of the bismuth are very little changed.

7. Sulphur unites readily with bismuth. When equal parts of bismuth and sulphur are heated together in a crucible, the fusion of the metal is greatly retarded. It requires a higher temperature than when the metal is alone. The sulphuret of bismuth is of a shining dark gray colour, and crystallizes by proper cooling into needle-form prisms, shaded with splendid blue and deep-red colours. The crystals are obtained by piercing the surface when it becomes solid after fusion, and pouring out the liquid parts; a cavity is thus left in which they are formed.

Bismuth, &c.

1664 Sulphuret.

Sulphurated hydrogen gas occasions a dark colour on the surface of bismuth, and converts the oxides into a deep black colour, which is the commencement of reduction.

8. Bismuth combines with many of the metals, and forms alloys; but its combinations with the metals, already described, are little or scarcely at all known. Bismuth also combines with the acids, and forms salts. 1665 Alloys and salts.

9. The affinities of bismuth and its oxides are arranged by Bergman in the following order: 1666 Affinities.

Bismuth.	Oxide of Bismuth.
Lead,	Oxalic acid,
Silver,	Arsenic,
Gold,	Tartaric,
Mercury,	Phosphoric,
Antimony,	Sulphuric,
Tin,	Muriatic,
Copper,	Nitric,
Platinum,	Fluoric,
Nickel,	Saclactic,
Iron,	Succinic,
Sulphur.	Citric,
	Lactic,
	Acetic,
	Prussic,
	Carbonic.

I. Salts of Bismuth.

The solutions of bismuth in the acids, and also the crystallized salts which are obtained from them, resemble each other, but differ from almost all other metallic solutions, as well as from all other salts; and particularly in one circumstance, which is, that water in sufficient quantity decomposes them, and precipitates an oxide of bismuth of a white colour. This shows that bismuth is strongly oxidated by the action of the acids, to which it adheres with no great affinity, and that it forms with them compounds which are not very permanent. It seems at the same time remarkable, that this metal should be more oxidated in this way, than by the usual process of oxidation, by means of heat, and by the action of water; and that it should have a white colour, while in the usual way it is of a yellowish gray. 1667 Different from other metallic solutions.

1. Sulphate of Bismuth.

Concentrated sulphuric acid has no action on bismuth in the cold; but this metal decomposes the acid at a boiling temperature. Sulphurous acid gas is disengaged, and the bismuth is oxidated, and converted into

Bismuth, &c.

into a white powder. If the heat be strong, sulphur is sublimed. When the remaining mass is washed with water, it carries off the remaining acid and a small quantity of the oxide of bismuth. The solution, by proper evaporation, affords small soft needle-formed crystals, which are sulphate of bismuth. This sulphate is decomposed by water, which separates a white oxide.

2. Sulphite of Bismuth.

Sulphurous acid has no action on bismuth; but it unites with its oxide, and forms a white sulphite, which is insoluble in water, and even in its own acid; of a sulphurous taste; fusible by the blow-pipe into a reddish yellow mass, which is reduced on charcoal into metallic globules; decomposed with effervescence by means of sulphuric acid; giving out by distillation sulphurous acid, and leaving behind a pure white oxide.

3. Nitrate of Bismuth.

1668 Violent action.

1. Nitric acid exhibits a very violent action with bismuth. When the acid is a little concentrated, and the bismuth in the state of powder, there is a violent effervescence, with the evolution of nitrous gas. There is at the same time great heat produced. The bismuth is converted into white oxide at the expence of the acid, and when the action ceases, if no more acid be added than what is necessary to its oxidation, remains dry.

1669 Properties.

2. The nitric solution, thus prepared, is colourless, and affords crystals by evaporation. It crystallizes in tetrahedral prisms, compressed into obtuse three-sided summits. It has sometimes been obtained in flattened rhomboidal parallelopipeds, similar to those of Iceland crystal. When this salt is thrown on red hot coals, it melts, boils, and frothes up; exhales nitrous vapour, and leaves behind a greenish yellow oxide. It dries in the air, and becomes moist when the air is humid. When it is brought into contact with water, it becomes turbid, is decomposed, and a white oxide is precipitated. The decomposition is effected with the nitric acid, which is poured gradually into a large quantity of water. The oxide which is thus obtained was formerly called *magistery of bismuth*. It is known in the shops by the name of *pearl white*. It becomes of a deep gray, brown, or even black colour, when it is exposed to the action of sulphurated hydrogen gas.

4. Muriate of Bismuth.

1670 Preparation.

Muriatic acid has but a feeble action on bismuth. It is necessary to assist its action, that the acid be concentrated, and long digested with the metal, or distilled off it in the state of powder. During the process, a fetid odour is emitted, which is owing to the decomposition of water, its oxygen combining with the metals, and the hydrogen being set at liberty. By evaporating this solution, small needles of muriate of bismuth are obtained; but only in very small quantity; for the greatest part of the oxide of bismuth is separated by water. The muriate is sublimed by heat into a thick, solid, fusible matter, which was formerly called *butter of bismuth*. It is deliquescent, and may be decomposed by water, which separates a very fine white oxide.

Oxymuriatic acid readily dissolves bismuth, and forms with the oxide, which is previously produced, a salt similar to the preceding.

5. Fluate of Bismuth.
6. Borate of Bismuth.

These two salts may be formed by adding a fluate or borate of an alkali to a solution of nitrate of bismuth. A white precipitate is formed of the fluate or borate of bismuth; but little is known of their properties.

7. Phosphate of Bismuth.

This salt is formed by combining the acid with the oxide of the metal, when precipitated by an alkali. The phosphate of bismuth is in the state of an insoluble white powder.

8. Carbonate of Bismuth.

This salt may be formed by precipitating the oxide of bismuth from its solution in acids, by means of an alkaline carbonate.

9. Arseniate of Bismuth.

Arsenic acid acts upon bismuth with the assistance of heat. A white powder appears on the surface of the metal, and the oxide is precipitated from the solution, by adding water. The arseniate of bismuth may be formed by adding arsenic acid to a solution of the nitrate of bismuth. The arseniate of bismuth falls to the bottom in the form of precipitate.

10. Tungstate of Bismuth.

Unknown.

11. Molybdate of Bismuth.

Muriate of bismnth is precipitated, if there be no excess of acid, by molybdic acid. The molybdate of bismuth, thus formed, is of a white colour.

12. Chromate of Bismuth, }
13. Columbate of Bismuth. } Unknown.

14. Acetate of Bismuth.

This salt may be formed, by adding a solution of acetate of potash to a solution of nitrate of bismuth. A precipitate of acetate of bismuth is formed. The addition of acetic acid to the nitrate of bismuth, Guyton observes, prevented the latter from being precipitated by means of water.

15. Oxalate of Bismuth.

Oxalic acid combines with the oxide of bismuth, and forms with it a salt in the state of white powder, which is scarcely soluble in water. Oxalic acid added to nitrate of bismuth, occasions a precipitate in the form of small transparent crystals, which are oxalate of bismuth.

16. Tartrate of Bismuth.

Tartaric acid added to the solution of bismuth in any of the mineral acids, precipitates the oxide in the form of a white powder, which is the tartrate of bismuth, and is insoluble in water.

17. Benzoate of Bismuth.

Benzoic acid combines readily with the oxide of bismuth. The solution, by evaporation, affords crystals in the form of needles. They undergo no change by exposure to the air, are soluble in water, and decomposed by sulphuric and muriatic acids. This salt is also decomposed by heat, which drives off its acid.

18. Succinate of Bismuth.

Succinic acid combines with the oxide of bismuth, at a boiling heat. By evaporating the solution, crystals of succinate of bismuth are obtained, in the form of plates, and of a yellow colour.

II. Action of Alkalies, Earths, and Salts, on Bismuth.

671 1. Scarcely any thing is known of the action of the alkalies on bismuth. Ammonia, it is said, communicates to it a yellow colour, and the oxide of bismuth is soluble in ammonia in the liquid state.

672 2. The oxide of bismuth combines by fusion with silica, to which it communicates a greenish yellow colour.

673 3. Bismuth is not changed by the action of the sulphates or sulphites. It is oxidated by the nitrates. When it is strongly heated, and thrown into a red-hot crucible with nitrate of potash, it detonates feebly, and without much inflammation. It is reduced to the state of oxide, of which one part combines with the potash. Bismuth has no action on muriate of ammonia, but its oxide very readily decomposes this salt. In the cold, it disengages a little ammonia, by simple trituration; but when exposed to heat, it is totally decomposed, and there remains a muriate of bismuth.

674 4. Bismuth is applied to a great many uses. It forms some important alloys with the softer metals, to give them hardness and consistency. The oxides of bismuth are of still more extensive utility. It is employed in this form by the manufacturers of porcelain, for the preparation of yellow enamels, and it is mixed with other oxides, to give variety of shade to their colours. It is sometimes employed in the fabrication of coloured glasses, to communicate a greenish yellow. The white oxide, which is most commonly employed for these different purposes, is also employed as a paint for the skin, under the name of *pearl white*; but it is extremely improper for this purpose, for besides the injury which it does to the skin, it becomes black, when it is exposed to the action of sulphurated hydrogen gas. It is sometimes used also to give a black colour to the hair.

SECT. XIII. *Of Antimony and its Combinations.*

675 1. It does not appear that the ancients were acquainted with antimony as a distinct metal, although it is supposed that it was employed by them in alloys of other metals. It is said, that they were acquainted with the oxide of antimony, and that it was employed as an external remedy in inflammation of the eyes. As a peculiar metal it was not certainly known till the time of Basil Valentine, who lived about the end of the 15th century. In his work, entitled *Currus Triumphalis Antimonii*, he has detailed all that was then known of this metallic substance, and he has particularly described the process by which it is extracted from its ore.

No substance has been more the subject of investigation than antimony, and on no subject, perhaps, has there been so much written. The alchemists regarded antimony as peculiarly appropriate to the object of these researches. Their labours on this subject were almost incredible; and indeed this is scarcely to be wondered at, since it appears that they were inspired with the hope of making, by its means, the fortunate discovery of the universal medicine. It was therefore tortured and tried in every possible way, to obtain the object of their researches; and on this account it is almost impossible to reckon up the number of medicinal preparations which were proposed and employed with this metal and its ores. It is owing to these views and researches concerning antimony, that its nature and properties are now so fully known.

2. About the end of the 17th century, Lemery published a treatise, which was the first correct and rational account of antimony. In this he arranged and detailed the discoveries of his predecessors, and added some of his own, with a number of curious experiments and accurate processes for many of the preparations of antimony and its sulphuret. Mender afterwards published a very complete history of all the facts that were then known concerning antimony; and it has been since examined by more modern chemists; among whom Bergman, Scheele, Berthollet, Proust, and Thenard, are the principal writers on this subject.

3. Antimony exists in nature in four different states: 1676 Ores.
In the state of native antimony, that of sulphuret, hydrosulphuret of the oxide of antimony, and muriate. Native antimony is easily distinguished by its colour and brilliancy. It has been found in Sweden and in France. The most common ore of antimony is the sulphuret, which is of a grayish colour, and stains the fingers. It is sometimes crystallized in square prisms, which are slightly rhomboidal, and terminated by four-sided pyramids. The hydrosulphurated oxide of antimony is in shining filaments, of a deep red colour, disposed in rays going from a common centre, adhering to the surface or cavities of the sulphuret. The muriate of antimony, which is a rare production, is of a brilliant, pearly-white colour, in the form of small divergent needles, somewhat resembling radiated zeolite.

4. To obtain the pure metal from the sulphuret of 1677 Analysis.
antimony, the ore is first roasted, to separate the greatest part of the sulphur. It is then mixed with its own weight of black flux, formed into a paste with oil, and exposed to a strong heat in a crucible, at the bottom of which the metal is found reduced. By a shorter process, eight parts of sulphuret of antimony, six of tartar, and three of nitre, reduced to powder, and well mixed, are projected in small quantities into a red-hot crucible. At each projection there is a strong detonation; the tartar forms, by means of the nitre, a black flux, and the sulphuret being burnt, the metal is fused, but not oxidated, on account of the charcoal of the tartar

Antimony, &c. tar with which it is surrounded, and the liquid alkali which covers it. The whole is then fused in a conical iron pot; and, when it is cool, the metallic antimony is found at the bottom, marked on its surface with needle-shaped crystals, arranged in the form of a star.

1678 Properties. 5. Antimony, in a state of purity, is of a brilliant white colour, having a good deal of resemblance to that of silver or tin. It has a lamellated texture, composed of plates which cross each other in all directions. It exhibits sometimes perceptible traces of crystallization. The form of the crystals, which was discovered with difficulty by Hauy, on account of its complicated structure, is the octahedron, composed of a great number of regular tetrahedrons. Antimony has a very perceptible taste and smell, and particularly if it is rubbed for some time on the hands. The specific gravity is 6.702. It is very brittle, so that it can be reduced to powder, which is of a grayish white colour.

1679 Action of water. 6. Antimony undergoes no change by being exposed to the air, nor is there any perceptible action between antimony and water in the cold; but when water comes in contact with antimony red-hot, it is instantaneously decomposed, and accompanied with a violent detonation, and a very brilliant white flame. Accidents of this kind have happened, attended with considerable danger.

1680 Of heat. 7. When antimony is heated to the temperature of 808°, it melts. If the heat be continued after its fusion, it is sublimed, and if the process be performed in close vessels, it is condensed in shining crystallized plates. If it be allowed to cool slowly, and part of it be poured off when the surface becomes solid, the cavity is lined with pyramidal crystals, composed of small octahedrons.

1681 Oxides. 8. When antimony is kept in fusion in the open air, it rises in the form of white vapour, which is precipitated on the surface of the metal, or upper part of the crucible, and crystallizes in long prisms, or in small, white, brilliant needles. This is an oxide of antimony, which was formerly called *argentine flowers*, or *snow of regulus of antimony*. By this process it is found, that the antimony has acquired an addition of weight of about 50 per cent. This oxide may be obtained, by exposing the antimony in a crucible to a white heat, and then by suddenly agitating it in contact with air, it takes fire with a kind of explosion, and burns with a white light.

Thenard, in his researches concerning antimony, distinguishes six different degrees of oxidation of this metal. But in a memoir on the same metal by Proust, he considers that the oxides of antimony may be reduced to two. According to the experiments of this chemist, 100 parts of antimony treated with nitric acid in a retort, uniformly afford 130 of a yellow oxide in the state of powder. It is reduced to 126 by washing with water before drying it, because the nitric acid dissolves a small proportion. This oxide is not reduced by being exposed to a red heat, but it is sublimed, and condensed in close vessels, in groups of crystals. It is insoluble in water. It is the same oxide which was formerly distinguished by the name of *argentine flowers*. The component parts of this oxide, according to Proust, are,

Antimony	77
Oxygen	23
	100 *

* Jour. de Phys. lv. p. 330.

The oxide, with a smaller proportion of oxygen, is formed by dissolving antimony in muriatic acid; and by adding water to the solution, a white powder is precipitated, which being washed, is separated from any acid that may adhere to it. To purify it still more, it is to be boiled with carbonate of potash, and afterwards washed, and dried on a filter. This oxide is of a yellowish white colour, and has little brilliancy; it melts at a moderate red heat, and when it is allowed to cool, it crystallizes on the surface. The crystals are of a yellowish white colour, which are thrown together in heaps, in a radiated form. This oxide was formerly known by the name of *powder of algaroth*. Its component parts are,

Antimony	81.5
Oxygen	18.5
	100.0 †.

† Ibid.

9. There is no action between antimony and azote, hydrogen, or carbon. 1682 Phosphuret.

10. Antimony enters into combination with phosphorus, and forms with it a phosphuret. Equal parts of phosphoric glass and antimony are fused together in a crucible, or with the addition of $\frac{1}{8}$ of charcoal, or by projecting pieces of phosphorus on the metal in fusion in a crucible; and thus a phosphuret of antimony is obtained. The phosphuret has a metallic lustre, is brittle, and has a lamellated fracture. When it is placed on burning charcoal, it melts, gives out a small green flame, and is converted into the white oxide of antimony, which is sublimed.

11. Antimony combines very readily with sulphur, 1683 Sulphuret. and forms with it an artificial sulphuret, which is exactly similar to the native sulphuret. It is formed by mixing the antimony and the sulphur together, and fusing them in a crucible. This sulphuret is of a brilliant gray colour, is more fusible than the metal itself, and by slow cooling, may be obtained in crystals. The component parts of the sulphuret, according to Proust, are,

Antimony	75.1
Oxygen	24.9
	100.0

12. The yellow oxide of antimony combines with 1684 Oxides with sulphur. different proportions of sulphur, and forms compounds of different colours, and which were formerly distinguished by different names. With eight parts of the oxide and one part of the sulphuret, a red-coloured, semitransparent mass is obtained, which was formerly called *glass of antimony*. When two parts of sulphuret are added to eight parts of the oxide, a yellowish mass is formed, which was known by the name of *crocus metallorum*. Six parts of oxide and one of sulphur, form a dark red opaque mass, with a vitreous fracture, which is the true *liver of sulphur*. In these combinations,

Antimony, &c.

tions, the sulphur deprives the oxide of part of the antimony, and combines with it, forming a sulphuret. This sulphuret then combines with the oxide †.

† Journ de Physique, lv. 330.

13. Antimony enters into combination with the acids, and forms salts. It also forms alloys with many of the metals. The affinities of antimony and of its oxides are, according to Bergman, in the following order : 685 Affinities.

Antimony.	Oxide of Antimony.
Iron,	Muriatic acid,
Copper,	Oxalic,
Tin,	Sulphuric,
Lead,	Nitric,
Nickel,	Tartaric,
Silver,	Saclactic,
Bismuth,	Phosphoric,
Zinc,	Citric,
Gold,	Succinic,
Platinum,	Fluoric,
Mercury,	Arsenic,
Arsenic,	Lactic,
Cobalt,	Acetic,
Sulphur.	Boracic,
	Prussic,
	Carbonic.

I. Salts of Antimony.

1. Sulphite of Antimony.

Sulphuric acid has no action on antimony in the cold. At a boiling temperature the acid is decomposed ; sulphurous acid gas is emitted with effervescence, and if distilled in a retort to dryness, sulphur is sublimed. There remains a white oxide of antimony. If this mass be washed with water, the acid which adheres to it is carried off, with a small portion of the oxide ; and what remains is the white oxide, which is insoluble. By adding a large quantity of water to the solution, the oxide which it had carried off is precipitated ; but this solution being evaporated yields no crystals. It is decomposed by the earths and the alkalies, which precipitate a white oxide. Sulphuric acid, therefore, oxidates antimony, but does not seem to have the property of forming a salt.

2. Sulphate of Antimony.

Sulphurous acid, with the assistance of heat, is decomposed by antimony. The metal is oxidated, and there is formed a sulphite of antimony. This salt may be also obtained by adding sulphurous acid to the solution of antimony in muriatic acid. A white precipitate appears, which is insoluble, of an acrid, bitter taste, and is decomposed by heat. When it is distilled in close vessels, it yields a little sulphurous acid, then sulphuric acid, and the residuum is a reddish brown mass, which is soluble in fixed alkali, and may be precipitated by means of muriatic acid, into a hydrosulphuret of antimony.

3. Nitrate of Antimony.

Nitric acid is rapidly decomposed by antimony, even in the cold. There is evolved a great quantity of nitrous gas, and sometimes the rapidity of the oxidation is such, that it is accompanied with actual combustion. The water also is partially decomposed. The antimony is converted into a white oxide. The hydrogen of the water combines with the azote of the acid, and forms ammonia, which combines with part of the nitric acid, and the compound is nitrate of ammonia. The small quantity of oxide of antimony which is dissolved in nitric acid, is precipitated by water, so that it adheres very slightly to the acid.

4. Muriate of Antimony.

Muriatic acid acts on antimony very feebly. By digesting the metal with the acid for a long time, it dissolves a small quantity, and the solution becomes of a yellowish colour. The white oxide is more soluble in this acid, and forms with it a colourless solution. The first solution yields crystals by evaporation, in the form of small needles, which are deliquescent, and sublimed by heat, and are precipitated and decomposed by water. The solution formed with the oxide is fixed in the fire, and crystallizes in brilliant plates. It is also decomposed by water. Muriatic acid dissolves more readily the sulphuret of antimony, for it does not require the aid of heat. There is disengaged a strong odour of sulphurated hydrogen gas. When the mixture is heated, the whole of the metal is dissolved.

Nitromuriatic acid dissolves antimony more readily than any of the acids which have been mentioned. This solution is colourless. The muriate of antimony which remains after the evaporation, by being distilled, comes over of a thicker consistence, in proportion as it is concentrated. The muriate of antimony was formerly called *butter of antimony*. It is of a grayish white colour, and sometimes crystallizes in four-sided prisms. It is deliquescent in the air, and extremely caustic and corrosive. When it is diluted with water, a white powder is precipitated, which is the *powder of algaroth*.

5. Fluate of Antimony.

6. Borate of Antimony.

Fluoric and boracic acids have no action on antimony, but combine with its oxide, or precipitate it from its solution in acids, in the form of white powder, forming a fluate or borate of antimony.

7. Phosphate of Antimony.

Phosphoric acid combines with the oxide of antimony. The solution, by evaporation, yields a blackish green mass.

8. Phosphate of Lime and Antimony.

This triple salt is formed by calcining together equal parts of sulphuret of antimony and the ashes of bones ; or, according to the process recommended by Mr Chenevix, by dissolving white oxide of antimony and phosphite of lime in equal parts in muriatic acid ; and then by adding this solution to a sufficient quantity of distilled water, which contains pure ammonia. A precipitate is formed in the state of white powder. This 1686 James's powder.

Antimony, &c.

This powder is nearly insoluble in water. It has been long known as a diaphoretic and emetic, under the name of *James's Powder*. According to the analysis of Dr Pearson, it is composed of

Phosphate of lime	43
Oxide of antimony	57
	100

9. Carbonate of Antimony.

Unknown.

10. Arseniate of Antimony.

By digesting together arsenic acid and antimony, a white powder is obtained, which is arseniate of antimony. Muriatic acid dissolves this powder, but it may be separated by adding water. This salt may be formed, also, by adding an alkaline arseniate to the solution of antimony in muriatic, tartaric, or acetic acids.

11. Molybdate of Antimony.

Muriate of antimony is precipitated by molybdic acid; and if the acid be not in excess, the precipitate is white.

12. Acetate of Antimony.

Acetic acid dissolves a small portion of the oxide of antimony, and according to some, yields small crystals. The acetate of antimony has been employed as an emetic.

13. Oxalate of Antimony.

Oxalic acid combines with the oxide of antimony, and the solution affords crystals in the form of small grains, which are scarcely soluble in water.

14. Tartrate of Antimony.

Tartaric acid also combines with a small portion of the oxide of antimony, and affords a salt which assumes the form of a jelly.

15. Tartrate of Potash and Antimony.

This triple salt was formerly prepared by boiling together the preparation of what was called crocus metallorum, and tartar, in water. But if the white oxide be mixed with its own weight of tartar, and the mixture boiled in 10 or 12 parts of water, till the tartar be saturated, and the solution filtered and evaporated, crystals are obtained, which are crystals of the tartrate of potash and antimony, which have been long and better known by the name of *tartar emetic*. This salt is of a white colour, and it crystallizes in regular tetrahedrons. It effloresces by exposure to the air, and is soluble in 80 parts of cold, and in half that quantity of water at the boiling temperature. When it is exposed to heat, it is decomposed. It is also decomposed by the alkalies and their carbonates.

1687 Tartar emetic.

According to the analysis of Thenard, this salt is composed of

Antimony	38
Acid	34
Potash	16
Water	8
	96, loss 4. *

This salt has been greatly employed as a diaphoretic and emetic, from which property it has derived its name. An account of the mode of preparing a similar powder, which, it is said, was invented by an earl of Warwick, and became famous in Italy as a powerful and effectual medicine, was published in Italy, in the year 1620. The preparation of tartar emetic itself was first published in 1631.

* Annal. Chim. xxxvii. p. 39.

16. Benzoate of Antimony.

Benzoic acid combines with the oxide of antimony, and, by evaporating the solution, crystals are obtained. This salt is not altered by exposure to the air, but it is readily decomposed by heat.

II. Action of Alkalies, &c. on Antimony.

1. All the alkalies have a peculiar action on the sulphuret of antimony. Sulphuret of antimony and potash form a preparation which is known by the name of *kermes mineral*, a name which it derives from the red animal called *kermes*. This is prepared in the dry way by mixing together one part of sulphuret of antimony and two of potash, and in proportion to the quantity of sulphuret, add a sixteenth part of sulphur. Fuse the mixture in a crucible, and pour it into an iron mortar. When it is cool, reduce it to powder, and boil it in water; filter the liquid, and as it cools, a reddish brown powder is deposited. Wash the precipitate, first with cold and then with boiling water, till it comes off insipid. It may be prepared in the humid way, by boiling 10 or 12 parts of pure liquid alkali with two of sulphuret of antimony, for half an hour, and then filtering the liquid; the kermes is deposited as it cools. 1688 Alkalies.

The compound which is first formed, is a hydrosulphuret of potash and antimony. When boiling water is added in sufficient quantity, the whole is dissolved, but the solution becomes turbid in cooling, and divides into two parts; the one, which is deposited in the form of a reddish brown powder, is the kermes mineral, and the other which remains in solution, containing a smaller proportion of sulphur and oxide of antimony than the former, has been distinguished by the name of *golden sulphur*. The cause of the separation is, that the alkali, if it is not in great quantity, cannot hold the sulphurated oxide of antimony in solution while it is cold. What remains in solution after the spontaneous precipitation, contains a greater proportion of sulphur, and less of the oxide of antimony. When an acid is added to this solution, another precipitate is formed, which is of an orange yellow colour, from the greater proportion of sulphur, and on this account has been called *golden sulphur*. Kermes mineral, or the hydrosulphuret of antimony, according to Thenard, contains the following proportions.

Brown

Brown oxide of antimony	72.760
Sulphurated hydrogen	20.298
Sulphur	4.156
Water and loss	2.786
	100.000

From the analysis of the same chemist, the golden sulphur, or *sulphur auratum*, is also a hydrosulphuret, having a greater proportion of sulphur, and a smaller proportion of the oxide. The component parts are the following:

Brown oxide of antimony	68.300
Sulphurated hydrogen	17.877
Sulphur	12.000
	98.177*

2. The oxide of antimony has the property of combining with some of the earths during their vitrification, and communicating to them different shades of colour, more or less yellow and orange.

3. Most of the salts have a peculiar action on antimony or its sulphuret. By fusing in a crucible two parts of sulphuret of potash and one of antimony, the metal disappears, and a vitreous mass of a yellow colour is formed, which has a caustic property. Dissolved in hot water, it affords, on cooling, a hydrosulphuret of antimony. The antimony has carried off the oxygen of the acid, and combined in the state of oxide, with the sulphuret of potash, which is formed by the sulphur of the acid uniting with the potash during the process.

The nitrates have a powerful action on antimony and its sulphuret. A mixture of two or three parts of nitrate of potash and one of antimony in fine powder, well rubbed together in a mortar, produces a lively detonation, by throwing it on burning coals, or projecting it into a red-hot crucible, or heating it to redness in a close vessel. This detonation is accompanied with a bright white flame: and the antimony is strongly oxidated by the oxygen of the nitre, which is decomposed, and reduced to its alkaline base. The residuum of this detonation is a white scorified mass, which being washed with water, leaves a portion of the oxide of antimony united to a small quantity of potash, and affords, besides, another compound, with more of the alkali. The white matter which is first deposited, has been called *washed diaphoretic antimony*. The water which remains holds in solution a portion of metallic oxide, united to the potash of the nitre. The oxide in this case performs the part of an acid. This compound has been found susceptible of crystallization. It is decomposed by acids, and the precipitate from it, which is an oxide of antimony, has been distinguished by the names of *ceruse of antimony*, *magistery of diaphoretic antimony*, and *pearly matter of Kerkringius*.

When equal parts of nitre and sulphuret of antimony are treated in the same way, a vitrified mass is obtained, similar to what has been already described by the name of *liver of antimony*.

III. Alloys.

Antimony enters into combination with the metals, and forms alloys with them, some of which are of considerable importance. But the alloys of antimony, with the metals already described, are either little known, or have been applied to no use. The alloys of cobalt and nickel, with antimony, have not been examined. With manganese antimony forms but an imperfect alloy, and the compound of antimony and bismuth is very brittle.

Besides the various preparations of antimony used in medicine, which are now comparatively but few in number, it is much employed in many arts. In the metallic state it is of the greatest importance as an alloy with other metals which will be afterwards mentioned. In the state of oxide, it is much used in the fabrication of coloured glass, and of enamels for pottery and porcelain: particularly in forming different shades of brown, orange, and yellow colours. The oxide is mixed with different other metallic oxides, to produce various shades of colour. 1691 Uses of antimony.

Sect. XIV. *Of Tellurium and its Combinations.*

1. In the year 1782, Muller of Richenstein, in examining a gold ore, distinguished by the names of *aurum paradoxum* and *aurum problematicum*, conjectured that it contained a peculiar metal. Bergman, to whom this mineralogist had sent a specimen of the mineral, could not, from the small quantity which he had received, ascertain whether it was really a new metal, or merely antimony, with which it possesses some common properties. He inclined, however, to the former opinion. This mineral was analyzed by Klaproth in the end of the year 1797, the account of which was published in 1798. By this analysis the conjecture of Muller was verified, and to the new metal Klaproth gave the name of *tellurium*. 1692 History.

2. This metal has been found in four different minerals. First, In that in which Klaproth first detected it, which is called *white gold ore*, a mineral found in the mountains of Fatzbay in Transylvania. In this mineral the tellurium is combined with iron and gold. The second is what is called *graphic gold ore*, which is composed of tellurium, gold, and silver. The third is known by the name of *yellow gold ore of Nagyag*. This mineral contains, besides tellurium, gold, silver, and a little sulphur. The fourth is a variety of the last, and is denominated *gray gold ore*. Besides the metals in the former, it contains a little copper. To obtain the metal from the ore, a quantity of it is slightly heated with six parts of muriatic acid, and having added three parts of nitric acid, it is then boiled. A considerable effervescence takes place, and the whole is dissolved. The solution being diluted with distilled water, is mixed with a solution of caustic potash, to dissolve the precipitate; and there remains only a brown, flaky matter, formed of the oxides of gold and iron. The alkaline solution of the oxide of tellurium is mixed with muriatic acid, to saturate the potash, and there is deposited a copious, very heavy, white powder. By forming this powder into a paste with oil, and heating it to

Tellurium, &c.

to redness in a small glass retort, the metal is obtained, partly fused and crystallized at the bottom of the retort, and partly sublimed at the upper part.

1693 Properties. 3. Tellurium is of a white colour, somewhat resembling lead, and has a considerable lustre. It is very brittle, and may be easily reduced to powder. It has a lamellated texture, similar to antimony. By slow cooling it assumes a crystalline form, especially on the surface. Its specific gravity is 6.115. It is one of the most fusible of the metals, and when heated in close vessels it boils readily, and is sublimed in the form of brilliant globules, which adhere to the upper part of the vessels.

1694 Action of heat. 4. When tellurium is heated by the action of the blow-pipe on charcoal, it burns, after being melted, with a lively flame, of a blue colour, and green at the edges. It is entirely volatilized in the form of a grayish white smoke, diffusing a fetid odour, which Klaproth compares to that of radishes.

The oxide of tellurium is very fusible. By heating it in a retort, a yellow, straw-coloured mass is obtained, which assumes a radiated texture on cooling. When the oxide is heated on charcoal, and surrounded with it, it is so rapidly reduced, that it is accompanied with a kind of explosion.

1695 Sulphuret. 5. Tellurium enters into combination with sulphur, and forms with it a sulphuret. This sulphuret is of a grayish colour, of a radiated structure, and is easily crystallized.

I. Salts of Tellurium.

1. Sulphate of Tellurium.

One part of tellurium mixed in the cold, in a close vessel, with 100 parts of concentrated sulphuric acid, communicates to it a beautiful crimson colour. By adding water drop by drop to this solution, the colour vanishes, and the metal is deposited in the form of black flakes. When the solution is heated, the colour also disappears, and the oxide of tellurium is gradually precipitated in the state of white powder; but when diluted sulphuric acid is employed, with the addition of a small quantity of nitric acid, a larger portion of tellurium is dissolved. The solution is transparent and colourless, and is not decomposed by adding water.

2. Nitrate of Tellurium.

Nitric acid readily dissolves tellurium, and forms a transparent, colourless solution, which being concentrated, spontaneously affords small, light, white, needle-shaped crystals, disposed in a dendritical form.

3. Muriate of Tellurium.

Nitromuriatic acid very readily dissolves tellurium, which is precipitated by adding a considerable quantity of water in the form of oxide. This is a white powder, which is soluble in muriatic acid.

The infusion of nut-galls added to solutions of tellurium in acids, occasions a flaky precipitate, which is of a yellow colour.

II. Action of Alkalies and Earths.

1696 Alkalies and earths. 1. All the pure alkalies precipitate the solutions of tellurium in acids, in the form of white oxide. With an excess of alkali the precipitate is redissolved. With the alkaline carbonates a precipitate is obtained, which is much less soluble in excess of alkali.

2. The alkaline sulphurets added to solutions of tellurium in acids, produce a brown or black precipitate, as the metal is more or less oxidated. This precipitate sometimes resembles the hydrosulphurets of antimony. The hydrosulphuret of tellurium thus formed, exposed to heat on burning coals, burns with a small blue flame, and is volatilized in white smoke. No precipitate is formed by the prussiate of potash.

3. The action of the oxide of tellurium with the earths is not known; but from its great fusibility, it has been supposed that it is susceptible of forming a vitreous matter with the earths, and communicating to them a straw colour.

III. Action of metals.

The alloys of tellurium are unknown.

Tellurium is separated from its solutions in acids, by zinc and iron, in the form of small, black flakes, which may be reduced to the metallic state on burning charcoal, or even by simple friction. Antimony causes a similar precipitation in a solution of nitrate and sulphate of tellurium. Tin produces a similar effect. 1697 Precipitated by zinc and iron

Tellurium has hitherto been found in such small quantity, that it has not yet been applied to any use. Were it found in abundance, it has been supposed, from its easy fusibility, that it might be of considerable importance in some of the arts. 1698 Uses.

Sect. XV. *Of Selenium.*

This metal is contained in minute quantity in the pyrites of Fahlun in Sweden, and was discovered in consequence of the attention of Berzelius being directed to a red precipitate, which appeared in the manufacture of sulphuric acid from the sulphur of that mineral. From the odour of this substance, he conjectured it at first to contain tellurium, but found it to be a new metal, which, from its analogies to tellurium, he named from the moon *selenium*. It has a gray colour, and a brilliant metallic lustre. It becomes soft at 212, and fuses a few degrees higher. When cooling, it shews great ductility, admitting of being kneaded between the fingers, and drawn out into fine threads. When cold, it shows a granulated fracture, or rather crystalline or radiant, like that of a piece of sulphur. It gives a fine blue tinge to the flame of the blow-pipe, and exhales a smell of horse radish, so strong, that $\frac{1}{50}$ of a grain is sufficient to give a complete impregnation to the air of a large apartment. It combines with most of the metals, often with ignition. With the fixed alkalies it forms compounds of a cinnabar red colour. In fixed oils it forms red-coloured solutions. The nitric acid, in acting on this metal, oxidizes it to such a degree, that the compound is found to possess the qualities of an acid, and has been so considered, under the name of the *selenic*. 1699 History and properties.

Sect. XVI. *Of Mercury and its Combinations.*

1. Mercury appears to have been known from the earliest ages. By comparing its properties with silver, and being in the fluid state, it has been called *quicksilver*. Mercury was long the subject of the researches of 1700 History.

of the alchemists, with the view of discovering the method of transmuting it into gold or silver. It was supposed to approach so near to these metals, particularly to the latter, in its nature, that all that was wanted for this transmutation, was to fix it, or bring it to the solid state. In consequence of the numerous experiments to which it was subjected, and the great variety of forms it assumed, they regarded it as the principle of all other bodies, and one of the elements of nature. It was supposed to exist in all metals, and also to form one of the component parts of many bodies. Hence, according to this theory, there were two kinds of mercury; the one the principle of a great number of bodies, and the other common mercury, or the metal known by that name. Hence, according to Beccher, it was called *the mercurial principle*, or *the mercurial earth*. But however extravagant the researches of the alchemists may now be considered to have been, it is to their labours that chemistry is indebted for the knowledge of many important properties and combinations of this metal.

701 2. Mercury is found in four different states. In the metallic state, alloyed with other metals, combined with sulphur, and with muriatic acid. 1. Native or virgin mercury is found in the cavities or clefts of rocks, in strata of clay, or of chalk, in the form of liquid globules, which are easily distinguished by their brilliancy. 2. It is found more frequently alloyed with other metals, or, as it is called when mercury is combined with a metal, *amalgamated*, and most frequently with silver. 3. A frequent ore of mercury is the red sulphuret, which is known by the name of *cinnabar*. The sulphuret of mercury is of various colours, from vermilion red to brown. Sometimes it effloresces on the surface of the ore, when it is called *flowers of cinnabar*, or *native vermilion*. 4. The fourth ore of this metal is the muriate. This salt is white and brilliant, and of a lamellated structure.

702 ysis. 3. Native mercury is frequently alloyed with other metals; it is therefore of importance to be able to ascertain the proportions. For this purpose it is to be dissolved in nitric acid. If it contain gold, this metal remains in a state of powder at the bottom of the vessel. If alloyed with bismuth, it may be precipitated with water, which does not separate the oxide of mercury. Silver is detected by precipitating the solution by means of muriate of soda. The muriate of silver and the muriate of mercury fall down together; but the latter being more soluble in water than the former, may be easily separated.

The sulphuret of mercury may be decomposed by boiling it with eight times its weight, of a mixture of three parts of nitric, and one of muriatic acid; the metallic part is dissolved, and the sulphur remains in the state of powder.

703 iscover rity. It may be known whether mercury has been adulterated with other metals, by its dull and less brilliant lustre, and by its soiling the hands, or white bodies on which it is rubbed, and by its dividing with more difficulty into round globules, which appear flat and uneven, adhere to the vessels in which they are agitated, and when poured along a smooth surface, by their *dragging* a tail. Mercury is also impure, when the globules do not readily run together, and when it is agitated with water, separating from it a black powder.

To procure mercury in a state of purity, or to revive it, as it is called, two parts of cinnabar and one of filings of iron are well triturated together, and distilled in an iron retort, introducing the beak of the retort into a receiver, with water. The iron has a greater affinity for the oxygen and the sulphur of the mercury than the latter. The mercury, therefore, rises in vapour, and is condensed by the water. There remains in the retort a sulphuret of iron, in which the metal is a little oxidated. The mercury thus obtained, being dried, and passed through a skin, is very pure and brilliant. 1704 Purification.

4. Mercury is of a white colour, is one of the most brilliant of the metals, and when its surface is clean and not tarnished, makes a good mirror. Next to gold, platinum, and tungsten, it is the heaviest of the metals; its specific gravity is 13.568. It has no perceptible taste or smell. 1705 Properties.

5. At the ordinary temperature of the atmosphere mercury is always in the liquid state; but when it is exposed to a degree of cold equal to —39° it becomes solid. This was first discovered in the year 1759 by the academicians of Petersburgh. Similar experiments have since been frequently repeated. In 1772, Pallas succeeded in the congelation of mercury at Krasnojark, by a natural cold equal to —$55\frac{1}{2}$° Fahrenheit. Mercury was also congealed by a natural cold in 1775 at Hudson's bay. The freezing of mercury is now a common experiment by means of artificial cold, and the method of producing this has been already described, in treating of freezing mixtures. In some experiments which have been made on the congelation of mercury, it was remarked, that a slight shock was communicated to the person who held the tube containing the metal, by its sudden contraction at the moment it became solid. Mercury crystallizes in very small octahedrons. It appears to be malleable, for by striking it with a hammer in the solid state, it was flattened and extended.

6. At the temperature of 660° mercury boils, and is then converted into vapour. This vapour, like common air, is invisible and elastic. When mercury is exposed to the air, the surface becomes tarnished, and is covered with a black powder. This change is owing to the absorption of the oxygen of the air, and the conversion of the mercury into an oxide. This process is greatly promoted by applying heat to the mercury, or by shaking it, so that it may be brought in contact with the air. To this black powder, which is the first degree of the oxidation of the metal, the name of *ethiops per se* was formerly given, because it is obtained without the assistance of any other substance. According to Fourcroy, this oxide contains 1706 Action of heat. 1707 Oxides. 1708 Black.

Mercury	96
Oxygen	4
	100

By a strong heat the oxygen is driven off, and the mercury is reduced to the metallic state: but when the oxide is exposed to a more moderate degree of heat, it combines with more oxygen, and is converted into the red oxide, so called from its colour. This oxide may also be obtained, by exposing a quantity of mercury for some length of time in a vessel provided 1709 Red.

with a long narrow neck, by which means the vapours of the mercury are prevented from escaping, while the air is admitted. By this process the mercury is also converted into the red oxide; and, obtained in this way, it was formerly called *precipitate per se*, or *red precipitate*. This oxide may also be obtained by dissolving mercury in nitric acid, evaporating to dryness, and exposing the mass to a very strong heat, to drive off the acid. What remains being reduced to powder, is the red oxide of mercury, or red precipitate. This oxide, according to Fourcroy, contains one-tenth of its weight of oxygen. It is of an acrid disagreeable taste, and has so powerful an effect upon animal matters, that it may be considered as a poison. It corrodes the skin with which it comes in contact. When this oxide is exposed to heat, it is decomposed; part of its oxygen is given out, and it is converted into the black oxide. Even by exposure to the light of the sun, this change is effected, as it passes through different shades of colour.

1710 Action of hydrogen.

7. Mercury does not enter into combination with azote, hydrogen, or carbon; but if hydrogen gas be kept in contact with the red oxide, it is gradually converted into the black oxide. If hydrogen gas be made to pass through a tube heated to redness, containing red oxide of mercury, a detonation takes place. The oxygen and hydrogen combine together to form water, while the mercury is reduced to the metallic state. This oxide may be also reduced by means of charcoal, with the assistance of heat. The oxygen of the oxide combines with carbon, and forms carbonic acid, and the mercury is revived.

1711 Phosphuret.

8. Phosphorus combines with mercury with difficulty. Pelletier took equal parts of phosphorus and red oxide of mercury, and introduced them into a matrass, to which he added a little water, to cover the mixture. It was exposed to the heat of a sand bath, and agitated from time to time. The oxide soon became black, and united to the phosphorus. The water retained phosphoric acid; so that it appears to be a compound of phosphorus and the black oxide of mercury. The phosphuret of mercury, thus formed, becomes soft in boiling water, and acquires some consistence in the cold. When it is heated, it is decomposed. The phosphorus and the mercury are separately emitted. Exposed to a dry air, it diffuses white vapours, which have the odour of phosphorus.

1712 Sulphuret.

9. Mercury combines readily with sulphur, either by simple trituration in the cold, or by the action of heat. One part of mercury and two of sulphur, triturated together in a mortar, the mercury soon disappearing, form a black powder, which was formerly distinguished by the name of *ethiops mineral*. Fourcroy is of opinion, that in this process the mercury is oxidated, and the sulphur is combined with the black oxide; in support of which, he states that the sulphur cannot be separated from the mercury, but by some chemical action. Berthollet supposes that this substance contains sulphurated hydrogen; and hence it is concluded that *ethiops mineral* is a hydrogenous sulphuret of mercury, composed of mercury, sulphur, and sulphurated hydrogen.

When this compound is heated in an open vessel, the sulphur, which is in a state of minute division, takes fire, and is soon reduced to sulphurous acid gas. The mercury is at the same time more strongly oxidated; is converted to a deep violet-coloured powder; and if in this state it be heated in a matrass, it is sublimed in the form of a deep red cake, of a brilliant, crystalline appearance. This substance was formerly called *artificial cinnabar*, or, in the present language of chemistry, *red sulphurated oxide of mercury*. Various processes have been given for the preparation of this substance. Seven parts of mercury squeezed through leather to purify it, are to be fused with one part of sulphur in an earthen vessel, agitating the mixture till it is completely reduced to the black sulphurated oxide. Introduce this into a matrass, placed in a crucible furnished with sand, and expose it gradually to the heat of a furnace, which is to be increased till the matter is sublimed, and collected, at the top of the vessel. It is then removed, and when the vessel is broken, a red mass is obtained, with a degree of beauty and brilliancy in proportion to the temperature which has been employed, and the small quantity of sulphur which it retains. Fourcroy considers this as a compound of sulphur and the red oxide of mercury: but according to Proust, it is a sulphuret of mercury; that is, a compound of sulphur and metallic mercury. Its component parts are, 171 Cinnaba

Mercury	85
Sulphur	15
	100

This sulphuret is of a fine scarlet colour. It is not altered by exposure to the air, and is insoluble in water. The specific gravity is 10. When a sufficient degree of heat is applied to it, it takes fire, and burns with a blue flame. When reduced to powder, it is then called vermilion, which is well known as a paint. 171 Proper 171 Vermil

10. The order of the affinities of mercury is the following: 171 Affiniti

Mercury.	Oxide of Mercury.

Iron.	Nitric,
	Fluoric,
	Acetic,
	Boracic,
	Prussic,
	Carbonic.

I. Salts of Mercury.

1. Sulphate of Mercury.

1. Sulphuric acid forms salts with the different oxides of mercury, and with different proportions of these oxides, so that there is a considerable variety of the 17 Differ sulph

rcury, &c. the sulphates of mercury. This seems to depend on the nature of the action between sulphuric acid and mercury, according to the temperature in which the combination is made, and the quantity of acid employed.

2. Sulphuric acid has no effect on mercury in the cold; but if two parts of mercury and three of sulphuric acid be introduced into a retort, and exposed

718 ara- to heat, an effervescence takes place, with the evolution of sulphurous acid gas. If the process be stopped, when the mercury is converted into a white mass, and there yet remains part of the liquid, it is found to be acrid and corrosive, and it reddens vegetable blues. This is the sulphate of mercury with excess of acid. This acidulous sulphate of mercury contains very different proportions of sulphuric acid, according to the original quantity employed. If this sulphate be washed with a smaller quantity of water than is necessary for its complete solution, and if this be repeated till the water no longer changes vegetable blues, there remains a white salt without acidity, and which is much less acrid and corrosive than the saline mass from which it is obtained. This may be considered as a neutral sulphate of mercury.

719 erties. 3. It is of a white colour, crystallizes in plates, and in fine, needle-shaped prisms. The taste is not acrid. It is soluble in 500 parts of cold water, and in one half that quantity of boiling water. When crystallized, it is composed of

Mercury	75
Oxygen	8
Sulphuric acid	12
Water	5
	100

It is soluble both in cold and hot water, without being decomposed. The pure alkalies and lime water occasion a precipitate of a grayish-black powder. When sulphuric acid is added, it is then reduced to the state of acidulous sulphate, and its solubility increases in proportion to the additional quantity of acid. A twelfth part of acid renders it soluble in 157 parts of cold water, and in 33 of boiling water. But if $\frac{1}{4}$ of this quantity of cold water be added, it combines with the whole excess of acid, and forming a liquid of greater density than when it is diluted with 157 parts of water necessary for its complete solution, it dissolves much more of the sulphate of mercury, and brings the salt to a state of greater acidity. It then requires 500 parts of water for its solution.

720 ferent by con- ng the 4. But if the same proportions of sulphuric acid and mercury, namely, three parts of acid, and two of mercury, be exposed for a longer time to the action of heat, a greater proportion of sulphuric acid is decomposed, and the mercury combines with a greater proportion of oxygen. The salt thus obtained, possesses different properties from the former. It crystallizes in small prisms, and when it is neutralized, it is of a dirty-white colour; but if it be obtained in the dry state, it is pure white, and in this state it is combined with an excess of acid. It is then deliquescent in the air; but, in the neutral state, it undergoes no change. When hot water is added to this salt, it is converted into a yellow powder, which has been long distinguished by the name of *turpeth mineral*. Mercury, &c.

5. It was formerly supposed that turpeth mineral, which is obtained by the addition of warm water to this salt, was a simple oxide of mercury, without any portion of sulphuric acid. Fourcroy mentions, that Rouelle first conjectured, that it was combined with a certain portion of the acid, and that his experiments have verified and confirmed this conjecture; for in treating turpeth mineral, after being well washed with muriatic acid, this solution precipitates by means of muriate of barytes, a sulphate of barytes from this base. Fourcroy denominates this salt *sulphate of mercury with excess of acid*, or *yellow sulphate of mercury*. It is soluble in 600 parts of boiling water; but another sulphate of mercury remains in the solution. This contains an excess of acid, and is therefore more soluble in water.

6. From a series of experiments which Fourcroy made on this subject, he concludes, that there are three distinct sulphates of mercury. 1721 Three sulphates. 1. The first is the neutral sulphate of mercury, which crystallizes, is soluble in 500 parts of cold water, and forms a copious precipitate with the alkalies, which is not decomposed by nitric acid, but forms a mild muriate of mercury with the addition of muriatic acid. 2. The acidulous sulphate of mercury, which is more soluble than the former, is precipitated of an orange colour by means of the alkalies. 1722 Acidulous sulphate. The excess of acid is removed, and also a portion of the salt, with $\frac{1}{4}$ of the water necessary for its complete solution. The neutral sulphate of mercury remains behind, and is not decomposed by means of nitric acid. 3. The third sulphate of mercury contains an excess of base, or of the oxide of mercury. 1723 Subsulphate. It is of a yellow colour, soluble in 200 parts of water, and is precipitated of a gray colour by the alkalies. It is decomposed by nitric acid; and muriatic acid converts it into a hyperoxymuriate of mercury.

2. Sulphate of Ammonia and Mercury.

This triple salt is formed by adding ammonia to a solution of neutral sulphate of mercury. 1724 Preparation. A copious gray precipitate is thrown down, which, being exposed to the light of the sun, is partly reduced to the metallic state, and partly to that of a gray powder. This last is the sulphate of ammonia and mercury. It is soluble in ammonia; and by evaporation, brilliant polygonal crystals are formed. Or, if a large quantity of water be added to the solution, it becomes white and milky, and there is precipitated the same salt, but without any regular form. This salt has a pungent, austere taste. 1725 Properties. When it is heated, it gives out ammonia, azotic gas, a small quantity of metallic mercury, and a little sulphite of ammonia. There remains in the retort yellow sulphate of mercury. According to the analysis of Fourcroy, this triple salt is composed of 1726 Composition.

Sulphuric acid	18
Mercury	39
Ammonia	33
Water	10
	100

Mercury, &c.

3. Nitrate of Mercury.

1727 Preparation.

1. Nitric acid is rapidly decomposed by mercury. It is accompanied with effervescence, and the evolution of nitrous gas. The mercury combines with part of the oxygen of the acid; it is thus oxidated, and is then dissolved in the remaining portion of the acid. This solution of mercury in nitric acid, when it is made in the cold, is colourless, very heavy, and so extremely caustic, that it has been employed as an escharotic, under the name of *mercurial water*. It produces an indelible brownish black spot on all animal and vegetable substances. By spontaneous evaporation it affords regular transparent crystals, composed of two four-sided pyramids, truncated near their bases, and on the four angles which result from the union of the pyramids. But different crystals are formed, according to the nature of the solution, and the evaporation, whether it has been more slowly or more rapidly conducted. When this solution of mercury in nitric acid is made in the cold, the compound formed is a nitrate of mercury without excess of the oxide or base; but if mercury be added to this solution, and the action be aided by heat, a new portion of the oxide is dissolved. It is then a nitrate of mercury with excess of base. Fourcroy distinguishes three nitrates of mer-
1728 Three nitrates. cury. 1. Nitrate of mercury neutralized. From this regular crystals are obtained, and it is not precipitated by water. 2. The acidulous nitrate of mercury, or with excess of acid. This is obtained by dissolving the first in water containing nitric acid, or by adding this acid to the other nitrates. 3. The nitrate of mercury with excess of oxide. This exists in the solution precipitated by water, or by exposing the other nitrates to the action of heat. In this way is produced what was formerly called *nitrous turpeth*.

2. These different nitrates of mercury possess many common properties, but are sufficiently distinguished by others, and particularly by their decomposition. When the nitrate of mercury is placed upon burning coals, it detonates feebly, although with a vivid white flame, when it has been sufficiently dried; but when it is moist it melts, blackens, extinguishes that part of the coal which it touches, and throws out small red sparks, with a slight decrepitation about the dried edges of the mass. The nitrate of mercury with excess of oxide possesses a still more feeble detonating property. The nitrate of mercury with excess of acid boils up, melts very rapidly, swells greatly, and exhales red vapours, with very little detonation. If the nitrate of mercury, neutralized, be heated in a crucible without any combustible matter, it melts, exhales nitrous gas, becomes of a deep yellow colour, then passes to an orange, and at last is converted into a deep red. In this state it was formerly called *red precipitate*. It is the red oxide of mercury, which is obtained by the decomposition of the nitrate.

3. The pure nitrate of mercury exposed to the air in the state of crystals, is soon changed. It gradually absorbs oxygen from the atmosphere, and passes from a white to a yellow colour. This is the *nitrous turpeth*. It is a yellow oxide of mercury combined with a small portion of nitric acid, or a nitrate of mercury with excess of base. The yellow colour becomes deeper with the addition of boiling water. The nitrous turpeth, it has been observed, contains a greater quantity of oxygen than that which is prepared by sulphuric acid, and from this circumstance it is more readily converted into red oxide by the action of heat.

4. The nitrate of mercury is decomposed by all the alkalies, but with different phenomena, according to the state of the combination, and particularly the degree of oxidation of the base. Bergman has distinguished the two solutions of mercury, that which is not precipitated by water, from that which is precipitated by the different products which are obtained by means of alkalies. The nitrate of mercury affords, with potash, a yellowish white oxide; with carbonate of potash, a white oxide; and with ammonia, an oxide of a dark gray colour. Sulphuric acid and the sulphates occasion a precipitate in form of a white powder. Muriatic acid and the muriates give a thick mass resembling curd. But the solution which is precipitated by water, and which is more acrid, and less disposed to crystallize, affords precipitates by means of the fixed alkalies, of a deeper yellow or brown colour. By means of ammonia, a white precipitate is formed; by means of the sulphuric acid and the sulphates, a yellow precipitate, and by the muriatic acid, a more copious, curdled matter. Fourcroy has observed in the decomposition of nitrate of mercury with excess of acid, that a precipitate in the state of black powder is formed, with a great addition of the alkali; but if it be added in small quantity, the precipitate is white or gray. A copious precipitate is obtained, from the clear supernatant solution, by diluting it with water. The same white precipitate is obtained, by mixing together nitrate of mercury and nitrate of ammonia. By evaporating the liquid, which is rendered turbid by the addition of water, six-sided prismatic crystals are deposited, as the ammonia is volatilized. The white precipitate is a brittle salt, which has very little solubility, having an excess of oxide, of mercury, and ammonia. The component parts of this salt, according to Fourcroy are, 1730 Composition.

1731 Howard's fulminating powder.

5. From a solution of mercury in nitric acid, Mr Howard prepared a fulminating powder possessed of peculiar properties; the process which he found to answer best is the following:

1732 Preparation.

"One hundred grains, or a greater proportional quantity, of quicksilver (not exceeding 500 grains) are to be dissolved with heat, in a measured ounce and a half of nitric acid. This solution being poured cold upon two measured ounces of alcohol, previously introduced into any convenient glass vessel, a moderate heat is to be applied until an effervescence is excited. A white fume then begins to undulate on the surface of the liquor; and the powder will be gradually precipitated upon the cessation of action and re-action. The precipitate is to be immediately collected on a filter, well washed with distilled water, and carefully dried in a heat not much exceeding that of a water bath. The immediate

Mercury, &c. immediate edulcoration of the powder is material, because it is liable to the re-action of the nitric acid; and, whilst any of that acid adheres to it, it is very subject to the influence of light. Let it also be cautiously remembered, that the mercurial solution is to be poured upon the alcohol.

"I have recommended quicksilver to be used in preference to an oxide, because it seems to answer equally, and is less expensive; otherwise, not only the pure red oxide, but the red nitrous oxide and turpeth may be substituted; neither does it seem essential to attend to the precise specific gravity of the acid or the alcohol. The rectified spirit of wine and the nitrous acid of commerce never failed, with me, to produce a fulminating mercury. It is indeed true, that the powder prepared without attention, is produced in different quantities, varies in colour, and probably in strength. From analogy, I am disposed to think the whitest is the strongest; for it is well known, that black precipitates of mercury approach the nearest to the metallic state. The variation in quantity is remarkable; the smallest quantity I ever obtained from 100 grains of quicksilver being 120 grains, and the largest 132 grains. Much depends on very minute circumstances. The greatest product seems to be obtained, when a vessel is used which condenses and causes most ether to return into the mother liquor; besides which, care is to be had in applying the requisite heat, that a speedy and not a violent action be effected. One hundred grains of an oxide are not so productive as 100 grains of quicksilver.

33 Properties. This powder, struck on an anvil with a hammer, explodes with a stunning disagreeable noise, and with such force, as to indent both the hammer and the anvil. Half a grain or a grain, if quite dry, is as much as ought to be used on such an occasion. The shock of an electric battery, sent through five or six

34 Decomposition. grains, produces a very similar effect. The powder explodes at the 368th degree of Fahrenheit's thermometer. A quantity of it, sufficient to discharge a bullet from a gun, with a greater force than an ordinary charge of gunpowder, always bursts the piece. Ten grains of the powder, exploded in a glass globe, produce only four cubic inches of air, consisting of carbonic acid gas and nitrogene, or azotic gas.

This powder is decomposed by sulphuric, nitric, and muriatic acids. When concentrated sulphuric acid is poured upon it, an immediate explosion takes place. According to the experiments of Mr Howard,

35 Composition. this powder consists of oxalate of mercury, and nitrous etherised gas. But it appears that the nature of the component parts varies with the different modes which are followed in its preparation. When it is prepared with little heat, it consists of nitric acid, oxide of mercury, and a peculiar vegetable substance; but by continuing the heat during the fermentation, a greenish colour is communicated to the powder. It is then found to be composed of ammonia, oxide of mercury, and a greater proportion of the vegetable matter. Its detonating power is more feeble, and it gives out a blue flame when placed on hot coals. By boiling the mixture for half an hour, it is composed of oxalate of mercury, and a small proportion of vegetable matter; does not detonate, but decrepitates when it is heated *.

4. Muriate of Mercury.

1. Muriatic acid has no action whatever on mercury; but it combines readily with its oxides, and forms salts which have been the subject of research among chemists, almost in every age. The muriates of mercury were known to the Arabians in the 10th and 11th centuries. They were the first objects of study and examination with the alchemists, in their search after the philosophers stone; and since chemistry assumed the form of a science, they have greatly occupied the attention of philosophers, in discovering their nature and properties. 1736 This compound long known.

2. There are two compounds of muriatic acid and the oxides of mercury, which possess very different properties, according to the degree of oxidation of the mercury. According to the views already mentioned, relative to the simple nature of chlorine, this substance is, when dry, considered as a compound of chlorine and mercury, with a double proportion of the former, and is therefore called a bi-chloride. The other is considered as a chloride. 1737 Two muriates.

3. Muriatic acid precipitates the oxides of mercury from their solutions in sulphuric and nitric acids. If muriatic acid be added to the yellow sulphate of mercury, or to the nitrate of mercury which is precipitable by water, a muriate of mercury is obtained, which is soluble in water, and which, on account of its properties, was formerly called *corrosive sublimate*, or *corrosive muriate of mercury*. But if muriatic acid be added to the acidulous sulphate of mercury, or to the nitrate of mercury which affords no precipitate with water, a white, insoluble, insipid precipitate is obtained, which was formerly called *sweet mercury* or *calomel*, and is now known by the name of *submuriate*, and sometimes *sweet muriate of mercury*. 1738 Preparation.

4. The muriate of mercury, or corrosive sublimate, may be prepared by the following process. Boil two parts of mercury with two and a half of sulphuric acid in a matrass, with the heat of a sand bath, to dryness. Let this dry mass be mixed with four parts of dried muriate of soda, and let the whole be sublimed in a glass vessel, by gradually increasing the heat. In the first part of this process, part of the sulphuric acid is decomposed; the mercury combines with the oxygen, and forms an oxide, which is dissolved in the undecomposed part of the sulphuric acid, and a sulphate of mercury is thus obtained. The muriate of soda being mixed with this salt, produces another decomposition. The muriatic acid combines with the mercury, forming the muriate of mercury, which is sublimed; and the sulphuric acid of the sulphate of mercury combines with the soda, forming a sulphate of soda, which remains behind. 1739 Of the muriate.

5. The muriate of mercury, thus obtained, forms a beautiful white, semitransparent mass, which is found to be composed of small prismatic crystals in the form of needles. It may be obtained by evaporation, in the form of cubes or rhomboidal prisms, or four-sided prisms, having the alternate sides narrower, and terminated by two-sided summits. The taste is extremely acrid and caustic, and the metallic impression remains long on the tongue. The specific gravity is 5.1398. It is soluble in 20 parts of cold water, and in less weight of 1740 Properties.

* [illegible]

Mercury, &c.

of boiling water. This salt is not altered by exposure to the air; and, when it is sublimed by heat, it remains unchanged. It is soluble in sulphuric, nitric, and muriatic acids, and, when these solutions are evaporated, the muriate of mercury is obtained unaltered. It is precipitated by all the alkalies and earths, of an orange-yellow colour, which gradually changes to a brick-red. The carbonates of the fixed alkalies afford a permanent yellow colour. Ammonia forms with it a triple salt. The component parts of this salt, according to Mr Chenevix, are,

1741 Composition.

Oxide of mercury	82
Acid	18
	100

Muriate of mercury is one of the most violent poisons known. When taken internally, it produces nausea and vomiting, with severe pain, and, in a short time, corrodes the stomach and bowels. Externally, it is employed as an escharotic for destroying fungous flesh. It sublimes readily when heated, and is extremely injurious in the state of vapour, to those who breathe it.

1742 Preparation.

Submuriate, or *Chloride of Mercury*.—This salt is prepared by triturating together in a glass mortar, four parts of muriate of mercury or corrosive sublimate, with three of mercury, till the latter disappear. When this is formed into an uniform mass, it is put into a matrass, of which it should fill $\frac{1}{3}$, and it is to be sublimed with the heat of a sand bath. When the process is finished, the phial is broken; and the white matter at the upper part of the vessel, and the red matter at the bottom, are to be separated, and the remaining part of the mass is to be sublimed, and afterwards reduced to a fine powder, which is to be well washed with boiling water.

In this process, it is obvious, that the mercury which is added, combines with part of the oxygen of the oxide of mercury, formerly combined with the muriatic acid; and the whole of the oxide of mercury having now a smaller proportion of oxygen, is combined with a smaller proportion of muriatic acid. This will appear from the proportions of its component parts, as they have been ascertained by Mr Chenevix.

1743 Composition.

Oxide of mercury in calomel contains,

Mercury	89.3
Oxygen	10.7
	100.0

Calomel composed of

Oxide of mercury	88.5
Muriatic acid	11.5
	100.0

1744 Properties.

Submuriate of mercury, or calomel, is generally in the form of a white, solid mass; but it is susceptible of crystallization in four-sided prisms, terminated by pyramids. It has scarcely any taste, has no poisonous property, and is very little soluble in water. The specific gravity is 7.1758. It becomes dark coloured by exposure to light, is phosphorescent when rubbed in the dark, and requires a higher temperature for its sublimation than the muriate of mercury. It is converted into muriate or corrosive sublimate, by the nitric and oxymuriatic acids.

1745 Different names.

This salt, which is now generally known in the shops by the name of *calomel* or *sweet mercury*, was formerly described under a great variety of names, derived from its effects, or the mode of its preparation. In the beginning of the 17th century, it was regarded as an important secret. But, in the year 1608, Beguin described it very accurately, in his *tyrocinium chemicum*, under the name of *the dragon tamed*, on account of the corrosive sublimate from which it was prepared, being deprived of its poisonous and destructive qualities. At different periods it was distinguished by other names, as *aquila alba*, *aquila mitigata*, *manna metallorum*, *panchymagogus quercitanus*, &c. The use of this salt as a purgative, and indeed in all cases where mercurial preparations are required, is well known.

5. Muriate of Ammonia and Mercury.

1746 Preparation.

If ammonia be added to a solution of muriate of mercury, or corrosive sublimate, a white precipitate is obtained, which is a triple salt, formed by the combination of the ammonia with the muriate of mercury. This white precipitate has at first an earthy taste, which becomes afterwards metallic and disagreeable. It seems to be insoluble in water. Sulphuric acid forms with this triple salt, corrosive sublimate, and sulphate of ammonia and mercury. Nitric acid converts it into corrosive sublimate and nitrate of ammonia and mercury. It is completely soluble in muriatic acid, and there is formed a muriate of mercury and ammonia. This preparation was known to the alchemists, and distinguished by the names of *sal alembroth*, and *salt of wisdom*. The component parts of this salt, according to Fourcroy, are

Acid	16
Oxide of mercury	81
Ammonia	3
	100*.

6. Hyperoxymuriate of Mercury.

1747 Preparation.

The salt was formed by Mr Chenevix, by passing a current of oxymuriatic acid gas through water, in which there was red oxide of mercury. The oxide became of a dark brown colour, and a solution appeared to have taken place. The liquor was evaporated to dryness, and a salt was obtained which consisted partly of corrosive sublimate, and partly of hyperoxymuriate of mercury. By separating the latter, and crystallizing it again, it was obtained nearly pure. This salt is more soluble than corrosive sublimate, four parts of water retaining it in solution. Hyperoxymuriatic acid is given out by the addition of sulphuric, or even weaker acids, and the liquid assumes an orange colour †.

1748 Properties.

7. Fluate of Mercury.

Fluoric acid combines only with the oxide of mercury; or the soluble fluates mixed with a solution of nitrate of mercury, produce a precipitate of a white colour, which is the fluate of mercury, of which the properties are little known.

8. Borate

* Fourc v. 309—342.

† Phil. Trans. 1802, p. 260.

8. Borate of Mercury.

Boracic acid has no direct action on mercury; but by mixing together a solution of borate of soda with a solution of nitrate of mercury, a yellowish precipitate is obtained, which is the borate of mercury. This salt acquires a greenish colour by exposure to the air. Lime water forms a precipitate of a red powder.

9. Phosphate of Mercury.

Phosphoric acid has no action on mercury, but it combines with its oxide. This salt may be prepared by precipitating the nitrate of mercury in solution, by means of phosphate of soda. A white precipitate is formed, which is phosphate of mercury. This salt is insoluble in water, phosphoresces when rubbed in the dark, and is decomposed by heat, giving out phosphorus.

10. Carbonate of Mercury.

By precipitating the solutions of mercury in the other acids by means of the alkaline carbonates, a white precipitate is obtained, which is a carbonate of mercury.

11. Arseniate of Mercury.

When arsenic acid is distilled in a retort with mercury, it is partially decomposed. Arsenious acid is sublimed, with a portion of metallic mercury and a small quantity of yellow oxide. There remains behind a yellow mass, which is arseniate of mercury. It is insoluble in water, and in sulphuric and nitric acids. It is soluble in muriatic acid, and affords by evaporation and sublimation, the muriate of mercury, or corrosive sublimate. Arsenic acid precipitates the sulphate and nitrate of mercury in the form of a white powder, which is also arseniate of mercury.

12. Tungstate of Mercury.

This salt is formed, by adding to a solution of nitrate of mercury, an alkaline tungstate. This salt is decomposed, and the tungstate of mercury is precipitated in the form of a white insoluble powder.

13. Molybdate of Mercury.

Molybdic acid precipitates mercury from its solution, in nitric acid, in the form of a white flaky powder. It is also insoluble in water.

14. Chromate of Mercury.

An alkaline chromate in solution, added to a solution of nitrate of mercury, forms a precipitate of a fine reddish purple colour. This is the chromate of mercury, which is insoluble in water, and which Vauquelin, who discovered it, suggests to be employed as a pigment.

15. Columbate of Mercury.

Unknown.

16. Acetate of Mercury.

1. Acetic acid combines with the oxides of mercury, and forms different salts, according to the oxide which enters into the combination. With the red oxide of mercury it forms a salt which does not crystallize; but when the liquid is concentrated, and evaporated to dryness, it affords a yellow deliquescent mass. When this salt is dissolved in water, it divides into two parts; the one falls down in the state of yellow powder, which is acetate of mercury with excess of base; and the other part remains in solution, because it contains an excess of acid.

2. But when nitrate of mercury is precipitated by means of alkalies, and the precipitate is dissolved in acetic acid, the solution yields, by evaporation and cooling, acetate of mercury, in thin brilliant flakes. This salt may also be formed by mixing together solutions of acetate of potash and nitrate of mercury. The acetate of mercury appears in the form of large flat crystals, which have an acrid taste, and are scarcely soluble in water. This latter salt is a compound of acetic acid and the oxide of mercury, with a smaller proportion of oxygen. It is employed in medicine, and forms the principal ingredient of *Keyser's pills.*

17. Oxalate of Mercury.

Oxalic acid combines with the oxide of mercury, and forms an oxalate in the state of white powder, which is scarcely soluble in water. It becomes black by exposure to the light. When it is heated it detonates. This salt may also be obtained, by adding oxalic acid to a solution of the nitrate or sulphate of mercury.

18. Tartrate of Mercury.

Tartaric acid forms an insoluble salt of a white colour, with the oxide of mercury, which becomes yellow by exposure to the light.

19. Tartrate of Potash and Mercury.

This triple salt may be prepared by boiling together in water, one part of oxide of mercury, and six of tartar. Crystals of the triple salt are obtained by evaporating the liquid.

20. Citrate of Mercury.

Citric acid produces an effervescence with the red oxide of mercury, changes into a white colour, and then unites it in one mass. This salt is scarcely soluble in water. It has a metallic taste, and is decomposed by nitric acid.

21. Malate of Mercury.

When malic acid is added to a solution of nitrate of mercury, a white precipitate is formed, which is malate of mercury.

22. Benzoate of Mercury.

Benzoic acid forms with the oxide of mercury a salt in the state of white powder, which is insoluble in water, and is scarcely altered by exposure to the air. It is decomposed by heat.

23. Succinate of Mercury.

Succinic acid combines with the oxide of mercury with the assistance of heat, and forms with it an irregular mass, in which some crystals are observed.

Zinc, &c.

24. Saccolate of Mercury.

By adding saclactic acid to a solution of nitrate of mercury, a white precipitate is formed, which is saccolate of mercury.

25. Mellate of Mercury.

Mellitic acid, added to a solution of nitrate of mercury, produces a copious precipitate, which is re-dissolved by the addition of nitric acid *.

* *Klaproth Essays*, ii. 102, *Trans.*

26. Prussiate of Mercury.

This salt is obtained by boiling the red oxide of mercury with Prussian blue. It forms crystals in four-sided prisms, terminated by four-sided pyramids. The specific gravity is 2.7612. It forms triple salts with sulphuric and muriatic acids, the properties of which are not known.

II. Action of Alkalies, &c.

There is no action between mercury and the alkalies of alkaline earths; but the alkalies combine with the oxides of mercury, and form with them compounds in which the latter seem to act the part of acids. Some of these compounds have been already treated of, in speaking of the action of ammonia on some of the mercurial salts.

Salts formed with the alkalies and earths have no action on mercury or its oxides, if we except the muriates. By dissolving the muriate of mercury in a solution of muriate of ammonia, a triple salt, which is muriate of ammonia and mercury, and which has been
1750 already described, is obtained.

Uses.

Mercury is one of the metals of the most extensive utility. In the metallic state it is applied to the construction of meteorological instruments, as the barometer and thermometer. Mercury is also applied to a great variety of purposes in the arts; in gilding with silver and gold; in forming an amalgam with tin for covering the back of mirrors; and in metallurgy for the purpose of separating gold and silver from their ores. Mercury is also of considerable importance for the purposes of chemistry. Many of its preparations form some of the most effectual and most certain remedies in different diseases.

Sect. XVII. *Of Zinc and its Combinations.*

1751 History.

1. Paracelsus is the first who speaks of zinc under its present name. It is supposed that the Greeks were acquainted with this metal in the state of compound with copper, which formed the famous Corinthian brass; but it does not appear that they made any distinction between it and other metals. It is particularly mentioned by Albertus Magnus, who died in 1280, and he seems to have known that it inflamed, and communicated a colour to metals with which it was combined. The method of obtaining zinc from the ore called *calamine*, is mentioned by Henckel in his Pyrotology in 1721. Swab extracted it by distillation in 1742, and Margraaf was occupied with this process in 1746. Zinc was supposed by the earlier chemists to be a variety or compound of some of the other metals. Lemery thought it was a kind of bismuth, and Homberg took it for a mixture of iron and tin; while others supposed that it was tin rendered brittle by sulphur, or that it was a coagulated mercury.

1752 Ores.

2. Zinc is found in four different states: In the state of oxide in the state of sulphuret, in that of sulphate, and in that of carbonate. 1. In the state of oxide it is known by the name of *calamine*, or *lapis calaminaris*, deposited in a regular form, or in that of incrustations and stalactites, in the cavities of metallic veins. 2. The sulphuret of zinc, known by the name of *blende*, is sometimes disposed in scales, and sometimes crystallized in tetrahedrons, or octahedrons. It is frequently found in lead mines, accompanying the ores of lead. 3. The sulphate of zinc, which is found native, is readily known by its white colour and transparency, its strong acrid taste, and solubility in water. It is generally found in a stalactitical form, or in fine silky crystals, like those of amianthus. 4. The native carbonate of zinc, which is sometimes confounded with the oxide or calamine, forms another ore of zinc. It is transparent, white, or yellowish. It is insipid and insoluble in water, and dissolves with effervescence in nitric and muriatic acids.

1753 Analysis.

3. To reduce oxides of zinc to the metallic state, the ore is pulverized and mixed with charcoal, and the mixture is heated in a crucible covered with a plate of copper. The zinc is sublimed in the metallic state, and combines with the copper, which it converts into brass; and in this rude process the richness of the ore is ascertained by the intensity of the colour. The sulphurets of zinc are reduced by roasting, by which process the sulphur is separated, and the residuum is then treated in the same way as the oxides. In the humid way Bergman has proposed to analyze the oxides of zinc by means of sulphuric acid, and then by precipitating the oxide by carbonate of soda, he has ascertained that 193 parts of this precipitate give 100 parts of the metal.

1754 Properties.

4. Zinc is of a brilliant white colour with a bluish shade, which is very perceptible in its metallic state, and of a distinct lamellated texture; but the plates of which it is composed are smaller than those of bismuth and antimony. The specific gravity is 7.190. Zinc is not quite so brittle as the preceding metals. It requires a smart and sudden blow to separate its fragments. It is susceptible of a slight degree of malleability, for, by gradual and cautious pressure, it may be formed into thin plates which have some degree of elasticity. It has a slight odour, and a peculiar taste, which is communicated to the fingers when they are rubbed on this metal.

1755 Action of heat.

5. When zinc is exposed to a heat of about 700° it melts, and by increasing the heat it evaporates, so that in close vessels it may be distilled. When allowed to cool slowly after being in fusion, it crystallizes in fine needles. When zinc is exposed to the air, it undergoes very little alteration in the cold. Its brilliancy is slightly tarnished, and it becomes at length covered with a thin gray oxide. When zinc is fused in close vessels and exposed to heated air, at the moment it becomes solid on the surface, it exhibits a great variety of shades of colour, which is the commencement of oxidation. When it is kept in fusion, in the open air, the surface becomes covered with a gray pellicle, which being removed, is succeeded by another, till the whole of

1756 Oxidation.

&c. of the zinc is converted into this gray-coloured matter, which is an oxide of zinc. This process may be promoted by agitating the vessel, so that the metal in fusion may be exposed to the air. By heating together the gray pellicles which have been collected in an open vessel, the whole is converted into a uniform gray powder, which at last assumes a yellowish colour. The yellow oxide, thus formed, has acquired an additional weight of about 17 per cent. of the metallic zinc.

When this metal is heated to redness in an open vessel, by agitating the vessel, it suddenly takes fire, and burns with a very brilliant white and somewhat greenish flame. Zinc is at the same time reduced to a state of vapour, which is condensed in the air, in light, filamentous, white flakes, of a very delicate texture. This is an oxide of zinc. It has been distinguished by different names, as *flowers of zinc*, *nihil album* or *white nothing*, *lana philosophica*, or *philosophic wool*.

7 Oxi two Thus, there are two oxides of zinc; the gray oxide, which consists of about 88 parts of zinc, and 12 of oxygen; and the white oxide, which, according to Proust, is composed of 80 parts of zinc, and 20 of oxygen.

8 Act of hyd gen. 6. There is no action between azote and this metal. Hydrogen gas, it is supposed, dissolves a small quantity of zinc; for, by dissolving zinc in diluted sulphuric acid, the hydrogen gas which is obtained by the decomposition of the water, has been found to hold a little zinc

59 Of bon. in solution, which is deposited on the sides of the jars containing the gas. It is supposed, too, that zinc is sometimes combined with carbon, because hydrogen gas, obtained by the above process, is sometimes contaminated with carbonated hydrogen gas.

60 Ph uret. 7. Zinc combines with phosphorus, and forms a phosphuret. This may be prepared by adding small bits of phosphorus to zinc in fusion, but previously throwing in a little resinous matter, to prevent the oxidation of the zinc. This was the process by which Pelletier formed the phosphuret of zinc. This phosphuret is of a white colour and metallic lustre. It has some degree of malleability. When it is hammered it emits

61 Ph ora- ted ide. the odour of phosphorus, and when exposed to a strong heat, it burns like zinc. Phosphorus also enters into combination with the oxide of zinc, and forms with it a phosphorated oxide. This is formed by distilling in an earthen-ware retort, equal parts of oxide of zinc, and phosphoric glass, with one-sixth of charcoal powder. A strong heat is applied, and a metallic substance of a silvery white colour is sublimed, which has a vitreous fracture. When it is heated by the blow-pipe, the phosphorus burns, and there remains behind a vitreous matter, which is transparent while in fusion, but becomes opaque when it is cold.

62 Sul uret. 8. Zinc has not been combined directly with sulphur. When they are heated together in a crucible, the sulphur separates without producing any other change on the zinc than that of being a little more infusible; but it has been observed that sulphur and zinc, when fused together in a crucible, enter into combination, as the zinc is oxidated. This compound assumes a brownish gray colour. Guyton afterwards discovered that sulphur and the oxide of zinc readily unite together by fusion, and that the compound is of a gray colour, similar to the native sulphuret of zinc, as it has been called, or the sulphurated oxide of zinc, according to this experiment; but according to Proust, the ore of zinc, which is known by the name of *blende*, is a sulphuret, that is, sulphur combined with zinc in the metallic state. Zinc, &c.

1763 Affinities. 9. The order of the affinities of zinc and its oxide is the following:

ZINC.	OXIDE of ZINC.
Copper,	Oxalic acid,
Antimony,	Sulphuric,
Tin,	Muriatic,
Mercury,	Saclactic,
Silver,	Nitric,
Gold,	Tartaric,
Cobalt,	Phosphoric,
Arsenic,	Citric,
Platinum,	Succinic,
Bismuth,	Fluoric,
Lead,	Arsenic,
Nickel,	Lactic,
Iron.	Acetic,
	Boracic,
	Prussic.
	Carbonic.

I. Salts of Zinc.

1. Sulphate of Zinc.

1764 Preparation. 1. Sulphuric acid diluted with water, acts very powerfully on zinc. A violent effervescence takes place; the mixture is strongly heated, and a great quantity of hydrogen gas is evolved. In this process, which is usually followed for obtaining the purest hydrogen gas for chemical purposes, the water is decomposed; its oxygen combines with the metal and forms an oxide, which is then dissolved in the sulphuric acid, and forms a sulphate of zinc, while the hydrogen, the other component part of the water, escapes in the form of gas. A black powder is sometimes observed floating in the solution, which is carburet of iron, with which the zinc is frequently contaminated. As the effervescence ceases, a white powder is formed, which gradually disappears towards the end of the process, and with the addition of water forms a transparent solution. By evaporation and cooling, the sulphate of zinc is obtained crystallized.

1765 Properties. 2. The sulphate of zinc is frequently contaminated with other metals, as with lead, iron, and copper; but when it is pure, it crystallizes in four-sided prisms, terminated by pyramids with four faces. This salt has an acrid, astringent, and strongly metallic taste. When it is exposed to the air it effloresces. It is soluble in less than two and a half parts of cold water, and more soluble in boiling water. The specific gravity of the crystallized salt is 1.912; but as it is generally met with in the shops, it is only 1.3275. When heated in a retort, it melts, loses its water of crystallization, and part of its acid in the state of sulphurous acid, and a little water. It is decomposed and precipitated in the state of white oxide by all the alkalies; and if the precipitate is formed by means of the carbonates, a white pigment is obtained. The sulphate of zinc is also decomposed with the assistance of heat, by means of nitre. The alkaline sulphurets and hydrosulphurets also precipitate the sulphate of zinc,

Zinc, &c. zinc, of a deep orange or brown colour. The component parts of this salt are, according to

1766 Composition.

	Bergman.	Kirwan.
Acid	40	20.5
Oxide	20	40.0
Water	40	39.5
	100	100.0

1767 White vitriol. 3. The salt known in commerce by the name of *white vitriol*, is a sulphate of zinc, and is supposed to contain an excess of acid. It is in the form of white granular masses, resembling sugar, and often marked with yellow spots. This salt is usually prepared by roasting the sulphuret of zinc or blende, by which means the sulphuret is converted into sulphuric acid. It is then dissolved in water, which is purified and evaporated, and the salt is crystallized by sudden cooling. Part of its water of crystallization is afterwards driven off by heat, so that it is obtained in a regular, solid, and granulated mass. It is generally contaminated with iron and other metals; but it may be purified from these, by adding filings of zinc, which precipitate the other metals, and leave a pure sulphate of zinc.

2. Sulphite of Zinc.

1768 Preparation. Concentrated sulphurous acid readily combines with the white oxide of zinc, without any effervescence, but with the evolution of heat, and the acid being deprived of its odour. When the saturation is completed, white crystals appear on the surface of the liquid. This salt has a pungent, astringent taste. It crystallizes readily. It is decomposed by the acids, with
1769 Properties. effervescence. It is insoluble in alcohol. It forms white precipitates with the alkalies, and when exposed to the air, it is readily converted into sulphate of zinc.

1770 Combines with sulphur. *Sulphurated sulphite of Zinc.*—When sulphurous acid is added to zinc in the state of powder or filings, a great degree of heat is produced; sulphurated hydrogen gas is disengaged; the liquid becomes at first brown, sometimes muddy, and assumes a yellow colour, and towards the end of the process it becomes transparent. The solution has an acrid, astringent, and sulphureous taste. Sulphuric and muriatic acids disengage with effervescence, sulphurous acid gas, and precipitate a yellowish white powder. Nitric acid at first separates sulphurous acid gas, and afterwards a flaky precipitate, which is pure sulphur. When this solution is exposed to the air, it becomes thick like honey, and affords crystals in the form of needles or fine four-sided prisms, terminated by four-sided pyramids.
1771 Properties. These are crystals of sulphurated sulphite of zinc, which become white by exposure to the air, and form a white powder insoluble in water. When this salt is heated by the blow-pipe, it swells up, gives out a bright light like burning zinc, and forms dendritical ramifications. This salt is partly soluble in alcohol. The part not dissolved, only gives out sulphurous acid gas by means of sulphuric acid, whilst the part which is dissolved affords, besides sulphurous acid gas, a copious precipitate of sulphur. When it is distilled in a retort, it gives out water, sulphurous acid, sulphuric acid, and sulphur sublimed. There remains behind oxide of zinc, mixed with a little of the sulphate.

1772 Theory of the process. In the solution of zinc in liquid sulphurous acid, water, and part of the sulphurous acid itself, are decomposed; for sulphurated hydrogen gas is disengaged, which is composed of the hydrogen of the water and part of the sulphur of the sulphurous acid. There is no precipitation of sulphur during the solution, for it combines with the sulphite of zinc, as it is formed; but this is not completely saturated, since alcohol dissolves only the portion of sulphurated sulphite which it contains, and separates the sulphite *.

* Fourcroy v. p. 380.

3. Nitrate of Zinc.

1773 Preparation. 1. Concentrated nitric acid produces a violent action with zinc, and sometimes even inflames it. To effect this solution, with a moderate action, the acid should be diluted with water. Great heat is produced, with violent effervescence and the evolution of nitrous gas. The acid is decomposed; its oxygen combining with the metal forms an oxide, which combines with the acid as it is formed.

1774 Properties. 2. This solution is of a greenish-yellow colour, and extremely caustic. By evaporation it affords crystals, in the form of four-sided, compressed, and striated prisms, terminated by four-sided pyramids. The specific gravity is 2.096. This salt is deliquescent in the air. When it is heated on burning coals, it melts, and detonates with a small red flame. When heated in a crucible, it gives out red vapour, and assumes a deep colour and gelatinous consistence. When cooled in this state, it retains its softness for some time. By continuing the heat, it dries, gives out nitrous and oxygen gases, and leaves behind a yellow oxide.

4. Muriate of Zinc.

1775 Preparation. Muriatic acid produces a rapid action on zinc. It is dissolved with effervescence, and with the evolution of pure hydrogen gas. The solution of zinc in muriatic acid is colourless; it does not crystallize, but assumes the form of a transparent jelly. It affords by distillation a small quantity of fuming acid, and a solid muriate of zinc, which is fusible with a moderate heat, and was formerly known by the name of *butter of zinc*. When this muriate of zinc is sublimed by heat, it becomes of a fine white colour, composing a mass of crystals in the form of small prisms. It is decomposed by
1776 Properties. sulphuric acid, and is precipitated by the alkalies. It is soluble in water, attracts moisture from the atmosphere, and is soon converted into a transparent jelly. The specific gravity is 1.577.

5. Muriate of Ammonia and Zinc.

This triple salt is formed by boiling white oxide of zinc in a solution of muriate of ammonia. The oxide of zinc is dissolved; part of which is afterwards deposited, when the solution cools, but what remains in the solution is not precipitated by the alkalies or the alkaline carbonates.

6. Fluate of Zinc.

Fluoric acid produces a violent action with zinc; there is considerable effervescence, with the evolution of of hydrogen gas. The metal is oxidated, and then dissolves in the acid; but the properties of this salt are little known.

7. Borate of Zinc.

Boracic acid combines with the oxide of zinc, by adding the borate of potash or soda to the solution of zinc in nitric or muriatic acid. This salt is insoluble in water.

8. Phosphate of Zinc.

777 P ara- ti Phosphoric acid diluted with water, acts upon zinc with the evolution of hydrogen gas, owing to the decomposition of water. A white powder is deposited, which is phosphate of zinc. By exposing phosphoric glass and zinc to a strong heat, a phosphuret of zinc is formed, by the decomposition of the acid.

9. Carbonate of Zinc.

778 P ara- ti Zinc reduced to a fine powder, and added to liquid carbonic acid, is oxidated and copiously dissolved in the acid, at the end of 24 hours. This solution, exposed to the air, is covered with a pellicle of carbonate of zinc of different colours. The carbonate of zinc is found native, and has been distinguished by the name of *calamine*, thus confounding it with the oxide of zinc. Carbonate of zinc, according to the analysis of Bergman, is composed of

Acid	28
Oxide	66
Water	6
	100

10. Arseniate of Zinc.

When arsenic acid is added to zinc, it produces an effervescence, with the evolution of hydrogen gas, holding arsenic in solution. A black powder is deposited, which is metallic arsenic. In this process, the zinc decomposes part of the water, and combines with its oxygen, and at the same time deprives the arsenic acid of its oxygen, by which it is reduced to the metallic state. The arseniate of zinc may be obtained by adding a solution of an alkaline arseniate to a solution of the sulphate of zinc. A white precipitate is formed, which is the arseniate of zinc. It is insoluble in water.

11. Tungstate of Zinc.

12. Molybdate of Zinc.

These salts may be formed by a similar process. A white powder is obtained, which is insoluble in water.

13. Chromate of Zinc.

This salt is obtained by combining an alkaline chromate with a solution of zinc in nitric acid. A precipitate is formed of an orange red colour, which is chromate of zinc.

14. Columbate of Zinc.

Unknown.

15. Acetate of Zinc.

Acetic acid dissolves zinc, and the solution by evaporation crystallizes in the form of rhomboidal or hexagonal plates. This salt has a bitter metallic taste, is not altered by exposure to the air, and is soluble in water. It burns with a blue flame when thrown on burning coals. When distilled, it yields water, an inflammable liquid, and some oil. At the end of the process, when the salt is completely decomposed, the oxide of zinc is sublimed, which being brought in contact with a candle, burns with a fine blue flame. The residuum is in the state of pyrophorus, but it has little combustibility. 1779 Preparation and properties.

16. Oxalate of Zinc.

Oxalic acid acts upon zinc with effervescence, and the evolution of hydrogen gas. Water is decomposed, and as the zinc is oxidated, it combines with the acid, forming an oxalate of zinc. It is in the state of white powder, of an acrid taste, and but little soluble in water.

17. Tartrate of Zinc.

Tartaric acid combines with zinc with effervescence, and the evolution of hydrogen gas. The properties of this salt have not been examined.

18. Citrate of Zinc.

Citric acid acts upon zinc with effervescence and the evolution of hydrogen gas. At the end of 24 hours the action ceases, and the liquid deposits on the sides of the vessel and on its surface, small, brilliant crystals in the form of plates, which are insoluble in water. The citrate of zinc has an astringent, metallic taste. It is composed of equal parts of acid and of oxide of zinc.

19. Malate of Zinc.

Malic acid dissolves zinc, and, by evaporating the solution, crystals may be obtained.

20. Benzoate of Zinc.

Benzoic acid readily dissolves zinc, and by evaporation the solution affords needle-shaped crystals. The benzoate of zinc is soluble in water and alcohol. When it is exposed to heat the acid is sublimed.

21. Succinate of Zinc.

Zinc is dissolved in succinic acid with effervescence. By evaporation the solution affords slender, foliated crystals.

22. Lactate of Zinc.

Zinc is soluble in lactic acid with effervescence, and by evaporating the solution, the salt may be obtained crystallized.

II. Action of Alkalies, &c. on Zinc.

1. When zinc is immersed in a solution of potash or soda, it is tarnished, and becomes black; and when it is boiled in the solution, hydrogen gas is evolved. The solution assumes a dirty-yellow colour, from which an oxide of zinc may be precipitated by acids. 1780 Fixed alkalies.

2. Ammonia

1781 Ammonia. 2. Ammonia has a still more powerful action on zinc. Hydrogen gas is more copiously evolved, and the oxide which is formed is more abundantly dissolved in the liquid, and at the end of some time a considerable quantity of white oxide is deposited. These alkaline solutions become turbid by exposure to the air; its oxygen and carbonic acid, acting at the same time, precipitate the oxide.

1782 Sulphates. 3. The alkaline and earthy sulphates are readily decomposed by zinc, with the assistance of heat. It attracts the oxygen of the sulphuric acid, and thus decomposing it, separates the sulphur, which combines with the bases of the sulphates. Alum boiled in solution with zinc, is decomposed, and there is formed a triple salt, which is sulphate of zinc and alumina.

1783 Nitrates. 4. The nitrates produce a vivid inflammation with zinc at a red heat. The acid is decomposed, its oxygen combines with the metal, and by this rapid combination, a violent detonation is produced. The azotic gas is disengaged, and the zinc is fully oxidated. Three parts of nitre well dried, and one of zinc in fine powder, well mixed together and projected into a red-hot crucible, produce a very brilliant inflammation. The burning matter is sometimes thrown out to a considerable distance; so that the experiment should be made with caution. This compound is sometimes employed in fire-works.

1784 Muriates. 5. Zinc has a considerable action on the muriates. Triturated with the muriate of ammonia, the salt is decomposed, and ammonia is disengaged. By distilling this salt with zinc, ammoniacal and hydrogen gases are obtained; the latter is obviously owing to the decomposition of the water contained in the salt, by means of the zinc, which combines with the oxygen, and then forms a muriate of zinc with the muriatic acid.

1785 Phosphates, &c. 6. The phosphates and borates combine by fusion with the oxide of zinc, which communicates to the glass thus formed a greenish-yellow colour.

7. Zinc decomposes the greatest number of the metallic salts from their solutions, by its strong affinity for oxygen. They are precipitated in the metallic form, or in the state of oxide, but deprived of a portion of oxygen.

1786 Uses. 8. Zinc is employed in many of the arts. It forms useful alloys with some of the other metals, some of which will be mentioned afterwards. It is also employed in medicine. The sulphate of zinc is sometimes exhibited as an emetic, and frequently used in solution as an eye-wash. The oxide of zinc, or the flowers of zinc, have been prescribed as an antispasmodic, and particularly in cases of epilepsy.

Sect. XVIII. *Of Tin and its Combinations.*

1787 History. 1. Tin has been known from the earliest ages. It was much employed by the Egyptians in the arts, and by the Greeks as an alloy with other metals. Pliny speaks of it under the name of white lead, as a metal well known in the arts, and even applied in the fabrication of many ornaments of luxury. He ascribes to the Gauls the invention of the art of tinning, or covering other metals with a thin coat of tin. The alchemists were much employed in their researches concerning tin. They gave it the name of *Jupiter*, from which the salts or preparations of tin were called *jovial*. Since their time, the nature and properties of tin have been particularly investigated by many chemists, and it has proved the subject of some important discoveries in chemical science. So early as the year 1630, John Rey threw out a conjecture, that the air was fixed in this metal during its calcination. Boyle, towards the end of the same century, attempted to account for the increase of weight which this metal acquired during this process; but this was only fully ascertained by Lavoisier, who repeated the experiment of Boyle, and calcined the metal in close vessels; but the method of conducting this experiment and the result of it, have been already detailed.

2. Tin exists in nature in three different states. It is found native, in the state of oxide, and in that of sulphurated oxide. Native tin is in brilliant plates, or regularly crystallized. The native oxide of tin, which is the most common ore of this metal, exists under a variety of forms. It is generally found crystallized. The sulphuret of tin is of a pale or dark gray colour, and when pure, has some resemblance to an ore of silver. 1788 Ores.

3. To obtain the metal from its ores, they are first roasted, and then treated with a flux, to reduce the metal. It has been recommended by some, to mix a small quantity of pitch with the fused mass, to prevent the oxidation of the tin. After the ore is roasted, it fuses readily with three times its weight of black flux, and a little decrepitated muriate of soda. 1789 Analysis.

In the humid way, native tin may be dissolved in nitric acid, which readily oxidates, and reduces it to the state of white powder, which is an oxide of tin; and if it contain iron and copper, these two metals remain in the solution.

4. Tin is of a white colour, nearly as brilliant as silver. The specific gravity of tin is 7.291. It is one of the softest of the metals. It may be scratched with the nail, and easily cut with a knife. It is extremely flexible, and produces a peculiar noise when it is bent or folded. It is so malleable, that it can be easily beaten out to $\frac{1}{1000}$ part of an inch, which is the thickness of tinfoil. It has little elasticity or tenacity. A wire of this metal about $\frac{1}{10}$ of an inch in diameter supports a weight of about 30 lbs. without breaking. 1790 Properties.

5. Tin is susceptible of very considerable expansion by means of caloric, and on this account it has been proposed to employ it as a pyrometer. Tin is one of the most fusible of the metals, and melts at the temperature of 442°, but it requires a very high temperature to raise it in vapour. If it be allowed to cool slowly, and when the surface becomes solid, by pouring out part of the liquid metal, crystals are formed, in large rhomboids, composed of a great number of small needles. 1791 Action of heat.

6. Tin is a good conductor of electricity. It possesses a peculiar odour, which is communicated to the hands by friction. It has also a perceptible taste. 1792 Odour, &c.

7. When this metal is exposed to the air, it is soon tarnished, and assumes a grayish white colour; but it undergoes no farther change. When it is melted in an open vessel, it is soon covered with a grayish pellicle, which is the commencement of the oxidation of the 1793 Oxidation.

the metal. When this pellicle is removed, another forms, and so on successively sill the whole is oxidated. By continuing the heat, and by agitation, the process goes on more rapidly, and the metal is converted into a whitish powder. This oxide contains about 20 parts of oxygen in 100 of the metal. With the addition of lead to promote the oxidation, this oxide is the *putty of tin*. It contains about two parts of oxide of lead, and one part of oxide of tin. But when tin is strongly heated, it is converted into a fine white oxide, which during the process gives out a vivid white flame. This oxide is condensed in the cold, and crystallizes in shining transparent needles.

1794 o ox-

According to Proust, tin combines with two proportions of oxygen, thus forming two oxides. The yellow oxide, which has the smaller proportion of oxygen, may be prepared by dissolving tin in nitric acid diluted with water, without the aid of heat. By precipitating the oxide with pure potash, it is obtained in the form of a yellowish powder. Its component parts are those already stated, namely,

20 oxygen,
80 tin,

100

By dissolving tin in concentrated nitric acid, with the assistance of heat, the whole is converted with effervescence into a white powder, which falls to the bottom of the vessel. The component parts of this oxide are, 28 oxygen, and 72 of tin.

8. There is no action between tin and azote, hydrogen, or carbon, nor is there any perceptible action between tin or its oxides and water.

1795 sphu.

9. Phosphorus combines very readily with tin, by projecting bits of phosphorus on melted tin in a crucible. A phosphuret of tin is thus obtained, which crystallizes on cooling. This compound is of a silvery white colour, may be cut with a knife, and extended under the hammer, but soon separates into plates. The filings of this phosphuret are like those of lead, and when they are thrown on red-hot coals, they take fire, and burn with the smell and flame of phosphorus. By the action of the blow-pipe, the phosphorus only burns, and the small metallic button which remains is surrounded with a transparent glass. Pelletier distilled this phosphuret often with hyperoxymuriate of mercury, and obtained a fuming muriate of tin, with the mercury reduced to the metallic state, and phosphorated hydrogen gas, which exploded as it came in contact with the air. There remained in the retort a spongy inflammable matter, which he supposed to be a compound of tin and phosphorus.

1796 phuret.

10. Sulphur combines very readily with tin, by adding the sulphur to the metal while in a state of fusion. This compound forms a grayish or bluish matter, which has a metallic lustre, a lamellated structure, and crystallizes in cubes, or in octahedrons. It is decomposed by acids with effervescence. The component parts are, according to

1797 posi-

	Bergman.	Pelletier.
Tin	80	85
Sulphur	20	15
	100	100

11. If equal parts of oxide of tin and sulphur be fused together in a retort, sulphurous acid and some sulphur are disengaged, and there remains in the vessel a compound of a brilliant golden colour. It crystallizes in six-sided plates. It is not acted on by the acids. When it is strongly heated, it gives out sulphurous acid and sulphur, and there remains behind a black mass, which is sulphuret of tin. This compound, which is a sulphurated oxide of tin, was formerly distinguished by the name of *aurum musivum*, *musicum*, or *mosaicum*. The component parts of this sulphurated oxide of tin are, 1798 Sulphurated oxide.

Oxide of tin	60
Sulphur	40
	100

12. Tin enters into combination with many of the metals, and forms alloys with them, some of which are of great importance. It also combines with acids, and forms salts. The affinities of tin and its oxides are in the following order: 1799 Affinities.

Tin.	Oxide of Tin.
Zinc,	Tartaric acid,
Mercury,	Muriatic,
Copper,	Sulphuric,
Antimony,	Oxalic,
Gold,	Arsenic,
Silver,	Phosphoric,
Lead,	Nitric,
Iron,	Succinic,
Manganese,	Fluoric,
Nickel,	Saclactic,
Arsenic,	Citric,
Platinum,	Lactic,
Bismuth,	Acetic,
Cobalt,	Boracic,
Sulphur.	Prussic.

I. Salts of Tin.

1. Sulphate of Tin.

1. Sulphuric acid acts very feebly on tin in the cold. The acid, however, is at last decomposed; its oxygen combines with the metal, sulphurous acid gas is emitted, and the oxide falls to the bottom in the state of white powder. In this case, the oxide has the smaller proportion of oxygen, and then the solution is more permanent. There is no precipitation by water. 1800 Two sulphates.

2. But when the solution of tin in sulphuric acid is promoted by the action of heat, the acid is still farther decomposed; a greater quantity of sulphurous acid is given out, and sulphur is deposited. In this case the white oxide of tin is formed. This compound, when evaporated, assumes the form of a jelly, and does not crystallize by the addition of water. It is precipitated in the form of white powder. The first might be called the yellow sulphate of tin, and the second the white sulphate of tin.

2. Sulphite of Tin.

When tin is immersed in liquid sulphurous acid, it assumes a yellow colour. At the end of some days it becomes

becomes black like charcoal, and there is deposited in the liquid a black powder. In this process part of the sulphurous acid is decomposed; its oxygen combining with the metal, forms an oxide, which enters into combination with another part of the acid, and forms the sulphate of tin. A portion of sulphur is deposited along with a white sulphite, which is not very soluble, and another portion remains in solution with part of the sulphite, forming a sulphurated sulphite. A third portion of the sulphur combines with part of the metallic tin, and forms a black sulphuret, on which the acid has no action *.

*Fourcroy Connaiss. Chim. iv. p. 30.

3. Nitrate of Tin.

1801 History.

1. Nitric acid produces a very violent action with tin. It is accompanied with great heat, and the evolution of nitrous gas. The metal is converted into a white oxide, which gives to the liquid the appearance of coagulated milk. It had been long observed by chemists, that the solution of tin in nitric acid was not permanent, for by evaporating or concentrating the solution, the oxide is always precipitated. This difficulty has been solved by the discoveries of modern chemistry.

1802 Preparation.

2. If tin be dissolved in nitric acid, diluted with water, and the great increase of temperature moderated by the application of cold, as by immersing the vessel in cold water, a solution of a small quantity of the oxide of tin is effected. The solution is of a yellow colour, and contains the oxide of tin, with a smaller proportion of oxygen, which is the yellow oxide. In this process the tin is chiefly oxidated by the decomposition of the water. In this process, too, ammonia is formed from the azote of the acid combining with the hydrogen of the water. This becomes perceptible by adding potash to the liquid. When the solution is heated, the oxide of tin is separated in great abundance.

1803 In different proportions.

3. But when nitric acid is more concentrated, a more violent action takes place between this acid and tin. The metal is oxidated, and the whole of it separates from the liquid. To one part of pure nitric acid Guyton added $1\frac{1}{2}$ of tin in a retort, when a violent effervescence took place, but no gas was given out. In this experiment a quantity of ammonia equal to $\frac{1}{20}$ of the weight of the acid and tin employed, was formed. The acid and the water are decomposed, and the oxygen of both combines with the tin, and forms an oxide, while the azote of the acid and the hydrogen of the water combine together and form ammonia. In this state of oxidation, the tin does not combine with the acid.

4. Muriate of Tin.

1804 Preparation.

1. Concentrated muriatic acid dissolves tin, either in the cold or with the assistance of a gentle heat. The acid is soon deprived of its fuming property, and of its yellow colour. A slight effervescence takes place, which is owing to the decomposition of water, and the evolution of a fetid hydrogen gas. This peculiar odour is supposed to be occasioned by the hydrogen gas holding in solution a portion of the metal. Muriatic acid dissolves more than $\frac{1}{2}$ its weight of tin. No precipitate is formed, as with the other acids. When it is

1805 Properties.

evaporated, it furnishes crystals in the form of brilliant needle-shaped prisms, which are deliquescent in the air.

1806 Decomposition.

2. This muriate of tin is precipitated by the alkalies in the form of a copious white oxide, which is re-dissolved with an excess of alkali. The alkaline solution is of a brownish yellow colour. The sulphuret of ammonia precipitates this salt in the form of powder, which becomes black as it dries, and by distillation yields ammonia and *aurum musivum*. The sulphuret of potash produces a yellow precipitate, which, by distillation, furnishes sulphurous acid and sulphur, and what remains is converted into *aurum musivum*, or the sulphurated oxide of tin. This oxide, precipitated by means of soda, and distilled with its weight of sulphur, yields sulphurous acid gas, sulphur, and the residuum is *aurum musivum*.

1807 Absorbs oxygen.

3. This solution of tin absorbs oxygen, with the evolution of heat, from oxymuriatic acid, which is deprived of its odour. With nitric acid, a violent effervescence takes place. Nitrous gas is disengaged, and in both these cases, the oxide of tin combines with an additional portion of oxygen. With the addition of sulphurous acid, this solution of tin deposits the yellow sulphurated oxide of a fine bright colour. This solution converts arsenic acid into the metallic state, and it produces the same effect on the molybdic and tungstic acids, by combining with their oxygen. The red oxide of mercury, the hyperoxymuriate of mercury, the white oxide of antimony, the oxides of zinc and silver, are all reduced to the metallic state by being deprived of their oxygen by the muriate of tin. This muriate also precipitates from the solution of gold, *the purple powder of Cassius*, by attracting that portion of oxygen which renders the oxide of gold soluble. In all these processes, the results of which were ascertained by Pelletier, the muriate of tin is converted into an oxymuriate.

1808 Forms an oxymuriate.

1809 Formed another process.

4. This oxymuriate of tin is formed by making a stream of oxymuriatic acid gas pass into a solution of muriate of tin. It is also prepared by triturating equal parts of an amalgam, consisting of two parts of tin, and one of mercury, and muriate of mercury, or corrosive sublimate, and distilling this mixture in a glass retort, with a very moderate heat. A colourless liquor first passes over, which is followed with the sudden evolution of a white vapour, which lines the inside of the receiver. This vapour is condensed into a transparent liquid, which, in the air, exhales a copious, heavy, white vapour, from which this liquid has been called *the smoking liquor of Libavius*, or the *oxymuriate of tin*. When this liquor is included in a vessel, it no longer gives out any visible vapour, but it deposits at the top of the vessel needle-shaped crystals, while similar crystals are precipitated to the bottom. Water does not precipitate the fuming muriate of tin. When it is thrown into the water, it produces a noise similar to that which is occasioned by concentrated sulphuric acid. A number of transparent bubbles of air being evolved from the mixture, collect on the surface, and become white by the contact of air. By agitating the water, they are more readily dissipated, and the liquid fumes no longer.

1810 In nitromuriatic.

5. Nitromuriatic acid, which is composed of one part of nitric acid, and two or three of muriatic acid, very readily dissolves tin. A strong heat is produced, which

which may be moderated by immersing the vessel, in which the solution is made, in cold water. The metal should be added in small portions, and one part should be dissolved before the addition of another. In this way the acid will dissolve half its weight of tin. It is by this process that the muriate of tin is obtained for the purpose of dyeing scarlet; but it is found to vary considerably in its effects, which, no doubt, depends on the strength of the acids employed, and the different proportions in the mixture. This solution is almost always coloured. Sometimes it affords a gelatinous mass on cooling, which becomes in time more solid. Sometimes it is of a white colour like milk. This solution has not the fetid odour of the simple solution of tin in muriatic acid. It often happens, that it does not assume the viscid or solid form, without the addition of $\frac{1}{4}$ its weight of water. It is then slightly opaque, which is owing to the precipitation of part of its oxide. When this solution is heated, an effervescence takes place; the tin is more strongly oxidated, and it is generally after this process that it assumes the form of a transparent jelly.

5. Fluate of Tin.

Fluoric acid has very little action on tin, but it dissolves its oxide, and forms with it a solution which assumes a gelatinous form. The fluate of tin may be also obtained by adding a solution of an alkaline fluate to a solution of tin in muriatic acid.

6. Borate of Tin.

By a similar process boracic acid combines with the oxide of tin, and forms a borate of tin, which is insoluble.

7. Phosphate of Tin.

This salt may be formed by precipitating the oxide of tin from its solution in muriatic acid, by means of an alkaline phosphate. A phosphate of tin is thus obtained, which is insoluble in water.

8. Carbonate of Tin.

This salt is prepared by precipitating the oxide of tin from its solution in muriatic acid, by means of the carbonates of the alkalies. When this carbonate of tin is dissolved in an acid, it effervesces; but, according to Bergman, the oxide of tin, precipitated by an alkaline carbonate, is not found to have received any sensible addition of weight, so that the effervescence occasioned by the action of an acid, on what is supposed to be a carbonate of tin, probably depends on the decomposition of the acid itself.

9. Arseniate of Tin.

Arsenic acid, with a moderate heat, dissolves a small quantity of tin, and the solution assumes the form of a jelly. Arseniate of tin is formed by adding to a solution of tin in muriatic acid, an alkaline arseniate. A precipitate is formed, which is arseniate of tin in the state of insoluble powder.

All the metallic acids are decomposed by means of tin. They also combine with the oxide of tin, and form salts in the state of powder, which has little solubility.

10. Acetate of Tin.

Acetic acid dissolves only a small portion of tin; but when the acid is boiled on tin, the action is more powerful, and the solution, which is of a whitish colour, affords by evaporation small crystals. The solution of tin in acetic acid sometimes does not crystallize, but affords only a gelatinous mass; so that, by the action of acetic acid on tin, the metal is either in different degrees of oxidation, or there are different proportions of the acid and base.

11. Oxalate of Tin.

Oxalic acid added to tin in thin plates or filings, first blacken the surface, which is afterwards covered with a white powder. The oxalate of tin, which is soluble in water, has an austere metallic taste. By slow evaporation it furnishes needle-shaped or prismatic crystals. When it is more rapidly evaporated, it affords a transparent mass like horn.

12. Tartrate of Tin.

Tartaric acid dissolves the oxide of tin, but the nature of this salt has not been examined.

13. Tartrate of Potash and Tin.

This triple salt may be obtained by boiling together the oxide of tin and tartar in water. It is a soluble salt, and crystallizes with difficulty. It is not precipitated by the alkalies or the alkaline carbonates.

14. Benzoate of Tin.

This salt is formed by adding to a solution of tin in muriatic acid benzoate of potash. The benzoate of tin is precipitated, which is soluble in water, with the assistance of heat.

15. Succinate of Tin.

The oxide of tin is dissolved by succinic acid with the assistance of heat. When the solution is evaporated it affords thin transparent crystals of succinate of tin.

II. Action of Alkalies, &c. on Tin.

1. Tin in the metallic state is little changed by the action of the alkalies; but the oxides of tin readily combine with these bodies. The combination of the oxide of tin with the fixed alkalies is effected, either in the dry or humid way; and with the assistance of heat the oxide of tin combines with liquid ammonia. This combination takes place most readily when the oxide is recently precipitated, when it is in the state of minute division. 1811 Alkalies.

2. The oxide of tin combines with the earths by fusion; and with the addition of a fixed alkali, forms an opaque vitreous mass, which is employed for the purposes of enamel. 1812 Earths.

3. Most of the salts are decomposed by means of tin, in consequence of the strong affinity of this metal for oxygen. All the sulphates, when heated with this metal, are more or less rapidly converted into sulphurets. Equal parts of sulphate of potash and tin, heated together in a crucible, afford a greenish coloured mass, which has no metallic appearance, and which seems to be a sulphuret of potash and tin. The nitrates produce 1813 Salts. 1814 Sulphates. 1815 Nitrates.

Tin, &c. duce deflagration with this metal, with the assistance of heat. If the tin be melted in a crucible, and brought to a red heat, and dried nitre in powder be projected into it, a white brilliant flame is produced, and when the detonation has entirely ceased, the tin is found to be oxidated. This experiment may be also made, by mixing together tin filings with three parts of nitre in
1816 Muriates. powder, and projecting the mixture into a red-hot crucible. Muriate of ammonia is decomposed by tin; and by adding sulphur, the sulphurated oxide of tin, or *aurum musivum*, is obtained. Eight parts of tin united to eight parts of mercury, with six of sulphur, and four of muriate of ammonia, afford, according to the process of Pelletier, a very beautiful *aurum musivum*.

It was observed by this philosopher, that during the process, sulphurated hydrogen gas, sulphuret of ammonia, and muriate of tin, were produced; that the tin oxidated and united to the sulphur, formed aurum musivum; and that a part of this matter, composed of the different substances, in a state of vapour, was deposited in lamellated, hexangular crystals, in the upper part and in the neck of the retort.

The alkaline hyperoxymuriates, but especially that of potash, produce a violent detonation with this metal. Three parts of this salt, mixed with one of tin in fine powder, rapidly deflagrates when brought into contact with a burning body. During this combustion, there is a brilliant and sudden flame, and the metal is reduced to the state of vapour. The same mixture by percussion produces a violent detonation with a considerable flame in the dark.

Many of the metallic solutions and metallic salts are decomposed by means of tin, and are either reduced to the metallic state, or deprived of a considerable portion of their oxygen.

III. Alloys.

1817 Arsenic. 1. Tin and arsenic form an alloy by fusion. The compound, when the proportion of arsenic is considerable, is white, brittle, more sonorous and harder than tin. In the proportion of 15 parts of tin and one of arsenic, the alloy crystallizes in large plates, is more infusible than tin, and more brittle than zinc. By exposure to the air, and with the assistance of heat, the arsenic is driven off.

1818 Cobalt. 2. With cobalt tin forms an alloy which is in small grains, and of a light violet colour.

1819 Bismuth. 3. Tin combines with bismuth. The tin is then harder, more sonorous and brighter. The compound in certain proportions becomes more fusible than either of the two metals. The alloy of equal parts of tin and bismuth melts at 280°. Eight parts of tin and two of bismuth melt at 390°, and two of tin and one of bismuth at 330°.

1820 Antimony. 4. Tin combines with antimony, and forms an alloy which is white and brittle, and has a specific gravity less than that of the two metals taken separately. The antimony gives hardness to the tin, and changes its texture. This alloy is employed in many arts, and particularly for the plates on which music is engraved.

1821 Mercury. 5. Tin combines very readily with mercury, and in all proportions. The tin is even dissolved when the quantity of mercury is considerable. This union takes place in the cold, but it is greatly promoted by means of heat. The heated mercury is poured upon the tin in fusion. The amalgam of tin is susceptible of crystallization in the form of cubes. Sage observed the crystals of this amalgam in gray brilliant plates, thin towards the edges, and leaving between them polygonal cavities.

This amalgam is employed for covering mirrors. In applying it, tinfoil is spread on a smooth flat stone or table, and mercury, in which a certain proportion of tin has been already dissolved, is poured upon it. It is then spread equally over the whole with a feather or a piece of cloth. The plate of glass, one side of which is to be covered, is then applied to the edge of the table, and cautiously moved along the tinfoil, so that the redundant part of the mercury may be carried before it. What remains enters into union with the tin. The glass is then to be equally loaded with weights, to press out any part of the mercury which may yet remain uncombined with the tin. In the course of a few hours the amalgam of the two metals adheres so firmly to the glass, that the weights may be removed.

182 Zinc. 6. Zinc readily forms an alloy with tin by fusion. The compound affords a hard metal with small grains, the ductility of which corresponds to the quantity of tin. The alloy of tin and zinc forms part of the compound which is known by the name of *pewter*.

182 Uses. Tin is applied to a great many important purposes. In the arts and domestic economy, it is formed into a great variety of vessels and instruments. The alloys of tin with other metals are not less important. It forms a component part of type metal, and bell metal. The oxides of tin are employed for the purpose of polishing glass and metallic substances, and combined with the earths and alkalies for the fabrication of enamels. The salts of tin are employed for the preparation of colours in dyeing, or as a valuable mordant for fixing certain colours. Tin in the metallic state has been exhibited as a remedy against worms. It is then granulated by constant agitation while it cools after fusion; but it is supposed, if it produces any effect as a vermifuge medicine, that it is merely by its mechanical action.

Sect. XIX. *Of Lead and its Combinations.*

182 History. 1. Lead has been known from the earliest ages. Pliny speaks of it under the name of black lead, probably to distinguish it from tin, with the properties of which he was also acquainted, for he observes that it was sometimes the practice to contaminate tin with lead.

182 Ores. 2. Lead is found in great abundance in many parts of the world, and in a great variety of forms and combinations. Lead has rarely, if ever, been found native, and it is doubted whether it has yet been discovered in the state of oxide. The most common form of lead is in the state of sulphuret, when it is combined with sulphur. In this state it is of a gray, brilliant colour, of a lamellated texture, very brittle, and breaks into cubes. This is the most frequent combination of lead, and it is generally found in this state in veins. Lead is also frequently met with combined with several of the acids. The carbonate, phosphate, and arseniate of lead are not uncommon productions in the cavities of the veins of sulphuret of lead. The chromate, molybdate, and sulphate of lead, are more rare.

ad, &c. 826 lysis. 3. The sulphuret of lead, which is the most common ore, is reduced by roasting, and then fusing with black flux. The other ores of lead are to be analyzed according to the nature of the acid with which they are combined. To obtain lead in a state of purity, it may be dissolved in nitric acid, and precipitated by means of sulphate of soda. The precipitate, which is sulphate of lead, is well washed, and reduced in a crucible, by fusing it with three times its weight of black flux.

827 perties. 4. Lead is of a grayish or bluish white colour. It has considerable brilliancy, but it soon tarnishes when exposed to the air. The specific gravity of lead is 11.352. It gives out a peculiar odour when it is rubbed; it has at first scarcely any perceptible taste; but a disagreeable impression after some time remains on the tongue. When it is taken internally, it produces violent effects on the animal economy, even in very small quantity. The colica pictonum or dry belly-ach of the West Indies, or, as it is called in this country, *mill-reek*, which is a violent affection of the bowels, is occasioned by this metal being taken internally, either combined with some liquid, or in the state of vapour. This terrible disease often terminates in palsy. Lead stains the finger or paper of a bluish colour. It is one of the softest of the metals. It may be scratched with the nail or cut with a knife. It possesses considerable malleability, and may be reduced to plates thinner than paper. It has no great ductility, and its tenacity is less than that of the other metals. A lead wire of about $\frac{1}{12}$ of an inch in diameter can support only a weight of about 18 lb.

1828 on of t. 5. Lead is very fusible. It melts at the temperature of 540°, or, according to the estimation of Guyton, at 594°. When it is kept a long time melted, and at a red heat, it sublimes, and evaporates in the air. By slow cooling it crystallizes in quadrangular pyramids composed of octahedrons.

1829 dation. 6. When lead is exposed to the air, it soon tarnishes, is deprived of its lustre, and becomes first of a deep gray, and afterwards of a grayish white colour; but this process is extremely slow, for the white crust which is formed on the surface defends the metal from the action of the air, and its farther oxidation by absorption of oxygen.

When lead is melted in the open air, and heat continued, an iridescent pellicle is formed on the surface, which afterwards assumes a uniform gray colour. When this is removed, another pellicle is formed, and in this

1830 y oxide. way the whole may be converted into an oxide. When these pellicles are heated and agitated together, the whole is converted into a grayish powder, mixed with yellowish or greenish spots. This is the gray oxide of lead, which is the first state of its oxidation.

1831 low. When the gray oxide of lead is more strongly heated in contact with air, it absorbs a greater quantity of oxygen, and is converted into a yellow oxide, which is known in the arts by the name of *massicot*. It contains about nine parts of oxygen in the hundred. This oxide, which is much employed in some of the arts, is prepared in the large way, by constantly agitating it while heated, in contact with air, without applying so great a heat as to reduce the metal to the state of the next oxide.

1832 l. If this oxide of lead be reduced to a fine powder, and exposed to a strong heat in a furnace for about 50 or 60 hours, it is converted into a red powder, which is well known by the name of *minium*, or *red lead*. The heat necessary for this conversion is that of a cherry-red, in a reverberatory furnace. Lead, &c.

Lead is susceptible of combining with another portion of oxygen, and of forming another oxide. If a quantity of red oxide of lead, according to the process of Proust and Vauquelin, be put into a vessel with water, and oxymuriatic acid gas be passed through it, the oxide assumes a deeper colour, and is dissolved. By adding potash to the solution, the lead is precipitated of a brown colour, which is the brown oxide of lead. It is of a shining brown colour, and is composed of 1833 Brown.

Lead	79
Oxygen	21
	100

By the action of the blow-pipe it becomes yellow, and melts. On burning coals it is reduced, and when heated in a retort, gives out pure oxygen gas, and is converted into a vitreous matter. It inflames sulphur by triturating it with the oxide, and gives out a bright flame.

7. When lead has been converted into an oxide, and when this oxide is exposed to a more violent heat, it melts into a kind of glass, or semivitrified matter. In this state it is known by the name of *litharge*. It consists of small reddish brilliant scales, which from the colour is called *litharge of gold*. When it has been exposed to a greater degree of heat, and is more vitrified, it is distinguished by the name of *litharge of silver*. 1834 Litharge.

8. There is no action between lead and azote, hydrogen or carbon. Water has no action on lead, but it seems to promote the oxidation of this metal, when it is in contact with air. Leaden vessels which are frequently moistened with water, are covered with a white crust when exposed to the air.

9. Lead combines with phosphorus, and forms with it a phosphuret. This may be prepared by projecting phosphorus on lead melted in a crucible, or by distilling phosphorus with lead in a retort. The phosphuret of lead is of a silvery white colour, with a little of a bluish shade. It is of a lamellated structure, and may be separated in plates by hammering. It is so soft that it may be cut with a knife. It is somewhat less fusible than the component parts. During its fusion, a small quantity of phosphorus separates, and takes fire on the surface. The component parts of this phosphuret are, 1835 Phosphuret. 1836 Composition.

Lead	88
Phosphorus	12
	100

10. Sulphur combines readily with lead, either by melting sulphur and lead together in a crucible, or by throwing sulphur on melted lead. A black matter is thus obtained, of a brilliant appearance, fibrous texture, and less fusible than lead. This compound is brittle, and resembles the native sulphuret of lead, or *galena*. The component parts of this sulphuret are, 1837 Sulphuret.

Lead

Lead	86.8
Sulphur	13.2
	100.0

1838 Affinities. 11. Lead enters into combination with the metals, and forms alloys, and with the acids, and forms salts. The order of the affinities of lead and of its oxide is the following:

Lead.	Oxide of Lead.
Gold,	Sulphuric acid,
Silver,	Saclactic,
Copper,	Oxalic,
Mercury,	Arsenic,
Bismuth,	Tartaric,
Tin,	Muriatic,
Antimony,	Phosphoric,
Platinum,	Sulphurous,
Arsenic,	Suberic,
Zinc,	Nitric,
Nickel,	Fluoric,
Iron,	Citric,
Sulphur.	Lactic,
	Acetic,
	Boracic,
	Prussic,
	Carbonic.

I. Salts of Lead.

1. Sulphate of Lead.

1839 Preparation. Sulphuric acid has no action on lead in the cold; but when lead is boiled with the acid concentrated, it decomposes it, and sulphurous acid gas is disengaged with effervescence. The lead is converted into a white thick mass, which remains at the bottom of the vessel. Sulphate of lead may also be obtained by adding sulphuric acid or an alkaline sulphate to acetate of lead. This salt is precipitated in the state of a white powder. The white mass obtained by the first process, being washed with water, separates into two portions, one of which is oxide of lead containing a little sulphuric acid, and the other portion, which is sulphate of lead, is soluble in water, and may be obtained crystallized in needles. The specific gravity of this salt is 1.8742. It has scarcely any taste. It is found native, and crystallized in regular octahedrons, or four-sided pyramids,

1840 Composition. or transparent tables. The component parts of native sulphate of lead are, according to

	Kirwan.	Klaproth.
Oxide	75.00	70.50
Acid	23.37	25.75
Water	1.63	2.25
	100.00*	98.50†

This salt is deprived of great part of its acid by means of the alkalies.

* *Min. Wat.* p. 274.
† *Essays*, ii. 131. *Transl.*

2. Sulphite of Lead.

1841 Preparation. Sulphurous acid has no action on lead; but it combines readily with the oxide of lead, with a smaller proportion of oxygen. The red oxide of lead, added to liquid sulphurous acid, soon becomes white; the acid is deprived of its colour, and there is formed a saline mass of sulphate and sulphite of lead. The sulphite of lead cannot be obtained separately, but by treating the white oxide of lead separated from the nitrate by means of sulphurous acid. The sulphite of lead is tasteless and insoluble. By the action of the 1842 Action of heat. blow-pipe on charcoal, it melts, gives out a phosphoric flame, and becomes of a pale yellow colour on cooling. When it is heated for a longer time, it swells up, and is entirely reduced to the metallic state. When distilled in close vessels, it gives out water, sulphurous acid, and sulphur, and there remains behind, sulphate of lead of a greenish yellow colour. It is decomposed with effervescence and the evolution of sulphurous acid, by means of sulphuric and muriatic acid. It is not de- 1843 Decomposition. composed by nitric acid, but is converted into a sulphate, and red fumes of nitrous gas are given out. If, in place of treating the red oxide with sulphurous acid, this oxide be exposed to a red heat, along with sulphite of soda, the oxide is reduced, and the sulphite of soda is converted into a sulphate, but with excess of soda, because the sulphuric acid formed, cannot saturate the same quantity of soda. Hence it appears, that the red oxide of lead gives up part of its oxygen to the sulphurous acid when it is uncombined, and the whole of its oxygen to the acid, when it is in combination with potash or soda *.

* *Fourc.* viii. 86.

3. Nitrate of Lead.

1844 Preparation. 1. Nitric acid, a little diluted with water, acts upon lead, oxidates it, and dissolves it with effervescence. If the acid be too strong, there remains behind a dry oxide. This oxide is equally soluble in nitric acid. No precipitate is formed in the solution by the addition of water. It has at first a sweetish, then an astringent, acid taste. By evaporating the solution, it affords on cooling, regular crystals in the form of flat triangles; and by slow, spontaneous evaporation, the angles are truncated. Sometimes six-sided truncated 1845 Properties. pyramids are obtained, with the faces alternately broad and narrow. These crystals decrepitate strongly on burning coals, and give out brilliant sparks. The salt is decomposed, and a yellow or red oxide of lead remains behind. Nitrate of lead is decomposed by the alkalies, and precipitated in the form of white oxide. It is precipitated of a black colour, by means of the sulphurets and hydrosulphurets; it is also decomposed by sulphuric acid and the sulphates, which form a thick, white, soluble precipitate of sulphate of lead. Sulphurous acid also precipitates this salt in the form of sulphate of lead.

1846 With the white oxide. 2. The former salt is a compound of nitric acid and the yellow oxide; but when nitric acid combines with the white oxide, the salt crystallizes in yellow coloured brilliant scales, which are very soluble in water. This salt may also be prepared by boiling together a quantity of nitrate of lead with the yellow oxide, along with lead in the metallic state. The lead deprives the yellow oxide of part of its oxygen, and the whole is converted into the white oxide, and combines with the acid.

1847 Action of red oxide. 3. But if nitric acid be poured on the red oxide of lead, heat is produced, the oxide becomes white, part is dissolved, and part falls to the bottom in the form of a black powder. This powder is the brown oxide of lead, with the greatest proportion of oxygen, part of which it has derived from the red oxide, which is then converted into the white. About $\frac{6}{7}$ of the red oxide are dissolved in the acid, but are previously reduced to the state of white oxide, and the oxygen which has been given out, combines with the remaining $\frac{1}{7}$, and converts it to the state of brown oxide. Thus it appears, that the red and the brown oxides of lead do not form compounds with nitric acid. They must be deprived of a portion of their oxygen, and converted into the white or yellow oxides, before they are soluble in this acid.

4. Muriate of Lead.

1. Muriatic acid acts feebly on lead or its oxide; but when it is heated with the latter, part of the oxide combines with the acid, becomes soluble with excess of acid, and affords crystals in the form of shining silky needles, which are not deliquescent in the air, but are soluble in water, and have an astringent taste. This salt may be formed by adding an alkaline muriate to a solution of nitrate of lead. A white thick precipitate is immediately formed. The muriate of lead thus obtained, has a sweetish taste, and is soluble in about 30 times its weight of water. When heated, it readily melts, and gives out a white vapour, which condenses into a crystalline powder. When this salt is melted, it assumes the appearance of a semivitreous, shining, grayish mass, which has been called *plumbum corneum*, or *horny lead*. This salt is decomposed by sulphuric acid. Its component parts are, according to

	Klaproth.	Kirwan.
Acid	13.5	18.23
Oxide of lead	86.5	81.77
	100.0	100.00

2. When muriatic acid is slightly heated with the red oxide of lead, the acid is converted into oxymuriatic acid; while the oxide, deprived of part of its oxygen, unites to another portion of the acid, and forms muriate of lead in the state of white powder.

5. Hyperoxymuriate of Lead.

When oxymuriatic acid gas is made to pass through water, having a white, yellow, or red oxide of lead, it is absorbed. The oxide becomes at first black or brown, and is then dissolved. The hyperoxymuriate which is formed, remains in solution of a yellow colour. This solution being precipitated with potash or soda, the oxide of lead is deposited, of a reddish brown colour. This salt may be obtained by pouring oxymuriatic acid on nitrate of lead. No precipitate is at first formed, but in the end a brownish red powder appears. This salt is more soluble than muriate of lead, and is readily decomposed. The brown oxide of lead, which is obtained by decomposing this salt, according to the experiments of Vauquelin, possesses very different properties from those of the other oxides of this metal. It is of a deep, shining, velvet-brown colour. Heated with the blow-pipe, it becomes yellow, and melts. On red-hot coals it is reduced; it gives out pure hydrogen gas, when it is heated in a retort, and there remains behind a litharge of lead. It dissolves in nitrous acid, but is insoluble in nitric acid. The addition of sugar, honey, or some vegetable matter, by depriving it of part of its oxygen, renders it soluble in this acid.

Lead, &c.

6. Fluate of Lead.

This salt may be formed by pouring a solution of an alkaline fluate into a solution of nitrate of lead. An insoluble insipid salt is thus formed, which is decomposed by sulphuric, nitric, and muriatic acids.

7. Borate of Lead.

This salt is formed in the same way as the last, and is in the state of white powder. It melts before the blow-pipe, into a colourless glass.

8. Phosphate of Lead.

1. Liquid phosphoric acid acts very slowly upon lead, and converts it into a white, insoluble phosphate. It may be formed, however, by adding an alkaline phosphate to the nitrate of lead. With an excess of acid this salt becomes fusible by heat, and when it cools, assumes the form of regular polyhedrons. It is decomposed by red-hot charcoal, which converts it into phosphorus and lead, while the carbon of the charcoal is converted into carbonic acid. It is decomposed by sulphuric, nitric, and muriatic acids, and by the alkaline carbonates. 1852 Preparation.

2. This salt is frequently found native, crystallized in six-sided prisms, of a green or yellow colour. It is soluble in pure soda, but insoluble in water. The component parts of a phosphate of lead from Wanlockhead in Scotland, according to the analysis of Klaproth, are the following: 1853 Native.

Oxide of lead	80.00
Phosphoric acid	18.00
Muriatic	1.62
	99.62 *

* Essays, ii. 125. Transl.

9. Carbonate of Lead.

1. Carbonic acid which has no action on lead, combines with its oxide; which is converted into the carbonate of lead; or this salt may be prepared by the decomposition of a soluble salt of lead by an alkaline carbonate. Thus precipitated, it is in the state of white powder, which has neither taste nor smell, and is insoluble in water, but it is soluble in pure potash. 1854 Preparation.

2. This salt is frequently found native, of a whitish colour, and crystallized in tables, in six-sided prisms, or in regular octahedrons. The specific gravity is 7.2357. It is insoluble in water. By the action of the blow-pipe on charcoal, the acid is driven off, and the lead is revived. The component parts of carbonate of lead are, according to 1855 Native.

	Bergman.	Klaproth.
Acid	16	16.33
Yellow oxide	84	83.67
	100	100.00

3. Ceruse, or white lead, which is employed as a paint, is a carbonate of lead, combined with a certain proportion 1856 White lead

proportion of oxide. It is prepared by exposing thin plates of lead to the vapour of vinegar. A range of pots are placed on tanners bark or horse dung, that they may receive a moderate heat. These are covered with plates of lead, which are full of holes. Another range of pots is placed above these, covered in like manner with plates of lead, and so on, till the whole chamber is filled. The acid is decomposed; part of the lead remains in the state of oxide, while the greatest proportion is converted into a carbonate, which is the white lead of commerce.

10. Arseniate of Lead.

When lead is digested in a solution of arsenic acid, the surface is blackened, and becomes covered with a white powder. When lead filings are distilled with double their weight of solid arsenic acid, the mixture melts into a transparent mass. A small quantity of arsenious acid is separated, and there remains behind a whitish glass, which being diluted with water, lets fall a white powder, whilst part of the arsenic acid is dissolved. The lead in this case has deprived the arsenic acid of part of its oxygen, and in the state of white oxide has combined with another portion of the acid. The arseniate of lead is not soluble in water. By heat
1857 Composition. it fuses into a white glass. This salt is found native, and by the analysis of Mr Chenevix it is composed of

Acid	33
White oxide	63
Water	4
	100

11. Tungstate of Lead.

Tungstic acid separates the oxide of lead from its solution in nitric acid, and forms a tungstate of lead, in the form of a white powder.

12. Molybdate of Lead.

When molybdic acid is added to the solution of lead in nitric acid, it forms a copious white precipitate, which is molybdate of lead. This salt is found native, and crystallized in cubes or rhomboidal plates. It is of a yellow colour, insoluble in water, but soluble in fixed alkalies and nitric acid. It is decomposed by muriatic acid. The component parts, as ascertained by Klaproth, are,

Acid	34.7
Oxide	65.3
	100.0

13. Chromate of Lead.

An alkaline chromate mixed with the solution of nitrate of lead, forms a precipitate in the state of red powder, which is chromate of lead. This salt is found native, of a reddish yellow colour, and crystallized in four-sided prisms, terminated by four-sided pyramids. The specific gravity is about 6. It is soluble in the fixed alkalies, but insoluble in water. It is decomposed by muriatic and sulphuric acids, but dissolves without decomposition in nitric acid. According to the analysis of Vauquelin, it is composed of

Acid	34.9
Oxide	65.1
	100.0

14. Acetate of Lead.

1. The combination of acetic acid and lead was formerly known by the names of *extract of Saturn*, *salt of Saturn*, *sugar of Saturn*, or *sugar of lead*. This acid oxidates lead, and dissolves the oxides with great facility. It is formed by dissolving carbonate of lead or ceruse in acetic acid, or by exposing thin plates of lead to the action of acetic acid in earthen vessels. After the acid has been sufficiently saturated, and the solution concentrated by evaporation, the acetate of lead is deposited in small crystals. 185[?] Names. 185[?] Preparation.

2. This salt is in the form of small crystals, which are flat, four-sided prisms, terminated by two-sided summits. It has an astringent sweetish taste. The specific gravity is 2.345. It is not very soluble in water, without an excess of acid. It undergoes no change by exposure to the air. By its solution in water, a small quantity is deposited in the form of white powder, which is a carbonate of lead, formed by the carbonic acid which exists in the water. 186[?] Properties.

3. Acetate of lead is decomposed by sulphuric, muriatic, fluoric, and phosphoric acids. It is decomposed by heat. By distillation it affords, according to the experiments of Proust, from 160 parts of the salt 12 parts of slightly acidulated water; with a greater heat, 72 parts of a yellow liquid, having the odour of alcohol, which had something of an empyreumatic smell. Ammonia was disengaged, by adding lime to the liquid; and when the liquid was saturated with potash, and remained at rest for 24 hours, a third part of oil separated, and floated on the surface. This oil, which had a strong odour, was removed, and the liquid distilled with a moderate heat. The first part that came over mixed with water like alcohol, and was almost as volatile as ether. When it was brought into contact with a burning body, it gave out a white flame. 186[?] Decomposition.

15. Oxalate of Lead.

Oxalic acid very readily tarnishes lead, and at last corrodes it. It readily dissolves the oxide; and when it is saturated, the solution becomes thick, and deposits small shining crystals, which becomes readily opaque by exposure to the air. This salt may be formed by pouring oxalic acid into the solutions of nitrate, muriate, or acetate of lead. It is scarcely soluble in water, without an excess of acid. The component parts are,

Acid	41.2
Oxide	58.8
	100.0

16. Tartrate of Lead.

Tartaric acid combines with the oxide of lead, or forms a precipitate in the state of an insoluble white powder,

powder, from the solution of lead in nitric and muriatic acids. It is composed of

Acid	34
White oxide	66
	100*.

17. Tartrate of Potash and Lead.

This triple salt is obtained by boiling the oxide of lead in tartar with water. It is insoluble, and is not decomposed by the alkalies.

18. Nitrate of Lead.

By adding citric acid to a solution of acetate of lead, a citrate of lead precipitates in the form of powder, which is scarcely soluble in water.

19. Malate of Lead.

This salt is obtained by adding malic acid to a solution of the nitrate or acetate of lead. The malate of lead precipitates in the form of fine light flakes. It is soluble in acetic and diluted nitric acids.

20. Benzoate of Lead.

Benzoic acid has but a feeble action on lead. By evaporating the solution, crystals of a brilliant white colour are obtained, which are benzoate of lead. This salt undergoes no change by exposure to the air, is soluble in water and alcohol, is decomposed by heat, and by the sulphuric and muriatic acids.

21. Succinate of Lead.

Succinic acid combines with the yellow oxide of lead, and yields slender foliated crystals, which are nearly insoluble in water, but soluble in nitric acid.

22. Saccolate of Lead.

When saclactic acid is added to solution of nitrate of lead, a white precipitate is obtained, which is saccolate of lead.

23. Suberate of Lead.

Suberic acid forms a precipitate when added to the solution of lead in acetic and nitric acids.

24. Lactate of Lead.

Lactic acid, after it has been digested upon lead for some days, dissolves a portion of it. The solution has a sweet, astringent taste, but it does not crystallize.

II. Action of the Alkalies, &c. on Lead.

1. The alkalies and earths have no action whatever on lead. The alkalies, however, promote its oxidation by the air, on account of the attraction which they possess for the oxide of lead.

2. The alkalies and alkaline earths unite readily with the oxide of lead. Lime water digested some time with oxide of lead in the state of litharge, dissolves this oxide better than the red. When the solution is evaporated, it affords small, transparent, iridescent crystals, not more soluble than lime. The alkaline sulphates decompose this compound of oxide of lead and lime. It is also decomposed by sulphurated hydrogen gas, and by sulphuric and muriatic acids, which latter convert the lead into a sulphate and muriate. This solution blackens wool, the nails, hair, the white of an egg; but has no action, and produces no change, on silk, on the skin, or the yolk of an egg. It has been observed, that the simple mixture of red oxide of lead and of lime, which latter converts it to white, produces a black colour on animal matters. It is sometimes employed for dyeing the hair. It had formerly been observed by Bergman, that the caustic fixed alkalies dissolve the oxide of lead, which takes place when these bodies are added in excess to the precipitate of this metal from its solution.

1864 Earths.

3. The earths, but especially alumina and silica, readily combine with the red oxide of lead, by the action of heat; and, when the proportion of oxide is considerable, the compound is a heavy, uniform, vitreous mass, which has been called *glass of lead*. It is on account of the strong tendency of the oxide of lead to vitrification, and which it communicates to earthy matters, that it is employed in the composition of glass in the proportion of from $\frac{1}{3}$ to $\frac{1}{6}$. This oxide was only employed formerly, for the preparation of enamels, and for glazing pottery and stone ware; but it is now generally used after the example of the English manufacturers, in the fabrication of glass, in most countries of Europe.

1865 Sulphates, &c.

4. Lead has no action on the sulphates. It burns slowly with the assistance of the nitrates. When nitre, in the state of fine powder, is thrown into melted lead, raised to a red heat, there is scarcely any perceptible flame; and, when the action has ceased, the oxide is found in small yellowish semivitrified scales, similar to those of litharge.

1866 Muriates.

5. There is a perceptible action between lead and the muriates, some of which have given rise to several important processes in chemistry, and in the arts. It had been long observed, that a plate of lead immersed in water, saturated with muriate of soda, was soon covered with a crust of white oxide. It was also known, that the red oxide of mercury and litharge became white when kept in contact with muriate of soda dissolved in water. This process, which is promoted by agitation, is one of the great desiderata of modern chemistry, to be able to decompose common salt for the purpose of obtaining the soda. It was at first supposed, that this was a partial decomposition, from which a small quantity of muriate of lead only was obtained; that the decomposition was aided by heat; and that it was by this process that a brilliant yellow muriate of lead, much employed in painting under the name of *English yellow*, was prepared.

1867 Decomposition of muriate of soda.

This subject has been greatly elucidated by the experiments and researches of Vauquelin. He took seven parts of litharge reduced to powder, and one of muriate of soda, mixed together, and moistened with a sufficient quantity of water, to reduce them to the liquid state, and then agitated the mixture for several hours to promote the reciprocal action. The oxide became white, and increased in volume, and the mixture absorbing the water, became of a more solid consistence. Having added new quantities of water during four days, and diluted the whole in seven or eight parts of this

Lead, &c. this liquid, it was filtered. The liquid, which was now sensibly alkaline, contained a little muriate of lead, but no trace of muriate of soda. When it was evaporated to $\frac{1}{10}$ of its bulk, it yielded crystals of carbonate of soda, which were opaque, by being contaminated with muriate of lead. The oxide of lead which remained, had increased about $\frac{1}{5}$ of the weight; it became of a fine citron-yellow colour, with a moderate heat, and lost 0.025 of its weight. It was insoluble in water. Soda dissolved a portion of this oxide, as did also diluted nitric acid. By this means the muriate of lead was separated pure and crystallized; and the mass which remained after the action of muriate of soda and lead, exhibited the characters of a muriate of lead containing an excess of oxide.

From these experiments Vauquelin concludes, that the litharge which has been employed in the decomposition of sea salt, is a muriate of lead with excess of oxide; that the caustic alkalies dissolve this salt, but do not decompose it; that the affinity of muriate of lead for an excess of the oxide of this metal, is the cause of the decomposition of muriate of soda by means of litharge; that the excess of oxide gives to the muriate of lead the property of assuming a brilliant yellow colour by heat, a property which the simple muriate of lead does not possess; that the same excess of lead renders it insoluble in water, and that this excess may be taken up by the nitric acid, which reduces it to the state of ordinary muriate of lead. The same philosopher has confirmed these inferences, by shewing that caustic soda decomposes the common muriate of lead, only by bringing it to the state of muriate with excess of oxide, which is characterized by being in the form of powder, and the yellow colour, which is communicated by heat, and its decomposition by nitric acid, which converts it into nitrate of lead, and simple muriate of lead. Thus, it appears, that the oxide of lead decomposes the muriate of soda, by double affinity; namely, by the affinity of the oxide for muriatic acid, and that of the muriate of lead for an excess of oxide. A considerable quantity of the latter, therefore, is necessary for the complete decomposition. Five-sixths, at least,
1868 Muriate of ammonia. are required to form the muriate with excess of oxide. Litharge then decomposes sea salt completely, when in sufficient quantity, while soda only decomposes the muriate of lead partially, and reduces it to the state of muriate with excess of oxide; but the carbonate of soda effects the entire decomposition of this salt.

6. The decomposition of muriate of ammonia by lead, and especially by its oxide, has been long known. The oxides of lead triturated with this salt in a mortar in the cold, disengage ammonia, which is very perceptible by its smell. By distilling a mixture of one part of red oxide of lead and two of muriate of ammonia in a retort, very pure caustic ammonia is obtained. If the red oxide has remained for any length of time exposed to the air, it gives out, during the process, a little carbonate of ammonia. The hyperoxymuriate of potash produces a detonation with lead. A mixture of three parts of this salt with one of lead, gives out a vivid flame by percussion. The other salts, as the phosphates, fluates, &c. have no effect on lead. By the action of the blow-pipe, they combine with its oxides, and form yellowish, or gray, opaque, or transparent glasses.

III. Alloys.

1. Lead combines with arsenic by fusion, and the compound is a brittle lamellated alloy. When the oxides of these metals are combined together by means of heat, a vitreous mass of a red colour is formed. 1869 With arsenic.

2. The alloys of lead with tungsten, molybdena, and the newly discovered metals, are not known.

3. Cobalt seems to have little affinity for lead. 1870 Cobalt. Equal parts of the two metals being fused together, were found, when the mass cooled, to be in separate masses. The heaviest metal occupied the inferior part of the vessel, and the lighter the upper part. An alloy of lead and cobalt has been formed by introducing cobalt in powder within plates of lead, and covering them with charcoal, to exclude the air. A brittle mass, which assumed a better polish than lead, was obtained from equal parts of the two metals, by the application of heat. The two metals in different proportions afforded an alloy which differed in hardness, specific gravity, and malleability, according as the one or the other metal predominated.

4. Lead forms with bismuth an alloy of a close grain, 1871 Bismuth. and a dark gray colour. This alloy, when the bismuth is not in great proportion, possesses considerable ductility. Bismuth has the property of increasing the tenacity of lead. The specific gravity of the alloy of lead and bismuth is greater than the mean.

5. When lead is combined with one-eighth of its 1872 Antimony. weight of antimony, it forms an alloy which possesses great tenacity. When they are combined in equal parts, the alloy is very brittle. Two parts of lead with one of antimony, give a brittle alloy in small grains similar to those of iron. Four parts of lead with one of antimony, afford an alloy of greater ductility, and in larger grains. Four parts of lead with one-half of antimony, give a very soft metal in fine grains like steel, and having the same colour. The alloy of 16 parts of lead and one of antimony, differs only from lead in hardness. This alloy has a greater specific gravity than the mean, and possesses considerable tenacity. It is employed in the fabrication of printing types.

6. Mercury combines with lead very readily, and 1873 Mercury. in all proportions. An amalgam of lead and mercury may be formed by triturating the former in filings with the latter; or, by adding heated mercury to lead in fusion. This amalgam varies in solidity, according to the proportion of the two metals. It is of a white colour, is altered by exposure to the air, and affords crystals by cooling. The mercury is driven off by strong heat, and when it is triturated with water, a black powder, which is oxide of lead, separates. The amalgam of lead and mercury becomes very liquid, when it is triturated with the amalgam of bismuth. 1874 and bismuth. To equal parts of lead and bismuth melted in an iron vessel, half the quantity of the whole mass of hot fluid mercury was added, and the mixture was agitated till it cooled. A fluid amalgam was thus obtained, which does not become solid by rest, or exposure to the air, and which almost entirely passes through leather like mercury itself. This liquidity of lead and bismuth is ascribed to their increased capacity for caloric in a state of combination. When mercury is thus sophisticated, it may be detected by observing the

the smaller specific gravity, and subjecting it to the test formerly mentioned, of pouring it along a smooth
1875 inc. surface, when it is found to *drag a tail*.

7. An alloy of zinc and lead in equal parts is harder and whiter than lead, and is malleable. The lead is rendered volatile by the zinc, while the latter is in the proportion of 10 or 12 parts to one of the former; but if the zinc be in smaller proportion, it separates from the lead. The specific gravities of the alloys of zinc and lead are said to be greater than the mean of
1876 n. the two metals.

8. Lead combines with tin in all proportions. Lead, in general, is found to increase in density and hardness, when alloyed with tin. Three or four parts of tin with one of lead, according to Muschenbroek, form an alloy which possesses twice the hardness of pure tin. The alloy of three parts of tin and one of lead possesses the greatest tenacity of any proportion of these metals. Two parts of lead and one of tin
1877 lder. compose an alloy which is more fusible than either of the metals. This is the composition of common solder. Tinfoil is a compound of tin and lead; and the sheet lead employed for lining the boxes in which tea is brought from China to Europe, contains a certain portion of tin, which gives it hardness. This, however, is also found to be alloyed with zinc and bis-
1878 n and muth. muth.

One of the most singular alloys of lead is that with bismuth and tin, which has been called, from its easy fusibility, the *fusible alloy*. Eight parts of bismuth, five of lead, and three of tin, are the proportions proposed by Darcet for this alloy, which is so fusible, that it remains liquid at the temperature of boiling
1879 es of d, &c. water. This alloy crystallizes by slow cooling.

Lead and its various preparations are applied to a great variety of purposes in the arts. In the metallic state it is employed in the construction of numerous vessels. In the state of oxide it is used as a paint, and in the fabrication of enamels for porcelain and pottery, and in the preparation of coloured glass and artificial precious stones. Some of its salts are of great importance in the arts, as the acetate in dyeing, and the carbonate or ceruse in painting.

The greatest caution ought to be observed, however, in the use of leaden vessels in domestic economy, in which substances are preserved which are to be taken internally, particularly those which contain acids that are apt to dissolve the lead; and as the effects of lead are so deleterious to the animal economy when taken internally, this caution cannot be too strictly observed.

SECT. XX. *Of Iron and its Combinations.*

1880 tory. 1. Iron is one of the most important and most useful of the metals, and it is fortunately one of the most abundant. It is supposed that it was not so early known as some of the other metals, which, on account of their scarcity and durability, have been held in higher estimation, and dignified with the name of *precious metals*. But perhaps the difficulty of extracting and working iron prevented it from being so generally applied to those purposes to which, on account of
1881 y abun-t. its valuable properties, it is peculiarly appropriated.

2. Iron, as it is the most useful of the metals, so, as it has been observed, it is the most abundant, and at the same time the most universally diffused. Iron exists in five different states, but in these it exhibits the greatest variety of any other of the metals. It is found in the metallic state; in that of alloy with other metals; in the state of sulphuret; in the state of oxide, and combined with the acids forming salts. 1882
Ores. 1. Iron has only been found native in insulated masses, one of which, discovered by Pallas in Siberia, and another, which was found in South America, long occupied the attention of philosophers in speculations and discussions concerning their origin. This point remained unsettled till the discovery of numerous other facts with regard to similar productions, which have proved, whatever may have been their origin or mode of formation, that these metallic masses have fallen from the atmosphere. 2. Iron is frequently found in the state of alloy with other metals; but in this state it is generally in very small proportion. 3. Combined with sulphur. This compound, or sulphuret of iron, which is known to mineralogists by the name of *pyrites*, is a frequent production among the ores of iron. Sulphuret of iron is found crystallized in a great variety of forms. Iron is also frequently found combined with carbon. This compound, now distinguished by the name of *carburet of iron*, was formerly known by the name of *black lead*, or *plumbago*. 4. But the most ordinary state of iron is that of oxide, and in this state it exhibits a great variety of forms. It is sometimes in irregular and insulated masses; sometimes regularly crystallized, and disposed in veins. 5. The native salts of iron are very numerous. It has been found in the state of sulphate, phosphate, carbonate, tungstate, and prussiate, and there is reason to believe, that it exists in combination with many other acids.

3. The method of assaying iron ores, or of extracting 1883 Analysis.
the metal from these substances with which it is combined, varies according to the nature of the ore. It is first reduced into powder, and exposed to heat, to separate the moisture or sulphur, or other volatile matters. Four parts of the ore are then to be mixed with an equal quantity of decrepitated muriate of soda, and the same quantity of a mixture of equal parts of fluor spar and lime, with one-half part of charcoal. This mixture is exposed to a red heat in a crucible nearly an hour, after which the iron is found in the metallic state at the bottom of the crucible. In the humid way, a given quantity of iron ore may be reduced to powder, and digested with six parts of muriatic acid, which combines with the iron, and other substances soluble in that acid, but leaves the sulphur and siliceous earth behind. The solution is then to be saturated with potash, by which the iron is precipitated in the state of oxide, along with the earths with which it had combined. The precipitate is to be well dried, and subjected to a red-heat. It is then to be reduced to powder, and digested with diluted nitric acid. The acid combines with the earths, but leaves the iron, because it is too highly oxidated to be soluble in this acid. The oxide, after being well washed, is mixed with charcoal, and exposed to a strong heat in a crucible, by which the oxygen is driven off, and the iron remains behind in the metallic state.

4. Iron has a peculiar metallic brilliancy. It is of 1884 Properties.
a grayish or bluish-white colour. The specific gravity of

of iron is from 7.6 to 7.89, and according to some, even 8.16. It has an astringent taste, and when it is rubbed, gives out a peculiar smell. One of the singular properties of iron, is that of possessing the magnetic virtue, or of being attracted by the magnet. Iron possesses a considerable degree of malleability, but in this property it is inferior to gold or silver. It is extremely ductile. It may be drawn out into wire almost as fine as hai . The tenacity of iron is very great. A wire .078 of an inch in diameter will support a weight, without breaking, equal to more than 500lbs. avoirdupois *. The texture of iron seems to be fibrous, and to this, it is supposed, are owing its great ductility and tenacity.

* *Annal. de Chim.* 25. 9.

1885 Action of heat.

5. Iron is one of the most infusible of the metals. It is said that it requires a temperature equal to more than 150° Wedgwood for its fusion. It becomes red long before it melts, and different degrees of temperature are distinguished by the different shades of red which it exhibits. The first is called a *dull red*, the second a *cherry red*, the third a *bright red*, and the fourth a *white heat*, or *incandescence*.

1886 Oxidation.

6. When iron is exposed to the air, the surface soon becomes tarnished, and is covered with a brown powder, which is called *rust*. This process is greatly promoted by the moisture of the atmosphere. This is the oxidation of the metal, and its conversion into an oxide, by combining with the oxygen of the atmosphere. The process of rusting, then, is the oxidation of the iron, and it is owing to the strong affinity which exists between iron and oxygen. But rust is not merely a compound of oxygen and iron. It has combined with a certain proportion of carbonic acid. This was formerly called *saffron of mars*.

1887 Oxides two.

7. There are two oxides of iron; the first, or that which contains the greatest proportion of oxygen, is

1888 Red oxide.

common rust, or, as it is denominated from its colour, brown or red oxide of iron. This oxide may be formed by exposing iron filings in an open vessel to a red heat, and agitating them till they are converted into a red powder. This oxide consists of

Oxygen	48
Iron	52
	100

The red oxide of iron cannot be decomposed by heat; but when it is exposed to heat with its own weight of iron filings, there is no evolution of any gas, but the

1889 Black.

iron filings are converted into a black powder, and the red oxide is converted into a similar powder. This is the black oxide of iron, which contains the smaller proportion of oxygen. This oxide is composed of

Oxygen	28
Iron	73
	100

This oxide may also be obtained by heating iron filings for some time in water at a temperature not under 70°, or by making the vapour of water pass through a red-hot tube containing iron wire, or small fragments of iron. The water in these cases is decomposed, the hydrogen escapes in the form of gas, and the oxygen combines with the iron. This oxide was formerly called *martial ethiops*. It is this oxide which is obtained by burning iron wire in oxygen gas.

8. There is no action between iron and azote. Hydrogen gas, which is obtained from the decomposition of water by means of iron filings and sulphuric acid, holds a small quantity of iron in solution. When hydrogen gas is brought into contact with the red oxide of iron, it deprives it of that proportion of oxygen which it contains above the black oxide, and converts it into this oxide.

1890 Carburet.

9. Iron combines very readily with carbon, and forms a carburet. When the charcoal combines with one-tenth of its weight of iron, it constitutes a carburet, which is found native, and distinguished by the name of *plumbago*, or *black lead*. This compound has a metallic lustre, is of a bluish or dark-gray colour, has a greasy feel, and stains the fingers. It is well known as the substance of which black-lead pencils are composed. But there is another combination of iron with carbon, which forms one of the most important compounds, on account of its valuable properties, and the numerons uses to which it is applied. This is steel. The different states of iron are owing to its being perfectly free from contamination with other substances, or to its combination with carbon in different proportions. In these different states it is distinguished by the names of *cast* or *crude iron*, *wrought iron*, and *steel*.

1891 Process for obtaining.

Crude or *cast iron*.—When iron is first extracted from its ores, it is in the state of what is called crude iron. Iron is generally obtained from ores in the state of oxide, and this is frequently mixed with clay. It must therefore be separated from these substances. This is accomplished by reducing the ore to small pieces, and mixing it with a flux composed of limestone and charcoal. It is then exposed to a very strong heat. For this process, furnaces are constructed in such a way, that the heat can be raised to a very high temperature. The nature of the process must be obvious. The carbon of the charcoal combines with the oxygen of the iron, and forms carbonic acid, which is driven off in the state of gas. By the strong heat to which the lime and the clay are subjected, they are fused together, and form a vitreous matter, which, being lighter than the iron, rises to the surface. The iron also is in a state of fusion at the bottom of the furnace. When the process is finished, a hole is opened, through which the fluid iron flows, and is received into moulds. This is crude or cast iron, or, in the langnage of the workmen, *pig iron*. In this state it is extremely brittle and hard, and possesses scarcely any malleability. It still contains a considerable proportion of carbon, and it is not entirely free from oxygen.

1892 Soft iron.

Wrought Iron.—The next process in the manufacture of iron, is to deprive it of those substances which alter its properties, and prevent its application to the purposes of pure or malleable iron. The crude iron is again introduced into a furnace, where it is melted by the flame of combustible substances, which is directed to its surface; and while it is in the state of fusion, it is constantly stirred, that the whole of it may be uniformly brought into contact with the air. At last it swells, and gives out a blue flame, and when this is continued for about an hour, the iron begins to acquire some consistency, and at last becomes solid. While it is hot, it is removed from the furnace, and hammered ron, &c. hammered by the action of machinery. It is then in the state of wrought or soft iron.

Steel.—This is soft iron or wrought iron combined with a certain portion of carbon. There are different processes for the preparation of steel; and the steel prepared by these processes has received different names.

1893 tural el. What is called natural steel, is prepared by exposing cast iron to a strong heat in a furnace, while its surface is covered with scoriæ. In this process, part of the carbon of the crude iron combines with the oxygen, from which it is not entirely free, and is driven off in the state of carbonic acid gas. The iron remains combined with a small portion of carbon. The steel prepared in this way is of no inferior quality.

1894 cemen- ion. Steel of cementation is prepared by arranging bars of pure iron and charcoal in powder in alternate layers, in large troughs or crucibles, which are carefully closed up with clay. These are exposed to heat in a furnace for the space of eight or ten days, when the bars of iron are found converted into steel. This is sometimes called *blistered steel*, from blisters which appear on the surface, or tilted steel, when it is drawn out into smaller bars by the hammer. By breaking it into pieces, and repeated welding in a furnace, and afterwards drawing it out into bars, it is converted into what is called *German* or *sheer steel*. Steel formed in this way is generally of a superior quality to natural steel.

1895 t. *Cast steel* is prepared by fusing natural steel with charcoal powder, and pounded glass, in a close crucible; or by melting together 30 parts of iron, one of pounded glass, and one of charcoal. By this process the best kind of steel is obtained, and it is this which is generally used for the finer kinds of cutting instruments. Different opinions have been entertained concerning the proportions of iron and carbon in the composition of steel. According to some, the proportion of carbon amounts to $\frac{1}{12}$ part, though, according to others, it does not exceed $\frac{1}{140}$ part.

1896 perties teel. Steel possesses very different properties from iron. It is extremely hard and brittle, does not yield to the file, and retains the magnetic virtue for any length of time. When it is hammered, its specific gravity is greater than that of iron. It is not malleable when cold, but it has this property when red hot, and it may be reduced to thinner plates than iron.

1897 tin- hed iron. There is a very easy test by which steel may be distinguished from iron. If a drop of diluted nitric acid be let fall on steel, and allowed to remain for a few minutes, it leaves behind, after it is washed off, a black spot, which is owing to the conversion of the carbon of the steel into charcoal, by combining with the oxygen of the acid. But if nitric acid is dropt on iron, a whitish gray spot remains.

1898 sphu- 10. Iron combines with phosphorus, and forms with it a phosphuret. It may be formed by melting in a crucible 16 parts of phosphoric glass with 16 parts of iron, and one-half part of charcoal in powder. The phosphuret of iron is of a white colour when it is broken, and it is observed crystallized in some points in rhomboidal prisms. It is of a striated and granulated texture, and is magnetic. This phosphuret may be formed, also, by dropping small bits of phosphorus into iron filings heated red-hot. This is the *siderite* of Bergman, in which he supposed he had discovered a new metal, to which he gave the name of *siderum*. Iron, &c.

What is called *cold short iron*, from its being brittle when cold, but malleable when it is heated, contains a certain portion of phosphate of iron, to which this property is owing. 1899 Cold short iron. It was in the investigation of the nature of this iron, that Bergman obtained, by means of sulphuric acid, a white powder, which was converted into a brittle metal of a dark-gray colour. By the experiments of Klaproth and Scheele it was proved, that cold short iron is a compound of phosphoric acid and iron.

11. Iron combines with sulphur by different processes. 1900 Sulphuret. A sulphuret of iron may be prepared by fusing together in a crucible equal parts of powdered sulphur and iron filings. This is a mass which is remarkably brittle and hard, and of a deep gray colour. If this mass be reduced to powder, and moistened with water, the water is decomposed, its oxygen combines with the sulphur, which is converted into sulphuric acid, and the iron is oxidated. If equal parts of sulphur and iron-filings be well mixed together by trituration, and a sufficient quantity of water be added, to form the whole into a paste, and if this mixture be exposed to the air, it soon becomes hot, swells up and cracks, exhaling the vapours of sulphurated hydrogen gas, and sometimes is spontaneously inflamed. During this action the water is decomposed, the iron is oxidated, and the sulphur is converted into sulphuric acid, while the hydrogen of the water combines with a portion of sulphur, and forms sulphurated hydrogen gas. By observing the phenomena of this process, which also takes place, it is said, when the mixture is buried under ground, Lemery supposed that he could explain the nature and cause of volcanic eruptions.

If a mixture of three parts by weight of iron filings, and one of powdered sulphur, be put into a glass vessel on burning coals, a sulphuret of iron is obtained, with some remarkable phenomena. It first melts, and then all at once becomes red-hot, and sometimes, when the quantity is considerable, is accompanied with an explosion, at the moment when the combination takes place. According to the experiments of Proust, the component parts of sulphuret of iron are,

Sulphur	60
Iron	40
	100

According to the experiments of the same chemist, 1901 Pyrites. pyrites, which is found in great abundance in nature, and usually crystallized in cubes, is sulphuret of iron combined with an additional portion of sulphur. The component parts of pyrites are,

Sulphuret of iron	80
Sulphur	20
	100

12. Iron enters into combination with the acids, and forms salts, and with the metals, and forms alloys.

The affinities of iron and its oxides are, according to 1902 Affinities. Bergman, in the following order.

 IRON,

Iron, &c.

IRON.	OXIDE of IRON.
Nickel,	Oxalic acid,
Cobalt,	Tartaric,
Manganese,	Camphoric,
Arsenic,	Sulphuric,
Copper,	Saclactic,
Gold,	Muriatic,
Silver,	Nitric,
Tin,	Phosphoric,
Antimony,	Arsenic,
Platinum,	Fluoric,
Bismuth,	Succinic,
Lead,	Citric,
Mercury.	Lactic,
	Acetic,
	Boracic,
	Prussic,
	Carbonic.

I. Salts of Iron.

1. Sulphate of Iron.

1903 Preparation. 1. Concentrated sulphuric acid has scarcely any action on iron. When it is heated, the acid is decomposed, part of its oxygen combines with the iron, and sulphurous acid gas is evolved. But when diluted sulphuric acid is added to iron filings, a violent effervescence takes place, and hydrogen gas is disengaged. In this process, the water, with which the acid is diluted, is decomposed, the oxygen of which combines with the iron, and converts it into an oxide, while the hydrogen escapes in the state of gas. 1904 Properties. The solution is of a green colour, and, by evaporation, it affords crystals of sulphate of iron, which are transparent, of a fine green colour, in the form of rhomboidal prisms, and having an acrid astringent taste. This salt almost always reddens vegetable blues. It is very soluble: two parts of cold water, and less than its weight of boiling water, are sufficient for its solution.

1905 Found native. 2. This salt is, in many places of the world, a natural production. It is obtained from the decomposition of pyrites, which it is sometimes found necessary 1906 Manufacture. to promote by art. This is done by throwing them together into heaps, and watering them occasionally. Sometimes previous roasting is necessary, either to render them more brittle, and to separate the additional portion of sulphur above what is necessary to constitute a sulphuret. After a certain time an efflorescence takes place, and the surface is covered with the sulphate of iron, which is dissolved in water, concentrated by boiling, and evaporated, and then allowed to cool and crystallize. 1907 Names. This salt, which was known to the ancients, was denominated *misy*, *sory*, and *calchantum*. It is distinguished in commerce by a great variety of names, as *martial vitriol*, *Roman vitriol*, and most commonly by the name of *green copperas* or *green vitriol*.

1908 Action of heat. 3. When sulphate of iron is strongly heated, it melts, and is deprived of its water of crystallization. Sulphurous acid gas is then given out, it assumes a red colour, and is reduced to the state of powder. This was formerly called *colcothar*, and *colcothar of vitriol*. It is the salt almost entirely decomposed. Part of the iron is strongly oxidated, and to this the red colour is owing. It is also mixed with sulphate of iron; but the iron in this case is also converted into the red oxide with the greater proportion of oxygen. This change, it is obvious, depends on the strong affinity of iron for oxygen; for by the action of heat, the sulphate of iron, of which the green oxide forms the base, is decomposed; the oxygen of the acid combines with the iron, and converts it into the red oxide; part of which, as it is formed, unites with the acid, before the whole of it is decomposed; and in this way the product of this process is the red oxide of iron mixed with the red sulphate.

The component parts of this salt are, according to Bergman, 1909 Composition.

Acid	39
Oxide	23
Water	38
	100

These properties vary, according to the estimation of Mr Kirwan, who makes this salt to be composed of

Acid -	26
Oxide -	28
Water of composition	8
of crystallization	38
	100

This distinction made by Mr Kirwan between the water of composition and that of crystallization, is, that the former is combined with the oxide, and the latter with the salt.

4. When this salt is exposed to the air, it becomes 1910 Action of air. of a yellowish colour, opaque, and a powder forms on the surface. The same thing takes place, if the salt in solution in water be exposed to the air. From a fine transparent green colour, it becomes turbid and is converted into a yellowish red liquid, and there is precipitated a powder of the same colour. This change is owing to the absorption of oxygen, and the conversion of the green oxide with the smaller proportion of oxygen, into the red oxide with the greater proportion. This process is greatly promoted by the direct combination of oxygen, or by the addition of those substances which are readily decomposed, and give out their oxygen. When oxymuriatic acid is added to the solution, it becomes instantly yellow, and there is formed a red precipitate. The same change takes place when the salt is dissolved in water impregnated with carbonic acid. The iron decomposes the acid, and combines with its oxygen. Thus it appears, that the decomposition of the sulphate of iron is owing, in all these cases, to the absorption of oxygen, and to the higher degree of oxidation of the metal.

5. The sulphate of iron is converted into the red 1911 Decomposition. sulphate by means of nitric acid. It is decomposed by the alkaline earths and the alkalies, which precipitate it in the form of oxide. The pure fixed alkalies and lime separate an oxide of a deep green colour, which, being exposed to the air, is converted into the red oxide. Ammonia affords a precipitate of a deeper green colour. The sulphurets and hydrosulphurets precipitate from the solution of green sulphate of iron, a black sulphurated or hydrosulphurated oxide. Most of the salts decompose the sulphate of iron. When equal

parts of nitrate of potash and sulphate of iron are distilled together in a retort, a weak nitric acid at first passes over, then a nitrous acid, and at last a very small quantity of sulphurous acid. The muriate of soda is decomposed by the sulphate of iron, in consequence of the disengagement of sulphuric acid, which separates the muriatic acid from its base. Sulphate of soda, combined with the oxide of iron in the state of a vitreous mass, remains in the retort. The hyperoxymuriate of potash converts the green sulphate of iron into the red. This salt is also decomposed by the alkaline phosphates, borates, and carbonates.

1912 repara-on.

Red sulphate of iron.—In the detail which has been given of the properties of the green sulphate of iron, it appears, that it has a strong affinity for oxygen. The oxide of the green sulphate contains 27 parts of oxygen; but by absorbing another portion of oxygen, it is converted into the red oxide, which contains 48 parts of oxygen. This salt may be obtained by the direct combination of the red oxide of iron with concentrated sulphuric acid, with the assistance of heat. The salt remains in the solution from which the green sulphate of iron has been crystallized. This solution has been called the *mother water of vitriol.* The red sulphate of iron is very different in its properties from the green sulphate. It does aot afford crystals; it is distinguished by its red colour, and it deposits the oxide of iron, when brought in contact with the air, or by

1913 roperties.

the action of heat. It deliquesces in the air, and at last becomes liquid. It is more soluble in water than the green sulphate; and also soluble in alcohol, by which it may be separated from the green sulphate, which is not affected by the alcohol. When iron filings are added to a solution of red sulphate of iron, part of the oxide is separated, another part gives up a portion of its oxygen to the iron, and is converted into the green sulphate. The same effect is produced, as M. Proust, by whom this subject has been greatly elucidated, observes, by means of other metals, as mercury, zinc, and tin. The two sulphates of iron are distinguished by other properties. The infusion of nut-galls produces no change in the green sulphate of iron, but gives a fine black precipitate with the red sulphate.

1914 tion of ussiate of ash.

Prussiate of potash occasions no change of colour on the green sulphate of iron, but produces a deep blue precipitate with the red sulphate; from which it appears that there are two prussiates of iron, corresponding to the two oxides. The white prussiate contains the green oxide with the smaller proportion of oxygen; the blue prussiate, the red oxide with the greater proportion. Another characteristic property is, that the green sulphate of iron absorbs nitrous gas in considerable quantity, and assumes a yellowish colour; but no such absorption is effected by the red sulphate.

2. Sulphite of Iron.

1915 epara-n.

1. Sulphurous acid is decomposed by iron, and the portion of sulphur which is separated, remains in combination with the salt as it is formed. When liquid sulphurous acid is added to iron filings, it assumes a deep yellow colour; some hydrogen gas is evolved, with a production of heat, and the yellow colour soon changes to a greenish shade. Sulphuric or muriatic acid, added to this solution, produces an effervescence, but without any precipitation. It is necessary to add the acid in considerable quantity to obtain a precipitate of sulphur in white powder. Fuming nitrous acid separates the sulphur of a yellow colour, and in the form of a ductile mass. From these facts it appears, that the first portion of acids acts only on the simple sulphite of iron; but when a greater quantity is added, the sulphurated sulphite is decomposed, and the sulphur is deposited.

1916 Properties.

2. The solution of iron in sulphurous acid, exposed to the air, deposits a reddish-yellow powder, and affords crystals which are surrounded with this reddish powder. By adding water to this mass, it dissolves the crystallized part, and leaves the red powder, which being dissolved in muriatic acid, gives up its iron, and deposits sulphur, which is still mixed with a little iron. This precipitate, dissolved in water, affords a sulphurated sulphite of iron, with a smaller quantity of sulphur than the first solution. Exposed to the air after the first precipitate is formed, the surface is soon covered with a red pellicle. A red powder is deposited, and afterwards crystals of sulphite of iron.

1917 Sulphurated sulphite.

1918 Properties.

3. The sulphurated sulphite of iron remains permanent by exposure to the air. Its simple sulphite absorbs oxygen. The sulphurated sulphur deposits sulphur by the action of the acids. The sulphite gives out sulphurous acid. The sulphurated sulphite is soluble in alcohol; the sulphite is insoluble.

4. The red sulphate of iron with the greater proportion of oxygen, does not produce the same effect on sulphurous acid, by converting it into sulphuric acid, and thus to form a sulphate of iron, as the oxide of manganese, because iron has a stronger affinity for oxygen than sulphurous acid. Thus we have seen, in consequence of the same affinity of iron for oxygen, that it decomposes sulphuric acid, and converts part of it into sulphurous acid, and that it even decomposes sulphurous acid, by separating its sulphur, which combines with the oxide as it is formed, and constitutes the sulphurated sulphite of iron. Neither of these sulphites of iron give a black colour with the infusion of nut-galls, nor a blue colour with the prussiate of potash; from which it is inferred that the iron is in its minimum state of oxidation, or in that of a green sulphate of iron.

1919 Strong affinity of iron for oxygen.

3. Nitrate of Iron.

1920 Preparation.

Nitric acid acts with great violence on iron; a great quantity of nitrous gas is disengaged, especially when the acid is a little diluted with water. When diluted acid has been employed, the solution is of a yellowish green colour, and when it is exposed to the air, it assumes a pale colour, in consequence of the nitrous gas which it holds in solution, combining with oxygen, and being converted into nitric acid. When it is exposed to the air, or concentrated by evaporation, a precipitate of the red oxide of iron is formed, because it combines with another portion of oxygen, and is converted from the green to the red oxide. By means of the alkalies, the green oxide is precipitated from this solution.

1921 Properties.

1922 Preparation.

Red nitrate of iron.—This is the salt formed with nitric acid and the red oxide of iron. It is prepared by exposing the green nitrate of iron to the air, which absorbing oxygen, is converted into the red nitrate.

If

Iron, &c.

1923 Properties. If iron be dissolved in concentrated nitric acid, the iron is converted into the red oxide, and this combining with the undecomposed acid, also forms the red nitrate of iron. The solution of this salt, which is of a brown colour, does not crystallize; when it is evaporated, it assumes the form of a jelly, or deposits a red powder. When this salt is heated, the acid is driven off, and the red oxide remains behind.

1924 Action of nut-galls, &c. The red nitrate of iron gives a black colour with the infusion of galls, and a blue precipitate with prussiate of potash, from which it appears, that the iron is in its highest degree of oxidation. This has been fully demonstrated by an experiment made by Vauquelin. Concentrated nitric acid was kept for some months on black oxide of iron, without any apparent change. The nitric acid, however, lost its acidity, and acquired a neutral taste. The liquid had assumed a brown colour; and large crystals, transparent and white, with a slight tinge of violet by looking through them, were formed. The crystals were in square prisms, terminated by two-sided ridges. This salt was extremely deliquescent, and had a pungent inky taste. The solution in water becomes red, as is also the precipitate, by means of ammonia and potash. Prussiate of potash gives a fine blue precipitate.

4. Muriate of Iron.

1925 Action of muriatic acid in the state of gas. 1. When iron filings are exposed to muriatic acid gas they soon become black, and are converted into the state of red oxide. This is owing to the decomposition of the water which the gas holds in solution. The bulk of the gas is increased by the addition of hydrogen gas, from this decomposition of water. When the whole of the muriatic acid is absorbed by the iron in the state of oxide, hydrogen gas only remains in the vessel in which the process has been conducted. When a little water is added, it assumes a green colour, having combined with the muriate of iron in the liquid state.

1926 In the liquid state. 2. Liquid muriatic acid acts upon iron in proportion to its degree of concentration, and the action is the more violent as it is less concentrated. An effervescence takes place, with the disengagement of hydrogen gas. As the iron is oxidated by the decomposition of the water, it is dissolved in the acid. This solution is of a pale yellowish colour, and of a strong styptic taste. When it is evaporated to the consistence of syrup, it forms, on cooling, a viscid mass, in which are found needle-shaped, deliquescent crystals. When this solution is exposed to the air, or strongly heated, it assumes a brown colour, and deposits oxide of iron.

Red muriate of iron.—When the red oxide of iron is treated with muriatic acid, the acid dissolves the iron, and forms a solution of a deep brown colour. During the solution, oxymuriatic acid is formed and given out, which is owing to the combination of a portion of the oxygen of the oxide with the muriatic acid. The oxide, thus deprived of a portion of its oxygen, combines with the muriatic acid, and forms red muriate of iron. When this solution is evaporated to dryness, it affords a yellow coloured mass, which is deliquescent in the air. This salt does not absorb nitrous gas, and it is converted into muriate of iron by the action of sulphurated hydrogen gas. When it is precipitated by the alkalies, the oxide is not farther changed, by exposure to the air. The infusion of nut-galls gives a black colour, and the prussiate of potash a blue.

5. Hyperoxymuriate of Iron.

This salt was formed by Mr Chenevix, by directing a stream of oxymuriatic acid gas into water, having red oxide of iron diffused in it; but its properties have not been ascertained.

6. Fluate of Iron.

Fluoric acid has a very powerful action on iron, which is owing to the evolution of hydrogen gas, and the decomposition of water. The iron is oxidated, and dissolves in the acid, forming a fluate of iron. The solution has a styptic, metallic taste, does not afford crystals by evaporation, but assumes a gelatinous form. Evaporated to dryness, it becomes hard and solid; and when strongly heated, the acid is driven off, and there remains behind the red oxide of iron, so that this salt is the red fluate of iron. The red oxide of iron is also soluble in fluoric acid, and communicates to it, according to Scheele, an aluminous taste. The fluate of iron is decomposed by sulphuric acid, and is precipitated by the alkalies and the earths.

7. Borate of Iron.

Boracic acid promotes the oxidation of iron by water very slowly. The borate of iron may be obtained by precipitating the sulphate of iron by means of the borate of soda, or borax. The borate of soda is precipitated in the form of a whitish powder. It is insoluble in water, but its other properties have not been ascertained.

8. Phosphate of Iron.

Phosphoric acid combines very slowly with iron, but after the oxidation of the metal has taken place, it forms with its oxide an insoluble salt. 1927 Preparation. The phosphate of iron may be prepared by adding a solution of an alkaline phosphate to a solution of sulphate or nitrate of iron. The alkali leaves the phosphoric acid, and combines with the sulphuric or nitric; while the phosphoric acid combines with the iron, and forms a phosphate of iron, which is in the state of white precipitate. Phosphoric acid combines with both oxides of iron, and constitutes either a green or a red phosphate. The red phosphate of iron may be obtained by precipitating the red muriate of iron in solution, by means of phosphate of potash or soda; and when this latter salt is treated with pure fixed alkalies, a brownish red powder is precipitated, which is the red phosphate of iron, with excess of base. It is nearly insoluble in acids and in water, but is soluble in the serum of blood, and the white of an egg, communicating to them a brown colour. 1928 Colours the blood. This salt exists in the blood of animals, and to it the red colour of the blood is owing.

9. Carbonate of Iron.

Carbonic acid combines readily with the oxide of iron. This is the case when iron rusts in the air; for in proportion as the oxidation of the iron is effected, it combines with the carbonic acid of the atmosphere, and

Iron, &c. and forms a carbonate of iron. This acid dissolved in water, when brought in contact with iron, acts upon it slowly; and there is disengaged, but without effervescence, a perceptible odour of hydrogen gas, and the water acquires in the course of a few hours an astringent taste. When this solution is exposed to the air, as Bergman observed, it becomes covered with an iridescent pellicle, and is decomposed by lime and the alkalies. But the alkaline carbonates have no such effect. This solution of the carbonate of iron converts the syrup of violets to a green colour. When it is evaporated, it deposits the salt in the form of a reddish ochre. It is this carbonate of iron which exists in mi-
1929 neral waters, to which, for this reason, the name of *chalybeate* has been given to waters. Rust is a carbonate of iron, mixed with the oxide. Fourcroy found by distilling it, that it yielded carbonic acid gas and a little water, and there remained black oxide of iron; and distilled with muriate of ammonia, it afforded carbonate of ammonia. The component parts of this carbonate, according to Bergman, are,

Acid	24
Oxide	76
	100

10. Arseniate of Iron.

1930 Preparation. 1. When iron is digested with arsenic acid, it is dissolved, and towards the end of the process the solution assumes the form of a jelly. But if it be conducted in a close vessel, no coagulation takes place. By exposing it to the open air for some hours, the surface becomes so solid, that the vessel may be inverted without any part of it dropping out. The solution which has not been exposed to the air, affords a precipitate with potash, of a greenish-gray colour, from which there is disengaged by heat, arsenious acid, and there remains behind a red oxide of iron. One part of iron-filings distilled with four of concrete arsenic acid, swell up and inflame; the metallic acid is sublimed, and brown spots appear on the sides of the retort. From this experiment it appears, that the iron has carried off the oxygen from the acid.

2. Arsenic acid does not precipitate iron from its solutions, but the arseniates or arsenites form a very soluble precipitate, which becomes yellow or red in contact with the air. This precipitate, which is fusible at a high temperature, exhales the odour of arsenic when it is melted, is converted into black scoriæ when it is treated with charcoal, gives out a considerable quantity of arsenic, and is reduced to the state of black oxide of iron.

1931 Green arseniate. 3. Arsenic acid combines with both the oxides of iron. The green arseniate of iron may be obtained by adding a solution of arseniate of ammonia to a solution of sulphite of iron. The arseniate precipitates in the form of powder which is insoluble in water. The component parts of this salt, according to Chenevix, are

Acid	38
Oxide	43
Water	19
	100

Red Arseniate of Iron.—This salt is prepared, either by boiling arseniate of iron in nitric acid, or by adding arseniate of ammonia to a solution of red sulphate of iron. It is composed of Iron, &c.

Acid	42.4
Oxide	37.2
Water	20.4
	100.0

Both these salts have been found native.

11. Tungstate of Iron.

Tungstic acid has no great effect on iron in the cold. Iron immersed in a solution of this acid in muriatic acid, communicates to it a beautiful blue colour, which is owing to the decomposition of the tungstic acid, and to its reduction to the metallic state by means of the iron. Tungstic acid precipitates from the solution of iron in sulphuric acid tungstate of iron. Tungstate of iron exists native under the name of wolfram.

12. Molybdate of Iron.

The alkaline molybdates which are soluble precipitate iron from its solution in acids of a brown colour.

13. Chromate of Iron.

If chromic acid, combined with an alkali, be added to a solution of the red sulphate of iron, a precipitate is immediately formed, of a brown colour; but if an alkaline chromate be added to the green sulphate of iron, the precipitate is green, because the chromic acid is deprived of a portion of its oxygen, and is converted to the state of green oxide *.

14. Columbate of Iron.

The columbate of iron is found native, and from the only specimen which has yet been discovered, Mr Hatchet extracted a new metal, which has been described under the name of columbium. It is of a dark-brownish gray colour, has a vitreous lustre, and a lamellated structure. According to Mr Hatchet, it is composed of

Columbic acid	77.5
Oxide of iron	21.0
	98.5

15. Acetate of Iron.

1. Acetic acid dissolves iron with effervescence, with the evolution of hydrogen gas. The liquid assumes a reddish-brown colour, and by evaporation becomes a gelatinous mass, in which are found long brown crystals. This salt has a sweetish styptic taste. It is decomposed by heat, and is deliquescent in the air. When it is heated till it no longer gives out the odour of vinegar, it lets fall a yellowish oxide, which is easily reduced, and is attracted by the magnet. The alkalies separate the iron nearly in the state of black oxide. This solution affords a black precipitate with the infusion of nut-galls, and a blue with the alkaline prussiates. 1932 Preparation.

* Fourcroy Connaiss. Chim. vi. p. 217.

2. The

Iron, &c.

1933 In the large way.

2. The solution of this salt is prepared in the large way with old iron, and vinegar obtained from grain or molasses. They are exposed to the air in large vessels, and as the fermentation of the liquid goes on, it is converted into acetic acid, the iron is oxidated, and dissolved by the acid. This solution is employed in dyeing and calico-printing.

Green acetate of iron.—This salt has been formed by dissolving sulphuret of iron in acetic acid. It affords crystals by evaporation, in the form of prisms, and of a green colour. The taste is styptic and sweetish. It gives a white precipitate with the alkaline prussiates, and no change is effected by the infusion of galls. When the solution of this salt is exposed to the air, it very readily absorbs oxygen, and is converted into red acetate of iron*.

* *Jour. Roy. Instit.* i. p. 308.

16. Oxalate of Iron.

1934 Preparation.

Oxalic acid produces a violent action on iron, with the evolution of hydrogen gas. This solution has a very styptic taste, and forms by evaporation prismatic crystals of a greenish yellow colour. When this solution is exposed to the air, or, when it is heated, it assumes a red colour, which is owing to the absorption of

1935 Composition.

oxygen, and its conversion into red oxalate. The oxalate of iron is composed of

Acid	55
Oxide	45
	100

Red oxalate of iron.—Oxalic acid precipitates the red oxide of iron from the solution in sulphuric acid, and forms an oxalate of iron of a fine red colour. The red oxalate of iron does not crystallize, and has little solubility in water. This has been proposed to be employed as a pigment. None of the acids dissolve the oxides of iron more readily than oxalic acid, and especially the gallate of iron. On this account it answers well for removing spots of ink, for which purpose also the acidulous oxalate of potash, or salt of sorrel, is also employed.

17. Tartrate of Iron.

1. Tartaric acid dissolves iron with effervescence, and the evolution of hydrogen gas. The solution becomes of a red colour, and assumes the form of a gelatinous mass, but does not crystallize. This is the red tartrate of iron.

2. But when tartaric acid is added to the solution of sulphate of iron, and heat applied, a precipitate is formed, which is not very soluble, but affords lamellated crystals. This is the compound of tartaric acid with the green oxide of iron, for it does not form a precipitate with the alkaline prussiates, without the addition of nitric acid.

18. Tartrate of Potash and Iron.

This triple salt, which was formerly called *chalybeated tartar*, and *tartarised tincture of Mars*, is prepared by forming into a paste with water, six parts of iron filings with 16 of tartar in powder. The mixture is left at rest for 24 hours; and being diluted with 192 parts of water, is boiled for two hours, when crystals are deposited of tartrate of potash and iron.

19. Citrate of Iron.

Citric acid acts upon iron with effervescence, occasioned by the emission of hydrogen gas. The solution becomes of a brown colour; it deposits by spontaneous evaporation, small crystals of citrate of iron. By evaporating with heat, it becomes black as ink, and ductile while it is hot, but falls to powder, and becomes very black when it is cold. This salt has a very astringent taste, and is very soluble in water. It is composed of

Acid	69.62
Oxide	30.38
	100.00

The crystals which were obtained by spontaneous evaporation, were probably the green citrate; and the black mass, by the action of heat, is probably converted into the red citrate of iron.

20. Malate of Iron.

Malic acid gives a brown solution by its action on iron, but it does not crystallize.

21. Gallate of Iron.

It has frequently been mentioned, in describing the salts of iron, that the infusion of nut-galls, or gallic acid, produces no precipitate or change of colour, when it is added to salts of iron in solution, of which the black or green oxide constitutes the base; but when the acid is added to a solution of a salt of iron, having the red oxide for its base, a black precipitate is immediately formed. From this it appears, that the black precipitate can only be obtained from the red oxide of iron, or it is the gallate of iron in the highest degree of oxidation. Writing ink is a compound of the solution of gallate of iron and the tanning principle. The important qualities of good ink are, that it shall be durable, and have a black colour. On this subject Professor Robison observes, in his Notes on Dr Black's Lectures, that "the great art in ink-making is to have a superabundance of astringent matter to counteract the disposition of the iron to a farther calcination, which renders the ink brown. It would be a great improvement in the manufacture of writing paper, if some astringent matter could be introduced. A little ardent spirits effectually prevents the spoiling of ink by keeping, but makes it sink and spread.

1936 Gallic acid gives a black colour only with the red oxide

1937 Ink.

A good Proportion for Writing-Ink.

Rasped logwood, 10 ounces;
Best gall-nuts in coarse powder, 3 ounces;
Gum arabic in powder, 2 ounces;
Green vitriol, 1 ounce;
Rain water, 2 quarts;
Cloves in coarse powder, 1 drachm.

Boil the water with the logwood and gum to one half; strain the hot decoction into a glazed vessel; add the galls and cloves; mix and cover it up. When nearly cold, add the green vitriol, and stir it repeatedly. After some days, decant or strain the ink into a bottle, to be kept close corked in a dark place*.

* *Black Lec.* v. i. p. 401.

Ink

Ink is sometimes of a very pale colour when first used, but becomes black by exposure to the air. This
1938 eason of e pale lour. is owing to the absorption of oxygen. The green vitriol or sulphate of iron, which is employed in making ink, has not its base fully saturated with oxygen, or is not in the state of red oxide. It is the conversion of the green into the red oxide, which takes place when it is exposed to the air. The use of gum in the composition of ink is to prevent the precipitation of the black particles, and also, it is supposed, to act as a varnish, to defend it from the air, which might give it a brown colour by farther oxidation.

22. Benzoate of Iron.

Benzoic acid readily dissolves the oxide of iron, and forms with it yellowish crystals, which are sweet to the taste, effloresce in the air, and are soluble in water and in alcohol. Gallic acid produces a black precipitate, and the prussiates give a blue. It is decomposed by the alkalies, and by the carbonates of lime and barytes. The acid is driven off by heat *.

* Ann. de Chim. ix. 316.

23. Succinate of Iron.

Succinic acid combines with the oxide of iron; and the solution, by evaporation, affords small radiated crystals, which are transparent and of a brown colour. This salt is insoluble in water. It may be formed by adding an alkaline succinate to the solutions of iron in acids.

24. Suberate of Iron.

Suberic acid decomposes the sulphate of iron, and produces a deep yellow colour †.

† Ibid. xxiii. p. 48.

25. Mellate of Iron.

Mellitic acid produces a copious precipitate of an Isabella-yellow colour, in the solution of iron in nitric acid. This precipitate is readily dissolved in muriatic acid ‡.

‡ Klaproth, Essays, ii. 102. Transl.

26. Lactate of Iron.

Lactic acid combines with iron, and forms with it a salt which does not crystallize. The solution is of a brown colour.

27. Prussiate of Iron.

1. Prussic acid combines with both the oxides of iron. When the prussiate of potash is added to a solution of the green sulphate or muriate of iron, a white precipitate is obtained. This shews, as has been already observed, that the base of these salts is in its lowest degree of oxidation. It is in the state of green or black oxide. But if the prussiate of potash be poured into a solution of the red sulphate of iron, a fine blue precipitate is formed, which is Prussian blue, or a prus-
1939 Prussian blue. siate of iron in the state of red oxide.

2. When the white precipitate of iron is exposed to the air, it gradually absorbs oxygen, and is converted into the blue prussiate, or Prussian blue. On the other hand, the blue prussiate may be converted into the white, by preserving it in a close vessel, with plates of iron or tin. The metallic substance deprives the iron of part of its oxygen, and makes it pass to the state of green oxide; in which state, combined with prussic acid, it is colourless. Sulphurated hydrogen gas produces a similar effect, by depriving the iron of its oxygen. Nitric and oxymuriatic acids convert the white prussiate into blue, by giving up their oxygen, which combines with the iron, and forms the red oxide.

II. Action of the Alkalies, &c. on Iron.

1. Iron, in the metallic state, has a very feeble ac- 1940 Alkalies.
tion on the alkalies and earths. The alkalies, in their pure and concentrated state, promote the decomposition of water by means of iron. Hydrogen gas is disengaged, and the metal is converted into the state of black oxide, or *martial ethiops*; but there seems to be no perceptible solution of the oxide of iron, which is thus formed in the liquid alkalies.

2. The brown oxides of iron readily combine with 1941 Earths.
the earth suspended in water. This combination has been long employed on account of its properties of assuming a great degree of solidity and hardness, as a cement, and especially as a cement or mortar to be employed under water. Hence volcanic productions, as *pouzzolana earths*, which contain a considerable proportion of oxide of iron, are often employed for this purpose. The oxide of iron combines also with the earths by means of fusion, and communicates to them various shades of colour, according to the degree of oxidation, and the proportion of oxide employed. In this state it is used in the fabrication of enamels and coloured glass.

3. The alkaline sulphates are decomposed by iron 1942 Sulphates.
at a high temperature. The iron deprives the sulphuric acid of its oxygen, and reduces it to the state of sulphur. Fourcroy heated for an hour in a covered crucible, one part of sulphate of potash, with two of iron filings. He obtained a kind of granulated scoria, which had swelled up, and was of a deep green on the surface. It was extremely hard, and exhibited in some of the internal cavities, shining six-sided plates of black oxide of iron. It had a hot, acrid taste. When reduced to powder, it exhaled the fetid odour of sulphurated hydrogen gas. It was not deliquescent in the air; and diluted with 10 parts of water, it was of a deep green colour. This was a solution of hydrosulphuret of potash, holding a small quantity of iron in solution. Sulphur was precipitated by the addition of acids, with the evolution of sulphurated hydrogen gas.

The nitrates are also decomposed by means of iron 1943 Nitrates.
heated to redness. Two or three parts of nitre, with one of clean iron filings, well triturated together, and projected into a red-hot crucible, give out at each projection a great number of vivid sparks. After the detonation, a half-fused mass remains, of a reddish yellow colour, which, by washing with water, affords pure potash, and there remains an oxide of iron in its highest degree of oxidation. Steel also detonates with nitre, and gives out a very brilliant red flame. These mixtures are employed in artificial fire-works.

5. Some of the muriates are also decomposed by 1944 Muriates.
iron. The experiment of Scheele, in which the muriate of soda was decomposed by means of iron, has already been mentioned. The muriate of ammonia is readily decomposed by iron with the assistance of heat. Hydrogen and ammoniacal gases are disengaged. A preparation formerly known by the name of *martial*

Iron, &c. *ammoniacal flowers*, was made with 16 parts of muriate of ammonia and one of iron filings. This mixture is sublimed in two earthen vessels, the one being inverted over the other. A small quantity of the muriate of ammonia only is decomposed, and the salt assumes a yellowish colour, with a small portion of muriate of iron. The muriate of ammonia is also decomposed by triturating the red oxide of iron with this salt. Ammonia is disengaged, and the oxide combines with the acid.

6. Hyperoxymuriate of potash produces a violent detonation with iron. Two parts of this salt with one of iron filings, detonate strongly, and with a vivid red flame, by percussion, or even by sudden pressure, or by being brought in contact with a burning body.

7. There is no action between the fluates, borates, phosphates, or the carbonates, and iron, in the cold.

III. Alloys.

1945 Arsenic. 1. Iron combines with arsenic by fusion, forming a brittle alloy of a white colour, analogous to the native compound of arsenic and iron, known by the name of *mispickel*. It is more fusible than iron, and is therefore employed, on account of its lustre and fine polish, for different purposes to which iron is not applicable.

1946 Tungsten. 2. The alloys of iron with tungsten, molybdena, chromium, columbium, titanium, and uranium, are scarcely known. With titanium iron affords an alloy of a gray colour, which is extremely infusible.

1947 Cobalt. 3. The alloy of iron and cobalt possesses some of the properties of steel. It is extremely hard, its texture is fine-grained, and it is attracted by the magnet.

1948 Nickel. 4. Iron combines with nickel, and the affinity between these metals is so strong, that it is extremely difficult to deprive nickel entirely of iron.

1949 Manganese. 5. Manganese is frequently found in combination with iron, to which it communicates a white colour, and renders it brittle.

1950 Bismuth. 6. Bismuth forms a brittle alloy with iron. It is attracted by the magnet, even when the proportion of bismuth amounts to three-fourths of the whole. Twenty parts of iron and one of bismuth, were broken by a weight of 151 lb.; but four parts of iron and three of bismuth only supported 35 lb. These were the experiments of Muschenbroeek. Gellert has observed, that the alloy of iron and bismuth has an inferior specific gravity to the mean.

1951 Antimony. 7. Iron combines readily with antimony by fusion. An alloy of equal parts of these metals is not attracted by the magnet, has no ductility, and scarcely any malleability. This alloy was formerly called *martial regulus*. It is brittle and hard, and has a less specific gravity than the mean. Iron has a stronger affinity for sulphur than for antimony, for when the sulphuret of antimony is heated with iron, it is decomposed, and the iron combines with the sulphur.

1952 Mercury. 8. Iron, it has been long supposed, has no action on mercury; but by triturating together the amalgam of zinc and mercury with iron filings, and by adding to the mixture a solution of iron in muriatic acid, and afterwards by kneading this mixture and heating it, Mr Aiken obtained an amalgam of iron and mercury, having the metallic lustre *.

* Phil. Mag. xiii. 406.

1953 Zinc. 9. Zinc forms an alloy with iron, but combines with it in very small proportion. It has been observed that zinc may be applied to the surface of iron by fusion, so as to defend it from the action of the air, and thus to prevent it from rusting.

10. Iron combines with difficulty with tin. Bergman made a number of experiments on the alloy of iron and tin. He put a quantity of tin into a crucible, and covered it with iron filings. The crucible was then filled with charcoal, and closely covered. He exposed the apparatus to the heat of a forge for half an hour, and he always obtained two distinct alloys, corresponding to the weight of the metals which he had employed. 1954 Tin.

The one was iron combined with a small quantity of tin, and the other tin united to a small portion of iron. Tin alloyed with $\frac{1}{22}$ of iron was very malleable, might be cut with a knife, had lost a little of its lustre, and was a little harder. With the fusible phosphates it gave a brown glass, which was less fusible; and by the addition of nitric acid, it became black, and there was separated an insoluble powder. Iron combined with half its weight of tin, exhibits some of the properties of the latter. It is slightly malleable, cannot be cut with a knife, unites with difficulty with mercury and with the phosphates, and in fusion with the latter, gives out brilliant sparks, which do not appear from the iron or tin alone. This inflammation is still more brilliant when the quantity of tin is increased to $\frac{11}{100}$.

Tin combines with iron, and adheres strongly to its surface, forming a thin covering. This is one of the most useful combinations of tin, for it renders the iron fit for a great many valuable purposes, for which, otherwise, on account of its strong tendency to oxidation or rusting, it would be totally inapplicable. This is well known by the name of *tin-plate*, or *white iron*. The process of tinning iron is the following: The plates of iron being reduced to the proper thickness, are cleaned by means of a weak acid. For this purpose the surface is first cleaned with sand, to remove any rust that may have formed. They are then immersed in water acidulated with a small quantity of sulphuric acid, in which they are kept for 24 hours, and occasionally agitated. They are then well rubbed with cloths, that the surface may be perfectly clean. The tin is fused in a pot, the surface of which is covered with an oily or resinous matter, to prevent its oxidation. The plates of iron are then immersed in the melted tin, and are either moved about in the liquid metal, or are dipped several different times. They are then taken out, and rubbed with saw-dust or bran, to remove the impurities from the surface. 1955 Tin-plate. 1956 Process of tinning.

It is said by some chemical writers, that the tin not only covers the surface, but penetrates the iron completely, so as to give the whole a white colour. This seems to be quite a mistake, which may be very easily proved by the test of experiment. If the surface of a piece of tin-plate be scraped with a knife, the metallic particles which are at first separated, are not attracted by the magnet. As the process is continued, some of the particles are magnetic, which shows that they are particles of iron, scraped off, after the coating of tin is separated, and this coating may be so completely removed that the whole of the particles are attracted by the magnet. This, perhaps, it may be said, would take

Copper, &c. take place, even though the iron were alloyed with a certain proportion of tin; but when the coating of tin is entirely removed, and the iron is moistened, it is soon covered with rust, in the same way as if it
1957 Lead. never had been combined with a particle of tin.

11. Guyton has shewn, that an alloy may be formed of iron and lead, which it was formerly supposed could not be effected. By melting together equal parts of lead and filings of iron, he obtained two separate metallic buttons, of which the lead occupied the lower part of the crucible, and the iron the upper part. When these were subjected to the test of experiment, it appeared that the lead contained a small proportion of iron, and the iron a small proportion of lead *.

* Ann. de Chim. xliii. 48.

The uses of iron are extremely numerous and important, but they are so well known, that it is altogether unnecessary to enumerate them.

Sect. XXI. *Of Copper and its Combinations.*

1958 History.

1. Copper seems to have been known in the remotest periods of antiquity. It is among the first metals which were employed by the early nations of the world; and indeed this might have been expected, as it is not one of the scarce metals, is easily extracted from its ores, and not difficult to work. The Egyptians applied it to a great variety of uses, as it appears, from the earliest period of their history. The Greeks were acquainted with the mode of working copper, and employed it in many of the arts. It was the basis of the celebrated Corinthian metal. The Romans knew the uses of this metal, and it is generally supposed that of it they fabricated the greatest number of their utensils. The alloys which they made with copper, after the example of the Egyptians and Greeks, were very numerous, and applied to a great variety of uses.

1959 Ores.

2. Copper exists in considerable abundance in nature; it is found native, alloyed with other metals, combined with sulphur, in the state of oxide, and in that of salt. It is not unfrequently met with in the native state, sometimes crystallized in an arborescent form, and sometimes in more regular figures. Copper exists native, alloyed with gold and silver. The most abundant ores of copper are the sulphurets, and of these there is a considerable variety, exhibiting various colours, and various forms of crystals. In the state of oxide, it has been found in Peru, of a greenish colour, mixed with white sand. In the state of salt, copper is combined with the sulphuric and carbonic acids, forming native sulphates and carbonates of copper. The latter present many varieties, but may chiefly be referred to the blue and green carbonates.

1960 Analysis.

3. The extraction of the ores of copper is to be conducted according to the nature of the combination in which they exist. The following process is recommended for the treatment of the sulphurets of copper. The ore is first reduced to powder, and then boiled with five parts of concentrated sulphuric acid. The solution is evaporated to dryness, and the residuum well washed with warm water, to remove all soluble matters. The solution being sufficiently diluted, a plate of copper is immersed in it, which precipitates the silver, and afterwards a plate of iron to precipitate the copper. It is boiled with the plate of iron, till no farther precipitate takes place. The copper which is thus obtained, is dried with a gentle heat, so that it may not undergo oxidation. It is supposed that the copper is mixed with iron, the whole may be dissolved in nitric acid, and the process is again repeated by introducing the plate of iron. In this way it is easy to discover the quantity of copper in the sulphurets of this metal.

1961 Properties.

4. Copper is a very brilliant metal, of a fine red colour, different from every other metallic substance. The specific gravity of copper is 8.584. When it is hammered, it acquires a greater density. It possesses a considerable degree of hardness, and some elasticity. It is extremely malleable, and may be reduced to leaves so fine that they may be carried about by the wind. It has also a considerable degree of ductility, intermediate, according to Guyton, between tin and lead. The tenacity of copper is also very great. A wire .078 of an inch in diameter, will support a weight without breaking equal to more than 300 lbs. avoirdupois. Copper has a peculiarly astringent and disagreeable taste. It is extremely deleterious, when taken internally, to the animal economy, and indeed may be considered as a poison. It is distinguished by a peculiarly disagreeable odour, which it communicates to the hands by the slightest friction.

1962 Action of heat.

5. Copper does not melt till the temperature is elevated to a red heat, which is about 27° Wedgwood, or by estimation 1450° Fahrenheit. When it is rapidly cooled after fusion, it assumes a granulated and porous texture, but if it be cooled slowly, it affords crystals in quadrangular pyramids, or in octahedrons, which proceed from the cube, its primitive form. When the temperature is raised beyond what is necessary for its fusion, it is sublimed in the form of visible fumes.

1963 Oxidation.

7. When copper is exposed to the air, especially if it be humid, it is soon deprived of its lustre. It tarnishes, becomes of a dull brown colour, which gradually deepens, till it is converted into that of the antique bronze, and at last is covered with a shining green crust, which is well known under the name of *verdigris*. This process is the oxidation of the metal by the absorption of oxygen from the atmosphere; and it is promoted and accelerated, either by being moistened with water, or by the water which exists in the atmosphere. As this oxide is formed, the carbonic acid of the atmosphere combines with it, so that it is to be considered as a mixture of oxide and carbonate of copper.

7. But when copper is subjected to a strong heat, the oxidation proceeds more rapidly. If a plate of copper be made red-hot in the open air, it loses its brilliancy, becomes of a deep brown colour, and the external layer, which is of this colour, may be detached from the metal. This is the brown oxide of copper. This oxide may be obtained by immersing a plate of red-hot copper into cold water. The scales which are formed on the surface fall off by the sudden contraction of the heated copper. This may be repeated till the whole is converted into this oxide. The copper in this state is in the highest degree of oxidation. Sometimes it assumes a black, and sometimes a green colour, which, according to Proust, are owing to the combination of carbonic acid with the oxide. This oxide of copper may also be obtained by dissolving

Copper, &c.

dissolving copper in nitric or sulphuric acid, and then by precipitating with an alkali, which precipitate is to be dried, to separate the water. The component parts
1964 Black oxide. of this oxide are,

Oxygen	25
Copper	75
	100

But copper combines with a smaller proportion of oxygen, forming an oxide of an orange colour. If the black oxide of copper be mixed with less than an equal proportion of metallic copper in fine powder, triturated in a mortar, and introduced into a close vessel with muriatic acid, the whole of the copper is dissolved with the emission of heat, and the oxide is precipitated of an orange colour, by means of potash.
1965 Yellow. This is the oxide of copper with the smaller proportion of oxygen. The component parts of this oxide, according to Mr Chenevix, are

Oxygen	11.5
Copper	88.5
	100.0 *

* Phil. Trans. 1801, p. 235.

This oxide changes colour the moment it is exposed to the air, by the absorption of oxygen, for which it has a very strong affinity.

8. There is no action between azote, hydrogen, or
1966 Phosphuret. carbon, and copper.

9. Phosphorus readily combines with copper, and forms with it a phosphuret, which is prepared by fusing equal parts of copper and phosphoric glass, with $\frac{1}{6}$ of the whole of charcoal in powder. Or, it may be formed by projecting phosphorus on red-hot copper in a crucible. The phosphuret of copper is of a whitish gray colour, with a metallic lustre, and of a close texture. It is much more fusible than copper; it melts by the action of the blow-pipe; the phosphorus burns with deflagration on the surface, and the copper remains behind in the state of black scoria. Exposed to the air, it loses its brilliancy, blackens, and is converted into a kind of efflorescence, which is phosphate of copper. It is composed of 20 parts of phosphorus,
1967 Sulphuret. and 80 of copper.

10. Copper combines with sulphur by different processes. If sulphur in powder and filings of copper are mixed together, and formed into a paste with a little water, when they are exposed to the air, the mass swells up, becomes hot, and is converted into a brown matter, which effloresces slowly in the air, and is converted into sulphate of copper. This sulphuret may be also formed by heating together in a crucible equal parts of sulphur and copper filings. A deep-coloured mass is thus obtained, which is brittle, and more fusible than copper. This substance, which is employed in dyeing, is prepared by stratifying in a crucible plates of copper and sulphur. When the whole is melted, it is afterwards reduced to powder, and was formerly known by the name of *æs veneris*.

1968 Singular experiment. A singular and splendid experiment was first made by the society of Dutch chemists at Amsterdam, in the formation of sulphuret of copper. If three parts of flowers of sulphur, by weight, and eight parts of copper filings, be mixed together, introduced into a glass matrass, and then placed upon red-hot coals, the mixture melts, and afterwards, with a kind of explosion, becomes almost instantaneously red-hot. If it be then removed from the fire, it continues red-hot for some time, and is converted into a sulphuret of copper. The singular part of this experiment is, that it succeeds equally well without the access of oxygen; or even it may be performed, when the mixture is under water. It seems, therefore, at first sight, to be a case of combustion, or apparent combustion, without oxygen. Various opinions have been entertained concerning the nature of this process, and different theories have been proposed to account for the phenomena, which are seemingly irreconcileable with the present theory of combustion. Indeed it was at first held up as an objection to the Lavoisierean theory. It has been explained by some, by supposing that a small quantity of air may have remained within the apparatus, or mixed with the materials; or that the quantity of air necessary might be supplied from the moisture, from which the materials and the apparatus may not have been sufficiently freed. But this affords no satisfactory explanation; for the quantity of air or water which could remain when the experiment has been carefully performed, is not sufficient to furnish the necessary portion of air for the support of such a vivid combustion. Fourcroy considers it as a case of simple phosphorescence, a change or sudden increase of capacity for caloric, or as merely the separation of light, or the conversion of caloric into light; and in support of this opinion he states, that the compound is always sulphuret of copper, which would not have been the case, had real combustion been effected, for then it would have been a sulphate of copper. But it is explained by others according to the principles of the theory of combustion, which has been given by Gren, and which we have already detailed, in treating of heat. According to this theory, the light exists in combination with the combustible, which in this case is the copper. When heat is applied to the mixture, the sulphur melts, and therefore combines with a great quantity of caloric; but, when the sulphur combines with the copper, it returns to the solid state, and therefore gives out a quantity of caloric. The light from the metal at the same time combines with the caloric, and both appear in the form of fire. It is at the instant of combination that the mass becomes red-hot, in consequence of the sudden extrication of heat and light from the two substances which form the compound. 1969 Of difficult explanation.

Copper combined with sulphur is one of the most common ores of this metal. According to the experiments of Proust, the natural production, known by the name of copper pyrites, is a sulphuret of copper, combined with an additional portion of sulphur. It is distinguished by its brittleness, metallic lustre, and yellow colour. 1970 Copper pyrites.

11. The order of the affinities of copper and its oxide, is, according to Bergman, the following: 1971 Affinities.

Copper.	Oxide of Copper.
Gold,	Oxalic acid,
Silver,	Tartaric,
Arsenic,	Muriatic,
Iron,	Sulphuric,
Manganese,	Saclactic,
Zinc,	Nitric,

Copper.

Copper, &c.

Copper.	Oxide of Copper.
Antimony,	Arsenic,
Platina,	Phosphoric,
Tin,	Succinic,
Lead,	Fluoric,
Nickel,	Citric,
Bismuth,	Lactic,
Cobalt,	Acetic,
Mercury,	Boracic,
Sulphur,	Prussic,
Phosphorus.	Carbonic.

I. Salts of Copper.

1. Sulphate of Copper.

1972 Preparation. 1. Sulphuric acid has no action on copper in the cold; but when it is concentrated, and at a boiling temperature, it is decomposed by the copper, with the disengagement of sulphurous acid gas. By evaporating the liquid, and by slow cooling, crystals of a fine blue colour are obtained. This salt, which is a sulphate of copper with excess of acid, reddens vegetable blues, has a strong styptic, metallic taste, and is at the same time extremely acrid and caustic. Its specific gravity
1973 Properties. is 2.1943. It is soluble in 4 parts of cold, and in 2 of boiling water. It effloresces slightly in the air, loses its water of crystallization when it is heated, and is converted into a bluish white powder. By increasing the heat the acid is driven off, and the oxide remains
1974 Composition. behind. The component parts of this salt are, according to Proust,

Acid	33
Oxide	32
Water	35
	100

1975 Native. 2. This salt is generally found in great abundance in nature, and is obtained either by evaporating the water which holds it in solution, or by expressing the sulphuret of copper to air and moisture, by which it is converted into sulphate of copper. This salt is known in commerce by the name of *blue vitriol*, *blue copperas*, and *vitriol of copper*.

3. None of the acids have any action on the sulphate of copper. It is decomposed by the alkalies and earths, and precipitated in the form of a bluish-gray oxide, which becomes green when exposed to the air, by absorbing carbonic acid from the atmosphere. Ammonia decomposes and precipitates the sulphate of copper, and, with an excess of alkali, dissolves the oxide, which assumes a rich, brilliant blue colour. It is also partially decomposed by muriate of ammonia. Equal parts of this salt and sulphate of copper in a heated solution, appear of a yellow colour, but when the solution cools, it is converted into green. This solution has been employed as a sympathetic ink. Paper moistened with it appears of a yellow colour when it is heated, but, in the cold, the colour entirely disappears.

1976 Sympathetic ink. 4. When a small quantity of caustic potash is added to a solution of sulphate of copper, a greenish-coloured precipitate is formed, which is diffused in the solution. This is a sulphate of copper with excess of base, and, according to Proust, is composed of

1977 Composition of.

Acid	18
Oxide	68
Water	14
	100

Copper is reduced to the metallic state from its solutions in acids, by several metallic substances, as iron, zinc, tin. If a plate of iron be introduced into a solution of copper in an acid, the iron is in a short time covered with metallic copper. It is in this way that copper is obtained from its natural solutions in water.

2. Sulphite of Copper.

Sulphurous acid has no action whatever on copper; 1978 Preparation.
but the oxide of copper readily combines with this acid. Or, the sulphite of copper may be formed by adding a solution of sulphite of soda, to a solution of sulphate of copper. An orange-yellow precipitate is formed, and small crystals of a greenish white are deposited. These become deeper coloured by exposure to the air. Both the yellow precipitate and the greenish white salt have been proved by experiment to be sulphites of copper. The first contains a greater proportion of copper, and therefore has an excess of base, to which its colour and insolubility are owing. The second is a saturated sulphite, which is soluble and crystallizes. When these salts are heated by the blow-pipe, they melt, blacken, assume a grayish colour, and are at last reduced to the metallic state. By the addition of nitric acid they are converted into sulphate of copper. By the sulphuric acid the sulphurous acid is driven off, and there remains behind a brownish-coloured matter in the state of powder, which is the oxide of copper mixed with a portion of that metal in the metallic state.

3. Nitrate of Copper.

1. Nitric acid is decomposed by copper with great 1979 Preparation.
rapidity. Nitrous gas is given out in great abundance, the metal is oxidated, and dissolved in the acid. The solution, which is at first of a pale blue, assumes a deep colour, and by slow evaporation yields crystals in the form of long parallelopipeds. This salt has an acrid styptic taste, is extremely caustic, and corrodes the skin. It is deliquescent, and very soluble in water. This salt exposed to a heat, even under 100°, 1980 Properties.
melts; by increasing the heat, the water of crystallization is driven off; it detonates slightly on red-hot coals, and when mixed with phosphorus, by percussion.

2. If a quantity of this dried salt, reduced to powder, be spread on a sheet of tinfoil, it remains without any action; but if it be moistened a little with water, 1981 Violent action on tin.
and wrapped up, a violent action takes place. The salt is decomposed, and nitrous gas is disengaged with a great degree of heat. The tinfoil is burst to pieces, and sometimes it is even inflamed. In this process, the nitric acid of the nitrate of copper is decomposed, in consequence of the strong affinity of the tin for the oxygen of the acid. The tin is oxidated, nitrous gas is given out, and the copper is partly reduced to the metallic state.

3. The alkalies and earths precipitate the solution 1982 Decomposition.
of

of nitrate of copper in the form of a bluish-white oxide, which becomes green by exposure to the air. When it is precipitated by means of potash, if the potash predominate, a bulky precipitate is formed, of a fine blue colour. The precipitate is composed of the oxide of copper and water, from which Proust, who particularly examined it, has denominated it *hydrate of copper*. Lime thrown into this solution has the property of giving it a deeper shade of blue. It is by this process that the blue pigment known in commerce by the name of *verditer*, and which is employed for painting paper, is prepared.

4. If nitrate of copper be distilled in a retort, the salt becomes thick, and forms a green crust on the retort. It is then in the state of nitrate with excess of base, or *subnitrate*, which is insoluble in water.

1983 Composition. 5. The component parts of this salt are, according to Proust,

Acid	16
Oxide	67
Water	17
	100

4. Muriate of Copper.

1. Concentrated muriatic acid, with the aid of heat, acts on copper and dissolves it. It produces a
1984 Preparation. slight effervescence, with the evolution of hydrogen gas. The solution is of a fine green colour, by which it is distinguished from the sulphate and nitrate of copper. This salt may be formed by the direct combination of the green oxide of copper with muriatic acid, a little diluted with water. By evaporation and slow cooling, crystals may be obtained in the form
1985 Properties. of long small needles, or rectangular parallelopipeds, which are of a fine grass-green colour. This salt is extremely acrid and caustic; it melts with a moderate heat; it is deliquescent in the air, and is soon converted into a thick liquid like oil. The salt fuses at a moderate heat, and becomes of a uniform mass by cooling. It is not decomposed by sulphuric or nitric acids. The alkalies precipitate a bluish white oxide, which becomes
1986 Composition. green in the air; the copper is precipitated by zinc and iron. The component parts of this salt, according to Proust, are,

Acid	24
Black oxide	40
Water	36
	100

This salt is therefore the muriate of copper with the
1987 Submuriate. oxide in the highest degree of oxidation.

2. This salt, according to the experiments of Proust, may be distilled to dryness without any change; but by increasing the heat, a part of its acid is driven off in the state of oxymuriatic acid, and the copper remains behind in its lowest state of oxidation, and forms a muriate of copper of a white colour. This muriate may also be obtained by dissolving copper in nitro-muriatic acid. A greenish powder appears, which is a muriate of copper with excess of base. The component parts of this salt are,

1988 Composition.

Acid	12.5
Oxide	79.0
Water	8.5
	100.0

3. Muriatic acid also forms a salt with the oxide of copper in its lowest degree of oxidation. Proust obtained this salt by mixing salts of copper with muriate of tin, which latter deprived the copper of a portion of its oxygen, and afforded a salt of a white colour. It may be formed also by introducing a plate of copper into a bottle filled with muriatic acid. This salt crystallizes in tetrahedrons. It may be precipitated in the state of white powder; by diluting the solution with water, and by repeated washings, the orange oxide of copper is obtained. When it is exposed to the air, it soon combines with oxygen, and is converted into muriate of copper with the oxide in its maximum state of oxidation. This salt is soluble in ammonia, and forms with it a colourless solution, which, after being for some time exposed to the air, assumes a fine blue colour by the absorption of oxygen. 1989 With the orange oxide.

5. Hyperoxymuriate of Copper.

The oxide of copper diffused in water, is dissolved when a stream of oxymuriatic acid gas is directed through it. This salt is of a bluish green colour, difficult of crystallization. Paper impregnated with it is easily kindled, and burns with a remarkably fine green flame.

6. Fluate of Copper.

Fluoric acid readily oxidates and dissolves copper; but the properties of this salt are little known. It forms a gelatinous solution, and affords by evaporation cubical crystals.

7. Borate of Copper.

This salt is most readily formed by adding a solution of an alkaline borate to the solution of nitrate or sulphate of copper. A greenish precipitate is formed, which has very little solubility in water.

8. Phosphate of Copper.

Phosphoric acid is not decomposed by copper; but 1990 Preparation.
when it remains for some time in contact with the metal, it promotes the oxidation, and there is thus formed a phosphate of copper, which has little solubility. Or it may be obtained by pouring an alkaline phosphate into a solution of sulphate or nitrate of copper. The phosphate of copper is formed, which is almost insoluble. When it is heated with charcoal in a crucible it affords a gray phosphuret of copper, which has some brilliancy. The component parts of phosphate of copper, as they have been ascertained by Mr Chenevix, are, 1991 Composition.

Acid	35.0
Oxide	61.5
Water	3.5
	100.0

The above oxide is composed of 49.5 brown oxide, and 12 of water.

Copper, &c

9. Carbonate of Copper.

Carbonic acid has no action on copper, either in the
1992 repara-on. gaseous or liquid state; but it is very readily absorbed by the blue or green oxides of this metal. It may be formed by adding an alkaline carbonate to any of the solutions of copper in the other acids. To prepare this salt of the most brilliant and uniform colour, it should be precipitated with boiling water, washed carefully, and the vessel which contains it placed in the sun. The carbonate of copper is found native, and is known by the name of *malachite*. It contains the same proportions as the artificial carbonate. Its component
1993 omposi-on. parts are,

Acid	25.0
Brown oxide	69.5
Water	5.5
	100.0

10. Arseniate of Copper.

This salt may be formed by adding a solution of an alkaline arseniate to nitrate of copper; or by digesting arsenic acid on copper. A green solution is obtained, and the arseniate of copper is precipitated in the form of a bluish-white powder. The arseniate of potash added to a solution of sulphate of copper forms a precipitate of a very rich green, which was proposed by Scheele as a paint, because it is unaltered by the air, and hence it obtained the name of *Scheele's green*. It is the arsenite of copper. This salt may be formed by
1994 heele's een. the following process:

Dissolve a quantity of potash in water, and add white oxide of arsenic, till the potash is saturated. Filter the liquor, and add gradually a solution of sulphate of copper while it is hot, stirring the mixture during the addition. It is then left at rest for some time, after which the arsenite of copper precipitates in the form of a beautiful green powder. The precipitate is to be repeatedly washed with water, and dried. Several varieties of the arseniates of copper have been described, and analyzed by the Count de Bournon and Mr Chenevix, and an account of them published in the Philosophical Transactions for 1801.

11. Tunsgate of Copper.

Tungstic acid combines with oxide of copper, or forms a precipitate when added to a solution of sulphate of copper.

12. Molybdate of Copper.

Molybdic acid, added to a solution of nitrate of copper, produces a green precipitate.

13. Chromate of Copper.

This is formed by adding chromic acid to a solution of nitrate of copper. A red precipitate is obtained.

14. Acetate of Copper.

1995 para-. Copper is readily oxidated and dissolved in acetic acid. The solution is aided by heat, and gradually assumes a green colour. The oxide of copper, which is thus formed, is the verdigris of commerce. It is usually prepared by exposing plates of copper to the action of vinegar. The surface of the plates is covered with this bluish-green powder, which being dissolved in acetic acid affords a solution of a fine greenish blue colour. This solution by evaporation and cooling gives crystals of a deep blue colour, and in the form of quadrangular, truncated pyramids. The specific gravity is 1.779. This salt has a strong disagreeable taste, and is poiso- 1996
nous. It effloresces in the air, and is very soluble in Properties.
water. It is decomposed by all the alkalies; and by means of heat, or by distillation, it is decomposed, and gives out acetic acid. This salt, according to the analysis of Proust, is composed of

Acid and water	61
Oxide	39
	100

15. Oxalate of Copper.

Oxalic acid readily acts upon copper, and forms with it needle-shaped crystals of a green colour. It readily combines with the oxide of copper, and is then in the state of a bluish green powder, which is little soluble in water. Oxalic acid precipitates the sulphate, nitrate, and muriate of copper, in the form of a bluish gray powder.

16. Tartrate of Copper.

Tartaric acid dissolves copper, when exposed to the air, and at last converts it into an oxide. It combines readily with the oxides of copper, and forms with them a salt of little solubility, and of a green colour. When this acid is added to the solution of sulphate or muriate of copper, it forms a tartrate of copper, which appears after some time in irregular greenish crystals.

17. Tartrate of Potash and Copper.

This triple salt may be prepared by boiling together oxide of copper and tartar in water. By evaporating the solution, blue crystals are obtained, which have a sweetish taste. If the same solution be evaporated to dryness, a bluish green powder remains behind, which 1997
is employed as a paint, by the name of *Brunswick* Brunswick
green. green.

18. Citrate of Copper.

Citric acid dissolves the oxide of copper at the boiling temperature. The solution affords by evaporation greenish coloured crystals.

19. Benzoate of Copper.

Benzoic acid readily dissolves the oxide of copper. The solution yields small crystals of a deep green colour, which have little solubility in water. It is decomposed by the alkalies, the carbonates of lime, and barytes, and the acid is driven off by heat.

20. Succinate of Copper.

When succinic acid is long digested with copper, it dissolves a small portion, and the solution affords green crystals.

21. Suberate of Copper.

When suberic acid is added to a solution of nitrate

Copper, &c.

trate of copper, it produces a green colour; but there is no precipitate.

22. Mellate of Copper.

When mellitic acid is added to a solution of acetate of copper, it affords a precipitate, and the colour of verdigris, but it produces no change on muriate of copper.

23. Lactate of Copper.

Lactic acid, after digestion with copper, first assumes a blue colour, then changes to a green, and is afterwards converted into a dark brown. The solution does not yield crystals.

24. Prussiate of Copper.

1998 Preparation.

The prussiates of potash precipitate the salts of copper of different colours. The prussiates obtained from sulphate, nitrate, and muriate of copper, Mr Hatchet observes, are very beautiful; but the finest and deepest colour he obtained from the muriate. He has proposed the prussiate of copper as a paint; and on trial with oil and water, it has been found to answer the purpose. The method which he recommends for the preparation of this pigment, is to take green muriate of copper with 10 parts of distilled or rain water, and to add prussiate of lime, which he thinks is preferable to prussiate of potash, until the whole is precipitated. The prussiate of copper is then to be well washed with cold water, and to be dried without heat *.

* *Journ. Roy. Inst.* i. 307.

II. Action of Alkalies, &c. on Copper.

1999 Fixed alkalies.

1. The fixed alkalies in solution in water, digested with copper filings, and allowed to cool, promote the oxidation of the metal. The liquid assumes a slight blue colour, as well as the copper, but the action of the air is necessary for this process. It scarcely succeeds in close vessels.

2000 Ammonia.

Liquid ammonia, treated in the same way, becomes of a brilliant blue colour, but it dissolves only a very small quantity of the oxide. By the slow evaporation of this solution, the greatest part of the ammonia is separated in the form of gas; a very small quantity only remains combined with the oxide of copper. This solution, it has been said, yields transparent crystals of a fine blue colour. The dried mass assumes a green colour when it is exposed to the air, as the ammonia is dissipated, and the oxide absorbs carbonic acid. The green oxide of copper is instantly converted to a blue. This action is promoted by heat, and when the heat is increased, azotic gas is disengaged; the hydrogen of the ammonia combines with part of the oxygen of the oxide, and forms water; the oxide becomes of a brown colour, and the metal is at last revived.

2001 Glass coloured.

2. There is no action between the earths and copper, excepting by fusion. With the vitrifiable earths and the oxides of this metal, a glass is formed, which is most commonly of a fine green colour, with different shades of brown or red, according to the degree of oxidation. The oxides of copper are frequently employed to colour glass, porcelain, and pottery.

2002 Sulphates.

3. Copper seems to have but a feeble action on most of the salts. The sulphates are not decomposed by this metal, even with the assistance of heat. When copper is boiled with the solution of alum, it is oxidated and partially dissolved, by the excess of sulphuric acid which this salt contains. The sulphate of copper thus formed, seems to combine in the state of triple salt with the sulphate of alumina and potash. It has been observed that alumina precipitated from alum, the solution of which has been kept for some time in copper vessels, is slightly tinged with a blue colour. The nitrates, especially the nitrate of potash, when fused together, give out sparks, but without inflammation or detonation. A brown oxide of copper is thus formed, mixed with potash. When it is washed with water, the alkali is dissolved, and there remains the pure oxide of copper, which is often prepared in this way for the fabrication of enamels. 2003 Nitrates.

Muriate of ammonia is decomposed by copper with the assistance of heat. Hydrogen gas and ammoniacal gas are disengaged, and there remains behind a muriate of copper. The solution of muriate of ammonia also acts upon copper, and becomes of a blue colour, when it is kept in vessels of this metal. When muriate of ammonia is sublimed with about $\frac{1}{60}$ of its weight of green oxide of copper, a small quantity of the muriate of ammonia is decomposed, and the muriate of copper which is formed, combines with the undecomposed salt. This was formerly called *cupreous flowers of sal ammoniac*, or *ens veneris*. If a quantity of lime water, with about $\frac{1}{16}$ of its weight of muriate of ammonia, be kept in a copper vessel for 10 or 12 hours, the liquid assumes a fine blue colour. This was formerly called *celestial water*. In this process a small quantity of ammonia is disengaged by the lime, and it dissolves some portion of the copper, which communicates a blue colour to the whole solution. This compound may also be formed, by adding a small quantity of copper filings to a mixture of the solution of muriate of ammonia and lime water. 2004 Muriates.

4. The phosphates, fluates, borates, and carbonates, have no other action on copper than by means of the water in which they are dissolved. This action is greatly promoted by exposure to the air.

III. Alloys.

1. Copper readily combines with almost all other metals, by means of fusion; and many of the alloys which are thus formed are of great importance in the arts.

2. When copper is combined with arsenic, by melting them together in a close crucible, and covering the surface with muriate of soda, to prevent oxidation, a white brittle alloy is formed, which has been called *white tombac*. With a certain proportion of zinc and tin, this alloy is employed in the fabrication of various utensils. 2005 Arsenic.

3. The alloys of copper with tungsten, molybdena, chromium, columbium, titanium, and uranium, are either altogether unknown, or have not been examined.

4. Little is known of the alloy of copper and cobalt. It is said that it resembles cobalt itself in texture and brittleness. 2006 Cobalt.

5. Copper forms with nickel a white hard alloy, which has no ductility, and which is soon altered by exposure to the air. 2007 Nickel.

6. Copper unites with manganese, and gives an alloy of a red colour, which is very malleable. 2008 Manganese.

7. Equal

Copper, &c.

7. Equal parts of copper and bismuth, melted together, form a brittle alloy of a pale red colour. With one-eighth of bismuth, the alloy is extremely brittle, of
2009 Bismuth. a very pale red colour, and exhibiting in its texture nearly cubical fragments. The specific gravity of this alloy is exactly the mean of that of the two metals; and, as the proportion of bismuth is increased, the tenacity of the alloy is diminished.

2010 Antimony. 8. Copper combines readily with antimony by fusion. Equal parts of the two metals constitute an alloy of a beautiful violet colour, and of a greater specific gravity than the mean. This alloy is remarkable for its lamellated and fibrous texture. The alchemists gave it the name of *regulus of Venus*. A compound formed of equal parts of martial regulus and regulus of Venus, according to an alchemical prescription, the surface of which exhibits the appearance of meshes or cavities, was called *Vulcan's net*, because it seemed to envelope iron and copper, which were denominated *Mars* and *Venus*.

2011 Mercury. 9. Copper enters into combination with mercury with some difficulty. This alloy may be formed by triturating very thin plates of copper which have been rubbed with vinegar or common salt, with mercury; or, by triturating copper filings with the solution of mercury in nitric acid. It is also formed by other processes; but whatever be the process, this amalgam is of a reddish colour, and sufficiently soft to receive the most delicate impressions when it is a little heated. It becomes hard by exposure to the air. It is decomposed by heat, and the mercury is separated.

2012 Zinc. 10. The compound of copper and zinc constitutes one of the most important and useful alloys, of all the combinations of the metals. Muschenbroeck has given a particular description of several of these alloys. Equal parts of copper and zinc afforded a metal of a fine golden yellow, whose specific gravity was 8.047; one part of copper and half a part of zinc, formed a compound of a pale golden colour; one part of copper and three-fourths of zinc, composed an alloy of a golden colour, which yielded to the file; one part of copper and one-fourth of zinc, gave a compound of a finer colour than that of brass. According to the proportions of the metals which are employed, the alloys have received different names. The usual process for combining them, is either by fusing copper with a mixture of calamine, or native carbonate of zinc and charcoal; or by stratifying plates of copper with the same mixture, and exposing them to heat.

2013 Brass. The well known compound, distinguished by the name of *brass*, is an alloy of copper and zinc. The proportion of the zinc is about one-fourth of the copper. This alloy is of a fine yellow colour, less liable to tarnish, and more fusible than the copper. The density of this alloy is one-tenth more than the mean. It is malleable, and possesses considerable ductility.—A compound applied to a great variety of ornamental purposes, and known by the names of *Prince Rupert's metal*, *prince's metal*, or *pinchbeck*, is an alloy of zinc 2014 Pinchbeck. and copper in the proportion of three parts of the former to four of the latter. This alloy is less malleable than brass; but has a fine golden colour, which is pretty permanent, and little affected by exposure to air.

The compound of zinc and copper, called brass, it is supposed, was well known to the ancients. An ore of zinc was employed in the fabrication of it, although it does not appear that they were at all acquainted with zinc as a distinct metal. "It is probable," Professor Beckmann observes, after Pliny, "that ore containing zinc, acquired the name of *cadmia*, because it first produced brass." "Ipse lapis è quo fit æs, cadmia vocata." "When it was afterwards remarked, that calamine gave to copper a yellow colour, the same name was conferred on it also. It appears, however, that it was seldom found by the ancients, and we must consider cadmia in general as signifying ore that contains zinc. Gold-coloured copper or brass was long preferred to pure or common copper, and thought to be more beautiful the nearer it approached to the best *aurichalcum* (C). Brass, therefore, was supposed to be a more valuable kind of copper; and on this account Pliny says that cadmia was necessary for procuring copper, that is, *brass*. Copper as well as brass was for a great length of time called *æs*, and it was not till a late period, that mineralogists, in order to distinguish them, gave the name of *cuprum* to the former. Pliny says, that it was good when a large quantity of cadmia had been added to it, because it not only rendered the colour more beautiful, but increased the weight (D)*."

2015 Brass analyzed. To discover the proportions of the two metals in this alloy, Vauquelin dissolved a quantity of brass in nitric acid. When the solution is completed, he precipitates the two metals by means of potash, which is added in large quantity, to dissolve the whole of the oxide of zinc; and as the oxide of copper is not soluble by this alkali, it remains in the form of black powder, which is separated, washed, and dried. A fiftieth part of the weight of this precipitate is deducted for the oxygen with which it is combined; the remainder gives the weight of copper in the alloy. What is deficient of the whole weight of the alloy, is the weight of the zinc †.

11. Copper

* *Hist. of Invent.* iii. 74.

† *Fourcroy Connaiss. Chim.* vi. 159.

(C) According to Bishop Watson, the *aurichalcum*, or *orichalcum*, of the ancients, is to be considered as the same with our brass. *Manchest. Trans.* ii. 47.

(D) Mr Beckmann farther adds, "At first it was called *æs cyprium*; but in course of time only *cyprium*, from which at length was formed *cuprum*. It cannot, however, be ascertained at what periods these appellations were common. The epithet *cupreus* occurs in manuscripts of Pliny and Palladius, but we cannot say whether later transcribers may not have changed *cyprius* into *cupreus*, with which they were perhaps better acquainted. The oldest writer who uses the word cupreum, is Spartian, who says in the life of Caracalla, *cancelli ex ære, vel cupro*; but may not the last word have been added to the text as a gloss? Pliny, book xxxvi. 26. says, *addito cypreo et nitro*, which Isidore, xvi. 15. p. 363, expressed by the words *adjecto cupro et nitro*." *History of Inventions*, iii. 75.

Copper, &c.

2016 Tin. 11. Copper combines very readily with tin. This is a very important alloy in the arts. It is with this alloy that *bronze*, metals for casting statues and cannons, bell-metal, and metallic mirrors, are formed. Tin diminishes the ductility of copper, and increases its tenacity, hardness, and sonorous quality. According to Muschenbroeck, copper acquires the greatest solidity with the addition of one part of tin to five or six of this metal. By increasing the quantity of tin, the alloy becomes hard and brittle.

2017 For cannons. To form the alloy employed for cannons, 12 parts of tin are united to 100 of copper. In fusing the two metals for this alloy, it is necessary to stir or agitate the mixture, otherwise they remain uncombined. Bronze, or the metal which is used for statues, is not different from that of which cannons are made, excepting in the proportion of tin being either more or less, to vary the colour.

2018 Bell-metal. The component parts of bell-metal are usually 75 of copper and 25 of tin, or three of copper and one of tin. A small quantity of other metals is sometimes detected by analysis, in fragments of bells that have been examined, such as zinc, antimony, bismuth, and even silver. But these metals are not considered as essential to the alloy. Bell-metal is of a grayish white colour, of a close grain, and so hard as to be scarcely touched with the file. It is also elastic and sonorous. The specific gravity is considerably more than the mean, and it is more fusible than copper. A mixture of three parts of tin and one of copper, fused with a little arsenious acid, and black flux, gives an alloy of the colour of steel, very hard, and susceptible of a fine polish, which is employed in the fabrication of mirrors for telescopes. But other proportions, with the addition of other metals, are employed by different opticians. Bismuth, antimony, and silver, are added, to increase the reflecting property of the mirror.

2019 Tinning copper. Copper vessels which are employed for the purposes of domestic economy are apt to be corroded or oxidated by the substances which are boiled or preserved in them. To defend them from the action of these substances, and to prevent the terrible accidents which would otherwise happen to those who employ any of these matters as food, the inside of such vessels is covered with a thin coating of tin. This is performed by the following process. The surface to be covered with tin, is scraped very clean with an iron instrument, or it is scoured with wine lees, or weak nitric acid and sand. The tin is then applied in two ways; in the first way, the tin is in a state of fusion, and the surface is covered with some resinous or oily matter, to prevent oxidation, in the same way as in tinning iron. The surface to be tinned is first immersed in a solution of muriate of ammonia, and dried, and then dipped into the melted tin. Another method is, to heat the copper vessel on charcoal, and then to apply to the inside of it a quantity of tin, which is then melted; a little muriate of ammonia being thrown in at the same time in powder. The surface is then rubbed with tow. The muriate of ammonia is employed, both to clean the surface of the copper, and also to prevent the tin from being oxidated. The coating of tin which can be applied to copper is extremely thin; and it cannot by any means be increased, to bear a heat greater than that which melts tin. Bayen in his researches concerning tin, found, that a vessel nine inches in diameter, and three lines in depth, acquired, by having its surface covered with tin, only 21 grains of additional weight.

In using vessels thus tinned, care should be taken not to allow acid substances to remain for any length of time in contact with them, because the tin would be corroded, and part of the copper afterwards dissolved, which would inevitably act as a poison. Pure tin ought only to be employed, at least without any mixture of lead.

2020 Lead. 12. Copper combines very readily with lead by fusion. With an excess of lead, the alloy is of a gray colour, is ductile, but brittle when it is hot, on account of the great difference of fusibility of the lead and copper. This alloy is employed in the fabrication of printing types for large letters. According to Savary, the proportion for this purpose is 100 of lead and 20 or 25 of copper.

2021 Iron. 13. Copper combines with iron, but with much greater difficulty than with the other metals. As the proportion of iron is increased, the alloy becomes of a darker gray, loses its ductility, and is more infusible. The alloy of copper with iron has been supposed to constitute that variety called *hot short iron*, which possesses greater tenacity than other kinds of iron, and on account of some peculiar properties is more applicable to a variety of purposes.

2022 Uses. Next to iron, copper is of the greatest importance, and most extensive utility, of all the metals. In the metallic state it is employed for a great variety of instruments and utensils; some of its oxides and salts are much used in painting, dyeing, and enamelling; and the alloys with other metals, especially with zinc and tin, are applied to many valuable purposes in the arts, and in domestic economy. But the uses of copper in its different states, and in its various combinations, are so familiar and well known, that it must appear quite unnecessary to enumerate them.

Sect. XXII. *Of Silver.*

2023 History. 2. Silver has been reckoned among the noble or perfect metals, and has been known from the earliest ages of the world. Its scarcity, beauty, and utility, have always rendered it an object of research among mankind, so that the nature and properties of this metal have been long studied and minutely investigated. In the midst of the rage for the transmutation of metals which for centuries fired the imaginations of the alchemists, silver occupied a great share of their attention and labour, with the hope of discovering the means of converting the baser and more abundant metals into this, which is more highly valued on account of its scarcity and durability. When the dawn of science commenced, and its light had dissipated the follies and extravagances of these pursuits, the earlier chemists were much employed in examining the properties and combinations of silver; nor has it been overlooked or neglected by the moderns.

2024 Ores. 2. Silver, which is neither in such abundance nor so universally diffused as many other metals, exists in nature in five different states; in the native state; in that of alloy with other metals, especially with antimony; in that of sulphuret, sulphurated oxide, muriate, and carbonate.

Silver, &c. carbonate. 1. Native silver, which is characterized by its ductility and specific gravity, is frequently tarnished on the surface, of a gray or blackish colour, and appears under a great variety of forms. In this state it is not perfectly pure. It is usually alloyed with a little gold or copper. 2. The alloy of silver and antimony, which is the most frequent, is distinguished by its brittleness and lamellated structure from native silver, which it resembles in lustre and colour. It crystallizes in prisms which are six-sided and pretty regular. 3. The sulphuret of silver, which is known to mineralogists by the name of *vitreous silver ore*, is of a dark gray colour, and has some metallic lustre. It is usually crystallized in the form of cubes, octahedrons with angular facets, or sometimes in the form of the dodecahedron. 4. The sulphurated oxide of silver and antimony. In this ore of silver the sulphur is combined with the metal in the state of oxide; in the former, in the metallic state. This ore is called *red silver ore.* It is of a deep red colour, sometimes transparent, and sometimes nearly opaque, frequently having the lustre of steel on the surface. The primitive form of its crystals is the rhomboidal dodecahedron. 5. The muriate of silver, which has been long known to mineralogists by the name of *corneous silver*, is found in irregular masses of a grayish colour, frequently opaque, but sometimes semitransparent. It is soft and very fusible.

2025 Analysis.

3. The analysis of silver ore varies according to its nature and combinations. Native silver, after being broken down and washed, is rubbed with liquid mercury, which by strong trituration dissolves, and combines with the silver. This amalgam is subjected to pressure, to separate the excess of mercury. It is then distilled, and afterwards heated in a crucible, to volatilize the mercury, and the silver remains pure. When silver is combined with antimony and sulphur, the ore is to be strongly roasted, to separate the antimony or sulphur. It is then melted with a proper quantity of alkaline flux. The sulphurated oxide of silver and antimony may be treated in the same way.

2026 Silver purified by cupellation.

But by these processes the silver is not in a state of perfect purity. To obtain it pure, by the separation of other metals, as copper or iron, it is subjected to the process called *cupellation.* This depends on the peculiar property of lead, when it is oxidated and afterwards vitrified, of combining with the metals, and leaving the silver in a state of purity. A small flat cup made of the powder of burnt bones, which has received the name of *cupel*, is employed for this purpose. The silver to be purified is included in a plate of lead, usually double the weight of the silver. The cupel is introduced under a *muffle* in the middle of the furnace. The use of the muffle is to increase the heat, by allowing the metal to be surrounded on all sides with coals, and at the same time preventing the admixture of any part of the fuel with the fused matter. The heat is then to be applied sufficiently great, that every part of the metal may be in fusion, but not such as to sublime the lead too rapidly. As the process advances, the lead is oxidated and vitrified, and having combined with all the other metals except the silver, sinks into the porous cupel, and leaves the silver pure. The lead, which is now in the state of litharge, is extracted from the cupel, and applied to the usual purposes.

2027 Properties.

4. Silver is of a fine white colour, and great briliancy. The specific gravity is 10.474, and according to some, when it is hammered, 10.535, and sometimes nearly 11. The hardness of silver is intermediate between iron and gold. The elasticity of silver is considerable, and it is one of the most sonorous of the metals. It possesses very great ductility and malleability. It may be beaten out into leaves $\frac{1}{100000}$ of an inch thick, and a grain of silver may be so extended as to be formed into a hemispherical vessel of sufficient capacity to hold an ounce of water, or to be drawn out into a wire 400 feet in length. The tenacity of silver is very great. A wire .078 of an inch in diameter, will support a weight of 187 lbs. avoirdupois.

2028 Action of heat.

5. Silver is a good conductor of caloric. Its expansive power is less than that of lead and tin, and greater than that of iron. When it is exposed to a white heat it melts. The temperature necessary to bring it to fusion has been calculated at the 1000° of Fahrenheit; but according to Kirwan, it requires a higher temperature than 28° Wedgwood to melt it, although at that temperature it continues in a state of fusion. When it is cooled slowly after fusion, it exhibits some marks of crystallization. It assumes the form of four-sided pyramids, or of octahedrons. If the heat be increased after the silver is melted, it boils and may be reduced to vapour. The surface of melted silver is so extremely brilliant, that it seems to throw out sparks, which is called *coruscation* by the workmen.

2029 Electricity, &c.

6. Silver is a good conductor of electricity. It has no perceptible taste or smell.

2030 Of air.

7. Silver is not altered by exposure to the air, although it is soon tarnished, which is owing, as Proust ascertained, to a thin covering of sulphuret of silver, which is formed by sulphureous vapours to which it is exposed; but when it is subjected to a strong heat for a long time, in an open vessel, it combines with the oxygen of the atmosphere, and is converted into an oxide. In the experiments of Macquer, the oxidation 2031 Oxidation.
of silver was effected by exposing it for 20 times successively in a crucible, to the strong heat of a porcelain furnace. At last perceptible traces of oxidation were observed, and vitreous matter of an olive colour was obtained. In other experiments, silver being acted on by the heat of a burning glass, was covered with a white powder, which was afterwards converted into a crust of a green colour. Van Marum passed electric shocks through silver wire, which was instantly reduced to a kind of powder, with a greenish white flame, and the oxide which was formed was dissipated in vapour. The oxide of silver, which is formed by these processes, is of a greenish or yellow colour. It is composed of about ten parts of oxygen, and 90 of silver. The oxide of silver is very easily reduced, for the affinity of oxygen for this metal is very feeble. It is decomposed by the application of heat, and even when it is exposed to the light. By heating it in close vessels, pure oxygen gas is obtained, and the metal is converted to the metallic state, by melting it in a crucible.

8. Azote, hydrogen, or carbon, have no action whatever on silver.

2032 Phosphuret.

9. Silver combines with phosphorus, forming a phosphuret. One part of silver in filings, with two of

phosphoric

phosphoric glass, and half a part of charcoal, exposed to heat in a crucible, yielded a phosphuret of silver which had acquired one-fourth of its primitive weight of silver. This phosphuret is of a white colour, brittle, of a granulated texture, and may be cut with a knife. By throwing pieces of phosphorus on silver red-hot in a crucible, the metal is instantly melted, and the phosphuret which is formed remains at the bottom. At the moment when the surface becomes solid, a quantity of phosphorus is thrown out with a kind of explosion, and the surface of the metal then exhibits a lamellated appearance. Pelletier, who first made this experiment, concludes from it, that silver is susceptible of retaining a greater proportion of phosphorus in combination with it, when it is in fusion than in the solid state, and that the separation of the phosphorus is owing to the sudden contraction of the silver. A hundred parts of silver in fusion retain 25 of phosphorus, but only 15 when it becomes solid. Phosphorus has the property of reducing the oxides of silver, and of precipitating them from this solution in acids, in the metallic form.

2033 Sulphuret. 9. Sulphur combines readily with silver, both in the dry and humid way. By stratifying in a crucible plates of silver alternately with sulphur, and melting them rapidly, a deep violet-coloured mass is obtained, which is more fusible than silver, brittle, crystallized, and has a metallic lustre. It may be cut with a knife, and has a good deal of resemblance to vitreous ore of silver. When this sulphuret of silver is exposed to heat for a considerable time, the sulphur is gradually dissipated, and the silver remains pure and ductile. Silver combines very readily with sulphur, when it is long exposed to those matters which gradually deposit this substance. This effect is immediately produced, when silver is brought into contact with sulphurated hydrogen gas, or when it is immersed in water impregnated with this gas, as in natural sulphureous waters. It is owing to the same cause that a silver spoon is tarnished by a boiled egg, and particularly if the egg has begun to spoil. Sulphurated hydrogen gas which is exhaled by the egg, is decomposed, the sulphur combines with the silver, and forms a thin layer of sulphuret of silver, which is of a dark or violet colour. The same thing happens, when silver is exposed in places that are much frequented, as in churches and theatres.

2034 Affinities. 10. Silver forms alloys with most of the metals, and salts with the acids. The order of the affinities of silver and its oxide, as they have been arranged by Bergman, is the following.

Silver.	Oxide of Silver.
Lead,	Muriatic acid,
Copper,	Oxalic,
Mercury,	Sulphuric,
Bismuth,	Saclactic,
Tin,	Phosphoric,
Gold,	Sulphurous,
Antimony,	Nitric,
Iron,	Arsenic,
Manganese,	Fluoric,
Zinc,	Tartaric,
Arsenic,	Citric,
Nickel,	Lactic,
Platinum,	Acetic,
Sulphur,	Succinic,
Phosphorus.	Prussic.
	Carbonic.

I. Salts of Silver.

1. Sulphate of Silver.

1. Sulphuric acid has no action on silver in the cold; 2035 Preparation. but three or four parts of the concentrated acid, boiled with one part of silver in filings or small pieces, produce an effervescence, with the evolution of sulphurous acid gas. A white powder is formed, which is entirely soluble in water acidulated with sulphuric acid. With excess of acid, a solution of sulphate of silver is obtained, which is colourless, very acrid and caustic. By evaporation it affords crystals, which are white and brilliant, and in the form of fine prisms or needles. When the solution is more concentrated, a deposition is formed as it cools, and then it crystallizes in large white, brilliant plates, which seem to be composed of compressed four-sided prisms.

2. This salt is not very soluble in water. When ex- 2036 Properti posed to heat, it melts and swells up; at a higher temperature it blackens, gives out sulphurous acid, and oxygen gas, and is then reduced to the metallic state. It is slowly decomposed by the action of light. It is decomposed by phosphorus, and vapour of sulphur in the cold, and by charcoal at a red heat. It is not altered by the action of the acids, excepting the muriatic. All the alkalies and the alkaline earths precipitate the oxide of silver from its solution in sulphuric acid, of a dark gray or brown colour, and especially in contact with light. Lime causes a precipitate of a greenish gray colour. Ammonia re-dissolves the precipitate. Sulphate of silver is decomposed by the muriates, phos- 203 Decomposition. phates, and fluates. The carbonates give a white insoluble precipitate of carbonate of silver. The alkaline sulphurets, sulphurated hydrogen gas, and water impregnated with this gas, decompose the sulphate of silver, and form in its solution a black precipitate of sulphuret of silver; for the oxide is reduced by the hydrogen, while the silver combines with the sulphur.

2. Sulphite of Silver.

Sulphurous acid combines readily with the oxide of 203 Preparation. silver. It assumes the form of small shining grains, of a pearly-white colour. It is not altered by exposure to light. Sulphurous acid precipitates the solution of silver in nitric acid, in form of a white powder of sulphite of silver. The same salt is obtained by adding a solution of sulphite of ammonia to a solution of nitrate of silver. An excess of this sulphite re-dissolves the precipitate, and forms a triple salt. This sulphite of ammonia and silver, exposed to the sun's rays, is soon covered with a pellicle of silver, and the liquid contains sulphate of ammonia. Sulphurous acid, aided by the affinity of ammonia, deprives the oxide of silver of its oxygen, and is converted into sulphuric acid, which combines with the ammonia, and forms a sulphate. Sulphite of silver is decomposed by muriate of ammonia; and the precipitate, which is formed, assumes a black 20 Decomposition. colour, and is partly reduced. When sulphite of silver is exposed to the action of the blow-pipe, it gives out

Silver, &c. out sulphurous acid, melts into a yellow mass, and leaves behind a metallic button of pure silver. This salt has an acrid metallic taste; it is soluble in the caustic alkalies, and forms with them a triple salt.

3. Nitrate of Silver.

2040 Preparation. 1. Silver dissolves nitric acid with effervescence, in consequence of the evolution of nitrous gas. If the solution be made in a tall conical vessel, the nitrous gas, which is disengaged from the bottom, is dissolved in the acid, and communicates a green colour to the lower part of the liquid. If the green colour is permanent, or passes to a blue, the metal is contaminated with copper; but if it be mixed with gold, a purple-coloured powder is deposited at the bottom of the vessel.

2. Nitric acid dissolves more than $\frac{1}{2}$ of its weight of silver. This solution is nearly colourless, very heavy, and extremely caustic. It colours the skin, first of a reddish purple, and then of a deep black. It produces the same effect on the nails, the hair, and all animal substances. It is employed to dye the hair of a black colour, but this should be done with great caution. When it is diluted with water, so as to deprive it of its causticity, it has an astringent bitter taste. By evaporating the solution till a pellicle is just formed on the surface, and by slow cooling, it crystallizes in transparent brilliant plates, sometimes of a metallic lustre, when the liquid has been exposed to the sun during
2041 Properties. the crystallization. These crystals are not very regular. They are sometimes six-sided, sometimes square, and sometimes triangular; but they seem to be composed of very fine small prisms. The taste is so extremely bitter, that it has been denominated *the gall of the metals*. It is not deliquescent in the air. When exposed to the light of the sun, it gradually blackens, and the silver is reduced. When it is heated in a crucible, it readily melts into a brown liquid, which swells up, as it is deprived of its water of crystallization:
2042 Lunar caustic. and in this state of fusion, if it be allowed to cool, it assumes the form of a deep gray or black mass. When the nitrate of silver is thus fused, and cast into small cylindrical moulds, the cylinders thus formed, which exhibit a radiated fracture, are well known in surgery by the names of *lunar caustic* and *lapis infernalis*. This is generally prepared by evaporating the solution of nitrate of silver to dryness, without previous crystallization.

2043 Action of heat. 3. When nitrate of silver is heated in a retort, it first gives out nitrous gas, then very pure oxygen gas, which is afterwards mixed with azotic gas. The silver is reduced at the bottom of the vessels. When a plate or crystal of nitrate of silver, well dried, is put upon burning coals, it produces a brilliant detonation; the silver is reduced, and adheres to the surface of the charcoal.

2044 Decomposition. 4. The nitrate of silver is very soluble in water, and
2045 By hydrogen, in this state it may be reduced by hydrogen gas and phosphorus. By exposing paper or silk moistened with a solution of nitrate of silver to hydrogen gas, the paper or silk is coated with metallic silver, in consequence of the reduction of the salt by the hydrogen, which
2046 and phosphorus. has a stronger affinity for the oxygen than the silver. The same effect takes place, if a cylinder of phosphorus be immersed in a solution of nitrate of silver. The phosphorus combines with the oxygen of the oxide, and the silver is deposited on the surface of the phosphorus in the metallic state. The phosphorus may be separated from the silver by melting it in boiling water. These experiments were made by Sage and Bouillon in France, and Mrs Fulham in England.

5. A mixture of this salt and phosphorus struck smartly with a hammer, produces a violent detonation. 2047 Detonation. Nine grains of nitrate of silver and three of sulphur produce no detonation, but only an inflammation of the sulphur, when they are struck with a cold hammer; but with a hot hammer, a detonation takes place, with the reduction of the silver.

6. Nitrate of silver is decomposed by sulphuric acid, and forms a precipitate of sulphate of silver, in the state of white powder. It is also decomposed by sulphurous acid. Muriatic acid produces a copious white precipitate, which is very insoluble, and is deposited in the form of thick heavy flakes of muriate of silver.

7. Nitrate of silver is decomposed by all the alkaline and earthy matters. A white precipitate is at first formed, which afterwards passes to an olive green; but the carbonates of the alkalies give a white precipitate which remains unaltered. Ammonia occasions a sparing precipitate, which is re-dissolved by an excess of alkali, when there is formed a triple salt. But a very peculiar action takes place between ammonia and the oxide of silver, by which both the one and the other are decomposed with a violent detonation. This is the celebrated *fulminating silver*, which was discovered by Berthollet in 1788. It is prepared by the following process.

A solution of pure silver in nitric acid is precipitated by lime water. 2048 Fulminating silver. The precipitate is placed on gray paper, which absorbs the whole of the water and the nitrate of lime. Pure caustic ammonia is then added, which produces an effect somewhat similar to the slaking of lime. The ammonia dissolves only part of this precipitate. It is left at rest for 10 or 12 hours, when there is formed on the surface a shining pellicle, which is re-dissolved with a new portion of ammonia, but which does not appear, if a sufficient quantity of ammonia has been added at the first. The liquid is then separated, and the black precipitate found at the bottom, is put in small quantities on separate papers. This powder is *fulminating silver*, which, even while it is moist, explodes with great violence, when it is struck with a hard body. When it is dry, it is sufficient to touch, or rub it slightly, to produce an explosion. If the liquid decanted off this precipitate be heated in a glass retort, it effervesces, gives out oxygen gas, and there are soon formed small, brilliant, opaque crystals, which have a metallic lustre, and which fulminate with the slightest touch, though covered with liquid, and break with violence the vessels containing them. In this action the most obvious circumstance is the tendency of the compound to decomposition. The oxygen of the oxide combines with the hydrogen of the ammonia, and forms water, while the azote of the ammonia escapes in the form of gas, and the silver remains behind in the metallic state. The violence of the explosion is owing to the sudden expansion of the azotic gas. The shining pellicle which appears on the surface, is part of the silver, from

Silver, &c. from which the ammonia has been separated by the action of the air; and to have the full effect, another portion of ammonia is necessary to dissolve it. Carbonate of ammonia dissolves the oxide of silver precipitated by lime, with effervescence, and the evolution of carbonic acid; but there remains enough of this acid to form a triple salt, which, when dried, is in the form of a yellow powder, but has no fulminating property. The preparation of this dangerous powder frequently fails. A mixture of copper, the absorption of carbonic acid by the oxide of silver, precipitated by means of lime, and left too long exposed to the air, and ammonia containing a little of this acid, either diminish or destroy its fulminating property.

2049 Action of salts. 7. Many of the salts decompose the nitrate of silver. All the sulphates produce a precipitate of sulphate of silver in the form of powder. The same effect is produced by the other salts, and the effect is similar to that which takes place with the acids of which they are composed.

2050 Of metals. 8. Most metallic substances have a stronger affinity for oxygen than silver has; it is therefore precipitated from its solution in nitric acid, either partially or entirely deprived of its oxygen, and in the metallic state.
2051 Mercury. In the precipitation which takes place by means of mercury, the silver is reduced in an arborescent form,
2052 *Arbor Dianæ*, or silver tree. which has long retained the name of *arbor Dianæ*. Different processes have been recommended to effect this decomposition. One part of silver, according to Lemery, is dissolved in diluted nitric acid. The solution is then to be farther dilnted with 20 parts of distilled water, and then to add two parts of mercury. It is said, that it requires, by this process, about 40 days for the formation of the metallic tree. Homberg gives a shorter process, which succeeds sufficiently well. It consists in making an amalgam in the cold of four parts of silver-leaf and two of mercury. This amalgam is then to be dissolved in a sufficient quantity of nitric acid, and the solution to be diluted with 32 times the weight of the metals of water. By introducing into part of this liquid a small ball of soft amalgam of silver, the formation of the tree immediately takes place. It may be formed also by putting a soft amalgam of silver into six parts of a solution of nitrate of silver, and four of a solution of nitrate of mercury. In these processes one part of the mercury of the amalgam attracted by that of the solution, and carrying off the oxygen of the silver, precipitates the latter in the metallic state. The precipitation of the silver is still favoured by the affinity between it and the portion of undissolved mercury, and also part of the silver of the amalgam. All these attractions conspire to effect the separation of the silver, when it is deposited in prismatic needles, which arrange themselves in an arborescent form.

2053 Copper. 9. Silver is precipitated from its solution in nitric acid, by means of copper. When a plate of copper is immersed in this solution, diluted with its weight of distilled water, the silver is immediately separated in whitish gray-coloured flakes. If this precipitate is scraped off, and well washed with water, afterwards fused in a crueible, and subjected to the process of cupellation with lead, pure silver may be obtained.

4. Muriate of Silver.

Muriatic acid has no action whatever on silver; but by adding muriatic acid to a solution of silver in sulphuric or nitric acid, the moment it comes in contact with these solutions it decomposes them, carries off the oxide of the silver, and forms with it a white insoluble salt, which is precipitated in a kind of coagulated state. The muriates also produce a similar precipitate, and hence it is that the nitrate of silver is employed as a re-agent, and a most delicate test of muriates or muriatic acid in mineral water. The muriate of silver, which is called *corneous silver* or *horny silver*, is extremely insoluble in water. Exposed to the light it becomes brown, violet, and black. By heating it gently in a matrass, it melts like tallow, and when it becomes solid by cooling, it assumes the form of a semitransparent gray substance, similar to some kinds of horn, from which it derived its name of *luna cornea*, or horn silver. If it be fused on a stone, it is converted into a kind of friable matter, crystallized in beautiful, brilliant, and as it were metallic needles. When it is strongly heated in a crucible, it filters through it, and is lost in the fire. The component parts of this salt, are, according to Proust, 2055 Composition. 2054 Preparation.

Acid	18
Oxide	82
	100

This salt is not decomposed by any of the acids, or by the pure alkalies. It is decomposed by the alkaline carbonates. The muriate of silver is very soluble in caustic liquid ammonia. This solution, which is transparent and colonrless, undergoes a remarkable change when it is exposed to the air. As the ammonia evaporates in the air, there is formed on the surface a pellicle which assumes a brilliant, bluish, or iridescent colour. This pellicle, which gradually increases in thickness, deepens in colour, and at last becomes of a dirty gray or black, by the contact of light. The substance thus separated is the muriate of ammonia, containing a small proportion of the metal reduced.

5. Hyperoxymuriate of Silver.

This salt may be prepared by passing oxymuriatic acid gas through water having the oxide of siver diffused in it. It is soluble in two parts of warm water, and crystallizes in cooling in the form of small rhomboids. It is decomposed by muriatic acid, and by nitric and acetic acids. The muriate of silver remains behind. Exposed to a moderate heat, it melts, oxygen gas is given out, and the salt is reduced to the muriate of silver. With one-half its weight of sulphur, it produces violent detonation, by slight percussion. It gives out a white vivid flash.

6. Fluate of Silver.

Fluoric acid dissolves the oxide of silver, and forms with it an insoluble salt. It is decomposed by sulphuric acid.

7. Borate of Silver.

Boracic acid combines with the oxide of silver, by adding

adding a soluble borate to the solution of nitrate of silver. The whole of the silver is precipitated in the form of a white, heavy, insoluble powder.

8. Phosphate of Silver.

Phosphoric acid dissolves the oxide of silver, and precipitates it from its solution in nitric acid. The precipitate is a white heavy powder; with considerable heat it melts into a kind of greenish enamel. It is not soluble in water without an excess of acid. When it is heated in a retort with charcoal, it gives out a little phosphorus, and is reduced, in great part, to phosphuret of silver.

9. Carbonate of Silver.

Carbonic acid combines readily with the oxide of silver. It may be prepared by adding an alkaline carbonate to sulphate or nitrate of silver. The carbonate of silver is precipitated in the form of a white powder. This salt, which blackens by the action of light, readily gives out its carbonic acid by heat.

10. Arseniate of Silver.

Arsenic acid dissolved in water, and heated with silver, has no action upon it; but when the water is evaporated, and the heat is increased to produce vitrification, arsenic is sublimed, and there remains a white vitreous matter, which contains the silver oxidated, and is covered with a deep yellow coloured glass. By heating water on this glass reduced to powder, the solution becomes of a brown red colour; the arsenic acid is dissolved, and carries with it a little oxide of silver, which is precipitated by adding muriatic acid. The brown insoluble powder is fused at a high temperature, and becomes semitransparent. By continuing the heat in a crucible, the silver is reduced. Arsenic acid gives a brown precipitate in the solution of nitrate of silver.

11. Tungstate of Silver.

Tungstic acid does not seem to have any action on silver; but, when added to a solution of nitrate of silver, it occasions a precipitate in the form of white powder, but its properties have not been examined.

12. Molybdate of Silver.

2056 Molybdate. Molybdic acid produces a white, flaky precipitate in a solution of nitrate of silver. Nothing is known of the properties of this salt.

13. Chromate of Silver.

2057 Chromate. By adding chromate of potash to a solution of silver in nitric acid, a precipitate is formed, of a most beautiful crimson red, which the action of light changes to purple. The precipitate, which is the chromate of silver, is in the state of powder. When heated by the action of the blow-pipe, it becomes black, and is reduced in part to the metallic state. Reduced to powder in this state, it is still of a purple colour; but when it is heated with the blue flame of a candle directed by the blow-pipe, it becomes green, and the silver is separated in globules. The chromic acid, decomposed by the hydrogen of the blue flame, passes to the state of green oxide, and the oxide of silver is reduced.

14. Acetate of Silver.

Acetic acid dissolves the oxide of silver. The acetate of silver may be prepared, by adding acetate of potash to a solution of nitrate of silver. The solution affords, on cooling, small prismatic crystals. This salt is very soluble in water, and has an acrid metallic taste. When heated, it swells up, and is decomposed. The acid is driven off, and the oxide remains behind. 2058 Acetate.

15. Oxalate of Silver.

Oxalic acid dissolves a small portion of the oxide of silver, which is precipitated from nitric acid, by means of potash, or, by adding oxalic acid to a solution of nitrate of silver. A white, thick, insoluble precipitate is formed, which is oxalate of silver. This salt is soon changed by the action of light. When exposed to the rays of the sun, it becomes black; and when it is heated in a spoon, it undergoes a kind of detonation. 2059 Oxalate.

16. Tartrate of Silver.

Tartaric acid combines with the oxide of silver, and forms with it a tartrate of silver, which becomes black by exposure to the air. This acid has no action on silver itself, nor does it produce a precipitate in the solution of nitrate of silver. 2060 Tartrate.

17. Tartrate of Potash and Silver.

When tartar is added to a solution of nitrate of silver, there is formed, according to Thenard, a triple salt, which consists of tartaric acid, oxide of silver, and potash.

It is decomposed by the alkalies and alkaline carbonates, and by the sulphates and muriates *.

* *Ann. de Chim.* xxxiii. 36.

18. Citrate of Silver.

Citric acid dissolves the oxide of silver, and forms with it an insoluble salt, which becomes black by being exposed to the sun. It has a harsh, strong, metallic taste. It affords by distillation concentrated acid, and leaves behind the silver reduced in an arborescent form, mixed with a little charcoal, at the bottom of the retort. This salt is decomposed by nitric acid. Its component parts are, 2061 Citrate.

Acid	36
Oxide of sulphur	64
	100

19. Malate of Silver.

Malic acid, added to a solution of nitrate of silver, produces a precipitate, the nature of which is unknown. 2062 Malate.

20. Benzoate of Silver.

Benzoic acid combines with the oxide of silver, and forms with it a salt which is soluble in water, is not deliquescent in the air, but becomes brown by exposure to the sun's rays, and is decomposed by heat; the acid being driven off, and the oxide reduced to the metallic state. 2063 Benzoate.

21. Succinate of Silver.

Succinic acid has no action on silver, but it combines with 2064 Succinate.

Silver, &c. with its oxide. The succinate of silver crystallizes in thin oblong prisms, which are arranged in a radiated form.

22. Saccolate of Silver.

2065 Saccolate. Saclactic acid poured into a solution of nitrate of silver produces a white precipitate, the nature of which has not been examined.

II. Action of the Alkalies, &c. upon Silver.

2066 Action of ammonia on silver. 1. The pure alkalies have no effect on silver. Its oxide is soluble in ammonia; but if this solution be long exposed to the light, the ammonia is decomposed, azotic gas is disengaged, water is formed by the combination of the hydrogen of the ammonia and the oxygen of the oxide, which is reduced to the metallic state.

2. Silver forms no compound with the earths; but in the state of oxide it combines with some of them, by vitrification, and in this state it colours glass and enamels of a yellow, olive green, or brownish shade. For this purpose the oxide of silver is employed in the arts.

3. None of the salts have any action on silver. It is not sensibly oxidated by the nitrates or hyperoxymuriates. The metals which are more easily oxidated, and with which silver is frequently contaminated, are acted on by these saline matters, and in this way, it has been observed, silver may be refined or purified by means of nitre.

III. Alloys.

1. There are few metallic substances with which silver does not enter into combination, and form alloys. Few of these, however, are applied to useful purposes. Arsenic combines with silver, and forms an alloy, which is externally of a yellow colour, but internally of a dark gray. It is brittle; and, when it is exposed to heat, the arsenic is sublimed, and the silver remains behind in a state of purity.

2067 Cobalt. 2. Cobalt is with difficulty alloyed with silver. When they are melted together in a crucible, they separate from each other, according to their specific gravities, each retaining a small proportion of the other.

2068 Bismuth. 3. Bismuth combines with silver very readily by fusion. The alloy is brittle, lamellated, and of an intermediate colour between bismuth and antimony. The specific gravity is greater than the mean. The two metals cannot be separated, but with difficulty. When this alloy is exposed to strong heat in the open air, the bismuth is oxidated, and vitrified at the same time that it is partially sublimed, so that it might be employed in place of lead for the cupellation of silver; and in some cases bismuth is preferred, on account of its more rapid oxidation.

2069 Antimony. 4. The alloy of antimony and silver is easily effected by fusion. It is heavier than the mean of the two metals. This alloy is brittle, and has not been applied to any use.

2070 Mercury. 5. Silver has a strong affinity for mercury. An amalgam may be formed of these two metals, by saturating silver leaf, or fine filings of silver, with mercury; or by adding to silver, while it is red-hot, heated mercury. The consistence of this amalgam varies according to the proportion of the two metals. In general it is white and soft, and the specific gravity is greater than the mean. It sinks to the bottom of liquid mercury. Exposed to a moderate heat for some time, it shoots out into a kind of vegetation, like the tree of Diana; and if, after fusion, it is allowed to cool slowly, it crystallizes in the form of small leaves, or in square prisms, terminated by four-sided pyramids. When it remains long exposed to the air, it becomes harder, and of a more solid consistence. This amalgam is much employed in gilding. 2071

6. Silver combines readily with zinc, by means of fusion, and forms with it a brittle alloy, which has not been applied to any use. Zinc. 2072

7. Silver combines easily with tin, and forms an alloy which is extremely brittle. The silver is entirely deprived of its ductility. This alloy, however, instead of being useful, is considered as one of the most troublesome in the working of silver, on account of the hardness and brittleness which it communicates, and it is found almost impossible to separate them entirely. Tin. 2073

8. Lead, it has been already observed, readily combines with silver by means of fusion. It is employed for the purification of lead in the process of cupellation. This alloy is very fusible, resembles lead in colour, and is less sonorous, but not less ductile than silver. The specific gravity is greater than the mean. Lead. 2074

9. An alloy of silver and iron in equal proportions has nearly the colour of silver. It is harder, has some ductility, and is attracted by the magnet. Steel is soldered with silver. Guyton fused together silver and iron, and obtained two buttons, which were placed by the side of each other, and strongly adhering, but sufficiently distinct. Each of the metals was found to be alloyed with a small proportion of the other. The silver renders the iron hard and compact, and the iron communicates to the silver properties which seem to render it applicable to many important uses. Iron. 2075

10. Silver combines readily with copper, and forms with it one of the most useful alloys. This alloy gives hardness to the silver, and the colour of the latter is not diminished, unless the quantity of copper is considerable. These properties render it extremely useful in the fabrication of various utensils, and especially of money. The density of the alloy is less than the mean of the two metals. If 137 parts of silver be alloyed with 7 of copper, the mean specific gravity is 10.301, but it is only 10.175, which shews an increase of bulk of $\frac{1}{81}$ part. This is the alloy of the silver coin of France *. The standard silver, which is employed in the British silver coin, is composed of 11 parts of silver and one of copper. Copper. 2076

* Jour. Mines. 30.

The uses of silver are as important and extensive as any of the metals, except iron, and especially when it is alloyed with copper; as it is applied as the medium of commerce by all civilized nations, and for various instruments and utensils, most of which are so familiar as to require no particular enumeration. Uses.

Sect. XXIII. *Of Gold and its Combinations.*

2077 History. 1. Gold is spoken of in the earliest histories of the world. The peculiar properties of this metal, its scarcity, durability, and beauty, have rendered it always an object of pursuit, and have raised it high in the estimation

Gold, &c. tion of mankind. The alchemists regarded gold as the purest, the simplest, the most perfect, and very justly the most indestructible of all the metals with which they were acquainted. Hence it was esteemed the noblest and most perfect of what they considered as perfect metals, and dignified with the pompous name of *king of the metals*. It was the object of all their labours and researches, to discover the means of transmuting the baser and more abundant metals into this precious metal.

2078 Universally diffused, but in small quantities. 2. Gold is supposed to be, next to iron, the most universally diffused of all the metals; but at the same time it is found in such small quantities, that it is one of the scarcest. It is most commonly found in the state of small grains, mixed with the sand or with the soil, almost in every part of the world. Gold is also found imbedded in stones, especially quartz, either in grains, or crystals, which are octahedrons; and it is probably from these that the grains found in the soil or in the sands in the beds of rivers, have been derived. Gold is, however, more abundant in the tropical regions of the earth, where it forms an article of commerce, under the name of *gold dust*. In this state it is found in the rivers of Africa, and exported to Europe. But although gold is always found in the metallic state, it is not absolutely pure. It is generally alloyed with copper or silver, and sometimes with iron and mercury.

2079 Extraction from its ores. 3. To separate gold from the metals with which it is alloyed, the process recommended by Bergman may be employed. It is first dissolved in nitro-muriatic acid; the silver is deposited spontaneously in the form of muriate of silver, which is insoluble; the gold is precipitated in fine powder by the sulphate of iron; the quantity of iron may be ascertained by prussiate of potash; and the copper is separated by means of iron. Each of these processes is performed on different portions of native gold, so that the quantity of gold, and the different metals with which it is alloyed, may be determined. In the large way, the extraction of gold is a very simple process. The auriferous sand of rivers is first washed to carry off all extraneous matters. It is triturated in a vessel with water, with 10 or 12 times its weight of mercury. The water is poured off, and carries with it the earthy matters. The amalgam is pressed in skins, to separate the excess of mercury, and the solid portion which remains is exposed to heat in stoneware retorts, to drive off the mercury, and the gold remains behind. To separate the gold from other metals, it is subjected to the process of cupellation, which has been already described in treating of the purification of silver.

2080 Properties. 4. Gold is of a reddish yellow colour. It possesses considerable lustre, although other metals have this property in a superior degree. Gold, next to platinum, is the heaviest body in nature, having a specific gravity of 19.3 and 19.4. It is not very hard, but is extremely ductile and malleable. It may be beaten out into leaves so thin as to equal $\frac{1}{282000}$ part of an inch. The method of extending gold, which is followed by the gold-beaters, is by hammering a number of thin rolled plates between skins or animal membranes. A single grain of gold may be beaten out in this way, so as to cover $56\frac{3}{4}$ square inches. The coating of gold which covers wire is still thinner. By computation it is found, from the diameter and length of the wire, and the quantity of gold employed, that it is only $\frac{1}{12}$ of the thickness of gold leaf. The tenacity of gold also is very considerable. A gold wire .078 of an inch in diameter will support a weight equal to more than 150 lbs. avoirdupois, without breaking. Gold has no perceptible taste or smell.

5. Gold melts, according to Guyton, at the temperature of 32° Wedgwood. It has been observed, that gold, in the state of filings or grains, melts with more difficulty than in larger masses; and that the small fragments, even after they are fused, remain in separate globules. To make them run into one mass, a little nitre or borax is thrown into the crucible. It has also been observed, that gold, which has only been subjected to the degree of heat necessary for its fusion, is brittle after cooling. To preserve its ductility, therefore, the temperature must be raised much higher. It is brittle also, when it is too suddenly cooled after fusion. By increasing the temperature while the gold is in fusion, it seems to become convex on the surface, and when it cools, it sinks, which is ascribed to the expansion and contraction of the metal. When it is slowly cooled, it crystallizes in the form of quadrangular pyramids, or regular octahedrons. If the heat be continued while it is in perfect fusion, it seems to be agitated, and to undergo a kind of ebullition. This was observed by Homberg and Macquer, by the action of the burning glass, or when a small globule of gold was acted on by the blow-pipe. According to Macquer, it rose in vapour to the height of five or six inches, and attached itself to the surface of a silver plate, which it gilded completely. 2081 Action of heat.

9. Gold is the most indestructible, and the least altered of all the metals, by exposure to the air. It preserves its lustre, its brilliancy, and colour, for any length of time. 2082 Of air.

7. The strongest heat of a furnace, which has been applied to gold in fusion, has been found incapable of producing the smallest change, or the least tendency to oxidation; but by the action of Tschirnhausen's powerful burning glass, Homberg having placed some gold in the focus, found that it rose in vapour; and that it was covered with a violet-coloured vitreous oxide. This change was at first ascribed to foreign bodies, particularly to the charcoal on which the gold was placed during the experiment. But Macquer repeated the same experiments with a more powerful glass, and obtained the same result. The vitrification after some time gradually extended, the gold diminished, and the support was impregnated with a purple-coloured matter. The effect of electricity on gold leaf, placed between two cards, was observed by Camus in 1773. The gold was converted into a violet-coloured powder, which adhered to the paper. This seeming oxidation was regarded by some as merely a minute mechanical division of the gold; but this objection has been removed by the experiments of Van Marum on the combustibility of gold by means of the powerful electrical machine at Haerlem. A strong electrical shock was passed through a golden wire suspended in the air. It kindled, burned with a perceptible green flame, and was reduced to fine powder, which was dissipated in the air. It was supposed by this philosopher, that the inflammation of gold might be effected 2083 Oxidation. 2084 By electricity.

Gold, &c. effected without the excess of oxygen gas, as he found it to take place in hydrogen gas and other elastic fluids, which are incapable of supporting combustion. But the force of this objection is removed by recollecting, that all gases hold in solution a quantity of water, and that water is very readily decomposed by electricity.

2085 By lightning. A similar oxidation has been observed to take place on the gilding in the inside of houses, or on the furniture, which has been struck with lightning. The purple oxide of gold, thus obtained, contains about five or six parts in the hundred of oxygen. Gold combines with a greater proportion of oxygen, forming a different oxide of a yellow colour; but this oxide is incapable of combining with any farther portion of oxygen. It remains, therefore, unchanged in the air, and retains for a long time its brilliant rich colour. This oxide, however, is decomposed by the action of heat; the oxygen is driven off, and the gold remains behind in the metallic state.

2086 Yellow oxide. When gold is dissolved in nitro-muriatic acid, or in a mixture of equal parts of nitric and muriatic acids, an effervescence takes place, and the solution becomes of a yellow colour. In this process the nitric acid is decomposed, its oxygen combines with the gold, and the oxide, as it is formed, is dissolved in the muriatic acid. By adding lime water, a precipitate is formed, which is the yellow oxide of gold, consisting of eight or ten parts of oxygen in the 100.

8. There is no action between gold and azote, hydrogen, carbon or sulphur. The oxides of gold, indeed, are readily decomposed by hydrogen.

2087 Phosphuret. 9. Phosphorus, according to the experiments of Pelletier, combines with gold, by heating together in a crucible a mixture of one part of gold in filings, with two parts of phosphoric glass, and one-eighth part of charcoal. Great part of the phosphorus is separated from the acid, and driven off, but there remains a small quantity united with the gold, forming a phosphuret of gold. This phosphuret is whiter and more brittle than the gold, and has some appearance of crystallization. It may be formed also by adding phosphorus to gold in a red heat in a crucible. It becomes pale coloured, granulated, brittle, and a little more fusible. This phosphuret contains $\frac{1}{24}$th part of phosphorus. It is decomposed by being kept some time in fusion; the phosphorus is driven off in the state of vapour, and inflamed.

2088 Affinities. 10. The order of the affinities of gold and its oxides, as they have been arranged by Bergman, is the following:

Gold.	Oxide of Gold.
Mercury,	Muriatic acid,
Copper,	Nitric,
Silver,	Sulphuric,
Lead,	Arsenic,
Bismuth,	Fluoric,
Tin,	Tartaric,
Antimony,	Phosphoric,
Iron,	Prussic.
Platinum,	
Zinc,	
Nickel,	
Arsenic,	
Cobalt,	
Manganese.	

I. Salts of Gold.

1. Nitrate of Gold.

When concentrated nitric acid is several times successively poured upon gold, boiled and distilled to dryness, the gold is dissolved, and the solution assumes a yellow colour. This effect was first observed by Brandt, in separating gold and silver, by means of this acid. But it appears from the observation of Deyeux on the solubility of gold in nitric acid, that the solution is more readily effected in proportion to the quantity of gas, or nitrous gas, which the acid contains. According to the experiments and observations of Fourcroy, gold leaf is dissolved in nitric acid, impregnated with nitrous oxide, and that it is owing to the nitrous oxide that the gold is oxidated, this oxide being more easily decomposed than nitric acid. Thus it happens that the acid is deprived of its colour as it acts on the gold, and the solution is more rapidly effected in the cold than with heat, because the nitrous gas is disengaged by heat. The acid which at first had been deprived of its colour, by the oxidation of the gold, as this oxide is dissolved, assumes an orange-yellow colour, holding in solution the nitrate of gold with excess of acid. The nitrate of gold cannot be obtained in crystals. It is decomposed by heat, or by exposure to the light of the sun. When this solution is filtered, it leaves on the paper a violet-coloured trace, which is the oxide of gold. The nitrate of gold is also decomposed by the alkalies, or by introducing a plate of tin or silver into the solution, and the purple oxide is precipitated in the form of powder. It is also decomposed by muriatic acid, which, at the instant of combination, converts the orange colour to a pure yellow. 2089 Preparation. 2090 Decomposed by heat and the alkalies.

2. Muriate of Gold.

1. Muriatic acid has no action whatever on gold, or on its purple oxide, but gold is immediately oxidated and dissolved by oxymuriatic acid; or if nitric acid be added to muriatic acid, the solution of gold is immediately effected. It is on account of this property that nitro-muriatic acid was distinguished by the name of *aqua regia*, because it dissolved gold, which was stiled by the alchemists, the *king of the metals*. The nature of the action is obvious. Gold is oxidated with great difficulty. This is effected by oxymuriatic acid, which readily parts with its oxygen, or by the addition of nitric to the muriatic acid, the former of which is decomposed, giving up its oxygen to the gold, which being oxidated, is dissolved in the muriatic acid, forming a muriate of gold. This solution of the muriate of gold is of a deep yellow colour, extremely acrid and caustic, has a very astringent, metallic taste, and stains the skin of a deep purple colour, which becomes darker by exposure to the air and the light. It continues permanent till the epidermis is renewed. It produces a similar effect on all vegetable and animal matters, and on marble and siliceous stones. By evaporating this solution, nitric acid is disengaged, and crystals are obtained, in the form of truncated octahedrons, or small quadrangular prisms, of a topaz colour. These crystals are easily procured by evaporating the solution to one half, and adding a little alcohol. They assume a red colour by the action of strong 2091 Preparation. 2092 Properties.

strong light. They attract moisture from the air, and spontaneously become liquid. By gradually heating in a retort this solution of gold in nitro-muriatic acid, there passes over nitric acid, muriatic acid, which carries with it a portion of gold, and even reddish-yellow crystals of muriate of gold. To the nitro-muriatic liquid, which is of a high colour, and which rises during the distillation, the alchemists gave the name of *red lion*. By evaporating the solution to dryness, a dry muriate of gold is obtained, which may be reduced by a strong heat, previously giving out oxygen gas, and leaving the gold behind in the metallic state.

2093 ecomposi- on.

2. The muriate of gold is very soluble in water. It is decomposed by hydrogen gas. If a piece of silk be moistened with a solution of muriate of gold, the salt is decomposed, and the gold, reduced to the metallic state, attaches itself to the silk. Muriate of gold is also decomposed by phosphorus. If a stick of phosphorus be introduced into a saturated solution of muriate of gold, the salt is decomposed, and the gold being reduced to the metallic state, forms a cylindrical covering to the phosphorus, which may be separated by dissolving the latter in hot water. A similar effect is produced by burning sulphur, by sulphurated and phosphorated hydrogen gases, and by sulphurous acid. If a solution of muriate of gold be cautiously added to sulphurous acid, a fine pellicle of gold appears on the surface, which is instantly precipitated in the form of small grains. These curious and interesting experiments were made by Mrs Fulham. It is easy to see the nature of the process. All the substances which have been enumerated, have a stronger affinity for oxygen than gold, so that the oxide of gold in combination with the acid is decomposed; the oxygen combining with the hydrogen, for instance, and forming water, or with the phosphorus or sulphur, and forming sulphuric or phosphoric acid. The reduction of muriate of gold, Mrs Fulham has observed, does not take place except in the liquid state, and she supposes that the decomposition of water is necessary to produce this effect. But the liquid state of the salt, it is supposed by others, is only necessary to expose it to the action of combustibles in a state of minute division, and that otherwise this theory does not account for the phenomena.

2096 lphurous d.

2097 ible in r.

3. The muriate of gold is soluble in ether. It forms with it a solution of a golden yellow colour, which floats on the top of the fluid. By adding ether to a solution of gold, and agitating the mixture, as soon as it is left at rest, the two liquids separate, the ether rises to the top, and assumes a yellow colour, while the nitro-muriatic acid remains below and becomes white. By this process a tincture of gold, or what was formerly called *potable gold*, was prepared. The solution of gold in ether is not permanent. It is soon reduced to the metallic state, and is sometimes found crystallized on the surface.

098 on of lies.

4. The muriate of gold is decomposed by all the alkalies and earths, and is reduced to the state of yellow oxide. This decomposition is effected slowly by the fixed alkalies, and if the alkali be added in sufficient quantity, the precipitate is re-dissolved, and the liquid assumes a reddish colour. It is owing to this solution of the oxide of gold by these alkalies, that the precipitation is slow and difficult. Triple salts are formed, the nature of which is unknown. The oxide of gold, thus precipitated, becomes of a purple colour by exposure to the light; by the action of heat it gives out oxygen gas, and the gold is revived.

2099 Fulminating gold.

The most singular precipitate from the muriate of gold is that by means of ammonia, which forms the compound called *fulminating gold*. It is prepared by the following process. To a solution of gold in nitro-muriatic acid, and diluted with three or four times its weight of distilled water, gradually add pure ammonia, as long as any precipitate is formed. No excess of alkali must be added, because the precipitate is re-dissolved. It is then washed and dried in the air on paper, and afterwards put into a phial, which should be covered only with a bit of cloth or paper, as the powder is apt to explode with the slightest friction.

2100 Another process.

Fulminating powder may also be obtained, by dissolving gold in a solution of two parts of nitrate of ammonia, and one of muriatic acid. The oxygen of the nitric acid combines with the gold, and forms an oxide, which is dissolved in a portion of the muriatic acid; nitrous gas is disengaged, and there remain in the liquid, muriate of gold, and muriate of ammonia. By precipitating this solution by means of a fixed alkali, fulminating gold is obtained. The alkali combines with the muriatic acid of the gold and ammonia, and the oxide of gold, uniting with the ammonia, forms the fulminating gold. The precipitate is washed and dried as in the former process. Basil Valentine, who first described this singular preparation, had observed that it produced detonation equally by means of heat, by friction, and percussion. When a small quantity of fulminating powder is exposed to heat, it produces a violent detonation; or, if it be rubbed with a hard body, a similar effect takes place. It explodes also, by being smartly struck with a hammer. These astonishing effects long excited the attention of philosophers, but received no satisfactory explanation, till the nature of the composition of this substance was discovered by modern chemists. It was examined by Scheele and Bergman; and at last the theory of its violent action was fully developed by Berthollet. This compound consists of the oxide of gold and ammonia, and as the oxide performs the part of an acid, it is sometimes denominated *aurate of ammonia*. During the explosion which takes place, whether by the application of heat, or by friction or percussion, the hydrogen of the ammonia combines with the oxygen of the oxide of gold, and forms water. This water, being suddenly raised to the state of vapour, and the azote, the other component part of ammonia, being at the same time suddenly converted into gas, produce the explosion. The gold is reduced to the metallic state.

2101 Theory.

2101 May be decomposed without explosion.

This substance may be deprived of its fulminating property, by being exposed for some time to a very gentle heat. It is then converted into a blackish brown powder. A similar effect is produced, by subjecting it for a long time to the temperature of boiling water. Its fulminating property is at least greatly diminished by the latter process. It appears, too, that the contact of air promotes this action: for when it was heated in an iron globe, in an experiment which

which Birch performed before the Royal Society of London, or in a sphere of strong copper, in an experiment by Bergman, no detonation took place. Berthollet applied a gentle heat to a quantity of fulminating gold, in copper tubes; and he obtained ammoniacal gas, and the gold was reduced to the state of purple oxide. By these experiments it appears, that this substance is decomposed without detonation, when the sudden dilatation of the gases which are disengaged is resisted by strong vessels, or when the heat is so moderate as to separate the ammonia without decomposition.

2103 Action of metals.

5. The muriate of gold is decomposed by almost all metallic substances. Some metals decompose it completely, and reduce it to the metallic state, while others deprive it of a portion of oxygen, and reduce it to the state of purple oxide. Bismuth, zinc, iron, copper, and mercury, reduce the gold to the metallic state. Lead, silver, and tin, occasion a precipitate in the form of purple oxide. The most singular of all these precipitates, and which has long occupied the attention of chemists, is that which is produced by

2104 Purple powder of Cassius.

means of tin. This is called the *purple precipitate*, or *powder of Cassius*. It was at first particularly described by Cassius, from whom it derived its name; but it was known long before, even so early as the time of Basil Valentine, by whom it is mentioned. If a plate of tin be immersed in a solution of muriate of gold, the surface of the metal is soon covered with a deep-coloured violet or purple powder, which is gradually diffused through the whole liquid. This is usually prepared by adding to a solution of gold in nitro-muriatic acid, a solution of muriate of tin recently prepared. The theory of this process is the following. The gold in solution is in the state of yellow oxide. It is deprived of part of its oxygen, and reduced to the state of purple oxide by the tin. The purple oxide is no longer soluble in the acid, and is therefore precipitated. The same effect is produced when a salt of tin is added, provided this salt be not fully saturated with oxygen, for in that case no precipitate is obtained. This is the reason, as Pelletier has shown, that muriate of tin, after it has been for some time exposed to the air, loses the property of producing the purple precipitate, because it has absorbed oxygen from the atmosphere, and is not susceptible of combining with a greater quantity. For the same reason no precipitate is obtained by the oxymuriate of tin, or the *smoking liquor of Libavius*, or the red sulphate of iron, because both these salts have their bases fully saturated with oxygen. Other metallic solutions have also the property of decomposing and precipitating the muriate of gold. The nitrate of silver produces a reddish precipitate, which is a mixture of white muriate of silver and purple oxide of gold. The nitrate of lead deposits a dark-coloured substance, composed of muriate of lead and oxide of gold.

2105 Metallic acids.

6. The metallic acids have no effect whatever on gold. Vauquelin found that chromic acid, mixed with muriatic acid, gave it the property of dissolving gold. This is owing to the chromic acid giving up part of its oxygen, which appears to be the case, from its passing from its natural colour, which is orange, to the state of green oxide.

II. Action of Alkalies, &c. upon Gold.

2106 Alkalies.

1. None of the alkalies have any action upon gold or on its purple oxide; but the yellow oxide precipitated from its solution by means of the fixed alkalies, and digested for some time with ammonia, is readily converted into fulminating gold.

2107 Earths.

2. The earths have no action on gold in the metallic state; but in the state of purple or yellow oxide, it combines with the earths which are vitrified by means of the alkalies, and forms with them enamels, which are of a violet or purple colour, or glass of a golden-yellow colour. It is on account of the latter property that the yellow oxide is employed in the fabrication of artificial topazes. It has been observed that glass coloured by means of gold, and which contains a considerable proportion of oxide of lead or of manganese, has a remarkable property of changing to a permanent purple or ruby-red colour, when it is slightly heated, and long before fusion. This is supposed to be owing to some change in the state of the oxidation of the different metals.

2108 Salts.

3. The most powerful salts, as the nitrates, the hyperoxymuriates, have no action on pure gold. It has, however, been observed, that borax diminishes its colour, and that nitre, which is employed in its purification, renders it more brilliant.

III. Alloys of Gold.

2109 With arsenic,

1. Gold is susceptible of combination with most metallic substances, which produce a very particular change on its properties. The alloy with arsenic is brittle, hard, of a granulated texture, and of a very pale colour. According to Mr Hatchet's experiments, arsenic readily combines with gold raised to a common red heat, when the former is in the state of vapour, and particularly when the combination is made in close vessels.

2110 Tungsten, &c.

2. The alloys of gold with tungsten, molybdena, chromium, titanium, and uranium, have not been examined.

2111 Cobalt.

3. The combination of gold and cobalt is not perceptibly different from pure cobalt. This alloy reduced to a fine powder, and heated in contact with air, gives, after its oxidation, and by strong heat, a deep blue glass. In Mr Hatchet's experiments, one part of cobalt and 14 of gold form a brittle alloy of a dull yellow colour. With $\frac{1}{65}$ of cobalt the alloy was brittle, but became ductile with $\frac{1}{130}$ part.

2112 Nickel.

4. Gold forms with nickel a white and brittle alloy. In Mr Hatchet's experiments $\frac{1}{28}$ of nickel rendered the alloy brittle. It was scarcely, if at all, brittle with $\frac{1}{65}$ part, and with $\frac{1}{130}$ of nickel it was completely ductile. One part of nickel and 16 of gold give an alloy of the colour of brass.

5. Mr Hatchet formed an alloy of gold with manganese. It was of a pale yellowish-gray colour, had something of the lustre of polished steel, and some ductility, although it was very hard. It contained about one-ninth of manganese. Acids produced no effect, nor was it altered by exposure to the air *.

* Phil. Trans. 1803.

2113 Bismuth.

6. Bismuth fused with gold, yields an alloy which is brittle in proportion to the quantity of bismuth employed. The specific gravity of this alloy is greater than

than the mean. In Mr Hatchet's experiments, this alloy was brittle, when the proportion of bismuth
2114 Antimony. amounted only to $\frac{1}{1920}$ part.

7. Antimony combines with gold, and renders it hard and brittle. Equal parts of these metals form an alloy not much different in appearance from gold itself. This compound was frequently employed by the alchemists in their researches. Antimony was called the *royal bath*. They pretended that the quantity of gold was increased when it was separated from the alloy, after having been fused with this metal. But it appears that this increase of weight was owing to part of the antimony, which was not separated from the gold. The sulphuret of antimony was formerly much employed for the purification of gold, to separate, by means of the sulphur, the metals which were combined with it; and from this property of acting on all the metals then known, excepting gold, the sulphuret of antimony was called by the alchemists, *the*
2115 Mercury. *wolf of the metals*.

8. Gold unites very readily with mercury. If gold be brought into contact with this metal, it is instantly covered with it; and if gold leaf be triturated with mercury, it totally disappears, and is dissolved in the mercury; so that even in the cold, mercury combines with the whole quantity of gold with which it can be alloyed. When the proportion of gold is increased, the amalgam becomes solid. When this operation is performed in the large way, the combination is promoted by means of moderate heat. This amalgam is of a yellowish-white colour; it is fusible at a moderate heat, and crystallizes in the form of quadrangular prisms. It is decomposed by a strong heat, and the mercury is dissipated. This amalgam is much employ-
2116 Zinc. ed in gilding.

9. Gold combines with zinc by means of fusion. This alloy is paler than gold, has little malleability, and if the proportion of the zinc be considerable, is very brittle. An alloy consisting of equal parts of the two metals, is of a greater specific gravity than the mean, is very hard, susceptible of a fine polish, and is not much altered by the air. It has been recommended, on account of these properties, for the fabrication
2117 Tin. of the mirrors of telescopes.

10. Gold combines easily with tin by means of fusion. This alloy, it is said, is the dread of the workmen, because it deprives gold of its ductility. They are even cautious in preserving gold from the contact of the vapour of tin in fusion, which renders the gold so brittle, that it may be reduced to powder in a mortar. It is extremely difficult to purify gold after it has been alloyed with tin, for it does not pass into the cupel with lead or with bismuth. Nitre, borax, and even the hyperoxymuriate of mercury, which are often employed with this view, do not always succeed. The most successful method is by treating the alloy with sulphuret of antimony, or with muriatic acid, which dissolves the tin when it is in considerable proportion. But in the experiments of Mr Hatchet and Mr Bingley, it appears that the universal opinion which has hitherto prevailed, of tin being so injurious to the ductility of gold, is, to a certain extent, erroneous; and it appears probable, that the ductility of gold being destroyed, as was supposed, even by the fumes of tin, ought to have been ascribed to other metals, as bismuth, lead, antimony, or zinc, with which the tin was contaminated.

11. Lead very readily combines with gold by fusion; this alloy deprives the gold of its ductility, and diminishes the colour. So small a proportion as $\frac{1}{1920}$ part of lead destroys the ductility of gold. This alloy, it has been already stated, is made for the purpose of purifying gold from other metals, in consequence of the easy oxidation and vitrification of the lead. 2118 Lead.

12. Gold is easily alloyed with iron, and forms with it a hard brittle mass. Some of these alloys are so hard, that Dr Lewis found them fit for cutting instruments. Equal parts of iron and gold form an alloy of a gray colour. Four parts of iron and one of gold afford an alloy nearly of the colour of silver, and the specific gravity of this alloy has been ascertained to be less than the mean. One part of iron alloyed with 12 of gold, according to Mr Hatchet, was of a pale-yellowish gray colour, and was so ductile that it might be rolled and cut. When gold is fused, it adheres readily to iron; and hence it has been proposed to solder small pieces of steel with gold, which seems to be preferable to copper. 2119 Iron.

13. Gold readily combines with copper by fusion. This is one of the most important alloys, on account of the hardness which copper communicates to gold, without diminishing its colour. This alloy, according to Muschenbroeck, possesses the greatest hardness, without sensibly diminishing its ductility, when the proportions are one part of copper and seven of gold. This alloy is more fusible than gold, and on that account it is employed as a solder for that metal. The gold coin of most countries consists of this alloy. The proportions in the gold coin of Britain and France are 11 parts of gold to one of copper. According to Brisson, the specific gravity of this alloy is greater than the mean. It is 17.486, but it ought to be 17.153. But, according to Mr Hatchet's experiments, there is no mutual penetration in the alloy of these metals, and therefore no increase of density. On the contrary, some degree of expansion was observed. Four hundred and forty-two grains of gold of specific gravity 19.172, were alloyed with 38 grains of copper of specific gravity 8.875. The specific gravity of the alloy was found to be 17.157. The bulk of the alloyed mass amounted to 27.98, while the natural bulk of the two metals before combination was 27.32, which shews an increase of expansion of the alloyed mass equal to $\frac{66}{100}$. Mr Hatchet observes that Brisson's experiment was probably made on part of a large bar or ingot, in which it generally happens, that the two metals are very unequally diffused, and this inequality, which is greater according to the quantity of the metal, is found to vary with the form, nature, and position of the mould, and therefore to produce variations in the specific gravity *. 2120 Copper.

* Phil. Trans. 1803. p. 112.

14. Silver forms an alloy with gold. Homberg found, that equal parts of these metals fused together in a crucible, formed an alloy which contained $\frac{1}{7}$ of its weight of silver. One part of silver and two of gold, according to Muschenbroeck, give to the alloy the greatest degree of hardness. One-twentieth part of silver changes the colour of gold very sensibly. This alloy is employed for soldering gold, being more fusible than this metal. 2121 Silver.

15. Mr

Gold, &c.

15. Mr Hatchet observes, that the obvious inference to be deduced from his experiments is, that only two metals are proper for the alloy of gold coin. These are silver and copper. All other metals either considerably alter the colour, or diminish the ductility of gold. According to the same philosopher, the ductility of gold is diminished by different metallic substances, nearly in the following decreasing order:

Bismuth, }
Lead, } These are nearly equal in effect.
Antimony, }
Arsenic,
Zinc,
Cobalt,
Manganese,
Nickel,
Tin,
Iron,
Platinum (E),
Copper,
Silver *.

* Phil. Trans. 1803, 95. 2122

Uses.

The uses of gold, many of which have been already detailed, in describing its properties and combinations, are too familiar to require particular enumeration (F).

SECT.

(E) Mr Hatchet supposes that the platinum not being quite pure, the place he has assigned to it is perhaps not precisely that which it ought to occupy.

(F) The metals which were earliest known, were long distinguished by particular names and characters, of which the following account is taken from the elaborate researches of Professor Beckmann. The following table exhibits their names and characters.

Metals.	Names.	Characters.
Gold,	Sun,	☉
Silver,	Moon,	☽
Mercury,	Mercury,	☿
Copper,	Venus,	♀
Iron,	Mars,	♂
Tin,	Jupiter,	♃
Lead.	Saturn.	♄

It cannot be doubted, Professor Beckmann observes, that these names were first given to the heavenly bodies; and the metals which were then known, amounting to the same number, were supposed to have some affinity or relationship to the planets, and with them to the gods, and were accordingly named after them. " To each god was assigned a metal, the origin and use of which was under his particular providence and government; and to each metal were ascribed the powers and properties of the planet and divinity of the like name; from which arose, in the course of time, many of the ridiculous conceits of the alchemists.

" The oldest trace of the division of the metals among the gods is to be found, as far as I know, in the religious worship of the Persians. Origen, in his refutation of Celsus, who asserted that the seven heavens of the Christians, as well as the ladder which Jacob saw in his dream, had been borrowed from the mysteries of Mithras, says, ' Among the Persians the revolutions of the heavenly bodies were represented by seven stairs, which conducted to the same number of gates. The first gate was of lead; the second of tin; the third of copper; the fourth of iron; the fifth of a mixed metal; the sixth of silver; and the seventh of gold. The leaden gate had the slow tedious motion of Saturn; the tin gate the lustre and gentleness of Venus; the third was dedicated to Jupiter; the fourth to Mercury, on account of his strength and fitness for trade; the fifth to Mars; the sixth to the Moon; and the last to the Sun.' ' Celsus de quibusdam Persarum mysteriis sermonem facit. Harum rerum, inquit, aliquod reperitur in Persarum doctrina Mithrasisque eorum mysteriis vestigium. In illis enim duæ cælestes conversiones, alia stellarum fixarum, errantium alia, et animæ per eas transitus quodam symbolo representantur, quod hujusmodi est. Scala altas portas habens, in summa autem octava porta. Prima portarum plumbea, altera stannea, tertia ex ære, quarta ferrea, quinta ex ære mixto, sexta argentea, septima ex auro. Κλιμαξ ὑψιπυλος, επι δ᾽ αυτη πυλη ογδοη. Ἡ πρωτη των πυλων μολιβδου, ἡ δευτερα κασσιτερου, ἡ τριτη χαλκου, ἡ τεταρτη σιδηρου, ἡ πεμπτη κερασου νομισματος, ἡ ἑκτη αργυρου, χρυσου δ ἡ ἑβδομη. Primum assignant Saturno, tarditatem illius sideris plumbo indicantes: alteram Veneri, quam referunt, ut ipsi quidem putant, stanni splendor et mollities; tertiam Jovi, aheneam illam quidem et solidam; quartam Mercurio, quia Mercurius et ferrum, uterque operum omnium tolerantes, ad mercaturam utiles, laborum patientissimi. Marti quintam, inæqualem illam et variam propter mixturam. Sextam, que argentea est, lunæ; septimam auream soli tribuunt, quia solis et lunæ colores hæc duo metalla referunt.' *Contra Celsum*, lib. vi. 22. p. 161. Here then is an evident trace of metallurgic astronomy, as Borrichius calls it, or of the astronomical or mythological nomination of metals, though it differs from that used at present. According to this arrangement, tin belonged to Jupiter, copper to Venus, iron to Mars, and the mixed metal to Mercury. The conjecture of Borrichius, that the transcribers of Origen have, either through ignorance or design, transposed the names of the gods, is highly probable: for if we reflect that in this nomination men, at first, differed as much as in the nomination of the planets, and that the names given them were only confirmed in the course of time, of which I shall soon produce proofs, it must be allowed that the causes assigned by Origen for his nomination do not well agree

with

Sect. XXIV. *Of Platinum and its Combinations.*

2123 History. 1. Platinum in most of its properties is equal to gold, but in others, it is superior. It was first clearly ascertained to be a distinct metal, by Scheffer, a Swedish chemist, in the year 1752. It had been indeed taken notice of at an earlier period. A quantity of it was brought from Jamaica in 1741, by Mr Wood. It is particularly mentioned by Antonio de Ulloa, a Spanish mathematician, in the account of his voyage to Peru with the French academicians, to measure a degree of the meridian, which was published in 1748. After this period numerous experiments were made upon this new substance, all of which tended to prove that it is a different metal from any formerly known; Scheffer

with the present reading, and that they appear much juster when the names are disposed in the same manner as that in which we now use them. Borrichius arranges the words in the following manner: Secundam portam faciunt Jovis, comparantes ei stanni splendorem et mollitiem; tertiam Veneris æratam et solidam; quartam Martis, est enim laborum patiens, æque ac ferrum, celebratus hominibus; quintam Mercurii, propter misturam inæqualem ac variam, et quia negotiator est; sextam Lunæ argenteam; septimam Solis auream. *Ol. Borrichius de ortu et progressu chemiæ.* Hafniæ 1668, 4to. p. 29.

"This astrological nomination of metals appears to have been conveyed to the Brachmans in India; for we are informed that a Brachman sent to Apollonius seven rings, distinguished by the names of the seven stars or planets, one of which he was to wear daily on his finger, according to the day of the week. This can be no otherwise explained than by supposing that he was to wear the gold ring on Sunday; the silver one on Monday; the iron one on Tuesday, and so of the rest. Allusion to this nomination of the metals after the gods occurs here and there in the ancients. Dydimus, in his explanation of the Iliad, calls the planet Mars the iron star. Those who dream of having had any thing to do with Mars are by Artemidorus threatened with a chirurgical operation; for this reason, he adds, because Mars signifies iron. Heraclides says also in his allegories, that Mars was very properly considered as iron; and we are told by Pindar that gold is dedicated to the sun.

"Plato likewise, who studied in Egypt, seems to have admitted this nomination and meaning of the metals. We are at least assured so by Marsilius Ficinus; but I have been able to find no proof of it, except where he says of the island Atlantis, that the exterior walls were covered with copper and the interior with tin, and that the walls of the citadel were of gold. It is not improbable that Plato adopted this Persian or Egyptian representation, as he assigned the planets to the demons; but perhaps it was first introduced into his system only by his disciples. They seem, however, to have varied from the nomination used at present; as they dedicated to Venus copper, or brass, the principal component part of which is indeed copper; to Mercury tin, and to Jupiter electrum. The last-mentioned metal was a mixture of gold and silver; and on this account was probably considered to be a distinct metal, because in the early periods mankind were unacquainted with the art of separating these noble metals.

"The characters by which the planets and metals are generally expressed when one does not choose to write their names, afford a striking example how readily the mind may be induced to suppose a connection between things which in reality have no affinity or relation to each other. Antiquaries and astrologers, according to whose opinion the planets were first distinguished by these characters, consider them as the attributes of the deities of the same name. The circle in the earliest periods among the Egyptians was the symbol of divinity and perfection; and seems with great propriety to have been chosen by them as the character of the sun, especially as, when surrounded by small strokes projecting from its circumference, it may form some representation of the emission of rays. The semicircle is, in like manner, the image of the moon, the only one of the heavenly bodies that appears under that form to the naked eye. The character ♄ is supposed to represent the scythe of Saturn; ♃ the thunderbolts of Jupiter; ♂ the lance of Mars, together with his shield; ♀ the looking-glass of Venus; and ☿ the caduceus or wand of Mercury.

"The expression by characters adopted among the chemists agrees with this mythological signification only in the character assigned to gold.—Gold, according to the chemists, was the most perfect of metals, to which all others seemed to be inferior in different degrees. Silver approached nearest to it, but was distinguished only by a semicircle, which, for the more perspicuity, was drawn double, and thence had a greater resemblance to the most remarkable appearance of the moon; the name of which this metal had already obtained. All the other metals, as they seemed to have a greater or less affinity to gold or silver, were distinguished by characters composed of the characters assigned to these precious metals. In the character ☿ the adepts discover gold with a silver colour. The cross placed at the bottom, which among the Egyptian hieroglyphics had a mysterious signification, expresses, in their opinion, something I know not what, without which quicksilver would be silver or gold. This something is combined also with copper, the possible change of which into gold is expressed by the character ♀. The character ♂ declares the like honourable affinity also; though the semicircle is applied in a more concealed manner; for, according to the properest mode of writing, the point is wanting at top, or the upright line ought only to touch the horizontal, and not to intersect it. Philosophical gold is concealed in steel; and on this account it produces such valuable medicines. Of tin one half is silver, and the other consists of the something unknown; for this reason the cross with the half moon appears in ♃. In lead this something is predominant, and a similitude is observed in it to silver. Hence in its character ♄ the cross stands at the top, and the silver character is only suspended on the right hand behind it.

"The mythological signification of these characters cannot be older than the Grecian mythology; but the chemical

Platinum, &c.

Scheffer, gave it the name of *white gold*, because it resembled this metal in many of its properties. In the year 1754, Dr Lewis published an account of a very full and elaborate set of experiments on platinum, in the Philosophical Transactions. The properties of this new metal were still farther investigated by Margraaf in 1757, and by Macquer and Beaumé in 1758. It became afterwards the subject of research with many other philosophical chemists. Among these may be mentioned Buffon, Bergman, Sickengen, and more lately Guyton, Lavoisier, and Pelletier. It was at last denominated *platinum*, signifying *little silver*, from the Spanish word *plata*, *silver*.

2124 Where found.

2. Platinum has only been found among the gold ores of South America, and especially in the mine of Santa Fe near Carthagena, and in the district of Choco in Peru. It is found in the form of small grains or scales, of a white or grayish colour, intermediate between that of silver and iron. These grains are mixed with several other substances, as particles of gold, a black ferruginous sand, and some particles of mercury. Some of these grains extend under the hammer; others, which seem to be hollow, containing particles of iron and a whitish powder, break to pieces. To these grains of iron is ascribed the magnetic property which platinum seems to possess (G).

2125 Purification.

3. To obtain platinum in a state of purity, it is first separated from the substances with which it is contaminated. Mercury is driven off by exposing it to a red heat, and the particles of iron are separated by the magnet. The grains of platinum are then heated with muriatic acid, which dissolves the remaining part of the iron. By this process, Bergman has observed that the platinum diminishes in weight about 0.05. The platina is now only alloyed with gold, which is to be separated by dissolving both in nitro-muriatic acid, and by precipitating the gold by means of the green sulphate of iron. But even after these processes, the platinum is not in a state of absolute purity, as will appear afterwards (H).

2126 Properties.

4. This metal is of a white colour, but less bright than silver, and it possesses nothing of the brilliancy of either silver or gold. Platinum is the densest body, and therefore the heaviest yet known. Its specific gravity, when it is hammered, is 23; or, according to Chabaneau, 24. According to Guyton, it comes next to iron and manganese in hardness. It possesses very considerable malleability, for it may be hammered

---

mical may be traced to a much earlier period. Some, who consider them as remains of the Egyptian hieroglyphics, pretend that they may be discovered on the table of Isis, and employ them as a proof of the high antiquity, if not of the art of making gold, at least of chemistry. We are told also that they correspond with many other characters which the adepts have left us as emblems of their wisdom.

"If we are desirous of deciding without prejudice respecting both these explanations, it will be found necessary to make ourselves acquainted with the oldest form of the characters, which, in all probability, like those used in writing, were subjected to many changes before they acquired that form which they have at present. I can, however, mention only three learned men, Saumaise, Du Cange, and Huet, who took the trouble to collect these characters. As I am afraid that my readers might be disgusted were I here to insert them, I shall give a short abstract of the conclusion which they form from them; but I must first observe that the oldest manuscripts differ very much in their representation of these characters, either because they were not fully established at the periods when they were written, or because many supposed adepts endeavoured to render their information more enigmatical by wilfully confounding the characters; and it is probable also that many mistakes may have been committed by transcribers.

"The character of Mars, according to the oldest mode of representing it, is evidently an abbreviation of the word Θουρος, under which the Greek mathematicians understood that deity; or, in other words, the first letter Θ, with the last letter ς placed above it. The character of Jupiter was originally the initial letter of Ζευς; and in the oldest manuscripts of the mathematical and astrological works of Julius Firmicus the capital Z only is used, to which the last letter ς was afterwards added at the bottom, to render the abbreviation more distinct. The supposed looking-glass of Venus is nothing else than the initial letter, distorted a little, of the word Φωσφορος, which was the name of that goddess. The imaginary scythe of Saturn has been gradually formed from the two first letters of his name Κρονος, which transcribers, for the sake of dispatch, made always more convenient for use, but at the same time less perceptible. To discover in the pretended caduceus of Mercury the initial letter of his Greek name Στιλβων, one needs only look at the abbreviations in the oldest manuscripts, where they will find that Σ was once written as C; they will remark also that transcribers, to distinguish this abbreviation from the rest still more, placed the C thus ◡, and added under it the next letter τ. If those to whom this deduction appears improbable will only take the trouble to look at other Greek abbreviations, they will find many that differ still farther from the original letters they express than the present character ☿ from the C and τ united. It is possible also that later transcribers, to whom the origin of this abbreviation was not known, may have endeavoured to give it a greater resemblance to the caduceus of Mercury. In short, it cannot be denied that many other astronomical characters are real symbols, or a kind of proper hieroglyphics, that represent certain attributes or circumstances, like the characters of Aries, Leo, and others quoted by Saumaise." *Hist. of Invent.* iii. 53.

(G) Collet Descostils observes, that among the metallic substances which are usually found accompanying platinum, there are two kinds of ferruginous sand; of which one is attracted by the magnet, and soluble in acids. This contains titanium. The other has no magnetic property, and is only partially soluble in acids. This last contains a considerable proportion of chromic acid. *Ann. de Chim.* xlviii. 154.

(H) Several new metals have been discovered in platinum, by some late experiments. These will be mentioned in a future section.

Platinum, &c.

mered out, although with difficulty, into very thin plates; and it is so ductile, that it may be drawn out into wire $\frac{1}{1040}$ of an inch in diameter. The tenacity of platinum is very considerable. A wire of .078 of an inch in diameter will support a weight, without breaking, equal to more than 274 lbs. avoirdupois.

2127 Fusing point unknown.

5. Platinum is the most infusible of all the metals. The temperature at which it enters into fusion is unknown. But small particles of platinum have been fused by means of the blow-pipe, or by directing a stream of oxygen gas on red-hot charcoal. Guyton also succeeded in fusing it by means of a flux, composed of eight parts of pounded glass, one of calcined borax, and one-half part of charcoal in powder. When platinum has been exposed to a white heat, it may be welded by hammering, like iron.

2128 Oxidation.

6. As platinum is infusible in the strongest furnace heat, so it remains otherwise unchanged (1). It does not appear to undergo, like most other metals, any degree of oxidation; but if platinum be dissolved in 16 times its weight of nitro-muriatic acid, by boiling,

2129 Yellow oxide.

the solution becomes at first of a yellow, and then changes to a brown colour. This solution is precipitated by means of lime, and the precipitate is in the form of a yellowish powder, which is the oxide of platinum. The proportion of oxygen in this oxide is supposed not to exceed .07. But according to the experiments of Mr Chenevix, it is composed of

Platinum	87
Oxygen	13
	100

2130 Green oxide.

The same chemist also found, that in the reduction of this oxide of platinum, it became of a green colour, and remained for some time in that state. Ammonia assumes a green colour when it holds oxide of platinum in solution. This Mr Chenevix considers as a second oxide of platinum, and it contains.

Platinum	93
Oxygen	7
	100 *.

* Phil. Trans. 1803. 314.

Platinum has also been oxidated by means of electricity. In Van Marum's experiments, a wire of this metal through which electric sparks were sent, burnt with a white flame, and was dissipated in the form of fine powder or dust.

7. Azote, hydrogen, and carbon, have no action whatever on platinum.

2131 Phosphuret.

8. Phosphuret of platinum was formed by Pelletier, by mixing together equal parts of platinum and phosphoric glass, with one-eighth of charcoal. This mixture being exposed to the temperature of 32° of Wedgwood for an hour, yielded a small button of phosphuret of platinum, of a silvery white colour, part of which had assumed the form of cubic crystals. It was so hard as to strike fire with steel, and was not attracted by the magnet. It was covered with a dark-coloured glass, which afterwards became green, bluish, and white. By exposing this phosphuret to a strong heat, the phosphorus is separated, and burns on the surface, and the metal remains behind very pure and malleable. Pelletier has proposed this process for the purification of platinum from other metals.

2132 Sulphuret.

9. Sulphur has been found in combination with native platinum. When native platinum is exposed to the action of the blow-pipe on charcoal, it exhales the penetrating odour of sulphur, accompanied with a vapour which does not render gold white, and which requires a higher temperature to sublime it than mercury *.

* Ann. de Chim. xxxviii. 149.

I. Salts of Platinum.

1. Sulphate of Platinum.

By adding sulphuric acid to a solution of platinum in muriatic acid, Mr Chenevix obtained an insoluble salt, which he found to be composed of

Oxide of platinum	54.5
Acid and water	45.5
	100.0

2. Sulphate of Platinum and Potash.

This triple salt is formed by adding a solution of potash to sulphate of platinum. The component parts of this salt are, sulphuric acid, oxide of platinum, and potash; but the proportions have not been ascertained by Bergman, who examined it.

3. Sulphate of Platinum and Ammonia.

This triple salt is formed in the same way as the former, by adding ammonia to the sulphate of platinum.

4. Nitrate of Platinum.

Nitric acid has no action on platinum, but it dissolves the yellow oxide. Mr Chenevix precipitated the oxide of platinum from its solution in nitro-muriatic acid by means of lime, and although it was added in excess, a great portion of platinum remained in the liquor. The precipitate was re-dissolved in nitric acid, and evaporated to dryness. The result was, a subnitrate of platinum, which consisted of

Yellow oxide	89
Nitric acid and water	11
	100

5. Nitrate of Platinum and Potash.

When potash is added to a solution of nitrate of platinum, crystals are deposited, forming a triple salt, and composed of nitric acid, oxide of platinum and potash.

6. Nitrate of Platinum and Ammonia.

This triple salt is formed by adding ammonia to a solution of nitrate of platinum.

(1) Guyton proposes to construct a pyrometer of platinum. See *Ann. de Chim.* xlvi. 276.

7. Muriate of Platinum.

2133 Preparation. Muriatic acid has no action on platinum, but the muriate of platinum may be obtained by dissolving the metal in nitro-muriatic acid. Boiled in 16 parts of a mixture consisting of one part of nitric acid and three parts of muriatic acid, it is gradually dissolved with effervescence. It may be also dissolved in oxymuriatic acid. The solution of platinum in muriatic acid is of a reddish or deep brown colour. It is extremely acrid and caustic, corrodes and burns animal matters, and leaves a dark brown spot on the skin. When the solution is concentrated, it deposits, on cooling, small irregular crystals, nearly in the state of powder, and of

2134 Properties. a brownish-yellow colour. When these crystals are washed and dried, they are found to be less soluble by boiling in water, than even the sulphate of lime. The solution is of a yellow colour. The muriate of platinum has a harsh, astringent taste; it is decomposed by heat; the acid is driven off, and the oxide remains. It is also decomposed by concentrated sulphuric acid. Potash produces in this solution small reddish crystals, frequently in the form of octahedrons, constituting the triple salt already described. The same triple salt is formed by the sulphate of potash. Ammonia, or the muriate of ammonia, also forms a triple salt, by being added to the solution of muriate of platinum. Soda in sufficient quantity occasions a precipitate of the yellow oxide of platinum, and a triple salt also is formed. Mr Chenevix found that the insoluble muriate of platinum

2135 Composition. is composed of

Oxide of platinum	70
Acid and water	30
	100

8. Muriate of Platinum and Soda.

Till the experiments of Collet-Descotils, little was known of this triple salt. It may be obtained by adding to a solution of platinum a salt with base of soda. By concentration and cooling it crystallizes in the form of long prisms, and sometimes in that of triangular tables, of a yellow or red colour. It is very soluble in water, and also in alcohol. It is decomposed by muriate of ammonia, and by a solution of soda; but an excess of this salt re-dissolves the precipitate. It may be reduced by the action of the blow-pipe on charcoal. This crystallized triple salt, if it has no excess of acid, changes from a red colour to a green by exposure to the air. If in this state it be dissolved in water, and oxymuriate of lime be added to it, a deep blue precipitate is formed, which being washed and collected, is soluble in muriatic acid, and communicates to it a beautiful blue colour. The addition of alcohol deprives the solution of its colour, but the oxymuriate of lime restores it *.

* *Ann. de Chim.* xlviii. p. 165.

9. Muriate of Platinum and Potash.

This salt is formed by adding potash to a solution of muriate of platinum. Small crystals of a red colour, in the form of octahedrons, are precipitated, which are a triple salt, consisting of muriatic acid, oxide of platinum and potash.

10. Muriate of Platinum and Ammonia.

1. A similar triple salt is formed by adding ammonia to the solution of muriate of platinum. The triple salt is precipitated in the form of crystalline grains, of a reddish yellow colour, which are soluble in water. By evaporating the solution of these triple salts to dryness, and by exposing it to a strong heat, the platinum is reduced. This fact with regard to the fusibility of platinum by means of potash or ammonia, was observed by Bergman, and it is by this process that platinum is purified and wrought.

2. When this salt is precipitated by means of potash, a fulminating platinum is obtained. This, according to Fourcroy and Vauquelin, by whom it was prepared, is a compound of oxide of platinum and ammonia. When it is exposed to sudden heat, it decrepitates and is agitated with a rapid motion, but when the heat is gradually applied, it detonates violently *.

* *Ann. de Chim.* xli. p. 179.

11. Oxalate of Platinum.

Oxalic acid combines with the oxide of platinum, and affords by evaporation crystals which are of a yellow colour.

12. Benzoate of Platinum.

Benzoic acid, according to Trommsdorf, dissolves a small quantity of the oxide of platinum. When this solution is evaporated, it crystallizes. This salt undergoes no change by exposure to the air, and is not very soluble in water. The acid is driven off by heat, and the oxide of platinum remains behind.

II. Alloys.

1. Platinum combines with many of the metals, and forms with them alloys, some of which are of considerable importance in the working of this metal.

Platinum forms an alloy with arsenic, which is brittle 2136 Combined with arsenic. and very fusible. It is in this state of alloy that platinum is susceptible of being formed into different utensils and instruments for which it is peculiarly fitted. It is first fused with this metal, and then cast into moulds, at first in the form of square plates. It is then exposed to a red-heat, and hammered into bars. By the heating and hammering, the arsenic is driven off, and the metal is purified and becomes infusible, but retains its ductility, so that it may be wrought like iron.

2. The alloys of tungsten, molybdena, chromium, columbium, titanium, uranium, and manganese, are unknown; nor have the alloys of cobalt and nickel with this metal been examined. 2137

3. Platinum combines with bismuth by means of fusion. Bismuth. This alloy is fusible and hard in proportion to the quantity of bismuth. It is altered by exposure to the air; it becomes yellow, purple, and black. 213[illegible]

4. Platinum readily combines with antimony, and Antimony. forms a very brittle alloy. The antimony may be separated by means of heat, but not completely. Some part remains, which diminishes the weight and ductility of the platinum. 213[illegible]

5. It has been found extremely difficult to combine Mercury. platinum and mercury. Guyton had observed that the adhesive force of platinum and mercury is greater than that

that of metals which do not combine with it, and that it is not inferior even to those which readily form alloys; from which he conjectured that the alloy of platinum and mercury might be effected by the following process. He placed a very thin plate of pure platinum at the bottom of a matrass containing a quantity of mercury. The matrass was put upon a sand bath, and heat applied, till the mercury boiled and the matrass became red hot. When the platinum was taken out, it was found to have acquired additional weight, and to have become very brittle. But this combination is different from the other combinations of mercury with the metals, for the platinum did not lose its solid form. Mr Chenevix, in the course of experiments and researches respecting a supposed new metal called palladium, succeeded in forming an amalgam with platinum and mercury. He heated purified platinum in the form of fine powder, with ten times its weight of mercury, and rubbed them together for a long time. The result was an amalgam of platinum, which being exposed to a violent heat, lost all the mercury it contained, and the original weight of the platinum remained.

2140 inc. 6. Platinum readily combines with zinc, and forms with it a fusible alloy, of a bluish colour, brittle, and hard. By heating, the zinc is sublimed, and burns on the surface.

2141 in. 7. Platinum alloys readily with tin. This alloy is one of the most fusible. It is hard and brittle, when the two metals are in equal proportions; but tin in the proportion of 12 parts to one of platinum, affords a very ductile alloy, which becomes yellow by exposure to the air. From this it appears that platinum diminishes the ductility of tin.

2142 ead. 8. Platinum readily combines with lead, by means of fusion. An alloy of equal parts of these metals is of a purplish colour, granulated in its fracture, brittle, and easily altered by exposure to the air. The cupellation of platinum by means of lead has been an object of considerable importance with chemists, in the view of being able to purify it in the same way as gold and silver; but on account of the infusibility and refractory nature of platinum, the attempts that have been made have rarely succeeded.

2143 on. 9. Dr Lewis failed in his attempt to combine platinum with iron, but he obtained an alloy by fusing together platinum and cast iron. This alloy was extremely hard, and possessed some degree of ductility. Platinum, as it is found native, is frequently alloyed with iron.

2144 pper. 10. Platinum combines with copper by means of fusion, and gives it hardness. When the proportion of copper is three or four times greater than that of platinum, the alloy is ductile, susceptible of a fine polish, and is not altered by exposure to the air. This alloy has been employed in the fabrication of mirrors for telescopes.

2145 ver. 11. Platinum readily combines with silver by fusion, although a very strong heat is required. The platinum greatly increases the hardness of silver, but diminishes its whiteness. When this alloy is kept in fusion for some time, the two metals are separated. During this fusion, Dr Lewis observed the silver forced towards the sides of the crucible with a kind of explosion.

2146 ld. 12. Gold combines readily with platinum, but it requires a very powerful heat for the fusion of these two metals. Platinum diminishes the colour of gold, unless it be in very small quantity. When the proportion of platinum is above $\frac{1}{17}$, the colour of the gold begins to be altered. There is no perceptible change in the specific gravity or the ductility of gold from this alloy.

Platinum, on account of its peculiar properties, its infusibility, density, and indestructibility, could it be obtained in sufficient quantity, and at a moderate price, would undoubtedly prove one of the most useful and most important of the metals yet known. The importance and utility of platinum, on account of its scarcity, have been hitherto limited to chemical purposes; and for different chemical instruments and utensils, it has been found peculiarly appropriate, as there are few chemical agents whose effects it cannot resist. There is indeed little doubt but it might be employed with equal advantage in the construction of instruments and utensils, in various arts and manufactures.

SECT. XXV. *Of* RHODIUM, PALLADIUM, IRIDIUM *and* OSMIUM, *metals obtained from crude* PLATINUM.

Rhodium, a metal discovered by Dr Wollaston, is separated from the ore of platinum by the following process.

When a solution of this ore in nitro-muriatic acid has been precipitated as far as possible by muriate of ammonia, it retains considerable colour, and contains some metals. Let a plate of zinc or iron be immersed, and all the metals are separated in the form of a black powder. The precipitate is to be washed (without being dried) with very dilute nitric acid, assisted by a gentle heat, and the copper and lead are thus dissolved. Digest the remainder in dilute nitro-muriatic acid, and add to the solution a portion of muriate of soda equal to $\frac{1}{30}$ part of the weight of the original ore. Evaporate by a gentle heat. The dry mass contains the soda-muriates of platinum, palladium, and rhodium. The two former are separated by alcohol, and the salt of rhodium remains. From its solution the metal is precipitated by zinc in the form of a black powder, amounting to $\frac{1}{100}$ of the weight of the ore. 2147 Rhodium. Separation.

It is infusible by heat, but may be fused by means of arsenic or sulphur, which may be expelled by a continued heat. The metallic button thus obtained is not malleable. Its specific gravity is 11. It unites readily with all the metals except mercury. It is insoluble even in nitro-muriatic acid till alloyed with bismuth, copper, or lead. The muriate of rhodium, thus obtained, has a rose colour, from which the name of the metal has been derived. 2148 Properties.

From the alcoholic solution above mentioned, containing the soda-muriates of palladium and platinum, the platinum is precipitated by muriate of ammonia, and palladium may be obtained from the remaining liquid by adding precipitate of potash. The precipitate is to be ignited and purified from iron, by cupellation with borax. Or it may be precipitated from the first solution of the ore, by prussiate of mercury in the state of a prussiate, which, on being heated, yields the metal in the proportion of about 1 in 200 of the ore. 2149 Palladium. Separation.

It has been found native in small fragments, which differ from the grains of platinum, in being formed of 2150 Sometimes native.

fibres

Palladium, &c.

fibres diverging in some degree from one extremity. A small portion of iridium is the only other ingredient in these fragments.

2151 Properties. The colour of palladium resembles that of platinum, but is a duller white. It is malleable and ductile. Specific gravity about 11. Has nearly the same conducting power with platinum, and is rather more expansible by heat. It forms a blue solution with sulphuric acid, a beautiful red with nitric, and also with muriatic acid. The precipitates from these solutions by the alkalies and earths are generally of a fine orange. Green sulphate of iron precipitates palladium in the metallic state.

2152 Alloys. It combines readily with other metals. A very small proportion of it destroys the colour of gold. An alloy of gold and platinum is used for the graduation of a magnificent astronomical circle, constructed by Mr Troughton, for Greenwich observatory. It has the appearance of platinum, and is rendered peculiarly fit for receiving the graduations by its very great hardness.

2153 Iridium. Two other metals were discovered in crude platinum by Mr Tennant, in analyzing the black powder which remains after dissolving platinum. To the first of these metals Mr Tennant has given the name of *iridium*, from the various colours it assumes in solution. It possesses the following properties. It is soluble in all the acids, but less soluble in muriatic acid, with which it forms octahedral crystals. The solution with much oxygen is deep red; with a smaller proportion, green or deep blue. It is partially precipitated by the alkalies, and by all the metals except gold and platinum. Infusion of galls and prussiate of potash deprive this solution of its colour, but without any precipitate; thus affording an easy test of its presence. The oxide, therefore, loses its oxygen by water alone. When combined with gold or silver, it cannot be separated by the usual process of refining these metals. The same substance was examined by Descostils and Vauquelin, and the properties which they ascribe to this metal are the following. 1. It reddens the precipitates of platinum made by muriate of ammonia. 2. It is soluble in muriatic acid. 3. It is precipitated by the infusion of galls and prussiate of potash.

2154 Osmium. 5. Osmium is obtained by heating the black powder with pure alkali in a silver crucible. The oxide of this metal combines with the alkali, and may be expelled by an acid, and obtained by distillation, being very volatile. It does not redden vegetable blues, but stains the skin of a deep red or black. The oxide in solution with water has no colour; but by combining with alkali or lime, becomes yellow. With the infusion of nut-galls it gives a very vivid blue colour. It is precipitated by all the metals excepting gold and platinum. An amalgam may be formed with mercury, by agitating it with the aqueous solution of this oxide. When this amalgam is heated, the mercury is driven off, and the pure metal remains behind in the state of black powder. To this metal Mr Tennant has given the name of *osmium*, on account of the strong smell of the oxide †.

† *Nichol. Jour.* viii. p 118, and 220.

Chap. XV. Of the ATMOSPHERE.

Component Parts of the Atmosphere.

The atmosphere is that invisible elastic fluid which surrounds the earth. Its physical properties, such as density, elasticity, and pressure, have been long known; but its composition and constituent parts must be ranked among the discoveries of modern chemistry. In the present chapter we propose only to take a short view of the nature, constitution, and changes of the atmosphere, reserving the full discussion of the latter to meteorology, to which it properly belongs.

Sect. I. *Of the Component Parts of the Atmosphere.*

1. The air of the atmosphere was considered by the ancients as one of the four elements of which all bodies are composed. The same opinion was held by all philosophers, previous to the discoveries of modern chemistry. It was universally admitted to be a simple homogeneous substance, till by the discovery of oxygen gas by Dr Priestley, and that of azotic gas by Scheele, it was fully demonstrated that these two substances are the chief ingredients in atmospheric air. 2155 Is a compound 2156 of oxygen and azotic gases.

2. This compound possesses all the physical properties of the different kinds of air which we have hitherto examined. It is invisible, elastic, and may be indefinitely expanded and compressed. The specific gravity of atmospheric air is 0.0012, or it is 816 times lighter than water. A hundred cubic inches weigh 31 grains troy; but in consequence of the elasticity of the air, the absolute weight and the density must vary with the temperature and pressure. The estimation which we have here given, is taken at the ordinary temperature of the atmosphere, between 50° and 60°, and when the barometer, which indicates the pressure, stands at 30 inches. The density must vary by diminishing, according to the height above the surface of the earth. The experiments of naturalists, whose attention has been particularly directed to this subject, have shewn that the diminution of density is in the ratio of the compression, and therefore, that the increase of density is in geometrical progression, while the heights increase in arithmetical progression. 2157 Physical properties.

3. After the discovery of the composition of atmospheric air, it became an object with philosophers to determine the proportions of its component parts. It was observed by Priestley and Scheele, and other philosophers who were occupied in the prosecution of their discoveries, that a certain portion of a given quantity of atmospheric air only was absorbed during the processes of combustion and respiration. It was observed too, that certain substances combined with the portion of atmospheric air which disappeared during these processes, and that the same quantity of atmospheric air suffered no farther diminution, whatever length of time it was exposed to the action of these substances. The portion of the air absorbed is the oxygen gas, and on this principle is founded the construction of those instruments which have been denominated *eudiometers*, because they are employed to measure the purity of a given portion of air, by ascertaining the quantity of oxygen gas which it contains. Different eudiometers have been proposed for this purpose, but all depending on the same principle, namely, the abstraction of oxygen gas from a given quantity of air. The reader will probably recollect the effects which take place by mixing together nitrous gas and the air of the atmosphere, or oxygen gas. When these gases come 2158 Method of estimating the proportions.

Component Parts of the Atmosphere.

come into contact, red fumes are produced; the atmospheric air is partially diminished; but the oxygen gas entirely disappears. This is owing to the combination of the nitrous gas with the oxygen gas, forming nitric acid, which, if the experiment be made over water, is absorbed; thus diminishing the bulk of the air by the quantity of oxygen gas abstracted. This is the principle of the first eudiometer which was proposed by Dr Priestley; but it has been found that the results and experiments with this kind of eudiometer are far from being uniform and constant. It is subject to variation from the difference of purity of the nitrous gas employed, the water over which the experiment is made, and even the form and construction of the apparatus. The variations in the results of different experiments by different philosophers, are from 22. to 30. of oxygen gas in 100 parts of atmospheric air.

Scheele proposed a different eudiometer. A mixture of iron filings and sulphur formed into a paste with water absorbs the whole of the oxygen gas of any given portion of atmospheric air. The diminution of bulk of a portion of air, exposed to the action of this substance, therefore, indicates the proportion of oxygen gas, which it contains; but this absorption goes on slowly, and is therefore an objection to this mode of ascertaining the proportions of atmospheric air. This objection has been removed by an improvement of this eudiometer, in which hydrogenated sulphuret of potash or lime is substituted for the iron filings and sulphur. This is prepared by boiling together sulphur and lime water, or a solution of potash in water. By the use of this sulphuret, the absorption takes place in a few minutes. A given portion of air is agitated in a bottle with this sulphuret, taking care to exclude the external air with a ground stopper. The diminution of the bulk of this quantity of atmospheric air shews the proportion of oxygen gas which it contained.

Volta proposed to explode a given portion of atmospheric air with hydrogen gas, by means of the electric spark. The hydrogen and oxygen combine together and form water, and the diminution of the bulk of the airs employed is in proportion to the quantity of water formed. But to this method of ascertaining the quantity of oxygen gas in a given portion of atmospheric air, it has been objected, that the proportion of hydrogen gas requires to be accurately adjusted; for if it exceed, the superabundant quantity increases the bulk of the remaining air; and, if the proportion be too small, the oxygen and azote will form nitric acid by the action of electricity, and thus the residuary quantity of air will be too much diminished.

When phosphorus is exposed to the air, it absorbs the oxygen readily, and is converted into phosphorous acid. This, which was first proposed by Achard, has been improved by Berthollet, for the purposes of a eudiometer. A given portion of air is exposed to the action of phosphorus, in a vessel over water; when the absorption has ceased, the remaining air is measured, the diminution of which indicates the quantity of oxygen gas which it contained.

Sir H. Davy has proposed the green sulphate or muriate of iron dissolved in water, impregnated with nitrous gas. This solution is prepared by transmitting nitrous gas through green muriate or sulphate of iron dissolved to saturation in water. All the apparatus necessary is a small graduated tube, having its capacity divided into 100 parts, and greatest at the open end, and a vessel for containing the fluid. The tube is filled with the air to be examined, and then introduced into the solution. To promote the absorption, it is gently moved from a perpendicular to a horizontal position. In a few minutes the experiment is completed, and the whole of the oxygen condensed by the nitrous gas in the solution, in the form of nitric acid. But in this process it is necessary to observe the period at which the diminution stops, for after this the volume of residual gas is increased by the decomposition of the nitric acid, by means of the green oxide of iron *.

* Journ. Roy. Inst. i. p. 45.

From a number of comparative experiments made by Sir H. Davy with different eudiometers, and from other experiments on air in different places, and collected under different circumstances, it appears that the component parts of atmospheric air are always nearly the same. These proportions are from .21 to .22 of oxygen gas, and from .78 to .79 of azotic gas. The constituent parts therefore of atmospheric air by bulk may be taken at

2159 Composition.

Oxygen gas	22
Azotic	78
	100

But in estimating the proportions of given bulks of atmospheric air, it is necessary, as we have already hinted, to take into account the density and temperature, otherwise very great anomalies must happen.

2160 Water.

4. It is universally admitted, that water exists in the atmosphere; but philosophers are greatly divided with regard to the quantity of water, and the state in which it exists in the air. To ascertain the quantity of water, instruments called *hygrometers* or *measures of moisture*, have been contrived; the quantity of which is indicated by certain changes which take place by its absorption; but none of these instruments that have yet been invented are susceptible of great accuracy, and perhaps to this is owing the very different results in estimating the quantity of water in the atmosphere. There is also a very great difference of opinion whether this water exists in the atmosphere in the state of water, or whether it has been converted into vapour. According to the first opinion, the water is held in solution by the air, and the quantity increases as the temperature of the air is increased. But according to others, the water of the atmosphere is in the state of vapour. According to the experiments of naturalists, the quantity of water in the atmosphere varies in different climates, and at different seasons of the year, from $\frac{1}{60}$ to $\frac{1}{100}$ part of the weight of the atmosphere.

2161 In the state of vapour.

2162 Carbonic acid gas.

5. When lime-water, or an alkaline solution, is exposed to the air, it is soon covered with a crust or pellicle. This is owing to the absorption of carbonic acid, and the conversion of the alkali or lime to the state of carbonate. This shews that carbonic acid gas exists in the atmosphere. This gas has been found not only on the surface of the earth, where the density of the atmosphere is greatest, but also on the tops of some of the highest mountains. The quantity of carbonic gas

Component Parts of the Atmosphere.

acid gas in the atmosphere is supposed to vary from .01 to .005 parts.

Sect. II. *Of the Constitution of the Atmosphere.*

2163 Different opinions.

1. The component parts of the atmosphere are, azotic gas, oxygen gas, water, and carbonic acid gas. Here a question has arisen among philosophers, whether these parts are chemically combined, or merely form a mechanical mixture. According to one set of philosophers, the oxygen and azotic gases of the atmosphere are in chemical union, because their proportions are always found to be uniform and constant, which it is supposed could not be the case from the inequality of the causes acting in diminishing the quantity of oxygen gas, by the different processes of combustion and respiration, which are going on in the surface of the earth, if the component parts of the air were not in chemical combination. The air of the atmosphere too, it is said, possesses properties very different from the artificial mixture of its component parts. The processes of combustion and respiration continue for a greater length of time in the latter, because it parts with a greater proportion of its oxygen, and for the same reason it is more diminished by nitrous gas.

2164 In chemical union.

According to others, the air of the atmosphere is merely a mechanical mixture. This opinion is supported by Mr Dalton, in some ingenious speculations on the constitution of mixed gas, and particularly of the atmosphere. The principle on which Mr Dalton's hypothesis is founded is, that the particles of homogeneous elastic fluids only mutually act upon each other, and that the particles of an elastic fluid of one kind are neither attracted nor repelled by the particles of an elastic fluid of a different kind, when they are mixed together. According to this hypothesis, therefore, the particles of the oxygen gas of the atmosphere mutually act on each other, or are only attracted and repelled by those of their own kind *.

2165 Mechanical mixture.

2. Difference of opinion also prevails, whether the vapour of water, as it exists in the atmosphere, be merely a mechanical mixture, or chemically combined. The former opinion is also supported by Mr Dalton, upon the principle that all gases mixed with vapour, expand in a proportional degree to the elasticity of the vapour in that temperature.

* See *Manch. Mem.* vol. v.

Sect. III. *Of the Changes of the Atmosphere.*

2166 Temperature.

1. The changes which are produced in the atmosphere by heat and cold, are too obvious to escape observation; but it was not till the invention of the thermometer that these changes could be observed and marked with any degree of accuracy; and even after the invention and improvement of this instrument, it was long before any scientific application was made of the changes of the temperature which it indicated. The variable temperature of the same day, the great difference between midnight and midday, and the still greater difference between the heat of summer and the cold of winter, seem to hold out a number of insulated facts, without resemblance or connection, and incapable of being arranged under any general law. But more comprehensive views, and more extended observations, have not only shewn the possibility of establishing a general principle, but have enabled philosophers to arrange and classify phenomena which were otherwise seemingly unconnected.

Changes of the Atmosphere.

2. The great source of heat is the sun. This is fully demonstrated by the increase of temperature being in proportion to the duration and greater or less obliquity of the sun's rays. It has been imagined that the earth is heated by central fires: but this opinion seems to be fully disproved, by observing that the temperature depends invariably on the absence or presence of the sun; that this temperature is diminished, at least to a certain extent, by going deeper into the earth; and that the cold is greatest in places most distant from the sun's rays; so that the temperature, which is most uniform within the tropics, diminishes, other things being equal, in proportion to the distance from the equator towards the poles.

2167 The sun the source of heat.

3. In considering the difference of temperature which is observed in different places, it became an object with philosophers to discover some fixed points from which the whole amount of the changes for any given period could be ascertained. This was first thought of by Mayer, who proposed the method used by astronomers, of finding the mean of certain large periods, as for years and months; and he made the discovery by which the mean annual temperature of two latitudes being known, the mean annual temperature for every other degree of latitude may be also found. The application of this rule has been greatly improved and extended by Mr Kirwan, and upon this principle he constructed tables which exhibit the mean annual temperature for all degrees of latitude from the equator to the poles. These tables were constructed by finding from observation the temperature of what he calls a standard situation, that is, a place less liable to be affected by adventitious causes, but where the cause of temperature, or the communication of heat from the source, was most uniform and constant; and having discovered this standard situation, to compare the temperature of every other situation with it. The land, Mr Kirwan thought, owing to the operation of causes which occasion variations less easily appreciable, would not afford results sufficiently uniform. This situation, he then concluded, was to be sought for on the water; and that part of the ocean which he chose, was the immense tract of water which includes that part of the Atlantic lying between the 80° of north latitude, and the 45° of south latitude, extended westward as far as the gulf stream, and to within a few leagues of the coast of America; and all that part of the Pacific ocean reaching from the 45° north latitude to the 40° south latitude, and from the 20° to the 275° of longitude east from London. This includes the greater part of the surface of the globe. But for the method of constructing these tables, and for the tables themselves, we refer our readers to the article Meteorology, where they will be inserted.

2168 Fixed points of temperature important.

2169 Annual temperature.

The difference of temperature, it may be observed, within 10° of the equator and within the same distance from the poles, is very small; and the variation of temperature for different years within the same space, is also found to be very little: but, as the distance increases from the equator towards the poles, the difference of temperature is greater. In latitudes under 35°, it scarcely ever freezes, excepting in very elevated situations, Changes of the Atmosphere.

tions, and it scarcely ever hails in latitudes higher than 60°. In places near the sea, between the latitudes of 35° and 60°, it generally thaws when the sun's altitude is 40°, and seldom begins to freeze till the meridian altitude be below 40°.

2170 Monthly.

4. Mr Kirwan has also constructed tables to mark the mean monthly temperature. In every latitude the mean temperature of the month of April approaches nearly to the mean annual heat of that latitude. And from this analogy he proceeded, supposing that the temperature is always regulated by the direct action of the solar rays, unconnected with the other circumstances which occasion considerable variations. Taking all these into the account, and endeavouring to reduce them to strict calculation, he found it impracticable; and therefore he constructed his tables, partly from principle, and partly from the best observations he could procure from sea journals, and similar sources of information. The mean monthly temperature in these tables also refers to the standard ocean.

2171 Coldest season.

5. The coldest weather also prevails about the middle of January in all climates, and the warmest in July;

2172 Warmest.

but if it depended immediately on the sun's heat, the greatest heat should prevail in the latter end of June, and the greatest cold in the latter end of December. But as the earth requires a considerable time to absorb heat, so also it is some time before what has been absorbed is given out. All these observations and calculations refer to the surface of the ocean, which is less subject to variation from causes, the influence of which could not be ascertained with precision.

2173 The earth heats the atmosphere.

6. But as the earth is the chief source of heat in the atmosphere that surrounds it, the temperature must decrease with the elevation above the earth, and in the highest regions of the atmosphere, where the air is perfectly free from clouds, the greatest cold must prevail. Hence, in consequence of this elevation above the level of the ocean, the highest mountains, even under the equator, are covered with perpetual snow. Mr Bouguer found the cold on the top of Pinchinca in South America, immediately under the line, to vary from 7° to 9° below the freezing point every morning before sunrise, and hence at a certain height, which varies in almost every latitude, it constantly freezes at night in every season; although in some latitudes, in the warmer climates, it thaws next day. This height he calls the lower term of congelation, and he places it at the height of 15,577 feet between the tropics. In latitude 28° he thinks it should commence in summer at the height of 13,440 feet above the level of the sea. But at still greater heights it never freezes at all, because the vapours do not ascend so high. This height M. Bouguer denominates the *upper term of congelation;* and immediately under the equator he fixes at it 28,000 feet. As the weather is not subject to great variations under the equator, the height of both these terms is nearly constant; but in other latitudes this height is variable, both in summer and winter, in proportion to the degree of heat which prevails; and as there is a mean annual temperature peculiar to each latitude, so is there a mean height for each of these terms peculiar to each latitude. By taking the differences between the mean temperatures of every latitude, and the point of congelation, it will appear that whatever proportion the difference under the equator bears to the height of either of these terms, the same proportion will the difference peculiar to every other latitude bear to their height.

2174 Land and water different in temperature.

7. But there is not the same uniformity or capacity in air, land, and water, for receiving and returning heat. Hence arise very considerable deviations in the temperature of places, as they are more or less connected with these bodies. Air, when it is perfectly transparent, receives very little heat from the rays of the sun as they pass through it. Air which is over seas or large tracts of water, is generally many degrees warmer in winter, and colder in summer, than air which is incumbent on land, because the land receives the heat much more readily than the water; in general the air participates of the temperature of those substances with which it is in contact. Land, if dry, receives heat rapidly, but transmits or conducts it to great depths very slowly; but water receives it more slowly, and diffuses it more rapidly. From experiments made by Dr Hales, it appears that the earth is much heated during the summer, but that this heat descends very slowly, great part of it being communicated to the air; that during winter, the earth gives out to the air the heat it had received during the summer, and that wet summers must be succeeded by cold winters, because the heat is carried off by the greater proportion of evaporation during the wet season. At the depth of 80 or 90 feet below the surface of the earth, the temperature is found to vary very little, and it generally approaches to the mean annual heat. The temperature of the cave at the observatory of Paris, which is 90 feet below the pavement, is about 53.5°. The greatest variation which has been observed, does not exceed half a degree, and this only happens in very cold years. Hence, too, the temperature of springs is almost uniformly the same throughout the year, and corresponds with the mean annual temperature of the climate.

2175 Temperature varies according to the height of places.

8. There is not only a considerable difference in the temperature of land and water; but this variation also holds with regard to the land itself, according as it is elevated above the surface, and according to the nature of the surface, whether it is covered with vegetables, or only exhibits bare rocks, or sterile sand. A considerable deviation also is observed to take place in proportion to the distance from the ocean. All, these causes, however, are greatly modified by the relative situation of places with regard to seas and oceans, mountainous regions, and extensive tracts of level country covered with thick forests, or improved by cultivation. These causes too are modified by particular winds, which produce considerable deviations, as they proceed from the ocean, from low, flat countries, or elevated regions.

2176 Pressure.

9. Another remarkable change to which the atmosphere is subject, is the difference of its weight or pressure. The air, like all other matter, is influenced by the law of gravitation, by which it presses with a certain force on the surface of the earth. It has been found that the measure of this force is nearly equal to 15lb. on every square inch. The variations which take place in the atmosphere are measured by the barometer. The mercury in the barometrical tube is supported by a column of air of an equal base, and since this

Changes of the Atmosphere.

this column of air and the mercury in the tube mutually balance each other, it follows that they are of the same weight, and therefore the barometer may be employed as a measure of the weight or pressure of the air.

2177 The same at the level of the sea.

10. The first general fact with regard to the weight of the atmosphere is, that in all places at the level of the sea, the barometer stands nearly at the same point, and the mean height is about 30 inches. But as the elevation is increased, the barometer sinks, because then there is a shorter column of air to support it, which is therefore lighter. In no place does the weight of the air continue always the same. It is subject to daily variations, which are greater or smaller according to the latitude of the place, or the influence of particular causes. In all places within the tropics, the variations of the barometer have been observed to be smallest, and in elevated situations the variations are considerably smaller than on the level of the sea. The deviations of the mercury from its mean annual altitude are more frequent and extensive in the neighbourhood of the poles than in that of the equator, and they are greater and more frequent without the tropics in winter than in summer.

2178 Causes.

11. The causes which have been proposed to account for these variations, are changes of temperature, velocity of winds, and the agency of vapours. The air is subject to the action of heat, by which it is rarefied or condensed, according to the increase or diminutions of temperature. Dense air is heavier than that which is rarer; but if the masses of air remain the same, the weights must be the same, and consequently the heights to which they elevate the mercury will be also equal. If, therefore, a change of temperature occasion a variation of the barometer, it must be by increasing or diminishing the mass of the atmosphere. But it appears from observation, that a variation of the mass of the atmosphere is not a necessary consequence of a change of temperature, for the mercury is often at the same height at different seasons, and at different places at the same time, when the difference of temperature is very great. But even when the mercury changes with the temperature, this variation is often directly contrary to what it ought to be. The barometer has sometimes risen with an increase of temperature, instead of falling by the rarefaction of the air. The changes of temperature are very inconsiderable in the higher regions of the atmosphere, so that it would appear that the barometer can be little affected by changes of temperature. Mr Kirwan has endeavoured to show, that the influence of winds, or a greater or smaller quantity of vapours existing in the atmosphere, can have little effect in elevating or depressing the barometer. According to Mr Kirwan the variations of the barometer, or the difference of pressure of the air of the atmosphere, can only be accounted for from an accumulation of air over those places in which the mercury exceeds its mean height, and from the diminution or subtraction of the natural quantity of air, over those regions in which the mercury falls below its mean height.

2179 Winds.

12. The winds constitute another remarkable change in the atmosphere. The winds in general are subject to great irregularity; but in some parts of the world they are pretty regular and uniform. Between the 30° of N. Lat. and the 30° S. Lat. the wind, when it is not counteracted by local causes, continues to blow constantly from the same points. On the north side of the equator, that is from the equator to the 30° of N. Lat. it blows from the north-east, and from the equator to the 30° S. Lat. it blows from the south-east. This is called the *trade-wind*. Immediately under the equator the wind is observed to be pretty nearly from the east; that is, about the place where the two currents meet, the one from the north-east, and the other from the south-east; but receding from the equator, the direction of it deviates more and more from the easterly point, till it reaches the intermediate point between north and south, and then constitutes the north-east trade-wind on the north side, and the south-east trade-wind on the south side of the equator. Were the causes which produce the constancy and uniformity of the trade-winds uninfluenced by others, these winds would prevail without variation within the limits or near the boundaries of the torrid zone; but they are greatly counteracted, and subject to great variations, from the unequal influence of land and water, in rarefying or condensing the air.

2180 Trade-winds.

13. As the air of the atmosphere is a fluid body, and therefore subject to all the laws of fluids, if any part be removed, the remainder rushes in to restore the equilibrium, and hence an agitation or wind is produced, as air is capable of indefinite dilatation and compression. The denser air being heavier, must sink, and the rarefied air ascends, when air of unequal densities is mixed together. The greatest degree of mean temperature is within the torrid zone, in consequence of the sun's rays being more perpendicular, and acting with greater force on the earth's surface. The air therefore round the equator undergoes the greatest degree of rarefaction, and this extends to the north and south, in proportion to its distance from the equator, or rather its distance from the sun's place. Thus, when the sun is perpendicular to the equator, or middle part of the torrid zone, the air in that place being most rarefied, becomes lighter, ascends, and its place is filled with the colder air from the north and south. And thus, as long as the sun's influence continues to rarefy the air, would a north and south wind blow to that quarter where the rarefied air, being rendered lighter, had ascended. But as the earth has a diurnal motion on its axis from west to east; those parts of the earth's surface to the westward are first heated, and consequently the incumbent air is first rarefied. The denser air from the east must therefore rush in to restore the equilibrium. Thus, there is produced an easterly wind. But there is another current of air from the north and south: the two currents coming from the north-east trade-wind on the north side of the equator, and the south-east trade-wind on the south side. Such are the causes which are generally supposed to produce the regular trade-winds.

2181 Deviation.

14. These winds are regular and uniform in open oceans, such as the Pacific or Atlantic, but they are subject to considerable variation from the unequal rarefaction of the air over land and water. Thus, islands situated within the very course of the trade-winds have regular land and sea breezes, which are often directly contrary to the trade-wind. In consequence of the air incumbent on the land being more rarefied

Waters. rarefied during the day, the wind blows from the sea, constituting the sea breeze; but the air over the sea being warmer during the night, the wind blows from the land, from which it is called the *land wind*. To a similar cause is owing another remarkable deviation from the uniformity of the trade-winds, which is observed in the great Indian ocean. Here the winds
2182 Monsoons. called *monsoons* blow from one quarter during six months of the year, and from an opposite direction during the remaining six months. While the sun is in the northern tropic, the air over the extensive Indian continent is greatly rarefied; and, in consequence of this rarefaction, the denser air from the ocean rushes in to restore the equilibrium, and hence the current of the air or wind continues during this period of the year, constituting the south-east monsoon. But when the sun passes the equator to the southward, the air over the southern hemisphere is more influenced by his rays, and therefore more rarefied. The denser air then rushes in from the north, and thus produces the north-west monsoon, which blows during our winter, when the sun is in the southern tropic.

2183 ...art of the ...r suppos... to be ...stracted. 15. But even a superficial observation will shew, that the phenomena of the winds cannot be satisfactorily accounted for, merely upon the general principle of the unequal rarefaction of the air over land and water. Thus sudden changes of wind often happen in particular places, which are extremely limited, and altogether unconnected with the difference of density of the air over land and water. The hurricane has swept the land, whose effects have not been felt on the neighbouring ocean, and the storm frequently agitates the ocean without reaching the land. These and other phenomena of the winds, equally inexplicable, have been ascribed by naturalists to the abstraction or sudden destruction of a certain quantity of the air of the atmosphere in particular places. But for the full discussion of this subject, and the other phenomena of the atmosphere, we must refer our readers to METEOROLOGY.

CHAP. XVI. OF WATERS.

1. WE have already treated of the component parts of water, of the discovery of its composition, and of its most remarkable properties, and especially those which it exhibits by a change of constitution, as in the solid state, or that of ice, in the liquid state, and in the state of vapour. In these views water was considered as
2184 ...ter not ...d pure. perfectly pure; but this is rarely or never the case, as it is found in nature. Rain water, which is the purest, is not entirely free from impregnation, even when collected before it falls to the earth. It is slightly contaminated with certain substances, which it held in solution, as it existed in the clouds, or with which it combined in its passage through the atmosphere. But waters, as they flow on the surface of the earth, or are carried through the strata under the surface, must dissolve those soluble substances with which they come in contact. It is the object of our present investigation to examine the waters as they are found in nature, and the substances with which they are impregnated.

2. The properties of pure water are almost obvious to the senses, so that few substances, at least in any quantity, can be dissolved in water, without being easily recognized. Thus, the saline, nauseous taste of sea-water, the fetid odour, or the astringent taste of mineral springs, must readily be distinguished by these striking qualities. But although it is probable that the remarkable diversity of waters, from their obvious properties, could not fail to be early observed by mankind, it is only by chemical investigation that the nature of the substances to which they owe these properties, can be ascertained; and indeed we are indebted to the discoveries and improvements of modern chemistry for the knowledge which we possess of the nature and proportion of the ingredients which enter into the composition, either of sea-water or mineral springs. Sea-water. 2185 Can only be examined by chemical agents.

This subject has been particularly investigated by Bergman, Westrumb, Black, Fourcroy, Klaproth, and Kirwan. In the three following sections we propose to treat, 1. Of sea-water; 2. Of mineral waters; 3. Of the method of analyzing them.

SECT. I. *SEA-WATER.*

1. The saline taste of sea-water, we have already observed, could not fail to make it be distinguished from pure water; and this taste, it is well known, is chiefly derived from common salt which it holds in solution. Sea-water is also distinguished by a nauseous bitter taste, which is ascribed to the animal and vegetable matters which are floating in it. This taste has been considered as in some measure foreign to it; for it is only found in the water on the surface of the ocean or near the shores. Sea-water, taken up at considerable depths, contains only saline matters. The specific gravity of sea-water varies from 1.0269 to 1.0285. Its greater density is owing to the salts which are dissolved in it; and to this impregnation also it is owing, that it is not frozen till the temperature is reduced nearly to 28°. 2186 Properties.

2. The salts which are chiefly found in sea-water, are muriate of soda, or common salt, muriate of magnesia, sulphate of magnesia, sulphate of lime and soda. The quantity of saline ingredients in the waters of the ocean varies from $\frac{1}{24}$ to $\frac{1}{32}$ part. Mr Kirwan makes the average quantity about $\frac{1}{28}$ of its whole weight. The quantity of saline contents of water, taken up by Lord Mulgrave at the back of Yarmouth sands, in latitude 53°, amounted nearly to $\frac{1}{32}$; while Bergman found the water taken up in the latitude of the Canaries to contain about $\frac{1}{24}$ of its weight of saline matter. These quantities, however, vary, even in the same latitude, during rainy and dry seasons, near the land, or the mouths of great rivers. The difference of latitude does not seem to make any considerable difference in the proportion of saline matter. In latitude 80° north, 60 fathoms under ice, sea-water taken up by Lord Mulgrave, yielded about $\frac{1}{28}$; in latitude 74° nearly the same; and in latitude 60°, $\frac{1}{9}$. Pages obtained four per cent. from water taken up in latitude 81°, and the same quantity of saline matter from water taken up in latitude 45° and 39° north. In southern latitudes, the proportion was still greater; he found it to contain the following proportions; 2187 Salts. 2188 Proportion varies.

Lat.

Sea-water.

2189 In southern altitudes.

Lat.	Saline matter
49° 50′ S.	4.1666 per cent. of saline matter.
46° 00′	4.5
40° 30′	4
28° 54′	4
20° 00′	3.9
1° 16′	3.5

In the Mediterranean the proportion is said to be still greater; but the Euxine and Caspian seas are found to be less salt than the ocean. This also is the case with the Baltic. If the saline matters of the waters of the ocean did not consist of different kinds, the proportion of salts which it contains might be ascertained by the specific gravity. In the following table the specific gravity of sea-water taken up in different latitudes has been determined by Mr Bladh. The temperatures are reduced by Mr Kirwan to 62° of Fahrenheit; and the longitude is reckoned by Bladh from Teneriffe.

2190 Specific gravity in different latitudes.

Lat.	Long.	Sp. Gr. at 62°
N.	E.	
59° 39′	8° 48′	1,0272
57° 18′	18° 48′	1,0269
	W.	
57° 1′	1° 22′	1,0272
54° 00′	4° 45′	1,0271
44° 32′	2° 04′	1,0276
	E.	
44° 07′	1° 00′	1,0276
40° 41′	0° 30′	1,0276
34° 40′	1° 18′	1,0280
29° 50′	0° 00′	1,0281
	W.	
24° 00′	2° 32′	1,0284
18° 28′	3° 24′	1,0281
16° 36′	3° 37′	1,0277
14° 56′	3° 46′	1,0275
10° 30′	3° 49′	1,0272
5° 50′	3° 28′	1,0274
2° 20′	3° 26′	1,0271
1° 25′	3° 30′	1,0273
S.		
0° 16′	3° 40′	1,0277
5° 10′	6° 00′	1,0277
10° 00′	6° 05′	1,0285
14° 40′	7° 00′	1,0284
20° 06′	5° 30′	1,0285
25° 45′	2° 22′	1,0281
	E.	
30° 25′	7° 12′	1,0279
37° 37′	68° 13′	1,0276

From this table it appears that the proportion of saline matter is greatest near the tropics; and the smaller quantity near the equator is ascribed to the great quantity of rain that usually falls on that part of the globe.

2191 In the Baltic.

3. The experiments of Mr Wilcke show that the proportion of saline matter in the Baltic is less than that of the ocean; and that it is salter during the prevalence of a westerly wind, by which the water is driven from the ocean, than during an easterly wind. The following is the specific gravity of the waters of the Baltic, taken during the prevalence of different winds, and reduced by Mr Kirwan to the temperature of 62°. Mineral Waters.

Wind.	Specific gravity.
East,	1.0039
West,	1.0067
West, a storm,	1.0118
North-west,	1.0098

From this it appears, that the proportion of saline matters in the Baltic is increased by the influx of water from the ocean, and is considerably influenced during a storm, when the wind blows from that quarter.

4. Dr Watson has estimated the quantity of salt in water of different specific gravities. It is also reduced to the temperature of 62° by Mr Kirwan, as in the following table.

Salt.	Specific Gravity.
$\frac{1}{24}$	1.0285
$\frac{1}{25}$	1.0275
$\frac{1}{26}$	1.0270
$\frac{1}{27}$	1.0267
$\frac{1}{28}$	1.0250
$\frac{1}{30}$	1.0233
$\frac{1}{39}$	1.0185
$\frac{1}{44}$	1.0033
$\frac{1}{56}$	1.0105
$\frac{1}{108}$	1.0040
$\frac{1}{162}$	1.0023

These experiments were made with solutions of common salt, which was not perfectly pure, and therefore it is allowed that they may correspond pretty nearly with the proportions of saline matter in sea-water of the same specific gravities.

5. The proportions of the different salts, in an analysis by Bergman, are the following: 2192 Proportions.

Muriate of soda,	30.311
Muriate of magnesia,	6.222
Sulphate of lime,	1.000
	38.133

In 1000 parts of water taken up near Dieppe, Lavoisier found the following salts:

Muriate of soda,	1375
——— of lime and magnesia,	256
——— of magnesia, -	156
Lime, - - -	87
Sulphate of soda and magnesia,	84
	1958

Sect. II. *Of Mineral Waters.*

1. The name of *mineral waters* has been given to those waters which are distinguished by the smell, taste, or colour, from pure water, the obvious properties of which are, transparency and insipidity. These peculiarities of taste, smell, and other properties, are owing 2193 Characte

owing to the impregnation of certain mineral substances which they have acquired in their passage through the soil or strata of the earth. The effects which such waters produce on the animal economy, early attracted the attention of mankind, and led to their application as remedies in the cure of diseases. It was long indeed before any other distinction of mineral waters was made,
2194 except what was indicated by their sensible qualities,
lasses. and their effects on the human constitution. From these properties mineral waters have been divided into four classes: 1. Acidulous or gaseous water; 2. Saline waters; 3. Sulphureous or hepatic waters; and, 4. Chalybeate waters.

2195
cidulous. (1.) Acidulous waters are distinguished by their penetrating acid taste, the facility with which they boil; by sparkling when they are poured into a glass; and by the emission of bubbles of air, by agitation. The acid with which they are impregnated is generally the carbonic. These waters redden the tincture of turnsole, and precipitate lime-water.

2196
aline. (2.) The second class, or the saline waters, are sufficiently characterized by their taste, which varies according to the nature of the salt with which they are impregnated.

2197
ulphure-is. (3.) The sulphureous or hepatic waters are at once recognized by their fetid odour, and by blackening some metallic substances, as lead and silver. Some of these waters are impregnated with sulphurated hydrogen gas, while in others it is combined with lime, or with an alkali.

2198
halybeate. (4.) The fourth class, or the chalybeate waters, are distinguished by an astringent taste. With the prussiate of lime they give a blue colour, or a black with the infusion of nut-galls. This property is owing to a portion of iron which is held in solution, either by carbonic or sulphuric acid. Sometimes carbonic acid is in excess, and then the water has a penetrating slightly acid taste.

2199
ibstances und in ineral aters. 2. The substances which have been found in mineral waters, as they have been enumerated by Mr Kirwan, belong either to the class of gaseous bodies, acids, alkalies, earths, or salts.

2200
ases. 3. Oxygen gas was first discovered in waters by Scheele. It is generally in small proportion, and does not exist in waters with sulphurated hydrogen gas, or iron, because it is incompatible with these substances. Azotic gas has been found in the waters of Buxton, Harrowgate, and Lemington Priors. Common air was first discovered in mineral waters by Mr Boyle; the quantity scarcely exceeds $\frac{1}{27}$ of the bulk of the water. Fixed air or carbonic acid was first discovered in Pyrmont waters by Dr Brownrig. The proportions are very variable; but there are few mineral waters which are entirely free from it. A hundred cubic inches of most waters, contain from 6 to 40 of carbonic acid gas. A hundred cubic inches of Pyrmont waters contain, according to Bergman, 95 of fixed air; according to Dr Higgins, 160, and according to Westrumb, 187 cubic inches. Sulphurated hydrogen gas is the principal ingredient in sulphureous or hepatic water. Carbonated hydrogen gas is said to have been detected in some mineral waters in Italy.

2201
ids. 4. The next class of substances found in mineral waters, are the acids. Sulphuric acid has never been found, except in combination with other substances, forming salts in mineral waters. With some of these salts it exists in excess. Sulphurous acid has been detected in many of the hot mineral springs in Italy, in the vicinity of volcanoes. Muriatic acid has only been found in mineral waters, in combination with other substances. Nitric acid is said also to exist in mineral waters in Hungary, in a combined state. Boracic acid has been found in a separate state, in some lakes in Italy.

5. The alkalies are rarely found combined in mineral waters. In the state of carbonate they are frequent. Soda only was detected in the hot mineral springs of Iceland, by Dr Black. 2202 Alkalies.

6. Few of the earths, except in combination, have been found in mineral waters. Lime, it is said, exists uncombined in some waters; but Bergman observes that it must be in hot and not in cold mineral waters. Dr Black detected silica in the waters of Geyser and Rykum in Iceland. It has been found in those of Carlsbad by Klaproth, and it has not unfrequently been observed by others in different mineral waters. 2203 Earths.

7. The salts which have been found in mineral waters, are sulphates, nitrates, muriates, and carbonates. 2204 Salts.

Sulphates.—Sulphate of soda is frequently found in the waters of springs and lakes. Sulphate of ammonia has been found in mineral waters, in the neighbourhood of volcanoes. Sulphate of lime is one of the most common substances in most springs. Sulphate of magnesia, or Epsom salt, is not unusual in many mineral springs. Sulphate of alumina is rarely found in mineral waters; it is more commonly found in the state of triple salt or alum. Sulphate of iron is frequent in the springs and lakes of volcanic countries. It has also been found in other places. Sulphate of copper has only been detected in the waters which issue from copper mines.

Nitrates.—Nitrate of potash or nitre is rarely found in mineral waters. It has, however, been detected in several springs in Hungary; some traces of it have been observed in wells in Berlin, and in some salt springs in Germany. Nitrate of lime has been detected in springs in the sandy deserts of Arabia. Nitrate of magnesia is said also to have been found in mineral waters.

Muriates.—Muriate of potash is but rarely found in mineral waters. It has been detected in the springs of Uleaburg in Sweden. Muriate of soda or common salt exists in almost all waters, as well as in the ocean. Muriate of ammonia is not very frequent in waters; it has been detected, however, in some mineral lakes in Italy, and also in Siberia. Muriate of barytes is very rare, but according to Bergman, it has been found in some mineral waters. Muriate of lime is very generally found in mineral springs. Muriate of magnesia is very common in mineral waters. Muriate of alumina has been detected in some mineral waters by Dr Withering. Muriate of manganese was found by Bergman in some mineral waters in Sweden, and it has lately been discovered, in small proportion, in the waters of Lemington Priors, by Mr Lambe.

Carbonates.—Carbonate of potash, it is said, has been found in some mineral waters. Carbonate of soda exists very frequently in the waters of many springs and lakes. Carbonate of ammonia has been found in the

the waters of Rathbone Place in London, by Mr Cavendish, and in some waters in France. Carbonate of lime is commonly found in almost all waters, and it is held in solution by an excess of carbonic acid. Carbonate of magnesia very frequently exists in mineral waters. When it is fully saturated with carbonic acid, it is soluble in water, without any excess of acid. Carbonate of alumina is said to have been found in the waters of Avor in Anjon, in France. Carbonate of iron is frequently found in mineral waters. It is to this that chalybeate waters owe their distinguishing properties.

8. *Borax*, or the subborate of soda, is found in some lakes in Thibet and Persia.

2205 Hydro-sulphurets. 9. *Sulphurated alkali* and *sulphurated lime*, or the hydro-sulphurets of soda and of lime, have been found in mineral waters. It is to these substances that hepatic or sulphureous waters owe their distinctive properties.

2206 Bitumen. 10. Bituminous substances have also been discovered in some mineral waters. Sometimes they have been found combined with an alkali. Waters also sometimes contain vegetable and animal matters; but these are not, properly speaking, to be considered as ingredients in these waters.

Sect. III. *Of the Analysis of Mineral Waters.*

2207 Physical properties. In the analysis of mineral waters, the first thing to be attended to is to ascertain the temperature and situation of the springs from which they are obtained. The sensible properties are then to be examined, such as colour, transparency, smell, and taste. Of the physical properties of mineral waters, one of the most important, and the first to be ascertained, is the specific gravity. By this means, although not with perfect accuracy, the quantity of saline ingredients may be known; but it is only by means of chemical operations that the nature of the substances with which mineral waters are impregnated can be determined; and by obtaining these substances in a separate state, or forming new combinations, that their quantity or proportions can be accurately ascertained. In the analysis of mineral waters, therefore, after discovering their physical properties, the object of the chemist is first to detect the nature of the substances, and then the quantity or proportion of these substances which they contain. In both we shall follow the method pointed out by Mr Kirwan, in his Essay on the Analysis of Mineral Waters.

I. Of the Method of Discovering the Substances in Mineral Waters.

1. The nature of the component parts of mineral waters is discovered by the addition of certain substances which produce changes of different kinds. The substances employed for this purpose are known in chemistry by the name of *tests* or re-agents, because they act upon the substances with which the waters are impregnated, by decomposing them, and forming new combinations.

2208 Tests.

2209 Gaseous bodies. 2. Gaseous substances are easily detected, either by their escaping in the form of bubbles when the water is exposed to the air, or, if they are more permanently held in solution, by boiling a quantity of the water in a retort, and receiving the gas over water or mercury. The nature of the gas, thus collected, may then be examined by the usual tests for gases.

3. Carbonic acid is detected by the infusion of litmus, not, however, when the acid is saturated with any base, unless the acid be in excess. Saturated lime water may also be employed as a test for carbonic acid. One cubic inch of carbonic acid gas in 7000 grains of water, may be discovered by this test. These effects are not produced by carbonic acid, after the water has been boiled. 2210 Carbonic acid.

4. The infusion of litmus, or paper tinged with it, is also employed as a test for mineral acids existing in waters. A red colour is produced, either when the acid is combined, or united with a base in excess. In this case the redness is permanent, and is not destroyed by boiling. 2211 Mineral acids.

5. Sulphurated hydrogen gas reddens the infusion of litmus, and blackens silver or lead, or the solutions of these salts. It is also easily recognized by its peculiar odour. 2212 Sulphurated.

6. Carbonated hydrogen gas burns with common air without explosion; is not absorbed by lime-water, and has no peculiar smell. 2213 And carbonated hydrogen gas.

7. The fixed alkalies produce a reddish-brown colour with the infusion of turmeric. The same change takes place with the alkaline and earthy carbonates. The infusion of Brazil wood assumes a blue colour. Paper tinged blue with litmus, and reddened with vinegar, may be also employed as a test for alkalies; and by all the alkaline and earthy carbonates, the original blue colour is restored. The muriate of magnesia is precipitated only by the fixed alkalies. Potash forms with nitric acid a prismatic salt; with acetic acid a salt which does not deliquesce, and with sulphuric acid, a salt which effloresces. Ammonia, when in considerable quantity, is detected by the smell. If the proportion be small, it may be discovered by distilling part of the water with a gentle heat. 2214 Fixed alkalies.

8. The carbonates of the earths and the metals are precipitated by exposure to the air, or by boiling and evaporation. Carbonates of lime, of alumina, and of iron, are precipitated by boiling for a quarter of an hour. Carbonate of magnesia is only partially precipitated by the same process. 2215 Carbonates.

9. Iron, either in the state of carbonate, or combined with some other acid, is detected by tincture of galls, which produces a black or purple colour. A very minute portion of iron is detected by this test. Three grains of crystallized sulphate of iron dissolved in five pints of water, strike a purple colour in five minutes, with a single drop of this tincture. With this test the colour assumes different shades, according to the nature of the other substances which are in combination. If the water contains a carbonate of an alkali or an earthy salt, the colour is violet; it is dark purple with other alkaline salts; with sulphate of lime it is first whitish, and afterwards black; and with sulphurated hydrogen gas, the colour is purplish red. The latter, Mr Kirwan suspects, is occasioned by manganese. Iron, dissolved by carbonate of ammonia, is at first whitened, and afterwards blackened by tincture of galls. In the caustic fixed alkalies the precipitate is at first crimson red, but afterwards becomes black. Prussian alkali is a sensible test of iron; the 2216 Iron.

the precipitate is blue: but if an alkali exists in the water, it prevents a small portion of iron from striking a blue colour with this test, until it be saturated with an acid.

2217 ılphuric ɔid. 10. Sulphuric acid is detected by muriate, nitrate, or acetate of barytes, nitrate or acetate of lead, nitrate of mercury, nitrate, muriate, or acetate of strontites, and nitrate, muriate, or acetate of lime.

2218 luriatic. 11. Muriatic acid is readily detected by nitrate of silver. It forms a white precipitate, or a cloud in the water. If there are any carbonates of alkalies or earths in the water, they must be previously saturated with nitric acid. Sulphuric acid, or the sulphates, must be precipitated by nitrate or acetate of barytes. Acetate and sulphate of silver may be also employed for the same purpose.

2219 oracic. 12. Boracic acid, when it is uncombined, is detected by acetate of lead; but the alkaline and earthy carbonates must be previously saturated with acetic acid. The sulphates must be decomposed by means of acetate of strontites, and the muriates by acetate of silver.

2220 me. 13. Lime is readily detected with oxalic acid; but if the water contains any mineral acid, it must be previously saturated with an alkali. Barytes, if any exists in the water, must be precipitated by sulphuric acid. Magnesia is precipitated very slowly with oxalic acid, by which it is readily distinguished from lime.

2221 ırytes. 14. Barytes is detected by diluted sulphuric acid, with which it instantly forms an insoluble white precipitate.

2222 agnesia d alumina. 15. Magnesia and alumina are both precipitated by means of pure ammonia and lime water; but it is necessary that carbonic acid, if any exists in the water, be previously separated by means of a fixed alkali, and by boiling. If lime-water is employed, the sulphuric acid must be first precipitated with nitrate of barytes. If the two earths are precipitated together, the alumina may be separated from the magnesia, by boiling them with pure potash, which combines with the alumina.

2223 ca. 16. Siliceous earth may be discovered by evaporating a large quantity of water nearly to dryness, and then by re-dissolving the precipitate in nitric or sulphuric acid, and afterwards evaporating to dryness. The dry mass, re-dissolved in water and filtered, leaves the silica on the filter.

2224 ode of imating propor-ns. The proportions in which these different acids and salifiable bases are contained in a mineral water, are known by considering what is the proportion of them contained in any precipitate which they occasion.

2225 portant ws of Murray. Till lately it was a great object with chemists to ascertain the mode in which these substances existed in the water. It was conceived that every acid was combined in a definite manner to form either a binary or a ternary compound with one or more of the bases present; much pains were bestowed, by frequent evaporation and cooling of the water, to find out what salts it would afford, and it was conceived that these were the salts contained in the water in question. It now appears, however, by the researches of the late Dr Murray, which commenced with an analysis of the water of Dunblane, that these operations afford no information, and that the kind of binary salts which make their appearance depends on the circumstances of the evaporation. The former view proceeded on the presumption, that the least soluble combinations of the ingredients are those existing in solution, for these are compounds which appear in the form of crystals. This author conceives it most probable, that the most soluble binary compounds are those contained in the water, and that a water from which we obtain muriate of soda and sulphate of lime consists in reality of sulphate of soda and muriate of lime. By this consideration he explains the well known medicinal activity of waters, which afford, on evaporation, none but very inert combinations. It is to muriate of lime that he ascribes the active properties of the waters of Bath and others. Perhaps it is most probable, on the whole, that in mixed chemical solutions the acids and the bases are in universal cotemporaneous combination. Whatever be in this respect the case, all the information to be derived from analysis is obtained by discovering the different acids, salifiable bases, and other simpler ingredients which they contain.

31. Alkalies combined with bitumen are sometimes found in mineral waters. These mineral soaps, or bituminated alkalies, as they are called by Mr Kirwan, form a coagulum with the acids. This coagulum is soluble in the alkalies. 2226 Bitumen.

32. Extractive matter, which is sometimes found in mineral waters, is discovered by means of nitrate of silver, with which it forms a brown precipitate; but the water containing it must be freed from sulphuric and muriatic acids with nitrate of lead. Three grains of the precipitate, according to Westrumb, indicate one grain of extractive matter. 2227 Extractive matter.

33. Animal extractive matter gives a very disagreeable taste and smell to water. It is soluble in alcohol. 2228 Animal.

Chap. XVII. Of MINERALS.

In following out the arrangement which we have laid down at the beginning of this treatise, we should now enter upon the consideration of mineral substances. To preserve the chemical investigation of the different departments of nature unbroken, we proposed to employ this chapter in a general view of the characters of mineral bodies, of their composition and methods of analysis; but as this article has been unavoidably extended to so great a length, we shall reserve the whole to the article Mineralogy, where they will be fully detailed.

Chap. XVIII. Of VEGETABLES.

1. Natural bodies may be properly divided into organized and inorganized, each of which exhibit characters sufficiently discriminative. The substances included under the 17 preceding chapters, belong to the latter class. Organized substances are vegetables and animals, which are to be treated of in this and the following chapters. The distinction between these two classes of bodies, although in some cases it is less obvious, in general is easily recognized. The most perfect forms of inorganized matter afford no marks of resemblance to the varied and complicated structure of a plant or an animal. In the mode of formation, or the growth and increase of the individuals of these two classes, there is the most striking diversity, which exhibits plain and certain characters of distinction. In the one class the growth or increase takes place by the mere aggregation of the particles of matter already prepared, and according to the laws of affinity between the 2229 Division of natural bodies.

the particles; and no new properties exist in the aggregate, which did not exist in the minutest particles of which it is composed. The other class of bodies, comprehending vegetables and animals, exhibits a very different process. The substances which enter into their composition are received into tubes or vessels, are conveyed by them to every individual part of the vegetable or animal, are subjected to peculiar changes, and assume new forms, possessing properties and qualities which could not be previously detected in the simple elements, by any chemical or mechanical operation. This is indeed the essential characteristic of vegetables and animals. The particles which compose a crystal, formed by the evaporation of water, were held in solution by the water, and invariably and uniformly arranged according to certain laws; but the almost infinite variety of substances which compose vegetables and animals, are not to be found in the materials which are necessary to promote their growth and health; neither in the water, the earth, the air, the heat, nor the light, all which contribute their share to the same end. These undergo new changes, and enter in new combinations, none of which existed in the simple elements, and none of which can be effected by any mechanical or chemical process. Indeed the laws which regulate vegetable and animal operations, seem to be totally different from the established laws of chemical action. Hence, from observing this difference of action, the existence and influence of a different principle have been inferred in animals and vegetables. This has been called the *vital principle*, or the principle of life, because by its influence the varied and complicated phenomena of animals and vegetables are exhibited, which cannot be accounted for on mechanical or chemical principles. It is by the influence of this principle that the animal or vegetable seems to possess the remarkable power of resisting or counteracting to a certain degree the effects of chemical or mechanical agents which may prove injurious to its existence; the power of regulating and selecting what is beneficial and necessary, of supplying what is deficient, and of curtailing what is redundant. Organized substances admit of a natural division into vegetables and animals. The bodies included under each of these divisions have some points of resemblance; but in general are sufficiently characterized and distinguished from each other, by their form, structure, power of motion, component parts, and peculiarities of habits. The first of these divisions, namely vegetables, forms the subject of the present chapter.

2230 Structure of plants.

2. A vegetable is composed of a root, stem, leaves, flowers, fruits, and seeds; and when all these different parts are fully developed, the vegetable is said to be *perfect*. When any are deficient, or at least less obvious, the vegetable is said to be *imperfect*.

2231 Root.

The root is that part of the plant which is concealed in the earth, and which serves to convey nourishment to the whole plant. The stem which commences at the termination of the root, supports all the other parts of the plant. When the stem is large and solid, as in trees, it is denominated the *trunk*, which is divided

2232 Bark.

into the wood and the bark. The bark constitutes the outermost part of the tree, and covers the whole of the plant, from the extremity of the roots to the termination of the branches. The bark is composed of three parts, namely, the epidermis, the parenchyma, and cortical layers. The epidermis, which is a thin transparent membrane, forming the external covering of the bark, is composed of fibres crossing each other. When the epidermis is removed, it is reproduced. The parenchyma, which is immediately below the epidermis, is of a dark green colour, composed of fibres crossing each other in all directions, and is succulent and tender. The cortical layers, which constitute the interior part of the bark, are composed of thin membranes, and increase in number with the age of the plant.

2233 Wood.

The wood immediately under the bark is composed of concentric layers, which increase with the age of the plant, and may be separated into thinner layers, which are composed of longitudinal fibres. The wood next the bark, which is softer and whiter, is called the *alburnum*. The interior part of the trunk is browner and harder, and is denominated the *perfect wood*.

2234 Pith.

In the middle of the stem is the pith, which is a soft spongy substance, composed of cells, or *utriculi*, as they are called. In old wood, this part entirely disappears, and its place is occupied by the perfect wood. The leaves are composed of fibres arranged in the form of net-work, which proceed from the stem, and footstalks by which they are attached to the branches. These fibres form two layers in each leaf, which are destined to perform different functions. The leaves are covered with the epidermis, which is common to the whole of the plant. Each surface of a leaf has a great number of pores and glands, which absorb or emit elastic fluids. Flowers are composed of different parts. The *calyx* or cup is formed by the extension of the epidermis; the *corolla* is a continuation of the bark, and the stamina and pistilla, the internal parts of fructification, are composed of the woody fibres and pith of the plant. Fruits are usually composed of a pulpy, parenchymatous substance, containing a great number of *utriculi* or vesicles, and traversed by numerous vessels. Seeds are constituted of the same utricular texture, in the vesicles of which is deposited a pulverulent or mucous substance. These cells have a communication with the plant by means of vessels, and by these is conveyed the necessary nourishment during germination.

2235 Flowers and fruits.

2236 Vessels.

Plants contain different orders of vessels, which are distinguished from each other by their course, situation, and uses. Lymphatic vessels serve for the circulation of the sap. They are chiefly situated in the woody part of the plant. The peculiar vessels, which generally contain thick or coloured fluids, are placed immediately under the bark; they are smaller in number than the sap-vessels, and have their interstices filled up with utriculi or cells, with which they form a communication. Some of these proper vessels are situated between the epidermis and the bark, which are readily detected in the spring. Some are situated in the interior part of the bark, forming oval rings, and filled with the peculiar juices of the plant. Another set of proper vessels is placed in the alburnum, nearer the centre of the stock or trunk, and sometimes in the perfect wood. The utriculi or cells constitute another set of vessels, which seem to resemble a flexible tube, slightly interrupted with ligatures at nearly equal distances, but still preserving a free communication through

Functions of Vegetables. through its whole length. They vary in form, colour, and magnitude, in different vegetables, and exist in the roots, the bark, leaves, and flowers. The tracheæ or spiral vessels, which are readily detected in succulent plants, appear in the form of fine threads, and may be drawn out to a considerable length without breaking. These vessels are very numerous in all plants, especially under the bark, where they form a kind of ring, and are disposed in distinct bundles, in trees, shrubs, and stalks of herbaceous plants.

After these preliminary observations on the characters of organized substances, and the general structure of plants, we now proceed to give a short view of the functions, decomposition, and component parts of vegetables. These shall form the subject of the three following sections.

Sect. I. *Of the Functions of Vegetables.*

I. Of Germination.

2237 Temperature.

1. When the perfect seeds of a vegetable are placed in certain circumstances, they produce plants exactly similar to those from which they originated. The requisite circumstances for the germination of seeds are, heat, air, and moisture. It is well known that no vegetation goes on when the temperature of the air is at the freezing point, and very little till it rises a considerable number of degrees above it. The seeds of different plants, it is observed, require different degrees of heat for their germination, and hence the various seasons and climates in which different plants and seeds are found to vegetate.

2238 Air.

2. But whatever the temperature may be, no seeds germinate, unless they are exposed to the action of the air. It is the oxygen of the air which is necessary for the production of this change; for when it is entirely excluded no change can take place except that of decomposition, and when it is in greater quantity, vegetation is more rapid and more vigorous.

2239 Moisture.

3. Moisture is also necessary for the vegetation of seeds. The water must be applied in moderate quantity, for, with the exception of the seeds of aquatic plants, which are possessed of peculiar habits, most seeds are deprived of their vegetative power, and entirely decomposed, when kept immersed in water. Hence it is that many seeds do not vegetate in stiff clay soils, which retain too much water, nor in sandy lands, which allow the whole of the water to filtre through them. Many seeds, although they are exposed to the favourable action of these agents, do not vegetate when they are exposed to the action of light. It is on this account, and also no doubt, for the proper application of moisture, that seeds are covered with the soil, by which means germination is found to be greatly promoted.

2240 Parts of seeds.

4. A seed is composed of three principal parts, which have been denominated the cotyledons or lobes, the radicle, and plumula. The greatest number of seeds have two cotyledons. Some, however, as many of the farinaceous seeds and seeds of grasses, have only one. Others have three, and some six. Hence plants have been distinguished into *mono-cotyledinous*, *di-cotyledinous*, and *poly-cotyledinous*.

2241 Root formed.

5. The first change which takes place on a seed placed in circumstances favourable to germination, is the increase of size by the absorption of moisture. The radicle is next formed, which stretches downwards into the earth. The plumula afterwards shoots upward, and expands into leaves and branches. The peculiar function of the root is to convey nourishment from the earth for the future growth of the plant; but from what source is the nourishment derived for the formation of the root itself?

2242 Oxygen absorbed.

6. The very first change which takes place within the seed is, that the oxygen of the air which enters along with the moisture, combines with the carbon which exists in the lobes of the seed, and carbonic acid is thus formed, which is given out in the state of gas. The farinaceous matter of the seed being deprived of part of its carbon, is converted into a saccharine substance, which is destined for the nourishment of the embryo plant, till its parts are so far evolved, as to derive nourishment from the earth. But if oxygen gas be entirely excluded, no part of the process of germination goes on: or even if it has proceeded so far that the plumula shall have appeared above the surface in the form of seminal leaves; yet if these leaves are removed before others have been unfolded, the plant dies. The seminal leaves are the lobes which have been pushed out of the earth along with the plumula, so that if they are destroyed, the plant is cut off from the necessary source of nourishment for the evolution of its parts, and for the formation of roots and leaves, which are destined to perform the different functions of vegetation.

2243 Carbonic acid gas emitted.

II. Of the Food of Plants.

2244 Supposed to be water.

1. But air, heat, and moisture, are not only necessary for the first formation of the different parts of the plant; their continued action is absolutely requisite for its future health and growth. It could not long escape observation, that plants when entirely deprived of water cease to vegetate. Hence it became the opinion of the earlier physiologists, that water constituted the chief or the only food of plants; but it has been proved by experiments in analysing plants which have grown in pure water, that there is one of the necessary principles in their constitution, of which they receive no increase above that which previously existed in the seeds or roots from which they sprung. In a series of experiments instituted by Hassenfratz, on the roots of hyacinths, the seeds of kidney beans and other plants, he found that the quantity of *carbonaceous* matter in the full formed plant, was less than what previously existed in the bulb or seed.

2245 Not pure.

2246 Is the solvent of the food.

2. But pure water is necessary as a solvent for those substances which are considered as the proper food of vegetables. When impregnated with certain saline and earthy, and still more with carbonaceous matter, it is found to be most proper for promoting the growth and increase of vegetables. We have observed plants growing in a soil which was frequently moistened with the water from a dunghill, advance with a more rapid and vigorous growth, and attain to a larger size, than similar plants in the same soil, which received only the usual supply of rain and dew from the clouds. It has been found by experiment, that this water holds in solution a considerable portion of carbon. It is not improbable that it also contains some of those saline matters which have been detected by analysis in plants in the

Functions of Vegetables.

the greatest health and luxuriance. The waste of the soil requires to be repaired with frequent additions of manure, which may be considered as necessary supplies of food or nourishment.

2247 Peculiar structure of the root.

3. The food of plants, whatever it may be, is taken up by the roots in a state of solution in water, and conveyed by the vessels to every part of the vegetable. For this purpose it would appear that there is a peculiar adaptation of structure in the very extremities of the roots; for, if part of the fibre of a root be cut off, the plant ceases to vegetate till new fibres are formed capable of absorbing the necessary quantity of water.

2248 Sap.

4. This fluid, found in plants, is called the *sap*. It is most abundant in the spring, as the season of vegetation advances; and during that season, when the plant is wounded, it flows out copiously, and it is then said *to bleed*. This is particularly the case with some trees, such as the birch and a species of maple; the sap of which, by certain processes, even yields wine or sugar. The sap is contained in what is called the *lymphatic* or common vessels of the plant.

2249 Is prepared in the plant.

5. The fluids taken up by vegetables, it is probable, no sooner enter the plant, than they undergo some change. Vauquelin has directed his attention to this subject, and has analyzed the sap at different periods during the season of vegetation.

2250 Sap of the elm.

The sap of the common elm (*ulmus campestris, Lin.*) extracted from the tree early in the spring, was of a brown colour, had a sweet mucilaginous taste, but scarcely reddened the tincture of turnsole. Ammonia produced in this fluid a copious yellow precipitate, soluble with effervescence in acid. Barytes and lime-water produced a similar effect. Oxalic acid and nitrate of silver gave a white precipitate. Sulphuric acid, diluted with water, occasioned a brisk effervescence, with the evolution of the odour of acetic acid from the mixture. Oxymuriatic acid destroyed the colour of the sap, and formed in the liquid a yellow precipitate.

2251 Experiments.

Hydrosulphuret of potash and sulphate of iron effected no change, but alcohol threw down a flaky precipitate. A quantity of this sap being evaporated with a moderate heat, there was found on the surface a brownish pellicle; a brown matter separated in the form of flakes, and an earthy matter deposited on the sides of the vessel, which was dry to the touch. After evaporation to a certain degree, and cooling, a yellow earth was deposited, which dissolved with effervescence in muriatic acid. When the solution was completed, the liquid was filtered, to separate the insoluble vegetable matters. The muriatic solution mixed with carbonate of potash, yielded carbonate of lime. The liquid which had deposited the vegetable matter being evaporated with a gentle heat afforded a grayish extract, which strongly attracted moisture from the air, and had a very pungent, saline taste. It effervesced with the addition of concentrated sulphuric acid, and gave out the odour of radical vinegar. Distilled with three parts of sulphuric acid, it furnished very concentrated acetic acid, and there remained in the retort sulphate of potash with excess of acid.

6. From this analysis it follows, that the extract of the sap of the elm is chiefly composed of acetate of potash. One thousand and thirty-nine parts of this sap yielded nearly the following proportions.

Acetate of potash	9.240
Vegetable matter	1.060
Carbonate of lime	.796

2252 Compositions.

The deficiency was made up of water and some volatile matter.

When the season was farther advanced, the sap of the same tree was again subjected to analysis, and it was found that the quantity of acetate of potash and carbonate of lime had diminished, but that the quantity of vegetable matter was nearly double. At a still more advanced period of the season, the experiment was repeated, the result of which was, that the increase of the vegetable matter, and the diminution of the acetate of potash and carbonate of lime, were still greater. It appeared too, that carbonic acid existed in excess in the sap, and held in solution the carbonate of lime.

2253 Of the beech.

7. The same chemist analyzed the sap of the beech, and it was found to be composed of water, acetate of lime with excess of acid, acetate of potash, gallic acid, tan, mucus, extractive matter, and acetate of alumina; but the proportions of these parts are not mentioned. From this analysis it appears, that the sap of the beech differs from that of elm, in containing acetic acid uncombined, besides gallic acid and tan, having at the same time no carbonate of lime. When the sap of the same plant was examined later in the season, the proportion of gallic acid and tan had increased. Vauquelin also examined, by analysis, the sap of the carpinus sylvestris or hornbeam, and the betula alba or birch *. The component parts of the sap of the former were found to be, acetate of potash and lime, mucilage, sugar, and extract, with water; and the latter were found to be water, acetates of lime, alumina and potash, sugar, and vegetable extract. From these experiments it appears that the fluids which are taken up by plants, are immediately changed by certain processes within the plant; for some of the substances which are component parts of the sap of plants, are either not found in the liquids before they enter the plant, or exist in them in very small quantity.

2254 Of the hornbeam.

These changes, it appears too, from the same experiments, are considerably greater, at the later periods of the season of vegetation. Some of the component parts are greatly increased, while others are much diminished.

2255 Ascends through the wood.

8. The sap ascends from the root to the extremities of the branches, which has been proved by making incisions in the trunk of a tree at different heights in the spring season. The sap is observed to flow, first, from the lowest incision, and successively to the highest. It is through the vessels in the woody part of the tree, that it ascends, for none flows from an incision unless it has penetrated the wood, and in some trees it is necessary to make the incision nearly to the centre. It has been observed that coloured infusions always pass from that part of the wood called the alburnum.

2256 By the tracheæ.

9. The sap of plants is conveyed through those vessels which were described under the name of *tracheæ* or spiral vessels. These were denominated tracheæ or air-vessels by the earlier physiologists, because being found empty, when they were cut across and examined, they were supposed to convey nothing but air.

10. As the sap of vegetables moves with very considerable

* *Ann. de Chim.* xxxi. 20.

siderable force, it has given rise to much speculation about the nature of that power, or the cause by which this is effected. Malpighi ascribed the ascension of the sap to the alternate dilatation and contraction of the air in the air-vessels; while Grew supposed, that it was owing to the lightness of the vapour, in which state he conceived the sap entered the plant, and was conveyed through it. By many others the ascent of the sap has been ascribed to the force of capillary attraction; but the nature of this action, as it is demonstrated and explained by mechanical philosophers, seems to be incompatible with the phenomena of the circulation of the sap in vegetables, and has therefore been rejected as a hypothesis equally unsatisfactory with those which have been just mentioned. It has been ascribed with more probability to the action of the vessels themselves. This arises from what is termed the irritability of the vessels, or a certain power by which they are enabled to contract, when subjected to the action or influence of certain substances. The sap is supposed to have such an influence, and the action which takes place when it enters the roots, is owing to the irritability of the vessels. The sap is carried a certain length by the first contraction, and by successive contractions is propelled through every part of the plant, while at the same time new additions continue to enter the extremities of the root.

[Margin: ...nctions of Vegetables. 2257 ...use of ascent.]

III. Of the Functions of the Leaves.

1. Whatever be the nature of the process, the sap is carried to every part of the vegetable, and undergoes certain changes, which become more considerable according to the progress which it has made after its absorption. But the greatest changes which take place in the sap of plants, are effected in the leaves. The leaves are to be considered as essential organs of vegetables, for in them the sap is totally changed, and converted into the peculiar juice, the *succus proprius*, of the plant.

[Margin: 2258 ...duce ...t ...nges on ...sap. 2259 ...vert it ...the ...liar ...]

2. During the day, the leaves of plants transpire a very considerable quantity of moisture, the proportion of which appears from some experiments not to be much inferior to the quantity absorbed. From similar experiments, it appears that the quantity evaporated is in proportion to the extent of surface of the leaves. The quantity has been observed to be greatest during sunshine and warm weather. It is greatly interrupted during the night, and entirely checked by cold. When the quantity of moisture transpired is diminished, the moisture imbibed is found to be less in proportion. In experiments made on this transpired matter, by evaporating to dryness a quantity which had been collected, a small portion of carbonate of lime was obtained; from the residuum, a still smaller proportion of sulphate of lime, with a little gummy and resinous matter. It has been found that the transpiration of moisture takes place chiefly on the upper surface of the leaves, and this seems to be performed by a particular set of organs.

[Margin: 2260 ...ng the ...]

3. During the day, at least during bright sunshine, oxygen gas is given out by the leaves of plants. The quantity of oxygen gas emitted by leaves, as appears from the experiments of naturalists, depends on the quantity of carbonic acid gas absorbed by the plant; for it has been ascertained that vegetables grow rapidly and vigorously when exposed to this gas; nay, it is found essentially necessary to their health and growth. If the water with which plants are supplied be deprived of the whole of its air by boiling, no oxygen gas is emitted, and water which is impregnated with the greatest proportion of carbonic acid gas, gives out the greatest quantity of oxygen gas.

[Margin: 2261 ...en gas ...out. 2262 ...nic ...gas ...bed.]

Functions of Vegetables.

2263 Action of light.

4. This process goes on only during the day, and it is more vigorous during bright sunshine; from which it is natural to conclude, that light performs some necessary part in it. It is well known that plants which grow in the dark do not acquire a green colour: and it is found that such plants contain a smaller proportion of carbon than similar plants, in the same circumstances, exposed to the light. From this it may appear what is the nature of the process when carbonic acid gas is absorbed by plants, and oxygen gas emitted. It is the decomposition of the former, which is effected; the carbon being retained in the plant, and the oxygen given out; but light being a necessary agent in this decomposition, the process must be interrupted when it is excluded.

2264 Parenchyma of the leaf gives out the oxygen gas.

5. This decomposition takes place in the parenchymatous substance of the leaf; and the quantity emitted, it appears, is in proportion to the thickness of this substance. The green colour of plants, it has already been mentioned, depends on the action of light. Plants which vegetate in the dark, both have a smaller proportion of carbon, and continue of a white colour; but in a short time after they are exposed to the light, the green colour is restored.

2265 Vegetables the great source of oxygen.

6. Thus it appears, that it is one part of the functions of leaves of plants to exhale a considerable proportion of the moisture taken in by the roots; to absorb carbonic acid gas; to decompose this gas, by which its carbon is retained in the plant, and the oxygen is given out. It has also appeared from this fact, that vegetables are great sources of supply of oxygen gas, which is essentially necessary in the numerous processes of combustion, and the respiration of animals, which are constantly going on on the surface of the earth; and that thus the waste of this vital fluid is repaired, and the balance preserved between its destruction and supply.

2266 Function of leaves during the night.

7. The leaves of plants perform a very different function during the night. Instead of emitting moisture and oxygen gas, and absorbing carbonic acid gas, as they do during the day, the process is reversed. Carbonic acid gas is emitted, and moisture and oxygen gas are absorbed. The absorption of moisture seems to be chiefly performed by the under surface of the leaves, at least in many plants. It has been found by experiment, that plants, which have been made to grow in oxygen gas give out a greater quantity of carbonic acid gas, than when they grow in common air. From this circumstance it has been supposed, that the carbonic acid gas, emitted by plants during the night, is owing to the combination of the oxygen absorbed, with the carbon of the sap; for it is at the same time that oxygen is absorbed. It has also been ascribed to the decomposition of the water. By some comparatively recent experiments, indeed, it has appeared that the evolution of oxygen gas only takes place during the full and direct action of the solar rays, and that even by day, plants, when exposed only to the light reflected from

Functions of Vegebles. from the sky, give out carbonic acid. These experiments, however, require to be repeated on many species of plants before the doctrine here delivered can be subverted.

2267 Peculiar juice. 8. By these different processes which are carried on in the leaves of plants, the sap undergoes important changes. It is there converted into the peculiar juice of the plant, from which are derived, by other processes, the different substances produced in the different parts of plants, the nature of which is to be afterwards examined. The leaves of plants have been compared to the lungs and stomach of animals. There can be no doubt that they are essential organs in the economy of vegetables. In the very first step in the process of vegetation, during the germination of seeds, the moisture absorbed by the roots is carried to the seminal leaves, and there undergoes certain changes, before it is fit for the formation of the stem and the other leaves of the plant; for, if these leaves are removed, vegetation is entirely interrupted, and the plant dies. Even when plants have made farther progress, and are in full vigour, if they are entirely stripped of their leaves, the powers of vegetation cease, till these necessary organs are restored, and new leaves are formed. The progress of vegetation is also stopped when the surfaces of the leaves are varnished over, and the absorption and emission of the necessary fluids thus interrupted.

2268 Sap flows from the roots to the leaves. 9. The sap of plants, it has been already observed, flows from the roots towards the branches and leaves of the plant. In the leaves it undergoes peculiar changes, in consequence of part being exhaled, and in consequence of the absorption of different principles which combine with it, and no doubt contribute by this combination to the changes which take place. The sap, as we have already said, is then converted into the *succus proprius*, or peculiar juice. It is the sap of the plant, which is thus far prepared to be converted into the different parts of the plant, corresponding to its nature and properties; and, as the different parts, both of liquids and solids in plants, possess properties totally distinct from each other, and have derived these from the same nutriment, the processes by which these different substances are produced in different plants, and even in the same plant, must undoubtedly be specific.

2269 Peculiar juice from the leaves to the roots. 10. The peculiar juice of plants flows from the leaves towards the roots. If a ligature is fastened round the stem of a plant, the place immediately above the ligature, that is, between it and the leaves, swells out by the accumulation of this juice. Or if a wound be made in the bark, the peculiar juice flows in greater abundance from that side of the wound next to the leaves, than from the other side.

2270 Properties of it. 11. The peculiar juice of plants has a greater consistence than the other juices. It is readily recognized by some peculiarity of colour. In a great many plants it is milky, in some it is of a green colour, and in others it is red. The component parts of the peculiar juice of plants are little known; but from some experiments which have been made on this subject, it appears that some part of the vegetable is ready formed. In the experiments of Chaptal on the peculiar juice of plants, he detected a substance which possessed the properties of the woody fibre. In similar experiments on the seeds of plants, it was found that they contained a greater proportion of the woody fibre, from which it is inferred, that the peculiar juices of plants contain their nourishment ready prepared, and in that state in which it is found in the seed. The peculiar juices of plants contain a greater proportion of these elements which constitute the different parts of plants, than what is found to exist in the sap. These are carbon, hydrogen, and oxygen. Decomposition of Vegetabl[es].

12. Many plants cease to vegetate as soon as they have perfected their seeds, which is accomplished by some in one season, by others in two, and hence such plants have been called *annuals* and *biennials*. Other plants, however, continue to yield seeds and fruit for many successive seasons, and to live for a great length of time. The cause of this remarkable diversity among the vegetable tribes is to us unknown. 2271 Plants ha[ve] different periods o[f] duration.

Sect. II. *Of the Decomposition of Vegetables.*

1. As soon as the plants have ceased to vegetate, they undergo a new set of changes. The whole plant is broken down; the elements of which it is composed enter into new combinations, and new substances make their appearance, which did not previously exist in the plant. This decomposition is owing, partly to the affinities between the component parts of the vegetable themselves, and partly to the affinities which exist between some of the elementary principles of the plant, and the heat, air, and moisture, without which no decomposition takes place. While the plant continued to exhibit the phenomena of vegetation, that is, while it continued to live, it possessed a power of resisting this chemical action between the elements of which it is composed, and also to a certain extent the action of external agents. During this decomposition of vegetables, air, heat, and moisture, are necessary. Gaseous bodies are generally given out, and new compounds are formed. Some plants, and some parts of the same plant, have a greater tendency to undergo this decomposition than others, because they either possess a greater proportion of the substances which promote the decomposition, or a greater proportion of the substances of which the new compounds are formed. 227[2]

2. The changes or spontaneous decompositions of vegetables, as they are almost always accompanied with an intestine motion, have received the name of *fermentation*. The nature of these changes is very different, both with regard to the gaseous bodies which are absorbed or emitted, and the nature of the products which are obtained after the process is finished. Hence, fermentations have been usually distinguished into three kinds; namely, the *vinous*, the product of which is wine, when certain substances are subjected to this process, and beer, when other substances are employed; the *acetous* fermentation, during which vinegar is produced; and the *putrid* or *putrefactive* fermentation, in which the substances are still farther decomposed, and run into the state of putridity. These different kinds of fermentation might perhaps be considered merely as different stages of the same process; for unless it is checked at certain periods, it runs on through the different stages without interruption. According to some, these three species of fermentation do not include all the changes which have the characters of this process to Fermen[ta]tion.

Decomposition of Vegetables.

to which vegetables are subject. To these it has been proposed to add the saccharine fermentation, or that change which is induced on farinaceous seeds by heat and moisture, which is the germination of seeds or the process of malting; and the colouring fermentation, or that process by which the colouring matter of vegetables, as indigo, is developed. In the present section
2273 Four kinds. we propose to treat, 1. Of the vinous fermentation; 2. Of the acetous or acid fermentation; 3. The panary fermentation, or the formation of bread; and, 4. Of the putrid fermentation.

I. Of the Vinous Fermentation.

2274 History. 1. The vinous fermentation, otherwise denominated the spirituous, has been so called, because the first product is wine, which by distillation yields spirits. Boerhaave was the first who directed his attention to trace the causes, and to observe the phenomena of fermentation. The same subject was afterwards prosecuted by other chemists, and much was written on the nature and manufacture of wine; but till the discoveries of modern chemistry, and especially the important one of the composition of water, nothing was ascertained with precision concerning the nature of fermentation, or the changes which take place on the fermenting substances. To the experiments and researches of Lavoisier on the formation and decomposition of alcohol, chemistry is indebted for some of the most important facts with regard to the process of fermentation.

2275 Conditions. 2. Certain conditions are necessary to promote the vinous fermentation. The first indispensable condition is the presence of some saccharine matter. Experience has shewn that no vegetable substances are susceptible of this fermentation, which do not contain sugar. Thus, the sweet juices of fruits are usually employed in this process; and particularly, for the production of wine, the juice of the grape.

But sugar in a state of purity, or uncombined with other substances, is not susceptible of any change. A certain quantity of water, therefore, is necessary, that the saccharine matter may be in the liquid state. Water, therefore, is one of the essential conditions of the vinous fermentation; and it seems necessary that the water should neither be in too great quantity nor deficient. In the latter case the fermentation is interrupted; in the former it is promoted too rapidly, and is apt to be converted into the next stage, the acetous or acid fermentation. When the consistence is too great, water must be added, and when it is too fluid, the addition of sugar becomes necessary.

The vinous fermentation scarcely commences, if the temperature be below 60°, but at the temperature of 70° the process goes on briskly.

But sugar and water alone do not ferment, without the addition of some other substances. In the liquid expressed from grapes, which has received the name of *must*, there are, besides sugar, a portion of jelly, some glutinous matter, and tartar.

The contact of air has been considered as one of the requisites of the vinous fermentation; but this is not necessary, on account of the fermenting liquid deriving any addition from the atmosphere, for the process goes on equally well, when it is excluded, provided the gaseous bodies which are formed are permitted to escape.

A large mass is also favourable for promoting the vinous fermentation. A small quantity of saccharine matter scarcely at all undergoes this change, while it runs speedily to the acid fermentation.

3. When the substances which are susceptible of this fermentation, are placed in proper circumstances, the process commences in a few hours, or a few days, according to the temperature and the quantity of liquid employed. The liquid is then agitated with an intestine motion; it becomes thick and muddy; the temperature increases, and carbonic acid gas is disengaged. The liquid is increased in bulk, and the surface is covered with a voluminous, frothy matter, which is owing to the carbonic acid gas adhering for some time to the viscid matters in the liquid. The quantity of carbonic acid gas disengaged during this process is very considerable. It begins to be evolved at the commencement of the fermentation, and continues till its termination. At the end of a few days, or a longer or shorter time, according to the temperature and other circumstances, the fermentation ceases. The liquid becomes transparent, the matters which occasioned the muddiness having precipitated to the bottom, and from having a sweet taste, it becomes sharp and hot, and from having been viscid and glutinous, it becomes more liquid and lighter. It is now converted into wine. 2276 Phenomena of fermentation.

4. Such are the phenomena of fermentation, from which, and from the nature of the product, very considerable changes must have taken place on the component parts. One change has been observed during this process; namely, that the quantity of sugar is always diminishing, and, at the end of the process, is entirely decomposed. The liquid is now more fluid, is specifically lighter, and has obtained a vinous taste; which new properties are ascribed to the formation of alcohol which exists in all wine. It would appear, from the experiments of M. Lavoisier, that it is the sugar only which has suffered decomposition. It is divided into two portions, one of which separates, and is carried off in the form of carbonic acid gas, while the other, containing a greater proportion of hydrogen, remains in the liquid, in the form of alcohol. Part of the alcohol is carried off, and the alcohol which remains in the liquid is combined with the acids of the wine and the colouring matter, from which it must be separated by distillation. The tartaric acid, it has also been found, is partially decomposed during the process, and a portion of malic acid is formed. It appears from other experiments, that azotic gas is disengaged during this process, from which it is inferred, that some others of the constituents of the fermenting liquid have been decomposed, since sugar contains no azote. 2277 Decomposition of the sugar.

5. There is great variety in the colour, flavour, and strength of wines. These differences depend on the nature of the soil and of the grapes, and very often on the manner in which it is manufactured. But the component parts of wine are generally some acid matter, alcohol, extractive matter, oil, and colouring matter. It has been ascertained by experiment, that all wines redden the tincture of turnsole. The acid which exists in greatest abundance in wine, was found by Chaptal to be the malic acid; some portion of citric acid 2278 Component parts of wines.

acid also has been detected. Some wines, as champaigne, contain a considerable portion of carbonic acid.

It is to a certain portion of alcohol contained in wines that they owe their strength; and, when wines are subjected to the process of distillation, the alcohol passes over, and the spirit which is thus obtained is known by the name of *brandy*.

2279 Extractive matter.

The extractive matter found in wines has been observed to diminish in proportion to the age of the wines, as it separates gradually from the liquid, and is precipitated to the bottom.

2280 Volatile oil.

The flavour and odour of wines have been ascribed to a small quantity of volatile oil; but this quantity is so small, that no means hitherto employed have succeeded to obtain it in a separate state. Wines are distinguished by a peculiar colour, which is owing to the colouring matter originally derived from the husk of the grape.

2281 From other substances.

6. The juices of other fruits also afford materials for fermentation, as that of cyder from apples, and perry from pears. These are distinguished from wines properly so called, by containing a greater proportion of mucilaginous matter. The juice of the sugar cane also affords a fermenting liquid from which is obtained by distillation the spirit called *rum*.

2282 Beer.

7. Beer or malt liquors, as they are called in Britain, are fermented liquors obtained from farinaceous seeds. Different kinds of corn are employed for the purpose of making beer. In Britain, barley is the most common grain in the preparation of this liquid. It is first steeped in water, and afterwards thrown together in a heap for about 24 hours. During this period, in consequence of the moisture which has been absorbed by the grain, the process of germination commences, oxygen gas is absorbed, carbonic acid gas is given out, and heat is evolved, while the radicle is protruded. The process having advanced thus far, is checked by slowly drying the grain. For this purpose it is spread out on a floor, and in this state it is known by the name of malt. It is afterwards exposed to heat, fully dried, and ground to a coarse powder. An infusion is then made with water about the temperature of 160°, which is drawn off; more water is added till the whole soluble part of the malt is extracted. This infusion, which has a sweet taste, from having a portion of saccharine matter, is called *wort*. After being boiled with some bitter substances, as hops, it is allowed to ferment, and the process of fermentation is in a great measure similar to that which has been already described of the fermentation of wine. The temperature most proper for this fermentation is about 60°; the fermentation of wort is greatly promoted, and the quantity of the fermented liquor is more abundant with the addition of yeast.

2283 Fermentation goes on in close vessels.

It has been found, also, that the infusion of malt ferments in close vessels, and equally well as when exposed to the open air. During this fermentation carbonic acid gas is disengaged, which is mixed with a portion of the wort. By the distillation of the liquid obtained after the fermentation has ceased, alcohol is obtained; the nature and properties of which have been already described in treating of that liquid under inflammable substances.

II. Of the Acetous Fermentation.

1. In treating of acetic acid, which is the product of this fermentation, we have already detailed the method proposed by Boerhaave for the manufacture of vinegar, and we have also described the properties of that acid. All that is now necessary, therefore, is shortly to state the general phenomena which are exhibited during this fermentation. When wine or beer, which is the product of the vinous fermentation, is exposed to a temperature between 70° and 90°, it becomes gradually turbid; the temperature is increased; it is agitated with intestine motions, and flaky substances are seen floating through it in all directions. The intestine motions at last subside, the liquid becomes transparent by the matters which rendered it turbid precipitating to the bottom of the vessel. The liquid has now assumed different properties; it is converted into acetic acid or vinegar. 2284 Phenomena.

2285 Conditions.

2. The conditions necessary for the acetous fermentation are, a considerable elevation of temperature, and exposure to the air of the atmosphere. During this fermentation oxygen is absorbed from the air, and unless this absorption takes place, the fermentation does not go on. It is necessary that the substances to be subjected to this fermentation contain a certain proportion of extractive matter; for if they are entirely deprived of it, the process does not go on. Weak wines or beer are more readily converted into vinegar than strong wine; but when the process of fermentation has commenced on the latter, the product is a stronger and better vinegar.

2286 Changes.

3. In examining the products of this fermentation, it has been found, that the malic acid and the alcohol which previously existed in the wine, have entirely disappeared, so that by their decomposition, they have contributed to the formation of the vinegar. Some portion of the extractive matter also has been decomposed. The acetic acid is formed also during the decomposition of many vegetable substances, either by means of heat, or other chemical agents.

III. Of the Panary Fermentation, or of Bread.

2287 Nature of this fermentation.

1. The fermentation which takes place in making bread is supposed to be peculiar; but the phenomena and product have not been sufficiently examined to be able exactly to ascertain its nature. The process is extremely simple. Wheat flour, which is generally employed, is formed into a paste with water, the proportions of which vary according to the age and quality of the flour. After some time it is agitated with an internal motion, similar to the other fermentations, in consequence of the action of the component parts upon each other, the formation of new compounds, and the evolution of gaseous matter. Water is essentially requisite in this fermentation. One of the changes which have taken place during the process, is that the gluten which constitutes a part of the flour has disappeared. It is entirely decomposed. This matter has acquired a sour disagreeable taste, and if it is made into bread, it is found unfit to be eaten.

2288 Leaven.

A quantity of new paste is then prepared, and a small

Decomposition of Vegetables.

small quantity of the old sour paste is added to it. This produces rapid fermentation. The sour paste, thus added, to promote the fermentation, is called *leaven*, and the bread prepared by this process has received the name of *leavened bread;* a distinction which has been known to mankind from the earliest ages of the world. It is frequently mentioned in Scripture, in the Jewish history. It requires some attention to be able to determine the exact quantity of leaven necessary for the proper fermentation of the paste. When it is deficient in quantity, the process of fermentation is interrupted, and the bread thus prepared is solid and heavy, and if too much leaven be used, it communicates to the bread a disagreeable sour taste. When the fermentation succeeds, the paste swells up, and is greatly enlarged in bulk, which is owing to the formation of a quantity of gas, which is confined within the mass, by the viscidity of the glutinous part of the flour.

Other substances are employed to promote the fermentation of paste for the purpose of making bread; one of the most common is the matter which collects on the surface of fermenting liquids from farinaceous matters. This substance, which is called barm or yeast, is equally efficacious in producing fer-
2289 east. mentation, and is less apt to contaminate the bread with any disagreeable taste. As it is collected on the surface of fermenting beer, it was examined by Westrumb, and was found to contain a great variety of ingredients. Besides the water, which was in greatest proportion, it consisted of gluten, sugar, and
2290 omponent arts. mucilage, with a quantity of alcohol, and a small portion of malic, acetic, and carbonic acids. The essential parts of barm or yeast were found, by the same chemist, to be gluten mixed with a vegetable acid; and therefore yeast, which has been collected and put into bags strongly pressed and dried, by which means it is obvious many of the component parts must be separated, has been found equally fit for fermentation.

2291 aking of read. 2. When the paste has undergone the proper degree of fermentation, it is formed into loaves, and introduced into an oven, which has been previously heated. The same temperature is as nearly as possible employed for the baking of bread. This is regulated by throwing a little flour on the bottom of the oven. If it becomes black, without taking fire, the oven is supposed to have acquired a proper tem-
2292 hanges. perature. This is found to be about 448°.

3. If the fermentation has been properly conducted, the bread during the process of baking enlarges in bulk, becomes light and porous, and is full of eyes or cavities, in consequence of the extrication of the gas which was confined by the viscid, glutinous matter, and now driven off by means of heat. It is also considerably lighter, in consequence of the evaporation of moisture; and it still continues to lose weight by being kept, if it be exposed to the air. When it is first removed from the oven, bread is distinguished by a peculiar taste and odour. These are also carried off by the evaporation of the moisture, unless it be prevented by excluding the air. The component parts of bread, so far as they have been investigated, are quite different from those of the flour, so that these have undergone a chemical change.

4. Loaf bread is usually made of wheat flour, which is found most proper for this purpose, in consequence of the great proportion of gluten which it contains. Rye is also frequently employed in making bread, but being deficient in the proportion of gluten, it is less proper for the purpose. Bread made of rye has not the lightness and porousness of the wheaten loaf. Parmentier has described a process for making bread from potatoes. The potatoes are boiled and reduced to a fine paste; but before they can be converted into bread, it is necessary to add an equal weight of starch obtained from the same root. In this way a white, well-raised bread, it is said, is obtained. 2293 Bread of rye and potatoes.

To a fermentation somewhat similar is ascribed the production of the colouring matter of some vegetable substances, as for instance that of indigo; in this, however, greater changes are effected. In this process the indigo plants are put into water, which is soon agitated with an intestine motion. It is also accompanied with an increase of temperature, the production of a frothy matter on the surface, and the evolution of an elastic fluid, which is a mixture of carbonic acid and carbonated hydrogen gas. During this process, the colouring matter of the plant is separated and precipitated, from which Fourcroy proposes to denominate this the *colouring* fermentation. 2294 Colouring fermentation.

IV. Of the Putrid Fermentation of Vegetables.

1. The putrefactive process is the last stage in the decomposition of vegetable matters. In some the parts are completely separated, and resolved into their primary elements, by the escape of those substances by which they were mutually held together. In others new compounds are formed, by a new set of attractions and combinations. 2295 Nature.

2. Several conditions are necessary to promote putrefaction. The first requisite is water, without which the process does not go on. When vegetables are kept perfectly dry, they undergo no change. The contact of air is also necessary, and a moderate temperature. When the temperature is too high, the moisture is carried off by evaporation, before the changes in which this process consists can be effected; but when the moisture is not carried off, the higher the temperature, the more rapid is the putrefaction. 2296 Conditions.

3. When vegetables are placed in proper circumstances to favour this process, the colour and consistence are soon changed; the texture is destroyed, the fibres are separated; the soft and liquid parts swell up and are covered with froth; elastic fluids are disengaged, the temperature is increased, and sometimes so high as to produce actual inflammation. The gases which are disengaged, are, after the process has fairly commenced, accompanied with a fetid odour. They are composed of a mixture of carbonated hydrogen, carbonic acid, and azotic gases. After these phenomena have continued for some time, which is longer or shorter, according to the nature and consistence of the vegetable matters, great part, it appears, has been dissipated by evaporation. There remains a dark-coloured substance, containing the more fixed materials of the vegetable, as the earths combined with the acids and part of the carbon. 2297 Phenomena.

4. In observing the necessary conditions, the phenomena, and the products of the putrid fermentation of 2298 Changes.
vegetables,

Component Parts of Vegetables. vegetables, the influence of the numerous attractions of the different materials which enter into their composition is manifest. Part of the hydrogen combines with the oxygen, and is carried off in the state of water, part escapes in the state of gas combined with a portion of carbon, and another portion of hydrogen unites with the azote of those plants which contain it, and forms ammonia. A fourth part remains behind, and communicates odour and colour to the residuary mass. The carbon combines partly with the disengaged hydrogen, partly with the oxygen, forming carbonic acid, and part remains behind. The oxygen is divided between the hydrogen and carbon, forming compounds of which these elements are the base.

Sect. III. *Of the* Component *parts of* Vegetables.

1. Having in the two former sections given a short view of the functions and spontaneous decomposition of plants, we are now to consider the nature and
2299 Obtained by different processes. properties of those substances which enter into their composition. Some of these substances are obtained from plants, while they continue to exhibit the phenomena of vegetation; such are saccharine matters obtained from the sap, which is extracted by wounding the bark and wood, without much seeming injury to the health and growth of the plant; and such too are gummy and resinous matters, which many plants throw off by spontaneous exudation; and which, so far from being injurious, is perhaps necessary in some degree to vegetation; but, in general, the substances formed during the process of vegetation, or which are constituent parts of vegetable matters, can only be obtained by the destruction of the vegetable itself. These are procured by different processes, which we shall shortly describe, in treating of the nature and properties of each individual substance.

2300 Enumeration of substances. 2. The component parts of vegetables, so far as they have been examined, and sufficiently characterized by distinct properties, may be enumerated under the following heads:

1. Gum,
2. Sugar,
3. Jelly,
4. Acids,
5. Starch,
6. Albumen,
7. Gluten,
8. Extractive matter,
9. Colouring ditto,
10. Bitter ditto,
11. Narcotic ditto,
12. Oils,
13. Wax,
14. Camphor,
15. Caoutchouc,
16. Resins,
17. Gum-resins,
18. Wood,
19. Tan,
20. Suber,
21. Alkalies,
22. Earths,
23. Metals.

I

I. Of Gum.

Component Parts of Vegetables.

1. Gum exudes from many trees during the process of vegetation, in the form of a viscid, transparent, insipid fluid. The finer kind of gum is obtained chiefly from the *mimosa nilotica*, a plant which is very common in many parts of Africa. This gum is usually distinguished by the name of *gum arabic*. After it separates from the tree, the watery part evaporates, and the gum remains behind. It has then some degree of hardness, and is so brittle that it may be reduced to fine powder. It retains its transparency, is generally of a yellow colour; but, when pure, it is entirely colourless. It has neither taste nor smell. The specific gravity is from 1.316 to 1.481. 2301 Extraction and properties.

2. Gum is not changed by exposure to the air, but it is deprived of its colour by the action of the sun's light. When it is exposed to heat, it becomes soft, swells up, gives out air-bubbles, blackens, and is reduced to charcoal. During the change it gives out very little flame, and is greatly enlarged in volume. It readily dissolves in water. The solution is thick and adhesive, and well known as a paste, under the name of *mucilage*. This solution is little disposed to decomposition. By evaporation the whole of the gum may be obtained unchanged. 2302 Action of air and heat.

3. Gum is soluble in the vegetable acids without decomposition. Sulphuric acid decomposes it, and converts it into water, acetic acid, and charcoal. With the assistance of heat, muriatic acid produces a similar effect. Oxymuriatic acid converts it into citric acid. 2303 Of acids.

Gum is soluble in nitric acid with the assistance of heat. Nitrous gas is emitted during the solution, and, when it cools, saclactic acid is deposited. Malic acid appears at the same time; and, by continuing the heat, the gum is at last converted into oxalic acid. Four hundred and eighty grains of gum, digested with six ounces of nitric acid, afforded Mr Cruickshank 210 grains of oxalic acid, and six grains of oxalate of lime.

4. By puring alcohol into a mucilaginous solution, the gum is precipitated, so that it is insoluble in this liquid. It is also insoluble in ether. 2304 Alcohol.

5. Mr Cruickshank distilled 480 grains of gum arabic by exposing it to a red heat in a glass retort, and obtained the following products: 2305 Distillation.

Acetic acid mixed with some oil	210 grs.
Carbonated hydrogen and carbonic acid gases	164
Charcoal - - -	96
Lime and a little phosphate of lime -	20
	480

Thus the constituent parts of gum are, oxygen, hydrogen, carbon, azote, and lime. 2306 Constituents.

6. Besides gum arabic, the properties of which we have now described, there are different species of gum obtained from different plants, which, however, in their general properties resemble gum arabic. In some indeed they seem to be different, but these differences have not been distinctly ascertained. Gum tragacanth, the produce of the *astragalus tragacantha*, which is in the form of vermicular masses, is less transparent than gum arabic, less soluble in water, and more adhesive; but yields 2307 Obtained from other plants.

Component Parts of Vegetables.

yields by distillation similar products. Gum obtained from the cherry and plum tree, is of a brownish colour, softer and more soluble in water, but seems otherwise to possess nearly the same properties as gum arabic.

2308 Mucilage exists in many plants.

7. Gum in the state of mucilage exists in a great number of plants, and especially in the roots and leaves. It seems to be most abundant in bulbous roots, as those of the hyacinth, which contain such a quantity that they may be advantageously employed in place of gum arabic. It is obtained also in considerable quantity from many of the lichens, and most of the fuci. Mucilage is found in greatest proportion in young plants, but this proportion diminishes with the age of the plant. It is a principal constituent in the leaves and roots of esculent vegetables.

2309 Uses.

8. In the state of mucilage, gum constitutes a nutritious aliment. On account of its adhesive properties it is employed as a paste, and by the calico-printers to mix with their colours to give them consistency. It is well known as a component part of ink, to prevent the precipitation of its more insoluble ingredients, and it forms a very valuable article in the Materia Medica.

II. Of Sugar.

2310 In all parts of plants.

1. Sugar exists in every part of plants. It is found in the roots, as those of the carrot and beet root; in the stems, as in the birch, the maple, some palms, and especially the sugar-cane; in the leaves, as those of the ash; in the flowers, the fruits, and seeds.

2311 Sugar-cane.

2. But the sugar which now forms a very extensive article of commerce, and may be considered as a necessary of life, is entirely obtained from the juice of the sugar-cane, which is chiefly cultivated in the East and West Indies, for the purpose of extracting the sugar. When the plants have arrived at their full growth, which in the West Indies is in the course

2312 Manufacture.

of 12 or 14 months, they are cut down and bruised by means of machinery; the juice which is collected is conveyed to iron boilers, where it is boiled, with the addition of a small quantity of quicklime, and the impurities which rise to the surface are scummed off. The boiling is continued till it acquires the consistence of syrup, after which it is put into shallow vessels, where it is allowed to cool and granulate. In general, it is afterwards put into hogsheads, in which it is imported to Europe, the bottoms of which are perforated, that the molasses with which the sugar is mixed may be allowed to drain off. Sometimes it is put into conical earthen vessels, open at both ends, the base of which is covered with moist clay, so that the water filtres through the sugar, and carries with it a greater quantity of the molasses and other impurities. The sugar thus treated, is called clayed sugar. It is not different from the former, but in being somewhat purer. The addition of quicklime in the boiling is supposed to take up some vegetable acids which prevent the granulation of the sugar.

2313 Raw.

3. In this state the sugar is known in commerce by the name of *raw Muscovado sugar*. It is still farther purified by dissolving it in water, and boiling, when the impurities which rise to the surface are again removed; a quantity of lime is also added, and it is clarified with blood. When boiled down to a proper consistency, it is put into unglazed earthen vessels of a conical shape, and inverted to allow the water from the moist clay with which the base of the cone is covered, to pass through the sugar, and carry off its impurities. It is still farther purified by again dissolving it in water, and subjecting it to a similar process. According to the number of processes to which it has been subjected, it is called single or double refined sugar.

4. Sugar in this state is of a white colour; it is well known for its sweet taste; it has no smell. It has some degree of transparency when it is crystallized. It is considerably hard; but it is brittle, and may be easily reduced to powder. It is phosphorescent in the dark. When the solution of sugar in water is concentrated, it crystallizes in the form of six-sided prisms, terminated by two-sided summits. The specific gravity of sugar is 1.4045. 2314 Properties.

5. When sugar is exposed to heat, it melts, swells up, becomes of a dark brown or black colour, emits air bubbles with a peculiar smell, which has been called *caromel*. If a red heat be applied, it suddenly bursts into flames, with a kind of explosion. 2315 Action of heat.

6. Neither oxygen nor azote have any action on sugar. It is not altered by exposure to the air. If the air be moist, it absorbs a little water. There is no action between hydrogen and sugar. It is very soluble in water; at so low a temperature as 48° water dissolves its own weight of sugar. This power increases with the temperature of the water. When water is saturated with sugar, it is called syrup, which by concentration and rest affords crystals. 2316 Water.

7. Sugar is soluble in many of the acids. It is decomposed by sulphuric acid; when heat is applied, the acid itself is decomposed, and converted into sulphurous acid; and a great quantity of charcoal is deposited. 2317 Acids.

Nitric acid acts on sugar with considerable violence; an effervescence is produced, nitrous gas is emitted; and the sugar is converted into oxalic and malic acids.

Muriatic acid gas is slowly absorbed by sugar, which becomes of a brown colour, and acquires a very strong smell. Sugar is instantly dissolved when it is thrown in the state of powder into liquid oxymuriatic acid; it is converted into malic acid, while the oxymuriatic acid is deprived of its oxygen, and reduced to the state of muriatic acid. Alcohol readily dissolves sugar. One part of sugar is soluble in four of boiling alcohol. Sugar also combines with the oils, and by this means they may be mixed with water.

8. The fixed alkalies combine with sugar, and deprive it of its sweet taste; but by adding sulphuric acid, and precipitating the sulphate which is formed by means of alcohol, the taste is restored. Some of the earths as lime, combine with sugar, and form similar compounds. 2318 Alkalies.

9. The sulphurets, hydro-sulphurets, and phosphurets of the alkalies and some of the earths, decompose sugar, and reduce it to a state somewhat similar to gum. Mr Cruickshank dissolved a quantity of sugar in alcohol, and added to it phosphuret of lime. After exposing the mixture to the open air for some days, it was evaporated, and water was added. There was no evolution of gas, and the phosphuret was found converted into a phosphate. By filtering the liquid, and by evaporation, 2319 Sulphurets, &c.

poration, a tenacious substance, resembling gum, remained behind.

10. By distilling sugar in a retort, the first part of the product is water, nearly in a state of purity. Acetic acid with a little oil next comes over, and afterward empyreumatic oil. A bulky carbonaceous matter, which sometimes contains a little lime, remains behind. Mr Cruickshank obtained by the distillation of 480 grains of pure sugar, by means of a red-heat,

Acetic acid and oil	270 grs.
Charcoal	120
Carbonated hydrogen and carbonic acid gases	90
	480

2320 Constituent parts.

Sugar, therefore, is composed of oxygen, carbon, and hydrogen. The proportions of its constituent parts, according to Lavoisier, are the following:

Oxygen	64
Carbon	28
Hydrogen	8
	100

2321 Maple sugar.

11. Sugar is also obtained from the juice of the maple tree in North America. The juice is extracted from the tree during the ascent of the sap in the spring season. A single tree, it is said, yields from 20 to 30 gallons of sap, from which are obtained five or six libs. of sugar. It is manufactured in the same way as the juice of the sugar cane.

2322 Beet root.

It has lately been proposed to extract sugar from the root of the beet; and the attempt has been made, even in the large way, by Achard of Berlin. The process which he followed is to boil the roots, cut them into slices, and extract the juice by pressure. The roots are again put into water for 12 hours, and again subjected to the press. The liquids thus obtained are filtered through flannel, boiled down to 3, and filtered a second time. The remaining liquid is reduced by boiling to 1 of the original quantity, and again filtered. It is then evaporated to the consistence of syrup. The crust which forms on the surface must be broken from time to time, and the spontaneous evaporation allowed to continue till the surface is covered with a viscid pellicle, instead of the crystals which first form on it. The whole mass is then introduced into woollen bags, and the mucilage is separated by pressure. This sugar, which in many respects possesses the properties of common sugar, is contaminated with some matter, which communicates a bitter nauseous taste. Many other plants also contain sugar, either in the roots, the sap, or the seeds. It exists in wheat, barley, beans, pease, and other leguminous seeds, especially when they are young, in considerable quantity.

2323 Uses.

12. The uses of sugar are so familiar, that it is scarcely necessary to enumerate them. In most countries where it can be obtained, it may be considered in some measure as a necessary of life. It contains a great proportion of nutritious matter. It is not changed by the action of the air, so that it may be preserved for any length of time. It is employed to preserve other vegetable matters from putrefaction, and sometimes it is also advantageously applied to a similar purpose in the preservation of animal substances.

III. Of Jelly.

1. Jelly is a soft tremulous substance which is obtained from the juice of different fruits, especially from currants and bramble berries. The juice is extracted by expression, and when it is allowed to remain at rest, it coagulates. It is still mixed with a portion of aqueous liquid; but this being poured off, and the coagulated part washed with water, the jelly remains nearly pure. 2324 Preparation.

2. It is sometimes perfectly colourless, but frequently tinged with the colouring matter of the fruit. It is of a soft, tremulous consistence, and has an agreeable slightly acid taste. It dissolves readily in hot water, and again coagulates on cooling. In cold water it is nearly insoluble. It is deprived of the property of coagulating by boiling, and then it is similar to mucilaginous matter. 2325 Properties.

3. By coagulating the juices of the fruits which yield jelly, separating the liquid parts by filtration, afterwards washing the coagulum with cold water, and by allowing the mass to dry, it is found diminished in bulk, and is transparent and brittle, having many of the properties of gum; so that it has been supposed that jelly is this latter substance in combination with some vegetable acid. 2326 Resembles gum.

4. Jelly is converted into oxalic acid by means of nitric acid. It combines readily with the alkalies; and when it is distilled, it yields a considerable portion of acetic acid mixed with oil, but no perceptible quantity of ammonia. Jelly is found in all the acid fruits, as in gooseberries, oranges, and lemons. 2327 Action of nitric acid.

IV. Of Acids.

1. The acids which exist in many vegetables are at once recognized by their taste. These acids were formerly denominated *essential salts of vegetables*, and it was supposed, that all essential salts were the same, and were composed of tartar, or vinegar. But Scheele's discovery of the citric, malic, and gallic acids, which possessing distinct properties from those of tartaric and acetic acids, proved the contrary. Some vegetables contain only one acid, as oranges and lemons, which contain citric acid only. In other vegetables two acids are found, as in gooseberries and currants, the malic and citric acids; and sometimes three, as the tartaric, citric, and malic acids, which exist together in the pulp of the tamarind. As the acids which exist in vegetables have been already described, with the method of preparing them, it is now only necessary to enumerate the vegetable acids, specifying at the same time some of the plants from which they are obtained. 2328 Easily known.

2. Acetic acid has been discovered in the sap of some trees, and in the acid juice of *cicer arietinum*. In the latter it is mixed with oxalic and malic acids. Acetic acid was detected by Scheele in the *sambucus nigra* or elder. 2329 Acetic.

3. Oxalic acid exists in combination with potash, in the leaves of the *oxalis acetosella* or wood-sorrel. In other 2330 Oxalic.

Component Parts of Vegetables. other species belonging to the same genus, and in some species of rumex, it is in the state of acidulous oxalate of potash. Oxalate of lime has been found in the root of rhubarb.

2331 Tartaric. 4. The following vegetable substances contain tartaric acid; in which, however, it is combined with potash, in the state of acidulous tartrate of potash. In this state it is found in the pulp of the tamarind, the juice of grapes, of mulberries, of *rumex acetosa* or sorrel, of *rheum raponticum* or rhubarb, and of *agave americana*. It is found also in the roots of *triticum repens* or couch-grass, and in *leontodon taraxacum*, or dandelion.

2332 Citric. 5. Citric acid is found in the juice of oranges and lemons, in the berries of two species of *vaccinium*, the *oxycoccos* or cranberry, and the *vitis idæa* or red whortleberry, the *prunus padus* or bird-cherry, *solanum dulcamara*, bitter-sweet or nightshade, *rosa canina*, or wild rose.

2333 Malic. 6. Malic acid exists unmixed with other acids, in the apple, the barberry, plum, sloe, elder, rowan, or fruit of the mountain ash.

In the gooseberry, in the cherry, strawberry, currants, and some other fruits, malic and citric acids are found nearly in equal proportions.

Malic acid has been found mixed with tartaric acid in the *agave americana*, and in the pulp of tamarinds, along with citric acid. Vauquelin found it combined with lime, forming a malate of lime, in the *sempervivum tectorum* or house-leek; in three species of *sedum* or stone-crop, namely the *album*, *acre*, and *telephium*; in different species of *crassula* and *mesembryanthemum*, and in *arum maculatum*.

2334 Gallic. 7. Gallic acid is found in a great number of plants, and in them it exists chiefly in the bark. The following are the relative proportions of the quantity of gallic acid in different plants, as they have been ascertained by Mr Biggin.

Elm	7	Sallow	8
Oak cut in winter	8	Mountain ash	8
Horse-chesnut	6	Poplar	8
Beech	7	Hazel	9
Willow boughs	8	Ash	10
Elder	4	Spanish chesnut	10
Plum-tree	8	Smooth oak	10
Willow trunk	9	Oak cut in spring	10
Sycamore	6	Huntingdon or Leicester willow	10
Birch	8		
Cherry-tree	4	Sumac	14*

* Nichol. Jour. iii. 394. 4to.

2335 Benzoic. 8. Benzoic acid is found in benzoin, balsam of Tolu and Peru, liquid styrax, cinnamon, and vanilla. Fourcroy and Vauquelin suspect that it exists in the *anthoxanthum odoratum*, or sweet-scented grass, which communicates the aromatic flavour to hay.

2336 Prussic and phosphoric. 9. Prussic acid has been found in the leaves of the laurocerasus and peach, in bitter almonds, in the kernels of apricots; and it is supposed that it exists also in the kernels of peaches, of plums, and cherries. It is obtained from the kernels of apricots by distilling water off them with a moderate heat; and if lime be added to the concentrated infusion of bitter almonds, a prussiate of lime is formed.

10. Phosphoric acid has been found in different parts of plants; but it is generally combined with lime, forming a phosphate of lime. This salt exists in the leaves of many trees, in the *aconitum napellus* or monks-hood, and in all kinds of grain.

Some acids belonging to the vegetable kingdom, in addition to those enumerated in our chapter on acids, are now taken into the list. Such are the *kinic* acid, obtained from cinchona; the *meconic* acid, obtained from opium, in which it exists combined with a newly discovered alkali, *morphine* or *morphium*; *moric* acid, which exists in combination with lime in the bark of the *morus alba*; the *sorbic* acid, obtained from the *pyrus* (formerly called *sorbus*) *aucuparia*. 2337 New acids.

V. Of Starch.

1. If a paste be formed of wheat flour and water, and this be washed with additional quantities of water, till it is no longer turbid, but comes off pure and colourless, the mass which remains becomes tenacious and ductile. This is called *gluten*, which will be afterwards described. If the water with which the paste was washed be allowed to remain at rest, it deposits a white powder, which is distinguished by the name of *fecula* or *starch*. 2338 Preparation.

2. Starch is of a fine white colour, and is usually in the state of concrete columnar masses. It has no perceptible smell, and scarcely any taste. It is little altered by exposure to the air; when it is exposed to heat on a hot iron, it melts, swells up, becomes black, and burns with a bright flame. The charcoal which remains, contains a little potash. When it is distilled, it gives out water mixed with acetic acid, which is contaminated with oil. It gives out also carbonic acid and carbonated hydrogen gas. 2339 Properties. 2340 Action of heat.

3. Starch is not soluble in cold, but forms a thick paste with boiling water, and when this paste is allowed to cool, it becomes semitransparent and gelatinous; it is brittle when dry, somewhat resembling gum. If this paste be exposed to moist air, it is decomposed, for it acquires an acrid taste.

4. Sulphuric acid dissolves starch slowly; sulphurous acid is disengaged, and a great quantity of charcoal is formed. 2341 Of acids.

Muriatic acid also dissolves starch, and the solution resembles mucilage of gum arabic. When left at rest, a thick, oily, mucilaginous liquid appears above, and a transparent straw-coloured fluid below. The odour of muriatic acid remains; but when water is added, it is destroyed, and a strong peculiar smell is emitted.

Starch is also soluble in nitric acid, with the evolution of nitrous gas. The solution assumes a green colour, and when heat is applied, the starch is converted into oxalic and malic acids. Some part of the starch, however, is insoluble in nitric acid, and when this is separated by filtration, and washed with water, it has a thick oily appearance like tallow, is soluble in alcohol, and when distilled, yields acetic acid, and an oily matter similar to tallow in colour and consistence.

5. Starch is insoluble in alcohol, but is soluble in the alkalies; in pure potash it swells up, becomes transparent and gelatinous, and is then susceptible of solution in alcohol. The component parts of starch, as appears by distilling it, and by the action of re-agents, are oxygen, hydrogen, and carbon. 2342 Composition.

6. Starch exists in a great number of vegetable substances,

stances, but chiefly in the roots and seeds, and particularly those which are employed as food.

2343 Found in roots and seeds. Starch, it is well known, may be obtained from the potato. If the potato be grated down and washed with water till it comes off pure and colourless, this water being left at rest, deposits a fine white powder, which assumes something of a crystallized appearance, and is heavier than wheat starch.

2344 Potato.

2345 Sago. Sago, which is well known on account of its nutritious qualities, is obtained from the pith of different species of palms which grow within the tropics. The stem is cut into pieces, which are split into two; the pith is washed out with cold water, which being left at rest deposits the starch. The water is poured off, and before the remaining mass is fully dried, it is forced through a perforated vessed, and granulated, in which state it is brought to Europe.

2346 Saloup. Saloup, which is chiefly composed of starch, is prepared from the roots of different species of orchis. It is mostly imported from Persia.

2347 Cassava. Cassava, or cassada, is a kind of bread chiefly composed of starch, which is much used as an article of food in the West Indies. It is prepared from the roots of the *jatropha manihot*. The roots are well washed, grated down, and put into bags, which are subjected to strong pressure. By this process the whole of the juice is separated. This juice, or something at least which it holds in solution, when taken internally, is a deadly poison to most animals. The matter remaining in a bag is dried and sifted, and without any other addition, when it is spread thin on a hot stone, it forms a cake, which is the cassada bread, found to be of a very nutritious quality, in consequence of the great proportion of starch which it contains.

2348 Lichen. Some species of the tribe of lichen contain a considerable proportion of starch, as the lichen rangiferinus, or rein-deer lichen, which affords food to the rein-deer, and the lichen islandicus, which is formed into bread by the Icelanders, and is found to be extremely nutritious. The latter has lately been recommended as a remedy in consumption; but it probably possesses no other virtue in the cure of that fatal disease, than affording a great proportion of nutritious matter in small bulk.

VI. Of Albumen.

1. The existence of albumen in vegetable substances had begun to be doubted by chemists, till it was lately discovered, by Vauquelin, in the juice of the *carica papaya*, or *papaw-tree*, which grows in different countries within the torrid zone. The juice which exudes from this tree was brought home in the liquid state, mixed with an equal quantity of rum, and another portion of the juice was in the state of extract. The first was of a reddish brown colour, was semitransparent, and had the odour and taste of boiled beef. The second was of a yellowish white colour, semitransparent, and of a sweetish taste; had no perceptible smell, but was of a firm consistence, and in the form of small irregular masses. When the dried portion was macerated in cold water, it was almost entirely dissolved. When nitric acid was added, a copious white precipitate was formed. This was the albumen in the state of white flakes. When the extract of this juice was subjected to distillation, it yielded carbonate of ammonia, a thick, fetid, reddish coloured oil, carbonic acid, and carbonated hydrogen gases, and there remained behind a light carbonaceous matter; which, being burnt, left a quantity of white ashes, consisting almost entirely of phosphate of lime.

2. From other experiments to which this matter was subjected by the same chemist, from its solution in water, its coagulation by means of heat, its action with the acids, the alkalies, metallic solutions, the infusion of nut-galls, and alcohol, he concludes, that it is precisely of the same nature with animal albumen *. 2349 Resembles animal albumen.

* Ann. de Chim. xliii. p. 270. and xlix. p. 304.

VII. Of Gluten.

1. When a paste is formed with flour and water, and washed with more water till it passes off pure and colourless, a tenacious, ductile, soft, elastic mass, remains behind, which is gluten. 2350 Preparation.

2. This substance is a gray colour, extremely ductile and tenacious, and possesses considerable elasticity. It has a peculiar smell, but no perceptible taste. When it is suddenly dried, it increases much in volume, and, when it is exposed to heat, it cracks, swells, blackens, and burns like horn, exhaling a fetid odour. When it is distilled, it yields water impregnated with ammonia, and an empyreumatic oil: charcoal remains behind. When moist gluten is exposed to the air, it gradually dries, becomes hard, brittle, slightly transparent, and of a brownish colour, having some resemblance to glue. When it is broken, it resembles the fracture of glass. It is insoluble in water, but retains a portion of it, which it absorbs, and to which the elasticity and tenacity are owing. It is deprived of these properties by boiling. 2351 Properties.

3. When it is kept moist, it ferments with the evolution of hydrogen and carbonic acid gases. An offensive putrid odour is given out at the same time. The gluten afterwards, if the process be allowed to go on, exhales the smell, and acquires the taste of cheese. In this state it is found to contain ammonia and acetic acid. 2352 Ferments.

4. Gluten is soluble in all the acids. It is precipitated from this solution by all the alkalies, and is then nearly in the state of extractive matter, being deprived of its elasticity. It is decomposed by concentrated sulphuric acid; hydrogen gas is emitted, and water, charcoal, and ammonia are formed. It is also decomposed by nitric acid; azotic gas is emitted, and if the heat be continued, a portion of oxalic acid is formed. Yellow coloured oily flakes are precipitated. After gluten is fermented, it is soluble in acetic acid, and this solution may be employed as a varnish. 2353 Action of acids.

5. Gluten is insoluble in alcohol and in ether; but if fermented gluten be triturated with a little alcohol, and afterwards mixed with a quantity of the same liquid, part of it is dissolved and forms a varnish, which may be employed either for paper or wood, for cementing china, or for mixing with vegetable colours that are used as paints. Pieces of linen dipped in this varnish, adhere strongly to other bodies, and if lime be added to the solution, it constitutes a good lute. 2354 Of alcohol on fermented gluten.

6. With the assistance of heat gluten is soluble in the alkalies; and when they are much concentrated it is decomposed, and formed into a kind of soap, consisting of oil and ammonia. 2355 Of alkalis.

7. It appears from the distillation of gluten, and from

Component Parts of Vegetables. from its spontaneous decomposition, that it consists of oxygen, hydrogen, carbon, and azote. The vapour which is evolved during the fermentation of gluten blackens silver, from which it is inferred that sulphur
2356 Composition. is one of its constituent parts. From the properties and composition of gluten, the resemblance between this substance and animal matter is sufficiently obvious.

2357 In wheat. 8. Gluten exists in greatest abundance in wheat flour, but it is found in a great number of plants, and
2358 Leaves. in different parts of vegetables. It exists in considerable proportion in the juice of the leaves of many plants, as those of the cabbage, cresses, &c. When this juice is procured by expression, filtered through a cloth, and allowed to remain at rest, it deposits in the course of some days a greenish powder, which has been called the green fecula of plants. This fecula is chiefly composed of gluten mixed with a resinous matter, which gives it its colour, and a portion of woody fibre. If this juice be exposed to the temperature of about 130°, the fecula coagulates in the form of large flakes. It dries when separated from the water, and assumes the appearance of horn. When it is treated like gluten, it also acquires the smell and taste of cheese.

2359 In seeds and fruits. Gluten has been found in acorns, chesnuts, and horse-chesnuts, in barley, rye, pease, and beans; in apples and quinces; in the leaves of *sedum* of different species, hemlock, borrage, saffron; in the petals of the rose, in the berries of the elder, and in the grape. None was detected in the potato by Proust, although he found it in several other roots.

A substance which resembles the fibrina of the blood, was found by Vauquelin in the juice of the papaw-tree. When this juice is mixed with water, part is dissolved, and part remains insoluble. The latter has a greasy appearance, becomes soft in the air, viscid, brown, and semitransparent. It melted when thrown on burning coals, while drops of grease exuded. It was entirely consumed, without leaving any residuum. But according to some, this substance is exactly similar to gluten, and therefore, is not to be considered as one of the constituents of vegetable matter.

2360 Uses. 9. Gluten is one of the most important of the component parts of vegetable substances. It is one of the chief ingredients in wheat, and to this it is owing that wheat flour is fit for being formed into bread.

VIII. Of Extractive Matter.

2361 Preparation. 1. The word *extract* was formerly employed to signify the inspissated juices of vegetables, but of late it has been limited to a peculiar principle possessed of distinct properties. If saffron be infused in water for some time, and if the infusion be filtered and evaporated to dryness, the residuum is that substance to which the name of extractive principle is given.

2362 Properties. 2. The following properties of extract were ascertained by Vauquelin. 1. All extracts have an acid taste. 2. If a few drops of ammonia be added to a solution of extract, a brown precipitate is formed, which consists of lime, and part of the extract becomes insoluble. 3. Sulphuric acid disengages a penetrating acid vapour, which is found to be acetic acid. 4. When quicklime is added to a solution of extractive matter, ammonia is disengaged. A solution of sulphate of alumina without excess of acid, being poured into a solution of extractive matter, and boiled, there is formed in the liquid a flaky precipitate which is composed of alumina and vegetable matter, and rendered insoluble in water. 6. Almost all metallic solutions produce a similar effect. With muriate of tin an insoluble brown precipitate is formed, which is composed of the oxide of tin and vegetable matter. 7. Oxymuriatic acid poured into a solution of extractive matter, forms a copious, dark yellow precipitate. Muriatic acid remains in the solution. 8. If wool, cotton, or thread, be impregnated with alum, and boiled with a solution of extractive matter, these substances become charged with a great quantity of the extractive substance, they assume a fawn-brown tint, and the solution loses a great deal of its colour. The same effect is produced by immersing the substances to be dyed in a solution of muriate of tin. The effect is still better, if oxymuriatic acid be employed instead of alum, or the solution of muriate of tin. 9. When extractive matter is distilled in an open fire, it yields an acid liquid, which contains a greater portion of ammonia than when it is distilled in the humid way with lime or alkali. 10. When extractive matter is dissolved in water, and is left exposed to the open air, it is completely decomposed. The carbonates of potash, of ammonia, and of lime, and some other mineral salts which previously existed in the extractive matter, and are indestructible by putrid fermentation, remain behind.

3. It appears that extractive matter is found in greater proportion in old plants. It is found in different parts of the plant. It frequently forms one of the constituents of the sap. It is this extractive matter which precipitates during the evaporation of the sap, or when oxymuriatic acid is added to it. 2363 Exists in old plants.

Extractive matter has been found in the bark of many trees, and it is supposed that it exists in all barks which possess an astringent property. It has been found in the bark of the common willow, the Leicester willow, the oak, and the elm. 2364 In the bark.

Extractive matter has been obtained from the infusion of catechu, in which it is united with tan. If the powder of catechu be repeatedly washed with water, the liquid which passes off no longer precipitates gelatine. The residuum is extractive matter, of a reddish-brown colour, has no smell, but a slightly astringent taste. The solution in water is at first yellowish-brown, but acquires a red colour by exposure to the air. Many of the metallic salts form a precipitate with the solution of this matter. Linen boiled in it almost extracts the whole, and becomes of a light red brown colour. Extractive matter softens when exposed to heat; the colour becomes darker, but it does not melt. When it is distilled, it yields carbonic and carbonated hydrogen gases, acetic acid, and a small portion of extractive matter unchanged. A light porous charcoal remains behind. 2365 Catechu.

The infusion of the leaves of senna is of a brown colour, has a peculiar aromatic odour, and a bitter taste. When the air of the atmosphere or oxygen gas is made to pass through this infusion, a yellow coloured precipitate is formed. It is produced also by adding to the solution muriatic or oxymuriatic acid. In this state the extractive matter has combined with oxygen, and has assumed a yellow colour, and being no longer soluble 2366 Senna.

Component Parts of Vegetables.

soluble in water, it is precipitated. The taste is slightly bitter. It is soluble in alcohol, but when water is added, it is thrown down. It is soluble also in alkalies, and forms with them a deep brown solution. When placed on burning coals, it gives out a dense smoke, exhales an aromatic odour, and leaves behind a spongy mass of charcoal.

2367 Peruvian bark.

Extractive matter is obtained from the infusion of Peruvian bark, which being united with oxygen, becomes of a fine red colour. It is obtained by boiling water on it, and by slow evaporation, and then dissolving what remains in alcohol. By evaporating the alcohol, the peculiar extractive matter is deposited. The matter thus obtained was of a brown colour, of a bitter taste, soluble in hot water and alcohol, but insoluble in cold water. It is of a black colour when dry and brittle. It breaks with a polished fracture. With the addition of lime-water it was precipitated in the form of a fine red powder, which combined with alkalies, but is insoluble in water and alcohol.

IX. Of Colouring Matter.

2368 Exists in many plants.

1. Colouring matter is extracted from a number of plants for the purposes of dyeing, as from madder, carthamus, Brazil wood, logwood, yellow weed or reseda luteola, fustic or yellow wood, anatto, and indigo.

2369 Madder.

2. The colouring matter of madder or *rubia tinctorum*, is soluble in alcohol. By evaporation it leaves a residuum of a dark red colour. A violet precipitate is formed in this solution by a fixed alkali. Sulphuric acid produces a fawn-coloured precipitate, and sulphate of potash, a beautiful red. Precipitates of different shades of colour are obtained with alum, nitre, chalk, acetate of lead, and muriate of tin.

2370 Carthamus.

3. Carthamus (tinctorius) contains two colouring matters, the one yellow and the other red. The first only is soluble in water, but the solution is turbid. It becomes transparent with the addition of acids; with alkalies it inclines to an orange colour; a fawn-coloured precipitate is formed, and then the solution becomes clear. Alum produces a dark yellow precipitate, but not very copious. A slight tincture is extracted from the flowers of this plant by means of alcohol, after the whole of the yellow matter has been dissolved by water.

2371 Brazil wood.

4. Brazil wood, or *fernambouc*, is much employed in dyeing. A recent decoction of this wood gives a red precipitate inclining to fawn colour with sulphuric acid. The liquid in which the solution was made remains transparent and of a yellow colour. With the first addition of nitric acid the tincture first passes to a yellow colour; but with a greater quantity, becomes of a dark orange yellow and transparent, after having deposited a matter similar in colour to the former, but more copious. The same changes take place with the muriatic acid as with the sulphuric.

2372 Logwood.

5. Logwood or *Campeachy wood* yields its colouring matter to water and to alcohol, but more copiously to the latter. The tincture of logwood, or the solution in alcohol, is of a beautiful red colour, inclining to violet or purple. These different shades are more obvious in the decoction in water. When the aqueous solution is left to itself, it first becomes yellow, and then changes to black. The addition of acids produces a yellow colour; alkalies deepen the colour and restore the purple or violet. Sulphuric, nitric, and muriatic acids throw down a light precipitate which separates slowly. Sulphate of iron communicates a bluish colour somewhat resembling ink. A copious precipitate of a similar colour is formed at the same time.

2373 Yellow weed.

6. Yellow weed, or dyers weed (*reseda luteola*, Lin.) in solution in water yields a yellow colour inclining to brown. When it is diluted with a greater quantity of water, the yellow colour which was more or less bright changes a little to green. The colour becomes paler with the addition of acids. It becomes deeper by the action of alkalies.

2374 Fustic.

7. Fustic, or yellow wood, (*morus tinctoria*, Lin.) contains a great proportion of colouring matter. A strong decoction in water is of a dark reddish yellow colour. When water is added to this solution the colour becomes orange-yellow. The liquid grows turbid with the addition of acids. Alkalies render it much deeper and nearly red.

2375 Anatto.

8. Anatto is in the form of a dry hard paste, externally brown, and internally of a beautiful red colour. It is prepared from the seeds of the *bixa orellana*, by reducing them to powder, mixing them with water, and allowing them to ferment. Anatto is more soluble in alcohol than in water. With the addition of an alkali the solution is promoted, and the colour inclines less to red.

Beside these, a great variety of other vegetable substances give out their colouring matter to water or alcohol, and are employed in dyeing. To what has now been said, however, we shall only add a short account of one of the most important, namely, indigo.

2376 Indigo.

9. Indigo is a colouring matter which is obtained from several plants, and has some resemblance to fecula or starch. The indigo of commerce is chiefly obtained from the *indigofera tinctoria*, a shrubby plant which is cultivated in the East and West Indies, for the purpose of extracting the colouring matter.

2377 Preparation.

10. When the indigo plant has arrived at maturity, it is cut down, and conveyed to large wooden vessels, where it is covered with water, and soon commences a fermentation. When the plant is cut down at the period of its maturity, it produces a more beautiful colour, but in smaller quantity. If it be too late, the quantity is still diminished, and the indigo is of a bad quality. The putrefactive process soon commences, and succeeds best about the temperature of 80°. The water becomes turbid and of a green colour. The smell of ammonia, and carbonic acid gas are evolved. The fermenting process is finished in the period of from 6 to 24 hours, according to the temperature and state of the plant. The liquid is then poured off into flat vessels, in which it is constantly agitated till blue flakes appear. With the addition of a quantity of lime-water these flakes precipitate to the bottom. A yellowish liquid is poured off, and the blue precipitate is collected in linen bags, from which the water drains off. When the matter in the bag has acquired sufficient consistence, it is formed into small cakes, which are slowly dried in the shade. This is the indigo of commerce.

2378 From other plants.

11. Indigo may be also extracted from the *nerium tinctorium*, or rosebay, a plant which grows in abundance in the East Indies, from the leaves of which Dr Roxborough

Component Parts of Vegetables. Roxborough extracted it, by the following process. He digested the leaves in a copper vessel with water, kept at the temperature of 160° till they assumed a yellowish colour. The liquid becomes of a deep green; it is then poured off, and with the addition of lime-water is agitated till the indigo is precipitated. To produce one pound of indigo, two or three hundred pounds weight of green leaves were found necessary; but this quantity varies according to the season and state of weather in which they are collected.

2379 From woad. 12. The *isatis tinctoria*, or woad, which is a British plant, also yields indigo, by treating it in the same way as the indigo plant.

2380 History of indigo. 13. The history of indigo is curious. It was early known in India, but its value as a dye-stuff was not understood in Europe before the middle of the 16th century. But what is most singular, the use of this substance was either restricted or entirely prohibited in different countries from some prejudice that its effects in dyeing were injurious. The use of it was prohibited in England from the time of Queen Elizabeth till the reign of Charles II. It was also prohibited in Saxony. It is described in the edict as a corrosive substance, and denominated *food for the devil!* In France during the administration of Colbert, the dyers were restricted to the use of a certain quantity. For some time after, indigo was generally employed as a dye stuff in Europe, and was chiefly cultivated in the West Indies, and some parts of the American continent. This indigo was generally preferred in the market. What is now cultivated in the East Indies is found to be equal in quality.

2381 Properties. 14. Indigo is a light, friable substance, of a compact texture, and a deep blue colour. The shade varies from copper, violet, and blue tints. The lightest indigo is the best. It is always contaminated with extraneous matters. Bergman found in the purest indigo which he could procure, the following component parts:

2382 Composition.

Pure indigo	47
Gum	12
Resin	6
Barytes	10.2
Lime	10.0
Silica	1.8
Oxide of iron	13.0
	100.0

Other earths have been found in indigo. In some specimens Proust detected magnesia.

2383 Action of heat. 15. Pure indigo is a soft powder of a deep blue colour, which has neither taste nor smell. When exposed to heat, it emits a bluish red smoke, and then burns away with a faint white flame. The earthy part remains behind in the state of ashes. It undergoes no change by exposure to the air. It is insoluble in water, but if kept some time under it, a fetid odour is exhaled, owing to some change.

2384 Of acids. 16. Diluted sulphuric acid poured upon indigo dissolves only the earthy and mucilaginous matters; but if concentrated sulphuric acid be added, in the proportion of eight parts of acid to one of indigo, the latter is dissolved with the evolution of heat, in about 24 hours. The mixture is black and opaque; but if water be added, it becomes clear, and of a fine blue colour, producing various shades, according to the quantity of water. This solution of indigo in sulphuric acid is called *liquid blue*, or according to Bancroft, sulphate of indigo.

Bergman made a great number of experiments on the effect of different substances on this solution, some of which we shall now mention, in which the colour was either changed, or entirely destroyed. When it was dropped into sulphurous acid, the colour, which was at first blue, became green, and was at last destroyed. In diluted tartaric acid the colour became gradually green, and was at last converted into a pale yellow. In acetic acid it became green, and was at last destroyed. In potash, carbonate of potash, soda, ammonia and its carbonate, the colour became green, and at last disappeared. In sulphate of soda, the solution being diluted, after some time became green. It also became green in sulphate of iron, and at last disappeared. In the sulphurets the colour was very soon destroyed. Black oxide of manganese produced the same effect. These experiments have been mentioned, to shew that indigo is deprived either partially or totally of its colouring matter, by those substances which have a strong affinity for oxygen. From this it is inferred that indigo owes its colour to oxygen; and that it becomes green when it is deprived of it. 2385 Effects of different substances on liquid blue.

Concentrated nitric acid attacks indigo with such violence that it sometimes inflames it. By diluting the acid, the action is greatly moderated. The solution becomes of a brown colour; crystals appear, which are supposed to be oxalic acid, and a brown viscid substance remains behind. 2386 Nitric acid.

Muriatic acid dissolves indigo precipitated from sulphuric acid, and forms a liquid of a dark-blue colour. The other acids, as the phosphoric, acetic, and tartaric, exhibit similar phenomena. They readily dissolve indigo, which has been precipitated.

Oxymuriatic acid has little action on indigo in substance, but it destroys the colour of it in the state of solution.

17. Neither alcohol, ether, nor oils, have any action on indigo. Common indigo, when digested with alcohol and ether, communicates a yellow colour; but this, it is supposed, is owing to the solution of the resinous substance. 2387 Of alcohol.

18. The solution of the fixed alkalies readily dissolves indigo, when it is precipitated from its solution. The colour of the solution is at first green, and is at last destroyed. Liquid ammonia and its carbonate produce a similar effect, from which it appears, that indigo is decomposed by the alkalies. 2388 Alkalies.

19. Lime water also dissolves indigo precipitated from its solution. The colour is at first green, becomes gradually yellow; when exposed to the air, the green returns, and at last disappears.

20. Bergman subjected indigo to the process of distillation; from 576 grains he obtained the following products:

2389 Composition.

Carbonic acid gas - - -	19
Yellow acid liquid containing ammonia	173
Oil - - - - -	53
Charcoal - - - -	331
	576

The

Component Parts of Vegetables.

The component parts of indigo, therefore, appear to be oxygen, carbon, hydrogen, and azote.

X. Of Bitter Matter.

2390 In different substances. 1. A great number of vegetable substances are distinguished by a very bitter taste, such as quassia, a substance used in medicine, gentian, hops, chamomile. This taste is ascribed to a peculiar matter, called from this property *bitter matter*. It may be obtained by infusing quassia for some time in water. This solution, which is of a yellow colour, has an extremely bitter taste, but no smell. If the water be evaporated with a moderate heat to dryness, a brownish yellow substance, which has some degree of transparency and ductility, remains behind. After some time it becomes brittle.

2391 Properties. 2. When this substance, which has a very bitter taste, and a brown yellowish colour, is heated, it softens, swells, and blackens, then burns away without much flame, and leaves a small quantity of ashes. It is very soluble in water and alcohol. Nitrate of silver renders it turbid, and afterwards produces a yellow precipitate in the form of flakes. Acetate of lead produces a copious white precipitate.

XI. Of Narcotic Matter.

2392 Found in different plants. 1. A peculiar substance has been detected in opium, to which it is supposed the properties it possesses of producing sleep are owing. On account of this property this substance has received the name of *narcotic matter*. It is obtained from the milky juices of some plants, as those of the poppy, lettuce, and some others. Opium, which is extracted from the poppy, is prepared by the following process.

2393 Extraction of opium. The heads of the *papaver album* or white poppy, which is cultivated in India and different countries of the east for this purpose, are wounded with a sharp instrument; a milky juice flows out, which concretes, and is collected and formed into cakes.

2394 Properties. 2. In this state opium is a tenacious substance, of a brownish colour, has a peculiar smell, and a disagreeable bitter taste. It becomes soft with a moderate heat. It readily takes fire, and burns rapidly. By the analysis of opium, it appears to be composed of the sulphates of lime and of potash, extractive matter, gluten, mucilage, resinous matter, and an oil, besides the narcotic matter to which its peculiar properties are owing.

2395 Separation of the narcotic matter. 3. By digesting opium in water part of it is dissolved, and by evaporating the solution to the consistence of syrup, a gritty precipitate appears, which becomes more copious with the addition of water. This precipitate is composed of resinous and extractive matter, besides the peculiar narcotic matter which is crystallized. When alcohol is digested on this precipitate, the resinous and narcotic matters are dissolved, and the extractive matter remains behind. As the solution cools, the narcotic matter crystallizes, but the crystals are coloured with a portion of resin. By repeated solutions and crystallizations it may be obtained tolerably pure *.

* *Ann. de Chim.* xlv. 263.

2396 Of alcohol. If alcohol be digested on the residuum, it acquires a deep red colour; the same crystals are deposited on cooling, and may be purified in the same way from the resinous matter with which they are contaminated.

2397 Properties. 4. The narcotic matter, or, as it is called by Derosne, *the essential salt of opium*, when properly purified, is of a white colour, crystallizes in right-angled prisms, with a rhomboidal base, and has neither taste nor smell. It is insoluble in cold water, and requires 400 parts of boiling water for its solution, from which it is precipitated by cooling. The solution does not redden the tincture of turnsole. It is soluble in 24 parts of boiling alcohol, and requires about 100 parts when it is cold. When water is added to the solution in alcohol, it is precipitated in the form of a white opaque matter.

2398 Action of ether, &c. Ether and the volatile oils dissolve this salt with the assistance of heat; but on cooling it is deposited in the form of an oily liquid, and some time after crystals appear at the bottom of the vessel.

2399 Of acids. 5. One of the most decided characters of this substance is its easy solubility in all the acids, and without the aid of heat. It is precipitated from these solutions by means of an alkali, in the form of white powder. Pure alkalies increase the power of its solubility in water; and the acids, when not added in excess, occasion a precipitate. When nitric acid is poured on the crystals reduced to a coarse powder, it communicates to them a red colour, and readily dissolves them. When the solution is heated and evaporated, it yields crystals of oxalic acid in considerable quantity. The residuum has a very bitter taste.

2400 Of heat. 6. When it is thrown on burning coals, it gives out a copious flame. When heated in a spoon, it gradually melts like wax. Distilled in a retort with a moderate heat, it melts, and afterwards swells up, with the evolution of white vapours, which condense on the sides of the vessel, in the form of a yellow oily matter. There passes over, at the same time, a little water impregnated with carbonate of ammonia. Towards the end of the process, carbonic acid and carbonated hydrogen gas, with some ammonia, are disengaged. There remains in the retort a light, spongy, voluminous mass of charcoal, which, by burning, gives some traces of potash. The oily matter deposited in the neck of the retort is very viscid, and has a strong aromatic odour, with a pungent, acrid taste.

2401 Effect on animals. 7. Derosne tried the effects of this substance on animals, and in very small quantity. The symptoms which appeared, when it was given to dogs, were exactly similar to those which are produced when a large quantity of crude opium is swallowed. They were recovered from its effects by means of vinegar, which he accounts for on the principle of the easy solubility of this substance in acids.

2402 Composition. 8. From the effects of heat and of nitric acid on this substance, it appears to be composed of oxygen, hydrogen, carbon, and azote.

2403 Opium found in other plants. 9. This narcotic substance is also found in the milky juice, and in the extracts which are obtained from several other plants, as from different species of *lactuca* or lettuce, *hyoscyamus niger* or henbane. The leaves of some plants also produce similar effects, as those of the *deadly nightshade*, *foxglove*, and *conium maculatum* or hemlock.

:omponent Parts of 'egetables.

XII. Of Oils.

2404 ixed. 1. The nature, properties, and component parts of oils, have already been detailed, when treating of inflammable substances. Oils are of two kinds, fixed and volatile. Fixed oil exists chiefly in the seeds of plants, as linseed oil, almond oil, and rape-seed oil. Fixed oil is also found in the pulp of some fruits, as in that of the olive. Fixed oils are found in those seeds which have double lobes, or two cotyledons, and in these they are mixed with a quantity of mucilage. These oils are extracted from seeds by expression and boiling.

2405 olatile. 2. Volatile oils are found in all parts of plants excepting the seeds. In some plants they exist in the root, or the stem, and in others in the leaves, the flower, the pulp and rind of the fruit. The peculiar odour by which almost all plants are distinguished, is supposed to be owing to a volatile oil. These oils are also extracted by expression, and sometimes by distillation.

XIII. Of Wax.

2406 epara-n. 1. Wax, of which bees form their combs for containing honey, is collected from vegetables; and a similar substance being found in different parts of plants, it is to be considered as vegetable matter. The varnish with which the upper surface of the leaves of some trees is covered, possesses the properties of bees wax. If the bruised leaves are digested in water, and afterwards in alcohol, till the soluble part is extracted, and the residuum be mixed with six times its weight of a solution of ammonia, and after maceration, the solution being poured off and filtered, diluted sulphuric acid be added in excess to saturate the alkali, constantly stirring it, the varnish precipitates in the form of a yellow powder. It is then to be washed with water, and melted with a moderate heat. This substance is wax.

2407 operties. 2. Pure wax is of a white colour, has no taste, and scarcely any smell. The aromatic smell of bees wax is owing to some substance with which it is mixed, for it is entirely removed by exposure to the air, when the colour at the same time disappears. Pure wax undergoes no change by exposure to the air. The specific gravity is 0.96. It is insoluble in water.

2408 tion of it. 3. Wax becomes soft by the application of heat. Unbleached wax melts at the temperature of 142°. When it is pure it requires the temperature of 155°, and then melts into a colourless transparent fluid. By increasing the heat, the wax boils and evaporates; with a red heat the vapour takes fire, and burns with a bright flame.

2409 ids. 4. The acids have scarcely any action on wax. It is bleached by means of oxymuriatic acid, but no other effect is produced.

2410 cohol, 5. Wax is soluble in boiling alcohol. It requires 20 parts of alcohol to dissolve one of wax, and as the solution cools, the greater part is precipitated. With the addition of water the whole is thrown down. With the assistance of heat ether dissolves wax nearly in the same proportion, but on cooling it is also precipitated.

Wax is soluble in the fixed oils with the aid of heat. This compound is known by the name of *cerate*, which is much employed to form plasters for dressing wounds. It is soluble also in some of the volatile oils, as those of turpentine, with the assistance of heat. As the solution cools, part of the wax is precipitated. Component Parts of Vegetables.

6. Wax combines with the fixed alkalies, and forms with them substances similar to soap. 2411 Alkalies.

7. According to the analysis of Lavoisier, wax is composed of 2412 Composition.

Carbon	82.28
Hydrogen	17.72
	100.00

8. When wax is distilled with a temperature above 212°, water comes over, some acid, and a little fluid and odorous oil. The oil in the course of the process becomes thicker, and at last assumes the consistency of butter; and hence it has been called *butter* of wax. This substance by repeated distillation is converted into a volatile oil. A coaly matter remains in the retort. 2413 Butter of wax.

9. Wax is extracted from a number of plants, possessing different degrees of consistency, as that from the cacao, called the *butter of cacao;* from the *croton sebifera*, called the *tallow of croton;* and the myrtle wax extracted from the *myrica cerifera*, or *candle-berry myrtle* of America. The myrtle wax is obtained from the berries of this plant. They are collected and put into a kettle, and covered with water to the depth of half a foot. Heat is applied, and the berries are pressed against the sides of the vessel. The wax melts, and swims on the top. It is collected, passed through a cloth, dried and melted again, and then cast into cakes. The wax, it appears, exists chiefly in the outer covering of the berries. Myrtle wax is of a pale-green colour; the specific gravity is 1.015. When heated to the temperature of 109°, it melts; with a stronger heat it burns, giving out a white flame with little smoke; an agreeable aromatic odour is at the same time emitted. In its other properties it resembles bees wax. 2414 Obtained from many plants.

Proust has detected wax in the rind of plums, oranges, and similar fruits, and in the green fecula of many plants.

XIV. Of Camphor.

1. Camphor is obtained from the *laurus camphorata*, a species of laurel which grows in China and Japan. It is extracted by sublimation in an iron pot. The Dutch afterwards purify it by a second sublimation. 2415 Extraction.

2. It is a white, brittle substance, possessing a hot acrid taste. The specific gravity is 0.9887. It is not altered by exposure to the air, but it is so extremely volatile, that it disappears entirely if left in an open vessel. It crystallizes by sublimation in close vessels in the form of hexagonal plates or pyramids. It is insoluble in water, although at the same time it communicates some of its odour. 2416 Properties.

3. When a heat about the temperature of 300° is suddenly applied, it melts, and then is volatilized. It readily catches fire, and burns with a bright flame, without leaving any residuum. It even burns on the surface of water. When a small quantity of camphor in 2417 Action of heat.

a

a state of inflammation is introduced into a large glass vessel filled with oxygen gas, it bursts out into a vivid flame; the inside of the vessel is covered with a black powder, and a great deal of carbonic acid gas is disengaged. If a little water has been previously put into the vessel, it is impregnated with carbonic and camphoric acid.

2418 Acids. 4. Camphor is soluble in the acids, but with the addition of water or an alkali, it is precipitated unchanged. Camphor in sulphuric acid forms a red solution; in nitric acid, a yellow solution, which was formerly called *oil of camphor*. By the repeated distillation of nitric acid off camphor, it is converted into camphoric acid.

Sulphurous acid, muriatic acid, and fluoric acid, in the state of gas, dissolve camphor. If oxymuriatic acid gas be made to pass into a solution of camphor in nitric acid, it is immediately changed to a rose colour, and instantly afterwards it becomes yellow, which is permanent during the process. When water is added to the solutions of camphor in acids, it is separated. Camphor is also soluble in water impregnated with carbonic acid gas, and in acetic acid. The latter compound constitutes Henry's aromatic vinegar.

5. Alcohol readily dissolves camphor, but it is precipitated with the addition of water. By diluting alcohol which holds camphor in solution with water just so much as not to precipitate the camphor, the latter crystallizes in the form of feathers. The fixed and volatile oils dissolve camphor with the assistance of heat, but on cooling the camphor is precipitated, and crystallized, as in the solution with alcohol.

2419 Alkalies. 6. Camphor communicates to the alkalies a little of its colour, but is not otherwise soluble in these bodies.

2420 Composition. 7. According to the analysis of Bouillon Lagrange, by distilling one part of camphor with two of alumina, formed into a paste with water in a glass retort, the component parts of camphor are carbon and hydrogen; the proportion of carbon being much greater than in oils.

2421 Oil of camphor. In the course of the distillation, he obtained a volatile oil, of a golden yellow colour, which floated on the surface of the water in the receiver. It had an acrid burning taste, and aromatic odour, similar to that of thyme or rosemary.

2422 Found in many plants. 8. Camphor has been detected in many other plants. It has been extracted from the roots of thyme and sage, and in these plants it seems to be combined with volatile oil. If the oil be exposed to a temperature below 54° in the open air, it evaporates, and the camphor crystallizes. It may be also obtained by distilling the oil in a water bath, under the temperature of 212°, till a third part of the oil passes over. Part of the camphor is found crystallized in the vessel, and by repeating the process, the whole may be extracted from the oil. By mixing the camphor with a little dry lime, and subliming it, it may be purified.

XV. Of Caoutchouc.

2423 History. 1. Caoutchouc is a soft elastic substance, chiefly obtained from the inspissated juice of two trees, the *hævea caoutchouc* and *jatropha elastica*, which are natives of South America. This substance was first brought from America about the beginning of the 18th century. It is called by the inhabitants of *Esmeraldas*, a province of Quito, *heve*, and by the natives of the province of Mainas, *caoutchouc*.

2424 Preparation. 2. It is extracted by making incisions in the bark of the tree. A milky juice flows from it, which is collected in proper vessels. The juice is then applied, one stratum above another, on earthen moulds, and suffered to dry in the sun, or before a fire. Various figures are formed on the surfaces of the different pieces by means of a pointed instrument. They are then exposed to smoke, and, when perfectly dry, the moulds are broken. In this state it is brought to Europe. It is generally in the shape of bottles, but sometimes in other forms.

2425 Properties. 3. When caoutchouc is pure, it is of a whitish colour; it is soft and pliable like leather, extremely elastic, and possesses great tenacity. The specific gravity is 0.9335.

2426 Action of heat. 4. When caoutchouc is exposed to heat, it readily melts into a matter of the consistence of tar. It burns with a bright white flame, and diffuses a fetid odour.

5. Sulphuric acid decomposes caoutchouc; charcoal is precipitated, and the acid is partially converted into sulphurous acid. It is also decomposed by nitric acid; carbonic acid gas, azotic gas, and prussic acid gas, are disengaged, and oxalic acid is formed. Muriatic acid has no action upon it; but if oxymuriatic acid is poured upon the milky juice, the caoutchouc is immediately precipitated, and the acid is converted into muriatic acid. If a given quantity of air be confined in a vessel over a quantity of this milky juice, the oxygen of the air is absorbed, and a pellicle of caoutchouc is formed on the surface, from which it appears that the formation of caoutchouc is owing to the combination of its base with oxygen.

2427 Alcohol. 6. Caoutchouc is insoluble in alcohol. It is soluble in ether, but it is necessary that the ether be previously washed with water. By this treatment it is formed into syringes, catheters, and other instruments. It is soluble in the volatile oils, but it remains somewhat glutinous after the evaporation. A mixture of volatile oil and alcohol forms a good solvent for caoutchouc, and in this state it may be employed as a varnish for paper or stuffs. A varnish may also be formed with it by dissolving it in boiling wax. It is also soluble in rectified petroleum, and when the solution is evaporated, the caoutchouc remains unchanged.

2428 Alkalies. 7. According to some, caoutchouc is insoluble in the alkalies; but, according to others, all of these bodies are capable of dissolving it.

2429 Composition. 8. By distillation caoutchouc yields ammonia; and from this, and its decomposition by means of sulphuric and nitric acids, its constituent parts must be carbon, hydrogen, azote, and oxygen.

2430 Found in different vegetables. 9. Caoutchouc has been detected in different parts of many other plants, but it is mixed with resinous, gummy, and extractive matters. It has been found in different species of the misletoe, in opium and mastic. It has also been extracted from the *artocarpus integrifolia* or bread-fruit tree, the *urceola elastica*, and *ficus indica*.

XVI. Of Resins.

2431 Nature of. 1. Resinous bodies form a very numerous class of vegetable

Component Parts of Vegetables. vegetable substances. When volatile oils are exposed to the air, they become thick after a shorter or longer time, and are then found to be converted into a *resin.* The oil absorbs oxygen from the air, and is deprived of part of its carbon, which combining with the oxygen of the atmosphere, forms carbonic acid. Resinous substances, therefore, are generally considered as volatile oils saturated with oxygen. The general properties of
2432 resinous substances are the following.

Properties. 2. They are solid, brittle, and commonly of a yellowish colour, with some degree of transparency. The taste, resembling volatile oils, is hot and acrid. They have no smell. The specific gravity is from 1.0180 to 1.2289. All resinous bodies are electrics, and when excited by friction, the electricity is negative; hence it is called
2433 *resinous electricity.*

Action of heat. 3. They melt by being exposed to heat, and burn with a yellow flame, giving out a great quantity of
2434 smoke. Resins are insoluble in water.

Acids, &c. 4. Resinous substances are soluble in nitric acid; part is precipitated by the addition of water, and the whole by means of the alkalies. With the assistance of heat they are all soluble in alcohol, and in sulphuric ether. Resins are soluble in some of the fixed oils,
2435 and also in volatile oils.

Alkalies. 5. Resinous substances have been found to be soluble in the fixed alkalies.

6. We shall now enumerate some of the resins which
2436 are best known.

Rosin. *Rosin.*—This substance is extracted from different species of the fir, and the resinous matter obtained from it has received different names. That procured from the *pinus slyvestris* is the common turpentine; from the *pinus larix*, Venice turpentine; and from the *pinus balsamea*, balsam of Canada. The turpentine is obtained by stripping the bark off the trees; a liquid juice flows out, which gradually hardens. This juice consists of oil of turpentine and rosin. By distilling the turpentine the oil passes over, and the rosin remains behind. By distilling to dryness common rosin is obtained. When water is added, while it is yet fluid, and incorporated by agitation, what is called yel-
2437 low rosin is formed.

Pitch. *Pitch.*—Is a resinous juice obtained from the *pinus picea*, or pitch pine. It is purified by melting and squeezing it through linen bags, and it is then known by the name of *white* or *Burgundy pitch.* White
2438 pitch mixed with lamp black forms black pitch.

Mastic. *Mastic.*—This is a resinous substance obtained from the *pistacia lentiscus*, a tree which grows in the Levant. The fluid which exudes from the tree, concretes into yellowish semitransparent brittle grains. It has little taste, melts and exhales a fragrant odour when heated, and readily dissolves in alcohol and fixed oils. It con-
2439 tains a little volatile oil.

Sandarac. *Sandarac.*—This resinous substance is extracted from the juniper. It is a spontaneous exudation from this plant in the form of brown tears, which are semitrans-
2440 parent and brittle.

Labdanum. *Labdanum*, or *Ladanum.*—This is the produce of the *cistus creticus*, a shrub which grows in Candia. It is the exudation of a viscid juice, which concretes by
2441 exposure to the air. It has a fragrant odour and a

Dragons-blood. bitter taste.

Dragons-blood.—This resinous substance is a production of the *dracæna draco* and some other plants. It is of a dark-red colour, opaque and brittle. The powder is of a crimson colour. It melts when it is heated, and readily burns. It has no taste, is insoluble in water, but soluble in alcohol, to which it communicates a crimson colour. It is also soluble in the fixed oils, and gives them a red colour.

Resina animæ.—This resin is the produce of a spe- 2442 Anime.
cies of *hymenæa*, or locust tree, a native of North America. It is soluble in alcohol, and is employed as a varnish.

Copal.—This resinous substance is obtained from the 2443 Copal.
rhus copallinum, a tree native in North America. The copal most preferred is brought from Spanish America. It is a light brown transparent substance. It melts when heated, but is not directly soluble in alcohol, or in oil of turpentine, and it is with difficulty soluble in fixed oils. Copal forms an excellent varnish. Indeed it is one of the best that is known for beauty and durability.

If copal be treated with oil of turpentine in a close 2444 Varnish.
vessel, from which the vapours are not allowed to escape, they exert a great pressure, which prevents the the boiling, and thus the mixture acquires a higher temperature. A considerable portion of the copal is thus dissolved, and with the addition of a little poppy oil, it forms an excellent elastic varnish.

If copal be kept melted till a sour-smelling aromatic odour ceases to proceed from it, and if it be then mixed with an equal quantity of linseed oil previously rendered colourless by exposure to the sun, it combines with the oil, and thus forms a varnish. The substances varnished with this preparation must be dried in the sun.

Copal may be dissolved in alcohol, by previously dissolving half an ounce of camphor in 16 ounces of alcohol. This solution is poured on 4 ounces of copal in a matrass, which is stopped with a cork, and perforated with a pin. When the copal is nearly dissolved, the process is stopped, and the matrass allowed to cool, before the cork is removed. This solution forms a colourless varnish.

Copal, it is said, may be dissolved in alcohol, by exposing it to the action of the vapour. This process is conducted by boiling a quantity of alcohol in the bottom of a vessel, at the top of which a piece of copal is suspended. During the process the copal softens, and falls down like oil into the alcohol.

Elemi.—This resinous substance is the produce of 2445 Elemi.
the *amyris elemifera*, a tree which grows in the East and West Indies. It is semitransparent, of a pale yellow colour, softish, and hardens by keeping. It has a strong fragrant smell, and when distilled it yields a fragrant oil.

Opobalsamum, or *balm of Gilead.*—This resin is pro- 2446 Balm of Gilead.
cured from another species of amyris, the *Gileadensis*, a native of Arabia. The best kind, which is highly valued by the Turks, is never seen in Europe.

Copaiva, or *balsam of Copaiva.*—This resinous sub- 2447 Copaiva.
stance is obtained from the *copaiva officinalis*, a tree which is a native of South America. It exudes by wounding the trunk of the tree. It is transparent, of a yellowish colour, has a pungent taste, and an agreeable smell. It is at first of the consistence of oil, but afterwards becomes as thick as honey. By distillation the

the volatile oil, with which it is mixed, may be separated, and the resinous matter remains behind.

2448 Guaiac. *Guaiac.*—This resin is the produce of the *guaiacum officinale*, a tree which is a native of the West Indies. The resin exudes spontaneously in tears, but it is chiefly obtained by cutting the wood into billets, and boring them longitudinally. When one of these is heated on the fire, the resinous matter is melted, and runs through the hole as the wood burns. This resin is of a brownish-yellow colour, and has some degree of transparency. It is soluble in alcohol, and has neither smell nor taste. It melts when heated, and when it is thrown on hot coals, it diffuses an agreeable odour. When swallowed in the state of powder, it produces a strong sensation of heat in the throat.

2449 Lac. *Lac.*—This resinous substance is obtained from the *croton lacciferum*. It is of a deep red colour, with some degree of transparency. It is the basis of the finer kinds of sealing wax, and is employed as a varnish.

2450 Amber. *Amber.*—This substance possesses many of the properties of the resins, and it has been considered by some of vegetable origin. It is a brittle hard substance, transparent, sometimes colourless, but often yellow or deep brown. The specific gravity is 1.065. It has neither taste nor smell, except when it is heated, and then it becomes soft, and gives out a fragrant odour. It burns with a strong heat, leaving only a small residuum. It is insoluble in water, but alcohol dissolves a small quantity of it. When the solution is concentrated, it becomes milky with the addition of water. The precipitate which is formed is a resinous substance. It is soluble in the fixed alkalies at a boiling temperature.

2451 Effect of acids. Sulphuric acid converts amber into a black resinous mass. It is also soluble in nitric acid.

2452 Distillation. By the distillation of amber, carbonic acid gas and carburated hydrogen gas, an acid liquor, and an oil, which is at first thin and transparent, but afterwards larger and thicker, is obtained. Succinic acid sublimes towards the end of the process.

2453 Varnish. When amber is roasted, it becomes soluble in the oils, and forms a varnish. This varnish may be formed by spreading the amber on a flat-bottomed iron pan, and exposing it to heat till it melts. It is then covered up, and set by to cool. One part of this roasted amber, which has lost half of its weight, if the process be properly managed, is then to be mixed with three parts of linseed oil. The mixture is to be exposed to a gentle heat till the amber is dissolved. It is then to be removed from the fire, and four parts of the oil of turpentine are to be added when it is nearly cold. The clear part, after it has settled, is strained through a linen cloth.

2454 Benzoin. *Benzoin.*—This substance contains a resinous matter combined with an acid, and is commonly ranked among balsams. Benzoin is obtained from the *styrax benzoin*, a tree which is a native of Sumatra. It is a brittle substance, has a fragrant odour when rubbed, and when it is heated, the acid escapes. It may be dissolved in alcohol, but it is insoluble in water.

2455 Styrax. *Styrax.*—This substance, which is in a half-fluid state, exudes from a tree in Arabia. It is of a greenish colour, has an aromatic taste, and an agreeable odour. The benzoic acid, which is one of its component parts, dissolves in water. The whole of it is soluble in alcohol. It absorbs oxygen, and becomes harder by exposure to the air.

Storax.—This substance is procured from the *styrax officinale*, a native of the Levant. It is of a brown colour and brittle, has an aromatic taste, fragrant odour, and is soluble in alcohol. It gives out benzoic acid by heat. 2456 Storax.

Balsam of Tolu.—This substance is obtained from the *toluifera balsamum*, a native of South America. It is of a reddish brown colour, becomes solid and brittle when exposed to the air, and has a very fragrant smell. 2457 Balsam of Tolu.

Balsam of Peru.—This is obtained from the *myroxylon peruiferum*, a plant which is a native of South America. The resin is extracted by boiling the twigs in water. It is of the consistence of honey, has a brown colour, an agreeable smell, and an acrid taste. It is soluble in alcohol. The acid part is soluble in water. Benzoic acid is driven off by heat. 2458 Of Peru.

XVII. Of Gum-Resins.

1. This class of substances seems to be composed of a mixture of resinous matter with a portion of gummy and extractive matter. They are never obtained from plants by means of spontaneous exudation, but are procured by wounding the plants which contain them. The general properties of gum-resins are the following. 2459 Constituents.

2. They are always in the solid state, and commonly brittle and opaque. They are softened by heat, but do not melt, and are less combustible than the resins. They burn with flame. They have an acrid taste, with a strong smell, somewhat resembling garlic. They are partially soluble in water, and in alcohol. The solution in water is opaque and milky, and the solution in alcohol is transparent. They are partially soluble in vinegar and wine. They are soluble in nitric acid, and also in the alkalies, with the assistance of heat. 2460 Properties.

3. The gum-resins by distillation yield a portion of ammonia, which shews that azote forms one of their constituent parts.

4. Many of the gum-resins have been long known in medicine, and some of them are of considerable importance. We shall specify the peculiar properties of the following.

Olibanum.—This gum-resin is chiefly collected in Arabia, from the *juniperus lycia*. It is brought from Mecca to Cairo, and from thence to Europe, in the form of transparent brittle grains, not larger than a chesnut, of a yellow colour, a peculiar aromatic smell, but with little taste. With water it forms a milky fluid, but it is entirely soluble in alcohol. When heated it does not melt, but inflames and burns with an agreeable smell. It is the frankincense of the ancients, and is still employed to diffuse an agreeable fragrance in the Greek and Romish churches. 2461 Olibanum.

Scammony.—This substance is extracted from the *convulvulus scammonia*, a climbing perennial plant which grows in Syria. By cutting the roots, a milky juice flows out, which is collected and dried in the sun. It is of a dark-gray colour, a bitter acrid taste, and a nauseous smell. It forms a greenish milky fluid with water 2462 Scammony.

Component Parts of Vegetables. water. It is soluble in alcohol. It is employed in medicine as a cathartic.

2463 Euphorbium. *Euphorbium.*—This substance is obtained from the *euphorbia officinalis*, which is a native of Ethiopia. The milky juice which flows from incisions made in the plant, is dried in the sun. It is in the form of small yellow tears. It has no smell, and at first no perceptible taste, but it communicates afterwards a burning sensation to the mouth. It is soluble in alcohol. It has been considered as poisonous.

2464 Asafœtida. *Asafœtida.*—This gum-resin is obtained from the *ferula asafœtida*, a perennial plant, which is a native of Persia. It is extracted from the roots by cutting off the extremity. The milky juice flows out, which is dried in the sun. It is brought to Europe in large irregular masses, which are of a whitish, reddish, or violet hue. It has a strong, fetid, alliaceous smell, and a bitter acrid taste. It is but partially soluble, both in alcohol and in water. It is much employed in medicine as a stimulant and antispasmodic.

2465 Ammonia. *Ammoniac.*—This gum-resin is supposed to be obtained from another species of the ferula, a plant which grows in Abyssinia and in the interior parts of Egypt. It is brought from the East Indies, usually in large masses, which are composed of little lumps or tears, of a milky colour. When exposed to the air, it is changed to a yellow colour. It has a nauseous, sweet taste, which is succeeded by a bitter. It has a peculiar smell. It is not fusible; but when placed on hot coals, it burns away in flame. It forms a milky solution with water and vinegar, and it is partially soluble in alcohol.

2466 Myrrh. *Myrrh.*—It is not yet known from what plant this substance is obtained. It is brought from the East Indies in the form of tears; is light and brittle, of a reddish-yellow colour, and an unctuous feel. It has a bitter aromatic taste, and a strong but somewhat grateful odour. It does not melt, and burns with difficulty. It is more soluble in water than in alcohol. With the former the solution is yellow and opaque; with the latter it is transparent.

2467 Sarcocol. *Sarcocol.*—This substance is supposed to be the product of the *penæa sarcocolla*. It is brought from Persia and Arabia, in the form of small whitish-yellow grains. It has a bitter and somewhat sweetish taste. It is almost entirely soluble in water.

2468 Galbanum. *Galbanum.*—This substance is obtained from the *bubon galbanum*, a perennial plant which grows in Africa. The milky juice sometimes exudes from the joints of the old plant, but is most commonly procured by cutting them across. This juice becomes hard, and is the galbanum brought to Europe. It is in the form of whitish-yellow tears, has a bitterish acrid taste, and a peculiar smell. It forms a milky solution with water, wine, and vinegar. It is scarcely soluble in alcohol. It does not melt, but yields a considerable proportion of oil by distillation.

2469 Sagapenum. *Sagapenum.*—It is only conjectured that this gum-resin is obtained from the *ferula persica*. It is brought in large masses or distinct tears from Alexandria. It is of a yellow colour, becomes hot in the hand, but is not fusible. It has a hot, nauseous, bitterish taste, and a disagreeable garlic smell. It is sparingly soluble in alcohol, but dissolves almost entirely in water. It yields by distillation a fetid volatile oil.

Opoponax.—This gum-resin is obtained from the *pastinaca opoponax*, a perennial plant which grows wild in the south of Europe. It is obtained by wounding the stock or root, and is in the form of round drops or tears, or in irregular masses of reddish-yellow colour. It has a bitter, acrid, and somewhat nauseous taste, with a strong peculiar smell. It forms a milky solution with water, and yields an essential oil by distillation. 2470 Opoponax.

Gamboge.—This gum-resin is obtained from the *stalagmitis gambogioides*, a tree which grows wild in Siam and Ceylon. In Siam it is procured in drops by breaking the leaves and young shoots, from which it is supposed to derive the name of *gum guttæ*. In Ceylon it is obtained by wounding the bark and collecting the juice, which is afterwards dried in the sun. It is brought from the East Indies in cakes or rolls. It is of a orange-yellow colour, opaque and brittle, has no smell, and little taste, leaving only a slight sense of acrimony when it has been kept in the mouth. It forms a turbid yellow solution with water, and is almost entirely soluble in alcohol. It is employed in medicine, and is a violent cathartic. 2471 Gamboge.

Bdellium.—Little is known of this substance, or of the tree from which it is obtained. It is in the form of small pieces or tears of different sizes, of a golden-yellow colour, with a reddish tint. This substance, or a substance with the same name, was long celebrated among the ancient physicians. 2472 Bdellium.

XVIII. Of Wood.

1. If a piece of wood be boiled in a great quantity of water till it no longer gives out taste or smell, and if it be afterwards digested in alcohol, the substance which remains is the woody fibre. 2473 Preparation.

2. It is either in a fibrous, lamellated, or pulverulent form. This substance, which is more or less coloured, has neither taste nor smell, is not altered by exposure to the air, and is insoluble in water and alcohol. 2474 Properties.

3. When it is heated in contact with air, it blackens, exhales dense, acrid, pungent fumes, and leaves behind a coaly matter, which does not change its form. By reducing it to ashes, it is found to contain a little potash, sulphate of potash and lime, phosphate of lime. When it is distilled in a retort it yields water, acetic acid contaminated with oil, a thick oily matter, carbonated hydrogen and carbonic acid gases, and a portion of ammonia, combined with acetic acid. 2475 Action of heat.

4. By the action of nitric acid on quinquina, which resembles the woody fibre, Fourcroy obtained from 100 parts the following products: 2476 Compositions.

Oxalic acid	56.250
Citric acid	3.905
Malic acid	0.388
Acetic acid	0.486
Azotic acid	0.867
Carbonate of lime	8.330
	70.226
Residuum,	32.031

A quantity of carbonic acid gas was also disengaged, which

which was not estimated. The increase of weight is ascribed to the oxygen which combined with the bases of the acids which were formed during the decomposition of the woody fibre by the nitric acid. The residuum, by distillation, yielded a yellowish fluid mixed with alcohol and some acetic acid, a concrete oil solubl in alcohol, charcoal, and carbonate of lime, besides carbonic acid and carbureted hydrogen gases. The component parts of wood, therefore, appear to be, oxygen, carbon, hydrogen, azote, and lime.

2477 Proportions of charcoal. The relative proportion of wood in plants has been estimated by the proportion of charcoal which they afford. From different woods, Proust obtained charcoal in the following proportions.

Black ash	25
Guaiac	24
Pine	20
Green oak	20
Heart of oak	19
Wild ash	17
White ash	17

XIX. Of Tan.

2478 Preparation. 1. Tan is obtained from a great number of vegetable substances. It exists in considerable proportion in oak bark and nut-galls; and it is obtained from the latter by the following process.

Reduce a quantity of nut-galls to a coarse powder, infuse them in water till it is saturated, pour off the liquid, and boil it to dryness. A black matter remains, which is *tan*, nearly in a state of purity. It is proposed also to extract tan from nut-galls by other processes. If a solution of muriate of tin be added to the infusion of nut-galls, a copious precipitate of a yellow colour is produced. When this is separated by filtration, and dried, it is in the form of a buff-coloured powder. It is a compound of oxide of tin and tan. It is then mixed with water, and a stream of sulphurated hydrogen gas is passed through it. An insoluble sulphuret of tin is formed, and the tan is dissolved in water. By filtration and evaporation of this water to dryness, a brown substance remains, which is tan; but by this process it is not perfectly pure, being mixed with a portion of extractive matter. It has also been proposed to separate tan from the infusion of nut-galls by means of concentrated sulphuric or muriatic acid, carbonate of potash, or lime water.

2479 Properties. 2. Tan is a brittle substance, of a brown colour, has a very astringent taste, is soluble in water and alcohol, to both of which it communicates a brown colour and very astringent taste.

2480 Action of heat. 3. When it is heated, it becomes black, gives out carbonic acid gas, and burns in the open air, leaving behind a small quantity of lime.

2481 Acids. 4. Tan is precipitated from the infusion of galls, by means of sulphuric, nitric, and muriatic acids, and forms with them compounds which are soluble in water.

2482 Alkalies. 5. The alkalies combine with tan, and form compounds which are soluble in water. A reddish brown colour is produced in the liquid by the addition of potash or soda, and it loses the property of precipitating gelatine. Ammonia forms a similar compound with the infusion of galls.

6. Most of the earths combine with tan, and form with it compounds which are chiefly insoluble in water. Lime water, added to the infusion of galls, produces an olive-colonred precipitate. A similar precipitate is obtained by means of barytes, strontites, and magnesia. 2483 Earths.

7. The metallic oxides combine with tan, and form compounds which are nearly insoluble in water. Similar precipitates are obtained by means of many of the metallic salts. The green sulphate of iron produces no precipitate; but the red sulphate gives a deep-blue precipitate, which becomes black by exposure to the air, or when it is dried. This is the base of writing ink, as was formerly described in treating of the sulphate of iron. 2484 Metallic oxides and salts.

8. Tan forms an insoluble compound which gelatine, which is the principle of the important process of tanning leather, and is nothing more than the combination of tan with the animal matter called *gelatine* or *glue*. 2485 Gelatine.

9. Tan is chiefly found in the bark of trees; it is also found in the leaves, the wood, the sap, and sometimes it is obtained by spontaneous exudation, as is the case with the substance called *kino*. Several varieties of tan have been found in different vegetable substances, as in catechu, dragon's blood, sumach, and fustic. 2486 Exists in the bark chiefly.

10. The quantity of tan varies with the age and size of the tree, and at different seasons. The greatest proportion has been found in the inner bark. Sir H. Davy ascertained the quantity of tan obtained from the solid matter extracted by water, from an ounce of different vegetable substances. 2487 Proportion varies.

	Solid Matter.	Tan.
White inner bark of old oak	108 grs.	72 grs.
young oak	111	77
Spanish chesnut	89	63
Leicester willow	117	79
Coloured or middle bark of } oak	43	19
Spanish chesnut	41	14
Leicester willow	34	16
Entire bark of oak	61	29
Spanish chesnut	53	21
Leicester willow	71	33
elm	—	13
common willow	—	11
Sicilian sumach - - -	165	78

Phil. Trans. 1799.

XX. Of Suber.

2489 Constitutes the epidermis. 1. The vegetable substance denoted by the name of *suber*, is, according to Fourcroy, the epidermis or outer covering of trees. This substance is analogous to common cork, which is the epidermis of the *quercus suber*, from which the name of this peculiar vegetable substance is derived.

2490 Properties. 2. It is a light, soft, elastic substance, is insoluble in water, but readily absorbs this liquid. Common cork is the same substance, having greater density, and accumulated in greater quantity.

2491 Action of heat. 3. This matter is very combustible, and burns with a white vivid flame, leaving behind a very black, light, voluminous coaly matter. When distilled, it yields ammonia.

2492 Of nitric acid. 4. When cork is treated with nitric acid, carbonic acid gas and nitrous gas are evolved. The cork is decomposed, and converted, partly into a yellow, soft, unctuous matter, which swims on the surface, and partly into suberic acid; the nature and properties of which have been already described.

XXI. Of Alkalies.

2493 Fixed alkalies only found. 1. The fixed alkalies only have been detected in plants, and there are few plants which do not yield a smaller or greater proportion of one of these alkalies. It is supposed that they exist in plants, in combination with acetic and carbonic acids.

2494 Potash. 2. Potash, formerly called *vegetable alkali*, because it was supposed to exist only in vegetables, is found in all plants except those which grow near the sea. The process for extracting it has been already described. The vegetables are reduced to ashes by burning; the ashes washed with water, which is filtered and evaporated to dryness. The potash remains behind.

3. Shrubby and herbaceous plants yield a greater proportion of ashes than trees. The branches of trees afford more ashes than the trunks, and the leaves more than the branches. Other salts are found mixed with the potash, such as the sulphates of potash and of lime, muriate of potash, phosphate of lime, and phosphate of potash; the last of which has been detected in maize and wheat. In the following table the proportion of ashes obtained from 100 parts of different plants, and the quantity of potash which these ashes yield, are exhibited.

	Ashes.	Potash.
Sallow	2.8	0.285
Elm	2.36727	39.—–
Oak	1.351185	0.15343
Poplar	1.23476	0.07481
Hornbeam	1.1283	0.1254

4. Soda is generally found in all marine plants, and in many others which grow near the shore. The proportion of soda which many plants containing it yield, is very considerable. A hundred parts of the *salsola soda* afford 19.921 of ashes, from which may be extracted 1.992 part of soda. It is from different species of *fuci* that the soda or kelp of Britain is obtained. The soda of commerce is extracted from two species of salsola, the *sativa* and the *vermiculata*, which grow abundantly on the shores of Spain and the Mediterranean. 2495 Soda.

5. Of late several compounds of vegetable origin possessing alkaline qualities have been discovered by chemists, and ranked among the alkalies. The first of these is *morphine*, found in opium, in which it exists in combination with the *meconic acid*. The process for obtaining it consists of the following steps. 1. To boil a strong solution of opium along with a little magnesia. This earth combines with the meconic acid, and leaves the morphine free, but precipitated along with the meconate of magnesia. 2. The mixed precipitate, after being gathered on a filter and washed with cold water, is treated with weak alcohol at 150°, which separates the colouring matter. 3. It is then boiled in pure alcohol, which dissolves the morphine, and, while it cools, deposits it in white crystals. Morphine turns syrup of violets green, and turmeric brown. It is found to be the active matter from which opium derives its power over the animal economy. Another alkali has been obtained from the Angustura bark, and has been named *brucine*, from the name of the genus by which this bark is yielded, the *brucea anti-dysenterica*. A third, from the seeds of *delphinium staphisagria*, is called *delphine*; and a fourth, *strychnine*, is obtained from the *strychnos nux vomica*. Here a most extensive field has been opened for chemical research; and we may expect a rapidly increasing list of similar vegetable compounds, by manipulations performed on the different species of plants, particularly those known to possess active qualities, or the products of which present any remarkable character. 2496 New alkalies.

XXII. Of Earths.

1. Four of the earths have been detected in vegetables, namely lime, silica, magnesia, and alumina. Few 2497 Lime.

Component Parts of Vegetables.

Few plants have been found which do not contain some portion of lime. It is the most abundant of all the earths in plants.

2498 Silica. 2. Silica has been found in several plants, and chiefly in the epidermis, some of which are almost entirely composed of this earth. A hundred parts of the epidermis of the following plants yielded the annexed proportions of this earth.

Bonnet cane	90
Bamboo	71.4
Common reed	48.1
Stalk of corn	6.5

2499 Magnesia and alumina. 3. Magnesia is more rarely found in vegetables. It has been detected in considerable proportion in the fuci and other sea plants. The greatest proportion yet discovered is found in the *salsola soda*. A hundred parts of this plant have yielded 17.929 of magnesia.

4. Alumina is found in plants in very small quantity.

2500 Proportion of earths. 5. In the following table is exhibited the quantity of earths in general, found in 100 parts of different plants.

Oak	1.03
Beech	1.453
Fir	0.003
Turkey wheat	7.10
Sun-flower	3.72
Vine branches	2.85
Box	2.674
Willow	2.515
Elm	1.96
Aspen	1.146
Fern	3.221
Wormwood	2.444
Fumitory	14.000

Herbaceous plants, it appears, contain a greater proportion of earths than trees. In all the kinds of grain which Bergman examined, he found all the four earths. From 100 parts of oat grain, Vauquelin obtained a residuum of 3.1591, which by analysis he found to be composed of

Silica	60.7
Phosphate of lime	39.3
	100.0

By burning the stem and seeds of the same grain, the residuum by analysis afforded the following substances:

Silica	55
Phosphate of lime	15
Potash	20
Carbonate of lime	5
	95

Some traces of oxide of iron were also detected.

XXIII. Of Metals.

2501 Iron and manganese. The only metallic substances which have certainly been found in plants are iron and manganese. Iron has been detected in the ashes of salsola; and manganese has been found in the ashes of the pine, green oak, calendula, vine, and fig-tree. Gold, it is said, has been found in some plants, but in very minute proportion.

Chap. XIX. Of ANIMALS.

Functions of Animals.

Animals constitute the second division of organized matter. They are distinguished from vegetables by texture, form, and component parts. The more characteristic differences between animals and vegetables are, the locomotive power of animals, irritability, and sensibility. Animal matters pass to the putrid fermentation, and they are all soluble in the alkalies. Sulphuric acid reduces them to a carbonaceous matter. Charcoal is precipitated, and ammonia is disengaged. Nitric acid acts violently on animal substances, with the evolution of azotic gas. 2502 Characters.

In treating of animal matters, we shall first consider the functions of living animals; 2. The decomposition of animal matters; and, 3. Their component parts. These subjects shall occupy the three following sections.

Sect. I. *Of the Functions of Animals.*

In taking a view of animal substances, it is necessary to consider the functions of the living animal, so far at least as these functions admit of explanation on chemical principles. It is beyond the reach of human sagacity fully to understand the simplest processes in the animal economy. These cannot be explained on chemical or mechanical principles; but to comprehend clearly and fully, even what is known of the functions of living animals, it would be necessary to enter into a description of the structure and nature of the organs by which they are performed. This is not the province of chemistry; it belongs to Anatomy and Physiology. We must here content ourselves with giving a short account of the chemical changes which take place by the action of living animals. The functions of animals which have occupied the attention of chemical physiologists, and which we propose to treat of in this section, are respiration, digestion, secretion, and assimilation. 2503 Cannot be explained on chemical principles.

I. Of Respiration.

1. Respiration is to be considered as one of the vital functions of animals. No animal can exist when it is interrupted, nor indeed can it be suspended, even for a short time, without hazard. The mechanical part of this function, consists in alternately drawing air into the lungs, and expelling it. 2504 A vital function.

2. That all gases are not fit for respiration is well known. Some indeed, as carbonic acid gas, the moment they are inhaled, are destructive to life. Others, although not productive of such sudden effects, prove ultimately fatal to the animal which is forced to respire them. Animals are very differently constituted, both with regard to the structure of their respiratory organs, and with regard to the quantity of air which must be respired in order to support life. In these respects, the hot and cold-blooded animals differ much from each other; and even among the cold-blooded, there are some tribes which require a very small quantity of air, and can bear with much less apparent 2505 All gases not fit for respiration.

Functions of Animals.

apparent inconvenience a temporary interruption of this function; but for all animals, whatever be their nature, whatever be their structure, or whatever be the modifications of their respiratory system, the air of the atmosphere is best adapted for the support of life. It is the oxygen of the air which is necessary for the breathing of animals; but although animals live longer in a given quantity of oxygen gas

2506 [N]ot even [p]ure oxygen. than in atmospheric air, as appears from the experiments of Count Morozzo, related in the chapter on oxygen gas, yet it is too powerful, or too stimulating for their organs; for to such as have been confined to breathe it, it has been found highly injurious.

2507 [S]ome fatal [t]o life. 3. Some of the gases prove immediately fatal to life; such for instance is carbonic acid gas. It seems to be certain that no animal ever made a full inspiration of this gas unmixed, without being destroyed. It is so noxious to animal life, that the organs themselves, by an involuntary action, obstruct it in its passage to the lungs. Other gases are equally fatal after a few inspirations, such as hydrogen and azotic gases; and indeed it is probable, that if the lungs were completely emptied of air, before the inspiration of any gas whatever, excepting oxygen gas or atmospheric air, a single inspiration would prove fatal. This, however, is never the case; for after the fullest expiration, a considerable quantity of air remains in the lungs. We may conclude, therefore, that the air of the atmosphere is the only gaseous substance proper for the respiration of animals, and the support of life.

2508 [T]he same [ai]r can only be once [re]spired. 4. The same quantity of atmospheric air or oxygen gas, after having been once respired by animals, becomes totally unfit for farther respiration, either by the same animals or any other. It is then deprived of a great part of the oxygen, and contaminated with noxious gases. This even happens to fishes and insects, which require a very small quantity of air. If the water in which the former live be deprived of its air, it is equally fatal to them, as immersion under water is to those animals which live in the air of the atmosphere.

2509 [T]he quan[tit]y. 5. Attempts have been made by physiologists to ascertain the quantity of air respired by animals. This must be extremely different in the different classes. Even in the same class of animals, it is probable that it varies much. The difference of the results of experiments on man to ascertain this point is enormous. No conclusion whatever can be drawn from the number of respirations made in a given time, even if this could be determined with any degree of accuracy, which is scarcely to be expected. For no function of the body is sooner influenced by mental affections than the breathing. The very attention implied in reckoning the number of respirations has some effect in occasioning deviations from the natural number. Some have reckoned the number of respirations 14 in a minute, while others make it amount to 27, which shews that little dependence can be placed on any precise statement of the number. But even if this could be accurately ascertained, still it would not enable us to ascertain the quantity of air respired. For it is extremely probable that this quantity varies greatly in different men and in different animals, and in the same animal at different times, arising from causes, the operation of which either entirely eludes observation, or is altogether inappretiable. Accordingly we find that the differences of the results of observations made on the quantity of air taken in at a single inspiration, or of the quantity calculated in the lungs after expiration, are not less than those of the number of respirations.

6. The nature of the changes which the air inspired undergoes has been ascertained with more accuracy. 2510 Changes on the air.
Part of the air which is respired disappears; and this part consists of oxygen. Dr Menzies estimates the quantity of oxygen gas consumed by a man in 24 hours at rather more than 41 oz. troy. Lavoisier fixes it at $32\frac{1}{2}$ oz. nearly; and Sir H. Davy gives as the result of his experiments and calculations about $32\frac{1}{2}$ oz.

7. The air thrown out of the lungs by expiration contains at the same time a quantity of carbonic acid gas exactly equal in volume to the oxygen which disappears. 2511 Gases expired.

8. Water in the state of vapour is also thrown out of the lungs during respiration. 2512 Water.

9. The blood, as it flows from the left side of the heart, is of a bright red colour. It is conveyed from this organ by the arteries to every part of the body. It is then taken up by the veins, and carried back to the heart, by the venous system. The blood having thus circulated through the body, enters the right side of the heart, its colour being totally changed. It is now of a dark purplish red colour, instead of the bright red which it possessed when it passed out of the heart, to be distributed through the body. But before the blood can go to the left side of the heart to enter the general circulation again, it must pass through the lungs, where it re-acquires the bright red colour. From the lungs it proceeds to the left side of the heart, from which it flows as before through the arterial system to all parts of the body. The blood thus acquires this florid red colour in the lungs. 2513 Circulation of the blood.

10. This change was ascribed by some of the earlier chemical physiologists to the absorption of air. Dr Priestley observed that venous blood, which was of a dark colour, became of a bright red when exposed to oxygen gas, and that hydrogen gas produced a contrary effect. The same thing has been since observed by other chemists. According to Dr Priestley, the blood was deprived of its phlogiston as it passed through the lungs; according to the theory of Lavoisier and others, no part of the air inspired is absorbed; the blood gives out hydrogen and carbon, which, combining with the oxygen of the air, form water and carbonic acid. He supposed that the quantity of oxygen in the water and carbonic acid expired was equal to that which had disappeared during respiration. According to another theory, the oxygen gas combines with the blood, and while this combination takes place, the carbonic acid gas and water which are expelled from the lungs along with the azotic gas, are given out. According to later experiments, it appears that there is no reason for believing that any part of the air inspired passes into the blood. The oxygen, when it has entered the lungs, seems to unite there with the carbon, which is conveyed from the blood-vessels to the air-cells, by a species of secretion. Nor is there any reason for believing, that the formation of water by the combination of oxygen with hydrogen, 2514 Changes on the blood.

Functions of Animals.

gen, is one of the effects of the function of respiration.

2515 Purposes of respiration.

12. What are the purposes accomplished by these changes? What are the definite uses of respiration in the animal economy?—As the blood is the source from which are derived the materials for repairing the constant waste of the body, it is necessary that means should be provided to supply this waste, to which the blood is constantly subjected. This is accomplished, as we shall find afterwards, by the process of digestion, the product of which is conveyed to the blood. But before it can be converted into blood, it must undergo certain changes, which take place in the lungs. The separation of the superfluous carbon is an essential change, and the only one perfectly ascertained. There is one essential part of the blood, and an essential part also of solid animal organs, namely the fibrine, which does not exist in the chyle and lymph, which are the substances conveyed to the blood, to repair its waste, before they have passed through the lungs along with the blood. Hence it is supposed that one purpose of respiration is to form the fibrine of the blood.

2516 To form fibrina.

2517 To preserve temperature.

13. Another great purpose of respiration in the animal economy is to preserve the proper degree of temperature necessary for the health and life of the animal. It is well known that the temperature of animals is not regulated, like that of inorganized matter, by the surrounding medium. In whatever temperature animals are placed, except in those extreme degrees of heat or cold which destroy life, the temperature of the body continues almost uniformly the same, and this temperature, it appears, corresponds to the quantity of air inspired. Hence it is that the temperature of the lower orders of animals which require but a small proportion of air, as insects, fishes, and amphibious animals, is not much higher than that of the medium in which they live, and on this account they constitute a division of animals which have been distinguished by physiologists by the name of *cold-blooded animals.* The temperature of warm-blooded animals, whatever be that of the medium in which they live, is from 96° to 140°. The temperature of man is about 98°, while that of birds, which require a greater proportional quantity of air, is usually 5° or 6° higher.

2518 Theories of animal heat.

14. The manner in which the temperature of the body is kept up by means of respiration, has been thus accounted for, on the principles of Dr Black's theory of latent heat. Part of the latent heat of the air, which was inspired and combined with the blood, is given out, and thus raises the temperature of the blood, and that of the whole body through which it circulates. But if this change took place in the lungs, and all the latent heat of the air inspired was extricated in these organs, it was urged as an objection to this theory, that the temperature in them would be much higher than in other parts of the body. According to the theory of Crawford, the capacity of arterial blood for caloric, or the specific caloric of arterial blood, that is, the quantity of caloric which is necessary to raise it to a given temperature, is greater than that of venous blood; and the caloric disengaged in the lungs by the combination of oxygen with carbon, which is strictly analogous to the combustion of charcoal, immediately disappears again, being requisite to keep up the existing temperature of the blood, now enlarged in its capacity for caloric by passing from the venous to the arterial state. And the specific caloric of arterial blood, as it circulates through the body, is more and more diminished, in proportion as it is converted into venous blood; caloric, therefore, is evolved. In this way it has been proposed to obviate the objection of the temperature of the lungs being highest, if, as it has been supposed, the whole of the caloric is here evolved; and to account for its gradual evolution, and the consequent uniformity of temperature which exists in every part of the body. Such are two of the important purposes which seem to be accomplished by means of the function of respiration; namely, the complete formation of the blood, and the preservation of animal temperature.

II. Of Digestion.

1. The animal body is subject to continual waste, and the quantity of this waste varies according to the nature and age of the animal. This waste is repaired by the blood, which must consequently receive some supplies, to make up for its continual consumption. On this account, all animals require food or nourishment, to compensate for the waste of the body, and directly for the consumption of the blood from which this waste is supplied. 2519 Waste of the body.

2. Different animals, according to their nature, constitution, and the circumstances in which they are placed, require different kinds of food. Some animals live entirely on vegetables, others feed exclusively on animals, while a third class feed indiscriminately on vegetables and animals. But whatever be the kind of food, or whatever the nature of the animal, it is all converted, by the process of digestion, into the same uniform substance. In most animals the food, as it is taken into the mouth, is broken down, mixed with the saliva, and conveyed to the stomach, and after it has remained there for a short time, it is totally changed, and is converted into the uniform substance above alluded to, called *chyme.* 2520 Food of different animals different.

3. In attempting to account for the functions of the animal body, chemists and physiologists have been always too much disposed to consider the changes which take place within the body, as analogous to those which take place on inorganized or dead matter, in supposed similar circumstances. Accordingly we find among the speculations of philosophers, that digestion has been ascribed to fermentation. By one set it was ascribed to the vinous or acetous; and by another set to the putrefactive fermentation. But now, that the nature and circumstances of the processes both of fermentation and digestion have been more accurately observed, this opinion is exploded. The experiments of physiologists, also, have led to more rational views of the function. 2521 False analogies of physiologists.

4. It is now found, that the conversion of the food into chyme is effected by the action of a peculiar fluid secreted in the stomach, from which it has been denominated *gastric juice.* This liquid possesses different properties in different animals, for those animals which live entirely on vegetables cannot digest animal food, and the gastric juice of those which have been accustomed to live entirely on animals, has no effect on vegetables. It is true, indeed, that the nature of animals in this respect, as well as in most of their habits, may be 2522 Gastric juice.

Functions of Animals.

be completely reversed, when their habits are changed by slow degrees. All substances taken into the stomach are not equally acted upon by the gastric juice. Some of the hardest are readily dissolved, while others, seemingly less compact and durable, remain unaltered. The husks of grain in the stomachs of many animals resist its action, while the hardest bone is consumed.

2523 Its nature unknown. 5. No accurate knowledge has yet been obtained concerning the constitution of the gastric juice. According to some, it is of an alkaline nature; according to others, it possesses acid properties. But this difference of opinion is by no means to be wondered at, if we consider the difficulty, perhaps the impossibility, of obtaining the gastric juice in a state of purity, to subject it to chemical examination. Even if it were possible to collect it perfectly pure, its effects could not be the same as within the body, since all animal matters, the moment they are separated from the living body, begin to undergo new changes, and to exhibit new properties. All experiments, therefore, which have been made, to ascertain the nature of the gastric juice, and the process of digestion out of the body, must be regarded as inconclusive. They shew us the effects of this liquid in the state of dead matter, but can lead to no knowledge of its nature and properties while it exists in the living body (B).

2524 Food converted into chyme. 6. Whatever be the nature of this liquid, or the process of digestion, the food, as we have already observed, is broken down in the mouth and mixed with the saliva, which, in the first instance, probably contributes much to favour its commencement; for the process of digestion is considerably deranged when the secretion of saliva is interrupted, or its usual quantity diminished. All, then, that is certainly known concerning this change is, that the food conveyed to the stomach is in a very short time converted into chyme.

2525 Which is changed to chyle. 7. The chyme, which is a soft, pulpy matter, after being formed in the stomach, is carried to the intestines, where it is mixed with other substances, and undergoes new changes. As soon as it has passed into the intestines, it is converted partly into a milky fluid called chyle, and partly into excrementitious matter. Thus it is decomposed by some process, and separated into two parts, one of which is destined for the nourishment and reparation of the body, while the other is ejected.

2526 Chyle separated into two parts. 8. The chyle, when formed from the chyme, mixes with the bile which flows from the liver into the intestines. In consequence of this combination, it is supposed the excrementitious matter is separated from the chyle, and is thrown out of the body; while the chyle itself is taken up by a set of vessels called *lacteals*, which open on the inner surface of the intestines, and receiving this fluid, convey it to a large trunk in which they all terminate, denominated, from its situation in the thorax, the *thoracic duct*. The use of the bile is supposed to be, to separate the excrementitious matter which might prove injurious to the system, if it were absorbed along with the chyle; for this purpose the bile, it is supposed, is decomposed; its saline and alkaline constituents combine with the chyle, by which it becomes more liquid, while the resinous and albuminous matter, combine with the excrement, and in this state act as a stimulant to the intestines, so that the contents, which might prove injurious, if long retained, are the more speedily ejected.

9. As a proof that the food which has been taken into the body has been totally changed, substances have been detected in the excrement of different animals which did not previously exist in the food. According to Vauquelin, excrementitious matter is always distinguished by an acid property. Benzoic acid has been detected in that of horses and cows. An acid of a peculiar nature has been found in the dung of pigeons; in general this matter is much disposed to ferment, and at last gives out ammonia. 2527 Is totally changed.

In the analysis of the excrement of a hen by Vauquelin, compared with the nourishment, he found that while the oats which were taken in were composed of phosphate of lime and silica, that the shells of the eggs, and the excrements which were examined, consisted of phosphate of lime, carbonate of lime, and silica. The proportion of silica which was found in the excrement was less than the quantity taken in; but the quantity of phosphate of lime was increased, and a quantity of carbonate of lime, which did not previously exist in the food, was formed *.

* *Ann. de Chim.* xxix.

10. Little is known of the properties of the chyle, excepting that it possesses some in common with milk. Like milk, it coagulates, and divides into a serous and oily matter. In the thoracic duct the chyle is mixed with another fluid called the lymph, which is conveyed from all parts of the body by a set of vessels denominated the *lymphatics*. This fluid is in considerable quantity, is viscid and colourless; but from the difficulty of collecting it, little is known of its properties. The lymph and the chyle, thus mixed together, are conveyed by the thoracic duct to the blood-vessels. It is mixed with the blood in the veins, and conveyed by them to the right side of the heart, from which it is carried to the lungs, where it undergoes the changes already described in the account of respiration, and the whole is converted into arterial blood, which returns to the left side of the heart, from whence it is distributed to all parts of the body. 2528 Properties of chyle. 2529 Of lymph.

III. Of Secretion.

1. In the course of the circulation of the blood, different substances are separated from it, some of which are destined for the growth and nourishment of the body, as in young animals, or for the repair and supply of parts that are destroyed; while other substances, which seem either to be superfluous, or if retained, would 2530 Matter separated from the blood.

(B) The stomachs of young animals contain a substance which has the property of coagulating milk. Acids also have this property, from which it has been concluded that the substance in the stomach of young animals, which produces this effect on milk, is of an acid nature; but it ought to be recollected, that when used by us it is out of the body, and has undoubtedly undergone new changes; and besides, it is not known exactly what different substances may have the property of inducing this change on milk.

Functions of Animals.

would be injurious, are thrown out of the body. These secretions are performed by peculiar organs, the description and operation of which belong to ANATOMY and PHYSIOLOGY. At present we will give a short account of two of the most important of these secretions, namely, the secretion of urine, and that of perspirable matter.

2531 By the kidneys.

Secretion of urine.—The urine, which is an excrementitious matter, is separated from the blood by the action of the kidneys. According to the observations of anatomists and physiologists on the structure and office of these organs, a great proportion, or even, as some suppose, the whole of the blood, passes through them. As the urine secreted by these organs seems to serve no purpose in the animal economy, since the whole of it is thrown out, it is probable that the substances of which it is composed, or at least their constituents, would have proved injurious if they had been retained.

2532 Is an important change.

2. Whatever the change be which takes place on the blood by the action of the kidneys, it is of the utmost importance to the health and even to the life of the animal; for if these organs are destroyed by disease or accident, death is the certain consequence.

3. By the action of the kidneys on the blood, new substances make their appearance. Such are urea and uric acid, which exist in the urine, but cannot be detected in the blood; but the bases or constituents of these substances must have formed part of some of the matters of the blood, which are therefore decomposed for their evolution; and this decomposition must take place in these organs. The urine, or secreted matter, has been accurately analysed, and its component parts, after it is thrown out of the body, pretty well ascertained; but it is yet unknown what are the peculiar changes which the blood undergoes by the action of the kidneys.

2533 Secretion from the skin.

Perspiration.—1. A considerable quantity of matter is separated from the blood by means of a set of vessels on the skin of animals. This action is called *perspiration*, and the substance emitted, *perspirable matter*. The attention of physiologists and chemists has been long directed to ascertain the quantity and nature of the matter thus thrown off. To ascertain the first point, many experiments have been made. Sanctorius, an Italian physician, was the first who made this attempt, by weighing himself at stated times for many years, and estimating the quantity of food which was taken in, and the quantity of excrementitious matter thrown off. The difference, he supposed, indicated the quantity of matter perspired; but neither in his experiments, nor in those of many others, who endeavoured to ascertain the same thing, was any estimate made of the quantity of matter given out by the lungs.

2534 Quantity.

2. With this distinction in view, a set of experiments was instituted by Lavoisier and Seguin. The latter was inclosed in a varnished bag, which prevented the escape of every thing thrown off from the body, excepting what was lost by respiration. Having previously weighed himself, and continued the experiment for some time, the quantity of matter thrown off by respiration was ascertained, by weighing a second time. By weighing himself afterwards without the covering, and repeating the operation at the end of a similar interval, he was enabled to ascertain the quantity lost by cutaneous transpiration alone, by subtracting what had been previously ascertained to have passed off from the lungs, from the whole diminution of weight indicated in the preceding experiment. From the experiments thus conducted, the following conclusions were drawn.

a. In a state of health, and when there is no disposition to corpulence, the body returns to the same weight once every 24 hours.

b. Indigestion retards transpiration. The weight is increased for four days, and on the fifth the body returns to its original weight.

c. Drink only, and not solid food, increases the perspiration. It is least at the moment of taking food, and immediately after.

d. The perspiration is greatest during digestion.

e. The greatest quantity of matter perspired amounted in a minute to 26.25 grains troy; the least to nine grains.

f. The pulmonary transpiration is proportionally greater than that of the skin. It is greater in winter, on account of the necessity of preserving the temperature of the body.

3. The quantity of matter perspired is greatest during hot weather, and in hot climates. The quantity too bears a relation to the quantity of urine. The following are the results of the experiments of Rye, made in Ireland, on the relative proportion of urine and perspirable matter, which were excreted in the course of one day at different seasons of the year.

	Matter perspired.	*Urine.*
	Ounces.	Ounces.
Winter,	53	42
Spring,	60	40
Summer,	63	37
Autumn,	50	37

4. When the temperature to which the body is exposed is much elevated, the quantity of perspired matter is greatly increased, and it then appears in a visible liquid form called *sweat*. This answers a very important purpose in the animal economy, for by this means the equilibrium of temperature is preserved. The heat which is absorbed is carried off along with the matter which evaporates from the surface of the body, and thus the increase of temperature, which would otherwise prove fatal, is prevented. 2535 Sweat.

5. The next object of chemical physiologists was to ascertain the nature of the substance which is perspired. This has been found extremely difficult, on account of the small quantity which it has been possible to collect. But it has been ascertained to consist chiefly of water and carbon, with an oily matter. Phosphoric acid also, and phosphate of lime, have been detected in the perspirable matter. In the air which has been confined in contact with the skin, carbonic acid gas has been detected; from which it is concluded, that either the carbon must have been evolved, and combined with the oxygen of the air, or the oxygen gas must have been absorbed, and combining with the carbon, is given out in the state of carbonic acid. The former is the conclusion drawn. The oily matter which is emitted by the skin, is supposed to occasion the 2536 Component parts.

Functions of Animals. the peculiar smell by which animals are distinguished. The remarkable circumstance of a dog being able to trace another animal to a great distance by the smell, or to discover his master by the same means to a much greater distance, is ascribed to the emission of this matter. The matter perspired, according to Berthollet, possesses acid properties, and the acid he supposes is the phosphoric. Phosphate of lime has been detected in the skins of horses by Fourcroy and Vauquelin.

2537 Other secretions. Besides these there are other secretions which are destined for peculiar purposes in the animal economy, or immediately connected with the functions of particular organs, or parts of the system. Such is the secretion of saliva in the mouth, of tears in the eyes, of mucus in the nose, and wax in the ears. The secretion of milk in the female is destined for the nourishment of the offspring; but we shall not enter into the description of the organs employed in these secretions. The nature and properties of the matters secreted will come under our consideration in treating of the different parts of animals.

IV. Of Assimilation.

2538 Waste of the body must be repaired. 1. The continual waste and decay of the body require to be repaired. This, as we have already seen, is the purpose of taking nourishment into the body; part of which being subject to the processes of digestion and respiration, is converted into blood, from which source are derived those supplies of new matter which are wanted in the formation of new parts, or to make up the general decay of the system. New supplies of matter are peculiarly necessary, in young animals, in which the parts already formed increase in size and consistency, and in which, in the progress of the growth of the body, entirely new parts are evolved. But if there be any truth in the speculations of physiologists, of the whole matter in the body being periodically changed, even after it has arrived at its full growth, a constant supply of new matter becomes absolutely necessary. All these supplies are furnished by the blood, and for this purpose it is distributed to every part of the body. The materials for repairing the general waste, for increasing those parts which are already formed, or for the formation of new parts, are all derived from it. From this source are derived the most fluid, as well as the most solid parts of the body; the saliva of the mouth, and the gastric juice of the stomach, so necessary in the function of digestion, by which the health and life of the animal are preserved, as well as the bones and muscles, which give it strength, firmness and motion. The process by which the different substances furnished by the blood for the repair of some parts and the formation of others, has been distinguished by the name of *assimilation*, because, in consequence of new actions and combinations, matter exactly similar to the parts repaired or renewed, is deposited, which did not previously exist in the blood.

2539 By particular organs. 2. These changes are effected by the action of peculiar organs or vessels. Whatever be the nature of the food taken into the stomach, it is converted into chyme by the process of digestion. This again, by a farther change, as it passes into the intestines, forms the chyle, which is conveyed to the blood, and after this fluid has undergone the changes which are induced on it by respiration, it has acquired those properties which render it fit for the important purposes to which it is destined. Decomposition of Animal Substances.

3. By the action of the different secretory organs, the same matter is always separated in each from the blood, while the animal continues in the healthy state. The perspirable matter is separated by the glands or vessels on the skin, and the saliva is prepared by the glands of the mouth. The matter of bones, of muscles, or of nerves, is separated and deposited in those places where it is required, and no other. While the body continues healthy, muscular matter is not deposited among the bones, nor is osseous matter mixed with the muscles. 2540 Which always secrete the same matter.

4. The most astonishing part of the animal system is that power which it possesses of accommodating itself to particular circumstances. It would be less surprising that the same actions and the same functions, after they have commenced, should continue to be performed with uniformity and regularity. But, in the animal system, new actions take place, or at least those which were comparatively feeble and limited, become more powerful and more extensive. Thus, a part of the body which has been destroyed or removed is, by this new or extended action, completely renovated. A large piece of muscle in the healthy state of the body is soon renewed; and, what is more surprising, the constituent parts of bone are prepared, when necessary, and deposited in those places where large pieces of this substance have been removed. 2541 Functions vary with circumstances.

5. But although some, or perhaps all these changes which take place in the different processes going on in the animal system, are of a chemical nature, yet they are subject to the controul of some power, the characteristics of which are totally different from those of a chemical or mechanical agent. This is the living principle, which counteracts, regulates, and directs the effects of chemical agents. It is by means of this power that the materials of which the different parts of the body are composed, are deposited in their proper places. It is by means of the same power that a greater quantity of matter necessary for the renovation of any particular part which has been destroyed, is prepared and deposited exactly in that place where it is wanted. But the power of this agent is limited. Certain substances taken into the stomach, which are unfit for digestion or nourishment, are immediately rejected; others are too powerful, and destroy the organ itself. As the strongest proof of the existence and controul of this power, the constituent parts of animal bodies begin immediately to decompose each other as soon as its action has ceased. The gastric juice of the stomach, which acts only on the substances introduced into it in the living state, has been sometimes found to corrode and destroy the stomach itself, after death. But the investigation of the nature of this agent, and of its influence on the animal body, belong to PHYSIOLOGY. 2542 Are regulated by the living principle.

SECT. II. *Of the* DECOMPOSITION *of* ANIMAL SUBSTANCES.

1. As soon as an animal has ceased to live, its frame and texture are destroyed, the constituent parts are separated,

Decomposition of Animal Substances.

parated, they enter into new combinations, new substances are formed, and the component parts are totally changed. The rapid spontaneous decomposition of animal matters, which has been called *putrefaction*, is one of the most striking characters by which they are distinguished. Vegetable matters, we have seen, when vegetation ceases, are also subject to decomposition; but in them the process is slow and gradual, and many of the products are totally different.

2543 Decomposition of vegetables and animals different.

2544 Owing to the difference of composition.

2. The remarkable difference between the spontaneous decomposition of vegetables and animals, depends on the difference of the constituent parts of these two classes of organized substances. Animal matters are composed of a greater variety of constituent principles, and hence arises a greater variety of action, when the different component parts begin to act on each other. By the numerous and complicated attractions which exist among these constituent principles, decomposition is more readily effected, and a greater variety of new products make their appearance.

2545 Conditions of putrefaction.

3. But notwithstanding the varied and complicated structure of animal substances, total decomposition or putrefaction does not take place, except in certain circumstances, by which the mutual action of the constituent principles is promoted. The chief circumstances necessary for the putrefaction of animal matter are, moisture and moderate heat. Dry animal matters hardly undergo any change. Bones, when moistened with water, the soft parts of animals, and still more the liquid parts, run rapidly on to putrefaction. Heat is also necessary to promote this change. No putrefaction takes place at or below the freezing temperature. Before it commences, the temperature must be elevated some degrees above this point, and as the temperature rises, the rapidity of the process is proportional. This condition, however, has its limits; for when the heat reaches a certain point, so far from promoting the process of putrefaction, it totally retards or interrupts it, by carrying off the moisture. The contact of air was once thought necessary to favour this process; but although it appears that this is not an essential condition, putrefaction goes on more rapidly in the open air, perhaps by receiving and carrying off the elastic fluids as they are formed, as well as by the action of its oxygen. Matters which have already undergone this change, brought in contact with recent animal substances, promote and accelerate their putrefaction.

2546 Phenomena.

4. When animal matters are placed in favourable circumstances, the solid parts become soft, and the liquid parts more fluid. The colour changes, and is converted into a reddish brown, or deep green. The odour, which is at first disagreeable, becomes fetid and insupportable. An ammoniacal smell is diffused; but this is only temporary, while the putrid odour continues during the whole process. The liquids become turbid, the soft parts are melted into a kind of jelly, accompanied with an intestine motion, and an enlargement of the bulk of the whole mass, owing to the escape of elastic fluids, which are slowly disengaged. The whole matter is then reduced to one mass, the swelling ceases, the bulk is diminished, and the colour deepens. Towards the end of the process, a peculiar odour, somewhat aromatic, is emitted. When it ceases entirely, an unctuous, viscid, and fetid earthy mass remains behind.

5. The duration of this process is extremely various, according to the nature of the substances and the circumstances in which they are placed; but it has been divided by some into different stages. In the first there is merely a tendency to putrefaction, accompanied with a very slight change of texture and colour. The second change, or incipient actual putrefaction, exhibits some traces of acidity; the parts are more softened, a serous matter begins to flow from the relaxed fibres; the colour is more altered, and the putrid fetid odour exhaled. In the third or more advanced stage of putrefaction, the fetid odour is more or less mixed with the smell of ammonia; the dissolved putrid matter acquires a deeper colour, and is diminished in weight by the escape of a great quantity of volatile matter. In the last stage, or when the process is completed, the ammoniacal odour vanishes, the fetid smell becomes less powerful, and is often succeeded by something of an aromatic smell. The animal matter has diminished greatly in bulk, and has lost all appearance of organized structure. There remains only a dark brown, earthy substance, unctuous to the feel, which has been called *animal earth*. But these changes are regulated by the particular circumstances in which the process takes place.

Decomposition of Animal Substances.

2547 The period different.

2548 Elastic fluids.

6. In the course of the putrefactive process of animal substances, different gases are successively emitted. These are chiefly carbureted, sulphureted, and phosphureted hydrogen gases, water in the state of vapour, ammonia, and carbonic acid gas. These bodies are evolved and volatilized, carrying with them some of the principal constituents. Other products, formed at different periods of the process, and of a more fixed nature, make their appearance; such, for instance, are an unctuous matter, and a kind of soap, formed of this matter and ammonia; such too is nitric acid, which is frequently formed during this decomposition, and is combined with an earthy or alkaline base; and such finally is the unctuous earth which remains after the evolution and separation of the former products.

2549 Nature of the process.

7. The process of putrefaction, then, consists in a change produced by the action of affinities, more powerful than those which hold together the constituent principles of the animal matter. These constituents are, hydrogen, azote, carbon, and oxygen, with a small proportion of sulphur, phosphorus, and different species of phosphates. During the decomposition, a portion of the hydrogen combines with azote to form ammonia, while another portion probably combines with part of the oxygen to form water; part of the carbon is united with a portion of oxygen, to form carbonic acid; the union of azote with a third portion of oxygen constitutes nitric acid; a combination of hydrogen, carbon, and azote, yields a volatile or fixed oil, according to the proportion of the constituents; and finally, the saline, earthy, and metallic substances, which are little susceptible of change, during this process, remain unaltered, and constitute the residuum. Thus, in taking a general view of the affinities which come into action during this process, the amount of those which tend to combine the hydrogen with the azote, to form ammonia; the oxygen with the carbon, to form carbonic acid; the carbonic acid with the ammonia, to form carbonate of ammonia; the hydrogen, carbon, and oxygen, to form oil, and this last with ammonia

Component Parts of Animal Substances. ammonia to constitute soap, besides the hydrogen and oxygen to form water, is greater than the sum of the forces which retain in combination, the hydrogen, the azote, the carbon and oxygen, which are the principal constituents of animal compounds.

2550 In the open air. 8. Such are the results when the process is conducted in close vessels. When it takes place in the open air, similar results are obtained, but in a manner somewhat different, according to the nature of the compounds which are formed. In this case part of the animal substance is dissolved, and carried off by the air and the water. The ammonia and carbonic acid are dissipated as they are formed; part of the carbureted hydrogen is also volatilized by the increase of temperature, and no unctuous matter or ammoniacal soap is formed.

2551 Cause of the fetid odour. 9. It is well known that the odour which proceeds from putrid animal matters is extremely offensive. This is owing, in a great measure, to the sulphureted and phosphureted hydrogen gases disengaged. This is not merely offensive, but noxious to the health, and sometimes destructive to the life of animals. These effects are no doubt owing to the putrid effluvia which are exhaled, and which are taken into the lungs during respiration. To counteract the effects of those putrid exhalations, attention should be paid to agitate the air of inhabited places by proper ventilation, which may be done by burning wood in the vicinity of infectious air, so that the smoke may be mixed with it, or by directing currents of water into similar places. To destroy the noxious effects of putrid *miasmata*, which are produced in confined places, frequented by numbers of people, muriatic acid gas, disengaged from common salt by means of sulphuric acid, has been successfully employed. Oxymuriatic acid gas has also been proposed for the same purpose.

2552 Method of preserving animal matters. 10. It is an object of considerable importance in domestic economy, to prevent the process of putrefaction in those animal substances which are to be preserved and employed as food. It is also an object of some importance for many other purposes. Different methods have been proposed to accomplish this. It is effected by depriving the animal matters entirely of their moisture, without which the process is interrupted. Animal matters are also preserved by keeping them at the freezing temperature, or below it. The same object is attained by covering up matters to be preserved with such substances as readily enter into combination with water, and thus prevent its effects upon the animal matters. The acids, sugar, alcohol, and some salts, it is supposed, act in this way, by preventing putrefaction. With the same view aromatic and resinous substances, volatile oils, camphor, the powder of dried astringent and fragrant plants, charcoal and bitumen, are employed.

Sect. III. *Of the* Component Parts *of* Animal Substances.

Having given a short account of the functions of living animals, and of the spontaneous decomposition which takes place after death, we now proceed to take a view of their component parts, as they have been investigated by chemical analysis. This shall be the subject of the present section, which, for the sake of perspicuity of arrangement, will be subdivided under the four following heads: I. Of the constituent parts of animal substances in general. II. Of the liquid parts of animals. III. Of the solid parts; and IV. Of substances peculiar to different classes of animals. Component Parts of Animal Substances.

I. Of the Constituent Parts of Animal Substances in General.

The simple substances which enter into the composition of the different parts of animals, are chiefly azote, carbon, hydrogen, and oxygen, of which, arranged in different proportions, the soft parts are composed; phosphorus and calcium, which constitute the basis of the hard parts; sulphur, the fixed alkalies, muriatic acid, iron, and manganese. But by the constituent parts of animals, are here to be understood those substances into which they are resolved by analysis. Some of these are compound, and some are simple, as will appear from the following enumeration. 2553 Elements.

2554 Component parts.

1. Gelatine,
2. Albumen,
3. Fibrina,
4. Urea,
5. Sugar,
6. Oils,
7. Resins,
8. Phosphorus,
9. Sulphur,
10. Acids,
11. Alkalies, earths, and metals.

I. Of Gelatine.

1. Glue, a well known substance in the arts, is gelatine in a state of impurity. This may be obtained pure by repeatedly washing the fresh skin of an animal in cold water, afterwards boiling it, reducing it to a small quantity by a slow evaporation, and allowing it to cool. It then assumes the form of a solid tremulous substance called jelly. When this substance is dried in the air, it becomes hard and semitransparent. 2555 Preparation.

2. Gelatine has different degrees of hardness, and when pure, it is colourless and semitransparent. It is brittle, breaks with a vitreous fracture, and has neither taste nor smell. 2556 Properties.

3. When it is exposed to heat, in the dry state, it becomes white, then blackens, and is converted into a coaly matter. Tremulous gelatine melts before it undergoes these changes. When it is distilled, it affords a watery fluid, impregnated with ammonia and a fetid oil. A voluminous mass of charcoal remains behind. 2557 Action of heat.

4. Gelatine remains unaltered in the dry state by exposure to the air; but the solution in water is soon decomposed, giving out an acid, the nature of which is unknown, a fetid odour, and some ammonia. It is not very soluble in water; it increases in bulk, and becomes soft and tremulous. In this state it soon dissolves in warm water; but as the solution cools, it returns to its former state. 2558 Of air and water.

5. With the assistance of heat gelatine is readily dissolved 2559 Acids.

Component Parts of Animal Substances.

solved by the acids. Sulphuric acid acts slowly on this substance, and forms a brown solution, which becomes gradually darker with the evolution of sulphurous acid. Nitric acid, by digestion on gelatine, is decomposed; azotic gas is evolved, and afterwards a great quantity of nitrous gas. The gelatine is dissolved, and converted partly into oxalic and malic acids, and an oily matter which remains on the surface. Muriatic acid readily dissolves gelatine, and forms a brown-coloured solution, from which a white powder is gradually precipitated. When this solution is added to the solution of tan in water, a copious precipitate is formed.

2560 Alkalies.

6. Gelatine is readily dissolved by the alkalies, with the aid of heat. There is no action between any of the earths and this substance.

2561 Metallic oxides.

7. Some of the metallic oxides form precipitates with gelatine in its solution in water. The compound thus formed is insoluble. Similar precipitates are occasioned by some of the metallic salts.

2562 Tan.

8. Gelatine forms a copious white precipitate with tan. A brittle compound is thus produced, which is insoluble in water, and is not changed by exposure to the air.

2563 Composition.

9. The component parts of gelatine are carbon, hydrogen, azote, and oxygen, with some traces of phosphate of lime and of soda, but the proportions of these substances have not been determined.

2564 Different kinds.

10. There are various kinds of gelatine, probably arising from slight variations of the proportions of its constituents, or from the addition of other substances, the nature of which has not been distinctly ascertained. Glue is extracted from different animal substances, as bones, muscles, membranes, but especially from skins, by first steeping them in lime-water, to purify them from all extraneous substances, and afterwards boiling them with pure water. The strongest glue is obtained from the skins of old animals. What is called *size*, is a weaker kind of glue, which is colourless and transparent, and is extracted from the skins of eels, horses, cats, rabbits, and from some kinds of white leather. It is this which is employed in the manufacture of paper, and in gilding and painting. Isinglass, another kind of glue, is extracted from different parts of the sturgeon, and some other fish.

2565 Found in different parts of animals.

11. Gelatine forms a principal part both of the solid and fluid parts of animals. It is found in blood and in milk, in the bones, ligaments, skin, and other solid parts.

2566 Uses.

12. Animal jelly, which is gelatine, is well known as a very nutritious food, and is much employed in the state of glue, size, and isinglass, in numerous arts.

II. Of Albumen.

2567 Obtained from eggs.

1. The white of an egg consists chiefly of albumen. It is combined with a portion of soda and sulphur. From these substances it cannot be separated without decomposition, so that its properties are probably modified by them.

2568 Action of heat.

2. When albumen is exposed to a heat of about 165° it coagulates into a solid white mass, of different degrees of consistency, according to the duration of the heat applied. This is the characteristic property of albumen. In this state it has totally changed its properties. Formerly soluble in water, it cannot now be dissolved in that liquid, either hot or cold.

2569 Cause of coagulation.

Different opinions have been formed concerning the nature of this change, or the cause of the coagulation of albumen. It has been ascribed by some to the absorption of caloric, and by others to that of oxygen. The former opinion was that of Scheele, and the latter is supported by Fourcroy; but this coagulation is found to take place when air is entirely excluded, or without any change being produced in the surrounding air. It has been supposed by others, that the coagulation is produced by the extrication of caloric, as in other cases when fluid bodies are converted into solids. According to an experiment of Fourcroy, this extrication of caloric actually takes place; but it is ascribed by others to a different arrangement of the particles of the albumen, which is induced by the action of the heat applied.

2570 Properties of uncoagulated albumen.

3. The properties of albumen, it has been observed, are very different after coagulation. Before coagulation it is a glairy liquid which has scarcely any taste, and no smell. When dried in a moderate heat, it becomes brittle and transparent, and by being spread thin, forms a varnish. When thus dried, it is not changed by exposure to the air, but otherwise it soon becomes putrid.

2571 Action of heat.

4. Albumen is coagulated by means of the acids. With the aid of heat, sulphuric acid dissolves it, and forms a solution of a green colour. By the action of nitric acid, azotic gas is disengaged: the albumen is then dissolved; nitrous gas is given out, and oxalic and malic acids are formed, besides a thick oily substance which appears on the surface. The coagulation of albumen does not take place when it is dissolved in a great proportion of water. Albumen is also coagulated by means of alcohol and ether, but if the quantity of water in which it is dissolved be considerable, the coagulation is not effected.

2572 Acids.

2573 Alkalies.

5. By trituration with a concentrated solution of pure potash, albumen, left at rest for some time, coagulates, and is converted into a substance resembling jelly, which is brittle and transparent when it is dried. No change takes place on albumen by the action of the earths.

2574 Metallic salts.

6. Albumen is precipitated, from its solution in water, by many metallic salts. The precipitate is white, yellow, or brown, according to the metal employed.

2575 Tan.

7. Tan precipitates albumen from its solution in water, in the form of a copious yellow substance, which is insoluble in water. It becomes brittle when dry, and is not changed by exposure to the air.

2576 Properties.

Coagulated albumen.—1. Albumen, when it is coagulated, acquires new properties. It is then a tough, opaque substance, of a pearly white colour, and of a sweetish taste. It is insoluble in water, and is less subject to change. When it is dried in the temperature of 212°, it is converted into a hard, brittle, yellowish substance, of the transparency of horn. When it is some time digested in water, it becomes soft, white, and opaque, like albumen newly coagulated. By long action a small part seems to be dissolved, but no precipitation is formed in this solution by the infusion of tan.

2577 Action of heat.

2578 Acids.

2. The mineral acids, largely diluted with water, dissolve a portion of coagulated albumen; but by the addition

omponent Parts of Animal ıbstances.

addition of the same acids in their concentrated state, it is again precipitated. If coagulated albumen be kept in diluted nitric acid for several weeks, the acid acquires a yellow colour, which gradually deepens; the albumen becomes more opaque, but is not dissolved. By saturating the yellow-coloured acid with ammonia, no precipitate is formed, but it assumes a deep orange colour. If the albumen be then introduced into liquid ammonia, the latter assumes a deep orange colour, inclining to red. The albumen dissolves slowly, and after the solution is completed, it is of a yellowish-brown colour. By washing and boiling in water, the albumen thus treated with nitric acid is dissolved, the liquid becomes of a pale yellow, and assumes the form and appearance of jelly, when it is concentrated. If this mass be dissolved in boiling water, the solution is precipitated by tan; so that nitric acid has the property of converting coagulated albumen into gelatine.

2579 kalies. 3. Coagulated albumen is readily dissolved in a solution of potash by boiling. Ammonia is disengaged, and a soap is formed. If this soap be dissolved in water, and muriatic or acetic acid be added, a precipitate is formed which also has the properties of soap. When it is moderately heated, a portion of oil flows out, and a viscid brownish substance remains behind.

2580 mposition. 4. Albumen is composed of carbon, hydrogen, azote, and oxygen, but the proportions have not been determined. It is supposed by some that it contains a greater proportion of azote than gelatine.

2581 ists in ferent ts of mals. 5. Albumen constitutes an essential part in the composition of bones and muscles. Cartilage, horns, and hair, consist almost entirely of this substance, as well as the membranous portion of shells and sponge.

2582 es. 6. Albumen is advantageously employed for clarifying liquids. The liquid to be purified is mixed with the white of eggs, the serous part of the blood, or other substances containing albumen, and then heated. By the action of heat the albumen is coagulated, and falls to the bottom, carrying with it those substances which were mixed with the liquid, and occasioned the opacity, and which, on account of the minuteness of the particles, could not be otherwise separated.

III. Of Fibrina.

2583 ained n blood. 1. Fibrina is readily obtained by allowing blood to remain at rest for some time after it has been drawn from an animal. The clot, which has formed and falls to the bottom, is to be separated, put into a linen cloth, and repeatedly washed with water, till the liquid come off insipid and colourless. The fibrous part of the blood, as it has been called, or the fibrina, remains behind.

2584 m mus- Mr Hatchet obtained it by cutting lean beef into small pieces, macerating in water for fifteen days, changing the water daily, and squeezing it out at the same time by pressure. The muscular substance was boiled every day five hours for three weeks in a fresh portion of six quarts of water. The fibrous substance was then pressed, and dried with the heat of a water bath. What remained is considered as fibrina nearly pure.

2585 perties. 2. Fibrina is of a white colour, soft and elastic, when it is recently extracted from blood; and as it dries the colour becomes deeper. When it is extracted by boiling and maceration from muscular matter, it is brittle, has some degree of transparency, and does not become so deep in the colour. It has neither taste nor smell. It is insoluble in water and alcohol, and is not changed by exposure to the air.

3. When it is exposed to heat, it contracts suddenly, and emits the smell of burning feathers. It melts with an increase of temperature. It yields by distillation, water, carbonate of ammonia, a thick fetid oil, carbonic acid, and carbonated hydrogen gas, with some traces of acetic acid. The coaly matter which remains behind burns with difficulty, on account of the phosphate of soda, phosphate and carbonate of lime, with which it is mixed. 2586 Action of heat.

4. Fibrina is soluble in the acids. The solution in sulphuric acid is of a deep brown colour; charcoal is precipitated, and acetic acid formed. When diluted nitric acid is added to fibrina, azotic gas is copiously disengaged. Fibrina kept by Mr Hatchet for 15 days in nitric acid diluted with 3 times its weight of water, gave to the solution a yellow colour, and it resembled in its properties the solution of albumen in the same acid. By this process, after being dissolved in boiling water, and concentrated by evaporation, the fibrina is converted into gelatine, which is soluble in hot water, and is precipitated by tan. The fibrina in this state also is almost entirely dissolved by ammonia, and the solution is of an orange colour. Fibrina is dissolved in boiling nitric acid, in which ammonia produces a precipitate, composed chiefly of oxalate of lime. During the action of the nitric acid, prussic acid passes over, with carbonic acid gas and nitrous gas. Oxalic acid is formed, and a fatty matter appears on the surface. Fibrina is also soluble in muriatic acid, with which it forms a green-coloured jelly. It is dissolved also in acetic, oxalic, tartaric, and citric acids, with the assistance of heat; and is converted, by concentrating the solutions, into a gelatinous mass. Alkalies precipitate fibrina from its solution in the acids, in the form of flakes which have the properties of gelatine, and are soluble in hot water. 2587 Acids.

5. Concentrated potash or soda, boiled upon fibrina, forms a deep brown coloured solution, which has the properties of soap. During the process ammonia is given out.

6. Fibrina is composed of carbon, hydrogen, azote, and oxygen, but the proportions are unknown. It is found only in the blood and muscular parts of animals.

IV. Of Urea.

1. The nature and properties of urea have been chiefly investigated by Fourcroy and Vauquelin. It is obtained from urine. It may be extracted by the following process.

If a quantity of human urine which has been passed a few hours after taking food, be evaporated with a gentle heat, to the consistence of a thick syrup, and allowed to cool, it concretes into a crystalline mass. Add to this mass in separate portions four times its weight of alcohol; with the application of a gentle heat, great part is dissolved, and what remains consists of different saline substances. Separate the solution from the undissolved part, and introduce it into a retort. Distil with the heat of a sand bath, and continue 2588 Method of preparing.

Component Parts of Animal Substances.

the boiling till the liquid is reduced to the form of a thick syrup. The matter which remains in the retort crystallizes as it cools. The crystals thus formed are *urea*.

2589 Properties. 2. Urea, which is prepared by this process, is crystallized in the form of plates, crossing each other. It is viscid, resembling thick honey, and of a yellowish white colour. It has a strong acid taste, and a fetid alliaceous smell. It deliquesces in the air, and by attracting moisture is converted into a thick brown liquid. It is very soluble in water, and also in alcohol. The solution in water concentrated is of a brown colour. This solution is gradually decomposed, air is emitted, which is partly composed of ammonia, and acetic acid is formed in the liquid. If the solution in water be boiled, and as the evaporation goes on fresh portions of water be added, the urea is decomposed; carbonate of ammonia is disengaged, while acetic acid is formed and charcoal precipitated.

2590 Action of heat. 3. By the action of heat urea soon melts, enlarges in bulk, and evaporates, emitting an extremely fetid smell. By distillation, benzoic acid first passes over, afterwards carbonate of ammonia, carbonated hydrogen gas, with a small portion of prussic acid and oil. What remains behind consists of charcoal, muriates of ammonia and of soda. The benzoic acid, the muriate of ammonia and muriate of soda, are considered as extraneous matter, so that the products of

2591 Composition. urea by distillation consist of the carbonate of ammonia, carbureted hydrogen gas, and charcoal. The component parts of urea, therefore, are supposed to be,

Oxygen	39.5
Azote	32.5
Carbon	14.7
Hydrogen	13.3
	100.0

2592 Action of acids. 4. If one-fourth of its weight of diluted sulphuric acid be added to the solution of urea, and heat be applied, an oily matter appears on the surface, which concretes on cooling. Acetic acid is found in the liquid which is collected in the receiver, and sulphate of ammonia remains in the retort. The whole of the urea may be converted into acetic acid and ammonia by repeated distillation.

Nitric acid produces a violent effervescence with the crystals of urea. The liquid becomes dark red, and during effervescence nitrous gas, azotic gas, and carbonic acid gas, are evolved. A concrete white matter remains after the effervescence has ceased, mixed with a small portion of the red liquid. The residuum produces a detonation with the application of heat.

Urea is soluble in muriatic acid, but it remains unchanged. A diluted solution of urea absorbs very rapidly oxymuriatic acid gas. Whitish flakes appear, which soon become brown, and adhere to the sides of the vessel. After the absorption, the solution gives out carbonic acid and azotic gases. Muriate and carbonate of ammonia remain in the liquid after the effervescence ceases.

2593 Alkalies. 5. Urea is readily dissolved in solutions of potash or soda. Ammonia is also disengaged, when urea is dissolved in solutions of barytes, lime, or magnesia. It is also disengaged by triturating pure potash in the solid state, with urea. Heat is produced at the same time. The mixture assumes a brown colour, and an oily matter is deposited.

Muriate of soda, dissolved in a solution of urea in water, affords, by evaporation, crystals in the form of regular octahedrons; but muriate of ammonia, dissolved in the same way, crystallizes in the form of cubes.

V. Of Sugar.

1. Sugar has only been discovered among animal matters in milk and in the urine of persons labouring under *diabetes*. Sugar is obtained from milk by evaporating fresh whey to the consistence of honey. When it cools, it concretes into a solid mass. This is to be dissolved in water, and being previously clarified with the white of eggs, to be filtered and evaporated to the consistence of syrup. Crystals of sugar of milk are deposited on cooling. 2594 Extracted from milk.

2. When sugar of milk is pure, it is of a white colour, has a sweetish taste, but no smell. It crystallizes in the form of regular parallelopipeds, terminating in four-sided pyramids. The crystals are semitransparent. The specific gravity is 1.543. It is soluble in seven times its weight of water. 2595 Properties.

3. When it is burnt, it exhibits the same appearances as vegetable sugar, giving out at the same time the odour of caromel. Similar products are obtained by distillation as from vegetable sugar; but the empyreumatic oil has the odour of benzoic acid. 2596 Action of heat.

4. By means of nitric acid the sugar of milk is partly converted into saclactic acid. 2597 Acids.

Sugar from diabetic urine.—This is obtained by evaporating the urine of persons labouring under diabetes. One twelfth of the weight of urine of a sweet-tasted substance of the consistence of honey has been obtained by this process. When this substance is treated with nitric acid, it affords oxalic acid in the same proportion as vegetable sugar; but no saclactic acid is formed, as when sugar of milk is treated in the same way. It has not been crystallized. 2598 Method of obtaining it.

VI. Of Oils.

1. The oils which have been detected in animals have the characters of fixed oils. Sometimes they exist in the solid state, and sometimes they are liquid. Fat is a copious animal production, which has different degrees of consistence, as it is obtained from different animals. To purify it, it is cut into small pieces, which are to be well washed with water, and the membranous and vascular parts separated. It is then put into a shallow vessel along with some water, and kept melted till the whole of the water is evaporated. It is then of a pure white colour, without taste or smell. 2599 In different states.

2. It melts at different temperatures. Hogs lard requires only a temperature of 97°, while the fat extracted from meat by boiling requires a temperature of 127°. When the heat is raised to 400°, a white smoke is given out; as the heat increases it is decomposed, and becomes black. When hogs lard is distilled in a retort, carbonated hydrogen and carbonic acid gases, accompanied 2600 Action of heat.

omponent Parts of Animal bstances.

accompanied with a very offensive smell, pass over. A portion of water is also obtained, and a white oil which concretes in the receiver. Acetic acid and a portion of sebacic acid are also found in the receiver. A black mass remains behind in the retort.

2601 ids. 3. Fat is insoluble in water and alcohol. It is dissolved and decomposed by the strong acids. If nitric acid be poured upon fat, and a moderate heat applied, the acid is decomposed, and the fat is converted into a yellow coloured ointment. Fourcroy calls this an oxide of fat; the oxygen of the acid having combined with the oily matter.

2602 kalies. 4. Fat combines with the alkalies in the same way as other oily substances, and with them it forms soap.

2603 mposi- n. 5. The constitnent parts of fat, as appears from the products which are obtained from its decomposition, are oxygen, hydrogen, and carbon.

There are besides some other oily substances obtained from different parts of animals, as spermaceti from the head of the spermaceti-whale, spermaceti-oil, which is separated in the purification of the spermaceti, and train oil, extracted from the blubber of the whale, and from other sea animals.

VII. Of Resins.

1. Resinous substances are found in different parts of animals, or rather they exist in those substances which are secreted by animals.

2. A resinous substance is extracted from the bile of animals. It is extracted from the fresh bile of the ox, by muriatic acid, in the proportion of one part of the latter to 32 of the former. The mixture remains for some hours, is filtered, and a white coagulated substance is separated. The filtered liquid, which has a fine green colour, is to be evaporated in a glass vessel with a gentle heat. The evaporation is continued till a green-coloured substance precipitates, which is to be separated, and washed with pure water. This substance is the *resin of bile.*

2604 perties. 3. It is of a dark-brown colour, but when spread thin, is of a fine green. The taste is extremely bitter.

2605 tion of it. 4. When it is heated to the temperature of 122°, it melts. By increasing the heat, it takes fire and burns. It is soluble in cold and hot water, and also in alcohol; but it is precipitated from the latter by water. The alkalies also dissolve this substance, and form a compound which has the properties of soap. This substance is precipitated from all these solutions by means of diluted acids.

A resinous substance has also been discovered in human nrine, in ambergris, which will be afterwards described, and in castor, civet, and musk.

VIII. Of Phosphorus.

2606 ven out ing pu- action. During the putrefaction of animal matters, phosphorus is given out in the state of phosphureted hydrogen gas, so that it must have entered as a constituent into these matters.

IX. Of Sulphur.

2607 und in umen. Albumen is always mixed with a portion of sulphur. It has been detected in the white of eggs and in milk, in the blood, in the urine and fæces, in the muscles, and in the hair. According to Proust, sulphur exists in the blood, in combination with ammonia, forming a hydrosulphuret of ammonia. Component Parts of Animal Substances.

X. Of Acids.

No less than 12 different acids have been detected ready formed in animal bodies. These are; 2608 Enumeration of acids.

Sulphuric,	Malic,
Muriatic,	Benzoic,
Phosphoric,	Lactic,
Carbonic,	Uric,
Acetic,	Rosacic,
Oxalic,	Amniotic.

1. Sulphuric acid has been found combined with soda, forming sulphate of soda, in the liquor of the amnios of cows. Sulphate of lime has been detected in the urine of quadrupeds.

2. Muriatic acid exists in combination with soda in almost all the animal fluids, forming muriate of soda.

3. Phosphoric acid is found in great abundance in different parts of animals. The phosphate of lime constitutes the basis of the bones, and it exists also in almost all the solid parts of animals, and in most of the fluids. In the blood it is combined with iron.

4. Carbonic acid is found combined with lime in the urine of horses and cows. It has also been detected in fresh human urine.

5. Acetic acid is found in urine; but it has been detected in great abundance in the red ant, and was formerly called *formic acid*, at least combined with malic acid.

6. Oxalic acid has been found in urinary calculi.

7. Malic acid has been found in the liquid obtained from the red ant. This is obtained by bruising the ants, and macerating them in alcohol. The alcohol is driven off by distillation, and an acid liquid remains behind. By saturating this liquid with lime, and adding acetate of lead to the solution, a copious precipitate is formed, which is soluble in acetic acid, so that this liquid contains something besides acetic acid. If nitrate of lead be mixed with the acid liquid after it is saturated with lime, a precipitate is formed, which is the malic acid combined with lead.

8. Benzoic acid has been detected in human urine, and in considerable quantity in the urine of cows. It has been fonnd in the blood, white of eggs, in glue, silk, or wool, in the sponge, and in mushrooms.

9. Lactic acid is obtained from milk, when it becomes sour. It is also said, that it has been found in new milk.

10. Uric acid exists in human urine, and forms one of the constituents of urinary calculi. One species of calculus, indeed, is composed entirely of this substance.

11. Rosacic acid is obtained from the urine of persons labouring under fevers and other disorders, when the urine deposits what is called a *lateritious sediment.*

12. Amniotic acid is obtained from the liquid of the amnios of the cow.

Component Parts of Animal Substances.

XI. Of Alkalies, Earths, and Metals.

2609 Alkalies. 1. The common alkalies have been found in animal fluids. Potash has been found in considerable abundance in the urine of quadrupeds. It has also been detected in the milk of cows. Soda is found in all the fluids. It is usually mixed with albumen. It is frequently combined with the phosphoric and muriatic acids. Ammonia also has been detected in urine.

2610 Earths. 2. The earths which have been detected in animals are, lime, magnesia, and silica. Lime forms, in combination with phosphoric acid, the basis of bones. It is also found in the same state in the other solid parts, as well as in most of the fluids. The shells of animals are composed chiefly of carbonate of lime. Magnesia has been found in human urine, combined with phosphoric acid and ammonia. It forms also one of the component parts of urinary calculi. Silica has only been found in similar concretions.

2611 Metals. 3. The only metal which has been detected in animals is iron, in combination with phosphoric acid, which forms a constituent part of the blood.

II. Fluid parts of Animals.

2612 Enumeration. We shall treat of the animal fluids in the following order:

1. Blood,	7. Humours of the eye,
2. Bile,	8. Wax of the ear,
3. Urine,	9. Synovia,
4. Milk,	10. Semen,
5. Saliva,	11. Liquor of the amnios,
6. Tears and mucus of the nose,	12. Fluids secreted by disease.

I. Of the Blood.

2613 Properties. 1. The blood is a fluid of a red colour, which circulates through the body, and is distributed by means of the arteries to every part of it, communicating, as we have seen, heat and nourishment. It is then reconveyed by the veins from the extremities to the heart. Human blood, and that of some other animals, is of a fine, purplish-red colour, has some degree of consistency, soft and soapy to the feel, of a sweetish saline taste, and a peculiar odour. The blood is found to vary in consistence, so that its specific gravity also varies from 1.053 to 1.126.

2614 Separates into two parts. 2. When blood, after it has been separated from the body, remains for some time at rest, it separates into two parts. One part, called the *clot* or *cruor*, is coagulated, and continues of a red colour; the other part, called the *serum*, remains fluid. The usual proportion of cruor to serum, is about one part of the former to three of the latter. This proportion, however, is subject to considerable variation.

2615 Action of acids. 3. The acids also coagulate blood, and decompose it. Concentrated sulphuric acid occasions a brown colour, with the production of charcoal. It is coagulated by nitric acid, with the evolution of azotic gas, and the production of carbonic and oxalic acids, besides some unctuous matter. Muriatic acid also coagulates blood, but without any perceptible change of colour. Oxymuriatic acid renders it as black as ink. Acetic acid also produces a coagulation.

2616 Alkalies. 4. The caustic alkalies dissolve the coagulum of blood, even when it has been produced by acids. If they are mixed with blood recently drawn, the coagulation is interrupted. Many saline bodies produce a similar effect by preventing coagulation, or decomposition.

2617 Metallic oxides. 5. The metallic oxides have little perceptible action on blood, except those which readily part with their oxygen. It is then coagulated. Almost all metallic solutions coagulate blood, and have the property, as well as the alkaline salts, of preserving it from putrefaction.

2618 Vegetable productions. 6. Many vegetable substances, when mixed with blood, prevent its putrefaction, such as sugar, volatile oils, camphor, resins. It is coagulated by solutions of gum and of starch. Tan produces a copious precipitate in blood, and gallic acid gives a black colour, owing to the iron which is contained in blood. The latter precipitate may be obtained by diluting the blood with a considerable proportion of water.

2619 Serum. 7. Blood, by remaining at rest, it has been observed, separates into two parts, the serum and the cruor. The serum is of a pale, greenish yellow colour, of a thinner consistence than blood; but retains its taste, smell, and soapy feel. The specific gravity is about 1.0287. In consequence of its containing a portion of soda, it gives a green colour to syrup of violets. Serum coagulates at the temperature of 156°. The same effect is produced by adding boiling water. This coagulum is of a grayish white colour, resembling the white of eggs. By breaking the coagulum to pieces, a fluid may be expressed from it, which has been called the *serosity* of blood. The residuum being washed with boiling water, exhibits the properties of albumen.

2620 Gelatine. 8. By diluting serum with six times its weight of water, and boiling it, the albumen is coagulated. The remaining liquid, if evaporated with a gentle heat, till it is considerably concentrated, assumes the form of jelly, and thus shews that it possesses the properties of gelatine.

2621 Sulphur. 9. By heating the coagulated serum in a silver vessel, the silver is blackened, in consequence of its conversion into a sulphuret, by combining with sulphur contained in the coagulum. It has been already mentioned, that this sulphur exists in the blood, in combination with ammonia, in the state of hydrosulphuret.

2622 Different salts. 10. The serum of blood contains muriate of soda, carbonate of soda, phosphate of soda, and phosphate of lime. These salts may be obtained by mixing serum with double its weight of water, applying heat to coagulate the albumen, which being separated, and the remaining liquid filtered and evaporated, crystals are deposited on cooling. The soda exists in blood combined with gelatine and albumen, and is in its caustic state. It unites with the carbonic acid of the air during the evaporation. The component parts of serum, therefore, are the following:

2623 Composition of serum.

Albumen,
Gelatine,
Hydrosulphuret of ammonia,
Soda,

Muriate

Component Parts of Animal Substances.

Muriate of soda,
Phosphate of soda,
Phosphate of lime.

2624 Cruor. 11. The cruor or clot of the blood, the other portion into which it spontaneously separates, is of a red colour, and has considerable consistence. Its specific gravity is about 1.245. By washing this substance with a small quantity of water, and continuing the process till the water passes off colourless, part of it is dissolved in the water, and part remains in the state of a solid white elastic substance, which is the fibrina of the blood. That part which is held in solution by the water contains the colouring matter. This solution converts the syrup of violets to a green colour. By exposure to the air it deposits albumen in the form of flakes. By the evaporation of this solution to dryness, and the addition of alcohol, part is dissolved. If

2625 Albumen and soda. this solution be evaporated, the residuum converts vegetable blues to green, and mixes with water like soap. This residuum contains albumen and soda.

2626 Iron. 12. If the watery solution be evaporated to dryness with a moderate heat, a quantity of iron remains behind, which may be separated by the magnet. It has been said that the quantity of iron in the blood of a healthy man amounts to more than two ounces; but this is little better than conjecture, founded on vague calculation. The iron in blood is combined with phosphoric acid. If the watery solution be evaporated to dryness, and the residuum obtained be calcined

2627 Quantity conjectured. in a crucible, a red mass remains, which amounts to 0.0045 of the blood which was employed. Part of this residuum, which is phosphate of iron, is dissolved by digestion in nitric acid. From this it is precipitated of a white colour, by ammonia. With the addition of pure potash, the precipitate becomes red. By adding lime water to the solution which contains the potash, a precipitate is formed, which is phosphate of lime. By the action of these re-agents, it appears that the iron in the blood combined with phosphoric acid, is in the state of sub-phosphate. Phosphate of iron is insoluble in water, but soluble in the acids. It is partially decomposed by the alkalies, which carry off part of its acid, and leave the remainder with excess of iron. Thus it is that this salt is preserved in the state of sub-phosphate, by means of the soda which exists in the blood.

2628 Fibrina. 13. The method of obtaining fibrina from blood has been already described. This substance may be separated by agitating, or stirring rapidly with a stick, the blood which has been newly drawn from the animal. The fibrina or fibrous matter being well washed and dried on paper, loses about two-fifths of its weight, and becomes hard and brittle. The mean proportion of fibrina in the blood of man has been estimated at 0.0028. The fibrina is formed in the blood as it passes through the lungs, and is deposited in the muscular part of animal bodies, of which it forms one of the principal constituents. When the fibrina is separated from the blood, the latter is no longer disposed to coagulate when it is left at rest. A flaky matter only is separated, which appears on the surface.

2629 Distillation. 14. Blood dried with a moderate heat, exhales a quantity of water which possesses a peculiar odour, owing to a portion of animal matter which it holds in solution. If the blood thus dried be distilled in a retort, a watery fluid passes over, afterwards carbonic acid gas, carbonate of ammonia, which crystallizes in the neck of the retort, a fluid oil, carbonated hydrogen gas, and an oily matter of the consistence of butter. A green powder is precipitated from sulphate of iron by the watery fluid. A portion of this powder is soluble in muriatic acid, and a small quantity of Prussian blue remains behind, from which it appears that prussic acid and an alkali are contained in the watery liquor.

A quantity of dried blood amounting to 9216 grs. was introduced into a large crucible, and being gradually heated, it became at first nearly fluid; it then swelled up, gave out abundance of yellowish-coloured fetid fumes, and at last took fire, and burnt with a white flame. The flame and the fumes ceasing to be emitted, were succeeded by a light, acrid smoke, which had the odour of prussic acid. When the matter had been deprived of about five-sixths of its weight, at the end of six hours it melted again; a purple flame appeared on the surface, with the evolution of dense acrid fumes, which being collected were found to possess the properties of phosphoric acid. One hundred and eighty-one grains of a deep black colour and metallic brilliancy constituted the residuum. It was attracted by the magnet. From these observations it appears that the constituent parts of the blood are the following. 2630 Action of heat. 2631 Composition.

1. Water,	6. Soda,
2. Fibrina,	7. Subphosphate of iron,
3. Albumen,	8. Muriate of soda,
4. Gelatine,	9. Phosphate of soda,
5. Hydrosulphuret of ammonia,	10. Phosphate of lime,
	11. Benzoic acid.

15. The constituent parts of blood vary considerably at different periods of life, and in different states of the body. The colouring matter of the blood of the fœtus has been found to be darker and more copious. It contains no fibrina or phosphoric acid. 2632 Varies at different periods, &c.

16. The blood of persons labouring under inflammatory disorders seems to possess different properties from that of persons in health. It then exhibits, soon after it is drawn from the body, what has been called by physicians the *buffy coat*, which is considered to be the characteristic of inflammation. This inflammatory crust has been found to consist of fibrina, so that the cruor deprived of this matter becomes soft, and is almost entirely soluble in water. The albumen of the serous part has also undergone some changes. It assumes a milky appearance when mixed with hot water, and does not coagulate when it is heated. 2633 Inflammatory.

17. The serum of the blood of persons labouring under diabetes, is deprived of its saline taste, has the appearance of whey, and somewhat of a saccharine taste. 2634 Diabetic.

II. Of Bile.

1. Bile is an important fluid in the animal economy. It seems to perform an essential part in the function of digestion. It is secreted from the liver, and is of a yellowish-green colour, has a soapy feel, a bitter taste, and 2635 Importance and properties.

and a peculiar odour; but it varies in colour, and in some other of its properties, in different animals. It varies also in its specific gravity. It has been estimated at 1.0246. The experiments which have been made on bile relate chiefly to that obtained from the gall-bladder of the ox, hence denominated *ox-gall.* When bile is strongly agitated, it forms a lather like soap; and hence it has been called an *animal soap.* It mixes in all proportions with water, to which it communicates a yellow colour.

2636 Action of heat. 2. When bile is exposed to a moderate heat, it becomes thick, having lost a great part of its weight. The vapour it exhales has a peculiar offensive odour. A solid brown mass is thus obtained, which has a bitter, with somewhat of a sweetish taste, becomes soft with the heat of the hands, is ductile, attracts moisture from the air, and is soluble in water. This substance effervesces slightly with acids, and acquires a perceptible odour of musk or amber, when kept for some time. This has been called the *extract of bile.* When this process is conducted in close vessels, with the heat of a water bath, it gives out a clear aqueous fluid of a disagreeable odour, which undergoes no particular change by means of re-agents, if the distillation has not been carried too far, or the bile has not become in some degree putrid. If this latter circumstance has taken place, the watery product has frequently a strong odour of musk, and becomes turbid on cooling.

2637 Distillation. When this extract of bile is heated in a retort, it is decomposed with peculiar appearances. When heat is gradually applied, a watery fluid, which is slightly muddy, and of a fetid odour, passes over. This fluid precipitates metallic salts, and contains almost always sulphurated hydrogen. The matter in the retort enlarges in volume, and the fluid which then comes over is of a brown colour, extremely fetid, and contains carbonate and zoonate of ammonia. Soon after an oil is evolved, which is at first liquid, and afterwards becomes of a brownish colour, thick, and empyreumatic, and of a most offensive fetid odour. At the same time carbonate of ammonia crystallizes on the sides of the receiver. There is then a copious evolution of an elastic fluid, composed of carbonic acid, carbonated and sulphurated hydrogen gases, holding in solution a small portion of oil. The carbonate of ammonia thus obtained, does not amount to the one-eighth part of the quantity which is extracted from the blood and from the bones of animals, from which it is supposed that the bile is less animalized than many other animal substances. There remains behind a black spongy mass of coal, which is easily burnt. This coaly matter, by exposure to the air, effloresces on the surface, which is found to be carbonate of soda. When it is well burnt, it preserves a deep gray colour; and there is separated, by means of cold water, nearly half its weight of carbonate of soda, a little muriate of soda, phosphate of soda, phosphate of lime, and some traces of iron.

2638 Action of acids. 3. Bile is decomposed by all the acids. A precipitate is formed, which is always of a green colour. Part of this precipitate remains suspended in the solution, and is even dissolved by agitation. The solution being filtered, leaves on the filter a portion of coagulated albumen. By evaporation the liquid deposits a deep green flaky substance like pitch, which has considerable tenacity, swells up when put upon hot coals, readily takes fire, and burns like resinous matter. After the separation of this matter, the liquid affords by evaporation a salt with a base of soda.

Three different saline substances have been obtained by the action of acids on bile; the first with a base of soda, the second which crystallizes in small needles has lime for its base, and the third is a crystalline matter, of a slightly sweet taste, which is supposed to be similar to sugar. Thus it appears that acids act on bile in three different ways; they coagulate the albumen, which is precipitated; they combine with the soda by separating the oily matter which constituted the saponaceous part of the bile; and they decompose the phosphoric salts.

Concentrated sulphuric acid coagulates bile in the form of dense flakes, and communicates to it a deep colour. Nitric acid, after having formed a precipitate, of a green colour in the cold, assumes a golden yellow colour, when it is heated for a sufficient length of time. It converts a portion of bile into oxalic and prussic acids. Muriatic acid at first produces a green precipitate, which afterwards assumes a shade of a reddish violet colour, especially by means of heat. Oxymuriatic acid renders it white and turbid like milk. It changes the properties of the different constituents of bile, and occasions a precipitate similar to that matter which frequently constitutes *biliary calculi.*

2639 Phosphate of lime. 4. When the precipitate from bile by means of the acids is treated with alcohol, and every thing soluble in this liquid separated, there remains a whitish matter which is infusible, nearly insipid, insoluble, whether with cold or hot water, but soluble in solutions of the caustic fixed alkalies, which burns on red hot coals with the odour of horn, and which gives by analysis, similar products, especially carbonate of ammonia in considerable quantity. The coal which remains contains a portion of phosphate of lime.

2640 Action of alkalies. 5. The alkalies deprive bile of its bitter taste; but they do not coagulate it.

6. Thus it appears that the constituent parts of bile are the following.

Water,	Saccharine matter,
Albumen,	Muriate of soda,
Resin,	Phosphate of lime,
Soda,	Phosphate of soda,
Sulphurated hydrogen,	Iron.

2641 Uses. 7. Bile, it has been already observed, performs an important part in the function of digestion. The albuminous and saline parts combine with the chyle, and are conveyed to the blood. The resinous portion combines with the excrementitious part of the chyle, and is thrown out of the body.

Bile is employed in the arts for removing spots of grease and oil from woollen stuffs. It is also employed as a pigment. It is evaporated and reduced to the form of extract, and diluted with a little water, in which state it gives a brown colour.

III. Of Urine.

2642 Properties. I. The properties of urine vary considerably, according to the constitution and health of the body, and the period when it is voided after taking food. The

Component Parts of Animal Substances.

The urine of a healthy person is of a light orange colour, and uniformly transparent. It has a slightly aromatic odour, in some degree resembling that of violets. It has a slightly acrid, saline, bitter taste. The specific gravity varies from 1.005 to 1.033. The aromatic odour, which leaves it as it cools, is succeeded by what is called the *urinous smell*, which latter is converted to another, and finally to an alkaline odour. Urine converts the tincture of turnsole into a green colour, from which it is concluded that it contains an acid.

2643 Phosphate of lime. 2. By adding a solution of ammonia to fresh urine, a precipitate is formed in the state of white powder, which is found to be phosphate of lime. But if lime water be employed in place of ammonia, a more copious precipitate, of phosphate of lime, is obtained, from which it is concluded, that the phosphate of lime is held in solution with an excess of acid.

2644 Phosphate of magnesia. 3. A small portion of magnesia is also found mixed with the phosphate of lime which has been precipitated, derived from phosphate of magnesia, which has been decomposed by the alkali or lime.

2645 Carbonic acid. 4. The froth which appears when urine is evaporated is ascribed to the evolution of carbonic acid gas.

2646 Carbonate of lime. 5. Urine which has been kept in new casks, deposits small crystals, which effloresce in the air. These crystals have been found to possess the properties of carbonate of lime.

2647 Uric acid. 6. A brick-coloured precipitate is frequently formed in urine as it cools. This substance is uric acid, which exists in all urine, and may be obtained by evaporating fresh urine, dissolving it in pure alkali, and precipitating by means of acetic acid.

2648 Rosacic acid. 7. The urine of persons labouring under intermitting fevers, and some other diseases, deposits a copious sediment called the lateritious sediment, which consists of rosacic acid.

2649 Benzoic acid. 8. Benzoic acid also exists in urine. It is obtained by evaporating fresh urine to the consistence of a syrup, and adding muriatic acid. A precipitate is thus formed, which is benzoic acid. But it may be obtained by evaporating urine to dryness, separating the saline substances, and applying heat to the residuum. By this process the benzoic acid is sublimed, and crystallized in the receiver. The quantity of benzoic acid is more considerable in the urine of horses and cows than in human urine.

2650 Albumen and gelatine. 9. Albumen or gelatine has been found in urine, and is precipitated by means of an infusion of tan. The cloud which appears as urine cools, consists of these substances, which are increased in proportion during different diseases. The urine of persons labouring under dropsy contains a large quantity of albumen; and in the urine of those persons who are subject to indigestion, the albumen and gelatine are greatly increased.

2651 Urea. 10. Urea is the principal constituent of urine. The method of obtaining it from urine has been already described. It is to this substance that the taste, smell, and peculiar characters of urine are owing. If concentrated nitric acid be poured upon urine, evaporated to the consistence of syrup, crystals appear, which are the nitrate of urea. The quantity of urea secreted is very different in different circumstances.

11. A resinous substance resembling the resin of bile has been detected in urine, to which its colour is ascribed. Urine evaporated to the consistence of extract, mixed with sulphuric acid and distilled, gives out this resinous matter, which is soluble in water and in alcohol. 2652 Resin. When urea has been separated from urine by evaporation and crystallization, a saline mass remains. If this be dissolved in hot water, and spontaneously crystallized in a close vessel, two kinds of crystals are deposited. Those at the bottom are in the form of rhomboidal prisms, and consist of phosphate of ammonia mixed with a little phosphate of soda. The crystals in the upper part of the vessel are in the form of rectangular tables, composed chiefly of phosphate of soda. These were formerly called *sable salt of urine, microcosmic salt.*

12. Muriate of soda was the first saline substance detected in urine. 2653 Muriate of soda. It may be obtained by slowly evaporating it to the consistence of syrup. The salt crystallizes upon the surface, but in this case the form of the crystal is that of an octahedron, and not the cube, the usual form. The cause of this deviation is ascribed to the urea.

13. Muriate of potash is also found among the crystals which are formed during the evaporation of urine. 2654 Muriate of potash.

14. Muriate of ammonia is one of the salts which are found in urine. 2655 Muriate of ammonia. The crystals of this salt which are usually octahedrons, when they are formed in urine, assume that of the cube, a deviation which is also ascribed to the action of the urea.

15. Urine contains sulphur, which may be detected 2656 Sulphur. by holding paper stained with acetate of lead over urine when it is become putrid. The paper is blackened, which is owing to sulphur exhaled with the carbonic acid. Sulphate of soda and sulphate of lime have also been detected in urine.

16. No less than 30 different substances have been 2657 Component parts. detected in urine by chemical analysis, the principal of which are the following:

Water,	Rosacic acid,
Phosphoric acid,	Benzoic acid,
Phosphate of soda,	Benzoate of ammonia,
Phosphate of soda and ammonia,	Gelatine,
	Albumen,
Phosphate of ammonia,	Urea,
Phosphate of lime,	Resin,
Phosphate of magnesia,	Muriate of potash,
Phosphate of magnesia and ammonia,	Muriate of soda,
	Muriate of ammonia,
Carbonic acid,	Sulphur,
Carbonate of lime,	Sulphate of lime,
Uric acid,	Sulphate of soda.
Urate of ammonia,	

2658 Putrefaction of urine. 17. Urine is particularly prone to spontaneous decomposition. The time when this process commences, and the rapidity of the changes which take place, depend on the quantity of the gelatine and albumen. When the proportion of these substances is considerable, the decomposition is very rapid. This is owing to the great number of substances, and the united force of their attractions, overcoming the existing affinities of the different compounds of which fresh urine consists, Component Parts of Animal Substances. consists, and especially to the facility with which urea is decomposed. This substance is converted during putrefaction into ammonia, carbonic acid, and acetic acid. Hence the smell of ammonia is always recognized while urine is undergoing these changes. Part of the gelatine is deposited in a flaky form mixed with mucilage. Ammonia combines with phosphoric acid, and the phosphate of lime is precipitated. It combines also with phosphate of magnesia, and forms a triple salt. The other acids, the uric, benzoic, the acetic and carbonic acids, are all saturated with ammonia. The following substances, therefore, are obtained from urine by putrefaction.

- Ammonia,
- Phosphate of ammonia,
- Phosphate of magnesia and ammonia,
- Carbonate of ammonia,
- Urate of ammonia,
- Acetate of ammonia,
- Benzoate of ammonia,
- Muriate of ammonia,
- Muriate of soda.

Products nearly similar are obtained by the distillation of urine. The remarks, however, which we have formerly made, under the head of mineral waters, on the mode of combination of the ingredients of mixed saline solutions, apply to urine of all kinds, and in every state; i. e. the salts which are actually obtained, are not those which exist in the liquid, any more than other salts capable of being formed by different combinations of the acids and alkalies which are present. See N° 2225.

2659 Varies in different circumstances. 18. Such are the properties of human urine in its healthy state; the changes to which it is subject; and the products which are obtained, either by means of chemical analysis or spontaneous decomposition. But the nature and properties of urine vary considerably, according to the period of life, the time it is voided after taking food, different seasons of the year, the nature of the food, the influence of passions, and disease.

2660 Urine of infants. In the urine of infants no phosphate of lime is found. The proportion of benzoic acid is considerable, and the quantity of urea is small. There is less acrimony, odour, and colour. As the period of life advances, the saline matters increase, especially the phosphate of lime, which is no longer required for the formation of bone.

2661 After taking food. The urine, which is passed immediately after taking food, is white and colourless, and seems to contain little else but water. It is not till seven or eight hours after a repast, that the urine is completely formed.

2662 In warm seasons. Urine voided during the warmer seasons of the year, or by persons who inhabit hot climates, is high-coloured and acrid, which is ascribed to a greater proportion of saline matter and urea. In winter also the urine is red and high-coloured, owing to a greater proportion of the earthy phosphates and of uric acid, which it then contains. It is no doubt considerably influenced by the modification of the action of the skin.

2663 Kinds of food. The food frequently communicates its properties to the urine. The odour of garlic, of resinous substances and some aromatics, is often perceptible in the urine a few minutes after these substances are taken into the stomach, or even only applied to the skin. The fetid odour of the urine of those who have eaten asparagus, is well known. The colouring matters of some substances are communicated to the urine; such as the red colour of beet-root, the orange-yellow of rhubarb, or the colour of madder. Component Parts of Animal Substances.

2664 Passions. The passions of the mind have great influence on the secretion of urine, both in changing its properties and increasing its quantity. In these cases the urine is generally colourless, insipid, and without odour.

2665 Diseases. But the nature and properties of urine undergo still greater changes during disease. From these changes the empiric has attempted to form prognostics of the nature, progress, and termination of diseases.

At the commencement of fevers and inflammatory disorders, the urine is high-coloured and extremely acrid, scarcely becomes turbid on cooling, and deposits no sediment. In affections of the liver, such as jaundice, it is of a yellow orange colour, like saffron, and communicates its colour to the vessels into which it is received, or to those substances which are immersed in it. It is then called *bilious urine*. It seems to contain a portion of the colouring matter of bile. Towards the termination of febrile disorders, the quantity of urine is increased; and it deposits, as it cools, a crystalline or scaly matter, of the colour of peach flowers, which is called *critical urine*. The sediment is composed of phosphate of lime, rosacic and uric acids. During nervous affections, as in hysteria, the urine is perfectly limpid and colourless, inodorous and insipid. It has been observed, that the urine of gouty persons contains a smaller proportion of acid than usual. At the commencement of a paroxysm, the quantity of phosphoric acid seems to be diminished; but it gradually increases towards the termination of the fit, and is then in greater proportion than in ordinary health. The urine of persons labouring under rickets deposits a great portion of lime. The urine of an infant who died of worms, was found on analysis to contain oxalate of lime. In some cases of diabetes, the urine is colourless and insipid; in others it contains a great proportion of saccharine matter.

2666 Different animals. 19. The urine of other animals exhibits different characters from that of man, according to their nature, the diversity of their organs, their food, manner of respiration, and the medium in which they live.

2667 The horse. The urine of the horse has a strong peculiar odour. It is turbid when voided, or soon after becomes muddy. A pellicle, which is carbonate of lime, forms on the surface when it is exposed to the air. It changes the syrup of violets to a green colour, effervesces with acids, and is precipitated by the alkaline carbonates. The urine of the horse yields no phosphorus. The component parts of the urine of this animal, as they have been ascertained by Fourcroy and Vauquelin, are the following:

Carbonate of lime	0.011
Carbonate of soda	0.009
Benzoate of soda	0.024
Muriate of potash	0.009
Urea	0.007
Water and mucilage	0.940
	1.000 *

* Mem. l'Inst. ii. p. 445.

The

Component Parts of Animal Substances.

2668 The cow. The urine of the cow possesses nearly the same properties as that of the horse. It has a soapy feel, and a strong peculiar odour. It gives a green colour to syrup of violets, effervesces with acids, but is not altered by the alkaline carbonates. When it is exposed to the air, small crystals form on the surface. Its component parts are,

Carbonate of potash,
Sulphate of potash,
Benzoic acid,
Urea.

2669 The camel. The urine of the camel is more distinguished by its odour than any other, but it is analogous to that of the cow. It is not mucilaginous, and does not deposit carbonate of lime. The specific gravity of this urine is greater than any other. It produces a slight change on the infusion of violets, communicating a green colour. It effervesces with acids, and furnishes nitre, sulphate and muriate of potash, with the addition of sulphuric, nitric, and muriatic acids. It contains

Carbonate of potash,
Sulphate of potash,
Muriate of potash,
Urea.

2670 The rabbit. The urine of the rabbit, examined by Vauquelin, exhibits similar characters with that of the horse, the cow, and the camel. It becomes milky, and deposits carbonate of lime by exposure to the air. It converts vegetable blues to a green colour, and effervesces with acids. It contains the following substances:

Carbonate of lime,
Carbonate of magnesia,
Carbonate of potash,
Sulphate of potash,
Sulphate of lime,
Muriate of potash,
Urea,
Gelatine,
Sulphur,

2671 Guinea pig. The urine of the Guinea pig is analogous in its nature and properties to that of the larger animals already described.

2672 Graminivorous animals. It appears that the urine of graminivorous animals belonging to the class of mammalia, or which live on vegetables in general, contains no phosphoric salts, or uric acid; that it is loaded with carbonate of lime, salts having a base of potash, and benzoic acid. The only substance which the urine of these animals possesses in common with human urine is urea. The urine of

2673 Carnivorous. carnivorous animals, of which indeed scarcely any thing is known, is supposed to possess different properties from that of the animals just mentioned. The strong fetid odour of the urine of the cat is well known. Muriate of ammonia has been obtained from the urine of this animal by evaporation; but it is supposed, from the peculiar odour, that it contains urea.

2674 Of birds. The urine of birds affords a copious sediment, which seems to be carbonate of lime.

A substance which was found in the urinary bladder of the turtle, in the form of paste, and which was examined by Vauquelin, was composed of 2675 Turtle.

Muriate of soda,
Phosphate of lime,
Animal matter,
Uric acid.

IV. Of Milk.

1. Milk, which is secreted in particular organs by the females of viviparous quadrupeds and cetaceous fishes, included under the class *mammalia*, and destined for the nourishment of the offspring, is a white opaque fluid, varying in its properties according to the different species of animals, and the nature of their food. The milk of the cow, which is most easily and most abundantly procured, has been chiefly the subject of chemical investigation. To it, therefore, the following observations are chiefly applied. 2676 Properties.

2. Milk is distinguished by an agreeable sweetish taste, and a peculiar smell. But these properties belong to it only when it is just separated from the cow, for in the course of a few hours they are considerably different. The specific gravity varies at different periods. It is greater than that of water, and has been found to amount to 1.0324. The boiling and the freezing points of milk are also variable. 2677 Of cows milk.

3. If milk be left at rest for some time, it separates into two parts; an unctuous matter which floats on the surface, called *cream*, and a denser fluid which still retains many of the properties of milk. The quantity of cream obtained from milk, and the time it requires to separate, vary according to the nature of the milk and the temperature. 2678 Separation of cream.

4. Cream thus obtained is of a yellow colour, and acquires a greater consistence by being exposed to the air. It is lighter than water, has an unctuous feel, and becomes rancid like oils, by keeping. When it is boiled, a small portion of oil appears on the surface. Cream is not soluble in alcohol or in oils. When cream is agitated for a longer or shorter time, according to the temperature to which the milk has been exposed during its separation, and perhaps to some circumstances which have not yet been observed, it separates into two parts; one which has a solid consistence, is bitter, and another which remains fluid. 2679 Its properties.

5. Butter is of a yellow colour, and has all the properties of an oil, combined with a portion of the curd and serum of the milk. It melts at the temperature of 96°, and mixes readily with other oily matters. When butter is kept for some time, it is decomposed; it becomes rancid, which is ascribed to the whey and the curd with which it is combined; for when these substances are previously separated, it may be preserved sweet much longer. Butter yields by distillation water, an acid liquid, an oily substance, which is at first fluid, but becomes afterwards concrete. A small portion of carbonaceous matter remains behind. 2680 Butter.

6. When fresh cream, or the whole of the milk fresh drawn from the cow, is churned, it requires the process to be continued a much longer time than when the cream 2681 Changes in the process of churning.

cream or milk is left to repose, as is usually the case, till it has acquired a slightly acid taste. But when cream which has become sour, is churned, the butter separated has no acid properties, and the milk which remains is even less sour than the cream previous to the commencement of the process. An acid, therefore, has been evolved, and this acid is supposed to be the carbonic. When fresh cream or fresh milk is subjected to this process, in which the acid has not been formed, it requires greater agitation to complete this previous part of the change which the cream or milk must undergo, before the separation of the oily part or the butter. The milk which remains after the butter has been separated, or, as it is called, the butter-milk, has all the properties of milk from which the cream has been separated.

2682 Coagulation.

7. The milk which remains after the separation of the cream, may be coagulated by the addition of several substances, particularly by the addition of runnet, which is in most common use, and which is prepared by digesting the inner coat of the stomach of young animals, especially that of the calf. This coagulum separates into two parts, the curd and the serum or whey.

2683 Curd.

Curd is a white solid substance, and somewhat brittle, when the whole of the whey is expressed. It is soluble in acids, but it is necessary that the mineral acids be greatly diluted, and the vegetable acids concentrated.

2684 Cheese.

Cheese is prepared from curd, by separating the whey by expression. The quality of the cheese depends upon the quantity of cream which remains in the milk. The best cheese is obtained by coagulating the milk at the temperature of about 100°, and expressing the whey slowly and gradually, without breaking down the curd.

If milk be not too much diluted with water, it may be coagulated by a great number of different substances. Among this number are acids, alcohol, neutral salts, gum arabic, and sugar.

2685 Whey.

8. Whey expressed from coagulated milk is of a yellowish green colour, and has an agreeable sweet taste. If it is boiled, a quantity of curd separates, and after being left at rest for some time the whole of it is precipitated, and the liquid remains transparent and colourless. By slow evaporation it deposits white-coloured crystals of sugar of milk, with some muriate of potash, muriate of soda, and a little phosphate of lime. The liquid which remains after the separation of the salts, is converted, by cooling, into a gelatinous substance. If whey be kept for some time, it becomes sour, by the formation of an acid, which is lactic acid. It is to this acid that the spontaneous coagulation of milk, after it remains at rest for some time, is owing.

2686 Koumiss.

9. If milk, after it has become sour, be kept in a proper temperature, it ferments, emitting carbonic acid gas, and exhibiting the other phenomena of fermentation. A vinous intoxicating liquor is thus prepared, which has been long known among the Tartars, and called by them *koumiss*. They prepare it from the milk of the mare.

2687 Vinegar.

10. Milk is susceptible of the acetous fermentation. If about six spoonfuls of alcohol be added to eight pints of milk, and the liquid be excluded from the air, vinegar will be formed in four or five weeks. Although the air is to be excluded, yet the carbonic acid gas must be allowed to escape as it is disengaged.

By the distillation of milk with the heat of a water-bath, water passes over, after which the milk coagulates, and an oily yellowish white substance remains behind, which, by increasing the heat, yields a transparent liquid, a fluid oil, ammonia, an acid, a thick black oil, and in the end carbonated hydrogen gas. The coaly matter in the retort contains potash, muriate of potash, phosphate of lime, and sometimes muriate of soda, with a small portion of magnesia and iron.

The constituent parts which enter into the composition of milk are the following: 2688 Composition.

1. Water,
2. Oil,
3. Curd,
4. Gelatine,
5. Sugar of milk,
6. Muriate of soda,
7. Muriate of potash,
8. Phosphate of lime,
9. Sulphur.

11. Although the milk of different animals be composed nearly of the same substances, the proportions vary so much, as to give them very different properties. 2689 Milk different in different animals.

The following are the results of the investigations of Deyeux and Parmentier with regard to the properties of the component parts of the milk of different animals compared together. 2690 Compared.

A. Every kind of milk, when left at rest, produces cream on the surface, but it is different in the milk of different animals.

a. In the milk of the cow it is copious, thick, and of a yellow colour.

b. In women's milk it is more liquid, white, and in small quantity.

c. In goats milk it is more abundant than in that of the cow, thicker and whiter.

d. In ewes milk it is nearly as abundant, and of the same colour as that of the cow, but has a peculiar taste.

e. In asses milk it is thick, less abundant, and in a great measure resembles that of women's milk.

f. In mares milk it is very fluid, and similar in colour and consistence to good cows milk before the cream appears on the surface.

B. Butter obtained from the milk of different animals, has the following comparative properties. 2691 Butter.

a. That of the cow is sometimes of a deep yellow, sometimes pale or white, and has always a considerable consistency.

b. It is difficult to separate the butter from the cream of women's milk. It is in small quantity, insipid, and of a pale yellow. It has been erroneously supposed that no butter could be obtained from this milk.

c. The butter of asses milk is always very white, soft, and disposed to become rancid.

d. The butter from goats milk is easily separated from the cream. It is abundant, always white, soft, and disposed to become rancid.

e. The butter from ewes milk is of a yellow colour, soft, and soon becomes rancid.

f. The butter of mares milk is difficult to be obtained, and in small quantity. It has little consistence, and is readily decomposed.

C. The curd of milk varies in different animals. 2692 Curd.

a. That from the milk of the cow is bulky, tremulous, and retains a great deal of the serum.

b. That

Component Parts of Animal Substances.

b. That from women's milk is in small quantity, little coherent, has an unctuous feel, and retains but a small portion of the whey.

c. The curd of asses milk is similar to the former, but without being unctuous.

d. Curd from the milk of the goat is in great proportion, of a firmer consistence than that of the cow, and retains less whey.

e. Curd from ewes milk is fat, viscid, and communicates a soft paste to cheese.

f. The curd from mares milk is in very small quantity, and similar to that from women's milk.

2693 Whey. D. The serum or whey constitutes a very great proportion of the milk, and exhibits the following varieties.

a. Whey from the milk of the cow is of a greenish-yellow colour, a sweet taste, and contains sugar of milk and neutral salts.

b. The whey from women's milk has little colour, but has a very sweet taste, containing a considerable proportion of saccharine matter.

c. The whey of asses milk is colourless, and contains less salts and more sugar than that of the cow.

d. Whey of the goat is of a slight yellow colour, and contains very little sugar and saline matter. The latter consists almost entirely of muriate of lime.

e. The whey of ewes milk is always colourless, and contains the smallest quantity of sugar, and but a small portion of muriate and phosphate of lime.

f. The whey of mares milk has little colour, and contains a great proportion of saccharine matter and of saline substances *.

* *Fourcroy*, [illegible] 435.

V. Of Saliva.

2694 Properties. 1. The saliva which is secreted by peculiar glands, and which flows into the mouth, is a clear, viscid fluid, without taste or smell. Its specific gravity varies from 1.0167 to 1.080. It has generally a frothy appearance, being mixed with a quantity of air.

2695 Combines with oxygen. 2. Saliva has a strong attraction for oxygen, which by trituration it communicates to some metallic substances, as mercury, gold, and silver. When saliva is boiled in water, albumen is precipitated, and when it is slowly evaporated, muriate of soda is obtained. A vegetable gluten remains behind, which burns with the odour of prussic acid.

2696 Action of acids. 3. Saliva becomes thick by the action of acids. Oxalic acid precipitates lime. Saliva is also inspissated by alcohol. It is decomposed by the alkalies; and the nitrates of lead, of mercury, and of silver, precipitate muriatic and phosphoric acids.

2697 Distillation. 4. By distillation in a retort, it froths up, affords near four-fifths of its quantity of water nearly pure, a little carbonate of ammonia, some oil, and an acid. What remains behind consists of muriate of soda, phosphate of soda and of lime. The constituent parts of saliva are the following.

2698 Composition.

1. Water,
2. Mucilage,
3. Albumen,
4. Muriate of soda,
5. Phosphate of soda,
6. Phosphate of lime,
7. Phosphate of ammonia.

2699 Saliva of the horse. 5. The saliva of the horse is of a greenish yellow colour, a disagreeable smell, a saline taste, and soapy feel. It is coagulated by the acids, alcohol, and boiling water. A black earthy residuum remains after spontaneous evaporation. By distillation it yields an insipid watery liquid, carbonate of ammonia, carbonated hydrogen and carbonic acid gases, and a black empyreumatic oil.

2700 Pancreatic juice. 6. The pancreatic juice, it is supposed, possesses properties analogous to those of saliva, and is destined for similar purposes, namely, to contribute to the solution of alimentary substances, and to their conversion into chyme; but very little is known of its nature and uses.

VI. Of the Humours of the Eye.

2701 Parts of the eye. 1. The eye is composed of three substances, which in anatomy have received the name of humours. These are the aqueous, the vitreous, and the crystalline humours or lens. The following observations are from Mr Chenevix's experiments on this subject *.

* *Phil. Trans.* 1802.

2702 Eyes of sheep. 2. The aqueous humour of the eye of the sheep is transparent like water, and has scarcely any taste or smell. The specific gravity is 1.0090. It evaporates slowly when exposed to the air; a coagulum is formed by boiling. When 100 parts are evaporated to dryness, eight parts remain behind. None of the metallic salts produce any precipitate except nitrate of silver, which throws down the muriate of silver. Tan also produces a precipitate in the aqueous humour. The component parts, therefore, of this substance, are albumen, gelatine, and muriatic acid, or rather muriate of soda, as the acid is in combination with soda. The vitreous humour exhibits the same properties.

3. The crystalline lens of the sheep is solid, composed of concentric coats, and transparent. The specific gravity is 1.1. When fresh it has scarcely any taste. It is soluble in water, and the solution is coagulated by heat. Tan produces a copious precipitate, both before and after coagulation. Its component parts are, therefore, albumen and gelatine, with water.

2703 Human eye. 4. The human eye was found to be composed of the same substances. The specific gravity of the aqueous and vitreous humours is 1.0053; of the crystalline lens, 1.0790. The specific gravity of the aqueous and vitreous humours of the eye of the ox is 1.008; the crystalline lens 1.0765. The composition is the same as that of the sheep.

VII. Of Tears and Mucus.

2704 Properties. 1. The tears are secreted by the lachrymal gland, for the purpose of lubricating the eye. This liquid is transparent and colourless, has no perceptible smell, but a saline taste. It communicates to vegetable blues a permanent green colour. When it is evaporated nearly to dryness, cubic crystals are formed, consisting of muriate of soda. The soda is in excess, for vegetable blues are converted by it to green. A portion of mucilaginous matter, which becomes yellow as it dries, remains after the evaporation. This liquid is soluble in water and alkalies. Alcohol produces a white flaky precipitate, and when it is evaporated, soda and muriate of soda remain behind. By burning the residuum, some traces of phosphate of lime and of soda are detected. The component parts of tears are, therefore,

Water,	Muriate of soda,
Mucilage,	Phosphate of lime,
Soda,	Phosphate of soda.

2705 Composition. The mucilage of tears absorbs oxygen from the atmosphere, and becomes thick, viscid, and of a yellow colour. It is then insoluble in water. Oxymuriatic acid produces a similar effect. It is converted into muriatic acid, so that it has been deprived of its oxygen, or rather has acquired hydrogen from the water, the oxygen of which has combined with the mucilage.

2706 Mucus. 2. The mucus of the nose consists of the same substances as the tears; but being more exposed to the air, it acquires a greater degree of viscidity from the mucilage absorbing oxygen.

VIII. Of the Wax of the Ear.

2707 Properties. 1. The wax of the ear, or *cerumen*, is a liquid secreted by glands, which are situated in the internal ear. It is of a viscid yellow colour, and becomes concrete by exposure to the air. The taste is bitter; it melts with a moderate heat, gives out an aromatic smell, and stains paper like oil. When thrown upon burning coals, it gives out a white smoke, melts, swells, becomes dark-coloured, and gives out the odour of ammonia. A light coaly matter remains behind. It forms a kind of emulsion by agitation with water.

2708 Action of alcohol. 2. Alcohol dissolves a portion of cerumen; the undissolved part exhibits the properties of albumen mixed with oil. By evaporating the alcohol, an orange-coloured residuum, similar to turpentine, is left behind. It has the properties of resin of bile. This matter is also soluble in ether. By burning the albumen of the cerumen, some traces of soda and phosphate of lime are detected. The component parts of cerumen are,

2709 Composition.

Albumen,
Resin,
Colouring matter,
Soda,
Phosphate of lime.

IX. Of Synovia.

2710 Properties. 1. The liquid secreted within the capsular ligaments of the joints, to facilitate motion by lubricating these parts, is called *synovia*. The synovia of the ox is a viscid, semitransparent fluid, of a greenish-white colour, which soon acquires the consistence of jelly, and not long after becomes again fluid, depositing a filamentous matter.

2711 Action of water. 2. Synovia mixes with water, and renders it viscid. When this mixture is boiled, it becomes milky, and some pellicles are deposited on the sides of the vessel. Alcohol produces a precipitate when added to synovia. This precipitate is albumen. After this matter is separated, the liquid still remains viscid; but if acetic acid be added, the viscidity disappears, and it becomes transparent, depositing a white filamentous substance, which resembles vegetable gluten. It is soluble in cold water, and in concentrated acids and pure alkalies. This fibrous matter is precipitated by acids and alcohol in flakes.

2712 Acids. 3. The concentrated mineral acids produce a flaky precipitate, which is soon re-dissolved; but the viscidity of the liquid is not destroyed till they are so much diluted with water, that the acid taste is only perceptible.

4. When synovia is exposed to dry air, it evaporates, and cubic crystals remain in the residuum with a white saline efflorescence. The first are muriate of soda, and the latter carbonate of soda. This substance soon becomes putrid, giving out ammonia during its decomposition. By distillation in a retort, it yields water, which soon becomes putrid; water containing a portion of ammonia, and an empyreumatic oil, with carbonate of ammonia; by washing the residuum, muriate and carbonate of soda may be obtained. A small portion of phosphate of lime is found in the coaly matter. The constituent parts of synovia are the following: 2713 Salts separated.

2714 Composition.

Fibrous matter	11.86
Albumen	4.52
Muriate of soda	1.75
Soda	00.71
Phosphate of lime	00.70
Water	80.46
	100.00 *.

* *Ann. de Chim.* xiv. p. 123.

X. Of Semen.

2715 Properties. 1. Semen is secreted in the testes of male animals: but when it is ejected it is composed of two substances; the one is fluid and milky, and the other of a thick mucilaginous consistence, in which appear a great number of white silky filaments, especially if it be agitated in cold water. It has a disagreeable odour, and an acrid irritating taste. The specific gravity varies considerably, but is always greater than that of water. When it is rubbed in a mortar, it froths up, and acquires the consistence of pomatum from the air with which it mixes. It converts the flowers of mallow and of violets to a green colour, and it precipitates the calcareous and metallic salts; which shews, that it contains an uncombined alkali. The thick part of the semen, as it cools, becomes transparent, and assumes a greater degree of consistence; but it afterwards becomes entirely liquid, even without absorbing moisture from the air. This change takes place in about twenty minutes from the time of its emission.

2716 Action of air. 2. If semen be exposed to the air after it has become liquid at the temperature of 60°, it becomes covered with a transparent pellicle, and at the end of three or four days deposits fine transparent crystals of a line in length, crossing each other like radii from a center. When they are magnified, they appear to be four-sided prisms, terminated by long four-sided pyramids. When semen is exposed to a warm air, in considerable quantity, it is decomposed; it assumes the colour of the yolk of egg, and becomes acid, either by absorbing the oxygen from the atmosphere, or by a different combination and arrangement of its own constituent principles. It then emits the odour of putrid fish, and is covered with the *byssus septica*.

2717 Of heat. 3. Heat accelerates the liquefaction of semen; and when it has undergone this change it is no longer susceptible of coagulation. It is decomposed by the application of strong heat. Water is first separated; it then blackens, swells up, and emits yellow fumes, having

Component Parts of Animal Substances.

having an empyreumatic, ammoniacal odour. A light coal remains behind, which burns readily to white ashes.

2718 Of water. 4. Before it has become fluid, semen is not soluble in water either cold or hot. To the latter it communicates an opal colour. But in the fluid state it combines readily with either hot or cold water, from which it is separated by alcohol or oxymuriatic acid in the form of white flakes. The alkalies promote the solution of semen in water.

2719 Of lime. 5. No ammonia is disengaged from fresh semen by means of quicklime; but when it has been exposed for some time to a warm and moist air, it is separated in great abundance, so that ammonia is formed during its exposure to the air.

2720 Acids. 6. The acids readily dissolve semen, and this solution is not decomposed by the alkalies; nor indeed is the alkaline solution of semen decomposed by the acids. Wine, cyder, and urine, also dissolve semen, but it is in consequence of the acid which is combined with these liquids. Water acidulated with sulphuric acid acquires the same property. Oxymuriatic acid coagulates semen in white flakes, which are insoluble in water and in acids. The same acid produces the coagulation of fluid semen. This is owing to the absorption of oxygen derived from the acid, which is converted into muriatic acid.

2721 Salts. 7. Barytic salts are not decomposed by the seminal fluid which has been liquefied in a close vessel; but when it has undergone this change in the open air, rhomboidal crystals are formed with the addition of these salts. The calcareous and metallic salts are decomposed by semen in both conditions. From these facts it appears that semen contains an uncombined alkali, which has not the property of decomposing the barytic salts till it has combined with the carbonic acid from the atmosphere.

2722 Semen contains phosphate of lime. 8. The crystals which form in semen by spontaneous evaporation in the open air, and which are entangled in the viscid matter, may be separated by adding water. These crystals have neither smell nor taste. They melt under the blow-pipe into a white opaque globule, which is surrounded with a yellowish flame. This salt is insoluble in water, and is not acted on by the alkalies; but is soluble in the mineral acids without effervescence, from which solutions, lime water, the alkalies, and oxalic acid, throw down a precipitate. Alcohol added to the concentrated muriatic solution of this substance, dissolves part of it, which exhibits all the characters of muriate of lime; and there remains another substance which melts under the blow-pipe into a green transparent glass, soluble in water, which precipitates lime water and reddens vegetable blues. This salt, therefore, as is demonstrated from these experiments, is phosphate of lime. After the formation of the above salts, a great number of small, white, opaque bodies, appear on the surface. They are also phosphate of lime.

2723 And soda. 9. By burning 40 grains of dried semen in a crucible, it first became soft, and then gave out the odour of burnt horn accompanied with yellow fumes. It blackened and emitted the odour of ammonia. The coaly matter which remained was lixiviated with water. This was evaporated, and afforded crystals in the form of rhomboidal plates, which effervesced with acids; with sulphuric acid afforded sulphate of soda, and with muriatic acid formed muriate of soda. The alkali, therefore, was soda.

10. The alkaline matter being separated, the residuum was still exposed to strong heat, and furnished 13 grs. of white ashes, which had the following properties. By the action of the blow-pipe it is converted into an opaque white enamel, which attracts moisture from the air, is soluble in acids, and the solution has all the characters of phosphate of lime. The component parts of semen, therefore, are,

Mucilage	6
Soda	1
Phosphate of lime	3
	100 *

* Vauquelin, Ann. de Chim. ix. 64—80.

XI. Of the Liquor of the Amnios.

1. This liquid is secreted in the *amnios* or bag which surrounds the fœtus in the uterus. It is very different in different animals, so far at least as its nature and properties have been investigated. The liquor of the amnios of women and cows only has been examined. The following are the results of the experiments of Vauquelin and Buniva on these liquids *.

* *Ann. de Chim.* xxxiii. 269.

2725 Properties. 2. This liquid in women is of a milky colour, an agreeable odour, and a saline taste. It becomes transparent by filtering and separating some coagulated matter which is suspended in it, and which communicates the white colour. The specific gravity is 1.005. It seems to contain both an acid and an alkali; for it converts syrup of violets to a green colour, and reddens the tincture of turnsole. It froths when agitated, becomes opaque when heated, and exhales the odour of the white of egg. 2726 Action of heat.

2727 Acids. 3. It is rendered more transparent by acids; but alcohol and the alkalies occasion a flaky precipitate, which is like glue when it is dried. The infusion of nut-galls gives a copious brown precipitate; and nitrate of silver produces a white precipitate, which being insoluble in nitric acid, is muriate of silver.

4. By slow evaporation this liquid assumes a milky appearance; a transparent pellicle forms on the surface, and a very small residuum is left. By adding water to the residuum, and evaporating the solution, muriate and carbonate of soda are obtained. The ashes which remain, after burning the residuum, consist of carbonate of soda, phosphate and carbonate of lime. During the burning, a strong, fetid, ammoniacal odour is exhaled.

2728 Composition. 5. From these experiments, it appears that this liquid consists of a great proportion of water, of albumen, muriate of soda, of soda, phosphate of lime, and lime.

2727 Crust on the fœtus. 6. A white shining soft substance, somewhat resembling soap, is deposited on the body of the fœtus in the uterus. It is insoluble in water, alcohol, and oils. The caustic alkalies dissolve a portion of it, and form a kind of soap. It decrepitates on burning coals, then dries, blackens, and gives out the odour of an empyreumatic oil. It leaves behind a coaly matter, which burns with difficulty. When it is heated in a crucible of platina, it decrepitates, while an oily matter

Component Parts of Animal Substances. matter exudes. It then curls up like horn, inflames, and leaves behind gray ashes, which effervesce with acids, and which seem to be composed chiefly of carbonate of lime.

2730 Composition. 7. This matter seems to be a mixture of animal mucilage and fat, originating from the albumen, which has undergone some peculiar change. The parts of a fœtus which have remained in the uterus after death, have been found converted into a fatty matter.

2731 Characters. *Liquor of the amnios of the cow.*—1. This liquid differs from the former in being of a reddish brown colour, in having an acid bitter taste, an odour resembling the extracts of some vegetables, and the viscidity of a solution of gum. The specific gravity is 1.028. It reddens the tincture of turnsole, forms a copious precipitate with muriate of barytes, and with alcohol a precipitate of a reddish matter.

2732 Amniotic acid. 2. When it is evaporated, a thick scum forms on the surface, which is easily separated, and which, on cooling, is found to contain white crystals of a slightly acid taste. A viscid matter like honey appears, by continuing the evaporation. When this matter is treated with boiling alcohol, it furnishes, on cooling, an acid which crystallizes in shining needles. This is the *amniotic acid* which has been already described. The matter which remains after the separation of the crystals is insoluble in alcohol, and is firm and tenacious.

2733 Sulphate of soda obtained. 3. Having extracted the whole of the acid, if the evaporation be continued till the liquor acquire the consistence of a syrup, large transparent crystals are formed, which have a bitter taste, and are soluble in water. These crystals were found to be sulphate of soda, which are obtained in a state of purity, by burning the residuum of a quantity of the liquid evaporated to dryness, dissolving the coaly residuum in water, and evaporating.

2734 Animal matter. 4. The animal matter which accompanies the saline substances, is of a reddish brown colour and a peculiar taste, very soluble in water, but insoluble in alcohol, which even separates it from water. It neither combines with tan, nor is it susceptible of being converted into jelly, so that it does not possess the properties of animal mucilage. When it is heated strongly it swells up; exhales at first the odour of burning mucilage; afterwards that of ammonia and an empyreumatic oil; and at last that of prussic acid. When it is burnt, there remains behind a bulky coal, the ashes of which are white, and contain phosphate of magnesia and a small portion of phosphate of lime.

2735 Composition. 5. The constituent parts of the liquor of the amnios of the cow are the following.

Water,
Acid,
Sulphate of soda,
Animal matter.

XII. Of Fluid Morbid Secretions.

1. During the diseased action of the vessels of different parts of the body, liquids are secreted, as for instance when the muscular or bony parts are wounded, a matter is exuded, which continues to flow till the wound is healed up; in dropsical diseases a liquid is secreted in the different cavities of the body; and when the skin is irritated by the action of blisters, a fluid collects between the cuticle and true skin.

Liquor of dropsy.—This liquid is of a yellowish green colour, has sometimes considerable transparency, but is sometimes turbid. In its chemical properties it seems to correspond with the serum of the blood.

Liquor of blisters.—The liquor which is secreted by the action of blisters is usually transparent. The constituent parts are the same as those of the serum of the blood. Two hundred parts of this liquid yielded

Albumen	36
Muriate of soda	4

	200 *.

* Ann. de Chim. xiv. 225.

Pus.—What is called healthy pus is about the consistence of cream, and of a yellowish-white colour, an insipid taste, and when it is cold, without smell. It produces no change on vegetable blues.

2. When pus is exposed to a moderate heat, it dries, and assumes the appearance of horn. By distillation it gives out water in considerable proportion, ammonia and some gaseous substance, and an empyreumatic oil; a shining coaly matter remains behind, the ashes of which, after being burnt, afford some traces of iron. 2736 Action of heat.

3. When this liquid is exposed to the air, it becomes acid. It is soluble in sulphuric acid, forming with it a purple-coloured solution. With the addition of water the pus separates, and the dark colour disappears. With concentrated nitric acid it forms a yellow coloured solution, which effervesces during the combination. Water produces a precipitate. Pus is also soluble in muriatic acid, and is separated by means of water. Pus is not soluble in alcohol, but it is thickened; nor is it soluble in the oils. 2737 Of air and acids.

4. A whitish ropy fluid is formed by the addition of a solution of the fixed alkalies, and by adding water the pus is precipitated. Pure ammonia forms with pus a transparent jelly, and dissolves it in considerable proportion. 2738 Alkalies.

5. A precipitate is occasioned by means of nitrate of silver, and it is still more copious with nitrate and oxymuriate of mercury. 2739 Metallic salts.

6. The following tests have been given to distinguish pus from mucus, which is of considerable importance in cases where the formation of pus is suspected in the lungs. 2740 To distinguish pus.

(1.) Pus is soluble in sulphuric acid, and precipitated by water. Mucus swims. (2.) Pus may be diffused through water, diluted sulphuric acid, and brine; but mucus is not. (3.) Pus is soluble in alkaline solutions, and is precipitated by water; but this is not the case with mucus.

7. These are the properties of pus when it is secreted from a sore which is said to be in good condition, or in a disposition to heal. Its properties are very different in what are called ill-conditioned sores. In these cases the matter secreted is thin, fetid, and acrid. Matter secreted by cancerous sores, which has been examined, converts the syrup of violets to a green colour, and from 2741 Varies in its properties.

Component Parts of Animal Substances.

from this matter sulphurated hydrogen gas is separated by means of sulphuric acid. This gas is supposed to exist in combination with ammonia.

Subdivision III. Of the Solid Parts of Animals.

2742 Enumeration. The following are the solid parts of animals, which we shall treat of in the order in which they are enumerated.

1. Bones,
2. Skin,
3. Muscles,
4. Cartilage, tendons, &c.
5. Brain and nerves,
6. Hair and nails,
7. Morbid concretions,

1. Of the Bones.

2743 Of different density. 1. The bones are those parts of animals which give firmness, strength, and shape to the body. Bones are very different with regard to solidity and density, not only in different parts of the body, but even in the same bone. The specific gravity, therefore, of bones, must be various. They are of a white colour, of a lamellated structure, and inflexible.

2744 Action of heat. 2. When bones are burnt, they are converted into a white, porous, insipid substance, which still retains the shape of the bone.

2745 Contains fat. 3. When bones are broken into small pieces, and boiled in water, a considerable quantity of fat rises to the surface; an oily matter, therefore, is one of the constituent parts of bones.

2746 Gelatine. 4. If the boiling be continued for a greater length of time, the water dissolves another substance, which, being concentrated and left at rest, assumes a gelatinous form. Bones, therefore, contain a portion of gelatine.

2747 Cartilage. 5. If bone is kept for some time in diluted muriatic acid, it is converted into a white flexible substance, which retains the shape of the bone. It becomes brittle and semitransparent when dried; it is soluble in nitric acid, and when this acid is diluted, it is converted by its action into gelatine. It forms a soap with the fixed alkalies. From these properties it resembles coagulated albumen. This substance, which is called cartilage, is the first part of the bone which is formed.

2748 Salts. 6. Besides these substances, bones contain a considerable proportion of earthy salts. These are phosphate of lime, which is in great proportion; carbonate of lime in smaller proportion, with a still smaller of sulphate of lime.

2749 Composition. 7. The component parts of bones, therefore, are earthy salts, cartilage, gelatine, and fat. The following table exhibits the proportions of these constituent parts in the bones of different animals. It was drawn up by Merat-Guillot. A hundred parts of bones were employed, and as much dried as possible, and to this quantity the proportions specified refer *.

	100.0

II. Of the Skin.

1. The skin, which forms the external covering of animals, consists of three parts; the epidermis or cuticle, the true skin, and a soft substance called the *rete mucosum*, which lies between the cuticle and true skin. 2751 Consists of three parts.

2. The epidermis, which may be separated from the cutis, by macerating the skin in hot water, is a thin elastic substance, which is insoluble in water and in alcohol. 2752 Epidermis.

3. Sulphuric and muriatic acids have little action for some time on this substance; but it is immediately converted into a yellow colour by means of nitric acid, and 2753 Action of acids, &c.

Component Parts of Animal Substances.

and at last entirely decomposed. It is entirely soluble in the caustic fixed alkalies. From these properties the epidermis is supposed to be coagulated albumen in a peculiar state of modification.

2754 Cutis. 4. The cutis or true skin is denser and thicker. When it is heated, it first contracts, then swells, exhaling a fetid odour, and leaving behind a dense mass of charcoal. By distillation the same products are obtained as from fibrina.

2755 Action of heat. 5. The skin is softened by weak acids, is rendered transparent, and is at last dissolved. It is converted into oxalic acid and fat by nitric acid, with the evolution of azotic gas and prussic acid. It is converted by means of the concentrated alkalies into oil and ammonia.

2756 Contains gelatine. 6. After maceration for some time in water, a small proportion of gelatine may be obtained, by evaporating the water; but if the skin be boiled for a considerable time in water, it is entirely dissolved, and the liquid, by evaporation, assumes the consistence of jelly. The skin is thus converted into glue. It is from the skin of animals that glue is chiefly extracted; and it is obtained of different degrees of strength from the skin of different animals.

2757 Tanning. 7. As skin consists chiefly of gelatine, it combines readily with tan. This compound forms leather; and the process by which it is effected is called *tanning*, for the detail of which see the article TANNING.

2758 Rete mucosum. 8. The mucous substance, or *rete mucosum*, lies between the epidermis and true skin. It is this which gives the black colour to the skins of negroes. It is deprived of its colour, even in the living body, by means of oxymuriatic acid. The foot of a negro became nearly white by being kept for some time in water impregnated with this acid. The black colour, however, returned in a few days.

III. Of the Muscles.

2759 Structure. 1. The muscular, or fleshy parts of animals, are of a reddish-white colour, and fibrous structure. If a quantity of muscular substance is separated into small

2760 Action of cold water. pieces, it becomes white. If the water be heated, it coagulates. Albumen and a portion of fibrina are obtained. It becomes gelatinous by farther evaporation; and when the process is carried on to dryness, and alcohol added, a peculiar matter is dissolved; which, after the alcohol is expelled by heat, appears of a reddish-brown colour, has an aromatic smell, and a very acrid taste; and it is soluble both in water and alcohol. The gelatine formed in the mass evaporated to dryness, with a little phosphate of soda and ammonia, remains undissolved by the alcohol. When this extractive matter is distilled, it affords an acid, which is combined with ammonia.

2761 Boiling. By boiling the same muscular matter for some time in water, another portion of albumen is obtained; and, when the water is concentrated by evaporation, it is converted into a jelly; and by treating with alcohol as before, after evaporating to dryness, the extractive matter is taken up, and the gelatine and phosphoric salts remain undissolved. The fibres of the muscle are then of a gray colour, insoluble in water, and become brittle when dry. This substance is fibrina, which constitutes the chief part of muscular matter.

2. If muscular matter be dissolved in nitric acid, and ammonia added to the solution, a precipitate of phosphate of lime is obtained; but no phosphate of lime is obtained, when treated in this way, after being long boiled in water, for it is either combined with the gelatine, or is thus rendered soluble. Carbonate of lime, however, is found after boiling the muscular substance, and is converted into oxalate of lime by means of nitric acid. 2762 Nitric acid.

3. The constituent parts of muscular matter are the following: 2763 Composition.

Fibrina,	Phosphate of soda,
Albumen,	Phosphate of ammonia,
Gelatine,	Phosphate of lime,
Extractive,	Carbonate of lime.

4. From the difference of solubility of the substances which enter into the composition of muscular matter, and the different effects of heat on these substances, the sensible qualities at least must vary considerably, according to the manner in which this matter is prepared for food. Accordingly, when the flesh of animals is boiled, those parts which are soluble in water combine with it. These are, the gelatine, the extractive matter, and part of the saline bodies. It is to these that the nutritious property of soups is ascribed. But when the flesh of animals is roasted, it has a much higher flavour, in consequence of these substances not being separated from it, and particularly the extractive matter, on which the odour and flavour depend. This extractive matter, according to Fourcroy, composes the brown crust which is formed on flesh during its roasting. 2764 Properties of muscular matter for food. 2765 Boiled. 2766 Roasted.

5. The muscular part of different animals, from its sensible qualities at least, seem to possess very different properties. Hence the difference in the taste, flavour, and nutritious quality, of the flesh of different animals. 2767 Different properties.

6. When the muscular parts of animals are exposed for a considerable length of time to the action of running water, they are converted into a peculiar substance, resembling in some measure spermaceti. The same change, indeed, in similar circumstances, takes place on the other soft parts of animals. This was first observed in the year 1786, in the Innocents burying-ground in Paris, where great numbers of bodies were thrown together into the same pit. The time which was required for this conversion was supposed to be in general about thirty years. But it has since been found, that animal matters are converted into a substance exactly similar, and in a much shorter period, by exposing them to the action of running water. 2768 Conversion of muscular matter into spermaceti.

7. The matter produced by this change is of a white colour, soft and unctuous to the feel, and melts like tallow. It is decomposed by diluted acids; and an oily matter, with which it is mixed, is separated. By the action of alkalies and lime, ammonia is evolved. By exposure to the air, it is deprived of its white colour; the ammonia is almost entirely carried off, and a substance resembling wax remains behind. The oily matter, which is separated by a diluted acid, is of a white colour, and concrete. It becomes of a grayish brown colour by drying, and assumes a crystalline, lamellated texture, like spermaceti. At the temperature of 126° it 2769 Properties.

Component Parts of Animal Substances.

it melts. It is soluble in alcohol at the temperature of 120°. It forms a soap with alkalies, and burns like oil; but exhales a disagreeable odour, which is the chief objection to its use as a substitute for oil, as it is supposed it may be obtained at a cheaper rate. A manufacture indeed has been established at Bristol for the preparation of this substance.

IV. Of Membranes, Tendons, and Ligaments.

2770 Membranes. 1. Membranes are those parts of the body which include some of the internal parts of animals. Many of them are extremely thin, and they possess different degrees of transparency. They become pulpy by maceration in water, and by boiling are almost entirely converted into gelatine, so that they are chiefly composed of this substance. No phosphate of lime or other saline matter has been detected in the membranous substances hitherto analyzed.

2771 Tendons. 2. Tendons are reduced by boiling to a gelatinous substance, so that they are composed of a similar matter with membranes.

2772 Ligaments. 3. The ligaments afford a portion of gelatine by boiling, but are not, like the two former, entirely reduced to a jelly, so that some other substance besides gelatine enters into the composition of ligaments.

V. Of the Brain and Nerves.

2773 Action of water, &c. 1. The matter of the brain and nerves has a soft, soapy feel, and a close texture. When exposed to the air at the temperature of 60°, it soon becomes putrid, exhaling an offensive smell, and giving out a considerable quantity of ammonia. It is not soluble in cold water; but triturated with water in a mortar, a part is dissolved, and if this be heated moderately it coagulates. If sulphuric acid be added to this solution, white flakes appear on the surface, and the liquid assumes a red colour. Similar flakes are produced by the action of nitric acid, but the colour of the liquid is yellow. If nitric acid be added till a slight acidity is produced, a coagulum of a white colour separates, which is insoluble in water and alcohol, is softened by heat, and becomes transparent when it is dried. This matter, therefore, possesses many of the properties of albumen.

2774 Sulphuric acid. 2. If a quantity of brain be triturated with diluted sulphuric acid, part is dissolved, and part is coagulated. The liquid part is colourless, and when it is evaporated, it becomes black, while superfluous acid is exhaled, and crystals are formed. When it is evaporated to dryness, a black mass remains behind. By diluting this with water, charcoal separates. The matter therefore is entirely decomposed, ammonia is disengaged, and combines with the acid, forming sulphate of ammonia. By evaporating the water, sulphate of ammonia and sulphate of lime, phosphoric acid, and phosphates of soda and ammonia, are obtained; and these salts may be separated by means of alcohol.

2775 Nitric acid. These salts, however, exist in brain in small proportion. By treating in the same way a quantity of brain with nitric acid, part is dissolved, and part coagulated. When the solution, which is transparent, is evaporated till the acid is concentrated, carbonic acid and nitrous gases are evolved; a great quantity of ammonia is separated with effervescence, and charcoal remains behind, mixed with oxalic acid.

3. If a quantity of brain be evaporated to dryness with a gentle heat, a portion of transparent liquid separates, and the residuum assumes a brown colour when it is dried. 2776 Of heat. The weight of this residuum does not exceed one-fourth of the quantity employed. If the residuum be repeatedly boiled with alcohol, more than one-half is dissolved; and when the alcohol cools, it deposits a yellowish white substance in the form of shining plates, which may be reduced to a kind of ductile paste. It becomes soft with the heat of boiling water, and blackens with an increase of temperature, exhaling empyreumatic and ammoniacal fumes; a charred matter remains behind. By evaporating the alcohol, a yellowish black matter is deposited, which reddens paper stained with turnsole.

4. Brain is soluble in concentrated caustic potash; 2777 Alkalies.
and during the solution, a great quantity of ammonia is given out.

VI. Of Hair and Nails.

1. If we include all those substances which form the 2778 Different in appearance.
covering of animals, as bristle, hair, wool, and down, under the general name of hair, and particularly as they possess nearly the same properties, we shall find that it varies greatly in size, in length, and colour, in different animals, and even in different parts of the body of the same animal.

2. If hair be boiled in water, a quantity of gelatine 2779 Action of water.
is obtained, and, by continuing the boiling, the hair becomes so brittle, that it crumbles to pieces. The part which remains, after the gelatine has been separated, seems to be coagulated albumen. But besides gelatine and albumen, it appears from the combustion of hair, that it contains a portion of oily matter. Berthollet obtained by the distillation of a quantity of hair, carbonate of ammonia, water having the smell of burnt hair, some oil, and elastic fluids, which were probably carbonated hydrogen and carbonic acid gases. The oil was of a brownish colour, and was concrete in the ordinary temperature of the atmosphere. It was soluble in alcohol, and burnt with a vivid flame. 2780 Distillation
The charcoal which remained could scarcely be calcined, but some of its particles were attracted by the magnet.

3. The acids soften and destroy the colour of hair. 2781 Acids.
It is decomposed by sulphuric acid with the assistance of heat; charcoal is deposited, and carbonic acid gas given out. Nitric acid communicates a yellow colour to hair, and dissolves it with the aid of heat. An unctuous matter is separated, and oxalic acid is formed. Muriatic acid at first whitens hair; but it becomes yellow when it dries. Oxymuriatic acid also bleaches hair; but at the same time destroys its texture. It is converted into a pulp when it is introduced into oxymuriatic acid gas.

4. Hair is soluble in the alkalies, and is converted 2782 Alkalies.
into a reddish-coloured soap, with the evolution of ammonia. If muriatic acid be added to the solution of hair in potash, sulphurated hydrogen gas is evolved, from which it appears that hair contains sulphur. Silver is blackened by the same solution.

5. The metallic oxides also have the effect of blackening 2783 Metallic oxides.

Component Parts of Animal Substances.

ening hair. It is in this way that the hair is dyed black. The red oxide of lead, the acetate of lead, and sometimes even the nitrate of lead, and the nitrates of mercury and silver, are employed for this purpose.

2784 Nails. *Nails.*—The nails are considered as an elongation of the epidermis. They are attached to it, and separate when it is removed. They become soft by long maceration in water. There is no precipitate formed in this solution with tan. Nails are soluble in the acids and the alkalies. They are stained with metallic oxides, and combine with colouring matters. 2785 Composition. From these properties the nails are considered as a kind of coagulated albumen, with a small proportion of phosphate of lime, and, according to some, carbonate of lime.

VII. Of Morbid Concretions.

2786 Found in different parts of the body. 1. Earthy matters are frequently found in different parts of animal bodies, which are to be considered as extraneous, and occasioning, at least in the human body, some of the severest disorders to which it is subject. These earthy matters are generally combined with an acid, and in some cases entirely composed of an acid. These substances, which have been called *concretions* and *calculi*, are formed, sometimes in the solid parts of the body, but chiefly among the fluids.

2787 Pineal. *Pineal concretions.*—These concretions are almost always found in the pineal gland of the human brain. They are indeed so rarely wanting in the brain, that they are considered as natural, as they do not seem to produce any inconvenience or disease. They have been found to consist of phosphate of lime, mixed with some animal matter.

2788 Salivary. *Salivary concretions.*—Concretions form in the salivary glands, and in the ducts which convey the secreted fluid from these glands to the mouth. The component parts of these concretions have been found to be also phosphate of lime and animal mucilage.

2789 Tartar of the teeth. The tartar of the teeth is composed of the same substance. When this was examined with the microscope, it seemed to be composed of small shining grains united to each other, and containing a great number of pores or small angular cavities, resembling the cells of polypi, on account of which some naturalists have ascribed its formation to insects; but it is more natural to suppose that it is merely a crystalline arrangement of the saline matter of which it is composed.

Concretions have also been found in the pancreas, and its ducts, and are supposed to consist of the same materials.

2790 Pulmonary. *Pulmonary concretions.*—These concretions are formed in the lungs during asthmatic and phthisical disorders. They are small hard bodies, unequal and rough, of a gray or reddish colour, which become white as they dry in the air. They are also composed of phosphate of lime mixed with animal matter.

2791 Intestinal. *Intestinal concretions.*—These are more rarely met with in the human body. When they are found, they have been generally formed on the stones of fruits, or some other hard body which has been swallowed. They are more frequent in the intestines of the inferior animals, as in those of the horse. Some that have been examined were of a gray colour, and of a radiated or crystallized structure. The component parts of a stone of this description, analyzed by Berthollet, were the following:

2792 Composition.

Magnesia	18.0
Phosphoric acid	26.0
Ammonia	3.2
Water	46.0
Animal matter	4.0
	67.2 *

* Ann. de Chim xxiii. 130.

2793 Biliary composed *Biliary concretions.*—Biliary concretions, or calculi, are formed, either in the liver itself, in the gall-bladder, or in the gall ducts, hence they have also been called *gall-stones.* Some found in the liver itself are composed of phosphate of lime combined with some animal matter. The calculi which have been found in the gall-bladder are different, both in structure 2794 of inspissated bile; and composition. Some of them seem to be composed of concentric layers of inspissated bile. These have different degrees of consistence; they are sometimes friable, and of a brown or reddish colour. The gall-stones of the ox, which are used by painters, are of this kind. Another kind of biliary calculi differ only 2795 of a substance like spermaceti from the former in having a smooth whitish or grayish covering, resembling spermaceti. They are sometimes found in considerable numbers in the gall-bladder.

2796 of shining plates; A third species is of a white or gray colour, opaque, or semitransparent. These are composed of shining crystalline plates, or have a radiated structure. They are frequently solitary, and are then about the size, and have the form, of a pigeon's egg. The nucleus of this kind of gall-stone is composed of inspissated bile.

2797 or mixed. A fourth species is composed of different proportions of the spermaceti substance and the concrete bile. These are the most frequent of all the kinds of gall-stones, and are also the most numerous. They are of a deep green or olive colour. Sometimes they exhibit, internally, small shining plates of a deep yellow colour.

2798 Action of alkalies, &c. All these calculi are soluble in the caustic alkalies, in solutions of soap, in fixed and volatile oils, in alcohol, and partially in ether.

2799 Urinary calculi. *Urinary concretions.*—1. These concretions, which are frequently formed in the urinary bladder of man, and produce one of the most excruciating disorders to which he is subject, have long attracted attention, with a view to prevent their formation, or to effect their dissolution after they have been formed. Little, however, has yet been done, to accomplish either of these ends; but the nature of the concretions themselves has been carefully investigated, and their component parts minutely examined by different chemists. 2800 Found in different parts of the organs. Among these the labours of Fourcroy and Vauquelin are not the least conspicuous. Urinary calculi are found, either in the kidneys, the ureters, or the urinary bladder itself. Calculi, as found in the kidneys, vary considerably in size, form, colour, and internal structure. They are usually small, round, concrete bodies, smooth and shining externally, of a reddish-yellow colour, and so hard as to be susceptible of a polish. They pass readily along the ureters to the bladder, and from thence are ejected along with the urine. It is the formation of these small concretions

Component Parts of Animal Substances.

tions which constitutes the disease called *gravel*. Some of these concretions sometimes remain in the kidneys, and increasing in volume by receiving new additions of matter, form large calculi. This happens, however, but rarely. The calculi which have been found in the ureters have originated from the kidneys, and being too large to pass along the ureters, receive new additions of matter as it is deposited from the urine, and enlarge in size, at the same time dilating the ureter.

But by far the most common are those which are found in the bladder itself. These calculi have either originated from small concretions formed in the kidneys, and these passing along the ureters into the bladder, form a nucleus on which successive layers of matter are deposited from the urine; or they have their origin and complete formation in the bladder itself, or have been formed on some extraneous substance introduced into the bladder through the urethra. The first
2801 are the most frequent.

Physical properties.

2. The form of urinary calculi is various, but they are frequently of a spheroidal or egg-shape, or compressed on two sides. Sometimes they are polygonal, which happens when there are several in the bladder at the same time. Some have been found of nearly a cubical form. Their extremities are frequently either pointed or obtuse. Their size is extremely various. Sometimes they are not larger than small beans, while some have been of such an extraordinary size as to fill the bladder itself; but they are most frequently from the size of a pigeon's egg, to that of a hen's egg. Some are of a yellowish-brown colour, resembling wood. These are composed of uric acid. Those which are white, or grayish-white, consist of the earthy phosphates, and those which are of a deep gray or blackish colour, are composed of oxalate of lime. Some exhibit all these different shades mixed together. The surface of urinary calculi is sometimes smooth and polished; sometimes it is rough and unequal, and tuberculated. Some urinary calculi having their surface mamellated, are called *mulberry stones*, from some resemblance to a cluster of mulberries. Some of the white calculi are soft and smooth, semitransparent, and covered with shining crystals. The specific gravity varies from 1.213 to 1.976. The odour of urinary calculi is sometimes perceptibly urinous and ammoniacal, which is discovered by rasping or sawing them; sometimes it is faint and earthy, as in the white calculi; and sometimes it resembles that of ivory sawed or rasped, and is analogous to the odour of semen. Mulberry calculi are distinguished by this
2802 odour.

Constituent parts.

3. The following substances have been discovered in urinary calculi.

Uric acid,	Oxalate of lime,
Urate of ammonia,	Carbonate of lime,
Phosphate of lime,	Silica,
Phosphate of magnesia and ammonia,	Animal matter.

2803 Uric acid.

Uric acid exists in almost all urinary calculi. Many calculi indeed are entirely formed of it; but it is found in greater or smaller proportion, in almost all that have been analyzed. The nature and properties of this acid have been already described. The calculi composed of it are of a brown colour, are smooth and polished, and have the appearance of wood. When this substance is triturated with a concentrated solution of potash or soda, it forms a thick saponaceous matter, which is precipitated by diluted acids. It is dissolved by nitric acid, and is converted into a red colour. This acid is a compound of azote, carbon, hydrogen, and oxygen; and when decomposed by chemical agents, it is converted into ammonia, malic, oxalic, prussic, and carbonic acids. 2804

Urate of ammonia.

Urate of ammonia, the next substance found in urinary calculi, is also soluble in potash and soda, but the solution is accompanied with a copious evolution of ammonia. Calculi composed of this substance, consist of thin layers, and are not always smooth. They are generally of a small size, and resemble an infusion of coffee. The earthy phosphates are frequently interposed between the layers of calculi composed of this substance, and it is often mixed with phosphate of ammonia and magnesia. 2805

Phosphate of lime.

Phosphate of lime frequently enters into the composition of calculi. It is usually in thin layers, which are friable, and have little consistency. They are of a grayish-white colour, and opaque, without taste or smell. The phosphate of lime is usually mixed with gelatinous matter; is soluble in different acids, and is precipitated by the alkalies. Some calculi have been discovered entirely composed of phosphate of lime. 2806

Of ammonia.

Phosphate of ammonia and magnesia is in the form of white, semitransparent layers, and it is sometimes found crystallized on the surface of calculi in the form of prisms. When reduced to powder it is of a brilliant white, very soluble in diluted acids, and is decomposed by the fixed alkalies. 2807

Oxalate of lime.

Oxalate of lime is usually mixed with phosphate of lime and uric acid, but sometimes it is combined only with animal matter in mulberry calculi. The calculi composed of it are of a dark green colour, and extremely hard. It dissolves with difficulty in diluted nitric acid, and is decomposed by the carbonates of potash and soda. 2808

Carbonate of lime.

The carbonate of lime constitutes the greatest part of some urinary calculi.

2809 Silica.

Silica has been rarely found in calculous concretions. It was detected mixed with phosphate of lime, only in two mulberry calculi, which were extremely hard. 2810

Animal matter.

In all calculous concretions there is a quantity of animal matter, which unites or cements together the layers or particles of the hard substances of which they are composed. This animal matter seems to possess the properties of albumen. Sometimes it seems to be composed of albumen mixed with urea, of coagulated albumen, or gelatine. 2811

Divided into three genera and 12 species.

4. Fourcroy and Vauquelin have analyzed more than 600 calculi, and by comparing the properties of each, they have arranged them into three genera and 12 species. The first genus comprehends those species which are composed of one substance. These are the three following:

1. Uric acid,
2. Urate of ammonia,
3. Oxalate of lime.

The second genus includes those species which are composed

composed of two substances. It consists of the following seven species :

1. Uric acid and the earthy phosphates, in distinct layers.
2. Uric acid and the earthy phosphates intimately mixed together.
3. Urate of ammonia and the phosphates in distinct layers.
4. The two preceding intimately mixed.
5. Earthy phosphates mixed or in thin layers.
6. Oxalate of lime and uric acid in layers.
7. Oxalate of lime and earthy phosphates in layers.

The third genus consists of two species, which are composed of three or four substances.

1. Uric acid or urate of ammonia, earthy phosphates, and oxalate of lime.
2. Uric acid, urate of ammonia, earthy phosphates, and silica.

We shall now state the general characters of these different species.

Genus I.

Species I. *Uric acid.*—These calculi are easily known by their colour, which resembles wood. It is reddish, or yellowish. They are of a radiated, dense, fine texture, completely soluble in pure alkalies, without emitting any odour. They vary greatly in size, and have generally a smooth polished surface. The specific gravity is from 1.276 to 1.786. It usually exceeds 1.5. Of 600 calculi which were analyzed by Fourcroy and Vauquelin, 150 consisted of pure uric acid. The sand or gravel which is formed in the kidneys usually belongs to this species.

2. *Urate of ammonia.*—Calculi composed of this substance are usually of small size, soluble in caustic fixed alkalies, with the evolution of ammonia, of the colour of the infusion of coffee, and are composed of fine layers which are easily separated. The surface is commonly smooth, and sometimes shining and crystalline. The specific gravity is from 1.225 to 1.720. They are soluble in hot water, at least when reduced to powder. The external layer is sometimes pure uric acid. This species is rare.

Oxalate of lime.—This species is easily recognized by its rough, mamellated surface, from which those calculi have received the name of mulberry stones. The colour is brown, they are of a close hard texture, and when rasped or sawed, emit the odour of semen. They are soluble with difficulty in acids, and are insoluble in the pure alkalies. The specific gravity is from 1.428 to 1.976. This species frequently constitutes the nucleus of other calculi.

Genus II.

Species 1. *Uric acid and earthy phosphates in distinct layers.*—This species is known by its surface, which is white like chalk, friable, and semitransparent. The external layer is composed of the phosphate of lime, or of ammonia and magnesia. The nucleus consists of uric acid, and when the calculus of this species is sawed asunder, two substances of which it is composed are distinctly seen. It is indeed only then that the species can be recognized. Calculi of this description are not uncommon, and they are generally of the largest size of all the urinary calculi. The specific gravity is very variable.

2. *Uric acid and earthy phosphates intimately mixed.*—This species contains numerous varieties, from the different proportion of the constituent parts. Sometimes the uric acid and the earthy phosphates are arranged in layers so thin, that they are scarcely perceptible. Sometimes they are so mixed together that they can only be detected by analysis. But sometimes the layers are sufficiently distinct. The specific gravity is from 1.213 to 1.739. This species of calculus is common.

3. *Urate of ammonia and the phosphates in distinct layers.*—In this species the nucleus consists of urate of ammonia; and the external layers are most frequently composed of the earthy phosphates mixed together, or more rarely of phosphate of ammonia and magnesia. This species is usually of small size; its specific gravity is from 1.312 to 1.761. It is not very common.

4. *Urate of ammonia and earthy phosphates mixed.*—The calculi belonging to this species are very rare. They are of a pale yellow colour, and of less specific gravity than the second species of this genus, which they resemble in external characters. When they are treated with potash, ammonia is disengaged. This species is usually of small size.

5. *Earthy phosphates mixed, or in thin layers.*—This species is distinguished by its pure white colour. They are of a friable texture, insoluble in alkalies, and soluble in diluted acids. This species is pretty common, and often of a large size. The concretions formed on extraneous matters introduced through the urethra into the bladder, are of this kind. The specific gravity varies from 1.138 to 1.471.

6. *Oxalate of lime and uric acid in distinct layers.*—In this species the nucleus consists of oxalate of lime, and it is covered with a layer of uric acid. From external appearance they are not distinguished from those entirely composed of uric acid, till they are sawed asunder. The specific gravity varies from 1.341 to 1.754.

7. *Oxalate of lime and earthy phosphates in layers.*—The oxalate of lime constitutes the nucleus, and the earthy phosphates compose the external covering in this species of calculus. It can only be distinguished by being sawn asunder. The calculi belonging to this species vary greatly in form and size, but they are always white externally. The specific gravity is from 1.168 to 1.752.

Genus III.

Species 1. *Uric acid, urate of ammonia, the earthy phosphates, and oxalate of lime.*—In this species there are frequently three distinct layers. The centre or nucleus is composed of oxalate of lime; the next of uric acid or urate of ammonia; and the outermost of the earthy phosphates, which are usually mixed with uric acid, or urate of ammonia. The calculi of this species can only be distinguished by sawing them in two. There are many varieties of this species, from the different proportions and the different arrangement of the constituent parts.

2. *Uric acid, urate of ammonia, earthy phosphates,* and

Component Parts of Animal Substances. *and silica.*—In the calculi belonging to this species, the silica seems to hold the place of the oxalate of lime. It is mixed with uric acid and urate of ammonia, and covered with the phosphate of lime. This is the rarest species of all that have been examined.

2812 Causes of urinary calculi. 3. The investigation of the cause of the formation of calculous concretions has occupied a great deal of the attention of physiologists and physicians, and undoubtedly it is one of the most important on which their researches can be employed; for by obviating the cause of this disorder, its terrible effects might be prevented. Unfortunately, however, little is yet known on this intricate subject. In many cases, indeed, the formation of urinary calculi is obviously owing to the introduction of some extraneous substance into the bladder by the urethra. But this mode of formation is comparatively rare, and the calculi thus formed are composed of the earthy phosphates, which are deposited from the urine. All urine contains uric acid. This forms one of the most common species of calculi. The particles of gravel which are formed in the kidneys consist of this acid, so that it very often forms the nucleus of calculous concretions. But the production of an excessive quantity of uric acid, in whatever way this takes place, seems to be the most powerful cause of the production of urinary calculi. It has been observed, too, that the urine of those persons in whom these concretions are most frequent, is loaded with an unusual proportion of animal matter. This forms the cementing substance of these concretions. In the formation of these concretions, it would appear that the different substances of which they are composed, are secreted at different times, or in different proportions, since the different successive layers of calculi are composed of totally distinct substances. It is perhaps difficult or impossible to explain the formation of those calculi in which oxalic acid is a constituent part. This acid has scarcely ever been detected in the urine, at least of adults, so that it must be produced by some morbid action, by which some of the animal fluids are converted into this substance.

2813 Solvents. 4. It has long been an object with physicians, to discover the means of dissolving these substances after they have been formed; and the empiric has not been idle in offering his nostrums, which are held out as solvents of the stone, and which it is no wonder are eagerly received with the hope of relief from one of the most dreadful maladies which can afflict mankind. Nothing, however, can be done with this view on rational principles, without previously knowing the nature and properties of the substances which are to be dissolved; and even when this is known, it must appear, from considering the function of digestion, and the changes which all substances taken into the stomach undergo, that little can be expected from the exhibition of remedies in this way. After being subjected to the different processes of digestion, respiration, and secretion, the properties of these substances are totally changed, so that they can only produce some general effect on the system, and can have no specific action on particular organs. It has therefore been proposed by the French chemists, to employ these substances which possess the property of dissolving urinary calculi out of the body, by injecting them through the urethra into the bladder.

It has been found by experiment, that calculi composed of uric acid, or urate of ammonia, are soluble in solutions of pure potash and soda, even when these solutions are so much diluted with water that they may be taken internally, without producing any inconvenience.

Experiments have also shewn, that calculi composed of the earthy phosphates are soluble in nitric and muriatic acids, so much diluted that they may be taken internally without the smallest injury.

Calculi composed of oxalate of lime are less easily dissolved. They are, however, soluble in diluted solutions of carbonate of potash or soda.

The first difficulty, however, which presents itself in the use of these solvents, is to discover the nature and composition of the concretion to be dissolved. This can only be done by employing some of the solutions, and examining them after they have remained for some time, or as long as they can be retained in the bladder. If a weak solution of potash has been injected, it is to be filtered, as soon as it is thrown out; and if on the addition of a little diluted muriatic acid, or vinegar, a white precipitate appears, the calculus is to be considered as composed of uric acid. But if this solution has been employed for some time, and no precipitate is produced in this way, the solution for the phosphates is then to be employed, and when it is passed, after remaining some time in the bladder, a precipitate will be formed with the addition of ammonia. This precipitate will be phosphate of lime. 2814 Methods of using.

If no effect is produced by any of these solutions, and if the severity of the symptoms continues, there is some probability that the calculus consists of oxalate of lime. This, it has been observed, is the most difficult of solution. It may be dissolved, however, although slowly, in nitric acid greatly diluted with water, or in weak solutions of the carbonates of potash or soda. These solutions, therefore, must be employed when the others have failed. The effects of these solutions must be judged of by the alleviation of the symptoms, or by the actual examination of the stone itself at different times, by means of the catheter, or sound. Whatever solution is employed, it ought to be of the temperature of the body, and so much diluted as not to irritate or injure the internal surface of the bladder to which it is applied. Before the injection is made, the urine should be evacuated, and the injection retained, for at least a quarter of an hour, from that to an hour, or as long as it can be done without inconvenience. The injections should be repeated at first three or four times a day, and afterwards increased to six or eight times. As calculous concretions are frequently several years in forming, it is obvious that they must require a long time to dissolve them, so that the use of injections, if any relief is to be obtained from them, must be long continued.

5. Calculous concretions are not unfrequent in the urinary organs of other animals. They have been found in the horse, in the dog, the rabbit, the hog, and the rat. They are most frequently composed of carbonate of lime with some animal matter; sometimes of phosphate of lime, of phosphate of ammonia, and of carbonate of lime and phosphate of lime; but no traces of uric acid have yet been detected in these concretions. 2815 In other animals.

Component Parts of Animal Substances.

2816 Chalk stones. *Gouty concretions.*—1. Concretions, which are commonly called *chalk stones*, are sometimes formed in the joints of those who have been long subject to the gout. They have been discovered by chemical analysis to be composed of uric acid and soda.

2817 Properties. 2. These concretions are of a white colour, irregular in their form, and of a fine granulated texture. When they are boiled for a few minutes, in 100 times their weight of water, they are entirely dissolved. Sulphuric acid added to this solution produces a white precipitate, which asumes the form of small needles, which are crystals of uric acid. The remaining liquid, by being evaporated, affords sulphate of soda.

2818 Action of alkalies. 3. By treating a quantity of gouty concretion with 100 times its weight of a concentrated solution of potash with the aid of heat, it is almost entirely dissolved, exhaling at the same time the faint odour of animal matter. When the liquid is filtered, and muriatic acid added, it produces a white precipitate, which is uric acid. From this it appears, that gouty concretions possess similar properties with those formed in the urinary organs, excepting that they contain a greater proportion of animal matter.

2819 Acids, &c. 4. When it is dissolved in a small quantity of diluted nitric acid, it tinges the skin with a rose colour, and when evaporated, leaves a rose-coloured deliquescent residuum. By distillation this substance yields ammonia, prussic acid, and an acid sublimate.

2820 Artificial formation. 5. If a small portion of uric acid be triturated with soda and a little warm water, they combine; and after the superfluous alkali has been washed out, the remainder has all the chemical properties of gouty matter *.

* Phil. Trans. 1797, p. 386.

Subdivision IV. Of Substances peculiar to Different Animals.

Having briefly detailed the nature and properties of those substances which are common to animals, we shall now take a general view of some substances which are peculiar to different animals, and we shall treat of these according to the order in which they are arranged in natural history.

I. Of Substances peculiar to the Class Mammalia.

The substances peculiar to this class of animals are the following:

1. Ivory,	6. Civet,
2. Horn,	7. Castor,
3. Hartshorn,	8. Ambergris,
4. Wool,	9. Spermaceti,
5. Musk,	10. Bezoards.

2821 Ivory. 1. *Ivory*, which is the teeth of the elephant, is a bony substance, of a fine compact texture, white colour, and so hard as to be susceptible of a fine polish. It is composed, like the bones, of gelatinous matter and phosphate of lime, and when it is distilled, it furnishes water, a thick oil, and carbonate of ammonia; and when calcined to whiteness, it leaves pure phosphate of lime.

The component parts of ivory, are, according to Merat-Guillot, the following:

Phosphate of lime	64.0
Carbonate of lime	0.1
Gelatine	24.0
Loss	11.9
	100.0

2822 Horn. 2. *Horn.*—The substance called horn possesses different properties from that of bone. This matter is produced in the horns of different animals, as those of oxen, sheep, and goats. It has some degree of transparency, and when heated it becomes so soft and flexible, that it may be made to assume different shapes, and formed into different instruments and utensils. Horn yields a very small proportion of earthy matter. The other constituent parts seem to be coagulated albumen and gelatine.

The following are the proportions of the constituents of hartshorn:

Phosphate of lime	57.5
Carbonate of lime	1.0
Gelatine	27.0
Loss	14.5
	100.0

2823 Hartshorn. 3. *Hartshorn.*—The constituent parts of hartshorn, from the analysis which has been made, are exactly the same as those of bone, but they contain a greater proportion of gelatinous matter.

2824 Wool. 4. *Wool* is a kind of long hair, very fine and soft, which is a covering to different animals, especially the sheep. It has been considered as nearly analogous in its nature and properties to hair. It is entirely soluble in the caustic alkalies, and forms with them a soapy matter, which has been employed, it is said, with advantage, as a substitute for soap, in different manufactures.

2825 Musk. 5. *Musk* is a substance which is secreted in a bag situated near the umbilical region of the musk deer (*moschus moschifer*). It has an unctuous feel, is of a dark-reddish brown colour, has a very bitter taste, and is distinguished by a strong aromatic smell. It is partially soluble in water, to which it communicates the odour. A small portion of it also may be dissolved in alcohol, but it does not retain the odour. Musk is soluble in sulphuric and nitric acid; but in these solutions the odour is dissipated. The smell of ammonia is given out by the action of the fixed alkalies on musk. When it is laid on red hot iron, it takes fire, and is almost entirely consumed, leaving only a small portion of gray ashes. During its combustion it gives out the fetid odour of urine. Musk seems to possess many of the properties of the volatile oils, but its component parts have not been determined.

2826 Civet. 6. *Civet.*—This substance is extracted from a small bag near the anus of the *viverra civeta*, or *civet cat.* It is of a yellow colour, and of the consistence of butter. When first extracted it is said to be white. It has a very strong smell, and slightly acrid taste; it combines readily with oils, and is much employed as a perfume.

2827 Castor. 7. *Castor.*—This substance is extracted from two bags situated near the anus of the beaver. The best castor omponent Parts of Animal ibstances. castor is obtained from the large bag; that which is secreted in the small bag is said to be of an inferior quality. When castor is first taken from the animal, it is nearly fluid, and of a yellow colour. After it is exposed for some time to the atmosphere, it becomes hard, and of a darker colour, assuming a resinous appearance. It has an acid, bitter, and nauseous taste, and a strong aromatic smell, which it loses by drying. It becomes soft in water, and communicates to it a pale yellow colour. This infusion converts vegetable blues to a green colour. When it has been long macerated in water, the infusion becomes of a deeper colour, and yields by evaporation extractive matter, which is soluble in alcohol and in ether. A resinous matter is precipitated from the solution in alcohol, by means of water, which has similar properties with the resin of bile. According to the analysis of Lagrange, the component parts of castor are the following:

Carbonate of potash,
———— lime,
———— ammonia,
Iron,
Resin,
Mucilaginous extractive matter,
Volatile oil.

2828 nbergris. 8. *Ambergris.*—This is a substance which is supposed to be formed in the intestines of the spermaceti whale. It is frequently found floating in the sea. For its natural history, see AMBERGRIS, and CETOLOGY *Index*.

It is a soft light substance, of an ash-gray colour, with brownish-yellow and white streaks. It has an insipid taste, but an agreeable odour. The specific gravity is from 0.844 to 0.849. It melts at the temperature of 122°, and with the heat of boiling water is completely dissipated in white smoke, leaving a small trace of charcoal. By distillation an acid fluid is first obtained, and a light volatile oil; and there remains behind a voluminous mass of charcoal. By sublimation benzoic acid is separated.

Ambergris is insoluble in water. Concentrated sulphuric acid separates a small portion of charcoal. It is dissolved in nitric acid. During the solution, nitrous gas, azotic gas, and carbonic acid gas are evolved. A resinous matter is obtained by evaporating the solution. Ambergris is soluble in the alkalies, with the assistance of heat. It is also soluble in the oils, in

2829 mposi-n. alcohol and ether. By the analysis of Bouillon la Grange, the constituent parts of ambergris are the following:

Adipocire	52.7
Resin	30.8
Benzoic acid	11.1
Charcoal	5.4
	100.0 *

* Annal. de Chim. vii. 84.

The substance called *adipocire* possesses the mixed or intermediate properties of fat and wax. This name was first given by Fourcroy to the matter into which the dead bodies found in the Innocents burying-ground were converted. In appearance and some of its properties it also resembles spermaceti. Component Parts of Animal Substances.

9. *Spermaceti.*—This is a production of the same whale which yields the preceding substance. It is an oily matter which surrounds the brain. It is separated from a fluid oil, with which it is mixed, by expression. Spermaceti is also found in other cetaceous fishes, and in other parts of the body, mixed with the oil. 2830 Spermaceti.

It is a fine white substance of a crystallized texture, very brittle, and has little taste or smell. It crystallizes in the form of shining silvery plates. It melts at the temperature of 112°. With a greater heat it may be distilled without change; but, by repeated distillation, it is decomposed, and partly converted into a brown acid liquid. It is soluble in boiling alcohol, but it separates when the solution cools. It is also soluble in ether, both cold and hot. In the hot solution it concretes on cooling into a solid mass. 2831 Properties.

Spermaceti is scarcely at all soluble in the acids. It combines readily with the pure alkalies, with sulphur, and with the fixed oils. By exposure to the air it becomes rancid. The uses of spermaceti are well known, and particularly in the manufacture of candles. 2832 Action of acids, &c.

10. *Bezoards.*—These are calculous concretions which are found in the intestines of different animals belonging to this class, particularly the horse. Some of very large size have been found in the elephant and the rhinoceros. These substances were once celebrated on account of their medical virtues, and they were formerly distinguished into oriental and occidental. The first were most highly valued, and frequently bore a high price, especially the bezoards obtained from a species of goat which inhabits the Asiatic mountains. Some that have been examined were composed entirely of vegetable matter. In general the nucleus is of vegetable matter, on which phosphate of ammonia and magnesia or phosphate of lime have been deposited. These substances are distinguished by a strong aromatic odour when they are rubbed or reduced to powder. The brown or golden-coloured matter which has been observed on the grinding teeth of ruminating animals, is found to be of the same nature with the bezoards which are formed in the intestines. 2833 Bezoards.

II. Of Substances peculiar to the Class of Birds.

The substances which are peculiar to this class of animals are the following:

1. Eggs,
2. Feathers,
3. Excrement,
4. Membrane of the stomach.

1. *Eggs.*—In a chemical view, three parts of an egg merit attention. These are the shell or external covering, the white, and the yolk. The white of egg, which consists of albumen, has been already described, so that it now only remains to give some account of the shell and the yolk. 2834 Eggs.

The shells of the eggs of birds which have been analyzed are composed of similar constituents with bone, but in very different proportions. The following is the result of the analysis of Vauquelin. 2835 Shells.

Carbonate

Component Parts of Animal Substances.

Carbonate of lime	89.6
Phosphate of lime,	5.7
Animal matter	4.7
	100.0 *

* Ann. de Chim. xxix. 6.

2836 Yolk. The yolk of egg is of a soft consistence, a yellow colour, and of a mild oily taste. It becomes solid by boiling, and crumbles easily into small particles. By heating gently after it has been boiled, and by expression, an oily liquid of a yellow colour, and insipid taste, is obtained. It is distinguished by the properties of fixed oil. What remains after separating the oil is albumen, still coloured with a small portion of oil. By boiling
2837 Composition. this residuum in water, a portion of gelatine is obtained, so that the yolk of egg is composed of oil, albumen, gelatine, and water.

2838 Feathers. 2. *Feathers*—are considered as possessing similar properties with hair, According to some, the solid part, or quill, may be reduced to the gelatinous state by boiling; but according to others, no gelatine whatever can be detected. The quill part is therefore supposed to consist chiefly of coagulated albumen. It becomes soft by the action of acids and the alkalies.

2839 Excrement. 3. *Excrement.*—This matter in birds is very different from that of the animals included in the class mammalia. It is generally of a white colour, less liquid, and less fetid. It is commonly accompanied with a glairy matter of different degrees of transparency, analogous to the white of egg. This seems to be owing to a quantity of albumen which is secreted in the oviduct. The white part of this matter is composed of carbonate and phosphate of lime and albumen. The colouring matter seems to be part of the food.

2840 Membrane of the stomach. 4. *Membrane of the stomach.*—The internal surface of the gizzard, or muscular part of the stomach of birds, is covered with a wrinkled membrane, which is susceptible of considerable extension, and through the pores of which gastric juice is copiously secreted. This membrane is easily separated from the muscular part. When it is boiled in water, it is converted into jelly, and communicates to the water the property of reddening vegetable blues, and coagulating milk. When it is dried and reduced to powder, it produces the same effect.

III. Of Matters peculiar to Animals in the Amphibious Class.

2841 Poison of the viper. 1. *Poison of the Viper.*—Some of the animals belonging to the snake tribe secrete a peculiar fluid in the mouth, which is of a poisonous quality. The poison of the viper is a yellow viscid liquid, somewhat resembling oil. It is secreted in two small bags, and from them conveyed to the fangs of the animal, which are hollow and perforated, and when it bites, the liquid is squeezed out of the bag, and flows through the teeth into the wound. It has no smell. It becomes thick by exposure to the air, and is converted into a transparent jelly; but it retains its poisonous property long after it is separated from the animal. It is soluble in water by agitation, but if thrown into the water when extracted from the vesicle, it falls instantly to the bottom like a heavy oil. It is soluble in warm water after it is dried, but not soluble in alcohol, or coagulated by boiling water. Acids and alkalies produce no perceptible change upon this matter. It is precipitated from its solution in water by alcohol. It resembles gum in so many of its properties, that it has been called an *animal gum*.

2. *Liquid secreted from the tubercles on the head of the Toad.*—It has been long supposed that the liquid secreted on the head of the toad is of a poisonous quality; but although it is said by some naturalists, that this fluid, brought in contact with the skin, produces inflammation, yet there seems to be no positive proof of this effect. 2842 Toad.

3. *Tortoise-shell.*—This substance, which forms a strong covering and defence to the body of the turtle, possesses many of the properties of horn; for it may be softened with heat, or in boiling water, and shaped into any form which may be wanted. It is composed of a number of hard plates or membranes, of different degrees of thickness, closely applied to each other. It becomes soft by maceration in nitric acid, and by burning it yields a very small proportion of phosphate of lime and soda, with some slight traces of iron. 2843 Tortoise shell.

IV. Of Substances peculiar to Fishes.

1. *Scales*—generally possess a silvery whiteness, and are composed of different laminæ. In many of their properties they resemble horn. By long boiling in water they become soft, and when they are kept for some hours in nitric acid, they are converted into a transparent membraneous substance. By saturating the acid with ammonia, a precipitate is formed, which is phosphate of lime. The constituent parts of scales, therefore, are membrane and phosphate of lime. 2844 Scales.

2. *Bones of fishes.*—These are composed of the same constituents as those of other animals, but have a greater proportion of animal matter. In some they are soft, flexible, and semitransparent, and hence they are called *cartilaginous*. In others they are hard and solid, having the usual appearance of bone. 2845 Bones.

3. *Fish oil.*—A great quantity of oil is extracted from the soft parts of different kinds of fish, and especially from the blubber of the whale. It is usually denominated *train oil*. It is obtained, either by expression, or by boiling. It is supposed that the oil obtained from the blubber of the whale, and from other fishes, possesses different properties, which are ascribed to the difference in the function of respiration of cetaceous and other fishes; but how far this difference really exists, does not seem to have been accurately ascertained. Fish oil is distinguished by a disagreeable smell, and it has long been an object to deprive it of this odour, as it is much employed in domestic economy and in many arts. By agitating the oil with a small portion of sulphuric acid, and adding water, the oil when left at rest, rises to the surface considerably purified. A portion of coagulated matter has separated, and the water is milky.

V. Of Substances peculiar to Insects.

1. *Wax.*—The nature and properties of this substance have already been described as a vegetable production.

2. *Propolis.*—This is a substance collected by bees, and with which they cover the bottom of the hive, or any 2646 Propolis.

Component Parts of Animal Substances.

any foreign matters which happen to be introduced into it, which they cannot remove. It is the substance which they collect on their legs and thighs. It is perhaps more properly to be considered as a vegetable production. It possesses more tenacity than wax, but has much of its ductility. It is insipid to the taste, but is distinguished by an aromatic odour. It is partially soluble in alcohol, to which it communicates a red colour. Another portion is dissolved in boiling alcohol, and part precipitates as the solution cools, which has the properties of wax. A resinous mass is obtained by concentrating the solution in alcohol and boiling in water. It is semitransparent and brittle. An acid was detected in the water in which it was boiled. The resinous substance is soluble in fixed and volatile oils. The following are the constituent parts of propolis.

Pure resin	57
Pure wax	14
Extraneous matter	14
Loss and acid	15
	100 *

* Nichol. Jour. v. p. 49.

2845 Honey.

3. *Honey.*—This also has been considered as a vegetable production, as it is collected from plants by bees. It is of white or yellowish colour, of a granular soft consistence, and has an aromatic smell; but these properties vary according to the plants from which it is collected, or the climate in which they grow. By distillation honey yields nearly the same products as sugar. It is converted into oxalic acid by means of nitric acid. It is very soluble in water, and is even somewhat deliquescent. It readily passes to the vinous fermentation, and affords a fermented liquor which has been called *hydromel.* It is partially soluble in alcohol, and by this means sugar may be extracted from it. The component parts of honey are sugar, mucilage, and an acid. If pure honey be melted, and carbonate of lime be added till the effervescence ceases, the sugar is separated, and is deposited in crystals.

2846 Cantharides.

4. *Cantharides* are a species of fly (the *meloe vesicatorius*, Lin.) which are much employed, from a peculiar property they possess, to raise blisters on the skin. For this purpose the whole of the insect is reduced to powder. Cantharides have been subjected to analysis; and by successive treatment with water, alcohol, and ether, four different substances have been extracted. 1. Three-eighths of their weight consist of extractive matter, of a reddish-yellow colour, very bitter, and which yields by distillation an acid liquor. 2. A little more than one-tenth of the weight consists of a concrete oil, something of the nature of wax, which is of a green colour and very acrid taste. To this is owing the peculiar odour of cantharides. This substance yields, by distillation, a very pungent acid substance and a thick oil. 3. About one-fiftieth of a yellow concrete oil, which seems to communicate the colour to the insect, is also obtained. 4. About one half the weight of a solid matter remains, the nature of which has not been ascertained. The blistering effect of cantharides seems to depend on the green waxy matter, part of which is extracted by means of warm water, and it is entirely soluble in ether.

2847 Millepedes.

Millepedes.—These insects, which are different species of oniscus, were formerly employed in medicine. By distillation with the heat of a water bath, they yield a watery liquid, which converts the syrup of violets to a green colour, and by this process they are deprived of five-eighths of their weight. By treating them afterwards with water and alcohol, they furnish one-fourth of their weight of an extractive and waxy matter; the latter is soluble in ether. The muriates of potash and lime have been detected in the expressed juice of these insects.

2848 Ants.

Ants.—These insects contain an acid liquid, which they emit from the mouth when they are irritated, or when they are bruised on paper. This liquid converts vegetable blues to red; and it has been observed that streaks of the same colour are communicated to blue flowers, over which the insects creep. The acid obtained from ants, and particularly from the *formica rufa*, or red ant, was formerly considered as possessing peculiar properties, and thence denominated *formic acid;* but it has been lately ascertained to consist of a mixture of acetic and malic acids.

2849 Lac.

Lac.—This is a substance which is formed on the branches of several plants, as the *ficus indica*, the *ficus religiosa*, and especially the *croton lacciferum.* It is produced by the puncture of an insect, but is considered as belonging to vegetable substances, among which the general properties have been already described, as well as the properties of an acid obtained from it, among the acids.

2850 Silk.

Silk.—This is the production of several insects, either for the purpose of covering up their eggs, or forming a net to catch their prey, as is the case with many of the spider tribe, or to cover up the insect during one of the stages of its metamorphosis. The silk of commerce is usually obtained from the *phalæna bombyx*, or silk-worm. This substance is prepared in the body of the larva of the insect, from which it is protruded through several small orifices in very fine threads; and with this it forms a covering for itself while it remains in the state of chrysalis or pupa.

Silk is a very elastic substance, and is of a white or reddish-yellow colour, when it is produced by the insect. The elasticity of silk has been ascribed to a varnish with which it is covered, of a gummy or gelatinous nature, which is precipitated by tan and muriate of tin. The yellow colour of silk is ascribed to a resinous matter which is soluble in alcohol. By distillation silk yields a large proportion of ammonia. It is soluble in sulphuric, nitric, and muriatic acids. By nitric acid it is partly converted into oxalic acid, and a fatty matter which swims on the surface.

2851 Cochineal.

Cochineal.—This is an insect which breeds on the leaves of the *cactus coccinelliferus*, Lin. sometimes called opuntia or nopal. The plant is cultivated in Mexico, for the purpose of rearing the insects, which are collected, dried, and employed as a beautiful dye stuff. By burning, the same results are obtained as from other animal matters; but with boiling water it gives a crimson violet colour, which becomes red and yellow by the action of acids, while a precipitate is formed of the same colour. The metallic solutions added to this decoction also produce a coloured precipitate. The muriate of tin throws down a beautiful red precipitate. The evaporated residuum of the decoction

Component Parts of Animal Substances

coction of cochineal, treated with alcohol, gives a fine red colour, and this, by evaporating the alcohol, assumes the form of a resin. Oxymuriatic acid converts the solution of this substance into a yellow colour, from which the proportion of colouring matter may be in some measure estimated, by the quantity of acid requisite to destroy its colour. Cochineal is well known by its producing a beautiful scarlet colour. It may be kept for any length of time, at least in a dry place, without being deprived of its colouring matter. It has retained this property for 130 years. Cochineal is employed in the preparation of the beautiful lake called *carmine*.

2852 Kermes. *Kermes.*—This also is an insect which is employed in dyeing, from whence it has been called *coccus infectorius*. It is the *coccus ilicis*, Lin. and is produced on a small kind of oak, the *quercus coccifera*. The insect attaches itself to the bark of the tree by a soft substance, which possesses many of the properties of caoutchouc.

When the living insect is bruised, it gives out a red colour. It has a slightly bitter, rough, pungent taste, but its smell is not unpleasant. The dried insect, or the kermes, imparts this odour and taste to water and to alcohol, and communicates also to these liquids a deep red colour. By evaporation, an extract of the same colour is obtained. It is employed in dyeing, and has been also used in medicine.

2853 Crabs eyes. *Crabs eyes.*—The substance which has received this name, merely from its form, is a concrete body, convex on one side, and concave on the other. Two of these bodies are usually found in the stomach of the crab, about the time that it changes its shell. After the shell is fully formed, they are no longer found, so that they are supposed to furnish the materials of the new shell. They are entirely composed of carbonate of lime, a small proportion of phosphate of lime, and gelatine.

The crustaceous coverings of the crab, lobster, and similar animals, are composed of carbonate of lime, phosphate of lime, and animal matter, or cartilage.

VI. Of Substances peculiar to Testaceous Animals.

The only substances to be mentioned peculiar to this class of animals are shells, mother of pearl, and pearl.

2854 Shells. 1. *Shells.*—Such as have been particularly examined by Mr Hatchett are divided into two classes. In the one he includes those which have the appearance of porcelain, and have an enamelled surface, which he calls *porcellaneous shells*. Such are the various species of *voluta* and *cypræa*. These shells were found by analysis to be composed of carbonate of lime, with a small portion of animal gluten.

2855 Mother of pearl. 2. *Mother of pearl.*—The second class comprehends those which are generally covered with a strong epidermis, under which is the shell, composed chiefly of the substance called *nacre*, or *mother of pearl*. Such are the *oyster*, the *river mussel*, the *haliotis iris*, and the *turbo oleareus*. In these the proportion of carbonate of lime is smaller, and that of the animal matter greater.

2856 Pearl. 3. *Pearl.*—This is a concretion formed in several species of shells, as in some species of the oyster and the mussel. It is considered by some as a morbid concretion, owing to an excess of the shelly matter, or to a wound of the shell containing the animal. Pearls are of a silvery or bluish-white colour, iridescent and brilliant. The refraction of the light is ascribed to the lamellated structure, for they consist of concentric layers of carbonate of lime and membrane alternately arranged. The constituent parts of pearl are the same as mother of pearl.

VII. Substances peculiar to Zoophytes.

2857 Zoophytes. The zoophytes, many of which have been examined by Mr Hatchett, are composed of carbonate of lime, phosphate of lime, and animal matter of different degrees of consistency. In some the constituents are only carbonate of lime and a gelatinous matter. Such are some species of the madrepore, as the *madrepora muricata*, *virginea*, and *labyrinthica*; some species of millepore, as the *millepora cerulea* and *alcicornis*, and the *tubipora musica*. Others again are composed of carbonate of lime and a membranaceous substance. Such are the *madrepora fascicularis*, the *millepora cellulosa* and *fascialis*, and the *iris hippuris*. White coral and articulated coralline are composed of similar substances. Another division of zoophytes is composed of carbonate of lime, a small portion of phosphate of lime and membrane. Such are the *madrepora polymorpha*, the *gorgonia nobilis* or *red coral*, and the *gorgonia setosa*; but some of the zoophytes are also found to consist chiefly of animal matter, with scarcely any portion of earthy substance. To this division belong some species of gorgonia and many species of sponge.

Chap. XX. *Of Arts and Manufactures.*

In this chapter it was intended to give a general view of the application of the principles of chemistry to different arts and manufactures, such as the manufacture of soap, of glass, and porcelain; the arts of dyeing, bleaching, and tanning. In this view it was proposed to explain the principles of these arts and manufactures, so far as they depend upon chemistry, leaving the detail to the different treatises on those subjects in the course of the work. But the unavoidable length to which this article has extended, obliges us to refer our readers for the whole to the different treatises.

APPENDIX.

APPENDIX.

2858 Oxygenation of acids and water. ONE of the most interesting trains of experimental research in chemistry that have recently occurred, is that of Thenard on the oxygenation of the acids and of water; of which we shall subjoin an account, as it is more recent than the date even of the Chemistry in our SUPPLEMENT, and the subjects which it implies are some of the most important novelties in this science. This eminent chemist has found, in the first place, that several of the acids are capable of being made to combine with an additional quantity of oxygen; and in the second, that water is susceptible of a similar combination. The leading instrument by which he was enabled to accomplish these combinations was the peroxide of barium, a compound discovered by himself, consisting of the metallic base of barytes (barium), in combination with a larger quantity of oxygen than that which constitutes this earth. That peroxide is formed simply by subjecting pure barytes to a high temperature in contact with pure oxygenous gas. The gas is absorbed, and the peroxide adapted to the following curious purposes is obtained. Diluted muriatic acid, poured slowly on this substance, dissolves it without setting at liberty any of its oxygen; we have then an oxygenated muriate of barytes. When to this we gradually add sulphuric acid, the barytes is precipitated in union with this last-mentioned acid, i. e. the sulphate of barytes, a very insoluble compound, is formed. This process is continued till the whole earth is precipitated.

2859 Oxygenated muriatic acid. The additional dose of oxygen which had made it a peroxide is neither evolved in the form of gas, nor precipitated with the earth; it remains in solution in union with the muriatic acid. Nitric acid is capable of being oxygenated by a similar process.

2860 Sulphuric acid. The oxygenation of sulphuric acid was not effected with equal simplicity. When that acid is brought in contact with peroxide of barium, it forms sulphate of barytes, by combining with that earth which is a protoxide of barium; and the overplus of oxygen is disengaged in the gaseous form, exactly in the same way as this acid operates on the peroxide (the black oxide) of manganese, combining with the deutoxide of that metal, and setting oxygenous gas at liberty. In order to effect the oxygenation of the sulphuric acid, we first procure an oxygenated muriatic acid. We must also be provided with liquid sulphate of silver. This solution is added to the oxygenated muriatic acid. A muriate of silver, a very insoluble precipitate, is formed by the combination of the oxide of silver with the muriatic acid. The sulphuric acid retains the liquid state; but the superabundant oxygen is transferred to it from the muriatic. We have now an oxygenated sulphuric acid.

2861 Oxygenated matter. When the substance last mentioned is treated with an aqueous solution of barytes, the sulphuric acid is precipitated in combination with this earth, and the oxygen remains in union with the water. The same portion of water may receive additional combinations of oxygen by a repetition of the same process. This combination is singular in this respect, that the oxygen is not so easily separated by certain processes as we might be apt to anticipate, while there are others which disengage it with astonishing rapidity. When oxygenated water is placed within the exhausted receiver of an air-pump, the oxygen is not liberated as it would be if it were retained in its state of union with that fluid in any degree by the pressure of the atmosphere. What is more, if it be placed in an exhausted receiver, which at the same time contains a bason of sulphuric acid, the water is gradually raised in vapour, while the oxygen continues united to the remaining portion. We can thus procure oxygenated water in a highly concentrated state, and are presented with a view of its properties in a more striking form. This fluid is heavier than pure water; it sinks in it like sulphuric acid, and has the same heavy and sluggish consistence.

The substances which most readily induce a separation of the oxygen, are some of the metallic oxides: 2862 Properties.
when these are added to it, the oxygen flies off with a sudden explosion; and it is a curious additional circumstance that the oxygen of the oxide is liberated along with it, and the metal reduced to a state of purity. Another singular fact is, that even the pure metal thrown into oxygenated water effects a separation of the oxygen. In order to account for such an agency in a substance which does not in consequence enter into any new chemicals tate, Thenard sagaciously suggests, that the agency exerted must be of an electrical nature. This subject, probably, presents much scope for farther ingenious research.

It is to be observed, that pure water does not retain this additional oxygen so strongly as the acids; and hence has arisen a question, whether in the latter this principle is in union with the acid as well as with the water. It appears, however, that other impregnations, such as saccharine and gummy substances, dissolved in water, give it, like the acids, the power of retaining the oxygen more strongly. The experiments on this part of the subject, however, do not yet seem to have been greatly extended.

Oxygenated water has the property of removing the 2863 Uses.
dark colour induced on white lead by sulphureted hydrogen, which in many cases occasions serious injury to ancient paintings. This purpose it fulfils so completely, without affecting the generality of other colours with which the white lead is in contact on the canvas, that it has been hailed by amateurs as a truly precious discovery.

Explanation of Plates.

EXPLANATION OF THE PLATES.

Plate CXLII.

Fig. 1. Represents Harrison's pendulum, constructed on the principle of the unequal expansion of metals.

Fig. 2. The calorimeter of Lavoisier and Laplace, see page 476.

Fig. 3. Iron bottle and bent gun-barrel for procuring oxygen gas from manganese. The black oxide is reduced to powder, and introduced into the bottle A. The bent tube is put on the mouth of the bottle at C, and luted with the materials described at the foot of page 490. The bottle is then exposed to a red heat, and the gas which comes over is received in jars on the pneumatic apparatus.

Fig. 3. and 4. represent the apparatus for the decomposition of water. See page 496.

Fig. 5. Pneumatic trough for collecting gaseous bodies. Suppose a quantity of sulphurated hydrogen gas is to be collected, which is described in page 505. The iron filings and sulphur which were melted together in a crucible, and which then form a black brittle mass, are to be introduced into the glass vessels. Fig. 6. B is a bent tube ground to fit the mouth D, and is air-tight. To the other mouth C is fitted the ground stopper A. One end of the bent tube is fitted into the mouth D, and the other placed under the glass jar F on the shelf of the pneumatic trough E, which is filled with water about an inch above the surface of the shell. The jar is also previously filled with water, cautiously inverted, and set on the shelf. The apparatus being thus adjusted, muriatic acid is poured into the opening C, and the ground stopper is immediately replaced. A violent effervescence takes place, a great quantity of gas is disengaged, and as there is no other way for it to escape it passes into the glass jar. When this is filled, it is removed to another part of the shelf; another jar which was previously filled with water is put into its place, and so on till the whole gas is collected.

Fig. 7. Papin's digester. A is the body of the vessel, which has been generally made of copper or iron, very thick and strong. BB are two strong bars fixed to the sides of the vessel. To the upper end of these bars is fixed the cross bar C, through which passes a strong screw D, which presses on the lid of the vessel at E, so that it is enabled to resist the elastic force of the vapour: and the water can thus be raised to a higher temperature than the ordinary boiling point.

Fig. 8. This represents an apparatus for distillation. A is the furnace, B is the body of the still, which is generally made of copper; C is the top or head, made of the same metal. The vapour, as it rises from the liquid by the application of heat, passes along the tube D, which communicates with a spiral tube in the refrigeratory E, which being filled with cold water, the vapour is condensed, and passes out at the other extremity of the tube F, and is received in the vessel G.

Fig. 11. Glass Alembic.
Fig. 12. Solution Glass.
Fig. 13. Crucible.

Fig. 14. Apparatus for obtaining muriatic acid from muriate of soda by sulphuric acid. The muriate of soda is introduced into the retort A, and by means of the bent tube B the sulphuric acid is added. The matrass C is adapted to the retort, to receive the portion of impure sulphuric acid and muriatic acid which passes over towards the end of the operation. D, E, and F, are bottles containing water; the quantity of which should be equal in weight to that of the salt employed. These bottles are furnished with tubes of safety GG; or the tube of safety may be applied as H in the bottle E.

Fig. 15. Apparatus for impregnating fluids with gases. A is a tubulated retort which is joined to B, a tubulated receiver, from which a bent tube C passes to the second receiver D. This last communicates with the bottle F by means of the bent tube E. The end of the tube C which enters the receiver D is furnished with a valve, which prevents the return of any gas from the receiver D to the receiver B, in case a vacuum should take place in the course of the operation in the receiver B, or in the retort A. The gas which is not absorbed by the water in the receiver D, passes through the tube E to the bottle F.

Fig. 16. A gazometer, which is a convenient apparatus for holding gases. It is usually made of tin plate. A is an inverted vessel, which exactly fits another, which is fixed within the cylinder B. When it is pressed down to the bottom of the cylinder, water is poured in, by which means the small quantity of air which remains in the intermediate spaces, is forced out, and the gas to be preserved may be introduced at the lower stop-cock C. The vessel A is nearly balanced by the weights DD, which are connected with it by means of the cords *a a a a*, which move on the pulleys *b b b b*. As the gas enters the apparatus, it forces up the vessel A, and in this way it may be completely filled. It is forced out by turning the stop-cock E, and pressing down the vessel A, and may be conveyed into a pneumatic apparatus, and received in jars by means of the flexible tube F.

CHEMNITZ, Martin, a famous Lutheran divine, the disciple of Melancthon, was born at Britzen in Brandenburg, in 1522. He was employed in several important negotiations by the princes of the same communion; and died in 1589. His principal work is the Examen of the Council of Trent, in Latin.

CHEMOSH. See Chamos.

CHEMOSIS, a disease of the eyes, proceeding from an inflammation; wherein the white of the eye swells above the black, and overtops it to such a degree, that there appears a sort of gap between them. Others define it differently.

CHENIER, Marie Joseph de, a French writer on politics and general literature. See Supplement.

CHENOPODIUM, Goose-Foot, or *Wild Orach.* See Botany *Index.*

CHEPELIO, an island in the bay of Panama and province of Darien, in South America, situated about three leagues from the city of Panama, which it supplies with provisions. W. Long. 81. N. Lat. 9.

CHEPSTOW, a market town of Monmouthshire in England, seated on the river Wye, with 2581 inhabitants in 1811. W. Long. 2. 40. N. Lat. 51. 40.

CHEQ, or Cherif, the prince of Mecca, who is, as it were, high-priest of the law, and sovereign pontiff of all the Mahometans of whatever sect or country they be. See Caliph.

The grand signior, sophis, moguls, khans of Tartary, &c. send him yearly presents, especially tapestry to cover Mahomet's tomb withal, together with a sumptuous tent for himself, and vast sums of money to provide for all the pilgrims during the 17 days of their devotion.

CHERASCO, a strong and considerable town of Italy, in Piedmont, and capital of a territory of the same name, with a strong citadel, belonging to the king of Sardinia, where he retired in 1706, during the siege of Turin. It is seated at the confluence of the rivers Sturia and Tanaro, upon a mountain. E. Long. 7. 55. N. Lat. 44. 35.

CHERBURG, a seaport town of France, in Normandy, with a harbour and Augustine abbey. It is remarkable for the sea-fight between the English and French fleets in 1692, when the latter were beat, and upwards of twenty of their men of war burnt near Cape la Hogue. The British landed here in August 1758, and took the town, with the ships in the bason, demolished the fortifications, and ruined the other works which had been long carried on for enlarging the harbour. The work was resumed in 1783, upon the the plan of sinking large conical masses of stone in the sea, to break the force of the waves. They were, however, thrown down, and the work was abandoned, about 1808. Since that an artificial harbour, capable of holding 50 sail of the line, has been excavated out of the solid ground. E. Long. 1. 38. N. Lat. 49. 38.

CHEREM, among the Jews, is used to signify a species of annihilation. See Annihilation.

The Hebrew worm *cherem*, signifies properly to *destroy*, *exterminate*, *devote*, or *anathematise*.

Cherem is likewise sometimes taken for that which is consecrated, vowed, or offered to the Lord, so that it may no longer be employed in common or profane uses. No devoted thing that a man shall devote unto the Lord, of all that he hath of man and beast, and of the field of his possession, shall be sold or redeemed; every devoted thing is most holy to the Lord; none devoted, which shall he devoted of men, shall be redeemed, but shall surely be put to death. There are some who assert that the persons thus devoted were put to death; whereof Jephtha's daughter is a memorable example. Judges xi. 29. &c.

Cherem is also used for a kind of excommunication in use among the Jews. See Niddui.

CHERESOUL, or Chahrzul, a town in Turkey in Asia, capital of Curdistan, and the seat of a beglerbeg. E. Long. 45. 15. N. Lat. 36. 0.

CHERILUS, of Samos, a Greek poet, flourished 479 years before Christ. He sung the victory gained by the Athenians over Xerxes, and was rewarded with a piece of gold for every verse. His poem had afterwards the honour of being rehearsed yearly with the works of Homer.

CHERLERIA. See Botany *Index.*

CHERLESQUIOR, in Turkish affairs, denotes a lieutenant general of the grand signior's armies.

CHERMES, in *Zoology*, a genus of insects belonging to the order of insecta hemiptera. See Entomology *Index.*

Chermes Mineral. See Kermes.

Cherry-island, an island in the northern ocean; lying between Norway and Greenland, in E. Long. 20. 5. N. Lat. 75. 0.

Cherry-Tree. See Prunus, Botany *Index.*

CHERSON, a town in Europe, in Russia, situated on the Dnieper, about 60 miles from its mouth. It was founded in 1778, and increased rapidly for some time; but owing to the unhealthiness of the situation, and the difficulty of navigating the river, it has since declined. E. Long. 33. 5. N. Lat. 46. 20.

CHERSONESUS, among modern geographers, the same with a peninsula; or a continent almost encompassed round with the sea, only joining to the main land by a narrow neck or isthmus. The word is Greek χερσονησος; of χερσος, *land;* and νησος, *island;* which signifies the same. In ancient geography, it was applied to several peninsulas; as the Chersonesus Aurea, Cimbrica, Taurica, and Thracica, now thought to be Malacca, Jutland, Crim Tartary, and Romania.

CHERT, Petrosilex, *Lapis Corneus*, the *Hornstein* of the Germans. See Mineralogy *Index.*

CHERTZEY, a market town of Surry in England, about seven miles west from Kingston upon Thames. W. Long. 30. N. Lat. 51. 25.

CHERUB, (plural, Cherubim); a celestial spirit, which in the hierarchy is placed next to the seraphim. See Hierarchy.

The term *cherub*, in Hebrew, is sometimes taken for a calf or ox. Ezekiel sets down the face of the cherub as synonymous to the face of an ox. The word *cherub*, in Syriac and Chaldee, signifies to *till* or *plow*, which is the proper work of oxen. Cherub also signifies *strong* and *powerful.* Grotins says, that the cherubim were figures much like that of a calf. Bochart thinks likewise, that the cherubim were more like to the figure of an ox than to any thing besides; and Spencer is of the same opinion. Lastly, St John, in the Revelation, calls cherubim *beasts.* Josephus says the cherubim were extraordinary creatures, of a figure unknown to mankind. Clemens of Alexandria believes,

lieves, that the Egyptians imitated the cherubim of the Hebrews in the representations of their sphinxes and their hieroglyphical animals. All the several descriptions which the scripture gives us of cherubim, differ from one another; but all agree in representing them as a figure composed of various creatures, as a man, an ox, an eagle, and a lion. Such were the cherubim described by Ezekiel. Those which Isaiah saw, and are called *seraphim* by him, had the figure of a man with six wings; with two whereof they covered their faces, with two more they covered their feet, and with the two others they flew. Those which Solomon placed in the temple at Jerusalem are supposed to have been nearly of the same form. Those which St John describes in the Revelation were all eyes before and behind, and had each six wings. The first was in the form of a lion, the second in that of a calf, the third of a man, and the fourth of an eagle. The figure of the cherubim was not always uniform. since they are differently described in the shapes of men, eagles, oxen, lions, and in a composition of all these figures put together. Moses likewise calls these symbolical or hieroglyphical representations, which were embroidered on the veils of the tabernacle, *cherubim* of costly work. Such were the symbolical figures which the Egyptians placed at the gates of their temples and the images of the generality of their gods, which were commonly nothing but statues composed of men and animals.

CHERVIL. See CHÆROPHYLLUM, BOTANY *Index*.

CHESAPEAK, in America, one of the largest bays in the known world. Its entrance is between Cape Charles and Cape Henry in Virginia, 12 miles wide; and it extends 270 miles to the northward, dividing Virginia and Maryland. Through this extent it is from 7 to 18 miles broad, and generally about 9 fathoms deep; affording many commodious harbours, and a safe and easy navigation. It receives the waters of the Susquehannah, Potomak, Rappahannock, York, and James rivers, which are all large and navigable.

CHESELDEN, WILLIAM, an eminent anatomist and surgeon, was born at Burrow on the Hill, in the county of Leicester, descended from an ancient family in the county of Rutland, whose arms and pedigree are in Wright's "History of Rutland." He received the rudiments of his professional skill at Leicester; and married Deborah Knight, a citizen's daughter, by whom he had one daughter, Williamina Deborah. In 1713 he published his Anatomy of the Human Body, one volume 8vo; and in 1723, A Treatise on the High Operation for the Stone. He was one of the earliest of his profession who contributed by his writings to raise it to its present eminence. In the beginning of 1736, he was thus honourably mentioned by Mr Pope: "As soon as I had sent my last letter, I received a most kind one from you, expressing great pain for my late illness at Mr Cheselden's. I conclude you was eased of that friendly apprehension in a few days after you had dispatched yours, for mine must have reached you then. I wondered a little at your query, Who Cheselden was?. It shows that the truest merit does not travel so far any way as on the wings of poetry: he is the most noted and most deserving man in the whole profession of chirurgery; and has saved the lives of thousands by his manner of cutting for the stone." He appears to have been on terms of the most intimate friendship with Mr Pope, who frequently, in his Letters to Mr Richardson, talks of dining with Mr Cheselden, who then lived in or near Queen Square. In February 1737, Mr Cheselden was appointed surgeon to Chelsea hospital. As a governor of the Foundling Hospital, he sent a benefaction of 50l. to that charity, May 7. 1751, inclosed in a paper with the following lines:

'Tis what the happy to th' unhappy owe;
For what man gives, the gods by him bestow. POPE.

He died at Bath, April 11. 1752, of a disorder arising from drinking ale after eating hot buns. Finding himself uneasy, he sent for a physician, who advised vomiting immediately; and if the advice had been taken, it was thought his life might have been saved. By his direction, he was buried at Chelsea.

CHESHIRE, a maritime county of England, bounded by Lancashire on the north; Shropshire and part of Flintshire on the south; Derbyshire and Staffordshire on the east and south-east; and Denbighshire and part of Flintshire on the west and north-west. It extends in length about 44 miles, in breadth 25; and is supposed to contain 676,600 acres. Both the air and soil in general are good. In many places of the country are peat mosses, in which are often found trunks of fir-trees, sometimes several feet under ground, that are used by the inhabitants both for fuel and candles. Here also are many lakes and pools well stored with fish; besides the rivers Mersey, Weaver, and Dee. The number of inhabitants in 1811 was 227,031. This county also abounds with wood: but what it is chiefly remarkable for, is its cheese, which has a peculiar flavour, generally thought not to be inferior to any in Europe; (see CHEESE). The principal towns are, Chester the capital, Cholmondely, Namptwitch, &c.

William the Conqueror erected this county into a palatinate, or county palatine, in favour of his nephew Hugh Lupus, to whom he granted the same sovereignty and jurisdiction in it that he himself had in the rest of the island. By virtue of this grant, the town of Chester enjoyed sovereign jurisdiction within its own precincts; and that in so high a degree, that the earls held parliaments, consisting of their barons and tenants, which were not bound by the acts of the English parliament: but the exorbitant power of the palatinates was at last reduced by Henry VIII.; however, all cases and crimes, except those of error, foreign plea, foreign voucher, and high-treason, are still heard and determined within the shire. The earls were anciently superiors of the whole county, and all the landholders were their vassals, and under the like sovereign allegiance to them as they were to the kings of England; but the earldom was united to the crown by Edward III. since which time, the eldest sons of kings of England have always been earls of Chester, as well as princes of Wales. Cheshire sends four members to parliament; two for the county, and two for the capital. See CHESHIRE, SUPPLEMENT.

CHESNE, ANDREW DU, styled the father of French history,

history, was born in 1584. He wrote, 1. A history of the popes. 2. A history of England. 3. An inquiry into the antiquities of the towns of France. 4. A history of the cardinals. 5. A bibliotheca of the authors who have written the history and topography of France, &c. He was crushed to death by a cart, in going from Paris to his country house at Verriere, in 1640.

CHESNUT-TREE. See FAGUS, BOTANY *Index*.

CHESS, an ingenious game performed with different pieces of wood, on a board divided into 64 squares or houses; in which chance has so small a share, that it may be doubted whether a person ever lost a game but by his own fault.

Each gamester has eight dignified pieces, viz. a king, a queen, two bishops, two knights, and two rooks, also eight pawns; all which, for distinction's sake, are painted of two different colours, as white and black.

As to their disposition on the board, the white king is to be placed on the fourth black house from the corner of the board, in the first and lower rank; and the black king is to be placed on the fourth white house on the opposite, or adversary's, end of the board. The queens are to be placed next to the kings, on houses of their own colour. Next to the king and queen, on each hand, place the two bishops; next to them, the two knights; and last of all, on the corners of the board, the two rooks. As to the pawns, they are placed, without distinction, on the second rank of the house, one before each of the dignified pieces.

Having thus disposed the men, the onset is commonly begun by the pawns, which march straight forward in their own file, one house at a time, except the first move, when it can advance two houses, but never moves backwards: the manner of their taking the adversary's men is sidewise, in the next house forwards; where having captivated the enemy, they move forward as before. The rook goes forward or crosswise through the whole file, and back again. The knight skips backward and forward to the next house, save one, of a different colour, with a sideling march, or a slope, and thus kills his enemies that fall in his way, or guards his friends that may be exposed on that side. The bishop walks always in the same colour of the field that he is placed in at first, forward and backward, aslope, or diagonally, as far as he lists. The queen's walk is more universal, as she takes all the steps of the before-mentioned pieces, excepting that of the knight; and as to the king's motion, it is one house at a time, and that either forward, backward, sloping, or sidewise.

As to the value of the different pieces, next to the king is the queen, after her the rooks, then the bishops, and last of the dignified pieces comes the knight. The difference of the worth of pawns, is not so great as that of noblemen; only, it must be observed, that the king's bishop's pawn is the best in the field, and therefore the skilful gamester will be careful of him.

It ought also to be observed, that whereas any man may be taken, when he falls within the reach of any of the adversary's pieces, it is otherwise with the king, who, in such a case, is only to be saluted with the word *check*, warning him of his danger, out of which it is absolutely necessary that he move; and if it so happen that he cannot move without exposing himself to the like inconveniency, it is check-mate, and the game is lost. The rules of the game are,

1. In order to begin the game, the pawns must be moved before the pieces, and afterwards the pieces must be brought out to support them. The king's, queen's, and bishop's pawns, should be moved first, that the game may be well opened; the pieces must not be played out early in the game, because the player may thereby lose his moves: but above all, the game should be well arranged before the queen is played out. Useless checks should also be avoided, unless some advantage is to be gained by them, because the move may be lost, if the adversary can either take or drive the piece away.

2. If the game is crowded, the player will meet with obstructions in moving his pieces; for which reason he should exchange pieces or pawns, and castle (A) his king as soon as it is convenient, endeavouring at the same time to crowd the adversary's game, which may be done by attacking his pieces with the pawns, if the adversary should move his pieces out too soon.

3. The men should be so guarded by one another, that if a man should be lost, the player may have it in his power to take one of the adversary's in return; and if he can take a superior piece in lieu of that which he lost, it would be an advantage, and distress the adversary.

4. The adversary's king should never be attacked without a force sufficient; and if the player's king should be attacked without having it in his power to attack the adversary's, he should offer to make an exchange of pieces, which may cause the adversary to lose a move.

5. The board should be looked over with attention, and the men reconnoitred, so as to be aware of any stroke that the adversary might attempt in consequence of his last move. If, by counting as many moves forward as possible, the player has a prospect of success, he should not fail doing it, and even sacrifice a piece or two to accomplish his end.

6. No man should be played till the board is thoroughly examined, that the player may defend himself against any move the adversary has in view; neither should any attack be made till the consequences of the adversary's next move are considered; and when an attack may with safety be made, it should be pursued without catching at any bait that might be thrown out in order for the adversary to gain a move, and thereby cause the design to miscarry.

7. The queen should never stand in such a manner before the king, that the adversary, by bringing a rook or bishop, could check the king if she were not there; as it might be the loss of the queen.

8. The

(A) *Castle his king*, is to cover the king with a castle; which is done by a certain move which each player has a right to whenever he thinks proper.

8. The adversary's knight should never be suffered to check the king and queen, or king and rook, or queen and rook, or the two rooks at the same time; especially if the knight is properly guarded: because, in the two first cases, the king being forced to go out of check, the queen or the rook must be lost; and in the two last cases a rook must be lost at least for a worse piece.

9. The player should take care that no guarded pawn of the adversary's fork two of his pieces.

10. As soon as the kings have castled on different sides of the board, the pawns on that side of the board should be advanced upon the adversary's king, and the pieces, especially the queen and rook, should be brought to support them; and the three pawns belonging to the king that is castled must not be moved.

11. The more moves a player can have as it were in ambuscade, the better; that is to say, the queen, bishop, or rook, is to be placed behind a pawn or a piece, in such a position as that upon playing that pawn or piece a check is discovered upon the adversary's king, by which means, a piece or some advantage is often gained.

12. An inferior piece should never be guarded with a superior, when a pawn would answer the same purpose; for this reason, the superior piece may remain out of play; neither should a pawn be guarded with a piece when a pawn would do as well.

13. A well-supported pawn that is passed often costs the adversary a piece; and when a pawn or any other advantage is gained without endangering the loss of the move, the player should make as frequent exchanges of pieces as he can. The advantage of a passed pawn is this: for example, if the player and his adversary have each three pawns upon the board, and no piece, and the player has one of his pawns on one side of the board, and the other two on the other side, and the adversary's three pawns are opposite to the player's two pawns, he should march with his king as soon as he can, and take the adversary's pawns: If the adversary goes with his king to support them, the player should go on to queen with his single pawns; and then if the adversary goes to hinder him, he should take the adversary's pawns, and move the others to queen (B).

14. When the game is near finished, each party having only three or four pawns on each side of the board, the kings must endeavour to gain the move in order to win the game. For instance, when the player brings his king opposite to the adversary's with only one square between, he will gain the move.

15. If the adversary has his king and one pawn on the board, and the player has only his king, he cannot lose the game, provided he brings his king opposite to the adversary's, when the adversary is directly before or on one side of his pawn, and there is only one square between the kings.

16. If the adversary has a bishop and one pawn on the rook's line, and this bishop is not of the colour that commands the corner square the pawn is going to, and the player has only his king, if he can get into that corner, he cannot lose; but on the contrary, may win by a stale (C).

17. If the player has greatly the disadvantage of the game, having only his queen left in play, and his king happens to be in a position to win, as above-mentioned, he should keep giving check to the adversary's king, always taking care not to check him where he can interpose any of his pieces that make the stale; by so doing he will at last force the adversary to take his queen, and then he will win the game by being in a stale-mate.

18. The player should never cover a check with a piece that a pawn pushed upon it may take, for fear of getting only the pawn in exchange for the piece.

19. A player should never cover his adversary up with pieces, for fear of giving a stale-mate inadvertently, but always should leave room for his king to move.

By way of corroborating what has been already said with respect to this game, it is necessary to warn a player against playing a timid game. He should never be too much afraid of losing a rook for an inferior piece; because, although a rook is a better piece than any other except the queen, it seldom comes into play to be of any great use till at the end of the game; for which reason it is often better to have an inferior piece in play, than a superior one to stand still, or moving to no great purpose. If a piece is moved, and is immediately drove away by a pawn, it may be reckoned a bad move, because the adversary gains a double advantage over the player, in advancing at the same time the other is made to retire; although the first move may not seem of consequence between equal players, yet a move or two more lost after the first, makes the game scarcely to be recovered.

There never wants for variety at this game, provided the pieces have been brought out regularly; but, if otherwise, it often happens that a player has scarce any thing to play.

Many indifferent players think nothing of the pawns, whereas three pawns together are strong; but four, which constitute a square, with the assistance of other pieces, well managed, make an invincible strength, and in all probability may produce a queen when very much wanted. It is true, that two pawns with a space between are no better than one; and if there should be three over each other in a line, the game cannot be in a worse way. This shows that the pawns are of great consequence, provided they are kept close together.

Some middling players are very apt to risk losing the game in order to recover a piece; this is a mistake; for it is much better to give up a piece and attack the enemy in another quarter; by so doing, the player has a chance of snatching a pawn or two from, or

(B) To *queen*, is to make a queen; that is, to move a pawn into the adversary's back row, which is the rule at this game when the original one is lost.

(C) When the king is blocked up so as to have no move at all.

or gaining some advantage over the adversary, whilst his attention is taken up in pursuing this piece.

If the queen and another piece are attacked at the same time, and that by removing the queen the piece must be lost; provided two pieces can be gained in exchange for the queen, the queen should be given up, it being the difference of three pieces, and consequently more than the value of the queen. By losing the queen, the game is not thrown into that disorder which it would otherwise have been; in this case it would be judicious to give the queen for even a piece, or a pawn or two; it being well known among good players, that he who begins the attack, and cannot maintain it, being obliged to retire, generally loses the game.

A player should never be fond of changing without reason, because the adversary, if he is a good player, will ruin his situation, and gain a considerable advantage over him. But rather than lose a move, when a player is stronger than the adversary, it is good play to change, for he thereby increases his strength.

When the game is almost drawn to a conclusion, the player should recollect that his king is a capital piece, and consequently should keep him in motion; by so doing, he generally gets the move, and often the game.

As the queen, rook, and bishop, operate at a distance, it is not always necessary in the attack to have them near the adversary's king.

If a man can be taken with different pieces, the player should take his time, and consider which of those pieces is the best to take it with.

If a piece can be taken almost at any time, the player should not be in a hurry about it, but try to make a good move elsewhere before he take it.

A player should be cautious how he takes his adversary's pawn with his king, as it often happens to be a safeguard to it.

After all that has been said, it is still necessary for us to advise those who would play well at this game, to be very cool and attentive to the matter in question; for it is impossible that any person in the universe can be capable of playing at chess if their thoughts are employed elsewhere. The laws at this game are,

1. If a player touches his man, he must play it; and if he quits it, he cannot recal it.

2. If by mistake or otherwise a false move is played, and the adversary takes no notice of it till he hath played his next move, it cannot be recalled by either of the parties.

3. If a player misplaces the men, and he plays two moves, it is at the option of the adversary to permit him to begin the game or not.

4. If the adversary plays or discovers a check to a player's king, and give no notice of it, the player may let him stand still till he does.

5. After the king is moved, a player cannot castle.

Sarasin has an express treatise on the different opinions of the origin of the Latin *schacchi*, whence the French *echecs*, and our *chess*, is formed. Menage is also very full on the same head. Leunclavius takes it to come from *Uscoches*, famous Turkish robbers. P. Sirmond, from the German *scache*, "theft;" and that from *calculus*. He takes *chess* to be the same with the *ludus latrunculorum* of the Romans, but mistakenly. This opinion is countenanced by Vossius and Salmasius, who derive the word from *calculus*, as used for *latrunculus*. G. Tolosanus derives it from the Hebrew, *scarch*, *valavit* and *mat*, *mortuus*; whence *check* and *checkmate*. Fabricius says, a celebrated Persian astronomer, one Schatrenscha, invented the game of *chess*; and gave it his own name, which it still bears in that country. Nicod derives it from *scheque*, or *xeque*, a Moorish word for lord, king, and prince. Bochart adds that *scach* is originally Persian; and that *scachmat*, in that language, signifies the king is dead.—The opinion of Nicod and Bochart, which is likewise that of Scriverius, appears the most probable.

Mr Twiss mentions a small treatise on chess, written, as he supposes, about 400 years ago; at the end of which is a representation of a round chess-board, with directions for placing the men upon it. In this the knight can cover the 64 squares on the board at as many moves. The board is divided into these 64 parts by four concentric circles, having an empty space in the middle; and each of these is divided into 16 parts. Number 1 is placed in the outermost circle; number 2 in the third circle counting inwards, in the division to the right hand of the former; number 3 is placed in the outermost circle, in the division to the right hand of 2; 4 in the third circle, counting inwards to the right hand of three; and thus alternately from the first to the third, and from the third to the first circle, till the round is completed by 16 on the third circle to the left hand of 1. Number 17 is then placed on the division of the innermost circle to the right hand of 1; 18 on the second circle counting inwards, to the right hand of 17; and thus alternately from the fourth to the second, and from the second to the fourth circles, until the round is completed by 32, directly below number 1. Number 33 then is placed on the third circle directly to the right hand of number 2; 34 on the fourth circle, to the right hand of 4; and thus alternately between the third and fourth circles, until the round is again completed by 48 on the fourth circle, directly below number 33. The numbers are now placed in a retrograde fashion; 50 on the outer circle in that division immediately to the right hand of 1; 51 on the third circle to the left hand of 2; and directly below number 32; 52 is then placed on the outer circle, immediately on the left hand of 1; 53 on the third circle directly to the left hand of 16; and thus alternately on the first and third circles, until the last ground is completed by 64 between the number 3 and 5. On this round chess-board, supposing the black king to be placed in number 48 on the fourth circle, the queen stands on number 17 at his left hand; the bishops in 33 and 2; the knights 18 and 47; the castles in 3 and 20; the pawns on 19, 4, 49, 64, and 46, 51, 32, 1. The white king will then stand in 25, opposite to the black queen; the white queen in 40 opposite to the black king, and so on. In playing on a board of this kind, it will be found, that the power of the castle is double to that in the common game, and that of the bishop only one half; the former having 16 squares to range in, and the last only 4. The king can castle only one way; and it is very difficult to bring the game to a conclusion.

With regard to the origin of the game at chess, we are much in the dark. Though it came to us from the

the Saracens, it is by no means probable that they were the original inventors of it. According to some, it was invented by the celebrated Grecian hero Diomedes. Others say, that two Grecian brothers, Ledo and Tyrrheno, were the inventors; and that being much pressed with hunger, they sought to alleviate the pain by this amusement.

According to Mr Irwin it is a game of Chinese invention. During his residence in India, he found that a tradition of this nature existed among the Bramins, with whom he frequently played the game. While he was at Canton in 1793, he gives the following account of the information which he acquired relative to the origin of the game of chess. ' A young mandarin, of the profession of arms, having an inquisitive turn, was my frequent visitor; and what no questions could have drawn from him, the accidental sight of an English chess-board effected. He told me, that the Chinese had a game of the same nature; and on his specifying a difference in the pieces and board, I perceived, with joy, that I had discovered the desideratum of which I had been so long in search. The very next day my mandarin brought me the board and equipage; and I found, that the Bramins were neither mistaken touching the board, which has a river in the middle to divide the contending parties, nor in the powers of the king, who is entrenched in a fort, and moves only in that space, in every direction. But, what I did not before hear, nor do I believe is known out of this country, there are two pieces, whose movements are distinct from any in the Indian or European game. The mandarin, which answers to our bishop, in his station and sidelong course, cannot, through age, cross the river, and a rocket-boy, still used in the Indian armies, who is stationed between the lines of each party, acts literally with the motion of the rocket, by vaulting over a man, and taking his adversary at the other end of the board. Except that the king has his two sons to support him, instead of a queen, the game, in other respects, is like ours; as will appear in the plan of the board and pieces I have the honour to enclose, together with directions to place the men and play the game.

" As the young man who had discovered this to me was of a communicative and obliging disposition, and was at this time pursuing his studies in the college of Canton, I requested the favour of him to consult such ancient books as might give some insight into the period of the introduction of chess into China; to confirm, if possible, the idea that struck me of its having originated here. The acknowledged antiquity of this empire, the unchangeable state of her customs and manners, beyond that of any other nation in the world; and more especially the simplicity of the game itself, when compared to its compass and variety in other parts, appeared to give a colour to my belief. That I was not disappointed in the event, I have no doubt will be allowed, on the perusal of the translation of a manuscript extract, which my friend Tinqua brought me, in compliance with my desire; and which, accompanied by the Chinese manuscript, goes under cover to your lordship. As the mandarin solemnly assured me that he took it from the work quoted, and the translation has been as accurately made as possible, I have no hesitation to deliver the papers as authentic.

" From these premises I have therefore ventured to make the following inferences:—That the game of chess is probably of Chinese origin. That the confined situation and powers of the king, resembling those of a monarch in the eastern parts of the world, countenance this supposition; and that, as it travelled westward, and descended to later times, the sovereign prerogative extended itself, until it became unlimited, as in our state of the game. That the agency of the princes, in lieu of the queen, bespeaks forcibly the nature of the Chinese customs, which exclude females from all power or influence whatever; which princes, in its passage through Persia, were changed into a single vizier, or minister of state, with the enlarged portion of delegated authority that exists there; instead of whom, the European nations, with their usual gallantry, adopted a queen on the board (D). That the river between parties is expressive of the general face of the country, where a battle could hardly be fought without encountering an interruption of this kind, which the soldier was here taught to overcome; but that, on the introduction of the game into Persia, the board changed with the dry nature of the region, and the contest was decided on terra firma. And lastly, that in no account of the origin of chess, that I have read, has the tale been so characteristic or consistent as that which I have the honour to offer to the Irish academy. With the Indians, it was designed by a Bramin to cure the melancholy of the daughter of a rajah. With the Persians, my memory does not assist me to trace the fable; though, if it were more to the purpose, I think I should have retained it. But, with the Chinese, it was invented by an experienced soldier, on the principles of war. Not to dispel love-sick vapours, or instruct a female in a science that could neither benefit nor inform her; but to quiet the murmurs of a discontented soldiery; to employ their vacant hours in lessons on the military art, and to cherish the spirit of conquest in the bosom of winter-quarters. Its age is traced by them on record near two centuries before the Christian era; and among the numerous claims for this noble invention, that of the Chinese, who call it by way of distinction, *chong kè*, or *the royal game*, appears alone to be indisputable."

Translation of an Extract from the Concum, or Chinese Annals, respecting the Invention of the Game of Chess, delivered to me by Tinqua, a soldier Mandarin of the Province of Fokien.

" Three hundred and seventy-nine years after the time

(D) That on the acquisition of so strong a piece as the vizier, the pao were suppressed, this possessing powers unintelligible, at that time, to other nations; and three pawns added, in consequence, to make up the number of men; and that as discipline improved, the lines, which are straggling on the Chinese board, might have been closed on ours.

Chess.

time of Confucius, or one thousand nine hundred and sixty-five years ago, Hung Cochu, king of Kiangnan, sent an expedition into the Shensi country, under the command of a mandarin, called Hansing, to conquer it. After one successful campaign, the soldiers were put into winter-quarters; where, finding the weather much colder than what they had been accustomed to, and being also deprived of their wives and families, the army, in general, became impatient of their situation, and clamorous to return home. Hansing, upon this, revolved in his mind the bad consequences of complying with their wishes. The necessity of soothing his troops, and reconciling them to their position, appeared urgent, in order to finish his operations in the ensuing year. He was a man of genius, as well as a good soldier; and having contemplated some time on the subject, he invented the game of chess, as well for an amusement to his men in their vacant hours, as to inflame their military ardour, the game being wholly founded on the principles of war. The stratagem succeeded to his wish. The soldiery were delighted with the game; and forgot, in their daily contests, for victory, the inconveniences of their post. In the spring the general took the field again; and, in a few months, added the rich country of Shensi to the kingdom of Kiangnan, by the defeat and capture of its king, Choupayuen, a famous warrior among the Chinese. On this conquest Hung Cochu assumed the title of emperor, and Choupayuen put an end to his own life in despair.

Explanation of the Position, Powers, and Moves of the Pieces on the Chinese Chess-board, or Chong Ke (Royal Game).

"As there are nine pieces instead of eight, to occupy the rear rank, they stand on the lines between, and not within, the squares. The game is consequently displayed on the lines.

"The king, or chong, stands on the middle line of this row. His moves resemble those of our king, but are confined to the fortress marked out for him.

"The two princes, or sou, stand on each side of him, and have equal powers and limits.

"The mandarins, or chong, answer to our bishops, and have the same moves, except that they cannot cross the water or white space in the middle of the board to annoy the enemy, but stand on the defensive.

"The knights, or rather horses, called *mãã*, stand and move like ours in every respect.

"The war-chariots, or tchè, resemble our rooks or castles.

"The rocket-boys, or paö, are pieces whose motions and powers were unknown to us. They act with the direction of a rocket, and can take none of their adversary's men that have not a piece or pawn intervening. To defend your men from this attack, it is necessary to open the line between, either to take off the check on the king, or to save a man from being captured by the paö. Their operation is, otherwise, like that of the rook. Their stations are marked between the pieces and pawns.

"The five pawns, or ping, make up the number of the men equal to that of our board. Instead of taking sideways, like ours, they have the rook's motion, except that it is limited to one step, and is not retrograde. Another important point, in which the ping differs from ours, is that they continue in *statu quo*, after reaching their adversary's head-quarters. It will appear, however, that the Chinese pieces far exceed the proportion of ours; which occasions the whole force of the contest to fall on them, and thereby precludes the beauty and variety of our game, when reduced to a struggle between the pawns, who are capable of the highest promotion, and often change the fortune of the day. The posts of the ping are marked in front *."

* *Irish Trans.* vol. v.

But according to Sir William Jones, this game is of Hindoo invention. "If evidence were required to prove this fact (says he †), we may be satisfied with the testimony of the Persians, who, though as much inclined as other nations to appropriate the ingenious inventions of a foreign people, unanimously agree that the game was imported from the west of *India* in the sixth century of our era. It seems to have been immemorially known in *Hindostan* by the name of *Cheturanga*, i. e. the four *angá's*, or members of any army; which are these, *elephants*, *horses*, *chariots*, and *foot soldiers*; and in this sense the word is frequently used by epic poets in their description of real armies. By a natural corruption of the pure Sanscrit word, it was changed by the old Persians into *Chetrang*; but the Arabs, who soon after took possession of their country, had neither the initial nor final letter of that word in their alphabet, and consequently altered it further into *Shetranj*, which found its way presently into the modern *Persian*, and at length into the dialects of India, where the true derivation of this name is known only to the learned. Thus has a very significant word in the sacred language of the Brahmins been transformed by successive changes into *axedrez*, *scacchi*, *échecs*, *chess*, and, by a whimsical concurrence of circumstances, has given birth to the English word *check*, and even a name to the *exchequer* of Great Britain."

† *Asiatic Researches*, vol. ii. mem. 9.

It is confidently asserted, that Sanscrit books on *chess* exist in Bengal; but Sir William had seen none of them when he wrote the memoir which we have quoted. He exhibits, however, a description of a very ancient *Indian* game of the same kind, but more complex, and in his opinion more modern, than the simple chess of the *Persians*. This game is also called *Chaturanga*, but more frequently *Chaturaji*, or the *four kings*, since it is played by four persons representing as many princes, two allied armies combating on each side. The description is taken from a book called *Bhawishya Purán*; in which the form and principal rules of this fictitious warfare are thus laid down: "Eight squares being marked on all sides, the *red* army is to be placed on the east, the *green* to the south, the *yellow* to the west, and the *black* to the north. Let the *elephant* (says the author of the *Purán*) stand on the left of the *king*; next to him the *horse*; then the *boat*; and before them all, four *foot soldiers*; but the *boat* must be placed in the angle of the board."

"From this passage (says the president) it clearly appears, that an army with its four *angás* must be placed on each side of the board, since an *elephant* could not stand, in any other position, on the left hand of each *king*; and RADHACANT (a Pandit) informed me, that the

Chess.

the board consisted, like ours, of 64 squares, half of them occupied by the forces, and half vacant. He added, that this game is mentioned in the oldest law books, and that it was invented by the wife of a king, to amuse him with an image of war, while his metropolis was besieged, in the second age of the world. A *ship* or *boat* is absurdly substituted, we see, in this complex game, for the *rat'h*, or armed *chariot*, which the *Bengalese* pronounce *rot'h*, and which the Persians changed into *rokh;* whence came the *rook* of some European nations; as the *vierge* and *fal* of the French are supposed to be corruptions of *ferz* and *fil*, the *prime minister* and *elephant* of the Persians and Arabs."

As fortune is supposed to have a great share in deciding the fate of a battle, the use of dice is introduced into this game to regulate its moves; for (says the Puran) "if *cinque* be thrown, the *king* or a *pawn* must be moved; if *quatre*, the *elephant;* if *trois*, the *horse;* and if *deux*, the *boat*. The *king* passes freely on all sides, but over *one* square only; and with the same limitation the *pawn* moves, but he advances straight forward, and kills his enemy through an angle. The *elephant* marches in all directions as far as his driver pleases; the *horse* runs obliquely, traversing the squares; and the *ship* goes over two squares diagonally." The *elephant*, we find, has the powers of our *queen*, as we are pleased to call the *general* or *minister* of the Persians; and the *ship* has the motion of the piece to which we give the unaccountable appellation of *bishop*, but with a restriction which must greatly lessen its value.

In the *Purán* are next exhibited a few general rules and superficial directions for the conduct of the game. Thus, "the *pawns* and the *ship* both kill and may be voluntarily killed; while the *king*, the *elephant*, and the *horse*, may slay the foe, but must not expose themselves to be slain. Let each player preserve his own forces with extreme care, securing his *king* above all, and not sacrificing a superior to keep an inferior piece." Here (says the president) the commentator on the *Pur'an* observes, that the *horse*, who has the choice of *eight* moves from any central position, must be preferred to the *ship*, which has only the choice of *four*. But the argument would not hold in common game, where the *bishop* and *tower* command a whole line, and where a knight is always of less value than a tower in action, or the bishop of that side on which the attack is begun. "It is by the overbearing power of the *elephant* (continues the *Purán*) that the king fights boldly; let the whole army, therefore, be abandoned in order to secure the *elephant*. The king must never place one *elephant* before another, unless he be compelled by want of room, for he would thus commit a dangerous fault; and if he can slay one of two hostile elephants, he must destroy that on his left hand."

What remains of the passage, which was copied from Sir William Jones, relates to the several modes in which a partial success or complete victory may be obtained by any one of the four players; for, as in a dispute between two allies, one of the kings may sometimes assume the command of all the forces, and aim at a separate conquest. First, "When any one king has placed himself on the square of another king (which advantage is called *sinhasana* or the *throne*), he wins a stake, which is doubled if he kill the adverse monarch when he seizes his place; and if he can seat himself on the throne of his ally, he takes the command of the whole army." Secondly, "If he can occupy successively the thrones of all the three princes, he obtains the victory, which is named *cheturaji;* and the stake is doubled if he kill the last of the three, just before he takes possession of his throne; but if he kill him on his throne, the stake is quadrupled. Both in giving the *sinhasana* and the *cheturaji*, the king must be supported by the *elephants*, or by all the forces united." Thirdly, "When one player has his own king on the board, but the king of his partner has been taken, he may replace his captive ally, if he can seize both the adverse kings; or if he cannot effect their capture, he may exchange his king for one of them, against the general rule, and thus redeem the allied prince, who will supply his place." This advantage has the name of *nripacrishta*, or *recovered by the king*. Fourthly, "If a *pawn* can march to any square on the opposite extremity of the board, except that of the king, or that of the ship, he assumes whatever power belonged to that square." Here we find the rule, with a slight exception, concerning the advancement of *pawns*, which often occasions a most interesting struggle at our common chess; but it appears that, in the opinion of one ancient writer on the Indian game, this privilege is not allowable when a player has three pawns on the board; but when only one pawn and one ship remains, the pawn may advance even to the square of a king or a ship, and assume the power of either. Fifthly, According to the people of *Laneé*, where the game was invented, "there could be neither victory nor defeat if a king were left on the plain without force; a situation which they named *cacacasht'ha.*" Sixthly, "If three ships happen to meet, and the fourth ship can be brought up to them in the remaining angle, this has the name of *vrihannauca;* and the player of the fourth seizes all the others."

The account of this game in the original Sancrit is in verse.

This game was very fashionable in former times in every part of Europe; though in this country it is not now very common, probably on account of the intense application of thought required to play at it. It has long been a favourite of the Icelanders and other northern people. There is little difference between their game and ours.

The game of chess has been generally practised by the greatest warriors and generals; and some have even supposed that it was necessary for a military man to be well skilled in this game. It is a game which has something in it peculiarly interesting. We read that Tamerlane was a great chess-player, and was engaged in a game during the very time of the decisive battle with Bajazet the Turkish emperor, who was defeated aud taken prisoner. It is also related of Al Amin, the caliph of Bagdad, that he was engaged at chess with his freedman Kuthar at the time when Al Mamun's forces were carrying on the siege of that city with so much vigour that it was on the point of being carried by assault. Dr Hyde quotes an Arabic history of the Saracens, in which the caliph is said to have cried out when warned of his danger, Let me alone, for I see checkmate against Kuthar! We are told that Charles I. was at chess when news were brought of the final intention of the Scots to sell him to the English; but so little was he discomposed by this alarming intelligence,

telligence, that he continued his game with the utmost composure; so that no person could have known that the letter he received had given him information of any thing remarkable. King John was playing at chess when the deputies of Rouen came to acquaint him that their city was besieged by Philip Augustus; but he would not hear them until he had finished his game.

The following remarkable anecdote we have from Dr Robertson in his History of Charles V. John Frederic, elector of Saxony, having been taken prisoner by Charles, was condemned to death. The decree was intimated to him while at chess with Ernest of Brunswic, his fellow-prisoner. After a short pause, and making some reflection on the irregularity and injustice of the emperor's proceedings, he turned to his antagonist, whom he challenged to finish the game. He played with his usual ingenuity and attention; and having beat Ernest, expressed all the satisfaction that is commonly felt on gaining such victories. He was not, however, put to death, but set at liberty after five years confinement.

In the Chronicle of the Moorish kings of Granada we find it related, that in 1396, Mehemed Balba seized upon the crown in prejudice of his elder brother, and passed his life in one continual round of disasters. His wars with Castile were invariably unsuccessful; and his death was occasioned by a poisoned vest. Finding his case desperate, he dispatched an officer to the fort of Salabreno to put his brother Juzaf to death, lest that prince's adherents should form any obstacle to his son's succession. The alcayde found the prince playing at chess with an *alfaqui* or priest. Juzaf begged hard for two hours respite, which was denied him; at last with great reluctance the officer permitted him to finish the game; but before it was finished, a messenger arrived with the news of the death of Mehemed, and the unanimous election of Juzaf to the crown.

We have a curious anecdote of Ferrand count of Flanders; who having been accustomed to amuse himself at chess with his wife, and being constantly beaten by her, a mutual hatred took place; which came to such a height, that, when the count was taken prisoner at the battle of Bovines, she suffered him to remain a long time in prison, though she could easily have procured his release.

The game of chess has undergone considerable variations since it was first invented. We have it on good authority, that, among the eastern nations, the piece now called the *queen* was formerly called the *vizir* or king's minister, and that the powers of the queen herself were but very small. The chess-boards used by Tamerlane were larger, and contained many more squares than those at present in use. Carrera invented two new pieces to be added to the eight commonly in use. One of these, which he calls *Campione*, is placed between the king's knight and castle; the other, named *Centaur*, between the queen's knight and castle, has the move of the bishop and knight united. This invention, however, did not survive its author. In another of this kind, the two additional pieces are called the *centurion* and *decurion*; the former situated between the king and his bishop, in its move the same with that of the queen, but only for two squares; the latter moves as the bishop, but only one square at a time. This, like the former, died with its inventor. The chess-board of Tamerlane was a parallelogram, having 11 squares one way and 12 the other. In the Memoirs of the late Marshal Keith, we find it related, that he invented an amusement something similar to that of chess, with which the king of Prussia was highly entertained. Several thousand small statues were cast by a founder; and these were ranged opposite to each other as if they had been drawn up in an army; making the different movements with them as in real service in the field.

A very complicated kind of game at chess was invented by the late duke of Rutland. At this the board has 14 squares in breadth, and 10 in height, which make in all 140 houses; and there are 14 pawns on each side, which may move either on two, or three squares the first time. The other pieces were the king, queen, two bishops, two knights, a crowned castle uniting the move of the king and castle, and a common castle. On the other side of the king was a *concubine*, whose move united that of the castle and knight, two bishops, a single knight, a crowned castle, and a common one. In this game the pawns are of very little use; and by the extent of the board, the knights lose much of their value, which consequently renders the game more defective and less interesting than the common one.

There is an amusing variety at the game of chess, in which the king with eight pawns engages the whole set, by being allowed to make two moves for every one of his adversary. In this he is almost certain of coming off victorious; as he can make his first move into check, and the second out of it. Thus he can take the queen when she stands immediately before her king, and then retreat; for he cannot remain in check. He cannot be check-mated unless his adversary has preserved his queen and both castles.

Chess-trees, (*toquets d'anjure*); two pieces of wood bolted perpendicularly, one on the starboard, and another on the larboard side of the ship. They are used to confine the *clue*, or lower corners of the main-sail; for which purpose there is a hole in the upper part, through which the rope passes that usually extends the clue of the sail to windward. See Tack.

The chess-trees are commonly placed as far before the main-mast as the length of the main-beam.

CHEST, in commerce, a kind of measure, containing an uncertain quantity of several commodities.

A chest of sugar, *v. g.* contains from ten to fifteen hundred weight; a chest of glass, from two hundred to three hundred feet; of Castile soap, from two and a half to three hundred weight; of indigo, from one and a half to two hundred weight, five score to the hundred.

Chest, or *Thorax*. See Anatomy *Index*.

CHESTER, commonly called *West-Chester*, to distinguish it from many other Chesters in the kingdom; the capital of Cheshire in England. It is a very ancient city, supposed to have been founded by the Romans; and plainly appears to have been a Roman station by the many antiquities which have been and are still discovered in and about the town. It was among the last places the Romans quitted: and here the Britons maintained their liberty long after the Saxons had got possession of the rest of their country. At present it it is a large, well-built, wealthy city, and carries on a considerable trade. Mr Pennant calls it *a city without a parallel*, on account of the singular structure of the four principal streets. They are as if excavated out of the earth, and sunk many feet beneath the surface; the carriages drive far beneath the level of the kitchens on a line with ranges of shops. The houses are mostly of wood, with galleries, piazzas, and covered walls before them; by which not only the shops, but those who are walking about the town, are so hid, that one would imagine there were scarce any inhabitants in it. But though by this contrivance such as walk the streets are screened from rain, &c. yet the shops are thereby rendered dark and inconvenient. The back courts of all the houses are on a level with the ground; but to go into any of the four principal streets, it is necessary to descend a flight of several steps. It contained 17,472 inhabitants in 1811.

Chester is a bishop's see. It was anciently part of the diocese of Litchfield; one of whose bishops removing the seat of his see hither in the year 1075, occasioned his successors to be frequently styled *bishop of Chester*. But it was not erected into a distinct bishopric until the general dissolution of monasteries, when King Henry VIII. in the year 1541, raised it to this dignity, and allotted the church of the abbey of St Werburg for the cathedral, styling it the *cathedral church of Christ and the blessed Virgin*; adding the bishopric to the province of Canterbury: but soon after he disjoined it from Canterbury, and added it to the province of York. When this abbey was dissolved, its revenues were valued at 1003l. 5s. 11d. This diocese contains the entire counties of Chester and Lancaster, part of the counties of Westmoreland, Cumberland, and Yorkshire, two chapelries in Denbighshire, and five parishes in Flintshire; amounting in all to 256 parishes, of which 101 are impropriations. This bishopric is valued in the king's books at 420l. 1s. 8d. and is computed to be worth annually 2700l.; the clergy's tenth amounting to 435l. 12s. To this cathedral belong a dean, two archdeacons, a chancellor, a treasurer, six prebendaries, and other inferior officers and servants. W. Long. 3. 0. N. Lat. 53. 12.

Chester-le-Street, the *Cuneacestre* of the Saxons; a small thoroughfare town between Newcastle and Durham, with a good church and fine spire. In the Saxon times this place was greatly respected on account of the relics of St Cuthbert, deposited here by Bishop Eardulf, for fear of the Danes, who at that time (about 884) ravaged the country. His shrine became afterwards an object of great devotion. King Athelstan, on his expedition to Scotland, paid it a visit, to obtain, by intercession of the saint, success on his arms; bestowed a multitude of gifts on the church; and directed, in case he died in his enterprise, that his body should be interred there. At the same time that this place was honoured with the remains of St Cuthbert, the bishopric of Lindesfarn was removed here, and endowed with all the lands between the Tyne and the Were, the present county of Durham. It was styled *St Cuthbert's patrimony*. The inhabitants had great privileges, and always thought themselves exempt from all military duty, except that of defending the body of their saint. Chester-le-Street may be considered as the parent of the see of Durham: for when the relics were removed there, the see in 995 followed them. Tanner says, that probably a chapter of monks, or rather secular canons, attended the body at this place from its first arrival; but Bishop Beke, in 1286, in honour of the saint, made the church collegiate, and established here a dean and suitable ecclesiastics; and, among other privileges, gave the dean a right of fishing on the Were, and the tythe of fish.

New-Chester, a town of Pennsylvania in America, and capital of a county of that name. It is seated on the Delaware: and has a fine capacious harbour, admitting vessels of any burden. W. Long. 74. 7. N. Lat. 40. 15.

CHESTERFIELD, a market-town of Derbyshire in England, pleasantly situated on a hill between two small rivers. It has the title of an earldom; and a considerable market for corn, lead, and other country commodities. The houses are for the most part built of rough stone, and covered with slate. Population 4476 in 1811. W. Long. 1. 25. N. Lat. 53. 20.

CHESTERFIELD, *Earl of*. See STANHOPE.

CHEVAL *de* FRISE, a large piece of timber pierced, and traversed with wooden pikes, armed or pointed with iron, five or six feet long. See Plate CXXXVII.

The term is French, and properly signifies a *Frise-land horse*; as having been first invented in that country.—It is also called a *Turnpike* or *Turniquet*.

Its use is to defend a passage, stop a breach, or make an entrenchment to stop the cavalry. It is sometimes also mounted on wheels with artificial fires, to roll down in an assault. Errand observes, that the prince of Orange used to inclose his camp with *Chevaux de Frise*, placing them one over another.

CHEVALER, in the manege, is said of a horse, when in passing upon a walk or trot, his off fore-leg crosses or overlaps the near fore-leg every second motion.

CHEVALIER, a French term, ordinarily signifying a KNIGHT. The word is formed of the French *cheval* "horse," and the barbarous Latin *cavallus*.

It is used, in heraldry, to signify any *cavalier* or horseman armed at all points; by the Romans called *cataphractus eques*: now out of use, and only to be seen in coat-armour.

CHEVAUX *de* FRISE. See *CHEVAL de Frise*.

CHEVIN, a name used in some parts of England for the CHUB.

CHEVIOT, or (TIVIOT) HILLS, run from north to south through Northumberland and Cumberland; and were formerly the borders or boundaries between England and Scotland, where many a bloody battle has been fought between the two nations; one of which is recorded in the ballad of Chevy-chase. These hills are the first land discovered by sailors in coming from the east into Scotland.

CHEVISANCE, in *Law*, denotes an agreement or composition, as an end or order set down between a creditor and his debtor, &c. In the statutes, this word is most commonly used for an unlawful bargain or contract.

CHEVREAU, URBAN, a learned writer, born at Lundun in 1613. He distinguished himself in his youth by his knowledge of the belles lettres; and became secretary

cretary of state to Queen Christina of Sweden. Several German princes invited him to their courts; and Charles Lewis, the elector palatine, retained him under the title of counsellor. After the death of that prince, he returned to France, and became preceptor to the duke of Maine. At length retiring to Lundun, he died there in 1701, aged 88. He was the author of several books, and amongst others of an Universal History, which has been often reprinted.

CHEVRON, or CHEVERON, in *Heraldry*. See HERALDRY.

CHEWING-BALLS, a kind of balls made of asafœtida, liver of antimony, bay-wood, juniper-wood, and pellitory of Spain; which being dried in the sun, and wrapped in a linen cloth, are tied to the bit of the bridle for the horse to chew; they create an appetite; and it is said, that balls of Venice treacle may be used in the same manner with good success.

CHEYKS. See BENGAL, No. 17.

CHEYNE, DR GEORGE, a physician of great learning and abilities, born in Scotland in 1671, and educated at Edinburgh under the great Dr Pitcairn. He passed his youth in close study, and with great temperance; but coming to settle at London, when about 30, and finding the younger gentry and free-livers to be the most easy of access and most susceptible of friendship, he changed on a sudden his former manner of living, in order to force a trade, having observed this method to succeed with many others. The consequence was, that he grew daily in bulk, and in intimacy with his gay acquaintance; swelling to such an enormous size, that he exceeded 32 stone weight; and he was forced to have the whole side of his chariot made open to receive him into it; he grew short-breathed, lethargic, nervous, and scorbutic; so that his life became an intolerable burden. In this deplorable condition, after having tried all the power of medicine in vain, he resolved to try a milk and vegetable diet; the good effects of which quickly appeared. His size was reduced almost a third: and he recovered his strength, activity, and cheerfulness, with the perfect use of all his faculties. In short, by a regular adherence to this regimen, he lived to a mature period, dying at Bath in 1742, aged 72. He wrote several treatises that were well received; particularly "An Essay on Health and Long Life;" and "The English Malady, or a Treatise of Nervous Diseases;" both the result of his own experience. In short, he had great reputation in his own time, both as a practitioner and as a writer; and most of his pieces passed through several editions. He is to be ranked among those physicians who have accounted for the operations of medicines and the morbid alterations which take place in the human body, upon mechanical principles. A spirit of piety and of benevolence, and an ardent zeal for the interests of virtue, are predominant throughout his writings. An amiable candour and ingenuousness are also discernible; and which led him to retract with readiness whatever appeared to him to be censurable in what he had formerly advanced. Some of the metaphysical notions which he had introduced into his books may perhaps justly be thought fanciful and ill-grounded; but there is an agreeable vivacity in his productions, together with much openness and frankness, and in general great perspicuity.

CHIABRERA, GABRIEL, esteemed the Pindar of Italy, was born at Savona in 1552, and went to study at Rome. The Italian princes, and Urban VIII. gave him public marks of their esteem. He wrote a great number of poems; but his lyric verses are most admired. He died at Savona, in 1638, aged 86.

CHIAN EARTH, in *Pharmacy*, one of the medicinal earths of the ancients, the name of which is preserved in the catalogues of the materia medica, but of which nothing more than the name has been known for many ages in the shops.

It is a very dense and compact earth; and is sent hither in small flat pieces from the island of Chios, in which it is found in great plenty at this time. It stands recommended to us as an astringent. They tell us, it is the greatest of all cosmetics; and that it gives a whiteness and smoothness to the skin, and prevents wrinkles, beyond any of the other substances that have been celebrated for the same purposes.

CHIAOUS, a word in the original Turkish, signifying "envoys," are officers to the number of five or six hundred in the grand signior's court, under the command of a chiaous baschi. They frequently meet in the grand vizir's palace, that they may be in readiness to execute his orders, and carry his dispatches into all the provinces of the empire. The chiaous baschi assists at the divan, and introduces those who have business there.

CHIAPA, the capital of a province of the same name in Mexico, situated about 300 miles east of Acapulco. W. Long. 98. 0. N. Lat. 16. 30.

CHIAPA el Real, a town of Mexico, in a province of the same name, with a bishop's see. Its principal trade consists in chocolate-nuts, cotton, and sugar. W. Long. 98. 35. N. Lat. 16. 20.

CHIAPA de los Indos, a large and rich town of North America, in Mexico, and in a province of the same name. The governor and most of the inhabitants are originally Americans. W. Long. 98. 5. N. Lat. 15. 6.

CHIARI, JOSEPH, a celebrated Italian painter, was the disciple of Carlo Maratti; and adorned the churches and palaces of Rome with a great number of fine paintings. He died of an apoplexy in 1727, aged 73.

CHIARI, a town of Italy, in the province of Brescia, and in the Austro-Venetian territories, 7 miles west of Brescia, and 27 east of Milan. Here the Imperialists gained a victory over the French in 1701. E. Long. 18. 18. N. Lat. 45. 30.

CHIARO SCURO. See *CLARO Obscuro*.

CHIAVENNA, a handsome, populous, and large town of Swisserland, in the county of the Grisons. It is a trading place, especially in wine and delicate fruits. The governor's palace and the churches are very magnificent, and the inhabitants are Roman Catholics. It was at one period, during the late contest with France, the scene of much carnage and bloodshed. It is seated near the lake Como. E. Long. 9. 29. N. Lat. 46. 15.

CHIAUSI, among the Turks, officers employed in executing the vizirs, bashaws, and other great men: the orders for doing this, the grand signior sends them wrapped up in a black cloth; on the reception of which they immediately perform their office.

CHICANE, or CHICANERY, in *Law*, an abuse of judiciary

judiciary proceeding, tending to delay the cause, to puzzle the judge, or impose upon the parties.

CHICANE, in the schools, is applied to vain sophisms, distinctions, and subtleties, which protract disputes, and obscure the truth.

CHICHESTER, the capital city of the county of Sussex, was built by Cissa, the second king of the South Saxons, and by him called *Cissan Cæster*. It is surrounded with a wall, which has four gates answering to the four cardinal points; from which run two streets, that cross one another in the middle and form a square, where the market is kept, and where there is a fine stone piazza built by Bishop Read. The space between the west and south gates is taken up with the cathedral church and the bishop's palace. It has five parish-churches; and is seated on the little river Lavant, which washes it on all sides except the north. This city would have been in a much more flourishing condition if it had been built by the sea side; however, the inhabitants have endeavoured to supply this defect in some measure, by cutting a canal from the city down to the bay. The principal manufactures of the town are malt and needles. The market of Chichester is noted for fish, wheat, barley, malt, and oats; the finest lobsters in England are bred in the Lavant; and it is observable, that this river, unlike most others, is very low in winter, but in summer often overflows its banks. Chichester is a city and county of itself; it is governed by a mayor, recorder, aldermen, common-council without limitation, and four justices of the peace chosen out of the aldermen; and it sends two members to parliament. It is a bishop's see. The cathedral church was anciently dedicated to St Peter. It was new built by Radulph, the twenty-fifth bishop; but being destroyed by fire, it was again built by Seffridus II. the twenty-ninth bishop. This see hath yielded to the church two saints, and to the nation three lord chancellors, two almoners, and one chancellor to the university of Oxford. Anciently the bishops of Chichester were confessors to the queens of England. This diocese contains the whole of the county of Sussex (excepting 22 parishes, peculiars of the archbishop of Canterbury), wherein are 250 parishes, whereof 112 are impropriated. It hath two archdeacons, viz. of Chichester and Lewes; is valued in the king's books at 667l. 1s. 3d. and is computed to be worth annually 2600l. The tenths of the whole clergy are 287l. 2s. 0¼d. To the cathedral belong a bishop, a dean, two archdeacons, a treasurer, a chancellor, thirty-two prebendaries, a chanter, twelve vicars-choral, and other officers. Population 6425 in 1811. W. Long. 50. N. Lat. 50. 50.

CHICK, or CHICKEN, in *Zoology*, denotes the young of the gallinaceous order of birds, especially the common hen. See PHASIANUS, ORNITHOLOGY *Index*.

CHICK-Weed. See ALSINE, BOTANY *Index*.

CHICKEN-Pox. See MEDICINE *Index*.

CHICKLING-PEA, a name given to the LATHYRUS. See BOTANY *Index*.

CHICUITOS, a province of South America, in the government of Santa Cruz de la Sierra. The chief riches consist of honey and wax; and the original inhabitants are very voluptuous, yet very warlike. They maintained bloody wars with the Spaniards till 1690; since which, some of them have become Christians. It is bounded by La Plata on the north-east, and by Chili on the west.

CHIDLEY, or CHIMLEY, a market town of Devonshire, situated in W. Long. 4. 0. N. Lat. 51. 0.

CHIEF, a term signifying the head or principal part of a thing or person. Thus we say, the chief of a party, the chief of a family, &c. The word is formed of the French *chef*, "head;" of the Greek κεφαλη, *caput*, "head;" though Menage derives it from the Italian *capo*, formed of the Latin, *caput*.

CHIEF, in *Heraldry*, is that which takes up all the upper part of the escutcheon from side to side, and represents a man's head. *In chief*, imports something borne in the chief part or top of the escutcheon.

CHIEFTAIN, denotes the captain or chief of any class, family, or body of men. Thus the chieftains or chiefs of the Highland clans, were the principal noblemen or gentlemen of their respective clans. See CLANS.

CHIELEFA, a strong town of Turkey in Europe, in the Morea. It was taken by the Venetians in 1685; but after that the Turks retook it, with all the Morea. E. Long. 22. 21. N. Lat. 26. 50.

CHIGI, FABIO, or Pope Alexander VII. was born at Sienna in 1599. His family, finding him a hopeful youth, sent him early to Rome, where he soon engaged in a friendship with the marquis Pallavicini, who recommended him so effectually to Pope Urban VIII. that he procured him the post of inquisitor at Malta. He was sent vice-legate to Ferrara, and afterward nuncio into Germany: there he had an opportunity of displaying his intriguing genius; for he was mediator at Munster, in the long conference held to conclude a peace with Spain. Cardinal Mazarin had some resentment against Chigi, who was soon after made a cardinal and secretary of state by Innocent X. but his resentment was sacrificed to political views. In 1665, when a pope was to be chosen, Cardinal Sacchetti, Mazarin's great friend, finding it was impossible for him to be raised into St Peter's chair, because of the powerful opposition made by the Spanish faction, desired Cardinal Mazarin to consent to Chigi's exaltation. His request was granted, and he was elected pope by the votes of all the 64 cardinals who were in the conclave: an unanimity of which there are but few instances in the election of popes. He showed uncommon humility at his election, and at first forbade all his relations to come to Rome without his leave; but he soon became more favourable to his nephews, and loaded them with favours. It is asserted that he had once a mind to turn Protestant. The newspapers in Holland bestowed great encomiums upon him; and acquainted the world that he did not approve of the cruel persecutions of the Waldenses in Piedmont. There is a volume of his poems extant. He loved the *Belles-Lettres*, and the conversation of learned men. He was extremely fond of stately buildings: the grand plan of the college *Della Sapienza*, which he finished, and adorned with a fine library, remains a proof of his taste in architecture. He died in 1667.

CHILBLAIN (*pernio*), in *Medicine*, a tumor affecting the feet and hands; accompanied with an inflammation, pains, and sometimes an ulcer or solution of

Chilblains ‖ Children.

of continuity; in which case it takes the denomination of *chaps* on the hands, and of *kibes* on the heels. Chilblain is componnded of *chill* and *blain*; *q. d.* a blain or sore contracted by cold. *Pernio* is the Latin name adopted by physicians; and is derived by Vossius from *perna*, "a gammon of bacon," on account of some resemblance. *Chap* alludes to *gape*, both in sound and appearance. *Kibes*, in Welch *kibws*, may be derived from the German *kerben*, "to cut;" the skin, when broke, appearing like a cut.

Chilblains are occasioned by excessive cold stopping the motion of the blood in the capillary arteries. See the article Pernio.

CHILD, a term of relation to *parent*. See Parent and Children.

Bartholine, Parè, Licetus, and many other writers, give an account of a petrified child, which has seemed wholly incredible to some people. The child, however, which they describe, is still in being; and is kept as a great rarity in the king of Denmark's museum at Copenhagen. The woman who was big with this, lived at Sens in Champagne in the year 1582; it was cut out of her belly, and was universally supposed to have lain there about 20 years. That it is a real human fœtus, and not artificial, is evident to the eyes of any observer; and the upper part of it, when examined, is found to be of a substance resembling the gypsnm or stone whereof they made the plaster of Paris; the lower part is much harder, the thighs and buttocks being a perfect stone of a reddish colour, and as hard as common quarry stone; the grain and surface of this part appear exactly like that of the calculi or stones taken out of human bladders; and the whole substance, examined ever so nearly, and felt ever so carefully, appears to be absolute stone. It was carried from Sens to Paris, and there purchased by a goldsmith of Venice; and Frederic III. king of Denmark purchased it of this man at Venice for a very large sum, and added it to his collection of rarities.

Child-Bed.
Child-Birth. } See Midwifery.

Child-Wit, a power to take a fine of a bond-woman unlawfully gotten with child, that is, without consent of her lord. Every repnted father of a base child got within the manor of Writtel in Essex, pays to the lord a fine of 3s. 4d.; where, it seems, child-wit extends to free as well as bond-women.

CHILDERMAS-DAY, or *Innocents Day*, an anniversary held by the church of England on the 28th of December, in commemoration of the children of Bethlehem massacred by order of Herod.

CHILDREN, the plural of Child.

Mr Derham computes, that marriages, one with another, produce four children not only in England, but in other parts also.

In the genealogical history of Tuscany, written by Gamarini, mention is made of a nobleman of Sienna, named Pichi, who of three wives had 150 *children*; and that, being sent ambassador to the pope and the emperor, he had 48 of his sons in his retinue. In a monument in the church-yard of St Innocent, at Paris, erected to a woman who died at 88 years of age; it is recorded, that she might have seen 268 *children* directly issued from her. This exceeds what Hakewell relates of Mrs Honeywood, a gentlewoman of Kent, born in the year 1527, and married at 16 to her only husband R. Honeywood of Charing, Esq. and died in her 93d year. She had 16 *children* of her own body; of which three died young, and a fourth had no issue; yet her *grandchildren*, in the second generation, amounted to 114; in the third, to 228; though in the fourth they fell to 9. The whole number she might have seen in her lifetime, being 367. 16+14+228+9=367. So that she could say the same as the distich does of one Dalburgh's family at Basil:

1 2 3 4
Mater ait natæ, dic natæ filia natam,
5 6
Ut moneat, natæ plangere, filiolam.

Children.

Management of Children. See Infant.

Overlaying of Children, is a misfortune that frequently happens; to prevent which, the Florentines have contrived an instrument called *arcuccio*. See Arcuccio.

Children are, in *Law*, a man's issue begotten on his wife. As to *illegitimate children*, see Bastard.

For the legal duties of parents to their children, see the articles Parent and Bastard.

As to the duties of children to their parents, they arise from a principle of natural justice and retribution. For to those who gave us existence, we naturally owe subjection and obedience during our minority, and honour and reverence ever after; they who protected the weakness of our infancy are entitled to our protection in the infirmity of their age; they who by sustenance and education have enabled their offspring to prosper, ought, in return, to be supported by that offspring, in case they stand in need of assistance. Upon this principle proceed all the duties of children to their parents, which are enjoined by positive laws. And the Athenian laws carried this principle into practice with a scrupulous kind of nicety, obliging all children to provide for their father when fallen into poverty; with an exception to spurious children, to those whose chastity had been prostituted with consent of their father, and to those whom he had not put in any way of gaining a livelihood. The legislature, says Baron Montesquieu, considered, that, in the first case, the father, being uncertain, had rendered the natural obligation precarious; that, in the second case, he had sullied the life he had given, and done his children the greatest of injuries, in depriving them of their reputation; and that, in the third case, he had rendered their life (so far as in him lay) an insupportable burden, by furnishing them with no means of subsistence.

Our laws agree with those of Athens, with regard to the first only of these particulars, the case of spurious issue. In the other cases, the law does not hold the tie of nature to be dissolved by any misbehaviour of the parent; and, therefore, a child is equally justifiable in defending the person, or maintaining the cause or suit, of a bad parent as of a good one; and is equally compellable, if of sufficient ability, to maintain and provide for a wicked and unnatural progenitor, as for one who has shown the greatest tenderness and parental piety. See further the article *Filial Affection*.

CHILI,

Chili.

CHILI, a province of South America, bounded by Peru on the north, by the province of La Plata on the east, by Patagonia on the south, and by the Pacific ocean on the west, lying between 75 and 85 degrees of west longitude; and between 25 and 45 of south latitude; though some comprehend in this province Patagonia and Terra del Fuego.

The first attempt of the Spaniards upon this country was made by Almagro in the year 1535, after he and Pizarro had completed the conquest of Peru. He set out on his expedition to Chili with a considerable body of Spaniards and auxiliary Indians. For 200 leagues he was well accommodated with every necessary by the Indians, who had been subjects of the emperors of Peru: but reaching the barren country of Charcas, his troops became discontented through the hardships they suffered; which determined Almagro to climb the mountains called *Cordilleras*, in order to get the sooner into Chili; being ignorant of the invaluable mines of Potosi, contained in the province of Charcas, where he then was. At that time the Cordilleras were covered with snow, the depth of which obliged him to dig his way through it. The cold made such an impression on his naked Indians, that it is computed no less than 10,000 of them perished on these dreadful mountains, 150 of the Spaniards sharing the same fate; while many of the survivors lost their fingers and toes through the excess of cold. At last, after encountering incredible difficulties, Almagro reached a fine, temperate, and fertile plain, on the opposite side of the Cordilleras, where he was received with the greatest kindness by the natives. These poor savages taking the Spaniards for deputies of their god Virachoca, immediately collected for them an offering of gold and silver worth 290,000 ducats; and soon after brought a present to Almagro worth 300,000 more. These offerings only determined him to conquer the whole country as soon as possible. The Indians among whom he now was had acknowledged the authority of the Peruvian incas, or emperors, and consequently gave Almagro no trouble. He therefore marched immediately against those who had never been conquered by the Peruvians, and inhabited the southern parts of Chili. These savages fought with great resolution, and disputed every inch of ground; but in five months time the Spaniards had made such progress, that they must infallibly have reduced the whole province in a very short time, had not Almagro returned to Peru, in consequence of a commission sent him from Spain.

In 1540, Pizarro having overcome and put Almagro to death, sent into Chili, Baldivia or Valdivia, who had learned the rudiments of war in Italy, and was reckoned one of the best officers in the Spanish service. As he penetrated southwards, however, he met with much opposition; the confederated caziques frequently gave him battle, and displayed great courage and resolution; but could not prevent him from penetrating to the valley of Masiocho, which he found incredibly fertile and populous. Here he founded the city of St Jago; and, finding gold mines in the neighbourhood, forced the Indians to work in them; at the same time building a castle for the safety and protection of his new colony. The natives, exasperated at this slavery, immediately took up arms, attacked the fort, and though defeated and repulsed, set fire to the outworks, which contained all the provisions of the Spaniards. Nor were they discouraged by this and many other defeats, but still continued to carry on the war with vigour. At last, Valdivia, having overcome them in many battles, forced the inhabitants of the vale to submit; upon which he immediately set them to work in the mines of Quilotta. This indignity offered to their countrymen redoubled the fury of those who remained at liberty. Their utmost efforts, however, were as yet unable to stop Valdivia's progress. Having crossed the large rivers Maulle and Hata, he traversed a vast tract of country, and founded the city of La Conception on the South-sea coast. He erected fortresses in several parts of the country, in order to keep the natives in awe; and built the city called *Imperial*, about 40 leagues to the southward of Conception. The Spanish writers say, that the neighbouring valley contained 80,000 inhabitants of a peaceable disposition; and who were even so tame as to suffer Valdivia to parcel out their lands among his followers, while they themselves remained in a state of inactivity. About 16 leagues to the eastward of Imperial, the Spanish general laid the foundation of the city *Villa Rica*, so called on account of the rich gold mines he found there. But his ambition and avarice had now involved him in difficulties from which he could never be extricated: He had extended his conquests beyond what his strength was capable of maintaining. The Chilesians were still as desirous as ever of recovering their liberties. The horses, fire-arms, and armour of the Spaniards, indeed, appeared dreadful to them; but thoughts of endless slavery were still more so. In the course of the war they had discovered that the Spaniards were vulnerable and mortal men like themselves; they hoped, therefore, by dint of their superiority in numbers, to be able to expel the tyrannical usurpers. Had all the nations joined in this resolution, the Spaniards had certainly been exterminated; but some of them were of a pacific and fearful disposition, while others considered servitude as the greatest of all possible calamities. Of this last opinion were the Araceans, the most intrepid people in Chili, and who had given Valdivia the greatest trouble. They all rose to a man, and chose Capaulican, a renowned hero among them, for their leader. Valdivia however received notice of their revolt sooner than they intended he should, and returned with all expedition to the vale of Araccea; but before he arrived 14,000 of the Chilesians were there assembled under the conduct of Capaulican. He attacked them with his cavalry, and forced them to retreat into the woods; but could not obtain a complete victory, as they kept continually sallying out and harassing his men. At last Capaulican, having observed that fighting with such a number of undisciplined troops only served to contribute to the defeat and confusion of the whole, divided his forces into bodies of 1000 each. These he directed to attack the enemy by turns; and, though he did not expect that a single thousand would put them to flight, he directed them to make as long a stand as they could; when they were to be relieved and supported by another body; and thus the Spaniards would be at last wearied out and overcome. The event fully answered his expectations. The Chilesians maintained a fight

for

for seven or eight hours, until the Spaniards, growing faint for want of refreshment, retired precipitately. Valdivia ordered them to possess a pass at some distance from the field, to stop the pursuit; but this design being discovered to the Chilesians by the treachery of his page, who was a native of that country, the Spaniards were surrounded on all sides, and cut in pieces by the Indians. The general was taken and put to death; some say with the tortures usually inflicted by those savages on their prisoners; others that he had melted gold poured down his throat; but all agree, that the Indians made flutes and other instruments of his bones, and preserved his skull as a monument of their victory, which they celebrated by an annual festival. After this victory the Chilesians had another engagement with their enemies; in which also they proved victorious, defeating the Spaniards with the loss of near 3000 men; and upon this they bent their whole force against the colonies. The city of Conception, being abandoned by the Spaniards, was taken and destroyed: but the Indians were forced to raise the siege of Imperial; and their progress was at last stopped by Garcia de Mendoza, who defeated Capaulican, took him prisoner, and put him to death. No defeats, however, could dispirit the Chilesians. They continued the war for 50 years; and to this day they remain unconquered, and give the Spaniards more trouble than any other American nation. Their most irreconcilable enemies are the inhabitants of Araccea and Tucapel, those to the south of the river Bobia, or whose country extends towards the Cordilleras.—The manners of these people greatly resemble those of North America, which we have already described under the article AMERICA; but they seem to have a more warlike disposition. It is a constant rule with the Chilesians never to sue for peace. The Spaniards are obliged not only to make the first overtures, but to purchase it by presents. They have at last been obliged to abandon all thoughts of extending their conquests, and reduced to cover their frontiers by erecting forts at proper distances.

The Spanish colonies in Chili are dispersed on the borders of the South-sea. They are parted from Peru by a desert of 80 leagues in breadth; and bounded by the island of Chiloe, at the extremity next the straits of Magellan. There are no settlements on the coast, except those of Baldivia, Conception island, Valparaiso, and Coquimbo or La Serena, which are all seaports. In the inland country is St Jago, the capital of the colony. There is no culture nor habitation at any distance from these towns. The buildings in the whole province are low, made of unburnt brick; and mostly thatched. This practice is observed on account of the frequent earthquakes; and is properly adapted to the nature of the climate, as well as the indolence of the inhabitants.

The climate of Chili is one of the most wholesome in the whole world. The vicinity of the Cordilleras gives it such a delightful temperature as could not otherwise be expected in that latitude. Though gold mines are found in it, their richness has been too much extolled; their produce never exceeds 218,750l. The soil is prodigiously fertile. All the European fruits have improved in that happy climate. The wine would be excellent if nature were properly assisted by art; and the corn-harvest is reckoned a bad one when it does not yield a hundred fold. With all these advantages, Chili has no direct intercourse with the mother-country. Their trade is confined to Peru, Paraguay, and the savages on their frontiers. With these last they exchange their less valuable commodities, for oxen, horses, and their own children, whom they are ready to part with for the most trifling things. This province supplies Peru with great plenty of hides, dried fruit, copper, salt-meat, horses, hemp, lard, wheat, and gold. In exchange it receives tobacco, sugar, cacao, earthen-ware, woollen cloth, linen, hats, made at Quito, and every article of luxury brought from Europe. The ships sent from Callao on this traffic were formerly bound to Conception Bay, but now come to Valparaiso. The commerce between this province and Paraguay is carried on by land, though it is journey of 300 leagues, 40 of which lie through the snows and precipices of the Cordilleras: but if it was carried on by sea, they must either pass the straits of Magellan or double Cape Horn, which the Spaniards always avoid as much as possible. To Paraguay are sent some woollen stuffs called *ponchos*, which are used for cloaks; also wines, brandy, oil, and chiefly gold. In return they receive wax, a kind of tallow fit to make soap, European goods, aad negroes.

Chili is governed by a chief, who is absolute in all civil, political, and military affairs, and is also independent of the viceroy. The latter has no authority except when a governor dies; in which case he may appoint one in his room for a time, till the mother-country names a successor. If, on some occasions, the viceroy has interfered in the government of Chili, it was when he has been either authorized by a particular trust reposed in him by the court, or by the deference paid to the eminence of his office: or when he has been actuated by his own ambition to extend his authority. In the whole province of Chili it was formerly computed there were not 20,000 white men, and not more than 60,000 negroes, or Indians, able to bear arms. Since 1810 this province has been the theatre of some revolutionary movements, which are not yet brought to a termination. See CHILI, SUPPLEMENT.

CHILIAD, an assemblage of several things ranged by thousands. The word is formed of the Greek χιλιας, *mille*, "a thonsand."

CHILIAGON, in *Geometry*, a regular plane figure of 100 sides and angles. Though the imagination cannot form the idea of such a figure, yet we may have a very clear notion of it in the mind, and can easily demonstrate that the sum of all its angles is equal to 1996 right ones: for the internal angles of every plane figure are equal to twice as many right ones as the figure hath sides, except those four which are about the centre of the figure, from whence it may be resolved into as many triangles as it has sides. The author of *l'Art de Penser*, p. 44. has brought this instance to show the distinction between imagination and conceiving.

CHILIARCHA, or CHILIARCHUS, an officer in the armies of the ancients, who had the command of a thousand men.

CHILIASTS, in church-history. See MILLENARIANS.

CHILLINGWORTH, WILLIAM, an eminent divine

vine of the church of England, was born at Oxford in 1602, and bred there. He made early great proficiency in his studies, being of a very quick genius. He was an expert mathematician, as well as an able divine, and a very good poet. Study and conversation at the university turning upon the controversy between the church of England and that of Rome, on account of the king's marriage with Henrietta daughter to Henry IV. king of France, Mr Chillingworth forsook the church of England and embraced the Romish religion. Dr Laud, then bishop of London, hearing of this, and being greatly concerned at it, wrote Mr Chillingworth; who expressing a great deal of candour and impartiality, that prelate continued to correspond with him. This set Mr Chillingworth on a new inquiry; and at last determined him to return to his former religion. In 1634 he wrote a confutation of the arguments which had induced him to go over to the church of Rome. He spoke freely to his friends of all the difficulties that occurred to him; which gave occasion to a groundless report, that he had turned Papist a second time, and then Protestant again. His return to the communion of the church of England made a great noise, and engaged him in several disputes with those of the Romish persuasion. But in 1635 he engaged in a work which gave him a far greater opportunity to confute the principles of the church of Rome, and to vindicate the Protestant religion, under the title of "The religion of Protestants a safe Way to Salvation." Sir Thomas Coventry, lord keeper of the great seal, offering him preferment, Mr Chillingworth refused to accept it on account of his scruples with regard to the subscription of the 39 articles. However, he at last surmounted these scruples; and being promoted to the chancellorship of the church of Sarum, with the prebend of Brixworth in Northamptonshire annexed to it, he complied with the usual subscription. Mr Chillingworth was zealously attached to the royal party; and, in August 1643, was present in King Charles I.'s army at the siege of Gloucester, where he advised and directed the making certain engines for assaulting the town. Soon after, having accompanied the Lord Hopton, general of the king's forces in the west, to Arundel castle in Sussex, he was there taken prisoner by the parliamentary forces under the command of Sir William Waller, who obliged the castle to surrender. But his illness increasing, he obtained leave to be conveyed to Chichester, where he was lodged at the bishop's palace; and, after a short sickness, died in 1644. He hath left several excellent works behind him.

CHILMINAR. See PERSEPOLIS.

CHILO, one of the seven sages of Greece, and of the ephori of Sparta the place of his birth, flourished about 556 years before Christ. He was accustomed to say that there were three things very difficult: "To keep a secret; to know how best to employ our time; and to suffer injuries without murmuring." According to Pliny, it was he who caused the short sentence *Know thyself*, to be written in letters of gold in the temple of Delphos. It is said that he died of joy, while embracing his son, who had been crowned at the Olympic games.

CHILOE, an island lying near the coast of Chili in South America, under the 43d degree of south latitude. It is the chief of an archipelago of 40 islands, and its principal town is Castro. It rains here almost all the year, insomuch that nothing but Indian corn, or some such grain, that requires but little heat to ripen it, can ever come to perfection. They have excellent shell-fish, very good wild-fowl, hogs, sheep, and beeves; as also a great deal of honey and wax. They carry on a trade with Peru and Chili; whither they send boards of cedar, of which they have vast forests.

CHILTENHAM, a town in Gloucestershire, six miles from Gloucester; noted for its purgative chalybeate spring, which has rendered it of late years a place of fashionable resort. This water, which operates with great ease, is deemed excellent in scorbutic complaints, and has been used with success in the gravel.

CHILTERN, a chain of chalky hills forming the southern part of Buckinghamshire, the northern part of the county being distinguished by the name of the *Vale*. The air on these heights is extremely healthful: The soil, though stony, produces good crops of wheat and barley; and in many places it is covered with thick woods, among which are great quantities of beech.—*Chiltern* is also applied to the hilly parts of Berkshire, and it is believed has the same meaning in some other counties. Hence the HUNDREDS lying in those parts are called the *Chiltern Hundreds.*

CHILTERN Hundreds, Stewards of. Of the hundreds into which many of the English counties were divided by King Alfred for the better government, the jurisdiction was originally vested in peculiar courts; but came afterwards to be devolved to the county courts, and so remains at present; excepting with regard to some, as the *chilterns*, which have been by privilege annexed to the crown. These having still their own courts, a *steward* of those courts is appointed by the chancellor of the exchequer, with a salary of 20s. and all fees, &c. belonging to the office: and this is deemed an appointment of such profit, as to vacate a seat in parliament.

CHIMÆRA, a port town of Turkey in Europe, situated at the entrance of the gulf of Venice, in the province of Epirus, about 32 miles north of the city of Corfu, near which are the mountains of Chimæra, which divide Epirus from Thessaly. E. Long. 20. 40. N. Lat. 40. 20.

CHIMÆRA, in fabulous history, a celebrated monster, sprung from Echidna and Typhon. It had three heads; that of a lion, a goat, and a dragon; and continually vomited flames. The fore parts of its body were those of a lion, the middle was that of a goat, and the hinder parts were those of a dragon. It generally lived in Lycia, about the reign of Jobates, by whose orders Bellerophon, mounted on the horse Pegasus, overcame it. This fabulous tradition is explained by the recollection that there was a burning mountain in Lycia, whose top was the resort of lions on account of its desolate wilderness; the middle, which was fruitful, was covered with goats; and at the bottom the marshy ground abounded with serpents. Bellerophon is said to have conquered the Chimæra, because he destroyed the wild beasts on that mountain, and rendered it habitable. Plutarch says that it was the captain of some pirates who adorned their ships with the images of a lion, a goat, and a dragon.

By a *chimæra* among the philosophers, is understood

Chimera, Chimes.

stood a mere creature of the imagination, composed of such contradictions and absurdities as cannot possibly anywhere exist but in thought.

CHIMES of a CLOCK, a kind of periodical music, produced at equal intervals of time, by means of a particular apparatus, added to a clock.

In order to calculate numbers for the chimes, and adapt the chime-barrel, it must be observed, that the barrel must turn round in the same time that the tune it is to play requires in singing. As for the chime-barrel, it may be made up of certain bars that run athwart it, with a convenient number of holes punched in them to put in the pins that are to draw each hammer; and these pins, in order to play the time of the tune rightly, must stand uprightly or hang down from the bar, some more, some less. To place the pins rightly, you may proceed by the way of changes on bells; viz. 1, 2, 3, 4; or rather make use of the musical notes. Observe what is the compass of your tune, and divide the barrel accordingly from end to end.

Thus, in the examples on Plate CXLIV. each of the tunes is eight notes in compass; and accordingly the barrel is divided into eight parts. These divisions are struck round the barrel; opposite to which are the hammer-tails.

We speak here as if there were only one hammer to each bell, that it may be more clearly apprehended; but when two notes of the same sound come together in a tune, there must be two hammers to the bell to strike it; so that if in all the tunes you intend to chime of eight notes compass, there should happen to be such double notes on every bell, instead of eight you must have sixteen hammers; and accordingly you must divide the barrel, and strike sixteen strokes round it, opposite to each hammer tail; then you are to divide it round about into as many divisions as there are musical bars, semibreves, minims, &c. in the tune.

Thus the hundredth-psalm tune has 20 semibreves, and each division of it is a semibreve; the first note of it also is a semibreve; and, therefore, on the chime-barrel must be a whole division, from five to five; as you may understand plainly, if you conceive the surface of a chime-barrel to be represented by the above figures, as if the cylindrical superficies of the barrel were stretched out at length, or extended on a plane; and then such a table, so divided, if it were to be wrapped round the barrel, would show the places where all the pins are to stand in the barrel; for the dots running about the table are the places of the pins that play the tune.

Indeed, if the chimes are to be complete, you ought to have a set of bells to the gamut notes; so as that each bell having the true sound of *sol*, *la*, *mi*, *fa*, you may play any tune with its flats and sharps; nay, you may by this means play both the base and treble with one barrel; and by setting the names of your bells at the head of any tune, that tune may easily be transferred to the chime-barrel, without any skill in music; but it must be observed, that each line in the music is three notes distant; that is, there is a note between each line, as well as upon it.

Chimes, Chimney.

CHIMNEY, in *Architecture*, a particular part of a house, where the fire is made, having a tube or funnel to carry off the smoke. The word *chimney* comes from the French *cheminée;* and that from the Latin *caminata*, "a chamber wherein is a chimney;" *caminata*, again, comes from *caminus;* and that from the Greek καμινος, "chimney;" of καιω, *uro*, "I burn."

Chimneys are usually supposed a modern invention, the ancients only making use of stoves; but Octavio Ferrari endeavours to prove chimneys in use among the ancients. To this end, he cites the authority of Virgil,

Et jam summa procul villarum culmina fumant:

and that of Appian, who says, "That of those persons proscribed by the triumvirate, some hid themselves in wells and common sewers, and some on the tops of houses and chimneys;" for so he understands καπνωδεις υπωροφιας, *fumaria sub tecto posita.* Add, that Aristophanes, in one of his comedies, introduces his old man, Polycleon, shut up in a chamber, whence he endeavours to make his escape by the *chimney.*

Chimneys, in Professor Beckmann's opinion, are comparatively of modern invention. We shall lay before our readers some observations from his elaborate dissertation on this subject. He thus explains the above passage of Virgil.

"When the triumviri, says Appian *, caused those who had been proscribed by them to be sought for by the military, some of them, to avoid the bloody hands of their persecutors, hid themselves in wells, and others, as Ferrarius translates the words, *in fumaria sub tecto, qua scilicet fumus è tecto evolvitur* (A). The true translation, however (says Mr Beckmann), is *fumosa cœnacula.* The principal persons of Rome endeavoured to conceal themselves in the smoky apartments of the upper story under the roof, which, in general, were inhabited only by poor people; and this seems to be confirmed by what Juvenal † expressly says, *Rarus venit in cœnacula miles.*

* *De bellis civilib.* lib. iv. p. 962. edit. Tollii.

† *Sat.* x. ver. 17.

"Those passages of the ancients which speak of smoke rising up from houses, have with equal impropriety been supposed to allude to chimneys, as if the smoke could not make its way through doors and windows. Seneca ‡ writes, 'Last evening I had some friends with me, and on that account a stronger smoke was raised; not such a smoke, however, as bursts forth from the kitchens of the great, and which alarms the watchmen, but such a one as signifies that guests are arrived.' Those whose judgments are not already warped by prejudice, will undoubtedly find the true sense of these words to be, that the smoke forced its way through the kitchen windows. Had the houses been built with chimney funnels, one cannot conceive why the watchmen should have been alarmed when they observed a stronger smoke than usual arising from them; but as the kitchens had no convenience of that nature, an apprehension of fire, when extraordinary entertainments

Chimney. ments were to be provided in the houses of the rich for large companies, seems to have been well founded; and on such occasions people appointed for that purpose were stationed in the neighbourhood to be constantly on the watch, and to be ready to extinguish the flames in case a fire should happen. There are many other passages to be found in Roman authors of the like kind, which it is hardly necessary to mention; such as that of Virgil *,

Et jam summa procul villarum culmina fumant.

* Eclog. i. ver. 83.

and the following words of Plautus †, descriptive of a miser:

† Aulular. act. ii. sc. 4.

Quin divum atque hominum clamat continuo fidem,
Suam rem periisse, seque eradicarier,
De suo tigillo fumus si qua exit foras.

"The passage of Aristophanes above alluded to, however (says the professor), which, according to the usual translation, seems to allude to a common chimney, can, in my opinion, especially when we consider the illustration of the scholiasts, be explained also by a simple hole in the roof, as Reiske has determined; and indeed this appears to be more probable, as we find mention made of a top or covering (τηλια) with which the hole was closed."

It has been said that the instances of chimneys remaining among the ruins of ancient buildings are few, and the rules given by Vitruvius for building them are obscure; but it appears that there exists *no* remains of ancient chimneys; and that Vitruvius gives *no* rules, either obscure or perspicuous, for building what, in the modern acceptation of the word, deserves the name of a chimney.

"The ancient mason-work still to be found in Italy does not determine the question. Of the walls of towns, temples, amphitheatres, baths, aqueducts, and bridges, there are some though very imperfect remains, in which chimneys cannot be expected; but of common dwelling houses none are to be seen, except at Herculaneum, and there no traces of chimneys have been discovered. The paintings and pieces of sculpture which are preserved, afford us as little information; for nothing can be perceived in them that bears the smallest resemblance to a modern chimney.

"If there were no funnels in the houses of the ancients to carry off the smoke, the directions given by Columella, to make kitchens so high that the roof should not catch fire, was of the utmost importance. An accident of the kind, which the author seems to have apprehended, had almost happened at Beneventum, when the landlord who entertained Mæcenas and his company was making a strong fire in order to get some birds sooner roasted.

——— ——— ——— *ubi sedulus hospes*
Pæne arsit, macros dum turdos versat in igne;
Nam vaga per veterem dilapso flamma culinam
Vulcano summum properabat lambere tectum ‡.

‡ Horat. lib. i. sat 5.

Had there been chimneys in the Roman houses, Vitruvius certainly would not have failed to describe their construction, which is sometimes attended with considerable difficulties, and which is intimately connected with the regulation of the plan of the whole edifice. He does not, however, say a word on the subject; neither does Julius Pollux, who has collected with great care the Greek names of every part of a dwelling-house; and Grapaldus, who in later times made a collection of the Latin terms, has not given a Latin word expressive of a modern chimney *."

* Francisci Marii Grapaldi de partibus ædium libri.

"*Camenis* signified, as far as I have been able to learn, first a chemical or metallurgic furnace, in which a crucible was placed for melting and refining metals; secondly, a smith's forge; and, thirdly, a hearth on which portable stoves or fire-pans were placed for warming the apartment. In all these, however, there appears no trace of a chimney." Herodotus relates (lib. viii. c. 137.), that a king of Libya, when one of his servants asked for his wages, offered him in jest the sun, which at that time shone into the house through an opening in the roof, under which the fire was perhaps made in the middle of the edifice. If such a hole must be called a chimney, our author admits that chimneys were in use among the ancients, especially in their kitchens; but it is obvious that such chimneys bore no resemblance to ours, through which the sun could not dart his rays upon the floor of any apartment.

However imperfect may be the information which can be collected from the Greek and Roman authors respecting the manner in which the ancients warmed their apartments, it nevertheless shews that they commonly used for that purpose a large fire-pan or portable stove, in which they kindled wood, and, when the wood was well lighted, carried it into the room, or which they filled with burning coals. When Alexander the Great was entertained by a friend in winter, as the weather was cold and raw, a small fire bason was brought into the apartment to warm it. The prince, observing the size of the vessel, and that it contained only a few coals, desired his host, in a jeering manner, to bring more wood or frankincense; giving him thus to understand that the fire was fitter for burning perfumes than to produce heat. Anacharsis, the Scythian philosopher, though displeased with many of the Grecian customs, praised the Greeks, however, because they shut out the smoke and brought only fire into their houses †. We are informed by Lampridius, that the extravagant Heliogabalus caused to be burned in these stoves, instead of wood, Indian spiceries, and costly perfumes ‡. It is also worthy of notice, that coals were found in some of the apartments of Herculaneum, as we are told by Winkelmann, but neither stoves nor chimneys.

† Plutarch, Sympos. lib. vi. 7. p 692.

‡ Æl. Lamprid. Vita Heliogab. cap. 31.

It is well known to every scholar, that the useful arts of life were invented in the east, and that the customs, manners, and furniture of eastern nations, have remained from time immemorial almost unchanged. In Persia, which the late Sir William Jones seems to have considered as the original country of mankind, the methods employed by the inhabitants, for warming themselves, have a great resemblance to those employed by the ancient Greeks and Romans for the same purpose. According to De la Valle, the Persians make fires in their apartments, not in chimneys as we do, but in stoves in the earth, which they call *tennor*. "These stoves consist of a square or round hole, two spans or a little more in depth, and in shape not unlike an Italian cask. That this hole may throw out heat sooner, and with more strength, there is placed in it an iron vessel of the same size, which is either filled with burning coals,

coals, or a fire of wood and other inflammable substances is made in it. When this is done, they place over the hole or stove a wooden top, like a small low table, and spread above it a large coverlet quilted with cotton, which hangs down on all sides to the floor. This covering condenses the heat, and causes it to warm the whole apartment. The people who eat or converse there, and some who sleep in it, lie down on the floor above the carpet, and lean, with their shoulders against the wall, on square cushions, upon which they sometimes also sit; for the *tennor* is constructed in a place equally distant from the walls on both sides. Those who are not very cold only put their feet under the table or covering; but those who require more heat can put their hands under it, or creep under it altogether. By these means the stone diffuses over the whole body, without causing uneasiness to the head, so penetrating and agreeable a warmth, that I never in winter experienced any thing more pleasant. Those, however, who require less heat, let the coverlet hang down on their side to the floor, and enjoy without any inconvenience from the stove the moderately heated air of the apartment. They have a method also of stirring up or blowing the fire when necessary, by means of a small pipe united with the tennor or stove under the earth, and made to project above the floor as high as one chooses; so that the wind, when a person blows into it, because it has no other vent, acts immediately upon the fire like a pair of bellows. When there is no longer occasion to use this stove, both holes are closed up, that is to say, the mouth of the stove and that of the pipe which conveys the air to it, by a flat stone made for that purpose. Scarcely any appearance of them is then to be perceived, nor do they occasion inconvenience, especially in a country where it is always customary to cover the floor with a carpet, and where the walls are plastered. In many parts these ovens are used to cook victuals, by placing kettles over them. They are employed also to bake bread; and for this purpose they are covered with a large broad metal plate, on which the cake is laid; but if the bread is thick and requires more heat, it is put into the stove itself *."

* *Hist. of Invent.* ii. 88.

The professor farther observes, the oldest account of them which he finds is an inscription at Venice, which relates, that in the year 1347 a great many chimneys were thrown down by an earthquake. It would appear, however, that in some places they had been in use for a considerable time before that period; for De Gataris, in his history of Padua, relates, that Francesco de Carraro, lord of Padua, came to Rome in 1368, and finding no chimneys in the inn where he lodged, because at that time fire was kindled in a hall in the middle of the floor, he caused two chimneys like those which had *long* been used at Padua to be constructed by masons and carpenters, whom he had brought along with him. Over these chimneys, the first ever seen at Rome, he affixed his arms, which were still remaining in the time of De Gataris, who died of the plague in 1405.

Method of Building CHIMNEYS *that will not smoke.* Workmen have different methods of drawing up the funnels of chimneys, generally according to their own fancies and judgments, and sometimes according to the customs of places. They are seldom directed by sound and rational principles. It will be found, for the most part, that the smoking of chimneys is owing to their being carried up narrower near the top than below, or zig-zag, all in angles; in some cases, indeed, it is owing to accidental causes; but, for the most part, to those two above mentioned. Where they are carried up in the pyramid or tapering form, especially if the house be of a considerable height, it is ten to one but they sometimes smoke. The air in the rooms, being rarefied, is forced into the funnel of the chimney, and receives from the fire an additional force to carry up the smoke. Now it is evident, that the further up the smoke flies, the less is the force that drives it, the slower it must move, and consequently the more room in proportion it should have to move in; whereas in the usual way it has less, by the sides of the chimney being gathered closer and closer together.

The method here proposed of carrying up chimneys will be objected to by some, thus: The wider a chimney is at the top, say they, the more liberty has the wind to blow down. Very true; but is it not resisted in going down, both by the form of the chimney and other evident causes, so that it must return again? In the other way, when the wind blows down, the resistance being less, the wind and smoke are, if we may use the expression, imprisoned, and make the smoke puff out below. This method has proved effectual after all others had failed; and that in a house placed in the worst situation possible, namely, under a high mountain to the southward, from which strong blasts blow down upon it. A vent was carried up without angles, as perpendicular as possible; and was made about three or four inches wider at top than at the bottom: the funnel was gathered in a throat directly above the fire-place, and so widening upwards. Since that time the house has not only ceased to smoke, but when the doors stand open, the draught is so strong, that it will carry a piece of paper out at the chimney head. See more on this subject, and the improvements by Count Rumford, under the article SMOKE.

CHIMNEY-Money, otherwise called *Hearth-money*, a duty to the crown on houses. By stat. 14. Char. II. cap. 2. every fire-hearth and stove of every dwelling or other house, within England and Wales (except such as pay not to church and poor), was chargeable with 2s. per annum, payable at Michaelmas and Lady-day to the king and his heirs and successors, &c.; which payment was commonly called *chimney-money*. This tax, being much complained of as burdensome to the people, has been since taken off, and others imposed in its stead; among which that on windows has by some been esteemed almost equally grievous.

CHIMPANZEE, in *Natural History*. See SIMIA.
